Chest CT serves as a valuable tool in screening high-risk individuals for lung cancer. Specifically, high-risk patients (those between the ages 55 of 77, who have smoked more than 30 pack-years, and who currently smoke or have stopped smoking within the past 15 years) may benefit from lung cancer screening. A large study of greater than 50,000 patients at high-risk for lung cancer demonstrated that the mortality rate or risk for death from lung cancer was reduced by 20% in patients who underwent screening chest CT versus a chest x-ray examination.[1] This technique uses lower radiation than standard chest CT studies—approximately one-fifth that of a standard chest CT.

Computed Tomography Angiography

The rapid scanning that can be performed on modern CT scanners has made CT angiography possible. To perform CT angiography, intravenous contrast dye is injected at a high rate to darken or opacify the vascular structures. A large-bore peripheral intravenous line in an antecubital vein or a peripherally inserted central catheter (PICC) or port catheter that can handle a high injection rate is required. CT angiography of the chest is most commonly utilized to evaluate the thoracic aorta (as for a dissection or tear in the aortic wall and the pulmonary arteries for a blood clot, also known as a pulmonary embolism). Advances in technology now allow for the visualization of pulmonary emboli in tiny peripheral arteries that were not visible on older CT scanners (Fig. 21.6).[2] More recent technologic advancements have made CT angiography of the coronary arteries possible, which can serve as an alternative to coronary artery catheterization.[3]

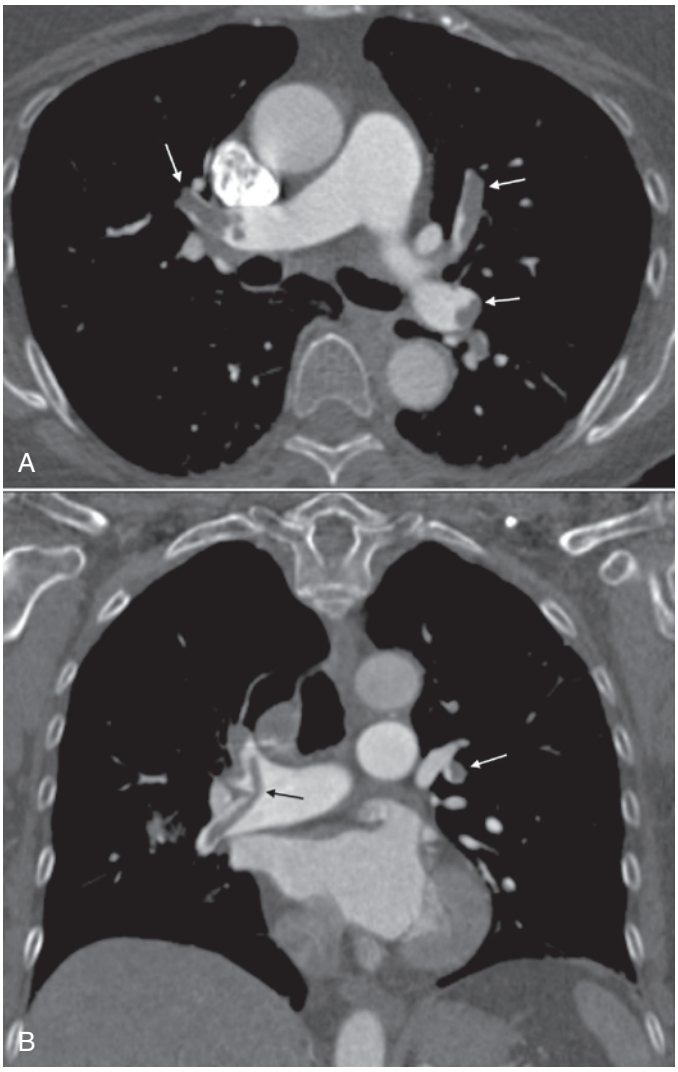

Fig. 21.6 Computed Tomography Angiogram of a Patient With Bilateral Acute Pulmonary Emboli. (A) The pulmonary emboli are seen as the dark filling defects *(arrows)* outlined by the white contrast-enhanced blood vessels *(arrows).* (B) Coronally reformatted image is helpful to visualize clot entering both the right upper and right lower lobar pulmonary arteries *(arrows).*

Three-Dimensional Reconstruction

The imaging processing capabilities of modern CT scanners allow for reconstruction of the chest in any direction and production of three-dimensional (3D) representations of some areas of the body (Fig. 21.7). These 3D images can be helpful for surgeons before surgery to visualize how anatomic structures may appear at the time of surgery. The images can also simulate what a physician would see during a bronchoscopy, referred to as *virtual bronchoscopy*.

Magnetic Resonance Imaging of the Chest

Magnetic resonance imaging (MRI) has many uses in the chest and is typically used as a problem-solving tool to answer specific clinical questions that cannot be answered by other imaging techniques such as a chest x-ray, chest CT, or ultrasound examination. MRI is generated by placing patients into a strong

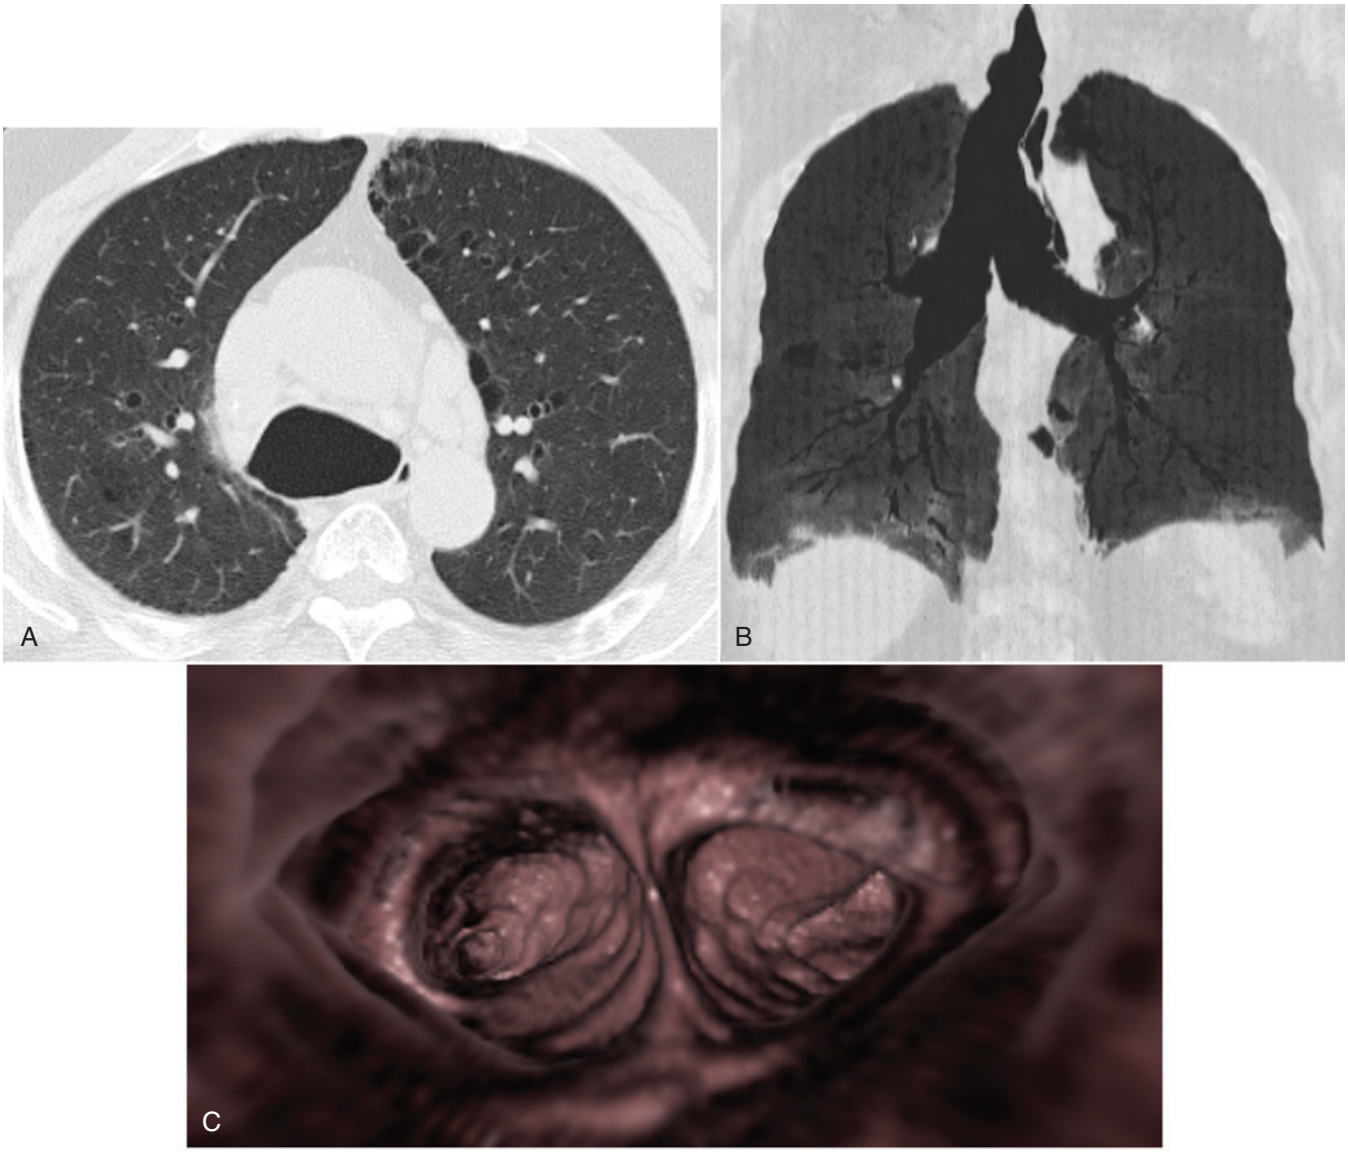

Fig. 21.7 Use of Two- and Three-Dimensional Images for Visualization of the Trachea. Axial computed tomography (A) image demonstrates a massively dilated trachea in a patient with tracheobronchomegaly (Mounier-Kuhn). A coronally reformatted minimum intensity projection (minIP) image (B) allows for visualization of the entire trachea and main stem bronchi. A three-dimensional image (C) endoluminal view of the inferior trachea looking downward at the carina with the left and right mainstem bronchi located on each side of the carina. The three-dimensional image, termed *virtual bronchoscopy,* can aid the bronchoscopist in planning a bronchoscopic procedure.

magnetic field. The physics of MR are complicated and beyond the scope of this chapter. Briefly, the strong magnetic field aligns nuclei with nonzero spins (nuclei that have an odd number of protons and neutrons), such as hydrogen atoms, with the magnetic field. Because hydrogen atoms are present in high concentration throughout the body (mainly water), they provide an excellent target for MRI evaluation. Pulses of radio waves are directed at the hydrogen nuclei, resulting in the alignment of hydrogen nuclei to change in orientation with the magnetic field. After the radio signal is stopped, the nuclei flip back to their original alignment and release their own radio waves. MRI uses the radio waves from the realigning nuclei to generate an image.

MRI has advantages over other imaging techniques in the chest that are useful in specific circumstances. MRI does not use x-rays and therefore does not expose patients to ionizing radiation, which is of particular importance in pediatric patients. MRI has superb soft tissue characterization, allowing for detailed analysis of soft tissue masses. The most common uses for MRI in the chest are for imaging the mediastinum, large vessels in the chest (e.g., for pulmonary emboli or vascular abnormalities), and the heart.[4] The superior soft tissue characterization of MRI allows for the confident diagnosis of a benign mediastinal mass (such as a thymic cyst or thymic hyperplasia) and can spare patients a percutaneous biopsy or surgery to establish a

diagnosis.[5] In patients in renal failure in whom there is clinical concern for a pulmonary embolism and who cannot receive intravenous contrast, an MR examination can be performed without contrast to establish a diagnosis. MR has only limited uses for imaging the lung parenchyma. For example, in a patient with lung cancer undergoing evaluation for possible resection, MRI can show whether a tumor has invaded the chest wall by determining if the lesion moves independently of the chest wall during both inspiration and expiration.

However, MRI does have significant limitations when applied to imaging the chest. MRI examinations take longer to acquire (at least 10 minutes and up to 1 hour) than other examinations (such as radiographs or CT); because of this, respiratory and cardiac motion are more significant obstacles. Imaging of critically ill ICU patients is therefore difficult because they may be unable to lie in the MR scanner for a long period of time. The lungs are primarily composed of gas; therefore there is little signal to generate images, as is required by MRI, making this modality less useful for evaluating the lungs.

In addition, the large magnet required for MR examinations generally contraindicates its use in patients with pacemakers or other significant iron-containing (also know as ferromagnetic) objects in their bodies to undergo MRI. A patient with a small metallic object in a crucial place, such as a surgical clip in the brain or eye, generally cannot undergo MRI. The powerful magnet will pull metallic objects into the magnet with great force, exposing both patients and health care providers to life-threatening risk. Medical equipment containing metal, such as ventilators and gas cylinders, also cannot be brought near the MR scanner. Deaths have been reported when metal objects (e.g., oxygen cylinders) have been brought into the magnetic field of the MRI, and RTs must be especially careful about this issue. In addition, special MRI-compatible ventilators that do not contain ferrous metals should be used when mechanically ventilated patients are being studied by this technique. As another precaution, MRI suites usually have well-marked warnings and areas beyond which conventional metal objects absolutely must not pass.

RULE OF THUMB Medical equipment containing metal (e.g., oxygen cylinders, conventional ventilators, infusion devices) must be kept away from the powerful magnet in an MRI machine. The hazard is that if such equipment enters the magnetic field of the MRI machine, the object will be pulled into the machine, endangering both the patient and medical personnel. Deaths have resulted from failure to observe this precaution. To prevent this, MRI suites usually have well-marked warnings and areas beyond which conventional metal objects absolutely must not pass. Also, special MRI-compatible medical equipment containing nonferrous metals is available.

Ultrasound

Ultrasound images are created by passing high-frequency sound waves into the body and detecting these waves as they bounce back (echo) from the tissues of the body. The pattern of the returning sound waves is used to generate an image of the tissue studied. Ultrasound of the chest is excellent for evaluating the heart (by echocardiography) and pleural fluid.[6]

Ultrasound imaging using small portable machines has become common practice in critical care units. Portable ultrasound units allow for the rapid assessment of heart function and volume status and are used to assist in many critical care procedures.[7] Ultrasound can accurately detect small pleural effusions and aid in performing a thoracentesis. Ultrasound is also commonly used to guide placement of central venous and arterial catheters. Blood vessels are easily identified using ultrasound. The compressibility of veins is used to differentiate veins from arteries (Fig. 21.8). Because the needle path can be clearly seen on the ultrasound screen, using ultrasound guidance for venous and arterial puncture allows the procedure to be more easily accomplished with less time, risk, and patient discomfort.

Nuclear Medicine

Nuclear medicine utilizes small amounts of radioactive material to diagnose and treat a wide variety of diseases. Radioactive material can be administered to patients by intravenous injection, inhalation, or oral ingestion. In the chest, the most commonly

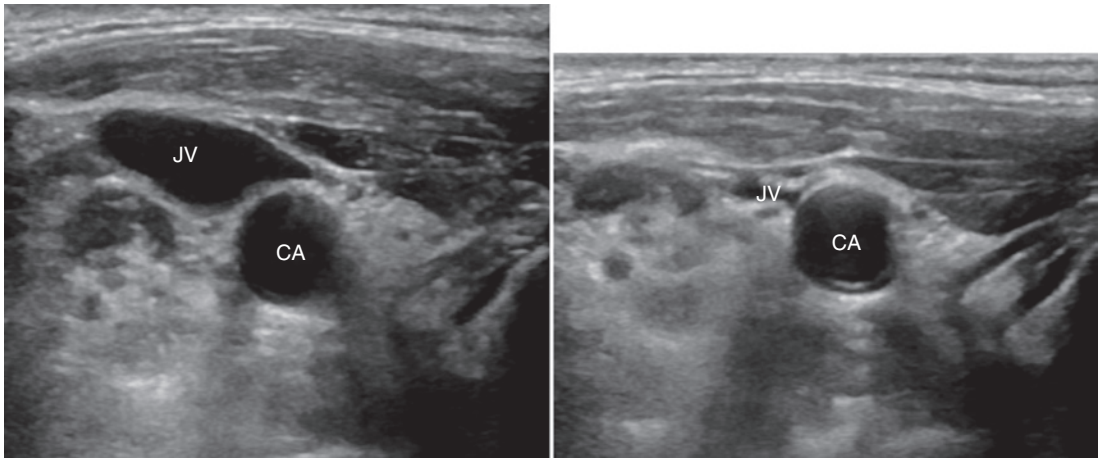

Fig. 21.8 Two ultrasound images of the right internal jugular vein *(JV)* and right carotid artery *(CA)*. In the first image, the jugular vein is distended; in the second image, the jugular vein is collapsed by gently applying pressure with the ultrasound transducer. The carotid artery did not compress.

performed nuclear medicine studies are *ventilation-perfusion (V/Q) scans* and *positron emission tomography-CT (PET-CT).* V/Q scans were initially the primary method to diagnose pulmonary emboli, although they have been largely replaced by chest CT angiography.[1] However, V/Q scans still have an important role in certain subsets of patients (such as those with renal insufficiency who may be harmed by intravenous contrast or in young patients where the V/Q scan may result in a lower radiation dose to the patient). PET-CT combines a nuclear medicine study (the injection of radioactive glucose) with chest CT and is used primarily to diagnose and stage disease in patients with suspected or known cancer. The radioactive glucose is selectively taken up by many cancer cells (and also by inflammatory cells), allowing areas of potential tumor involvement to be visualized. PET-CT is frequently used in the staging of cancers (including lung cancer [see Chapter 32]) in order to plan therapy.

The remainder of the chapter outlines commonly encountered abnormalities involving the pleura, lung parenchyma, and mediastinum. The findings of various imaging techniques are often a vital aspect of narrowing down the list of possible diseases (i.e., the differential diagnosis). You are encouraged to fine-tune your observational powers for assessing imaging studies because, as noted by Pasteur, "In the field of observation, chance favors the prepared mind."

RULE OF THUMB Three general steps to assessing a chest film are as follows:
1. Content assurance: Is the entire chest visible on the film?
2. Quality assurance: Is the chest x-ray properly exposed and centered?
3. Disciplined application of a personalized, consistent search pattern.

PLEURA

The thin membrane surrounding the lung parenchyma is referred to as the *pleura*. The lungs are surrounded by two thin pleural membranes. The outer pleural membrane, known as the *parietal pleura,* adheres to the inside of the chest wall, the upper surface of the diaphragm, and the lateral aspect of the mediastinum. The inner pleural membrane, or *visceral pleura,* closely adheres to the surface of each lung. The visceral pleura extends along the fissures that separate the lobes of the lung. The pleural membranes around the lung cannot be seen on a chest x-ray because they blend into the water density of the chest wall, diaphragm, and mediastinum. However, the visceral pleura separating the lobes can be seen if the pleural surface is parallel to the x-ray beam (as with the "minor" or "horizontal" fissure separating the right upper lobe from the right middle lobe on a PA chest x-ray). Although very thin, the visceral pleura separating the lobes is visible because it is contrasted with aerated lung on either side.

Pleural Effusion

A **pleural effusion** refers to the accumulation of excess fluid within the pleural space (see Chapter 27). In healthy individuals, it is estimated that 1 to 8 mL of pleural fluid is normally present.[8] Also normally, the diaphragm forms a dome that curves downward to attach to the chest wall on the lower ribs and thoracic and lumbar vertebra. On a chest x-ray, the arch of the diaphragm and the chest wall meet to form a point called the *costophrenic angle.* This angle is seen on both PA and lateral views (see Fig. 21.2). If the point of the costophrenic angle is rounded rather than sharp, it often indicates that a pleural effusion is present (Fig. 21.9).[9] This finding is sometimes referred to as "blunting of the CP angles." For a pleural effusion to cause blunting of the costophrenic angle on the frontal (PA/AP) view, at least 175 to 200 mL of pleural fluid must have accumulated. The lateral film detects smaller pleural effusions than are detected with the frontal view. The posterior costophrenic angle becomes blunted with 75 to 100 mL of fluid. The best view for detecting small amounts of pleural fluid is the lateral decubitus view, which is a frontal view taken as the patient is lying on his or her side with the side of the suspected pleural effusion down; 5 mL of pleural fluid can be detected on a decubitus radiograph.[10] As discussed later, ultrasound is also useful for detecting a pleural effusion.

Sometimes fluid can accumulate between the lung and the diaphragm and maintain a sharp costophrenic angle, hiding up to 500 mL of fluid.[11] Fluid that accumulates between the lung and the diaphragm is said to be in a *subpulmonic* location. The subpulmonic location is the first place pleural effusions accumulate in an upright patient.[12] The earliest sign of a left-sided pleural effusion on an upright chest x-ray is an increased distance between the inferior margin of the left lung and the stomach gas bubble. With a subpulmonic effusion, there may be an associated slight lateral shift of the point at which the diaphragm dips downward on the frontal chest x-ray (i.e., similar to a hockey stick with the blade toward the lateral chest wall).

If both air and fluid are contained within the same space, the interface between the air and the fluid forms a soft tissue density with a straight horizontal border that has air density above it. The interface may have a small meniscus on both sides. These straight, level interfaces between air and fluid are called *air-fluid levels*. An air-fluid level in the pleural space indicates the presence of a **hydropneumothorax** (Fig. 21.10), or both air and fluid in the pleural space.

Occasionally fluid accumulates in an unusual position, as within an interlobar fissure (which separates the lobes of the lung). Fluid is most commonly seen in the minor fissure, which is between the right middle and right upper lobes. Fluid within a fissure can be diagnosed on a chest x-ray by a characteristic biconvex lens-like, elliptical shape on either the PA or the lateral view (Fig. 21.11).

Pleural fluid is generally categorized as either a *transudate* or an *exudate* (see Chapter 27). However, an exudate cannot be distinguished from a transudate on a chest x-ray or chest CT. This distinction requires analyzing a sample of the pleural fluid. *Loculated* pleural fluid (fluid that does not move freely with changes in patient position) is more commonly seen in exudative effusions, hemothorax (blood in the pleural space), and empyema (infection of the pleural fluid).

Clues as to whether a pleural exudate results from inflammation or from cancer may be present on the chest x-ray. Clues that favor a malignant cause for a pleural effusion include the presence of pleural-based nodules, pulmonary nodules, or evidence of prior malignancy, such as surgical absence of the breast in a patient with breast cancer.

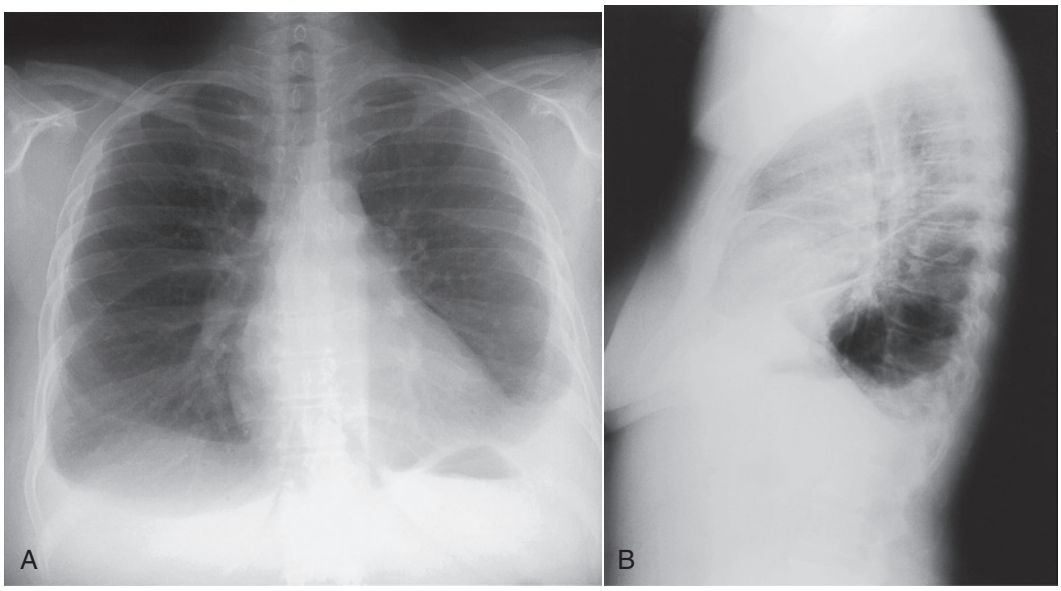

Fig. 21.9 Pleural Effusion. Posteroanterior (A) and lateral (B) chest x-rays in a 43-year-old patient with long-standing bilateral pleural effusions resulting from rheumatoid arthritis. Note that the bilateral meniscus sign is also visualized posteriorly on the lateral view.

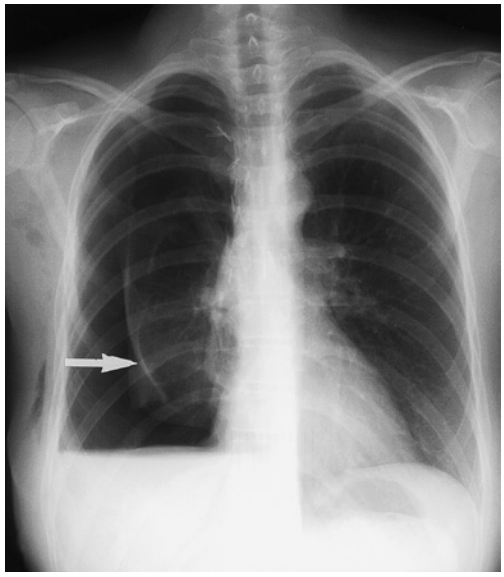

Fig. 21.10 Hydropneumothorax. Single posteroanterior view of the chest in a patient with a hydropneumothorax. Note the air-fluid level in the pleural space. The arrow points to the visceral pleura (lung border) being compressed by both air and fluid.

Ultrasound for Evaluating Pleural Fluid

Ultrasound reliably detects both small and large pleural effusions (Fig. 21.12). It is also useful in distinguishing pleural fluid from solid tissue[13] and readily identifies tissue bands associated with loculated effusions. Ultrasound is also helpful in guiding thoracentesis, in particular for small or loculated pleural effusions.

Computed Tomography

Pleural fluid can be easily identified on chest CT exams. In a supine patient, free fluid accumulates in the most dependent (posterior) portion of the chest. Pleural fluid that does not flow to the most dependent portion of the chest (i.e., the posterior portion of the chest when a patient lies down for a chest CT exam) is loculated.

With some forms of pleural disease, the pleural lining enhances (appears whiter) following intravenous contrast administration. Pleural thickening and nodularity are well seen on a contrast-enhanced CT scan. An elliptical pleural fluid collection with adjacent pleural thickening and enhancement suggests the presence of an **empyema** (see Chapter 27), which is infected pleural fluid.[14] The presence of gas within the pleural fluid without a recent history of surgery or needle insertion (which can introduce air) establishes the diagnosis of empyema (Fig. 21.13).

Pneumothorax

The term **pneumothorax** refers to the presence of air within the pleural space. The visceral pleura surrounding the lung becomes visible when air accumulates in the pleural space. A pneumothorax may occur spontaneously because of rupture of a *bleb* (a thin-walled subpleural gas-containing space deep to the pleura—a form of pulmonary air cyst) or from trauma or invasive procedures that puncture the pleura, such as transbronchial biopsy (see Chapter 22) or a percutaneous (CT-guided) lung biopsy. A pneumothorax may also occur as a complication of positive-pressure ventilation (which is called *barotrauma*). When the patient is upright, the air within the pleural space typically accumulates along the top (apex) of the lung and displaces the lung away from the chest wall. The clinician can detect a pneumothorax by observing a thin pleural line along the periphery of the lung with an absence of lung markings between the lung margin and the inner aspect of the chest wall (Fig. 21.14). If a diagnosis of pneumothorax is suspected, an upright chest x-ray should be obtained. Visualization of a small pneumothorax may be assisted by taking the chest x-ray when the patient exhales. When the patient is supine, the air within the pleural space moves to the highest point in the chest,

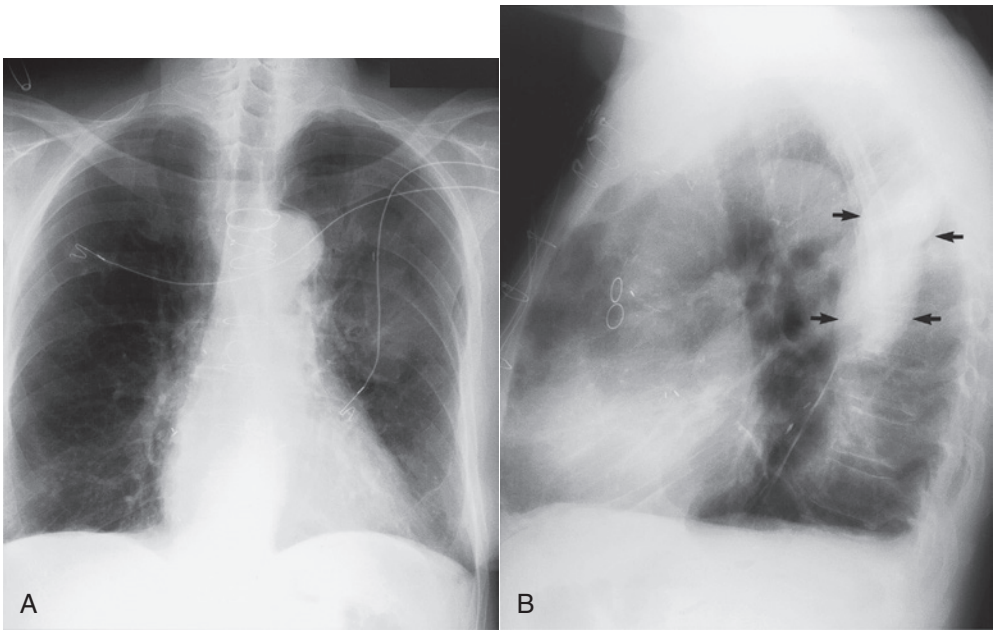

Fig. 21.11 Intrafissural Fluid. Two views of the chest showing fluid accumulating within the superior portion of the major fissure. In the posteroanterior view, (A) the fluid is seen as vague increased density in the left upper lobe. (B) Note the typical elliptic shape of the fluid on the lateral projection *(arrows)*.

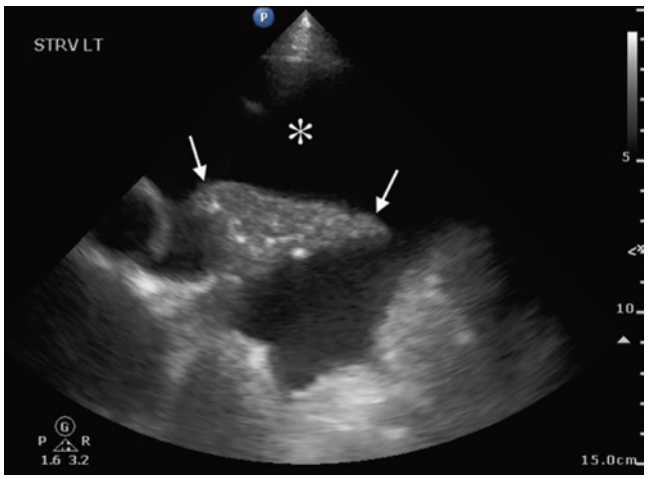

Fig. 21.12 Pleural Effusion. Ultrasound image demonstrates a large pleural effusion *(asterisk)*. Adjacent to the pleural effusion is a collapsed lung *(arrows)*.

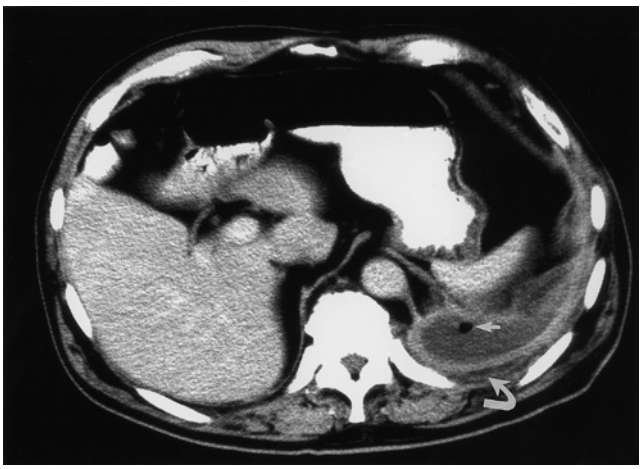

Fig. 21.13 Empyema. Cross-sectional computed tomography image shows an elliptic pleural fluid collection surrounded by thickened enhancing pleura (split pleural sign). The presence of the gas bubble *(short arrow)* within the fluid and the thickened extrapleural subcostal tissues *(curved arrow)* is strongly suggestive of empyema.

which is the anterior cardiophrenic sulcus.[15] Because air in this region may not create a visible edge between the pleura and the x-ray beam, radiographic clues to the presence of pneumothorax are more subtle in a supine patient.[15] A supine patient with a pneumothorax may have a *deep sulcus sign* (Fig. 21.15),[16] which refers to air accumulating anteriorly and outlining the heart's border below the dome of the diaphragm. In addition, the upper abdomen on the same side often shows increased lucency (i.e., the film is darker). If the diagnosis remains in doubt, a decubitus radiograph or cross-table lateral radiograph (in which the patient lies face up while the x-ray is directed across the body) can help make the diagnosis of pneumothorax. Ultrasound is an alternative to chest x-ray and is highly accurate in the diagnosis of a pneumothorax.[17]

A pneumothorax may be difficult to diagnose if a patient has bullous emphysema. If, after carefully examining the chest film, the RT is uncertain about the presence of a pneumothorax, a chest CT can resolve the question. Skin folds (i.e., when excess skin on the chest wall rolls over itself) can mimic a pneumothorax. To avoid mistaking a skin fold for a pneumothorax, the clinician should look carefully at what appears to be the lung margin. The absence of a pleural line along the lung margin and the presence of bronchovascular markings (i.e., markings of lung tissue and blood vessels) between the lung margin and the chest wall favors a skin fold rather than a pneumothorax.

Occasionally air within the pleural space may be under pressure or tension (Fig. 21.16); this is referred to as a *tension*

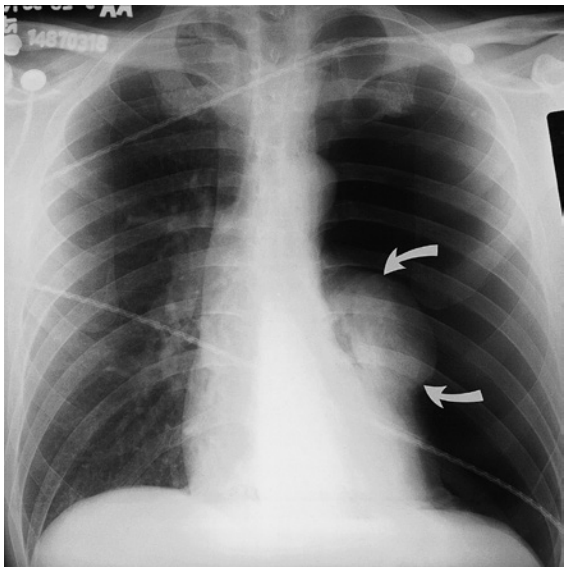

Fig. 21.14 Pneumothorax. Complete atelectasis of the left lung *(curved arrows)* resulting from a large left pneumothorax.

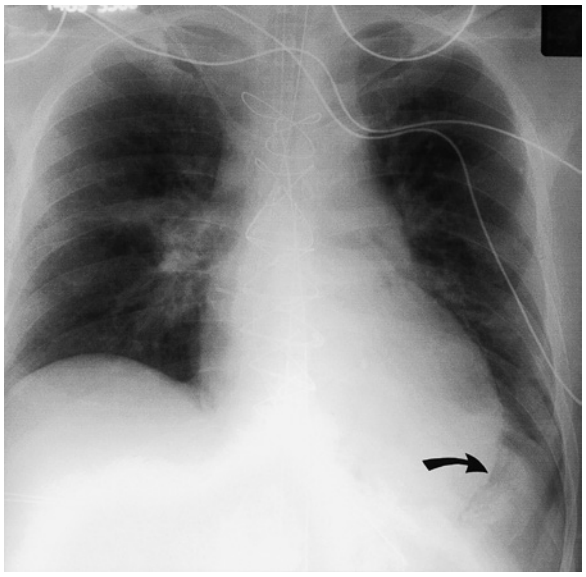

Fig. 21.15 Deep Sulcus Sign. Portable supine radiograph in a patient following median sternotomy. Note the increased lucency in the left upper quadrant. The highest portion of the thorax in a supine patient is the anterior cardiophrenic sulcus; this accounts for the well-defined low cardiac border *(arrows)* and the adjacent fat pad.

pneumothorax—an emergency that occurs when the tear in the pleura (which allows air to leave the lung and enter the pleural space) opens on inspiration but closes on expiration. Air continues to accumulate in the pleural space and can compress the heart and adjacent lung. Imaging features of a tension pneumothorax include inferior displacement of the hemidiaphragm on the side of the pneumothorax or mediastinal shift away from the pneumothorax. A tension pneumothorax requires immediate decompression with a chest tube, Heimlich valve, or needle aspiration of the air within the pleural space.

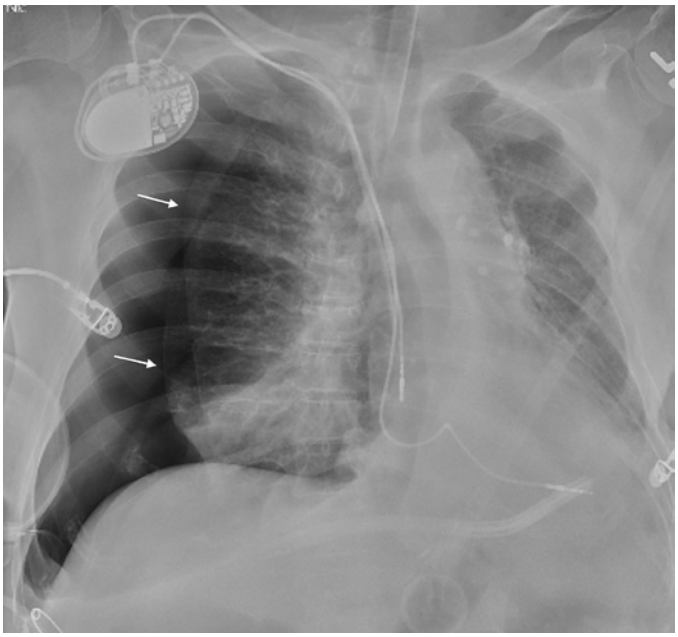

Fig. 21.16 Tension Pneumothorax. Portable chest x-ray after a recent liver transplant. Note the large right pneumothorax displacing the mediastinum to the left and the right hemidiaphragm inferiorly. These findings indicate the presence of a tension pneumothorax on the right, requiring immediate chest tube placement.

MINI CLINI

Use of the Silhouette Sign

Problem

A patient has an airspace opacity, secondary to pneumonia, in the lower half of the right lung. It is unclear if this abnormality is located in the right middle lobe or the upper portion of the lower lobe. Is there a way to identify the location of this infiltrate?

Discussion

If the right heart border is visible next to the airspace opacity or infiltrate, the pneumonia is located in the lower lobe behind the heart. If the right heart border is invisible, the airspace opacity must be located in the right middle lobe next to the right side of the heart. The disappearance of the right heart border in this circumstance is due to the silhouette sign. In this instance, pneumonia is considered a water density, and when two structures of similar density contact one another, the border between them (or the silhouette of the heart border) is not seen. Pneumonia in the upper segments of the lower lobe appears to be next to the heart on the PA chest film but does not obliterate the heart border in such cases because the water density of the pneumonia in the lower lobe is not adjacent to the water density of the heart. In this instance, the heart border is seen because the silhouette sign is not present.

LUNG PARENCHYMA

The lung parenchyma is made up of two main components: air sacs (alveoli) and interstitium (the supporting structures of the lung). Lung parenchymal disease often involves both components, although one component is usually affected more than the other.

Alveolar Disease

When alveoli are filled with material denser than air, they have a characteristic radiographic appearance regardless of the material

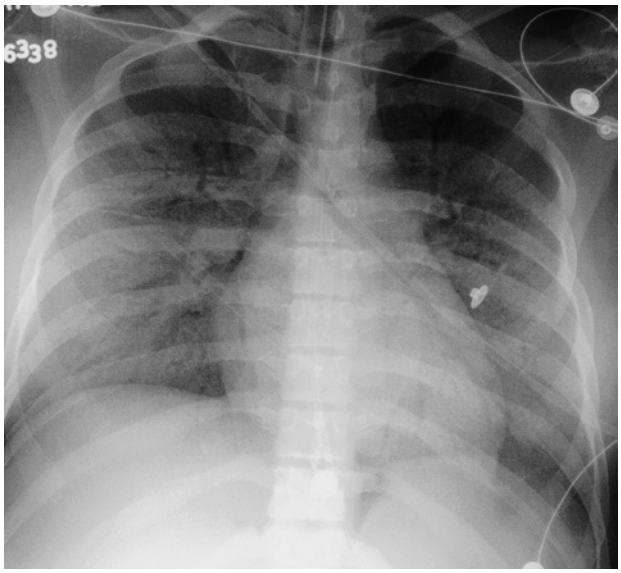

Fig. 21.17 Air Bronchograms. This portable radiograph shows increased density throughout both lungs highlighted by tubular lucencies. These are air bronchograms. They are visualized because of the alveolar filling that surrounds them. This typical alveolar filling pattern (airspace disease) suggests acute pneumonia, pulmonary hemorrhage, or pulmonary edema.

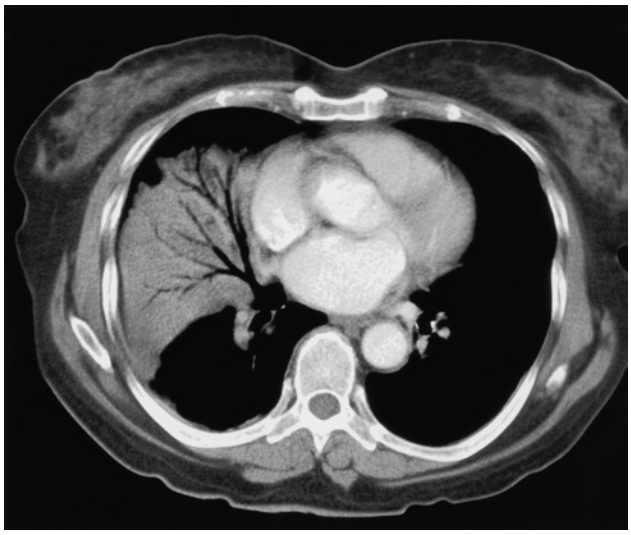

Fig. 21.18 Pneumonia, Right Middle Lobe. Computed tomography slice shows an alveolar filling process in the right middle lobe with tubular air bronchograms running through it. The patient is a 73-year-old woman.

that fills them. The type of fluid that fills the alveoli varies depending on the disease process. In the case of pulmonary edema, the alveoli are filled with a watery fluid that contains few cells. With bacterial pneumonia, the alveoli are filled with an exudative fluid containing numerous white blood cells (pus). In the case of pulmonary hemorrhage, the alveoli fill with blood. Both pneumonia and pulmonary hemorrhage can cause identical-appearing patchy, increased density shadows that tend to coalesce over time on the chest x-ray. These shadows are often referred to as *airspace opacities* or ***infiltrates.*** Although the term *infiltrate* is commonly used to describe an airspace opacity, caution should be used because some clinicians equate infiltrates with pneumonia whereas others take infiltrates to mean a much broader differential diagnosis, including pulmonary edema, pneumonia, or pulmonary hemorrhage.

The lucent tubular structures that course through dense airspace opacities or infiltrates on both chest x-rays and chest CT images are referred to as **air bronchograms** (Fig. 21.17). Normally patent airways are invisible in the outer two-thirds of the lung on a chest x-ray because of the lack of contrast between air in the airway and air in the lung parenchyma. However, the increased contrast produced by filling of the surrounding alveoli with fluid makes the airways more visible and causes the air bronchogram sign. Air bronchograms are the hallmark of infiltrates that fill alveoli (so-called *airspace disease*) (Fig. 21.18 and Box 21.2).

RULE OF THUMB Air bronchograms indicate that the imaging abnormality is located in the lung parenchyma and not in the pleural space, suggesting the presence of pneumonia.

Pulmonary Edema

Pulmonary edema is one of the most common chest x-ray findings in critically ill patients. It can be caused by vascular congestion, rupture of the pulmonary capillaries, or a combination of both. Edema from vascular congestion can be caused by failure of the left heart (cardiogenic pulmonary edema [see Chapter 31]), renal failure, or fluid overload. Breakdown in the integrity of the lung capillaries can also cause pulmonary edema, as in acute respiratory distress syndrome (ARDS; see Chapter 29).

The development of cardiogenic pulmonary edema can be described through a series of changes on the chest film. Before pulmonary edema develops, the pressure in the pulmonary veins increases. The increasing pressure in the pulmonary veins can be seen on the chest film as enlarging blood vessels that extend to the lung apexes. If the blood vessels in the upper lung zones are the same size or larger than the blood vessels in the lower lung zones, the vessels are said to be "cephalized" (Fig. 21.19). **Cephalization** of the pulmonary blood flow is often caused by left-sided heart failure.

As fluid builds up from the high venous pressures, thickening of bronchial walls *(peribronchial cuffing)* (see Fig. 21.19) and edema in the walls or septa that separate the lung lobules become

BOX 21.2 Radiographic Features of Alveolar Versus Interstitial Processes

Alveolar (Airspace) Disease
Air bronchograms
Fluffy opacities
Rapid coalescence
Acinar nodules
Segmental/lobar distribution

Interstitial Disease
Nodules
Linear/reticular opacities
Septal lines
Cysts
Honeycombing

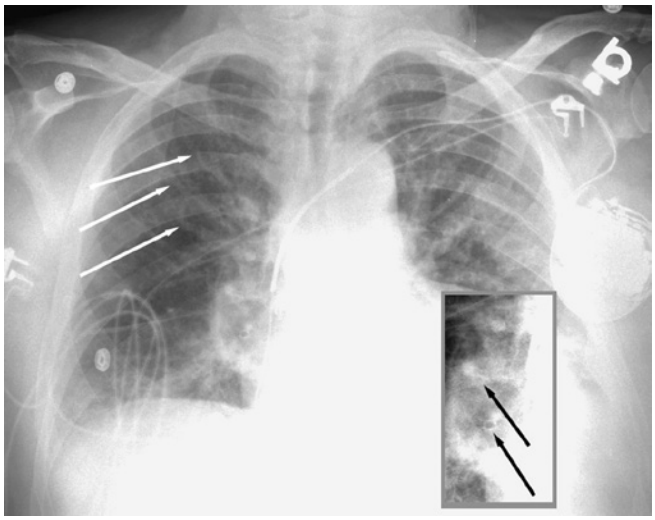

Fig. 21.19 Moderate Pulmonary Edema. Cephalization of blood flow is visible *(white arrows)*. The blood vessels to the apex of the lung are enlarged and similar in size to the blood vessels to the base of the lungs. The *inset* displays peribronchial cuffing *(black arrows);* the inset is from the right hilum of the same film but is enhanced to make the peribronchial cuffing easier to see.

evident. The thickened septa are most clearly seen as thin lines. Fluid may also accumulate in the lymphatics that drain the lung. Such accumulation within the lymphatics may appear on the plain radiograph as thin lines against the pleural edge that run perpendicularly away from the pleural edge. They are called **Kerley B lines** (Fig. 21.20).

RULE OF THUMB Radiographic signs of heart failure include the following:
- Cardiac enlargement
- Pleural effusions, usually bilateral
- Redistribution of blood flow to the upper lobes (cephalization of blood flow)
- Poor definition of the central blood vessels (perihilar haze)
- Kerley B lines
- Alveolar filling

These findings are shown in Fig. 21.20.

The development of pulmonary edema in the lung is seen first in the hila of the lungs by blurring of the normally distinct walls of the hilar blood vessels; this is followed by blurring and increased haziness caused by the edema progressing outward toward the pleura. The term *batwing appearance* is applied to the predominance of edema in the hilar regions of both lungs with progressively less edema in the more peripheral areas of the lungs (Fig. 21.21).

In addition to the previously mentioned classic signs of pulmonary edema, many patients with long-standing heart failure have an enlarged heart and pleural effusions. Such effusions from heart failure are usually bilateral, but if the effusion is visible only on one side, it is more common on the right than on the left.

The radiographic appearance of ARDS can be similar to other forms of pulmonary edema. Although they may appear similar, there are some key differences to help distinguish ARDS from pulmonary edema caused by high vascular pressures or congestive heart failure. The edema of ARDS (see Chapter 29) is patchy and bilateral and does not predominate in the central hilar regions. A chest film of a patient with ARDS also lacks cardiomegaly, cephalization, and Kerley B lines, which are often seen in cardiogenic pulmonary edema (see Chapter 31).

Interstitial Disease

Diseases that primarily involve the interstitium of the lung have a different radiographic appearance than alveolar disease (see Box 21.2). The interstitium of the lung represents the framework or scaffolding of the lung that supports the vessels and bronchi. The secondary pulmonary lobule is the smallest functional unit of the lung.[18] The *secondary pulmonary lobule* contains alveoli and alveolar ducts built around a central pulmonary arteriole and bronchiole, all surrounded by a thin sheet of fibrous connective tissue called the *intralobular septa*. Intralobular septa are invisible on a normal chest x-ray. Pulmonary edema due to poor left-sided heart function causes edema of the intralobular septa (see Chapter 31). As noted, short thin lines from the edematous intralobluar septa can be seen perpendicular to the pleura (see Fig. 21.19); these are Kerley B lines.

Interstitial lung disease (see Chapter 26) refers to a group of diseases that involve the lower respiratory tract. Chest x-rays of patients with interstitial lung disease may have several different appearances depending on the stage and type of interstitial lung disease (see Chapter 26). A chest x-ray of a patient with interstitial lung disease usually has diffuse, bilateral opacities. The opacities may resemble scattered, poorly defined nodules (nodular); a collection of scattered lines (reticular); a combination of both lines and nodules (reticulonodular); or *honeycombing,* which is the development of cystic spaces with well-defined walls seen in the periphery of the lung and resembling a honeycomb. Honeycombing represents irreversible scarring and indicates end-stage lung disease (Fig. 21.22). Lung volumes are generally decreased in patients with interstitial lung disease, a key finding that can aid in the diagnosis on a chest x-ray examination.

There are many types of interstitial lung disease. Causes include *occupational* exposures (e.g., to asbestos [asbestosis] or to silica [silicosis]) and *collagen vascular disease* (e.g., rheumatoid arthritis, scleroderma). The two most common interstitial lung diseases, *sarcoidosis* and *idiopathic pulmonary fibrosis,* have no known cause and are said to be idiopathic. Because many different types of interstitial lung diseases have similar appearances on the chest x-ray, the chest film rarely establishes the specific cause of interstitial disease. Clues to specific causes of interstitial lung disease on a plain chest film are reviewed in Table 21.2. HRCT has become an important tool in evaluating patients with suspected interstitial lung disease. HRCT is particularly helpful in diagnosing idiopathic pulmonary fibrosis because of a characteristic pattern with changes in the lower lobes exceeding those in the apices, a subpleural location, and the presence of honeycombing.[19-21]

Assessing Lung Volume

Incomplete expansion of a part of the lung, also called volume loss or *atelectasis,* is a common abnormality on chest x-rays, and the location and extent of volume loss produces characteristic

Fig. 21.20 Posterior (A) and lateral (B) chest films show an enlarged cardiac silhouette. The lateral lung margins are slightly displaced away from the inner chest wall in both costophrenic angles, which is consistent with bilateral effusions. There is thickening of the fissures on the lateral projection, indicating that the pleural fluid extends into the interlobar fissures. Numerous Kerley B lines are seen as linear densities extending to the pleural surface in the right lower chest. The definition of the central vessels is suboptimal, indicating interstitial edema. (C and D) The same patient after therapeutic diuresis. Note the decreased heart size, disappearance of Kerley B lines, and improved definition of the central pulmonary vasculature.

chest x-ray patterns. The degree of atelectasis can be described as subsegmental (involving less than a segment of lung), segmental (involving one or more segments of lung), or lobar (involving one or more lobes of the lung). A specific type of subsegmental atelectasis that has a classic radiographic appearance is called *plate-like* or *discoid* ***atelectasis*** (Fig. 21.23). Atelectasis commonly occurs after abdominal or thoracic surgery, adjacent to pleural effusions, or after pleural irritation from a rib fracture or pulmonary infarction.

Volume loss involving an entire lobe (lobar atelectasis) can sometimes be caused by central airway obstruction.[22] The collapsed lobe assumes the shape of a wedge, with the apex of the wedge at the hilum and its base on the pleural surface. This wedge is visible on a PA or lateral x-ray film, depending on which lobe is collapsed (Fig. 21.24). The central bronchial obstruction may be caused by cancer, a foreign body, or a mucous plug (Fig. 21.25). As shown in Fig. 21.26, a bulging convexity to the apex of the wedge may indicate a central tumor.

Atelectasis causes changes to the surrounding structures. As lung volume decreases, the surrounding tissues collapse to fill the space of the collapsed lung. The diaphragm becomes elevated on the side of the atelectasis, the mediastinum shifts toward the atelectasis, and poor expansion of the chest causes narrowing of the rib spaces. If the collapsed segment of the lung is in the upper lobe, the hilum and the minor fissure on the right are displaced upward.

RULE OF THUMB Radiographic signs of volume loss (atelectasis) include the following:

- Unilateral diaphragmatic elevation
- Mediastinal shift toward the atelectasis
- Narrowing of the space between the ribs
- Hilar displacement toward the atelectasis

See Figs. 21.23–21.26.

Assessment of lung volumes on a chest x-ray requires several observations. Rib counting is a popular method to assess lung volume. With a good inspiration, the sixth and sometimes the seventh anterior rib should project above the diaphragm. If more than seven anterior ribs are visible above the diaphragm, *hyperinflation* is present. Obstructive pulmonary disease is classically associated with increased lung volumes (hyperinflation). In patients with chronic obstructive pulmonary disease, there may also be an increase in the AP diameter of the chest, with associated enlargement of the retrosternal and retrocardiac (behind the sternum and the heart, respectively) airspaces and flattening of the hemidiaphragms. These findings are secondary signs of *pulmonary emphysema*. The only primary signs of emphysema are loss or shifting of pulmonary vessel markings and the appearance of the walls of bullous airspaces (Fig. 21.27).

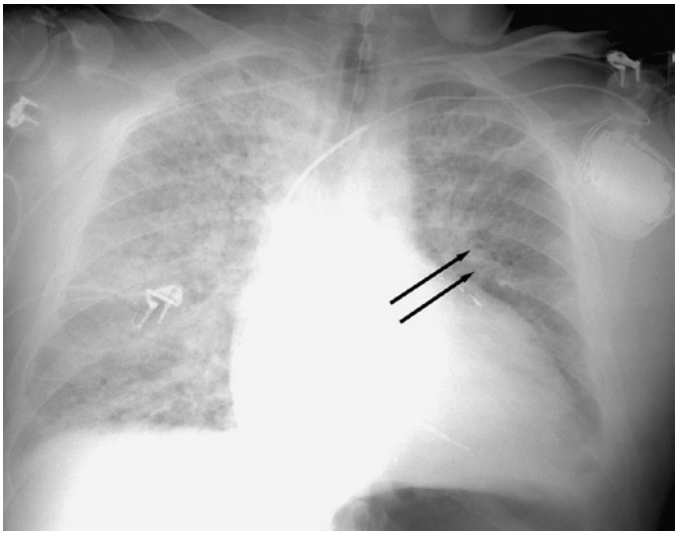

Fig. 21.21 Severe Pulmonary Edema. Both lungs are opacified in a batwing distribution. The hilar vessels are invisible because of the edema in the lung tissue surrounding these vessels. Peribronchial cuffing is indicated by the *black arrows*.

TABLE 21.2 Clues on Plain Chest X-Ray Indicating the Specific Cause of Interstitial Lung Disease

Clues on Radiograph	Cause of Disease
Pneumothorax	Lymphangioleiomyomatosis, Langerhans cell histiocytosis
Pleural effusion	Rheumatoid arthritis, systemic lupus erythematosus
Dilated esophagus	Scleroderma, CREST syndrome
Erosive arthropathy (shoulder joints, clavicles)	Rheumatoid arthritis
Mediastinal adenopathy	Sarcoidosis, progressive systemic sclerosis (scleroderma), metastatic cancer
Soft tissue calcification	Dermatomyositis, progressive systemic sclerosis (scleroderma)
Pleural plaque	Asbestosis

*CREST, C*alcinosis, *R*aynaud phenomenon, *E*sophageal dysmotility, *S*clerodactyly, and *T*elangiectasia.

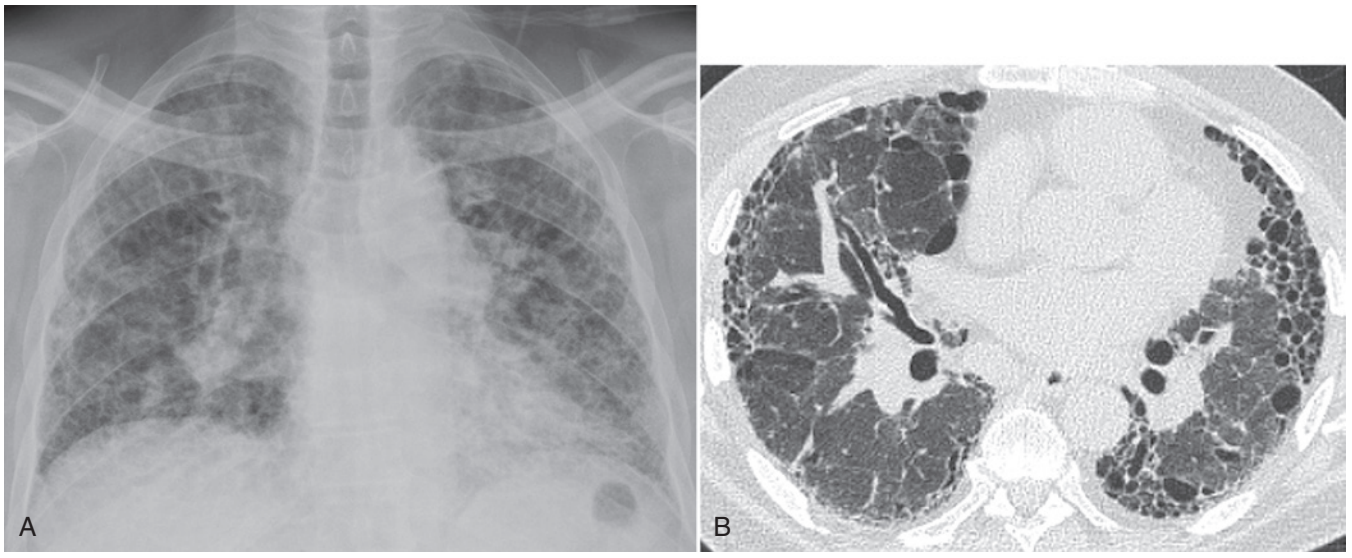

Fig. 21.22 Posteroanterior view (A) of the chest in a patient with shortness of breath. The chest x-ray shows interstitial lung disease. The lung volumes are small. Coarse linear and cystic lucencies represent pulmonary fibrosis. These findings are better visualized on the chest computed tomography image (B), where there is bronchiectasis, architectural distortion, and honeycombing. The patient has interstitial pulmonary fibrosis, the most common type of pulmonary fibrosis.

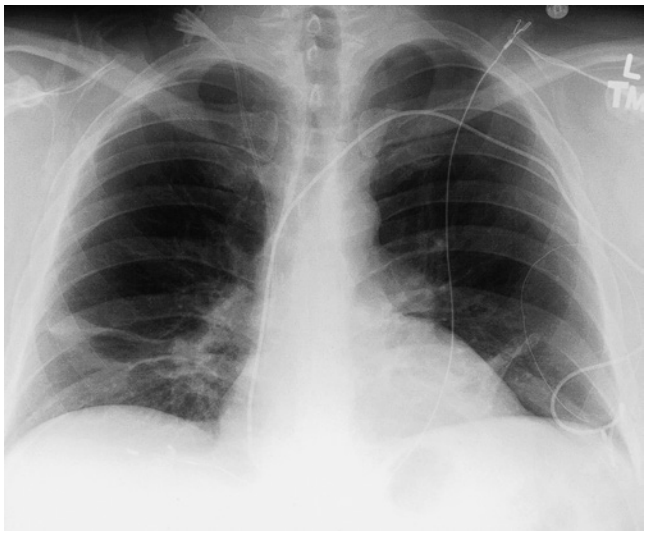

Fig. 21.23 Plate Atelectasis. Posteroanterior chest x-ray shows linear areas of plate atelectasis in both lower lobes.

RULE OF THUMB A good inspiratory effort by the patient is needed to obtain a good-quality chest x-ray examination. Visualization of 6 anterior or 10 posterior ribs above the level of the diaphragm on the PA view indicates a good inspiratory effort by the patient.

Because radiographic signs of emphysema (see Chapter 25) are apparent only with more advanced disease, the chest x-ray is generally considered insensitive for detecting obstructive lung disease. However, CT is far more sensitive and may show evidence of emphysema even when pulmonary function test results are normal.[23] Emphysema is often anatomically described in three patterns depending on which part of the secondary pulmonary lobule is affected. When only the central part of the lobule is affected, the pattern is called *centrilobular* or *centriacinar emphysema*. When the entire lobule is affected, the pattern of emphysema is called *panlobular* or *panacinar*. Finally, when the emphysema is confined to areas near the pleura, the pattern is called *paraseptal emphysema*. Fig. 21.28 shows a case of upper

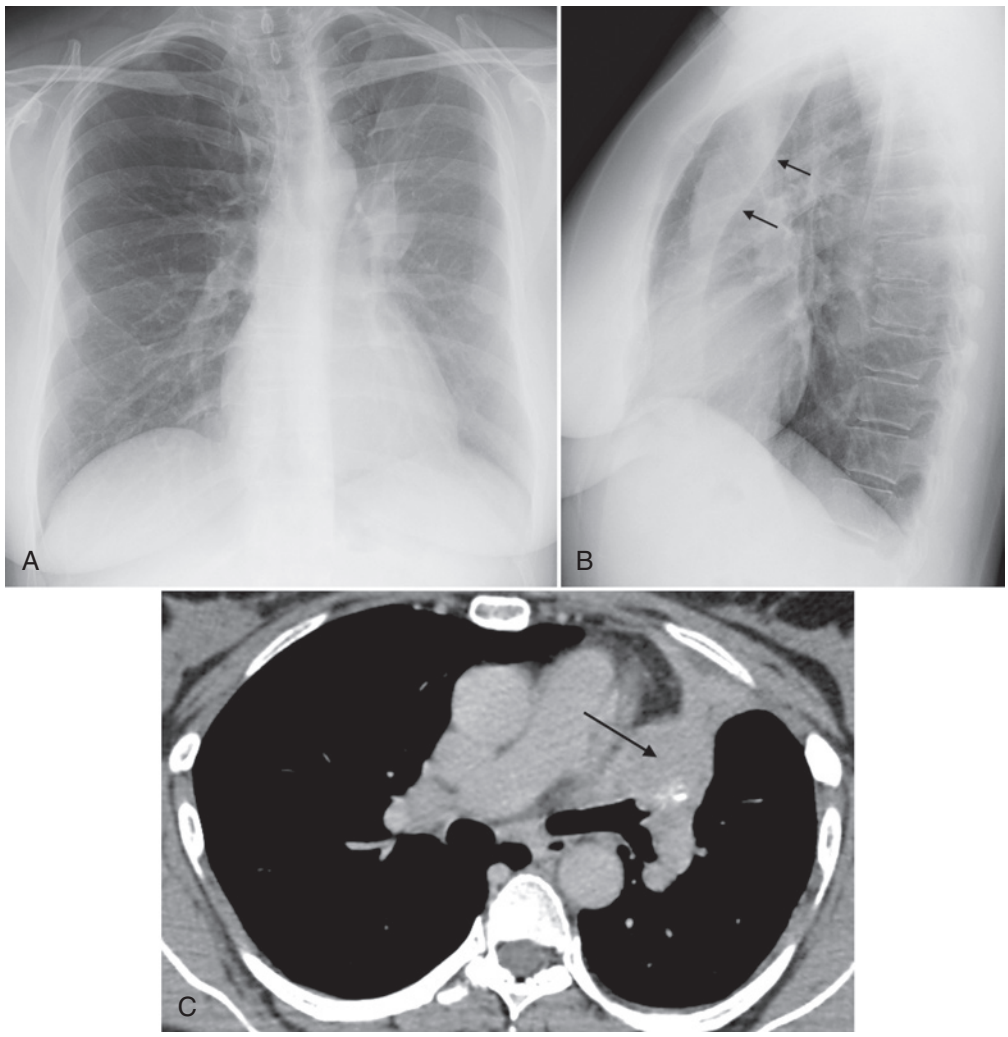

Fig. 21.24 (A) Posteroanterior view of the chest shows leftward mediastinal shift, a left hilar mass, and increased density overlying the left chest. (B) Lateral view shows a wedge of increased density *(arrows)* anteriorly with its apex at the hilum and its base on the pleural surface representing the collapsed left upper lobe. (C) Computed tomography image shows a partially calcified left hilar mass *(arrow)* with the collapsed left upper lobe distally. Biopsy of the mass revealed carcinoid tumor.

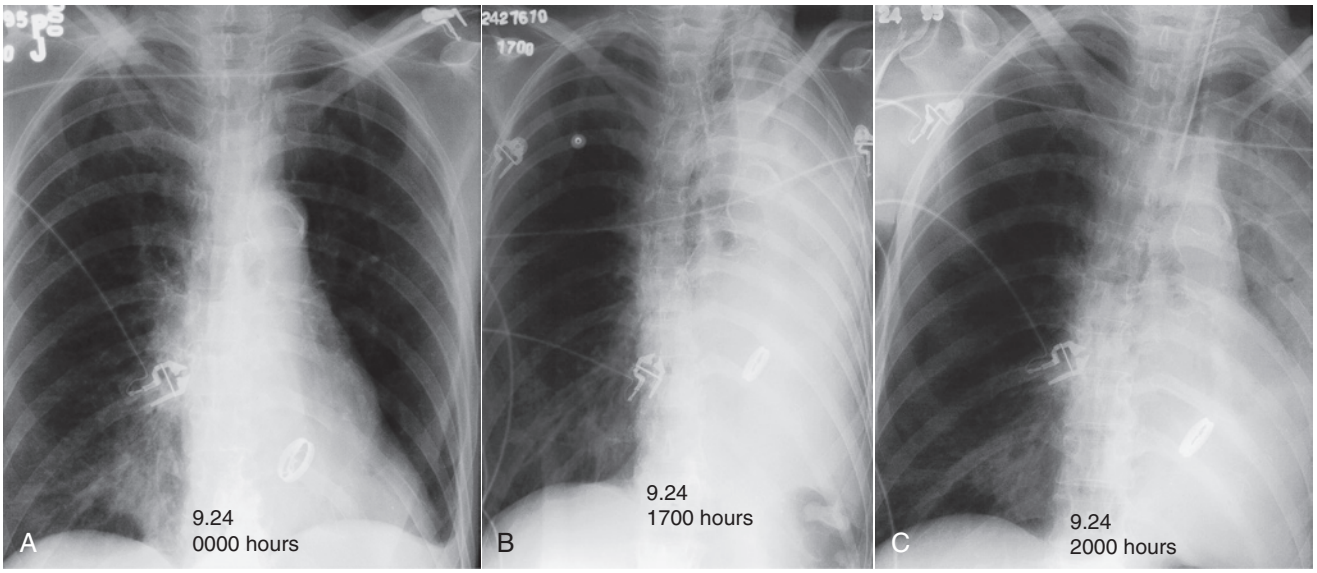

Fig. 21.25 Three Portable Chest Films Obtained Within a 20-Hour Time Span. (A) Good aeration of both lungs. (B) Film obtained 17 hours later shows complete opacification of the left hemithorax. Bronchoscopy performed after this film revealed a mucous plug in the left main bronchus. It was removed at bronchoscopy. (C) Partial reexpansion.

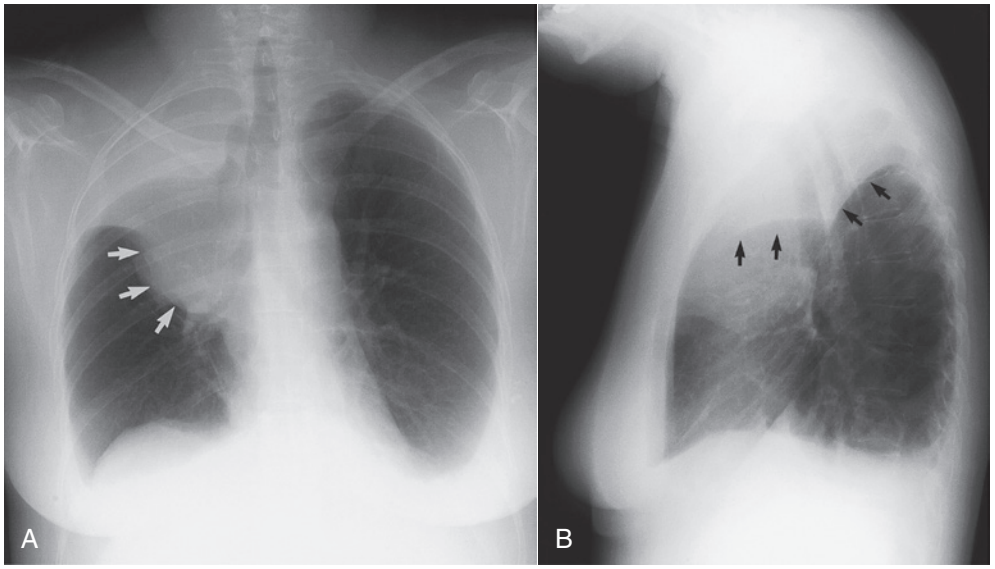

Fig. 21.26 Posteroanterior (A) and lateral (B) views of the chest in a patient with right upper lobe collapse. (A) Note the wedge opacity of the right upper lobe and the inferior bulge *(arrows)* of the minor fissure on the posteroanterior film. This bulge indicates the presence of a central mass. (B) The wedge shape of right upper lobe atelectasis *(arrows)* is well seen on the lateral film.

lobe paraseptal emphysema, characterized by cystic areas along the pleural surface. A chest CT scan may prove useful to help define which patients may benefit from treatments such as lung volume reduction surgery. Results of the National Emphysema Treatment Trial showed that patients with heterogeneous upper lobe–predominant emphysema (i.e., emphysema that is greater in the apices of the lung than in the bases) are good candidates for lung volume reduction surgery.[24]

Solitary Pulmonary Nodule

A **solitary pulmonary nodule** (SPN) is a parenchymal opacity smaller than 3 cm in diameter that is surrounded by aerated lung. Parenchymal opacities 3 cm or greater are referred to as lung masses. One or two SPNs are encountered in every 1000 chest x-rays. SPNs are important to identify because they may be caused by lung cancer or another malignancy that has spread or metastasized to the lung. The reported prevalence of malignancy in SPNs ranges from 3% to 6% in large surveys of the general population. In patients with SPNs who have surgical resection, 30% to 60% of the nodules are malignant.[25]

When first encountered, an SPN should be assessed for features listed in Table 21.3 that may help to establish a nonmalignant cause. The goal of imaging SPNs is to avoid resecting benign nodules while encouraging surgical removal of all potentially curable cancers. The axial anatomic display of CT, along with better density-discriminating powers, makes CT a preferred tool

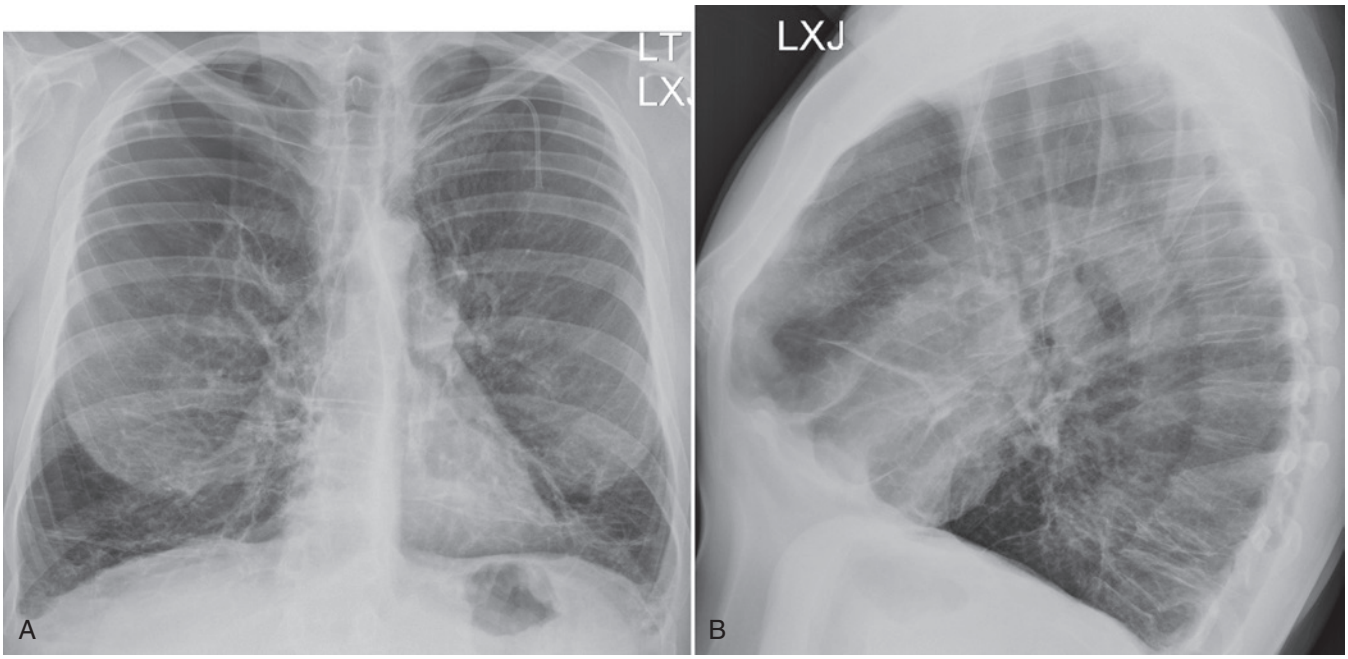

Fig. 21.27 Posteroanterior (A) and lateral (B) views of the chest of a patient with bullous emphysema, worse on the right. The lungs are hyperinflated with flattening of the diaphragms, increased retrosternal clear space, and areas in the upper lung zones that are devoid of any vascular markings.

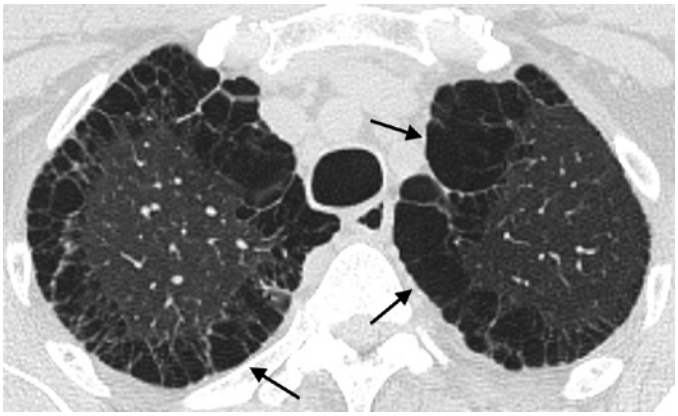

Fig. 21.28 Computed Tomography Image Through the Upper Lobes in a Patient With Pulmonary Emphysema. Numerous cystic lucencies are present in both lungs. Note the absence of bronchovascular markings within the lucencies. Most of the emphysematous areas are located in a peripheral distribution *(arrows)* along the pleural surface, representing paraseptal emphysema.

TABLE 21.3 Features Useful in Distinguishing Benign From Malignant Solitary Pulmonary Nodules

Feature	Favoring Malignant Nodule	Favoring Benign Nodule
Patient's age	>40 years old	<40 years old
Smoking status	Current or former smoker	Lifetime nonsmoker
Size of nodule	>3 cm	<3 cm
Shape of nodule	Lobulated	Spherical
Margins of nodule	Spiculated	Well defined
If cavity	Thick-walled	Thin-walled
Doubling time[a]	7–465 days	<7 or >465 days
Calcification	Rare, usually eccentric	Central, lamellar, popcorn

[a]Time necessary for the nodule to double in volume.

for evaluating SPNs. CT provides a detailed evaluation of the size, shape, border, and density of a nodule. For example, the presence of fat or the pattern of calcification can help to establish that a pulmonary nodule is benign (Fig. 21.29).

Central or lamellar swirls of concentric rings often result from calcification and strongly suggests a benign cause of an SPN or a granuloma. Eccentric (off-center), speckled, or amorphous calcification may be seen in lung cancer. A smoothly marginated round pulmonary nodule more often is benign, whereas a nodule with a lobulated, irregular, or spiculated border is more likely to be malignant (see Fig. 21.29). PET-CT is often very helpful in evaluating SPNs (Fig. 21.30). Nodules greater than 1 cm in diameter that take up the isotope used in PET-CT studies, fluorodeoxyglucose (FDG), are metabolically active and are more likely to be malignant than nodules without uptake. Unfortunately FDG uptake by a pulmonary nodule on a PET-CT is not specific for malignancy because infectious or inflammatory nodules (such as nodules caused by fungal infection with *Histoplasma,* areas of pneumonia) may also be FDG-avid and "light up." Similarly, slow-growing cancers (such as adenocarcinoma in situ) or small (<1 cm) malignant nodules may not take up FDG on PET-CT exams.

RULE OF THUMB Although a PET-CT scan can be useful in helping to evaluate whether a pulmonary nodule is benign or malignant, the test has limitations. Small nodules (<1 cm in diameter) can be PET-negative (i.e., they do not take up the FDG agent) despite being cancerous, and inflammatory nodules (e.g., due to infections) can be PET-positive despite not being cancerous.

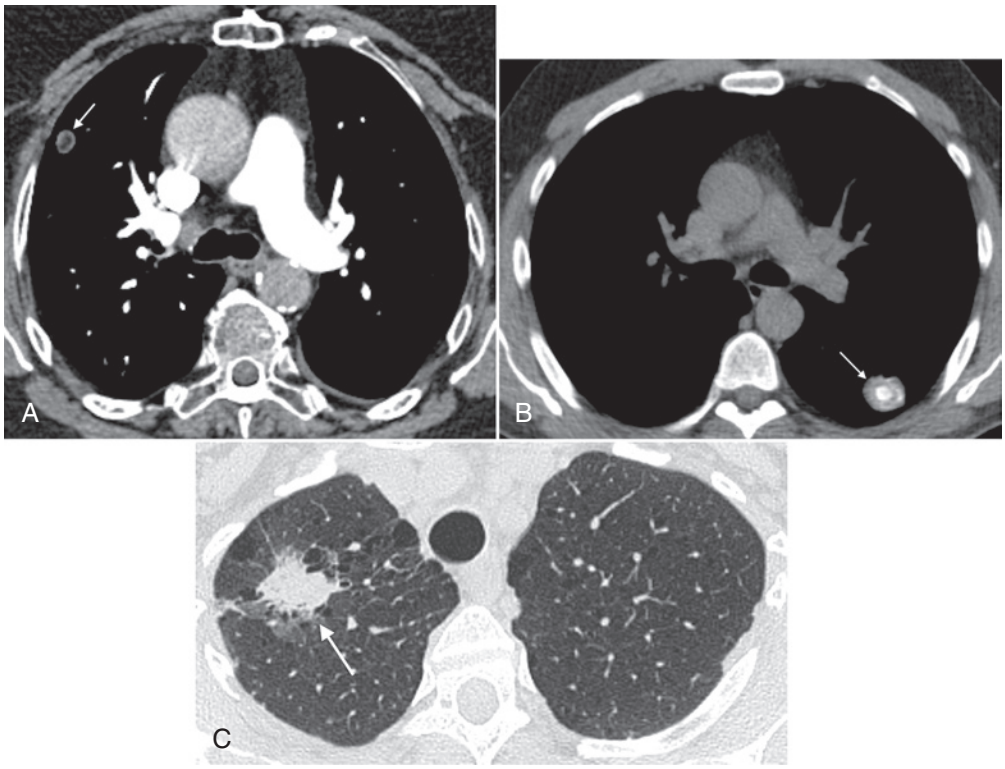

Fig. 21.29 Computed Tomography Examples of Solitary Pulmonary Nodules. (A) Nodular density in the right lung, containing fat. Note the same density within the nodule as the subcutaneous fat. This finding is diagnostic of a pulmonary hamartoma, a benign diagnosis requiring no further follow-up. (B) There is central calcification with this pulmonary nodule *(arrow)*, a benign form of calcification consistent with a granuloma. (C) The spiculated edge of this nodule *(arrow)* is suggestive of malignancy in this biopsy-proved primary lung adenocarcinoma.

MEDIASTINUM

The mediastinum consists of the structures that lie between the lungs—including the heart, great vessels, trachea, esophagus, and lymph. The mediastinum is divided into three compartments: (1) anterior, (2) middle, and (3) posterior. When a mediastinal abnormality is discovered, determining the precise location of the mediastinum is important to narrow the list of possible causes; this is called the *differential diagnosis*. The three mediastinal compartments are best defined on a lateral view (see Fig. 21.5). A line extending from the diaphragm along the posterior margin of the heart and the anterior margin of the trachea to the neck divides the anterior mediastinum from the middle compartment. A second line traversing the vertebral bodies 1 cm posterior to their anterior margins and extending from the neck to the diaphragm divides the middle from the posterior compartment. Some mediastinal masses are visible on both front and lateral projections, and the specific location within the mediastinum offers the first clue to diagnosis.

Table 21.4 lists the common causes of masses in the three mediastinal compartments. CT is the preferred imaging examination for evaluating most mediastinal masses. Fig. 21.31 shows the normal axial anatomic display on contrast-enhanced CT scan at the levels of the great vessels, aortic arch, carina, and cardiac chambers. The CT appearance of an anterior mediastinal mass (thymoma) is shown in Fig. 21.32. Fig. 21.33 shows a middle mediastinal mass (bronchogenic cyst) on an MRI examination. A large hiatal hernia located in the mediastinum can be easily confused with a mass on the frontal chest film but is easily seen on CT in Fig. 21.34.

TABLE 21.4 Mediastinal Abnormalities by Compartment

Anterior Mediastinum	Middle Mediastinum	Posterior Mediastinum
Thyroid or parathyroid mass	Aortic aneurysm (ascending/arch)	Aortic aneurysm (descending)
Thymic lesions	Lymphadenopathy	Neurogenic tumors
Lymphoma	Bronchogenic cyst	Lymphoma
Pericardial cyst/fat pad	Tracheoesophageal masses	Neurenteric cyst
Teratoma	Hiatal hernia	Bochdalek hernia[a]
Morgagni hernia[a]		
Ventricular aneurysm		

[a]Hernia in which the abdominal contents press through a gap in the diaphragm.

Pneumomediastinum

Pneumomediastinum, which is the accumulation of air in the mediastinum, is a form of barotrauma and may also be seen in cases of esophageal rupture (Fig. 21.35). This condition usually occurs in the distal portion of the esophagus in patients who

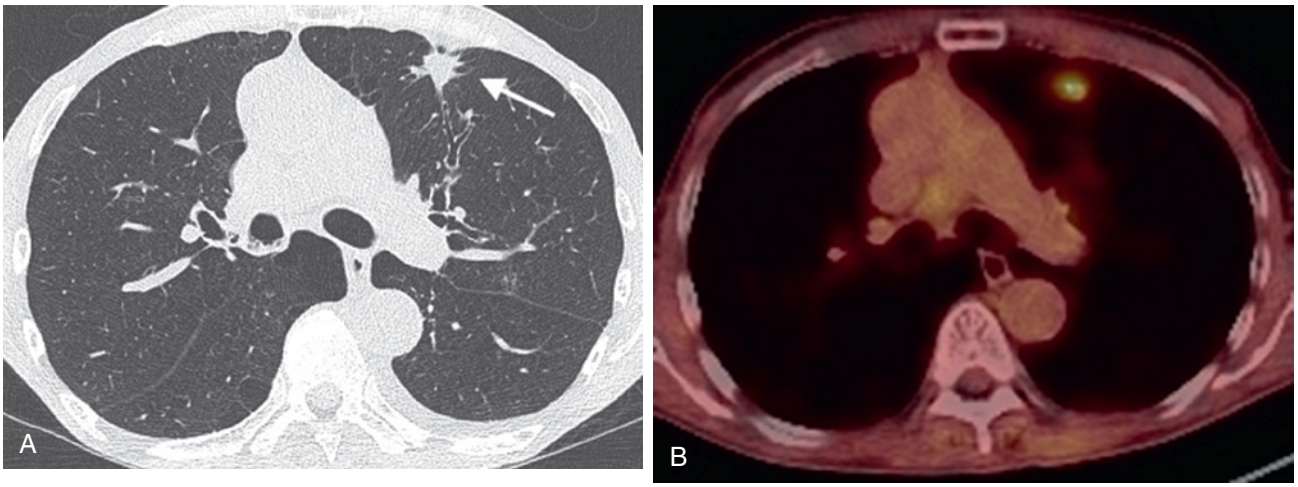

Fig. 21.30 (A) Chest computed tomography (CT) image of a speculated left upper lobe pulmonary nodule, indicated by the arrow. (B) A fused image (containing information from both a chest CT and information from the nuclear medicine exam) from a subsequent positron emission tomography-CT exam shows that the left-upper-lobe nodule is hypermetabolic, meaning that it takes up glucose. It appears yellow on the fused image. This nodule was biopsied and represents a primary lung adenocarcinoma.

undergo procedures to stretch or dilate the esophagus. Chest trauma may cause injury to the trachea or central bronchi (such as the trachea or mainstem bronchi), also allowing movement of air into the mediastinum. Rarely, air dissects down from the soft tissues of the neck after thyroid, parathyroid, or tonsillar surgery. Gas associated with a retrotonsillar abscess may extend inferiorly into the mediastinum through the fascial planes of the neck. Air that accumulates in the retroperitoneum may enter the mediastinum via openings in the diaphragm for the aorta or esophagus.

Catheters, Lines, and Tubes

Chest x-rays are commonly used to evaluate the position of catheters, lines, and tubes and to evaluate for potential complications that may arise from the placement of these devices. RTs must be skilled at examining the chest x-ray to determine the position of the endotracheal tube, chest tubes, central and peripheral catheters, and hemodynamic monitoring lines.

Endotracheal Tube

Endotracheal tubes are radiopaque, meaning that they block the transmission of x-rays and appear white on a chest x-ray. Radiographs are routinely obtained at the bedside after intubation to assess for correct endotracheal tube position. The chest x-ray shows the distal tip of the endotracheal tube and the carina. The position of the patient's neck is important. The neck position is usually neutral, but the position of the tip of the endotracheal tube can vary with neck position. Specifically, the endotracheal tube's position can move appropriately 4 cm toward the carina as the neck moves from full extension (high position) to full neck flexion (low position), which is one-third the length of the average adult trachea. In other words, when the neck is flexed, the endotracheal tube moves down deeper into the trachea. Although there is some variability in the literature, several studies suggest that when the head and neck are in the neutral position, the endotracheal tube should be positioned in the mid-trachea approximately 3 to 7 cm above the carina. Although it may be difficult to see on some chest x-ray images, the carina is generally located at the space between the T4 and T5 vertebral bodies in most adults.[26] Placement below the thoracic inlet (usually at C5 to C6 for adults) ensures that the tube is beyond the vocal cords (usually at C5 to C6). Fig. 21.36 shows an endotracheal tube that has been advanced too far into the airway and is positioned in the right mainstem bronchus. This creates a dangerous situation which can cause hyperinflation of the right lung and atelectasis of the left lung. Hypoxemia can result.

RULE OF THUMB The distal tip of the endotracheal tube should be positioned approximately 3–7 cm above the level of the carina in an adult patient.

RULE OF THUMB When the patient flexes his or her neck, the tip of the endotracheal tube moves down (into the lung). When the neck is extended, the endotracheal tube moves up (out of the lung toward the vocal cords). Thus proper positioning of an endotracheal tube is important to prevent its migration into a mainstem bronchus (usually the right mainstem bronchus) when neck flexion occurs or to prevent accidental extubation when neck extension occurs.

Tracheostomy Tube

Tracheostomy tubes should be two-thirds the diameter of the trachea and should project within the borders of the trachea on the radiograph. The tip should extend beyond half the distance from the stoma to the carina.

Central Line

A central venous catheter is typically placed via either the internal jugular or subclavian vein. A chest x-ray should be obtained after placement to assess the position and to exclude a procedural complication (e.g., pneumothorax, hemothorax). Ideally the tip of the central venous pressure catheter should be in the superior vena cava. This vessel usually forms at the level of the first

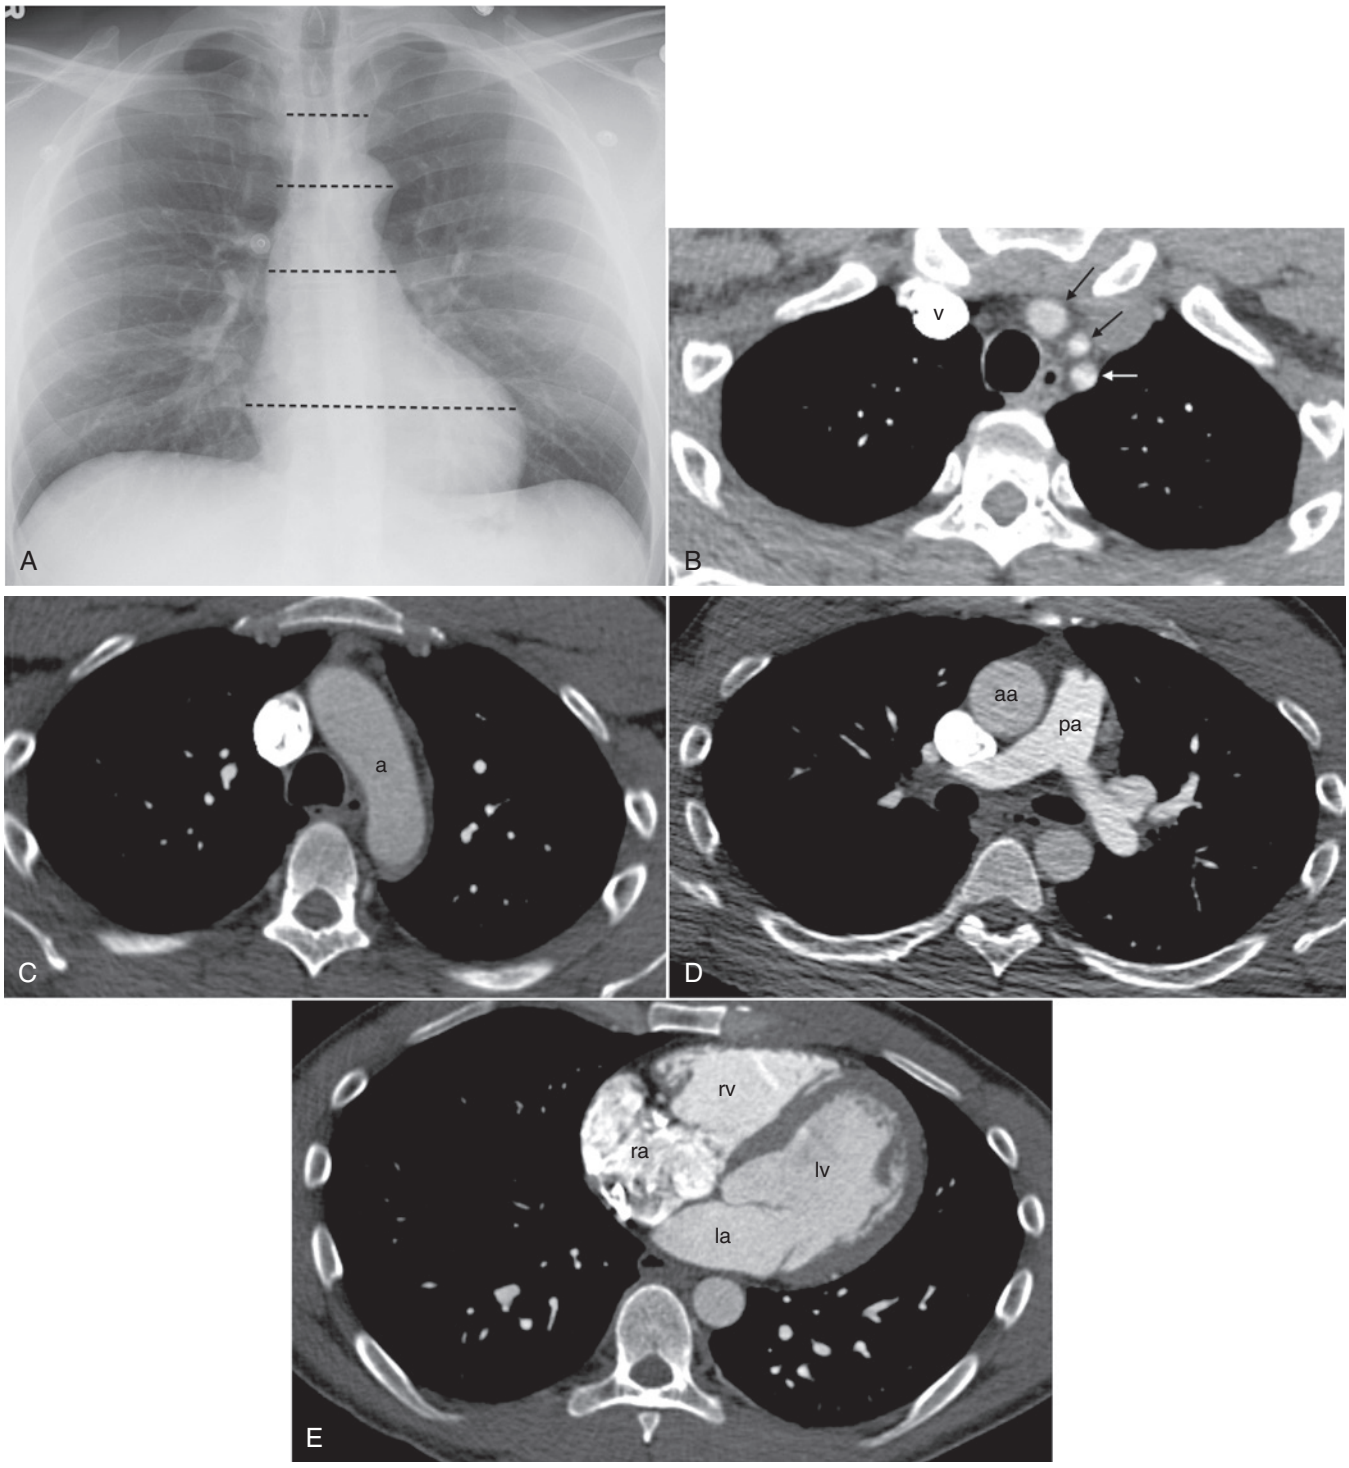

Fig. 21.31 (A) Posteroanterior chest x-ray indicating the four levels at which computed tomography scan slices (B) to (E) were obtained. (B) The most superior image is at the level of the great vessels. Contrast material fills the right brachiocephalic vein *(v)* and the three arch vessels, the right brachiocephalic, left common carotid, and left subclavian arteries. (C) At this level, the arch of the aorta *(a)* lies on the left side of the airway. The esophagus is seen in front of the vertebral body behind the airway. The opacified superior vena cava lies to the right of the arch anteriorly. (D) At the level of the pulmonary artery *(pa)* bifurcation, the right pulmonary artery crosses the mediastinum anterior to the right main bronchus. The vena cava lies to the right of the ascending aorta *(aa)*. The descending aorta is seen next to the vertebral body. (E) At the level of the heart, contrast material is seen filling the right atrium *(ra)* and crossing the atrioventricular (tricuspid) valve into the right ventricle *(rv)*. The thick, muscular left ventricular *(lv)* wall is visualized as it contracts. The left atrium *(la)* is seen anterior to the esophagus.

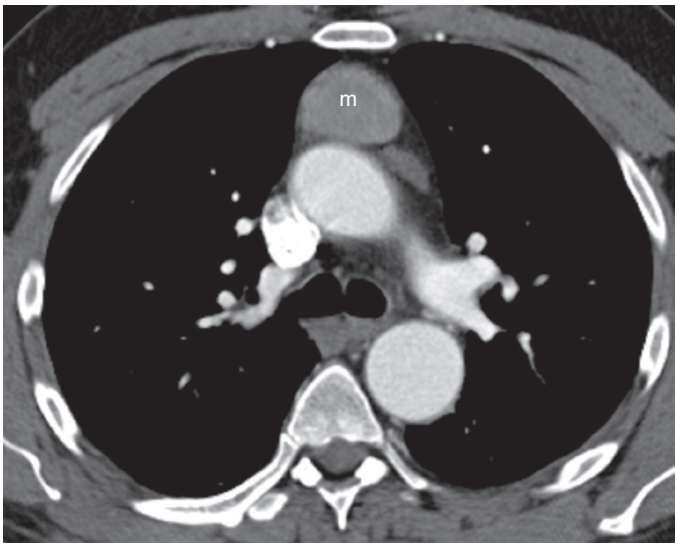

Fig. 21.32 **Anterior Mediastinal Mass.** Computed tomography slice at the level of the aortic arch shows a homogeneous encapsulated anterior mediastinal mass *(m)*. The diagnosis was thymoma.

anterior intercostal space where the brachiocephalic veins come together. The brachiocephalic veins contain valves, and these catheters ideally should be placed central to any valves.

Peripherally Inserted Central Venous Catheter

An alternative to placing a central venous catheter is a peripherally inserted central venous catheter (PICC), which is placed via a peripheral vein in either the left or right upper extremity. Advantages of a PICC are that it does not risk a pneumothorax, as would occur with central venous catheters; it can be used long term (often for several weeks); and it has a lower rate of infection than central venous catheters. The preferred location for a PICC is similar to that for a central venous catheter, with the tip of the catheter located in the superior vena cava.

Pulmonary Artery (Swan-Ganz) Catheter

Although not as commonly used as in the past, Swan-Ganz catheters are used to measure hemodynamic and central pressure variables such as pulmonary artery occlusion pressure (sometimes called the "wedge pressure"). Pulmonary artery catheters are

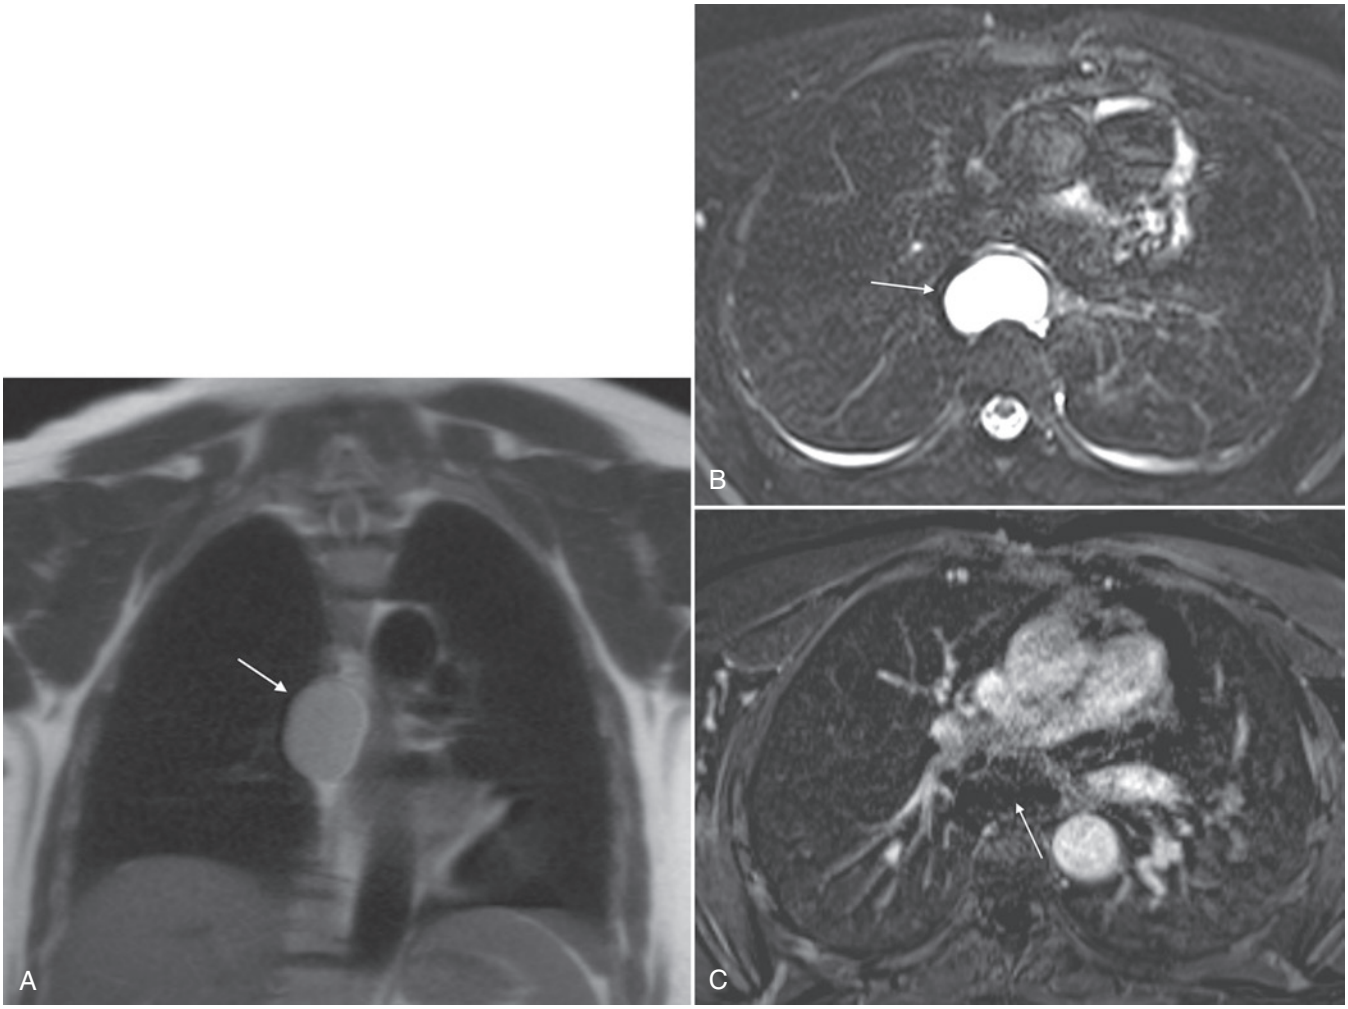

Fig. 21.33 **Middle Mediastinal Mass.** Magnetic resonance images demonstrate a subcarinal mass *(arrows)*. Coronal HASTE (A) and axial STIR (B) images demonstrate increased T2 signal (appearing gray or white) intensity in this mass, suggestive of a cystic lesion. Subtraction VIBE image (C) shows no enhancement (the mass is black), confirming no contrast enhancement. The diagnosis is a bronchogenic cyst, a benign lesion. HASTE, VIBE, and STIR refer to specific MRI imaging sequences and/or analyses used to optimize discrimination among tissue types. *HASTE*, Half-Fourier Single Shot Turbo Spin Echo; *VIBE*, Volumetric Interpolated Breath-Hold Sequence; *STIR*, TI Inversion Response.

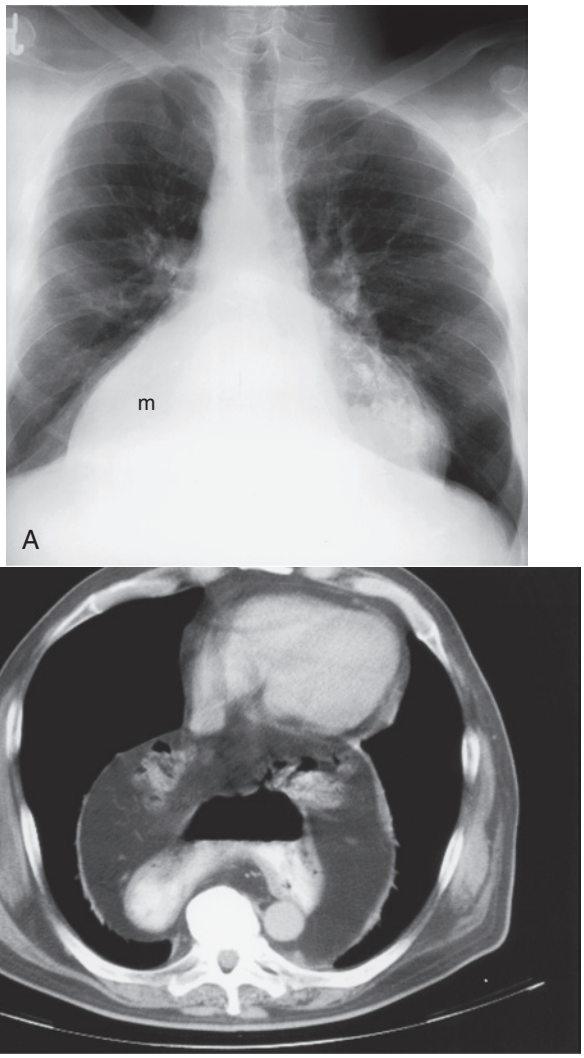

Fig. 21.34 Posterior Mediastinal Mass. (A) Posteroanterior chest x-ray shows a large soft tissue density *(m)* obscuring the right heart border and the right hemidiaphragm. (B) Computed tomography image at this level shows a large retrocardiac diaphragmatic hernia containing omentum and stomach.

placed at the bedside and ideally should reside in the proximal right or left main pulmonary arteries. They are floated into position using an inflatable balloon on the catheter tip. Because of this maneuver, they are placed in the right pulmonary artery more than 90% of the time. When the wedge or pulmonary artery occlusion pressure is measured, the balloon is inflated and the catheter moves out into a more peripheral vessel. As soon as the reading has been accomplished, the balloon should be deflated and the catheter pulled back to a central location. Persistent peripheral placement (i.e., when the catheter tip is far out in the lung parenchyma) can cause infarction of the lung beyond (distal to) the wedged catheter (Fig. 21.37) or result in injury to the pulmonary artery, such as formation of a pseudoaneurysm or even rupture.

Chest Tube

Chest tubes are small-bore to large-bore tubes placed into the pleural space from outside the chest wall (see Chapter 27). The most common indications for a chest tube are for a pneumothorax

Fig. 21.35 Pneumomediastinum. Posteroanterior view of the chest of an 11-year-old child with asthma shows linear lucencies (free air) in the mediastinum and extending into the soft tissues of the neck bilaterally. Note the free air around the lateral aspect of the right clavicle *(arrow)*.

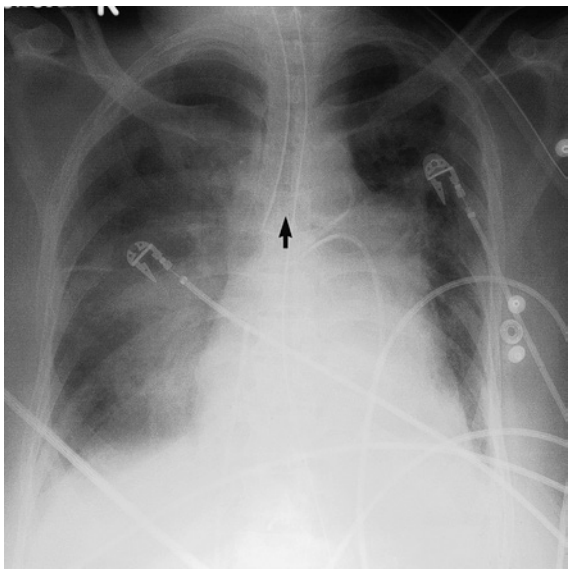

Fig. 21.36 Portable supine chest film shows malposition of an endotracheal tube in the right mainstem bronchus *(arrow)*.

(air in the pleural space) or an empyema (pus in the pleural space), although chest tubes may also be used to drain blood *(hemothorax)* or fluid *(hydrothorax)* or to install a sealant (e.g., the antibiotic doxycycline) to achieve closure of the pleural space, preventing a recurrent pneumothorax or hydrothorax. Radiographically, most chest tubes have radiopaque stripes along their axes so they can be seen on the chest x-ray. The chest tube should be within the pleural space; it usually follows the contour of the chest wall or diaphragm on the chest x-ray.

Intra-Aortic Balloon Pump

The intra-aortic balloon pump (IABP) is a counterpulsation device used to improve cardiac output and blood pressure in patients in cardiogenic shock. It is inserted through the femoral

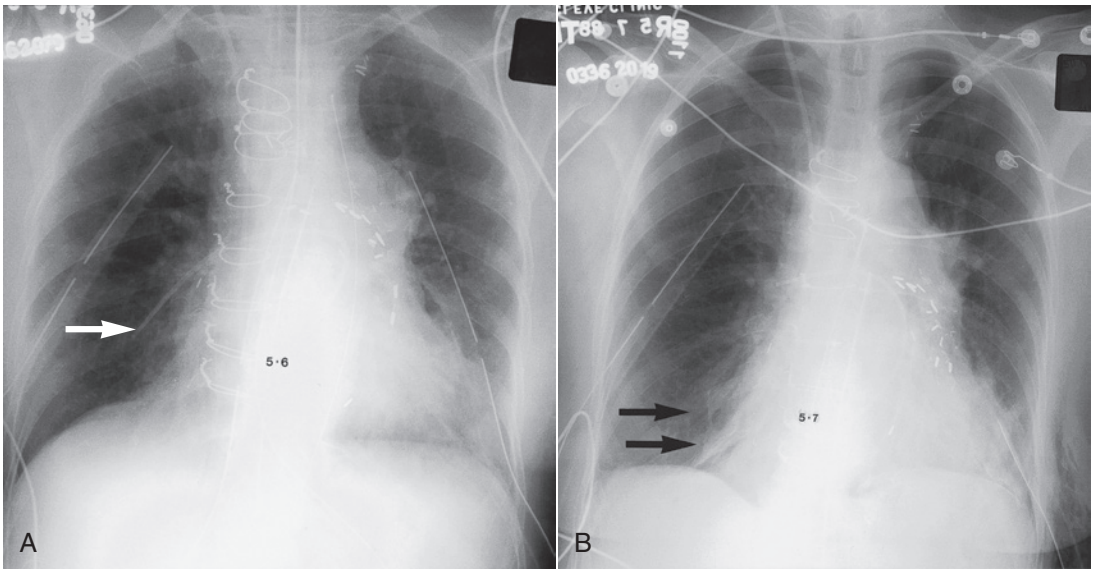

Fig. 21.37 Two Portable Supine Chest Films Obtained 30 Hours Apart. (A) Wedged Swan-Ganz (pulmonary artery) catheter in the right lower lobe *(arrow)*. (B) Film obtained after retraction of the catheter shows increased density at the site, reflecting an area of infarction caused by prolonged inadvertent wedging of the catheter *(arrows)*.

artery and advanced into the thoracic aorta. The device is approximately 26 cm long, and a radiopaque tip allows for radiographic verification of its position. The balloon inflates during diastole and deflates during systole to enhance perfusion of the coronary arteries and cardiac output. The radiopaque tip should reside just beyond the origin of the left subclavian artery within the proximal descending thoracic aorta. The carina can be used as a landmark with the tip of the IABP approximately 2 cm above the carina.[27] Correct positioning is important, as placement too proximally (superiorly) can occlude the branch aortic vessels to the neck and upper extremities, whereas placement too distally (inferiorly) can occlude vessels to the abdominal organs and intestines.

SUMMARY CHECKLIST

- Thoracic imaging is an important tool for evaluating the cause and degree of various pulmonary diseases. Various thoracic imaging techniques are available to diagnose and monitor patients with lung disease.
- The tissue densities seen on the plain chest x-ray are air, fat, soft tissue (water), and bone.
- The steps in interpreting the chest film include (1) reviewing the technique and quality of the chest film (rotation and penetration) and (2) taking a step-by-step, disciplined approach to reviewing all the anatomic structures seen on the chest film (i.e., bones, soft tissue, heart, lower neck, airways and lungs, pleura, mediastinum, upper abdominal contents).
- The lungs are considered radiolucent and the bones are radiopaque.
- The chest film is useful for detecting pleural diseases such as pleural effusion or pneumothorax.
- Airspace opacities in the lung represent alveolar filling usually caused by either water (pulmonary edema), blood (pulmonary hemorrhage), or pus (pneumonia).
- Air bronchograms are seen when air-filled airways are surrounded by consolidated lung.
- Radiographic signs of pulmonary edema secondary to heart failure include (1) redistribution of blood flow to the upper lobes, (2) Kerley B lines, and (3) alveolar filling.
- Signs of long-standing heart failure include cardiac enlargement and pleural effusions, which are usually bilateral.
- Signs of volume loss (atelectasis) in the lungs include (1) unilateral diaphragmatic elevation, (2) mediastinal shift, (3) narrowing of the rib spaces, (4) hilar displacement, and (5) fissure displacement.
- The chest film is useful in identifying the position of catheters and tubes. The tip of the endotracheal tube should be 3 to 7 cm above the carina when the neck is in a neutral position (i.e., neither flexed nor extended).
- CT provides much more anatomic detail than chest x-rays but exposes patients to more radiation.
- MRI is used less commonly for imaging the chest but has a role in evaluating vascular structures, mediastinal masses, and cardiac structures.
- Ultrasound can be useful in placing central lines, visualizing the presence of pleural fluid (e.g., to help guide thoracentesis), and detecting a pneumothorax.
- PET-CT can help differentiate between malignant (cancerous) and benign (noncancerous) lung nodules, but it has limitations.

Flexible Bronchoscopy and the Respiratory Therapist

Danai Khemasuwan and Atul C. Mehta

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Understand the difference between rigid bronchoscopy and flexible bronchoscopy.
- Understand the preprocedure assessment, type of sedation, and patient monitoring during bronchoscopy.
- Identify the use of several class of medications to sedate the patients during flexible bronchoscopy.
- Describe the difference between conscious sedation and deep sedation.
- Understand the indications, contraindications, and complications of flexible bronchoscopy and various diagnostic techniques.
- Recognize the roles of advanced diagnostic techniques, including endobronchial ultrasound and electromagnetic navigation bronchoscopy.
- Understand the indications, contraindications, and complications of various therapeutic bronchoscopic techniques.
- Recognize the difference between each thermal ablation technique.
- Recognize the difference between silicone and metallic stents.
- Identify bronchial thermoplasty as an emerging nonpharmacologic option for patients with steroid-dependent asthma.
- Describe the role of bronchoscopic-assisted intubation in patients with a difficult airway.
- Describe the role of the respiratory therapist in assisting with bronchoscopy.
- Identify special considerations for bronchoscopy during mechanical ventilation.
- Understand physiologic and mechanical alteration associated with flexible bronchoscopy in intubated patients.
- Describe the method of calculation minute ventilation requirements during flexible bronchoscopy in patients with mechanical ventilation.

CHAPTER OUTLINE

KEY TERMS

airway stents
argon plasma coagulation
brachytherapy
bronchial washings
bronchial brushings
bronchial thermoplasty
bronchoalveolar lavage
capnography
cryotherapy
electromagnetic navigational bronchoscopy
endobronchial biopsy
fiberoptic bundles
laser photocoagulation
Mallampati classification

BOX 22.1 Indications for Rigid Bronchoscopy

- Large foreign body extraction
- Large volume tissue biopsies
- Management of massive hemoptysis
- Silicone or self-expandable stent placement
- Mechanical coring of lesion using beveled tip and sequential mechanical dilation
- Using of adjunct therapies in management of endobronchial obstruction
  - Laser: (e.g., YAG)
  - APC
  - Electrocautery
  - Cryotherapy
  - Balloon dilation
  - Microdebrider

APC, Argon plasma coagulation; *YAG,* yttrium-aluminum-garnet.

Bronchoscopy is one of the most commonly performed procedures in pulmonary medicine. Bronchoscopy allows physicians to access the inside of the airways for both diagnostic and therapeutic purposes. The procedure can be performed using either a rigid (Fig. 22.1) or a flexible bronchoscope (FB). A rigid bronchoscope is a hollow, straight tube of stainless steel with proximal side ports which are used to connect to anesthesia circuits and light source. A rigid bronchoscope is used most often by otorhinolaryngologists, thoracic surgeons, and interventional pulmonologists. The rigid tube is placed through the mouth, past the vocal cords and down into the trachea. It can be placed as far as proximal mainstem airway. The larger diameter of rigid bronchoscopy (RB) allows for large foreign body extraction, silicone stent deployment, and performing any ablative therapy on endobronchial tumors. Indications for RB are shown in Box 22.1. The tip of the RB can be used to lessen bleeding by applying pressure to a bleeding tumor. One of the main disadvantages of RB is that the patient needs to be deeply sedated and paralyzed for almost the entire length of the procedure.

In contrast, flexible bronchoscopy is more widely used by pulmonologists and is more available in various practice setting ranging from community settings to tertiary care hospitals. The focus of this chapter is on flexible bronchoscopy due to its widespread availability and popularity.

The first bronchoscopy was performed by a German laryngologist, Gustav Killian, in the early nineteenth century. He removed a foreign body via the translaryngeal route with direct bronchoscopy[1] using a rigid esophagoscope. In the United States, Chevalier Jackson is considered to be the pioneer of RB. He reported the first bronchoscopic resection of an endobronchial tumor in 1917.[2] Over time, the technology has progressed remarkably. In 1966, the FB was introduced by Shigeto Ikeda, a Japanese thoracic surgeon. In 1970, the Olympus Company introduced the first FB for commercial purposes. Since then, advancements have led to a wide array of minimally invasive endoscopic diagnostic and therapeutic techniques that will be discussed in this chapter.

This chapter deals with the essential elements of the procedure, including the equipment, indications, contraindications, variations in the procedures, and emerging technologies. In addition, the role of the respiratory therapist (RT) and special considerations when performing bronchoscopy on patients under specific conditions (e.g., during mechanical ventilation) are also described.

FLEXIBLE BRONCHOSCOPY

The FB uses **fiberoptic bundles** to light up the endobronchial tree. Based on the imaging system, FBs are divided into fiberoptic, video, or hybrid types. The fiberoptic bronchoscope carries a second fiberoptic bundle that gathers the images from the distal tip of the instrument, which is visualized through an eye piece. The video bronchoscope uses somewhat different technology which employs a miniaturized charge-coupled devices (CCDs) chip at its distal tip to gather the images from the endobronchial tree and transmit them to the image-processing unit. The hybrid instrument uses a fiberoptic imaging system but also has a CCDs chip to convert the information into a digital format. Most modern FBs use video technology, whereas thinner bronchoscopes are hybrid in nature.

The proximal end of the FB is the controlling unit of the instrument, which helps the operator perform desired maneuvers to control the distal tip of the FB (Fig. 22.2). The distal tip of FB can be flexed in two directions—up to 180 degree in anteflexion and up to 130 degree in retroflexion positions (see Fig. 22.2). In addition to these controls, the operator rotates the instrument on its axis using the wrist. More recently, Olympus also added a feature that allows axial rotation of the instrument without totally relying on wrist movement (see Fig. 22.2).

Today, flexible bronchoscopy has become a standard procedure because of its diagnostic value, safety, and ease of performance. The procedure can be performed in an outpatient setting, under local anesthesia and moderate (conscious) sedation. The indications for FB have grown over the past years (Box 22.2) and are extensive. Box 22.3 presents the contraindications to performing FB. There are a few absolute contraindications for FB, which include refractory hypoxemia, hemodynamic instability, acute bronchospasm, increased intracranial pressure, uncorrectable coagulopathy, and inability to obtain informed consent for the procedure.

BOX 22.2 Indications for Flexible Bronchoscopy

- Hemoptysis
- Wheeze and stridor; suspected upper airway obstruction
- Pulmonary infiltrate of unknown cause
  - Infiltrates not responding to conventional treatment
  - Infiltrates in an immunocompromised host
  - Recurrent or unresolved pneumonia
  - Cavitary lesions
  - Interstitial infiltrates
  - New pulmonary nodule
- Unexplained lung collapse
- Suspected or known bronchogenic carcinoma
  - Staging
  - Follow-up after endobronchial treatments
- Mediastinal and hilar lymphadenopathy
- Lung transplantation
  - Evaluate airway anastomosis
  - Rejection surveillance
  - Cultures
- Endotracheal intubation
  - Bronchoscopy-assisted ET intubation
  - Confirm endotracheal tube position
  - Evaluate tube-related injury
- Evaluation of foreign body aspiration, chemical-related, or burn-related injury to the airway
- Unexplained superior vena cava syndrome
- Unexplained vocal cord paralysis or hoarseness
- Suspected fistulas (e.g., bronchopleural, tracheoesophageal and bronchoesophageal, trachea or bronchoaortic)
- Treatment of refractory asthma (bronchial thermoplasty)

BOX 22.3 Contraindications to Flexible Bronchoscopy

Absolute

- Refractory hypoxemia
- Lack of patient cooperation
- Lack of skilled personnel
- Lack of appropriate equipment and facilities
- Unstable angina
- Uncontrolled arrhythmias
- Increased intracranial pressure
- Uncorrectable bleeding diathesis

Relative

- Unexplained or severe hypercarbia
- Uncontrolled asthma attack
- Lack of patient cooperation
- Uncorrected coagulopathy
- Recent myocardial infarction
- Unstable cervical spine and impaired neck mobility
- Need for large tissue specimen

The discussion as to whether bronchoscopy is indicated or not involves the physician and often other members of the bronchoscopy team, including the RT. However, in the end, the final decision to perform the procedure must be individualized in conversation between the physician and the patient, based on the risks and benefits of the procedure.

Procedure, Sedation, and Monitoring

FB can be performed on spontaneously breathing patients via the oral or the nasal route and occasionally through a tracheostoma stoma. FB can also be performed on a patient with artificial airways such as endotracheal or tracheostomy tubes. Most

procedures are performed under moderate or deep sedation. When deep sedation is used, the procedure is performed via either a laryngeal mask airway or an endotracheal tube (ETT) of an appropriate size. As noted, RB is performed under deep sedation with muscle relaxation.

The goal of sedation is to improve the patient's comfort during the procedure and facilitate the procedure by minimizing patient movement and other potential interruptions. In addition to the risks for arrhythmias and fluctuations in blood pressure related to the procedure, airway manipulation during bronchoscopy may lead to coughing, hypoxemia, vomiting, bleeding, laryngospasm, and bronchospasm. All of these responses can affect the outcome of the procedure. Therefore, adequate sedation is a critical part of the procedure.

There is a wide range in the level of sedation that can be provided, including light sedation (anxiolysis), **moderate (conscious) sedation**, and deep sedation with general anesthesia. Moderate sedation is most commonly used during FB. At this level of sedation, patients can respond to verbal stimuli and demonstrate preserved protective airway reflexes. Several intravenous forms of benzodiazepines and opioids are commonly used during FB. Diazepam, midazolam, lorazepam, morphine sulfate, and fentanyl have been used either as a single agent or in combination based on the availability and physician preference.[3] The combination of a benzodiazepine (midazolam) and an opioid (morphine sulfate or fentanyl) has been shown to be safe and effective for sedation during FB. In addition, both benzodiazepines and opioids can chemically be reversed if necessary.[4] Propofol has also been proposed to be used in a combination with fentanyl in FB.[5,6]

Several techniques are used to apply local anesthetic agents to the upper and the lower airways. Using approximately 10 mL of 2% viscous lidocaine, "swish and swallow" is a simple and effective method to numb the upper airways. Another common method involves nebulizing 5 mL of 4% lidocaine.

The nasal passage is usually anesthetized using 5 mL of 2% lidocaine jelly. In addition, 1% to 2% of lidocaine is instilled directly into the lower airways through the working channel of the instrument in 2-mL aliquots during the procedure. The drug lidocaine has a very narrow therapeutic range. To help avoid unwanted hazards such as **methemoglobinemia**, the total dose of lidocaine should be limited to 5 to 7 mg/kg in adults (maximum of 400 to 500 mg in a 150-lb adult) during the procedure, with added caution in the elderly and in those with liver or cardiac disease.[7]

RULE OF THUMB For patient safety, to help avoid methemoglobinemia, the total dose of lidocaine should not exceed 7 mg/kg of body weight during a routine (<45 min) FB procedure. The use of benzocaine should be avoided as much as possible.

The assessment of the upper airway before the procedure helps identify those patients in whom it may be difficult to secure an airway in case of hypoventilation. The **Mallampati classification** is one of the most commonly used methods to identify individuals who may pose difficulty during intubation. The Mallampati score is assessed by having the patient open his or her mouth and protrude the tongue as much as possible without phonation (Fig. 22.3).

TABLE 22.1 American Society of Anesthesiologists Classification: Comorbid Conditions and Impact on Daily Living

ASA Class	Class Definition
I	A normally healthy patient
II	A patient with mild systemic disease
III	A patient with systemic disease that is not incapacitating
IV	A patient with an incapacitating systemic disease that is a constant threat to life
V	A moribund patient who is not expected to survive for 24 h with or without operation

MINI CLINI

Methemoglobinemia During Bronchoscopy

Problem

A respiratory therapist (RT) is assisting during a flexible bronchoscopy. The patient had local anesthesia with lidocaine nebulization and benzocaine spray. The patient developed central cyanosis and his oxygen saturation dropped to 85% via pulse oximetry. The procedure was aborted. An arterial blood gas check showed pH, 7.43; PCO_2, 43; and PO_2, 279; with an O_2 saturation of 85%. What condition should an RT consider in this situation?

Discussion

Methemoglobinemia should be suspected. Benzocaine, which is used as a local anesthetic, is a common cause of methemoglobinemia during such procedures. Benzocaine causes oxidization of the iron in hemoglobin (Hb) from the ferrous (Fe^{2+}) to the ferric state (Fe^{3+}). Fe^{3+} Hb is unable to carry O_2. The PO_2 is within normal range as shown by the machine measurement of dissolved O_2 in the blood, not in the Hb. Therefore, methemoglobinemia causes hypoxemia at the cellular level that is not detected by measuring PO_2 but can be uncovered by co-oximetry to measure methemoglobin directly. In terms of management, a methemoglobin level less than 30% usually resolves spontaneously over 15 to 20 hours after removal of the offending agent and with O_2 administration. Intravenous administration of methylene blue is the treatment of choice in patients when the methemoglobin levels exceed 30%.

RULE OF THUMB The Mallampati score should be assessed in every spontaneously breathing patient before flexible bronchoscopy.

Several maneuvers (e.g., chin-lift, jaw-thrust) may become necessary if the patient becomes oversedated during FB. In addition to an unfavorable Mallampati score, comorbidities can also affect the safety and outcome of the procedure. The recommendation from the American Society of Anesthesiologists (ASA) is to categorize patients based on their ASA score, which considers comorbid conditions and their impact on the patient's daily living (Table 22.1).[8]

During the FB procedure, continuous monitoring of oxygenation and hemodynamic stability are important. Pulse oximetry, heart rate, and blood pressure are monitored throughout the procedure. One of the most difficult parameters to monitor during FB is the depth of sedation. Intermittent boluses of sedation may be needed to ensure the adequate depth of sedation during the procedure. However, the depth of sedation must be balanced with the side effects of oversedation during and after

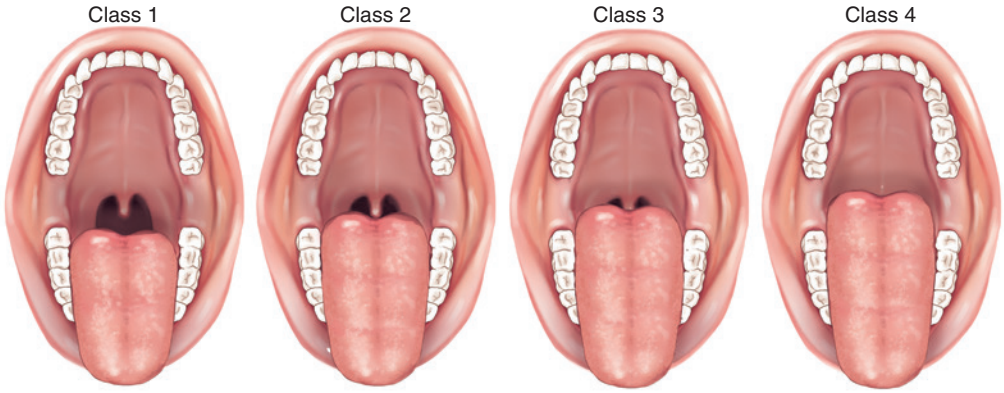

Fig. 22.3 Mallampati classification.

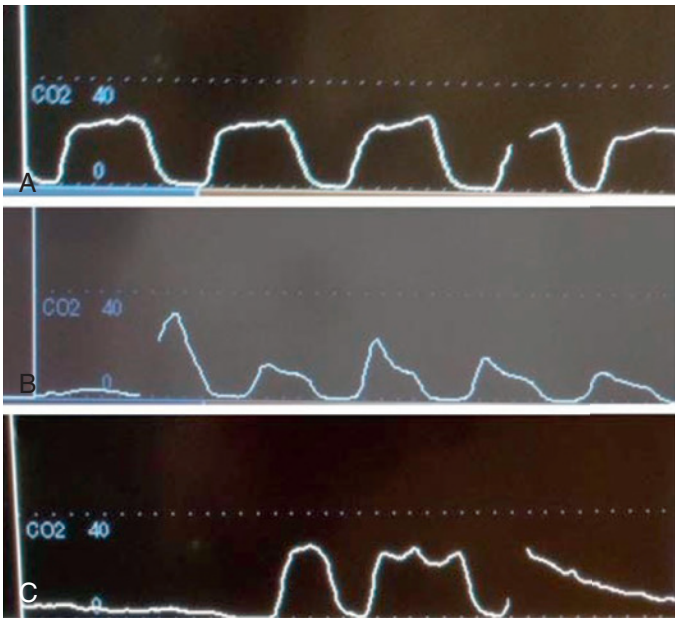

Fig. 22.4 (A) A normal capnography wave form of $EtCO_2$. (B) A capnography wave form demonstrating deteriorating ventilation as a result of airway obstruction during bronchoscopy. (C) A capnography wave form demonstrating the recovery of breathing pattern with patient stimulation and jaw thrust.

the procedure. To monitor the patient, the RT or other member of the bronchoscopy team should keep track of the patient's responses to verbal commands or spontaneous movements. Notably, chest movement may continue despite near total obstruction of the airway. To monitor the presence of a patient's slipping into deep sedation with associated hypoventilation, the ASA also recommends **capnography** monitoring while performing FB under moderate sedation.[9,10] Capnography is the real-time, noninvasive measurement and wave form display of the end-tidal carbon dioxide ($EtCO_2$). While a mainstream CO_2 sensor is frequently used in intubated patients, side-stream capnography is most useful in patients with spontaneous breathing. A fraction of gases from nasal cannula passed through the analyzer located in the monitor.[11] A simple, long, small bore tube may create a slight delay of CO_2 measurement by a few seconds. In spontaneous breathing patients, the actual $EtCO_2$ value may not be accurate. However, the trend and the shape of wave form can generally represent the degree of ventilation (Fig. 22.4).

RULE OF THUMB Continuous cardiac, blood pressure, and oximetry monitoring must be carried out during bronchoscopy. Capnography should be used if available.

DIAGNOSTIC BRONCHOSCOPY

A computed tomography (CT) scan of the chest should generally be performed (see Chapter 21) before all elective bronchoscopic procedures. The imaging information is very valuable in increasing the diagnostic yield of the procedure among patients suspected to have lung cancer. The scan also may eliminate the need for performing the procedure in 7% of patients.[12]

Diagnostic bronchoscopy begins with the examination of the upper airways. Proper upper airway examination is crucial to identify lesions involving nasal passages, pharyngeal, and laryngeal structures, including vocal cords. After examination of the upper airway structures, the lower airways are examined at least until the fifth- or sixth-generation bronchi. Examining bronchi deeper than this may be limited by the diameter of the bronchoscope. For diagnostic purposes, besides examining the airways, several different types of specimens can be collected through the working channel of the bronchoscope. Summaries of various diagnostic bronchoscopic techniques are presented in Table 22.2.

RULE OF THUMB A CT scan of the chest should generally be performed before all elective diagnostic bronchoscopic procedures in patients suspected of having lung cancer.

Bronchoalveolar Lavage

Bronchoalveolar lavage (BAL) is used to obtain specimens from the alveolar level of the lung. BAL is performed by instilling a small volume (up to 50 mL) of normal saline solution deep into the airways and then suctioning the instilled liquid back. BAL fluid contains both cellular and noncellular components of alveolar lining fluid (Fig. 22.5). As a form of "liquid lung" sample, the BAL fluid is thought to represent the contents of one million of alveoli as well as respiratory epithelial lining and colonizing organisms. BAL has become a standard diagnostic procedure in patients with pulmonary infiltrates of uncertain etiology (Box 22.4). A normal BAL sample includes 95% macrophages; 3% lymphocytes; 1% to 2% neutrophils, eosinophils, and basophils,

TABLE 22.2 Various Diagnostic Procedures With Flexible Bronchoscopy

Diagnostic Techniques	Methods	Diagnostic Roles	Complications
Bronchoalveolar lavage	Perform a good wedging, instilling a small volume of normal saline solution deep into the airways/alveoli and then suctioning the aliquot back	Infections, pulmonary hemorrhage, malignancy, Eosinophilic lung disease, pulmonary alveolar proteinosis, pulmonary, Langerhans cell histiocytosis, Lipoid pneumonia	Hypoxemia
Washing	Instilling a small volume of normal saline into tracheobronchial area, wedging is not necessary	Infections, malignancy	Hypoxemia
Brushing	Brushing the surface of the suspicious lesion	Malignancy	Focal bleeding
Endobronchial biopsy	Use of flexible forceps to obtain a tissue sample from a visible endobronchial lesion	Infections, malignancy	Focal bleeding, Hypoxemia
Transbronchial biopsy	Use of flexible forceps to obtain a tissue sample from lung parenchyma	Infections, allograft rejection, malignancy, sarcoidosis, Langerhans cell histiocytosis	Bleeding, pneumothorax
Transbronchial needle aspiration Endobronchial ultrasound guided	Use of flexible needle tip to obtain tissue sample from central airway or lung parenchyma. [a]Can be used with ultrasound guidance for needle aspiration for centrally located lesions	Malignancy, sarcoidosis,	Bleeding, mediastinitis, pneumomediastinum
Electromagnetic navigational bronchoscopy	Use low-frequency electromagnetic waves to locate peripheral nodules in real time with computer-generated guidance in three dimensions; in a combination with various diagnostic tools such as needle, brush, or forceps for biopsy	Malignancy, infections	Bleeding, pneumothorax

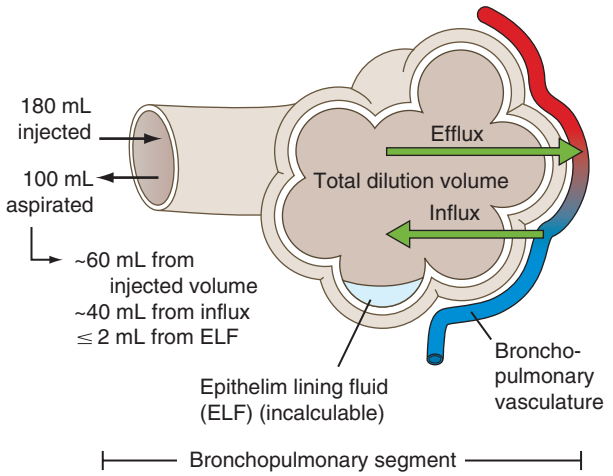

Fig. 22.5 Schematic presentation of the constituents of the bronchoalveolar lavage.

and few epithelial cells. In addition to routine culture and cell count, an estimation of the CD4/CD8 ratio of lymphocytes in the lavage fluid can be helpful in assessing the diagnosis of sarcoidosis and hypersensitivity pneumonitis.

Bronchoalveolar Lavage Technique

In order to minimize contamination of the working channel with the local organisms,[13-15] it is important to avoid using suction while inserting the FB through the nasopharynx and central airways. The amount of lidocaine used should be minimized to reduce its side effects, prevent its bacteriostatic properties from interfering with cultures, and avoid altering the cellular contents of the lavage fluid. The right middle lobe, lingual or the anterior segment of the right upper lobe is generally used to perform

BOX 22.4 Role of Bronchoalveolar Lavage in Diagnosis for Pulmonary Diseases

- Infection (e.g., bacteria, fungus, virus, and mycobacteria)
- Pulmonary hemorrhage
- Malignancy (e.g., solid tumor, lymphoma)
- Eosinophilic lung disease
- Pulmonary alveolar proteinosis
- Langerhans cell histiocytosis
- Lipoid pneumonia
- Diffuse alveolar hemorrhage

BAL in patients with diffuse diseases. With the patient in a supine position, gravity helps augment BAL return from these locations.[13,14] Meanwhile, in localized lung diseases, lavage is performed from the area of the focal abnormality.[14]

To obtain the lavage fluid, the bronchoscope is wedged at the level of fourth- or fifth-generation bronchus. A "good wedge" position means that the bronchoscope is advanced as far as possible while the distal lumen is still visible. In this position, BAL return is maximal. Twenty to 60 mL of normal saline are instilled into the appropriate bronchial segment and aspirated back manually for laboratory testing. In general, 15 to 20 mL of BAL volume is enough to conduct common laboratory tests such as microbiologic and cytologic tests; the total amount of fluid required may vary based on the differential diagnosis.[15]

Several complications may be associated with BAL. Hypoxemia is common, and its severity depends upon three factors: (1) the volume of fluid administered,[16] (2) the number of segments lavaged, and (3) the duration of the procedure. Introduction of 100 mL of lavage fluid can cause O_2 desaturation up to 7%, whereas 200 mL of lavage fluid can drop O_2 saturation up to

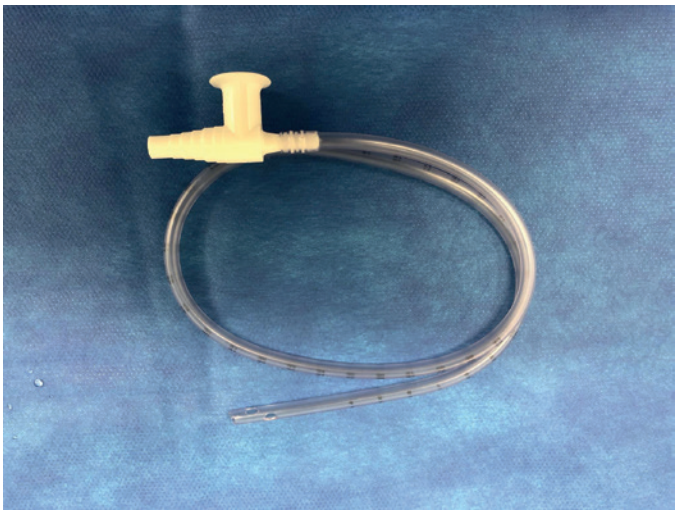

Fig. 22.6 Mini-bronchoalveolar lavage sampling catheter.

15% from the baseline value.[16] O_2 supplementation during BAL may lessen the degree of O_2 desaturation. Cases of pneumothorax from BAL have also been reported in patients with *Pneumocystis jiroveci* pneumonia and during therapeutic BAL for pulmonary alveolar proteinosis (PAP).[17,18]

RULE OF THUMB BAL should be obtained from the nondependent part of the lung to optimize the fluid return.

RULE OF THUMB Supplemental O_2 should be administered in all patients undergoing bronchoscopy to help avoid or minimize hypoxemia.

Mini-BAL is defined as non-bronchoscopic BAL (Fig. 22.6). Mini-BAL is most frequently performed in intubated patients when a catheter is passed through an ETT into the bronchi until the catheter lodges, after which saline is instilled for the lavage and then withdrawn. The volume of saline instillation is usually 25 mL or less. The return of fluid by aspiration is highly variable. Mini-BAL is a simple procedure for acquiring quantitative lower airway cultures in mechanically ventilated patients.[19] Colorimetric capnography can be used to confirm the tracheobronchial position of the catheter.[20] In some settings, RTs perform this procedure. Approximately 46% of mini-BAL cultures are found to contain at least one organism that is potentially contributing to a suspected episode of ventilator-assisted pneumonia.[21]

Bronchial Washings

Bronchial washings are generally obtained for a cytological examination for cancer and/or microbiologic analysis to diagnose mycobacterial or fungal infections. Unlike BAL, bronchial washings are obtained from the large airways. Bronchial washing is easy to perform, but is not very effective in diagnosing malignancy, successfully diagnosing only 22% to 29% of peripheral lesions[22,23] with a yield slightly higher for central lesions.[24,25] Bronchial washings are an inexpensive by-product of the bronchoscopy and are routinely obtained in patients suspected to have airway malignancy.[26]

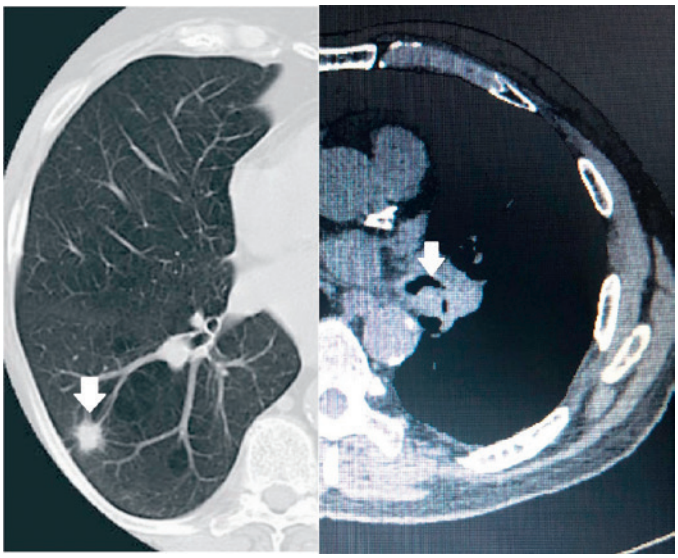

Fig. 22.7 *Left:* Peripheral lung nodule (located at ⅓ outer rim—arrow). *Right:* Central lung nodule (located in the proximal ⅔).

Bronchial Brushings

Bronchial brushings have been used as an adjunct diagnostic test in addition to endobronchial and transbronchial biopsies and transbronchial needle aspiration (TBNA). It involves brushing the surface of the suspicious lesion back and forth 5 to 10 times while rotating the handle. Brushes of various different diameters and bristle strengths are available in the market. Brushing is usually performed under direct visualization or with fluoroscopic guidance to avoid trauma to the bronchial mucosa and pneumothorax, respectively. Brushing can establish a diagnosis in 72% (range 44% to 94%) of patients with central lung cancers and in 45% of patients with peripheral lesions.[27,28] Centrally located cancers are found in the proximal ⅔ of visible bronchi (4th to 5th generation airway) and peripheral lesions are defined as occurring in the distal ⅓ (beyond 5th generation), which can be seen on the ⅓ outer rim on a chest X-ray or fluoroscopy (Fig. 22.7). Bronchial brushing is usually performed after obtaining all the other specimens to avoid bleeding or cellular degradation that may affect the overall interpretation of FB specimens. Once the specimen is collected, the cells are smeared onto a slide and the end of the brush is cut off and placed in a fixative solution for cytological examination.[29]

Endobronchial Biopsy

Endobronchial biopsy (EBBx) is a technique whereby flexible forceps are used to obtain a tissue sample from a visible endobronchial lesion. It provides specimens for histological examination. EBBx has been shown to successfully diagnose between 51% and 97% of central visible neoplasms.[30,31] The number of biopsy specimens that should be obtained depends on the suspected diagnosis. In patients suspected to have bronchogenic carcinoma, three biopsy specimens are often able to successfully diagnose almost all cases.[32] If the specimen is obtained from the surrounding necrotic tissue, the EBBx can fail to contain cancerous cells even though the patient has a malignancy. In such cases,

debridement of the necrotic tissue with the forceps or performing a TBNA may improve the overall diagnostic yield. EBBx of a highly vascularized lesion may lead to significant bleeding and must be undertaken with caution. The physician may take precautions such as instilling 5 mL to 10 mL of ice cold saline (−4°C) or 2 mL to 4 mL of either epinephrine or norepinephrine (1: 10,000) solution through the working channel of the bronchoscope to lessen the possible bleeding or using the TBNA approach.

Transbronchial Biopsy

Transbronchial biopsy (TBBx) is a technique of obtaining a specimen of the lung parenchyma by using flexible forceps positioned distally through the working channel of the bronchoscope. A large fenestrated alligator forceps is most commonly used to obtain the TBBx. Six to ten tissue specimens are obtained, depending on the suspected diagnosis. TBBx can be performed with or without fluoroscopic guidance (Fig. 22.8). The latter is a common practice while performing the TBBx in the intensive care unit setting.

The diagnostic value of TBBx varies depending on the underlying lung diseases and the patient population. For infectious diseases, 88% to 97% of cases of *P. jiroveci* pneumonia[33] and 57% to 79% of cases of *Mycobacterium tuberculosis* can be successfully diagnosed with TBBx.[34] In lung transplant surveillance, TBBx can detect the presence of allograft rejection in approximately 70% of cases.[35,36] In interstitial lung diseases, the diagnostic value is relatively low compared with the experience in infectious diseases. TBBx can successfully diagnose 40% to 90% of cases of sarcoidosis[37] and only 10% to 40% of those with Langerhans cell histiocytosis.[38] In a peripheral pulmonary nodule (PPN), the diagnostic value of TBBx depends upon the size and the location of the nodule. The presence of an airway leading to the nodule as seen on chest computed tomography scan is called a "positive bronchus sign" and, when combined with TBBx, increases the successful diagnostic yield from 31% to 79% for PPNs.[39]

The two major complications of TBBx are pneumothorax and bleeding. Adequate sedation and cough suppression are important to reduce the risk for pneumothorax arising from cough-induced barotrauma. Whenever available, fluoroscopy should be used to guide the TBBx, especially in patients with localized lesions. Fluoroscopy is also used to screen for pneumothorax after the TBBx.[40] The risk for developing pneumothorax is three times higher in mechanically ventilated patients compared to that among spontaneously breathing patients.[41,42] To reduce the risk for pneumothorax among the former group, the level of positive end-expiratory pressure (PEEP) level should be maintained below 5 cm H_2O. Also, in case of pneumothorax, prompt chest tube placement should be available.

Meanwhile, the prevalence of bleeding from TBBx is low (2% to 9%) in the absence of a bleeding tendency or coagulopathy; risk factors for bleeding after TBBx include renal insufficiency with creatinine greater than 3 mg/dL, pulmonary hypertension with a mean pulmonary artery pressure greater than 40 mm Hg, thrombocytopenia with platelets less than 50,000/mL, and international normalized ratio (INR) greater than 1.5.[43]

TBBx can be safely performed in patients who are receiving aspirin or nonsteroidal inflammatory drugs. However, several antithrombotic and antiplatelet therapies (e.g., clopidogrel) should be withheld for a specific period before TBBx (Table 22.3).[44] In the event of bleeding, wedging the bronchoscope in the involved subsegment helps tamponade, or compress, the bleeding site.

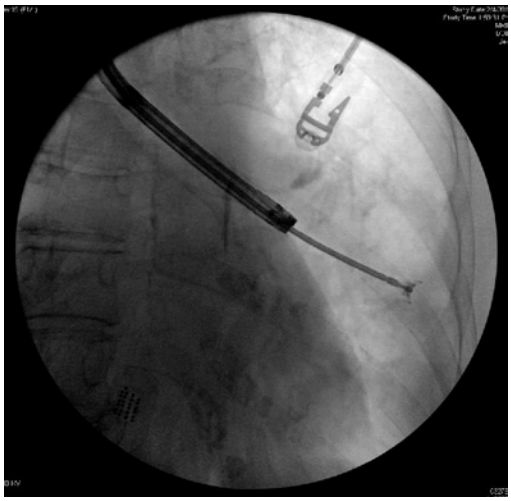

Fig. 22.8 Transbronchial biopsy under direct visualization with fluoroscopy.

MINI CLINI

Sudden Chest Pain and Clinical Deterioration During Bronchoscopy

Problem

An RT is assisting during an FB on a young female with suspected sarcoidosis. The patient is very anxious and, despite an adequate amount of narcotics and anxiolytic agents, continues to cough violently. The physician is performing TBBx under fluoroscopic guidance from the left lower lobe. In seven attempts, he manages to obtain three pieces of tissue before stopping the procedure. During the last attempt, the patient winced with mild pain. Soon after the last biopsy, the patient became tachypneic (respiration rate [RR] 30 breaths/min), with a heart rate of 110 beats/min, and the SpO_2 dropped to 82% on O_2 6 L/min via nasal cannula. Examination of the chest showed that it was tympanic on percussion with reduced breath sounds on auscultation on the left. What condition should the RT consider in this situation?

Discussion

The RT should consider pneumothorax in this situation and should also consider ruling out a tension pneumothorax. Pneumothorax is a potential complication following a TBBx.[45] The risk is further increased in the situation in which the patient cannot cooperate for the procedure and continues to cough during the biopsy. In this case, fluoroscopic examination can help confirm or rule out the condition. Meanwhile, the patient should receive an adequate amount of supplemental O_2 by a non-rebreather mask if needed. The RT should be prepared to assist the pulmonologist to place either a Heimlich valve or a chest tube, depending on the size of the pneumothorax and the patient's symptoms. If a tension pneumothorax is suspected, any size needle can be inserted into the pleural space and the air would be expected to rush out as the pressure is relieved.

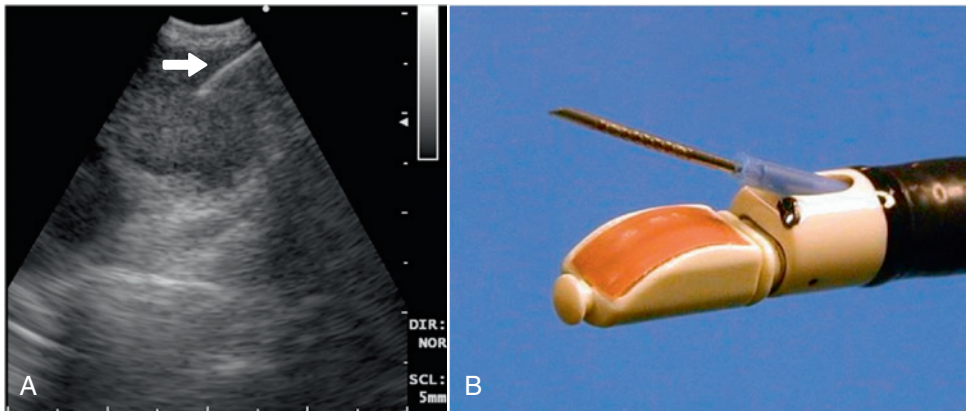

Fig. 22.9 (A) The distal tip of the endobronchial ultrasound endoscope with an aspiration needle. (B) Sonographic image of endobronchial ultrasound-transbronchial needle aspiration demonstrating needle inside lymph node.

TABLE 22.3 Antithrombotic Therapies and Recommended Interval Between Last Dose and Procedure[a]

Agents	Interval From Last Dose Before Procedure
Warfarin	3–5 days; or goal international normalized ratio <1.5
Unfractionated heparin	Intravenous 2–6 h
Low molecular weight heparin	24 h; depending on creatinine clearance
Dabigatran	1–2 days with creatinine clearance >50 mL/min 3–5 days with creatinine clearance <50 mL/min
Rivaroxaban	1 day with normal renal function 2–4 days with impaired renal function
Desirudin	2 h
Clopidogrel, ticlopidine, prasugrel, ticagrelor	5 days
Aspirin and dipyridamole	7–10 days

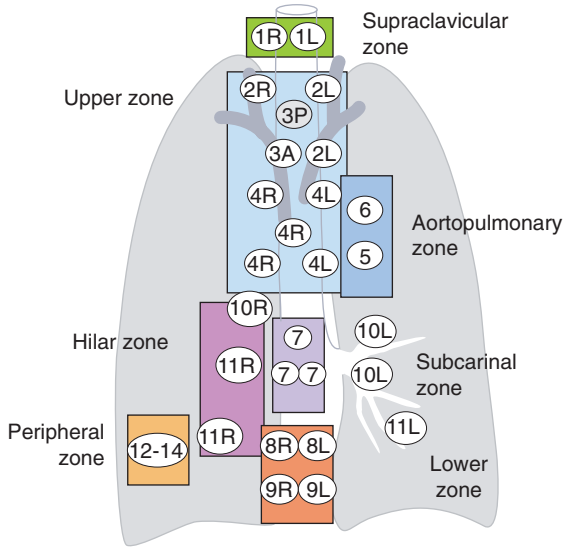

Fig. 22.10 The international association for the study of lung cancer (IASLC) lymph node map.

Transbronchial Needle Aspiration: Conventional and Ultrasound-Guided Procedures

Transbronchial needle aspiration (TBNA) is the technique that allows sampling tissue from the mediastinum or the peripheral lung by inserting needles through the bronchial wall. TBNA can be used to determine the cause of mediastinal lesions and PPNs in a minimally invasive fashion.[46,47]

With the availability of endobronchial ultrasound (EBUS), the accuracy of TBNA has improved dramatically. EBUS is essentially a bronchoscope with a linear ultrasound probe attached at its distal end. EBUS provides real-time ultrasonographic guidance for TBNA of target structures (Figs. 22.9 and 22.10). It has recently been found that in patients with potentially operable lung cancer, the diagnostic accuracy of EBUS-TBNA is far superior (98% diagnostic accuracy) to either positron-emission tomography or CT scans of the chest for mediastinal staging.[48,49]

Recently, the use of EBUS-TBNA has greatly expanded in the diagnosis and staging of non–small cell lung cancer because it is a minimally invasive procedure. Notably, mediastinal lymph nodes can be assessed more accurately with EBUS-TBNA than with conventional mediastinoscopy. Reported complications of EBUS-TBNA include pneumomediastinum, pneumothorax, mediastinitis, bacteremia, and, rarely, death.[50-53]

Today, genetic profiling of lung cancer is essential to identify biomarkers that significantly influence treatment decisions and responses. EBUS-TBNA can provide adequate tissue for genetic analysis.[54] The utility of EBUS-TBNA also has been investigated for restaging of lung cancer after chemotherapy, and evidence supports its use for this purpose.[55]

Electromagnetic Navigational Bronchoscopy

An advanced CT imaging technology has been innovatively combined with an electromagnetic navigation system to guide the biopsy of PPNs that lie beyond the reach of standard flexible bronchoscopy. **Electromagnetic navigational bronchoscopy** (ENB), peripheral EBUS, virtual bronchoscopy, ultrathin bronchoscopy,

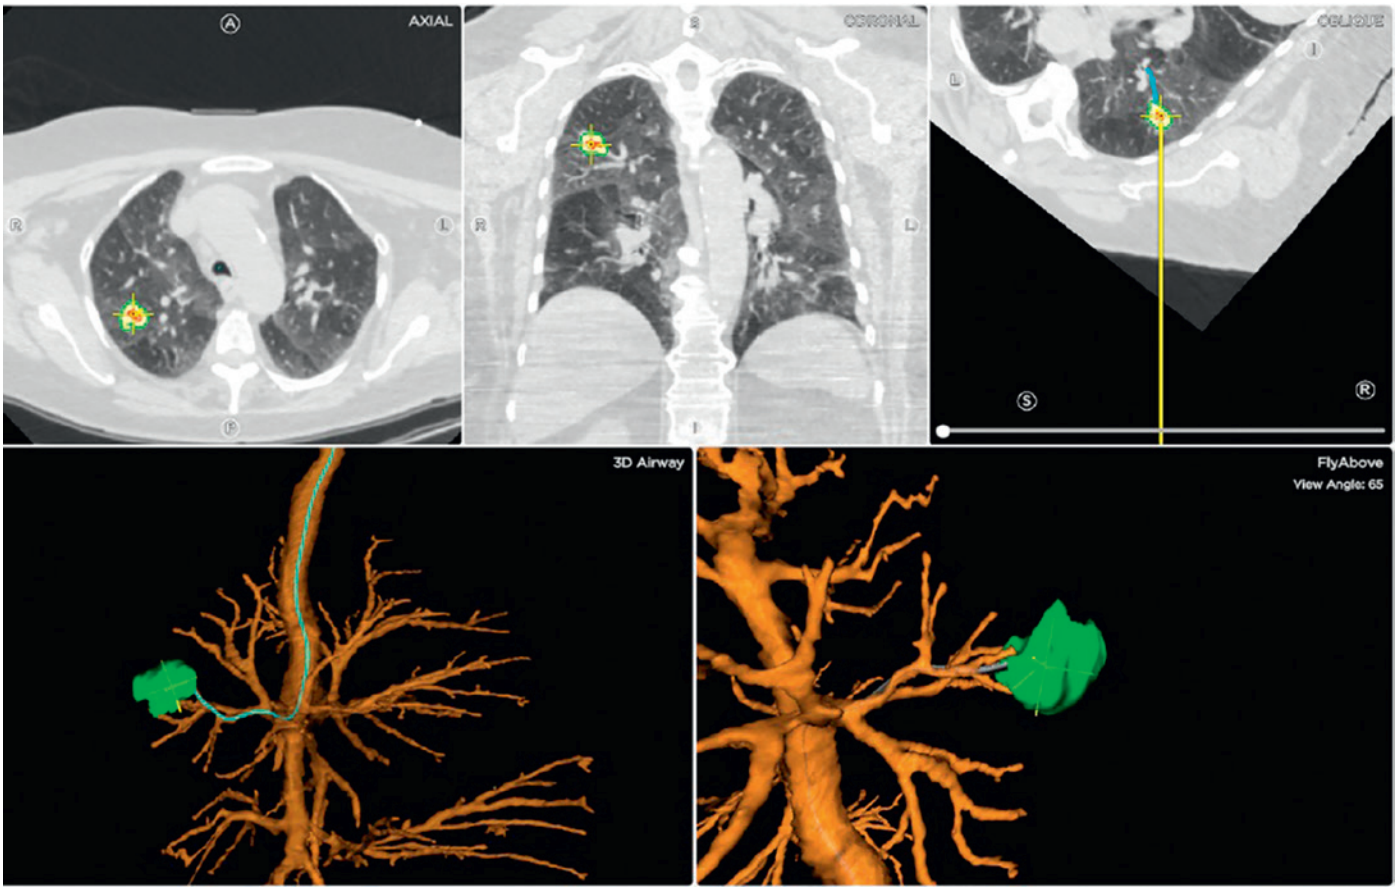

Fig. 22.11 Electromagnetic Navigation Monitor. Location of the pulmonary lesion is displayed in three different axes of computed tomography imaging.

and their combination have significantly increased the diagnostic value of FB for peripheral lesions, with an acceptably low complication rate of bleeding and pneumothorax.[56]

The ENB system uses low-frequency electromagnetic waves transmitted from a magnetic board placed below the patient's chest. As a result, the lesion can be visualized in real time with computer-generated guidance in three dimensions.

ENB is performed in several steps. The first step is planning the procedure by uploading high-quality CT images into the planning software. The software will generate the plan markers from the main carina to the lesion via multiple bronchial subsegments. The next step is aligning the virtual images to the patient's endobronchial anatomy, which is called the *registration* phase. Then the navigation is conducted by driving the locatable guide probe with its extended working channel (EWC) to the lesion, by following the three-dimensional CT images and the "tip view" (Fig. 22.11). Once the lesion is reached, the guide probe is removed, leaving the EWC in place. The position of the tip of the EWC may be confirmed by using the radial EBUS probe to determine the location of the lesion (Fig. 22.12). Various diagnostic tools such as needle, brush, or forceps for biopsy can be used through the EWC to obtain a tissue specimen. In terms of diagnostic value, ENB can successfully diagnose almost 75% of peripheral lesions, with accompanying pneumothorax in approximately 3.5% of such cases. The combination of radial probe EBUS with ENB can further increase the diagnostic value.[57,58]

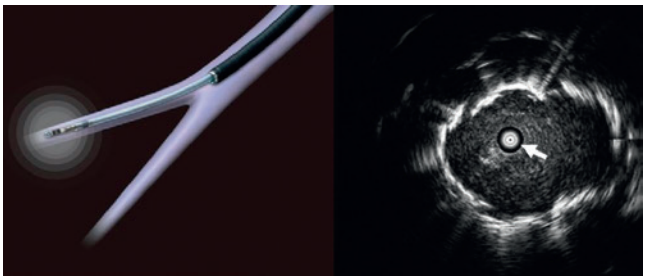

Fig. 22.12 Radial probe endobronchial ultrasound *(left)*. A radial probe is surrounded by lesion *(right, arrow)*. (*Left* from http://www.goldcoastrespiratoryandsleep.com.au/gcrsc-services.html.)

Ultrathin Bronchoscopy

The normal tracheobronchial tree divides approximately 24 times before it reaches the respiratory bronchioles. The external diameter of the adult FB is approximately 5.7 to 6 mm, which allows the physician to reach the fourth- or fifth-order bronchi. The ultrathin bronchoscope is approximately 2.8 mm in external diameter and can reach up to at least the eighth-order bronchi (Fig. 22.13). **Ultrathin bronchoscopy** can be helpful in diagnosing PPNs and can be used to inspect peripheral airways or to examine the airway beyond a pathologic airway narrowing.

The major technical challenge of performing ultrathin bronchoscopy is maintaining proper anatomic orientation in the peripheral airways. The instrument is seldom used without

Fig. 22.13 Comparison of the diameter of the tip of the ultrathin bronchoscope (2.8 mm) *(right)* with that of a standard-size bronchoscope *(left)*.

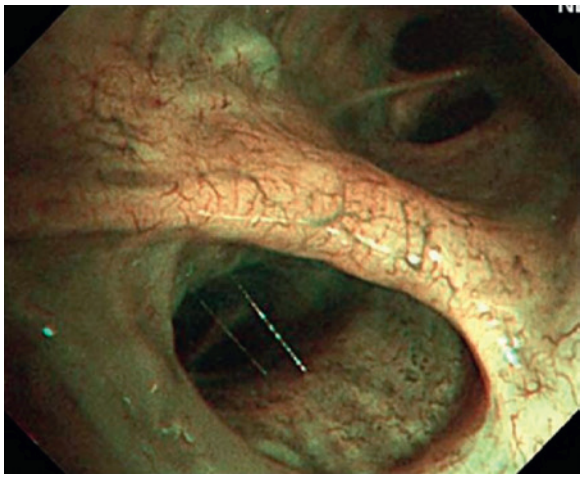

Fig. 22.14 Narrow band imaging.

real-time CT guidance, virtual bronchoscopy,[59] or a specially designed peripheral EBUS system. Another drawback of the ultrathin bronchoscope is its narrow working channel (1.7 mm) and miniaturized accessories (1 to 1.2 mm). These limit the diagnostic value of ultrathin bronchoscopy because the specimens that can be obtained are very small.

Narrow Band Imaging

Narrow band imaging (NBI) is a technique that uses specialized filters to separate wavelengths of white light and selectively emits red, green, and blue bands. The intensification of the blue band detects vessel growth and complex vessel networks in the bronchial mucosa and therefore may be useful to detect early malignant lesions (Fig. 22.14). The system involves two narrow band filters, one to detect 415-nm light that is absorbed by the surface level capillaries and a second to detect 540-nm light that is absorbed below the surface layer. NBI permits visualizing abnormal distribution and dilatation of blood vessels in the mucosa, which can be an early sign of malignancy.[60]

THERAPEUTIC BRONCHOSCOPY

FB has also been widely used for therapeutic purposes. Although the role of RB has declined, RB remains an invaluable tool for controlling a compromised airway, massive hemoptysis, silicone stent placement, and for removing asphyxiating foreign bodies. The major indication for RB is to manage central airway obstruction. Approximately 30% of patients with lung cancer may present with airway obstruction and its complications, such as hemoptysis, postobstructive pneumonia, and asphyxia.[61] Reducing the size of a tumor or establishing airway patency with or without stent placement can produce rapid relief of symptoms, improve quality of life, and increase survival.[62] The few contraindications to RB include the inability to hyperextend the neck and an unstable facial fracture.

Some of the common bronchoscopic therapeutic procedures that are performed through the FB are discussed in the following section. A summary of the various therapeutic bronchoscopic techniques is shown in Table 22.4.

Thermal Ablation of an Endobronchial Lesion

Newer modalities such as endobronchial electrocautery, **argon plasma coagulation** (APC), or **laser photocoagulation** can be used to coagulate, carbonize, or vaporize lesions that protrude into the airway lumen and obstruct the central airways. These modalities increase the temperature of the tissue by molecular agitation and can be applied either through a flexible or an RB. By applying the appropriate power density, the desired tissue reaction can be achieved.

Application of electrocautery requires use of accessories such as knives, snares, or probes. APC is a noncontact technique to apply electric current to an endobronchial lesion. The modalities involve application of an electrically charged argon gas through a special disposable catheter.[63] The presence of a pacemaker or a defibrillator is a relative contraindication to using these electrical modalities.[64]

Lasers can produce tissue reaction by thermal, photochemical, or electromagnetic effects. As stated earlier, it is the thermal effect of the laser that is mainly used to remove the endobronchial lesion. The most commonly used lasers for this purpose are neodymium: yttrium-aluminum-garnet (Nd-YAG) and neodymium: yttrium-aluminum-perovskite (Ng-YAP) lasers. Lasers produce more precise tissue reaction than the electrosurgery units.[65,66]

The thermal ablation of an endobronchial lesion in properly selected patients produces some relief in close to 90% of patients. Improper use of the thermal modalities can lead to perforation of the airway, vascular structures, or esophagus. In addition, hypoxemia, pneumothorax, bronchopleural, and bronchoesophageal fistulas are other reported complications.[65] In the presence of high FiO_2, endobronchial ignition has been reported as a rare complication of such therapies. As a result, the lowest FiO_2 needed to maintain adequate oxygenation (often at 40% or less) offers the highest possible safety margin. Refractory hypoxemia (i.e., an O_2 requirement of FiO_2 >40%) and extrinsic compression of the airway without an endobronchial lesion are contraindications to thermal ablation.

RULE OF THUMB During the application of "hot therapies" (thermal ablation) such as laser, electrosurgery, or argon plasma coagulation, the FiO_2 always should be maintained at or below 40% to prevent endobronchial fire.

TABLE 22.4 Various Therapeutic Procedures With Flexible Bronchoscopy

Therapeutic Techniques	Methods	Clinical Uses	Complications
Thermal ablation • Argon plasma coagulation • Laser photocoagulation • Electrocautery	• Ionized argon gas conducts electrons to spray on tissue surfaces, resulting in superficial coagulative necrosis • Thermal effect causes tissue coagulation and evaporation; photodynamic and electromagnetic effects • Coagulative necrosis at low temperature or tissue vaporization at high temperature. Energy can be delivered through several types of probes	Rapid palliation of central airway obstruction from either benign or malignant; Hemostasis for management of endobronchial hemorrhage	Hypoxemia, pneumothorax, bronchopleural and bronchoesophageal fistulas
Cryotherapy	Cause extracellular ice crystal formation and extraction of intracellular water; induces vasoconstriction, and endothelial injury leading to microthrombus formation and tissue necrosis	Slow palliation of central airway obstruction from malignancy, granulation tissue; organic foreign body extraction; may have roles in biopsy of lung parenchyma	Hypoxemia, pneumothorax, bleeding
Brachytherapy	Deliver short distance/local radiation therapy	Local treatment for endobronchial tumors	
Endobronchial stenting	Provide internal splinting of the airway lumen; immediate relief of airway obstruction from malignant or benign processes	External compression from malignancy; stabilizing airway patency after mechanical debulking of tumor; sealing esophagogastric-tracheobronchial fistula	Mucous impaction, bacterial colonization, migration, and granuloma formation
Bronchial thermoplasty	Thermal energy to reduce the airway smooth muscle (ASM) mass which can minimize bronchoconstriction and improve asthma symptoms	Severe asthma	In short-term (i.e., following the procedure), increases acute exacerbation risk

Cryotherapy

Cryotherapy is a method of destroying tissue by freezing and thawing. Cryotherapy leads to extracellular ice crystal formation and extraction of intracellular water. In addition, extreme cold induces vasoconstriction, and endothelial injury leading to microthrombus formation and eventually tissue necrosis. The cryoprobe can be used through either an FB or an RB. The cryogen (the agent that causes the freezing) is released from very-high-pressure storage to the atmospheric pressure. The sudden drop in the pressure leads to expansion of the cryogen and a drop in its temperature. This effect is also referred as Joule-Thompson effect. The cryoprobe is placed in contact with the target and the cryogen is released, producing a tissue temperature of −80°C. The temperature increases approximately 10°C per millimeter from the tip. Thus the effective zone for cryotherapy is approximately 5 to 8 mm. Multiple cycles of rapid freezing and gradual thawing are applied to cover the entire treatment area. The effect of cryotherapy depends on the sensitivity of the tissue. Cryoresistant structures (those which do not respond to cryotherapy) are fat, cartilage, nerve sheath, and connective tissue, whereas neoplasms, granulation tissue, skin, mucous membranes, nerves, and endothelium are cryosensitive. The cryosensitivity of the tissue mainly depends on its water content. Therefore, application of this technique to a cryosensitive tissue is essential for success.[67,68]

Cryotherapy has been used to treat patients with central airway obstruction. Cryotherapy is ideal for treating stent-related granulation tissue when the stent is made of an inflammable material. Cryotherapy can be also be used to remove organic foreign bodies, blood clots, and mucus plugs by cryoadhesion; ice crystal formation between the probe and the object that holds them together.[69] In addition, unlike the thermal ablation techniques, cryotherapy can be used safely when the patient requires a high FiO_2.

Recently, the cryoadhesion principle has been used for obtaining larger pieces of lung tissue compared to conventional TBBx and EBBx approaches (called cryobiopsy).[69] Several studies have shown that cryobiopsies yielded larger, more alveolated samples in various pulmonary conditions including lung transplant rejection and interstitial lung diseases.[70,71]

Brachytherapy

The term **brachytherapy** describes a method to deliver short distance radiation therapy. Brachytherapy involves temporary placement of encapsulated radioactive sources within or near a tumor through the bronchoscope. Brachytherapy is used as both in addition to external-beam radiation and as a palliative radiation option for lung cancer located near the airways. It also can be used in managing superficial endobronchial squamous cell carcinoma with a curative intent. In brachytherapy, a catheter is placed adjacent to the lesion and the location is confirmed by fluoroscopy. The catheter is then loaded with a radioactive source, usually radium or iridium, reaching a total dose of 500 to 4000 Gray over a precise duration.[72,73]

The main advantage of brachytherapy is that a higher dose of radiation can be delivered to the tumor cells while minimizing radiation to the normal tissue, thereby reducing complications. Brachytherapy is indicated in patients with inoperable lung cancer or cancer metastatic to the airways.

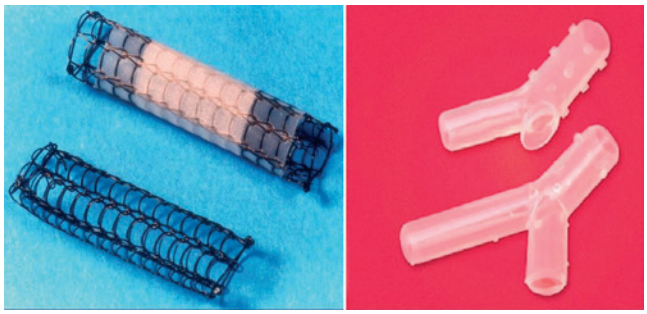

Fig. 22.15 Self-expanding metallic stents *(left)* and silicone stents *(right)*.

Endobronchial Stents

Stents are tubular devices designed for internal splinting of the airway lumen. **Airway stents** have been used to help reduce airway obstruction from malignant or benign processes that compress the airway from the outside. Airway stenting can offer immediate relief of acute respiratory distress, can allow successful extubation, and may prolong survival.[73,74] There are two major types of airway stents: metallic and silicone. Self-expanding metallic stents (SEMS) are commercially available in covered and uncovered forms (Fig. 22.15). Covered stents are designed primarily to prevent the growth of granulation tissue into the lumen of the stent. Current SEMS are made from nitinol, a nickel-titanium alloy that is well adapted for endobronchial applications. At room temperature, nitinol is extremely elastic. It can tolerate the extreme folding that is required when using a small deployment system but still return to its original shape without compromising its resistance to compression. The advantages of SEMS are ease of deployment, small internal-to-external diameter ratio, better conformity to the complex airway shapes, and ventilation across a lobar bronchial orifice (Table 22.5). The indications for SEMS placement include (1) extrinsic compression of central airways, (2) stabilizing airway patency after endoscopic removal of an intrinsic tumor, (3) sealing fistula between the airways and the gastrointestinal tract, and (4) managing of post–lung transplant anastomotic complications. SEMS is rarely used in benign central airway obstruction because there is a high-risk for stent-related granulation tissue formation. In 2005, the U.S. Food and Drug Administration issued a medical device safety warning against using SEMS for benign airway obstruction unless all other therapeutic options have been explored.[75]

Silicone stents have two major designs, straight and Y-shaped (for disease involving the carina). The stents are either made of transparent silicone (radiolucent) or silicone blended with barium sulfate (to make the stent radiopaque). The silicone stent is usually placed through a rigid bronchoscope. The advantages of silicone stents include easy customization, ease of repositioning/removal, minimal granulation tissue overgrowth, and lower cost than metallic stents. The indications for placing a silicone stent are similar to SEMS and include internal splinting for external compression/intraluminal growing cancer, benign strictures, collapsing airways, and tracheoesophageal fistulas. In terms of complications, mucous impaction (3.6%), bacterial colonization, migration (9.5%), and granuloma formation (7.9%) are most common. After stent placement, the patient should be given a stent alert card with details regarding the type, length/diameter, and location of the stent.

TABLE 22.5 Comparison of Silicone and Metallic Stent Properties

Comparison Factors	Metallic Stents	Silicone Stents
General Considerations		
Deployment	Flexible or rigid bronchoscopy	Rigid bronchoscopy only
Customization	No	Yes
Repositioning	Difficult	Easier
Conforms to complex airway	Yes	No
Internal-to-external diameter	Low	High
Elasticity	Excellent for nitinol	Poor
Mucociliary clearance	Yes for uncovered stents	No
Cost	More	Less
Complications		
Granulation tissue	More	Less
Migration	Less common	Significant
Fracture	Significant	Rare
Infection	More common	Less common
Tracheobronchial fistula formation	Possible	Very rare
Mucus impaction	Uncommon	Common

RULE OF THUMB SEMS should not be used in benign conditions unless all other therapeutic options have been exhausted.

Bronchial Thermoplasty

Bronchial thermoplasty (BT) is a nonpharmacologic treatment modality for asthma (Chapter 25). It uses thermal energy to reduce the airway smooth muscle (ASM) mass, thus minimizing bronchoconstriction. ASM has been found to play important roles in response to various stimuli with the production of growth factors, proinflammatory mediators, and adhesion receptors.[76] The thermal energy is delivered via the Alair system (Boston Scientific Co.), which is a radiofrequency catheter (Fig. 22.16). The catheter can pass through the working channel of an FB. The system delivers temperature-controlled thermal energy at 65°C for 10 seconds per each activation. BT is performed in a series of three separate bronchoscopy sessions, targeting different lobes of the lung except for the right middle lobe. This lobe is not treated due to concerns over stenosis of its small-diameter bronchus. [77]

In terms of clinical outcomes, BT can improve the patient's Asthma Quality of Life Questionnaire (AQLQ) score, decrease severe exacerbation, decrease days lost from school/work, and decrease emergency room visits, which led to FDA approval of BT for the treatment of severe asthma in 2010.[78] Long-term follow-up studies have demonstrated persistent benefits of BT, which have decreased severe exacerbations, ED visits, and hospitalizations significantly, by 45%, 55%, and 40%, respectively.[79]

Bronchoscopy in Difficult Intubation

It may be difficult to establish an artificial airway by conventional means in patients with cervical and oropharyngeal trauma or redundant supraglottic soft tissue. The ASA Task Force on difficult airway recommends alternative techniques to overcome such airway challenges, including flexible bronchoscopy.[80]

A FB can help place an ETT through the mouth or the nose. The ETT is placed over the FB, the vocal cords are visualized, and the ETT is then advanced into the trachea. Using the FB to aid ETT placement also allows for awake intubations with topical anesthesia and is particularly useful in patients with cervical injury, when immobilization of the neck is crucial.[81] The bronchoscope also may help identify causes of acute hypoxemia and help remove secretions or blood in the airway. The limitations of this approach include operator inexperience and the need for patient cooperation.

THE ROLE OF THE RESPIRATORY THERAPIST IN BRONCHOSCOPY

The RT has a major supportive role during bronchoscopic procedures. The RT may collaborate with other members of the patient care team to determine if the procedure is indicated. The RT is often responsible for ensuring that all documentation is in place before the procedure and that a preprocedure "time-out" takes place to ensure that the right procedure is being performed on the right patient. During the preprocedure evaluation, the RT helps recognize the patient's O_2 requirement and arranges for adequate O_2 supplementation during the procedure. The RT also administers inhaled bronchodilators before or during the procedure if the patient exhibits bronchospasm.

FB is usually performed on spontaneously breathing patients through the mouth (transoral) or nose (transnasal). The RT assists preparing the upper as well as lower airways for the procedure using local anesthetic agents. In mechanically ventilated patients, the RT may help optimize the length and the size of the ETT, place a bite-block in place to protect the equipment, and adjust ventilator settings before and during the procedure. In addition to monitoring vital signs and O_2 saturation during the procedure, the RT may assist the physician in operating the bronchoscopic accessories, including brush, forceps, needles, laser fibers, cryoprobe, and APC probes. In patients with suspected ventilator-associated pneumonia, the RT may perform mini-BAL, which may guide the escalation and deescalation of antibiotic therapy. Furthermore, the RT often identifies and can assist in responding to an adverse event associated with FB, such as hypoxemia. These and other aspects of the role of the RT are summarized in Box 22.5.

MINI CLINI

Awake Intubation Using Flexible Bronchoscope in a Morbidly Obese Patient

Problem

An RT was called to assist with intubation of an obese patient (weighing 320 pounds with a body mass index of 63 kg/m^2). The patient presented with acute respiratory distress from lobar pneumonia. Initial assessment of the patient's airway indicated that intubation was likely to be difficult, with a Malampatti score of 3, along with a history of severe obstructive sleep apnea. Despite the history, there were no adverse features related to mouth opening, thyromental distance, and neck movement. The procedure team determined that awake, tracheal intubation using an FB was the most appropriate approach. The patient agreed. How should the procedure be done?

Discussion

The patient should be placed in an upright position. In addition to preoxygenating the patient, topical anesthesia plays important role in the awake intubation. Two percent viscous lidocaine can be used to anesthetize the oral cavity; either in a swished and swallow form or as a spray. The FB can then be inserted through an ETT. An oral guard should be placed to protect the FB in case the patient inadvertently bites down during the procedure. The FB is inserted through the mouth. Upon reaching the glottic chink, 2% lidocaine should be instilled via the working channel to anesthetize the vocal cords. Once, the tip of FB passes the vocal cords and is positioned at the distal trachea, the ET tube should be slid over the FB into the trachea. The ET tube is then positioned and secured, and the FB is withdrawn.

SPECIAL CONSIDERATIONS FOR BRONCHOSCOPY DURING MECHANICAL VENTILATION

In addition to the role of the RT described earlier, the RT plays an even more important role when bronchoscopy is performed on mechanically ventilated patients. It is most important to note that FB carries a higher risk when performed on patients with reduced cardiopulmonary reserve, particularly those requiring mechanical ventilation. In such patients, the RT must ensure that the airway is properly secured, verify adequate ventilation and gas exchange, monitor the patient, and quickly communicate the development of any complications to the physician and any other members of the bronchoscopy team.

In mechanically ventilated patients, it is important to consider that the bronchoscope will occupy a greater proportion of the airway than for spontaneously breathing patients. The external diameter of a standard FB is 5.7 mm, but in some situations a smaller (5 mm or less) or larger (6.4 mm) diameter scope may

BOX 22.5 Role of the Respiratory Therapist in Bronchoscopy

- Preprocedure
  - Help identify potential need for a bronchoscopy such as retained secretions or foreign body removal.
  - Verify physician's order or protocol; review medical record for contraindications (e.g., excessive clotting times), hazards, and informed consent.
  - Prepare/ensure proper function of equipment, including bronchoscope, light source, TV monitor, video recorder, medications, specimen traps.
  - Outline plan for adequate oxygenation during the procedure.
  - Evaluate patient for bronchospasm and administer aerosolized bronchodilators if required.
  - Assist nursing staff in applying topical anesthesia to the upper airways (nasal passages, oropharynx, hypopharynx).
  - Identify patient and perform pre-procedure "time-out."
  - Mechanically ventilated patients/bedside bronchoscopy
    - Establish adequacy of the length and the diameter of the endotracheal or the tracheostomy tube based on the indication.
    - Ensure a bite-block is in place to avoid equipment damage.
    - Adjust ventilator settings for the safety of the procedure while maintaining proper oxygenation.
- During the procedure
  - Monitor vital parameters during the procedure, including capnography (if available).
  - Help identify and respond to adverse reactions (e.g., hypoxemia or pneumothorax).
  - Administer adequate amount of supplemental oxygen all throughout the procedure by choosing proper appliances (nasal cannula, mask, bilevel positive airway pressure).
  - Provide proper positioning of the patient to maintain patency of the upper airways (jaw-lift, etc.).
  - Assist use of endobronchial accessories (bite block, oral airways, nasopharyngeal tube, biopsy forceps, brushes, etc.).
  - Set up instruments for rigid bronchoscopy and silicon stent placement.
  - Help attend to emergent situations (pneumothorax, bleeding).
  - Help in placement of chest or endotracheal tubes.
- Postprocedure
  - Determine adequate oxygenation and ventilation and respond to adverse reactions.
  - Disinfect and properly store equipment.
  - Document procedure and relevant details.

be used. The narrowest point in the upper airway (and point of maximal resistance) is the cricoid space, the diameter of which averages 14 mm in women and 18 mm in men.[82] Thus in nonintubated, spontaneously breathing patients, inspiratory and expiratory effort (measured by tracheal pressure) appear minimally affected in most patients (−5 and +3.5 cm H_2O, respectively). However, in intubated, spontaneously breathing patients, the resistance imposed by the bronchoscope may cause tracheal pressures to increase noticeably (−10 and +9 cm H_2O) and may reach clinically unacceptable levels (−20 and +20 cm H_2O) in some patients.[83] Therefore the minimum size ETT that should be in place in order to use a standard adult-sized 5.7-mm bronchoscope is a 7.5 to 8.0 mm internal diameter ETT.[84]

RULE OF THUMB The minimal sized ETT that can be used with a standard 5.7-mm bronchoscope has a 7.5 to 8.0 mm internal diameter.

MINI CLINI

Bronchoscopy-Induced Hypoxemia

Problem

An RT is assisting during a flexible bronchoscopy on a spontaneously breathing patient that is taking longer than expected because of other adjunctive procedures, including BAL. Shortly after instilling the lavage solution into the airway through the bronchoscope, the patient's O_2 saturation drops from 97% to 88% via pulse oximetry, her heart rate increases from 90 to 118, and the patient's skin color changes from pink to pale. What is the condition that an RT should consider in this situation?

Discussion

Hypoxemia should be suspected in this case. Given that the bronchoscope occupies a significant amount of the anatomic airway during this procedure, additional airway resistance can partially impede ventilation during the procedure. In addition, the BAL solution introduced into the airway can temporarily interfere with ventilation, and gas exchange and hypoxemia can occur. In addition, frequent and prolonged suctioning can lead to severe, prolonged hypoxemia. Pausing the procedure and administering a higher FiO_2 or even 100% O_2 will generally alleviate this problem and boost the pulse oximetry to more acceptable levels (mid-90%). Once monitored blood O_2 levels return to normal, the procedure can be resumed. The patient's oxygenation and overall clinical status should be continually monitored for the balance of the procedure and for a period following it.

PHYSIOLOGIC AND MECHANICAL ALTERATIONS ASSOCIATED WITH FLEXIBLE BRONCHOSCOPY IN INTUBATED PATIENTS

Complications associated with a flexible bronchoscopy in intubated patients are infrequent (<10%) and usually mild.[85] However, serious complications may occur (Table 22.6). These include the following (along with their reported prevalence): transient hypoxemia with SpO_2 less than 90% (8%), tension pneumothorax (14%), bronchial hemorrhage greater than 30 mL (6%), hypotension with mean arterial pressure less than 60 mm Hg (7%), and tachycardia greater than 140 beats per minute (4%).[85] Pneumothorax is primarily associated with lung biopsy procedures,[86,87] whereas the risk for significant bleeding after biopsy increases when the platelet count is below 50,000/mm^3.[85]

As noted elsewhere in this chapter, some degree of hypoxemia may occur during FB. In those with normal lungs, the PaO_2 can decrease by 10 to 30 mm Hg, whereas in critically ill patients, the PaO_2 may be reduced by 60 mm Hg.[85,86] Hypoxemia during FB is partly caused by suctioning through the bronchoscope. This decreases PEEP and functional residual capacity and promotes atelectasis. For example, setting the vacuum at 100 mm Hg through a standard 2-mm suction port can evacuate approximately 7 L/min of gas.[85] The problem is accentuated if tidal volume delivery also is significantly compromised during FB. In fact, frequent suctioning during FB also causes pronounced tidal volume loss.[83] Because FB commonly is used to remove mucus plugs, this problem may be unavoidable. Both the RT and the physician performing the bronchoscopy must be mindful of the frequency and duration of suctioning, along with the

total procedure time to limit the potential for severe, prolonged hypoxemia. The risk for significant hypoxemia is elevated in those with acute respiratory distress syndrome (ARDS) and in patients who are insufficiently sedated.[83] Patients undergoing FB should be pre-oxygenated using an FiO_2 of 1.0 for 15 minutes. Resolution of hypoxemia depends on the presence and severity of the underlying pulmonary disease. For example, hypoxemia tends to resolve within 15 minutes after FB in those with normal lungs, whereas hypoxemia may persist for several hours in those with severe lung disease.

TABLE 22.6 Physiologic and Mechanical Alterations Associated With Flexible Bronchoscopy in Intubated Patients

System	Effects	Comments/Interventions
Respiratory mechanics	High peak inspiratory pressures and pressure cycling	Obstruction by the bronchoscope causes back-pressure that is not transmitted to the lungs. Use of high inspiratory flow rates/brief inspiratory time will accentuate the problem and may greatly reduce minute ventilation. Intervention: *Volume control ventilation:* Use a lower peak flow rate or decreasing ramp pattern and increased inspiratory time. *Pressure control ventilation:* Increase the pressure control level and extend the inspiratory time. *Before bronchoscopy:* Assess minute ventilation demand and blood gases with the physician to determine if the patient might tolerate mild to moderate respiratory acidosis during the anticipated procedure duration. Monitor peak inspiratory pressure.
	Intrinsic PEEP	Increased expiratory resistance can cause a 30% increase in functional residual capacity and may cause high levels of intrinsic PEEP to develop. With an 8-mm endotracheal tube, intrinsic PEEP levels are generally <20 cm H_2O, but have been reported to rise to 35 cm H_2O when bronchoscopy has been attempted with a 7-mm tube. *Consider* removing or reducing PEEP by 50% during the procedure. Monitor blood pressure as a signifier for possible intrinsic PEEP buildup. Either a sustained downward trend or abrupt drop in systolic blood pressure may indicate decreased cardiac output.
	Circuit leak, suctioning, and tidal volume loss	Circuit leaks with substantial loss of tidal volume were a common problem until the creation of specialized bronchoscopy port endotracheal tube adapters. These are commercially available and have largely eliminated the problem. When encountered, the rule of thumb has been to increase the preset tidal volume by 30%–40% to compensate for the leak.[86] Use lower peak inspiratory flow rate and longer inspiratory time. Frequent, prolonged suctioning during FB can greatly reduce tidal volume regardless of ETT size. Monitor: • Expired tidal volume • End-tidal PCO_2 and VCO_2 (CO_2 excretion) if volumetric capnography is available, particularly in those with baseline hypercarbia, acidosis, or hemodynamically unstable.
Gas exchange	Hypoxemia	Pre-oxygenate for 15 min on FiO_2 of 1.[86] Ensure adequate sedation before and during FB. Ensure continuous pulse oximetry. Consider using recruitment maneuvers to improve functional residual capacity before and (if necessary) after FB in patients with marginal oxygenation. To the extent possible: • Minimize tidal volume loss. • Avoid using a brief inspiratory time. • Limit the frequency and duration of suctioning.
	Acute hypercapnia and acidosis	On average, $PaCO_2$ tends to increase by 8 mm Hg during FB.[86] This would decrease arterial pH by only 0.06; and even less in patients with chronic hypercapnia. This mild change in $PaCO_2$ should be interpreted in the context of clinicians adjusting mechanical ventilator settings to attempt to maintain adequate ventilation. Given the relatively brief procedure time for FB, concern over the impact of hypercapnia should be focused on clinically unstable patients. In at-risk patients: • The procedure time should curtailed. Periodic withdrawal of the bronchoscope to ensure adequate ventilation. • Clinicians should determine the limits of what an acute rise in $PaCO_2$ and decrease in pH would be acceptable during the procedure and use clinical equations to estimate the minimum acceptable minute ventilation that must be maintained (see Mini Clini for details). • When FB must be attempted in patients with significant acidosis, consideration should be given to pre-procedure buffer therapy with a non–CO_2 generating agent (i.e., THAM) often used for procedures requiring apneic oxygenation.

TABLE 22.6 Physiologic and Mechanical Alterations Associated With Flexible Bronchoscopy in Intubated Patients—*cont'd*

System	Effects	Comments/Interventions
Hemodynamics	Heart rate and cardiac arrhythmias	Hypoxemia and hypercapnia increase sympathetic tone, which can lead to tachycardia, myocardial ischemia, and arrhythmias, and may result in hypotension and/or cardiac arrest. Heart rate tends to increase by ~40% during FB.[88] The occurrence of major arrhythmias is 3%–11%. Reduce the risk for arrhythmias by: • Preoxygenation with an FiO_2 of 1 • Minimizing procedure time • Periodic withdrawal of the bronchoscope to ensure adequate ventilation Ensure continuous cardiac monitoring.
	Alterations in blood pressure and cardiac output	Mean blood pressure and cardiac output tend to increase during FB by ~30%.[88] Hemodynamic variables tend to return to normal ~15 min after completion of FB.[86]

ETT, Endotracheal tube; *FB,* flexible bronchoscopy; *PEEP,* positive end-expiratory pressure; *THAM,* tris-hydroxymethyl aminomethane.

TABLE 22.7 High-Risk Patients for Flexible Bronchoscopy

Conditions	Considerations
Asthma	Greater tendency for laryngospasm and bronchospasm[87,88] Tendency for greater reduction in lung function after FB when lavage or biopsies are done Hypoxemia not uncommon Pretreatment with bronchodilators immediately before FB In patients with unstable lung function, consider pretreatment with steroids several days before FB
Acute brain injury	Intracranial hypertension is a predominant concern. Procedural goal: intracranial pressure <20 mm Hg with cerebral perfusion pressure ≥70 mm Hg Causes of increased intracranial pressure include sympathetic stimulation from discomfort and hypercapnia, hypoxemia. Build-up of intrinsic PEEP decreases venous return, causing cranial venous pooling. Procedural sedation and strategies to maintain minute ventilation assume even greater importance. Employing continuous drainage when subdural catheters are present should be considered. Either curtailing procedure time or frequent periods bronchoscope withdrawal to resume baseline minute ventilation also should be considered.
Acute respiratory distress syndrome (ARDS)	Tendency is for severe hypoxemia and respiratory acidosis, particularly in those with severe ARDS (PaO_2/FiO_2 <100) due to low lung volumes and high dead-space ventilation. Risk is increased if hemodynamic instability is present (e.g., mean arterial pressure <65 mm Hg and/or high vasopressor requirements). Loss of PEEP is particularly problematic. Consideration should be given to preprocedure use of recruitment maneuvers to optimize lung volumes and oxygenation and THAM to control acidosis.
Coronary artery disease	Adrenergic discharge during FB in response to under-sedation, hypoxemia, and/or acute respiratory acidosis may cause myocardial ischemia, arrhythmias, hypotension are cardiac arrest. In nonintubated patients, the need for high doses of topical anesthesia with lidocaine may cause sinus arrest and atrioventricular block.

FB, Flexible bronchoscopy; *THAM,* tris-hydroxymethyl aminomethane.

RULE OF THUMB Hypoxemia during FB on mechanically ventilated patients is related to several factors, including loss of lung volume during suctioning, particularly if tidal volume delivery also is compromised. Hypoxemia occurs more frequently in those with ARDS and in those who are insufficiently sedated.

It is the RT's responsibility to effectively manage the most common of these complications (see Table 22.6). In addition, the RT must anticipate which patients are most likely to suffer significant adverse events during bronchoscopy (Table 22.7). Before the procedure, the members of the bronchoscopy team, including the RT, should assess the patient's condition, discuss which adverse effects are most likely to occur, and discuss how these potential complications should be managed. This discussion should include the anticipated procedure time, whether the original plan for the procedure should be modified, the sedation strategy, hemodynamic management, and ventilator management. The RT should especially focus on the minimum clinically acceptable level of minute ventilation needed to complete the procedure. Depending on the procedure goal (e.g., diagnostic, removal of secretions), bronchoscopy tends to last between 7 and 17 minutes.[88,89]

EMERGING BRONCHOSCOPIC INTERVENTIONS

In addition to the interventions described earlier, others are emerging and hold promise for the future. Endobronchial valves

MINI CLINI

Estimating the Minimum Minute Ventilation Requirements During Flexible Bronchoscopy in a Patient With Severe Respiratory Failure

Problem

A patient with ARDS has deteriorating oxygenation associated with a new infiltrate on chest x-ray. Gram-negative bacterial ventilator-associated pneumonia is strongly suspected, and FB is deemed necessary before adjusting antibiotic therapy because the suspected pathogen is likely to be multidrug resistant. The patient has a high minute ventilation demand of 13 L/min to maintain a pH of 7.40 and $PaCO_2$ of 40 mm Hg. The patient has sepsis and currently requires norepinephrine at 12 mcg/min to maintain a mean arterial pressure of 65 mm Hg. The physician decides that during FB, a pH of 7.24 would be tolerable for the estimated procedure time of 10 minutes. The RT is asked if there is a clinical formula to estimate what rise in $PaCO_2$ would likely produce the target minimum pH. In addition, the RT is asked to estimate the minimum minute ventilation needed during FB that would likely maintain pH at 7.24.

Discussion

In patients without chronic hypercapnia, an acute rise in $PaCO_2$ of 10 mm Hg produces a decrease in pH of 0.008.[89] Because tidal volume can be greatly reduced during FB, the RT can reasonably begin with an estimated $PaCO_2$ increase of 20 mm Hg. This would yield an estimated drop in pH of 0.16 units (20×0.008) and a pH of 7.24 ($7.40 - 0.16$). The clinical formula for corrected minute ventilation then can be used to estimate the minimum acceptable minute ventilation.[88]

$$VE_{min} = VE_{measured} \times (PaCO_2 \text{ measured} \div PaCO_2 \text{ upperlimit})$$

$$VE_{min} = 13\,L/min \times (40 \div 60)$$

$$VE_{min} = 13\,L/min \times 0.67$$

$$VE_{min} = 8.7\,L/min$$

Patients with high minute ventilation demands who require vasopressor support to maintain adequate perfusion may be particularly sensitive to sudden respiratory acidosis. The fact that this patient already requires the highest recommended dose of norepinephrine to maintain an adequate blood pressure is cause for concern about the safety of performing FB. The steps described previously are only estimates for guiding management during FB and assessing the risk-to-benefit ratio.

and coil placement are being studied in the management of patients with severe emphysema. If shown to be effective, they could represent an alternative to lung volume reduction surgery for severe emphysema. Recently, an endobronchial valve (called the Zephyr valve) has received FDA approval as a treatment option for patients with severe emphysema. Studies have shown that the patients with Zephyr valve experienced improved FEV1, exercise tolerance, dyspnea, and quality of life compared with standard of care for COPD.[90]

CONCLUSION

Bronchoscopy is a common diagnostic and therapeutic procedure that has reduced the need for procedures such has percutaneous needle aspiration, mediastinoscopy, thoracoscopy, and open lung biopsy. In many settings, RTs play a major role in identifying patients who may benefit from bronchoscopy, setting up the equipment, and assisting with the procedure itself, as well as monitoring patients undergoing bronchoscopy.

SUMMARY CHECKLIST

- BAL, biopsy, and TBNA are the most commonly used diagnostic procedures during FB. BAL obtains samples from the alveoli. Needle aspiration has a role in sampling mediastinal lymph nodes to diagnose lung cancer, sarcoidosis, and some infectious processes. Biopsy has value in diagnosing some infiltrative pulmonary diseases.
- Emerging advanced diagnostic procedures, including EBUS and ENB, play important roles in managing lung cancer. The specimens are adequate for molecular studies, which play an important role in planning treatment.
- Various thermal ablation techniques (e.g., laser) can be applied through either a rigid or FB to treat endobronchial lesions. The most important point is to ensure a low FiO_2 environment before using any thermal ablative therapy to minimize the risk of an endobronchial fire.
- Airway stenting has been used to maintain airway patency after dilation of any obstructed major airways. It is important to recognize the difference between silicone and metallic stents.
- Bronchial thermoplasty (BT) is a novel bronchoscopic technique for patients with severe asthma. BT has been shown to improve quality of life and to decrease severe exacerbation frequency, days lost from school/work, and emergency room visits.
- Endobronchial valves and coil placement are being studied in the management of patients with severe emphysema as a minimally invasive lung volume reduction therapy.
- Awake intubation using an FB can be safely performed in patients with a suspected difficult upper airway (e.g., large neck mass, morbid obesity, tracheal stenosis).
- The RT plays a vital role in assisting before, during, and after the bronchoscopy procedure. There are many aspects to this role, but they include ensuring appropriate documentation, preparing the patient and the equipment, patient monitoring, and responding to possible adverse events.
- When bronchoscopy is performed in mechanically ventilated patients, the RT must especially ensure adequate ventilation and gas exchange before, during, and after the procedure.

Nutrition Assessment

Janet Reid-Hector

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how a comprehensive nutrition assessment is conducted.
- Calculate and interpret body mass index.
- Distinguish between two forms of protein-energy malnutrition.
- List the biochemical indicators of nutrition status.
- Describe the clinical manifestations of malnourishment.
- Describe how to obtain and evaluate a nutrition history.
- Estimate daily resting energy expenditure.
- List the indications, contraindications, hazards, and limitations of indirect calorimetry.
- Describe how to prepare a patient for indirect calorimetry.
- Interpret the results of indirect calorimetry.
- Adjust resting energy expenditure values to reflect the actual patient energy needs.
- Describe the effects of malnutrition on the respiratory system.
- Describe how to identify patients at high risk for malnutrition.
- State when enteral nutrition and parenteral nutrition are needed.
- Identify and minimize common respiratory complications of enteral feedings.
- List specific nutrition guidelines for specific pulmonary diseases.
- Explain how common pulmonary medications affect nutrition.

CHAPTER OUTLINE

KEY TERMS

albumin
adenosine triphosphate (ATP)
anemia
anergy
anthropometrics
azotemia
basal metabolic rate (BMR)
body mass index (BMI)
cachexic/cachectic
cellular respiration
creatinine-height index (CHI)
catabolism
creatinine
essential nutrients
gluconeogenesis
ideal body weight
indirect calorimetry
kilocalories
Krebs cycle (tricarboxylic acid [TCA] cycle)
kwashiorkor
marasmus
macronutrients
micronutrients

metabolic cart
metabolism
nitrogen balance
normometabolic
parenteral
parenteral nutrition (PN)
protein-energy malnutrition (PEM)
retinol-binding protein
respiratory quotient (RQ)
resting energy expenditure (REE)
skinfold measurement
transthyretin

Essential nutrients are required for life, health, and well-being. Second to the provision of oxygen is the provision of specific nutrients—carbohydrates (CHO), protein, lipids, vitamins, minerals, and water (H_2O), to sustain the function, growth, structure, maintenance, and repair of the body. A human deprived of O_2 for minutes can no longer function. Similarly, a human deprived of essential nutrients for days to weeks will experience cell death and life will cease to exist.

Inside each cell is a special organelle, known as the mitochondria, or the cells' "powerhouse," in which specific biochemical processes of the **Krebs cycle (tricarboxylic acid [TCA] cycle)** generate energy from nutrients. **Cellular respiration** is the process through which cells convert the chemical energy in the three energy yielding nutrients (CHO, protein, lipids) to high energy phosphorylated nucleotides comprised of the currency of life. The most common "energy currency" of cells is **adenosine triphosphate (ATP)**, a molecule which stores a lot of energy in its phosphate bonds. These bonds are broken to release that energy needed to drive all the physiological mechanisms that maintain life.[1,2]

Because ATP is not stable over extended periods of time, it is not used for long-term energy storage. Instead, CHO in its monomer form (glucose) and lipids are used as long-term form of storage, and cells must constantly process those molecules to produce new ATP. This is the process of respiration. The process of aerobic respiration produces a large amount of ATP from each molecule of glucose broken down from complex carbohydrates. In fact, each molecule of glucose digested by a plant or animal cell yields 36 to 38 molecules of ATP.

The overall reaction for cellular respiration is: $C_6H_{12}O_6$(glucose) + $6O_2$(oxygen) → $6CO_2$ (carbon dioxide) + $6H_2O$(water) + ~38 ATP (adenosine triphosphate), and is summarized in Fig. 23.1.[1-3]

Adequate nutrition is essential for good health. The relationship between nutrition and respiratory status is reciprocal throughout the human life cycle. A fully functioning pulmonary system supports the body by providing oxygen needed for cellular **metabolism** of the three **macronutrients**: carbohydrates (CHO), proteins, and lipids. Adequate nutrient intake maintains optimal nutritional status thereby ensuring growth, development and maintenance of the pulmonary system, including its structural mechanisms. The strength and functioning of skeletal and respiratory muscles, as well as, the nervous system and immune system, are dependent on optimal nutrition. A person's nutritional status and ability to metabolize CHO, proteins, and fats is directly related to a healthy pulmonary system. Pulmonary disorders that have direct significant, nutritional implications include asthma, cystic fibrosis, bronchopulmonary dysplasia, chronic obstructive pulmonary disease (COPD), emphysema, and acute respiratory distress syndrome. The nutritional requirements and status of patients with pulmonary disease are established major factors that influence acute and long-term patient outcomes.[4] The systemic presentation of muscle dysfunction observed in patients with COPD, which involves the loss of strength (ability to develop maximal effort); and/or endurance (ability to maintain submaximal effort over time) is exacerbated by nutritional abnormalities and nutrient deficiencies. A balanced supply of nutrients is needed for proper respiratory function; O_2 is required for ATP synthesis and muscle function, including the respiratory muscles. Poor or inadequate nutrient intake disrupts energy use and impairs normal organ function. Conversely, disease can impair nutrient intake or alter metabolism, causing malnutrition (Fig. 23.2).[5-7]

Patients with respiratory disease are particularly challenged because it is difficult to breathe and swallow at the same time. Breathing provides the oxygen necessary for metabolism of nutrients to meet the energy needs of individuals. Nutrition affects the efficiency of the metabolic processes and influences the amount of oxygen needed and the amount of carbon dioxide exhaled. Nutrition is key to proper functioning of the immune defense system, thereby affecting the patient's susceptibility to infection and ability to deal with physiologic stress. The tissues organs that maintain defense against antigens or invading microbes, require sufficient nutrients to function at an optimal level. The skin affords the largest physical barrier, and the lungs,

Fig. 23.1 Cellular respiration.

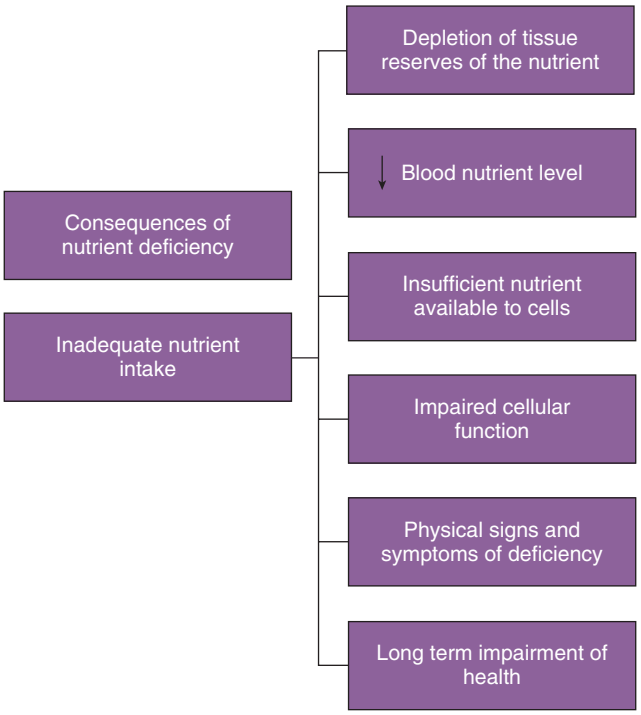

Fig. 23.2 Consequences of nutrient deficiencies.

mouth, and digestive tract are lined with membranes that block invading microorganisms. The linings of these organs are hyper sensitive to vitamin, protein, and other nutrient deficiencies, and examining of the skin and mouth often reveals signs of malnutrition.[2,4]

Understanding the role of and need for nutrition in maintaining normal respiratory function, and in treating pulmonary disease is important for respiratory therapists (RT). This chapter focuses on nutrition assessment—determining the nutrient needs of individuals.

NUTRITION ASSESSMENT

Nutrition assessment is the process of collecting and evaluating data to determine the nutrition status of an individual. Typically a registered dietitian (RD) gathers data to compare various social, pharmaceutical, environmental, physical, and medical factors to evaluate the nutrient needs of an individual. The purpose of nutrition assessment is to develop a *nutrition care plan* that ensures continual adequate nutrition for health. This is a critical process for the RT to understand as diseases of the pulmonary system varyingly increase energy requirements. In addition, complications and treatment of pulmonary disease affect the ability to ingest and digest adequate food and affect the circulation, cellular use, storage, and excretion of most nutrients. The increased work of breathing, chronic infection, and medical treatments used to treat pulmonary diseases, such as chest physical therapy and some medications, increase energy requirements. Medications such as bronchodilators, steroids, and antibiotics used to treat disease may have other nutritional implications and need to be considered in the nutritional evaluation and intervention. Patients with pulmonary disease usually present with a reduced nutritional intake attributed to fluid restrictions, gastrointestinal discomfort, vomiting, anorexia, shortness of breath, and decreased oxygen saturation when eating. A reduced ability to prepare foods because of fatigue and shortness of breath, impaired feeding skills, altered metabolism, and financial limitations all result in additional difficulties in achieving adequate nutritional intake. Also, some diseases, such as cystic fibrosis, affect not only the lungs but also the pancreas, resulting in inadequate production of certain enzymes necessary in the digestion of proteins, carbohydrates, and particularly fats. This puts patients with cystic fibrosis at risk for malnutrition, unless certain dietary supplements and pancreatic enzymes are taken to compensate.[4]

Data are obtained from numerous sources for nutrition assessment. Interviewing the individual or the caregiver to determine past and current eating practices is most helpful. Reviewing the patient's medical record provides additional information regarding pertinent social, pharmaceutical, environmental, and medical issues. Information gathered for a nutrition assessment is grouped into five domains: (1) food/nutrition-related history, (2) anthropometric measurements, (3) biochemical data and tests/procedures, (4) nutrition-focused physical findings, and (5) client history (Box 23.1).[8]

RULE OF THUMB The work of breathing is attributable to about 2% to 3% of the resting energy expenditure (REE) in the normal adult; however, in the pulmonary-compromised patient, approximately 25% of the REE can be attributed to the work of breathing.

Food-Related and Nutrition-Related History

Past dietary practices are identified to determine the pattern of food intake. Numerous means are available to determine food consumed by an individual. A registered dietitian may use a 24-hour recall or a usual daily intake recall, a food diary or food record, or a food frequency questionnaire. The 24-hour recall and the usual daily intake recall depends on past information in which the patient states the foods and amount consumed in an average day. This technique is easily incorporated into a clinical setting. Food frequency questionnaires incorporate information on the frequency and amount of the specific foods consumed and can help identify eating patterns. Patients are asked to write down daily everything they have eaten. The patient may record food intake over an extended time—most frequently, a 3-day or 7-day period.

Evaluation of Nutrition History

The information from a diet history may be evaluated for nutrient intake using a variety of tools, including the government-sponsored MyPlate platform, a nutrient analysis handbook, or a nutrient analysis software package.

MyPlate. The US Department of Agriculture and the US Department of Health and Human Services recommends balanced nutrition for US citizens.[9] The clinician or patient can go to http://www.choosemyplate.gov and compare diet history information to estimate the adequacy of the patient's diet.[10]

Nutrient Analysis Handbook. A handbook listing the nutrient content of specific foods may be used to calculate manually

BOX 23.1 Components of a Comprehensive Nutrition Assessment

Medical Chart
- History and physical examination
- Present diseases
- Current medications
- Activity level
- Physical assessment
- Social history

Anthropometrics
- Usual weight and height
- History of weight loss
- Actual versus ideal body weight
- Body mass index
- Body composition (triceps skin fold, arm muscle area)

Physical Assessment
- Signs of weight loss (cachexia)
- Edema that may mask weight loss
- Hair, skin, mouth, and tongue

Clinical Laboratory Tests
- Visceral proteins
- C-reactive protein
- Creatinine-height index
- Immune-related tests
- Nitrogen balance

Dietary History
- Usual food intake
- Food likes and dislikes
- Appetite

Total Caloric Requirements
- Resting energy expenditure predictive equations
- Indirect calorimetry

Access to Food
- Income
- Education
- Mobility
- Mechanical impediments

the adequacy of a 24-hour recall. This is a tedious and time-consuming task.

Nutrient Analysis Software. Computer programs can determine total calories, percent of calories of macronutrients (protein, carbohydrate, and fat), and units of **micronutrients** and fiber. The patient's individual foods and serving size are entered into a computer file to determine quickly the nutrient content of a diet history.

Anthropometrics

Anthropometrics refers to body measurements; the most frequently used are height and weight. Skin fold thicknesses, arm muscle measurements, waist and hip measurements, head circumference, and wrist diameter are useful body composition measurements when assessing nutrition status.

Height and Weight

A measured height and weight is preferred, but the clinician may ask the patient or caregiver for the height and weight. When recording these data, note the date and whether the height and weight were stated or measured.

Body mass index. **Body mass index (BMI)** expresses the relationship between weight and height and is used to classify patients as underweight, healthy weight, overweight, obese, or morbidly obese. The formula for calculating BMI in kilograms and meters is:

$$\text{BMI} = \frac{\text{Actual body weight (kg)}}{\text{height}^2\,(\text{m}^2)}$$

And when using pounds and inches is:

$$\text{BMI} = \frac{\text{Actual body weight (lb)} \times 703}{\text{height}^2\,(\text{in}^2)}$$

An Internet calculator for BMI is available at: http://www.cdc.gov/bmi.

RULE OF THUMB BMI categories for adults and children (male and female, age 2 to 20 years) are as follows.[11,12]

	Adult (BMI)	Children (BMI for Age)
Underweight	<18.5	<10th percentile
Healthy weight	18.5–24.9	10th–85th percentiles
Excessive weight	25.0–29.9	85th–95th percentiles
Obesity	>30	>95th percentile
Morbid obesity	>35	>99th percentile

Overweight and obesity. Simply defined, overweight and obesity occur over time with the consumption of too many calories or too little expenditure of calories through activity or exercise or both overconsumption and under expenditure. Other contributory factors include rare diseases, genetic predisposition, and loss of mobility through trauma or disease. Regardless, obesity occurs when too many calories are ingested for the amount of energy (calories) expended.

Kwashiorkor and marasmus. Undernutrition classifications include kwashiorkor and marasmus. Typically seen in children 6 to 18 months of age residing in impoverished areas of the world, **marasmus** results from a prolonged, extreme lack of calories and protein associated with food shortage, early weaning, or infrequent feeding of infants,[13] and obvious lack of muscle and fat characterize a child or adult with marasmus. Table 23.1 compares the two forms of protein energy malnutrition (PEM). **Kwashiorkor** results from a more sudden lack of protein and calories, as in a first-born infant weaned suddenly on the arrival of a new sibling, when a diet of nutrient-rich breast milk is traded for a nutrient-poor, cereal-based diet.[1,2] A protruding belly and edematous face and limbs are characteristic of kwashiorkor and result from decreased plasma proteins needed to maintain fluid balance and transport fat out of the liver.

Body Composition

Other anthropometric measurements useful in nutrition assessment evaluate body weight variations in individuals. Someone

TABLE 23.1 Comparison of Two Primary Forms of Protein-Energy Malnutrition

Parameter	Starvation (Marasmus)	Hypercatabolism (Kwashiorkor)
Cause	Inadequate energy intake	Response to injury or infection
Examples	Cancer, pulmonary emphysema	Sepsis, burns
Body habitus	Thin, wasted, cachexic	May be normal, edematous
Rate of malnutrition	Slow	Rapid
Metabolic rate	↓	↑
Fuel	Glucose/fat	Mixed
Catabolism	↓	↑
Gluconeogenesis	↓	Markedly ↑
Glucagon	↓	Markedly ↑
Insulin	↓	↑
Ketogenesis	↑	Slightly ↑
Catecholamines	Unchanged	↑
Cortisol	Unchanged	↑
Growth hormone	Increased	↑
Visceral proteins	Normal	Decreased ↓
Cytokines	Variable	Increased
Immune function	Normal	Impaired
Clinical course	Adequate responsiveness to short-term stress	Infections, poor wound healing, decubitus ulcers, skin breakdown
Mortality	Low unless related to underlying disease	High

with similar height may differ in the proportion of lean body mass, fat mass, and skeletal size. Common measurements are *arm muscle area* (index for muscle), *skin folds* (measures of fat), and waist-to-hip ratios. More sophisticated imaging technologies such as bioelectric impedance analysis or dual-energy x-ray absorptiometry scans determine body fat, body mass, ratio of intracellular water to extracellular water, and bone density, and are the most accurate arthrometric measurements for patients with nutritional disorders. These methods are expensive and are used more in research than clinical settings.[14,15]

Skin fold. **Skin-fold measures** subcutaneous fat with the assumption that it compromises 50% of total body fat. Usually the triceps and subscapular skin folds are the most useful for evaluation.[14] Skin-fold thickness measurements have limited clinical application in the acute care setting because of variation in proper equipment and examiner technique.

Arm muscle area. The triceps skin-fold measurement with the midarm circumference is used to calculate arm muscle area (AMA). The AMA indicates muscle stores available for protein synthesis or energy needs. AMA changes over time may signify protein or caloric deprivation and is useful as a predictor of mortality.[14,16]

Waist circumference. An alternative to BMI, waist circumference, can be a more accurate predictor of excess body fat and risks associated with obesity.[14,15,17] According to the US Department of Health and Human Services, the following individuals are at increased risk for developing chronic diseases[11]:

- Women with a waist circumference of more than 35 inches
- Men with a waist circumference of more than 40 inches.

The World Health Organization has recommended lower thresholds for waist circumference for Asian populations.[11] Therefore those at increased risk for developing chronic disease include:

- Asian women with a waist circumference of more than 31 inches.
- Asian men with a waist circumference of more than 35 inches.

Biochemical Indicators

Particularly significant laboratory values used in assessing nutrition status include serum proteins. Protein energy malnutrition may be reflected in low values for ***albumin***, ***transthyretin*** *(prealbumin), and* ***retinol-binding protein***. Blood levels of these markers indicate the level of protein synthesis and yield information about overall nutrition status. However, inadequate intake may not be the cause of low values; certain disease states, level of hydration, liver and kidney function, pregnancy, infection, and medical therapies may alter laboratory values for each of the circulating proteins.[14,15] The diagnosis of a nutritional disorder cannot be established based on a single laboratory value but requires other data to determine the nutritional status of the patient. Most laboratory values used in nutritional assessments lack sensitivity and specificity for malnutrition.[14,15]

Albumin

Albumin is the largest constituent protein in plasma. Because its half-life is only 14 to 21 days, its usefulness for monitoring the effectiveness of nutrition in the critical care setting is limited.[18] Albumin often reflects the metabolic response to and severity of disease, injury, or infection and can be a useful prognostic indicator. Albumin synthesis is affected by both nutrition and inflammation. Proinflammatory states diminish albumin production, and the combination of inflammation and hypoalbuminemia is linked with increased morbidity, mortality, and longer hospitalization.[4,18]

Transthyretin and Retinol-Binding Protein

Transthyretin, or *prealbumin,* has a half-life of 2 to 3 days, and retinol-binding protein has a half-life of 12 hours. Each of these proteins responds to nutrition changes more quickly than albumin. However, numerous metabolic states, diseases, therapies, and infections influence these laboratory values.[4,18]

Levels of each protein are influenced by many factors present in critically ill patients, and as visceral proteins, are more useful as markers of severity of illness, with limited reflection of nutrient deficiency. *Nonetheless, plasma proteins are useful in assessing the risk for future malnutrition.*[4,18] Inflammatory metabolism causes a 25% decrease in the synthesis of these visceral proteins; causing lean body mass depletion and anorexia. Therefore, it is important to evaluate their values with biomarkers of inflammation where there is a reverse relationship.

RULE OF THUMB Nutritional disorders cannot be made from a single laboratory value because, by themselves, they cannot adequately diagnose malnutrition. Instead, laboratory test results are used with other data as part of a comprehensive assessment of a patient's nutritional status.

RULE OF THUMB Increased metabolism associated with inflammation causes a 25% decrease in protein synthesis resulting in loss of lean body mass.

In proinflammatory states, the combination of inflammation and hypoalbuminemia is linked with increased morbidity, mortality, and longer hospitalization.

Biomarkers of Inflammation

Inflammation adversely affects a patient's nutritional status by both increasing **catabolism** and causing albumin leakage out of the vascular compartment. Inflammation triggers a chemical cascade that causes loss of appetite or anorexia, thereby decreasing dietary protein intake and further catabolism.[14,15]

The most commonly used clinical biomarker of inflammation is C-reactive protein (CRP), which increases with infection and inflammation while the production of albumin and prealbumin decreases.[19,20] Increased levels of C-reactive protein during stress, illness, and trauma have been linked to increased nutrition risk.[20] Other common biomarkers of inflammation include the white cell count and the erythrocyte sedimentation rate (ESR).[21]

Other Tests and Procedures

Creatinine-Height Index

Because the rate of **creatinine** formation in skeletal muscle is constant, the amount of creatinine excreted in the urine every 24 hours reflects skeletal muscle mass. Predicted values are based on gender and height, with reference values of approximately 18 mg/kg body weight per day for women and approximately 23 mg/kg body weight per day for men.[4,14] Factors that influence creatinine excretion and complicate its interpretation include age, diet, exercise, stress, trauma, fever, and sepsis.[4,21-23]

Nitrogen Balance (Protein Catabolism)

Approximately 16% of protein is nitrogen, and nitrogen is a major by-product of protein catabolism. Therefore, measuring **nitrogen balance** is an important aspect of nutritional assessment. The urinary excretion rate of nitrogen is used to assess protein adequacy. Nitrogen balance is calculated as follows:

$$\text{Nitrogen balance} = \text{Nitrogen intake} - \text{Nitrogen losses}$$

$$\text{Nitrogen intake} = \frac{\text{Protein intake}}{6.25}$$

$$\text{Nitrogen losses} = \text{Urine urea nitrogen (UUN) excretion in grams} + 3 - 5 \text{ g (for insensible losses)}$$

The dietary protein conversion factor is 6.25 g of nitrogen per 1 g of protein. The amount of nitrogen excretion in the urine is typically measured as the 24-hour urinary urea nitrogen. Between 3 g/day and 5 g/day is added to the 24-hour urinary urea nitrogen to estimate the average daily unmeasured nitrogen lost through other sources (skin and gastrointestinal [GI] sloughing, hair loss, sweat, feces). Theoretically, increasing exogenous protein reduces endogenous protein loss. However, the accuracy of 24-hour urine collection is limited by alterations in renal or liver function, large insensible losses (burns, high-output fistulas, wounds, or ostomies), and inflammatory conditions.[22]

Immune Status

Impaired immunity (**anergy**) is common in malnutrition, especially the kwashiorkor type. Two laboratory values, white blood cell count and percentage of lymphocytes, are indices of compromised immunity. The result is often a reduction in the total lymphocyte count. Many nonnutrition variables, including disease states and drugs, influence these laboratory values, so their usefulness in assessing nutrition status is questioned.[23]

Pulmonary Function

Pulmonary function test results may change with malnutrition. Respiratory muscle weakness reduces both maximal inspiratory and expiratory pressures and reduced vital capacity. These limitations in turn reduce the ability to maintain sufficient lung volumes to prevent atelectasis and produce an effective cough to clear secretions. Diminished strength and endurance of respiratory muscles increases the susceptibility to respiratory muscle fatigue and the inability to maintain effective spontaneous breathing. The negative effects of malnutrition on both respiratory muscle function and immunologic function increase the risk for respiratory infections and pneumonia.[24]

Skeletal muscle tissues, including the diaphragm and other respiratory muscles, lose muscle mass, leading to decrease in endurance and strength. In malnourished patients, respiratory muscle strength declines, resulting in decreases in forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV1), as the muscles of respiration as well as other skeletal musculature are catabolized for energy. In addition, the carbon monoxide diffusing capacity (DLCO) also decreases and is reflected in diminished gas exchange capacity of the lungs. The decline in FEV1 also correlates with a decreased **creatinine-height index (CHI)**, indicative of loss of muscle mass. Consequently, because immune antibodies are composed of proteins, persistent inadequate calorie and protein intake will compromise the immune system and restrict the body's ability to fight pneumonia or other infections.[4,13]

RULE OF THUMB Malnutrition promotes decline in respiratory muscle strength with resulting decreases in forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV1). The decline in FEV1 occurs with a corresponding decreased creatinine-height index (CHI), indicative of inadequate protein intake, and loss of muscle mass, that results in a cycle of diminished immune function, and limited capability to fight infections, including those that attack the respiratory system.

Nutrition-Focused Physical Findings

The physical signs of malnutrition often appear first in specific tissues where high cell turnover occurs[25] (e.g., hair, eyes, lips, mouth and gums, skin and nails), so incorporating the appearance of these features into the physical examination can alert the clinician to signs of nutrient deficiencies (Table 23.2 for physical signs and symptoms of potential nutrition disorders). In addition to malnutrition, other causes of these abnormalities

TABLE 23.2 Signs of Malnutrition on Respiratory Therapists Physical Exam

	Signs or Symptoms of Potential Nutritional Problems
Hair	• Look at the health of the patient's hair; check for sparseness, dyspigmentation, or easy pluck ability.
Nails	• Nails are fissured or ridged.
Skin	• Assess the skin for areas of drying, flaking, cracking, or pigment change, peeling skin with raw exposed areas, hyperpigmented plaques over areas of trauma. • Observe for decreased subcutaneous tissue: areas that are most affected are the legs, arms, buttocks, and face. • Observe for edema: areas that are most affected are the distal extremities and anasarca (generalized edema).
Mouth and upper extremities	• Observe for swollen parotid glands, changes in saliva production, or cheilosis, angular stomatitis, papillary atrophy. • Observe the amount of effort that can be generated during coughing. • Check for muscle weakness.
Abdomen	• Check for abdominal findings and observe for abdominal distension secondary to poor abdominal musculature. • Check for hepatomegaly secondary to fatty infiltration.
Weight	• Observe for cachexia, readily outlined bony structures with depression of the intercostal spaces; accessory muscles of respiration visible. • Observe for obesity.
Demeanor/ Affect	Observe for mental apathy and confusion.

The RT will often see nutritional deficiencies complicating an existing lung problem. Being alert to the effect of nutrition on respiratory function may help stabilize the condition of a patient with lung disease that was previously deteriorating because of nutritional neglect. When these signs are present in a patient, more sensitive and objective methods of assessment should be used to confirm or rule out compromised nutritional status.
From Ziegler J, Reid-Hector J: Nutritional assessment of patients with respiratory disease. In Heuer A, Scanlan CL, editors: *Wilkins clinical assessment in respiratory care*, ed 8, St Louis, 2017, Mosby.

include medical therapies, **anemia**, allergies, sunburn, medications, poor hygiene practices, aging, or various pathologic processes.[4,18,21] Patients with persistent malnutrition often appear very thin. When the bony structures of the chest are conspicuously visible, a patient is said to be **cachexic**. Special attention should be given to fluid retention because this can mask weight loss.[4,25-27] Other physical findings, such as skeletal muscle depletion, can be clinical indicators of inflammation or signs of systemic inflammatory response.

OUTCOMES OF NUTRITION ASSESSMENT

With nutritional intervention, patients improve their nutrient intake and reduce mortality and morbidity. Improved nutritional status increases the patient's tolerance of therapeutic regimens in the treatment of disease and decreases recovery time. The resulting economic benefits are multifaceted and include shorter and less frequent hospital stays, reduced need for medication or medical care or extended care, and increased years of productivity.[28]

BOX 23.2 Factors Influencing Energy and Macronutrient Needs

Energy Needs
- Height and weight
- Activity level
- Growth state: Infants through teens, pregnancy, and lactation
- Presence of infection or fever
- Surgery
- Trauma and fractures
- Presence of infection or inflammation

Protein Needs
- State of growth
- Surgery, trauma, fractures, and infection
- Renal (kidney) function
- Liver function
- Corticosteroid administration

Fat Needs
- Total energy needs
- Hyperlipidemia, and diabetes mellitus
- Liver, gallbladder, and pancreatic disorders
- Cardiovascular disease

MACRONUTRIENTS AND ENERGY REQUIREMENTS

The nutritional assessment is used to determine a nutrition care plan for the patient. Calorie or energy needs are fundamental to these recommendations. Several means are available to determine calorie needs. These include calculating total calories using a mathematical formula or predictive equation.

Macronutrients supply the energy requirements of the body. The three macronutrients are *protein, carbohydrate,* and *fat*. Each contributes to calorie intake with 4, 4, and 9 calories (kcal) per gram, respectively. Alcohol is the only other calorie source, with approximately 7 kcal/g. Box 23.2 outlines the factors influencing energy and macronutrient needs.

Estimating Energy Requirements

An individual's energy requirement represents the ratio of energy intake to energy expenditure relative to body weight, activity level, and stressors. The classic measure of energy expenditure is the **basal metabolic rate (BMR)**. Obtained after 10 hours of fasting, the BMR measures the number of calories (kcal) expended at rest per square meter of body surface per hour (kcal/m^2/h). BMR varies by body size, age, and gender. Caloric needs for energy expenditure increase beyond the BMR based on activity level, stage of growth (pregnancy, lactation), and extent of injury.

In clinical practice, interest is focused on a patient's *daily* energy requirements (**kilocalories** per day). Multiple methods are available for estimating daily energy needs. Predictive equations

BOX 23.3 Predictive Equations

Harris-Benedict Equations

Men: Resting metabolic rate (RMR) = 66.47 + 13.75(W) + 5(H) – 6.76 (A)

Women: RMR = 655.1 + 9.56 (W) + 1.7 (H) – 4.7 (A)

Equation uses weight (W) in kilograms (kg), height (H) in centimeters (cm), and age (A) in years.

Ireton-Jones Energy Equations (IJEE) 1992

Spontaneously breathing IJEE

(s) = 629 – 11 (A) + 25 (W) – 609 (O)

Ventilator dependent IJEE

(v) = 1925 – 10 (A) + 5 (W) + 281 (S) + 292 (T) + 851 (B)

Equations uses age (A) in years, body weight (W) in kilograms, sex (S, male = 1, female = 0), diagnosis of trauma (T, present = 1, absent = 0), diagnosis of burn (B, present = 1, absent = 0), obesity more than 30% above initial body weight from 1959 Metropolitan Life Insurance tables or body mass index (BMI) more than 27 kg/m^2 (present = 1, absent = 0).

Mifflin-St. Jeor Equations

Men: RMR = (9.99 × weight) + (6.25 × height) – (4.92 × age) + 5

Women: RMR = (9.99 × weight) + (6.25 × height) – (4.92 × age) – 161

Equations use weight in kilograms and height in centimeters.

Penn State Equations (PSU)

Also known as PSU 2010 (Modified Penn State Equation)

$$RMR = Miffin(0.71) + \dot{V}_E(64) + T_{max}(85) - 3085$$

Used for patients with BMI over 30 and older than 60 years old. Validated in 2010 by the ADA Evidence Analysis Library (EAL).

PSU 2003b (Penn State Equation)

$$RMR = Miffin(0.96) + \dot{V}_E(31) + T_{max}(167) - 6212$$

Used for patient of any age with BMI below 30 or patients who are younger than 60 years with BMI over 30. This equation was validated in 2009 by the EAL and is also referred to as the Penn State equation.

PSU 2003a (Penn State 2003a)

Invalidated in 2007 and 2009 by EAL

$$RMR = Miffin(0.85) + \dot{V}_E(33) + T_{max}(175) - 6433$$

(Use actual weight in all patients.)

From Academy of Nutrition and Dietetics. Evidence analysis library, 2014. Available http://www.andeal.org. Accessed May 15th 2018.

(Box 23.3) such as the classic *Harris-Benedict equation* are frequently used to estimate daily **resting energy expenditure (REE)**.

Several other predictive equations focus on specific patient populations and medical conditions. Additional data such as injury-stress, activity, medications received, and obesity have been added to improve accuracy. The *Mifflin-St. Jeor equation* is the most reliable in both nonobese and obese ill patients.[4,28,29] Other equations, such as the *Ireton-Jones* and *Penn State equations*, are used specifically in intubated patients to account for temperature and ventilation parameters. Although the predicted REE averages approximately 10% higher than the BMR, predictive equations may still tend to overestimate or underestimate actual energy need.[4,29]

To overcome the limitations of estimating formulas, energy needs can be measured using O_2 consumption and carbon dioxide production. From these data, an actual REE can be quickly computed. Indirect calorimetry is described in more detail later.

Energy needs vary according to activity level and state of health. Energy needs of sick patients can be significantly greater than predicted normal values. Energy needs for obese individuals are less because adipose tissue uses less energy than muscle. Energy needs should be reevaluated and adjusted whenever weight changes by more than 10 lb.

BOX 23.4 Clinical Situations in Which Indirect Calorimetry May Be Indicated

- Patients with morbid obesity
- Patients who are difficult to wean from ventilatory support
- Patients for whom weight estimates are unclear
- Patients with severe malnutrition
- Patients with high level of stress
- Patients at the extremes of weight or age
- Patients failing to respond to nutrition support

RULE OF THUMB To estimate the energy needs of an average adult in kilocalories per day, identify the goal and multiply the individual's actual body weight in kilograms times the factor listed as follows[27]:

Goal	Energy Needs (kcal/kg)
Weight maintenance	25–30
Weight gain	30–35
Weight loss	20–25

Indirect Calorimetry

Indirect calorimetry is the estimation of energy expenditure by measurement of O_2 consumption and CO_2 production. Data obtained can be used to assess a patient's metabolic state, to determine nutrition needs, or to assess response to nutritional therapy.[4,27,30] To guide practitioners in using indirect calorimetry, the American Association for Respiratory Care (AARC) has published the Clinical Practice Guideline: Metabolic Measurement Using Indirect Calorimetry During Mechanical Ventilation.[30]

Regarding the indications for indirect calorimetry, the determination of energy and protein needs by an empiric formula is sufficient for most patients. However, the use of indirect calorimetry improves nutritional care and reduces complications associated with underfeeding and overfeeding.[4,31] Specific clinical conditions supporting the need for indirect calorimetry as a tool in nutrition assessment are listed in Box 23.4.[27,30]

Equipment and Technique

Good calorimetry results require extensive preparation. Box 23.5 outlines the key preparatory steps to be taken before testing.[4,27,30,32] Indirect calorimetry can be performed with a Douglas bag, a Tissot spirometer, and CO_2 and O_2 gas analyzers. The patient's expired gas is collected in the Douglas bag, where it is sampled for O_2 and CO_2 concentrations; the Tissot spirometer measures expired volume. Commercially available **metabolic carts** are

BOX 23.5 Preparation for Indirect Calorimetry

30 Hours Before Test
- 24-Hour urine urea nitrogen collection (with sufficient time to receive result) if determination of carbohydrate, fat, and protein use desired

10 Hours Before Test
- Patient fasting if measuring energy requirements; if feeding is continued, results will reflect the patient's energy expenditure in response to feeding (may be spuriously high if patient is being overfed)

4 Hours Before Test
- Patient resting and avoiding physical activity, physical therapy, dressing changes

2 Hours Before Test
- Endotracheal tube suctioned for the last time before test; further ventilator changes or suctioning avoided

1 Hour Before Test
- Supine position, complete rest; analgesic or sedative administered if needed

BOX 23.6 Equations Used to Calculate $\dot{V}O_2$ and $\dot{V}CO_2$ Using the Gas-Exchange Method

$$\dot{V}O_2 = \dot{V}_E \times (3FiO_2 4) - (\dot{V}_E \times FeO_2)$$
$$\dot{V}CO_2 = \dot{V}_E \times FeCO_2$$
$$RQ = \dot{V}CO_2 / \dot{V}O_2$$

much easier to use. These automated systems either use a mixing chamber or perform breath-by-breath analysis. The breath-by-breath method provides real-time data, which may aid in ensuring optimal measurement conditions, particularly in mechanically ventilated patients.[32-34]

Open-circuit indirect calorimetry with a metabolic cart and mixing chamber is used during mechanical ventilation. Gas sampled from the inspiratory limb of the ventilator circuit is assessed for fractional inspired oxygen (FiO_2) using a paramagnetic or zirconium oxide O_2 analyzer. Volume exhaled by the patient is measured using a flow transducer. The patient's exhaled gas enters a mixing chamber, from which a sample is drawn to measure fractional expired carbon dioxide ($FeCO_2$) by infrared analysis and fractional expired oxygen (FeO_2). Exhaled gas is returned to the ventilator after volume and gas concentration measurements. After all measurements are obtained, O_2 consumption, CO_2 production, and ***respiratory quotient (RQ)*** are computed using the equations shown in Box 23.6. *All measurements must be corrected to standard temperature and pressure and dry conditions (STPD) before computation.*[34-36] The values are used in the abbreviated Weir equation to determine REE:

$$REE = [(O_2 \times 3.9) + (CO_2 \times 1.1)] \times 1.44$$

Indirect calorimetry is more difficult to perform on spontaneously breathing patients, especially patients breathing supplemental O_2. Although a mouthpiece with nose clips or a mask can be used to collect expired gas, these items tend to alter the patient's steady state and invalidate results.[4,33] Instead, most clinicians recommend using a plastic canopy that covers the patient's head. Expired gases are cleared from the canopy by a preset flow of air; expired gas concentrations are sampled and corrected for the air dilution.

Because standard modes of O_2 therapy do not deliver a consistent FiO_2 to spontaneously breathing patients, special delivery systems must be used. To overcome this problem, the clinician can substitute a precise O_2 mixture for the gas used to clear the canopy. Alternatively, a large gas reservoir (e.g., a Douglas bag) can be placed between an O_2 flow source and the subject to ensure a stable FiO_2 throughout the test procedure.[33-35]

Problems and Limitations

Indirect calorimetry is a technically complex procedure requiring rigorous attention to both instrument and procedure quality control. Regarding instrumentation, small errors in measurements can result in large errors in calculated O_2, CO_2, and therefore energy expenditure. For this reason, the calorimeters gas analyzers and volume measurement device must be properly calibrated before each patient use. Gas analyzers should be accurate to the hundredth percent and linear over the clinical range of O_2 concentrations.[32,35]

RULE OF THUMB The key to indirect calorimetry is that all inspired and expired air must be collected; improper calibrations of the gas analyzers and volume measuring devices will result in errors and results that cannot be clinically interpreted.

Regarding procedure quality control, it is essential that measurements be made during steady-state conditions. Although proper patient preparation (see Box 23.5) is helpful in this regard, steady-state conditions can be confirmed only during the test procedure itself. A common standard for ensuring steady-state conditions is five consecutive 1-minute averages with a variability of 10% of less.[36-39]

Perhaps the most significant problem in performing indirect calorimetry on mechanically ventilated patients is the presence of leaks (circuit, tracheal tube cuff, chest tubes).[4,39] Because any leak invalidates test results, no procedure should begin until a leak-free patient-ventilator-calorimeter system is confirmed. Other sources of error during open-circuit indirect calorimetry of mechanically ventilated patients are listed in Box 23.7.[4,39]

RULE OF THUMB The clinical efficacy of indirect calorimetry cannot be validated without accurate collection of all inspired and expired air, and any potential leaks in the closed ventilatory system leads to errors in the readings and uninterpretable results.

RULE OF THUMB The key to indirect calorimetry is that all inspired and expired air must be collected; improper calibrations of the measuring devices, and any potential leaks in the closed ventilatory system lead to errors in the readings and render the results invalid.

BOX 23.7 Sources of Error During Open-Circuit Indirect Calorimetry Of Mechanically Ventilated Patients

- Instability of FiO_2 because of changes in source gas pressure or ventilator or blender variability
- Delivery of high FiO_2 levels (>0.60)
- Inability to separate inspired and expired gases because of bias flow from flow-triggering systems, intermittent mandatory ventilation systems, or specific ventilator characteristics
- Presence of anesthetic gases or gases other than O_2, CO_2, and nitrogen in the ventilation system
- Presence of water vapor resulting in sensor malfunction
- Inappropriate calibration
- Adverse effect on functions of some ventilators (triggering, expiratory resistance, pressure measurement)
- Total circuit flow exceeding internal calorimeter flow (if using dilutional principle)
- Concurrent peritoneal dialysis or hemodialysis

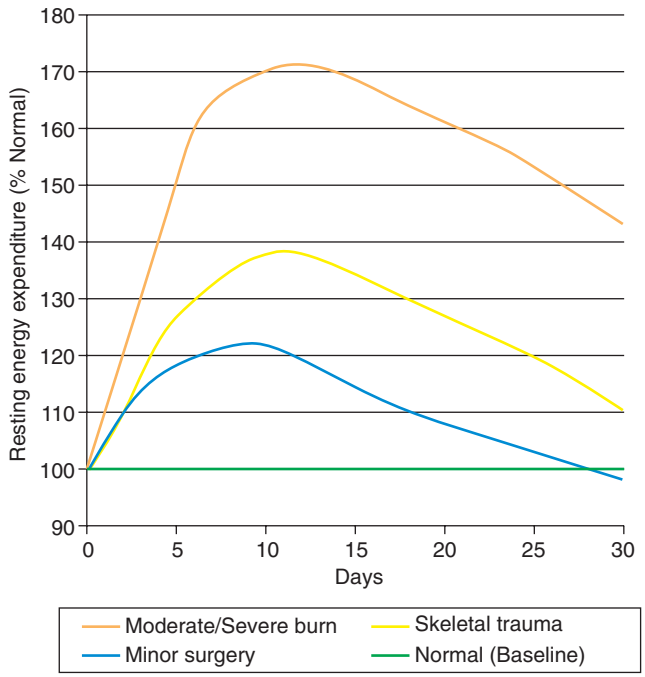

Fig. 23.3 Resting energy expenditure variation during illness and injury.

Interpretation and Use of Results

Results obtained from indirect calorimetry are used to assess metabolic status and plan nutrition support. Energy expenditure varies during illness and injury (Fig. 23.3),[4,34] which occurs in three phases: the stress response, the catabolic phase, and the anabolic phase. Because of the changing metabolic rate, it is important to reassess metabolic needs when there is a change in clinical status. Indirect calorimetry is an important tool because it can demonstrate these changes in energy expenditure. Energy expenditure can vary on a daily basis by 15% to 30%.[31]

In regard to assessing metabolic status, the first step is to compare the REE obtained by calorimetry with the REE predicted by predictive equations. If the calorimetry REE is within 10% of the predicted value, the patient is considered **normometabolic.** Measured REEs greater than 10% above predicted values indicate a hypermetabolic state, whereas values less than 90% of predicted indicate hypometabolism.

The second step in metabolic assessment is to interpret the RQ. The RQ is the ratio of moles of CO_2 expired to moles of O_2 consumed. Traditionally, the RQ has been used to determine substrate use, where carbohydrates have an RQ of 1.0, protein has an RQ of 0.82, and fat has an RQ of 0.7. Table 23.3 outlines the basic significance of the RQ relative to substrate use and traditional nutrition strategies.[4,33] RQ may have low sensitivity and reduced specificity in critically ill patients.[35-37] This finding limits the RQ as an indicator for substrate use and should be used only as a measure of test validity. If the RQ is outside its physiologic range of 0.67 to 1.3, this should alert the clinician to assess the validity of the study.

TABLE 23.3 Traditional Interpretation and Use of the Respiratory Quotient

Value	Interpretation	General Nutrition Strategy
>1.00	Overfeeding	Decrease total kilocalories
0.9–1.00	Carbohydrate oxidation	Decrease carbohydrates or increase lipids
0.8–0.9	Fat, protein, and carbohydrate oxidation	Target range for mixed substrate
0.7–0.8	Fat and protein oxidation	Increase total kilocalories

Note: Acute hyperventilation or acute metabolic acidosis increases the respiratory quotient (RQ) and can lead to misinterpretation. Metabolism of ketones or ethyl alcohol decreases RQ to less than 0.7.

RULE OF THUMB

RQ	0.67 to 1.3	Ideal range for test validity

Alternative Resting Energy Expenditure Measures

In patients with pulmonary artery catheters, REE can be measured using a modification of the Fick equation[4,37]:

$$\text{REE(kcal/day)} = \text{Cardiac output} \times \text{hemoglobin} \times (SaO_2 - S\bar{v}O_2) \times 95.18$$

In a patient with cardiac output of 4.2 L, hemoglobin of 11 g/dL, SaO_2 of 89%, and SVO_2 of 69%, the REE would be computed as follows:

$$\text{REE} = 4.2 \times 11 \times (0.89 - 0.69) \times 95.18$$
$$\text{REE} = 4.2 \times 11 \times (022) \times 95.18$$
$$\text{REE} = 879 \text{ kcal/day}$$

Another alternative method to assess REE in mechanically ventilated critically ill patients could be the use of VCO_2 measurements only, given that most mechanical ventilators provide the option to measure VCO_2 continuously. When VCO_2 is known, the Weir formula can be used to calculate VO_2, assuming the respiratory quotient RQ, is in the physiologic range of 0.67–1.2.

MINI CLINI

Nutrition Assessment in the Intensive Care Unit

Nutrition and Respiratory Problem

A 50-year-old woman presents with hemodynamic instability, hypoxemia, with a PaO_2 of 57 mm Hg (normal, 80 to 100 mm Hg). She is intubated and placed on the ventilator for septic shock. There is no clinical improvement on full ventilator support, and she is subsequently diagnosed with community acquired pneumonia and acute respiratory distress syndrome.

Medical history includes iron deficiency anemia, type 2 diabetes mellitus, morbid obesity, left lung lobectomy, episodic shortness of breath, fever, fatigue, and obstructive sleep apnea. She is admitted to the intensive care unit (ICU) for extracorporeal membrane oxygenation (ECMO) evaluation chest radiography, and bronchoscopy. The patient is started on broad-spectrum antibiotic therapy and oseltamivir; and continued on full ventilatory support. She is also treated with furosemide and metolazone, with a goal of net negative 1 Liter every 8 hours, with electrolytes supplemented. The patient becomes more hemodynamically stable and the RD and respiratory therapist (RT) collaborate to evaluate her nutritional requirements and to assess parameters for indirect calorimetry measurements.

Nutrition Assessment

Height: 162.6 cm, Admission Weight: 186.4 kg Dry Weight: 170 kg **Ideal Body Weight (IBW)**: 54.5 kg, Body Mass Index: 64.3 (per 170 kg)

Estimated Nutrition Goals: (per A.S.P.E.N./AND Guidelines [48, 16])

Energy: 1850 to 2400 kcal (11 to 14 kcal/kg, per 170 kg): Using the Penn State University equation recommended for mechanically ventilated patients, the RD sets a target goal of 2665 kcals/ day; Protein: 110 to 135 g (2 to 2.5 g/ kg, per IBW).

Nutrition Care Plan Diagnosis: Inadequate protein-energy intake related to increased nutrient needs, patient's clinical status as evidenced by patient nil per os status × 3 days.

Enteral Access: Nasogastric tube

Diet order: Nil per os

Skin: 2+ bilateral lower extremity chronic lymphedema.

Enteral nutrition (EN) support regimen recommendations: For the initial administration of feeding, the RD selects a 1.5-kcal/mL formula and starts administration at 20 mL/h, advancing by 10 mL every 8 hours until reaching the goal rate of 55 mL/h. on hospital day 3. This regimen provides 1320 mL formula, 1980 kcal, 82 g protein, and 1005 mL free water/per 24 hours.

Evaluation for Indirect Calorimetry (IC) Measurements by the RT

The RT evaluates and identifies desired patient parameters for valid IC measurements to include:

- Mechanical ventilation with fraction of inspired oxygen (FiO_2 ≤60)
- Positive end-expiratory pressure (PEEP) <10 cm H_2O
- Supine position capability for 30 minutes, in a quiet, thermoneutral environment, with patient displaying her usual patterns of voluntary muscle activity

The RT reviews the medical record and checks with nursing staff to ensure that administration of analgesics or sedatives were not given within 30 minutes of study initiation, with no painful procedures conducted within 1 hour of testing. The RT also establishes that general anesthesia was not administered within past 6 to 8 hours, ventilator settings remain unchanged within past 90 minutes before testing; and confirms with the RD and nurse that patient received stable nutrient delivery for 12 hours before initiation of study, on continuous feeding regimen if thermogenesis is to be included in the resting energy expenditure measurement. The RT checks for any problems that may result in contraindications for conducting IC, such as:

- Leaks around endotracheal or tracheostomy tube, including cuffless tubes
- Chest tube to suction and leaks around the chest tube
- Subcutaneous emphysema and communicating tracheal esophageal fistula
- Ventilatory modes that use bias flow or leak compensation

The RT completes a 20-minute IC study in which a 5-minute steady state is reached, and results are validated with measurement procedures, including:

1. Collect expired gas in a bag or Tissot spirometer for several minutes.
2. Analyze for carbon dioxide and oxygen (or oxygen and nitrogen).
3. Measure the volume of the gas collected in the bag.
4. Complete calculations:

   Evaluation of patient's steady state results:
   Oxygen consumption—450 (mL/min) coefficient of variation (3.4%)
   Carbon dioxide elimination 370 (mL/min) coefficient of variation (6%)
   Respiratory quotient—0.82 coefficient of variation (4%)
   Resting energy expenditure—2145 (kcal/day coefficient of variation [3.8%])
   ***Coefficient of variation goal is <10%

Discussion

A. Discuss the purpose of indirect calorimetry and why it is useful.

B. Interpret the results and compare to the predictive equation to the RT's indirect calorimetry measurements of the patient. Based on the results, suggest what changes would be made.

C. Discuss why it is critical that the RT ensures that there are no leaks in collection of exhaled gas.

(A) Critical illness can significantly affect metabolism, so an accurate measurement of the resting energy expenditure (REE) can help determine the energy requirements in ICU patients. REE (usually 70% of the total energy expenditure) can increase after burns, sepsis, trauma, and surgery. A precise calculation of energy expenditure may prevent overfeeding or underfeeding.

REE can be measured with indirect calorimetry using a metabolic cart, which is used to measure the oxygen consumption (VO_2) and carbon dioxide production (VCO_2). Every liter of oxygen consumed is equivalent to the energy cost of 5 kcal. Indirect calorimetry is a respiratory test that measures the patient's production of CO_2 and consumption of oxygen for approximately 30 minutes, until steady state is achieved. Results are worked into the modified Weir equation.

The test is useful in the patient on mechanical ventilation (MV) once a patient is relatively stable, with a fractional concentration of oxygen in inspired gas (FiO_2) <60% and peak end-expiratory pressure (PEEP) <10. Indirect calorimetry studies are helpful when overfeeding (diabetes mellitus, COPD, obesity) is undesirable and when underfeeding (renal failure, large wounds) is detrimental. It is highly recommended in patients whose physical or clinical factors promote alterations in energy expenditure (spinal cord injury), when drugs significantly alter energy expenditure (paralytic agents, β-blockers), and in patients who fail to respond as expected to calculated enteral/parenteral feeding administration.

A metabolic cart can also be used to assess the energy requirements and determine work capacity.

In general, metabolic cart is indicated for the following:

- To guide appropriate nutritional support
- To determine the oxygen cost of work of breathing and to help select appropriate ventilator mode and settings
- To determine the causes of increased ventilatory requirements (high glucose intake can increase carbon dioxide production, stimulating ventilation and complicating liberation from the ventilator)
- To measure cardiac output and aid with exercise physiology

(B) The patient's measured resting energy expenditure (REE) of 3145 kcal/day is higher than her original predicted energy needs and what her current enteral regimen is providing. A comparison of her measured REE to the daily average of 2135 kcal shows she is receiving only 67% of her nutrient needs. The patient is being underfed, therefore the RD will need to use nutrient dense liquid protein and fat modular added to the enteral formula to improve nutrient intake and aid with liberating from the ventilator.

MINI CLINI

Nutrition Assessment in the Intensive Care Unit—cont'd

Interpreting results of the patient's IC study requires the RT and RD to review whether the respiratory quotient (RQ) was within the human biological range of 0.67 to 1.3. RQ is the ratio of the volume of carbon dioxide produced (VCO_2) to the volume of oxygen consumed (VO_2). When values are outside of this range, the IC study should not be considered valid and the REE should not be used. Another parameter to review is patient's ability to achieve steady state. Steady state represents a period of metabolic equilibrium defined as a 5-minute interval in which the coefficient of variation for the REE (VO_2 and VCO_2) and the RQ are less than 10%. The patients' RQ of 0.82 serves to validate the IC. This patient reached a steady state, which also enhances the reliability of the IC, as the coefficients of variation were all less than 10%.

(C) IC measurements may be inaccurate in patients who require high levels of oxygen (FiO_2 ≥60%), high PEEP (>10 cm H_2O), air leaks, peritoneal or hemodialysis up to 4 hours after (the latter due to elimination of carbon dioxide across the artificial dialysis membrane). The key to indirect calorimetry is that all inspired and expired air must be collected; any potential leaks in the closed ventilatory system lead to errors in the readings or uninterpretable results.

Data from Mueller CM, Merritt RJ, McClave S, et al, editors: *The ASPEN adult nutrition support core curriculum*, ed 2, Silver Spring, MD, 2012, American Society for Parenteral and Enteral Nutrition; Ziegler J, Reid-Hector J: Nutritional assessment of patients with respiratory disease. In Heuer A, Scanlan CL, editors: *Wilkins clinical assessment in respiratory care*, ed 8, St Louis, 2017, Mosby.

In prolonged measurement periods, metabolic CO_2 production equals its excretion.

Nutritional RQ may be calculated considering 24-hours macronutrient delivery, using RQs of 1 for carbohydrates, 0.7 for fat, and 0.8 for protein. Nutritional RQ is calculated from the weighted average RQ for intake during the study period. For example, if the composition of the enteral formula is 16% protein, 49% carbohydrates, and 35% fat, the nutritional RQ is calculated as $0.16 \times 0.8 + 0.49 \times 1 + 0.35 \times 0.7 = 0.86$. After calculating nutritional RQ for the patient, EE:VCO_2 is calculated using the following rewritten Weir formula:

$$EE = 3.941 \times VCO_2\,(L/min) \div \text{Nutritional RQ} + 1.11 \times VCO_2\,(L/min) \times 1440.$$ [34,36,37]

RULE OF THUMB EE from ventilator-derived VCO_2 is accurate and more precise than predictive equations.

This method allows for continuous monitoring and is a viable alternative to indirect calorimetry.

EE (kcal/day) can be calculated at the bedside as $8.19 \times VCO_2$ (mL/min)

RULE OF THUMB Although predictive equations are highly useful tools in calculating a patient's energy expenditure needs, they do not always replace the need for performing indirect calorimetry, which is generally more accurate and provides additional information, including calculation of the RQ.

GENERAL ASPECTS OF NUTRITION SUPPORT

The primary goal of nutrition support is the maintenance or restoration of lean body (skeletal muscle) mass. This goal is accomplished by (1) meeting the patient's overall energy needs and (2) providing the appropriate combination of substrates to do so. The route of administration used to provide the support is also important.

Meeting Overall Energy Needs

When the patient's REE is derived, it needs to be adjusted to account for variations in activity and stress levels. If using a predictive equation, such as the Harris-Benedict or Mifflin-St. Joer equations, the predicted REE should be corrected for stress, activity levels, or both.[22] When the REE is derived from the Penn State equations or indirect calorimetry, a stress or activity factor should not be used.

BOX 23.8 Patients at High Risk for Malnutrition

- Underweight (BMI <18.5) or recent loss of 10% or greater of usual body weight
- Poor intake: Anorexia, food avoidance (e.g., psychiatric condition), nothing allowed by mouth (NPO) status for greater than 5 to 7 days
- Protracted nutrient losses: Malabsorption, enteric fistulas, draining abscesses or wounds, or renal dialysis
- Hypermetabolic states: Sepsis, protracted fever, extensive trauma, or burns
- Chronic use of alcohol or drugs with antinutrient or catabolic properties: Steroids, antimetabolites (e.g., methotrexate), immunosuppressants, antitumor agents
- Impoverishment, isolation, advanced age, limited mobility

Insufficient Energy Consumed

Malnutrition from undernutrition results from insufficient energy (calorie) intake over time. This insufficient intake leads to a state of impaired metabolism, in which the intake of essential nutrients falls short of the body's needs. Certain factors may place a patient at risk for malnutrition (Box 23.8).

Protein-Energy Malnutrition

Protein-energy malnutrition (PEM) has adverse effects on respiratory musculature and the immune response.[4,26] PEM may be either primary or secondary. Primary PEM results from inadequate intake of calories, protein, or both, and is typically seen only in developing countries.[22]

Secondary PEM is due to underlying illness. Illness may cause (1) decreased caloric or protein intake (e.g., anorexia, dysphagia), (2) increased nutrient losses (e.g., malabsorption or diarrhea), and (3) increased nutrient demands (e.g., injury or infection).[38,40]

RULE OF THUMB Fifty percent of hospitalized patients present with secondary PEM.

MINI–CLINI

Hospitalized Malnourished Patient

Mrs. Hernandez is a 70-year-old, underweight, African American patient with a HX of HTN, depression, and emphysema. She is 5'6" tall and weighs 100 pounds. She was recently seen by her primary doctor for signs of illness: fever, loss of appetite, fatigue, chills, dyspnea, and shortness of breath. She was diagnosed with bronchitis and started on a bronchodilator and corticosteroid nebulizer treatments as well as an oral antibiotic. However, she continued to feel ill without improvement, and became very confused with increased shortness of breath. She was taken to the hospital by ambulance and admitted with a diagnosis of pneumonia, and then started on 2 L of O_2 via a nasal canula and IV antibiotic. Mrs. Hernandez was placed on a regular diet. However, she ate sparingly and was not receiving the nutrients she needed.

Discussion

1. What are the main goals of medical nutrition therapy for this patient?
2. What factors are interfering with the patient's food intake?
3. What dietary recommendations might help Mrs. Hernandez get the nutrients that she needs during her hospitalization? And why should fluids be encouraged?

1. Patients with emphysema are more commonly underweight, appearing thin and often cachectic (nutritionally depleted). Emphysema produces a catabolic state that usually results in weight loss and mild hypoxemia. Nutritional depletion is evidenced by low body weight or body mass index (BMI) and a reduced triceps skinfold thickness measurement. Lean body mass may be decreased, although weight may be stable. BMI alone may not be indicative of a patient's nutritional status, and body composition measurement is preferred in this population to detect alterations in body compartments. Body composition can help differentiate lean body mass from adipose tissue and overhydration from dehydration because changes in hydration status can hide actual body wasting. In patients who retain fluids, it is important to carefully assess physical findings, anthropometric measurements, and biochemical measurements, and fluid status.

The main goals of medical nutrition therapy are to promote the achievement and maintenance of a healthy weight and to prevent muscle loss.

2. Several factors may impede food intake for patients with emphysema. Respiratory distress may interfere with chewing and swallowing. Appetite may also be affected by medications, depression or anxiety, or changes in taste perception. Physical changes in the diaphragm and lungs may reduce abdominal volume, creating early satiety. Some patients, because of their disability, may be unable to shop for food or prepare food without adequate support.

3. Because of her underweight status, Mrs. Hernandez may benefit from a high-calorie, high-protein diet with liquid supplements offered between meals. More frequent, small meals may be of benefit, since the lower energy content of small meals reduces the carbon dioxide load and abdominal discomfort, and dyspnea may be decreased when less food is consumed. Adequate fluids should be encouraged to help prevent the secretion of overly thick mucus. It may also be easier for some patients to drink fluid between meals in order not to interfere with their food intake.

When PEM is due to inadequate nutrient intake or excessive loss, the body responds by decreasing its metabolic rate, ventilatory drive, thyroid function, and adrenergic activity.[4,38,40] As calorie intake decreases, energy for metabolic processes is initially supplied by converting liver glycogen stores into glucose (***gluconeogenesis***). However, liver reserves of glycogen are adequate for less than 1 day at rest and only a few hours during exercise.[18] Thereafter, endogenous fat stores are mobilized in the form of free fatty acids (*ketogenesis*). When fat stores are depleted, nutrient needs must be met by catabolizing skeletal muscle protein. This type of PEM usually manifests as a gradual wasting process, as seen in patients with chronic diseases such as cancer and emphysema. The primary clinical sign is progressive weight loss.

When PEM results from increased nutrient demand, metabolism, thyroid function, and adrenergic activity all increase. Visceral protein levels tend to decrease early in the course of illness and are associated with impaired immunity.[37,38] This type of PEM typically occurs with acute catabolic disease, such as in sepsis, burns, or trauma. The two types of PEM are often referred to as *marasmus* and *kwashiorkor*,[13,18,22,40] as previously described (see Table 23.1).

Micronutrient Malnutrition

The same problems causing PEM can produce deficiencies in micronutrients. Deficiencies of nutrients that are stored only in small amounts (e.g., water-soluble vitamins) or lost through external secretions (e.g., zinc in diarrhea, fluid or burn exudate) are quite common.[18,22] Although the causes and results of micronutrient deficiencies are beyond the scope of this chapter, a few of the most common problems are described.

Signs of scurvy (vitamin C deficiency) may be observed in chronically ill patients and patients with alcoholism hospitalized for acute illnesses. Low folic acid blood levels are common whenever illness, alcoholism, or poverty is present. Alcoholism is also associated with thiamine deficiency. Zinc deficiencies impair immunity, clotting, and slow wound healing. Magnesium deficiencies can result in cardiovascular, neurologic, and electrolyte abnormalities (hypocalcemia, hypokalemia) and decreased respiratory muscle strength. Hypophosphatemia is seen frequently with cachexia or alcoholism, especially in patients receiving intravenous glucose or taking antacids. Severe hypophosphatemia can result in decreased muscle strength and contractility and acute cardiopulmonary failure.[4]

Respiratory Consequences of Malnutrition

Malnutrition affects all organ systems. In addition, malnutrition seems to interact with disease processes to increase the morbidity and mortality of respiratory, cardiac, and renal failure.[40,41] Specific effects of malnutrition on the respiratory system are listed in Box 23.9.[4,41]

Approximately one-third of all patients with acute respiratory failure have malnutrition. In these patients, the underlying diseases (e.g., sepsis, burns, trauma) increase energy expenditure and promote skeletal muscle catabolism. These patients are prone to hypercapnia and can be difficult to liberate from mechanical ventilation. Malnourished patients who require mechanical ventilation also have higher mortality rates than patients with normal nutrition status.[4,14,40]

Malnutrition also plays a role in COPD. The combined effect of increased energy expenditure (because of high work of breathing) and inadequate caloric intake contributes to a marasmus-type malnutrition. The resulting progressive muscle weakness

BOX 23.9 Respiratory Consequences of Malnutrition

Respiratory Muscle Dysfunction
- Loss of diaphragmatic mass and contractility
- Loss of accessory muscle mass and contractility

Effect on Control of Ventilation
- Decreased hypoxic and hypercapnic response

Increased Incidence of Respiratory Infections
- Decreased lung clearance mechanisms
- Decreased secretory immunoglobulin A
- Increased bacterial colonization

Changes in Lung Parenchymal Structure
- Unopposed enzymatic digestion
- Reduced production of surfactant

BOX 23.10 Underlying Causes of Malnutrition in Patients With Chronic Obstructive Pulmonary Disease

Increased Energy Expenditure
- Increased caloric cost of breathing
- Increased systemic inflammation
- Thermogenic effect of medications (e.g., bronchodilators)

Inadequate Caloric Intake
- Dyspnea while eating
- Chewing and swallowing difficulties
- Early satiety
- Taste alterations from medications, nasal cannulas, or a tracheostomy
- Suppressed appetite from medications (e.g., theophylline)

Psychosocial Factors
- Depression
- Poverty
- Difficulty shopping
- Tire easily when preparing food

BOX 23.11 Nutrition Status Changes Observable by Respiratory Therapists

- Mechanics of breathing can be affected by cachexia, obesity, pregnancy
- Increased coughing effort may indicate poor nutrition
- Viscosity of sputum, jugular venous pressure, ascites, and edema suggest fluid imbalance
- Lung crackles relate to fluid overload or oncotic pressure changes (loss of blood protein)
- Wheezing may be associated with food intolerances, alcohol, or aspirated food particles
- Late inspiratory crackles of atelectasis may result from decreased surfactant production from malnutrition
- S3 heart sounds of congestive heart failure may indicate fluid imbalance
- S4 heart sounds may be associated with severe anemia
- Pulmonary function measures may be related to:
  - FVC or FEV_1 decrease: Severe malnutrition
  - FVC: Excess fat weight
  - PEP and PIP decrease: Poor nutrition
  - Lung compliance: Fluid and serum albumin changes acutely or chronic malnutrition
- Arterial blood gas values may be related to:
  - $PaCO_2$ increases: Excess glucose, inadequate ventilation from lack of muscle energy
  - O_2 saturation, O_2 content, hemoglobin: Nutrition status
- Meal acceptance may be related to visible equipment—suction bottles, sputum specimens
- Lack of O_2 may increase difficulty of eating—ensure availability of O_2 via cannula if needed

FEV_1, Forced expiratory volume in 1 second; *FVC,* forced vital capacity; *PEP,* positive expiratory pressure; *PIP,* peak inspiratory pressure.

and dyspnea can limit caloric intake further, as can several profound psychosocial factors. Box 23.10 summarizes factors contributing to malnutrition in patients with COPD.[4,42] The RT may notice signs that could lead to malnutrition in patients for whom they provide care (Box 23.11).

Providing the Appropriate Combination of Substrates

After estimating energy requirements, the physician or registered dietitian determines the appropriate combination of macronutrients (protein, carbohydrate, fat) needed.

Protein

Amino acids or proteins are essential to maintaining or restoring lean body mass. Because illness usually increases protein catabolism and protein requirements, the Recommended Dietary Allowance (RDA) of 0.8 g/kg/day is generally insufficient for sick patients. Based on the assessment of the protein catabolism rate, protein intake may need to be doubled or tripled above the RDA (1.5 to 2.5 g/kg/day).[43] Ideally, approximately 20% of a patient's estimated caloric needs should be provided by protein. Higher percentages of protein may be needed in patients who are cachexic, have severe infections, or are otherwise critically ill. However, whenever high protein intake is administered, the patient should be monitored for progressive **azotemia** (blood urea nitrogen >100 mg/dL).[18,40]

Too much protein is harmful, especially for patients with limited pulmonary reserves. Excess protein can increase O_2 consumption, REE, minute ventilation, and central ventilatory drive.[43] In addition, overzealous protein feeding may lead to symptoms such as dyspnea.

Carbohydrate

Carbohydrates are the main source of fuel for the body. Adequate amounts of carbohydrates and fat help prevent protein catabolism. Glucose (dextrose) is the most commonly administered intravenous carbohydrate. Total calories per day from carbohydrates can range from 45% to 65%. In an average-sized patient, daily glucose provision is generally estimated at 200 g/day.[44]

For patients with pulmonary disease or patients requiring mechanical ventilation, high carbohydrate loads were initially blamed for increased CO_2 production and the RQ, resulting in increased ventilatory demand, O_2 consumption, and work of breathing.[45] More recent evidence indicates that this problem is

probably more closely related to total calorie load (overfeeding) than to the proportion of carbohydrate in the diet.[46,47] Therefore, overfeeding should be carefully avoided in patients with pulmonary disease and patients requiring mechanical ventilation.

Fat

The remaining calories (20% to 30%) should be provided from fat.[26,48,49] A minimum of 2% to 4% is needed to prevent essential fatty acid deficiency. Fat intakes greater than 50% of energy needs are associated with fever, impaired immune function, liver dysfunction, and hypotension.[16,18]

The initiation of nutrition support is determined by the patient's nutrition status, and the estimated length of time the patient will be unable to consume a diet by mouth to meet nutrition needs. To ensure satisfactory nutrition and metabolic response, early enteral nutrition begun within 24 to 48 hours provides significant benefits to critically ill patients, including reduced infectious complications and lengths of stay.[49]

RULE OF THUMB Begin enteral nutrition within 24 to 48 hours of intubation. Because nutrition is so important, nutritionally depleted or catabolic patients should never go without nutritional support for more than a day. To prevent alveolar collapse, surfactant is needed to lessen the surface-active forces that promote collapse of the lung. Malnutrition leads to decreased surfactant synthesis, as well as emphysematous changes in the lung. Humidity and mucociliary performance in the lung require adequate hydration. Smooth muscle function, macrophage activity, and secretion of immunoglobulins into mucus all depend on adequate administration of nutrients.[4,40,49]

ROUTES OF ADMINISTRATION

The two primary routes for supplying nutrients to patients are *enteral* (oral and tube feeding) and ***parenteral*** (peripheral or central venous alimentation). Box 23.12 provides guidelines for initiating nutrition support as recommended by the American Society for Parenteral and Enteral Nutrition.[48-50]

Enteral Feeding

Enteral feedings are the route of choice: "If the gut works, use it." The enteral route is safer and cheaper than the parenteral route. Enteral feeding stimulates gut hormones, exposes nutrients to the absorptive and metabolic controls of the intestinal tract and liver, and produces less hyperglycemia (providing for better immune function) than the parenteral route. In addition, the buffering capacity of enteral feeding can improve resistance against stress ulcers.[50] Finally, enteral feeding maintains a more normal intestinal mucosa than the parenteral route (the intestinal mucosa may undergo atrophy during parenteral nutrition [PN]).[15,49]

Enteral Tube Routes

There are six primary routes for enteral tube feeding: (1) nasogastric, (2) nasoduodenal, (3) nasojejunal, (4) gastrostomy, (5) jejunostomy, and (6) esophagostomy. Site selection depends on GI function, respiratory status, surgical state, and anticipated length of time the patient will be receiving tube feeding.

BOX 23.12 Guidelines for Initiation of Nutrition Support

Clinical Settings in Which Enteral Nutrition Should Be Part of Routine Care

- Protein-calorie malnutrition (>10% loss of usual weight) with inadequate oral intake of nutrients for previous 5 to 7 days
- Normal nutritional status with less than 50% of required nutrient intake orally for previous 7 to 10 days
- Severe dysphagia
- Moderate to severe pancreatitis (bowel rest anticipated beyond 5 to 7 days)
- Burns of greater than 15% total BSA in infants and children and greater than 25% total BSA in older children and adults
- Massive small bowel resection in combination with administration of total parenteral nutrition
- Low output (<500 mL/day) enterocutaneous fistulas

Clinical Settings in Which Parenteral Nutrition Should Be Part of Routine Care

- Patients with inability to absorb nutrients by the GI tract
- Severe malnutrition in the face of a nonfunctional GI tract (within 1 to 3 days)
- Severely catabolic patients with or without malnutrition when the GI tract is not usable within 7 to 10 days

BSA, Body surface area; *GI,* gastrointestinal.
From Mueller CM, Merritt RJ, McClave S, et al, editors: The ASPEN Adult Nutrition Support Core Curriculum, ed 2, Silver Spring, MD, 2012, American Society for Parenteral and Enteral Nutrition.

Gastric feedings are indicated if there are no physiologic factors affecting GI function (e.g., gastroparesis, delayed gastric emptying, or obstruction or upper GI tract surgery). Small bowel (duodenum and jejunum) feedings are indicated if the upper GI tract cannot be used. Intestinal feeding tube placement is recommended to minimize aspiration risk because it is believed to decrease the risk for gastric distention and gastroesophageal reflux; however, this remains controversial.[51]

Nasogastric and *nasoenteric* tubes are indicated for short-term enteral therapy (<30 days). The tubes are placed at the bedside and generally have a large internal diameter, which helps deliver viscous feedings and medications. *Nasoduodenal* and *nasojejunal* tubes are placed through the nose past the pylorus.

Long-term feeding tubes can be placed endoscopically and surgically. Percutaneous endoscopic placement of a feeding tube can be done to establish gastric (percutaneous endoscopic gastrostomy) or intestinal (percutaneous endoscopic jejunostomy) access. This method is preferred to surgical placement because of reduced costs associated with operating room time and the need for anesthesia.[52] Surgical laparotomy is indicated if endoscopy is contraindicated.

Tube Feeding Administration

There are three basic methods of tube feeding administration: bolus, intermittent, and continuous drip. *Bolus* feedings involve the rapid infusion of 250 to 500 mL of feeding several times daily. Feedings are provided by a syringe into the feeding tube port. There is an increased risk for aspiration associated with bolus feedings because of the rapid infusion of formula into the

TABLE 23.4 Enteral Product Reference Guide

Category	Indications	Examples
Oral supplements	Given with an oral diet to increase calorie and protein intake	Boost,[a] Ensure,[b] Carnation Breakfast Essentials
Standard/Polymeric	Made with intact nutrients. May vary in concentration (1.0–2.0 kcal/mL) and fiber content	Osmolite,[b] Jevity,[b] Promotel HN,[b] Nutren,[b] Isosource,[b] Fibersource,[a] Replete[a]
Blenderized	Made from natural foods and usually lower in sucrose and corn syrup than other formulas; beneficial if intolerance to synthetic formulas exists	Compleat,[a] Compleat Pediatric[a]
Elemental and semielemental	Impaired gastrointestinal function with impaired ability to digest or absorb intact nutrients	Peptamen,[b] Peptamen 1.5,[b] Tolerex,[b] Vivonex,[b] Vital,[a] Vital 1.5,[a] Vital HN[a]
Disease specific	Liver disease; renal disease; pulmonary disease; glucose intolerance; immune-enhancing; critically ill obese	Nutrihep[a]; Nepro,[a] NovaSource Renal,[b] Suplena,[a] Renalcal[b]; Pulmocare,[a] Oxepa,[a] Nutren Pulmonary[b]; Diabetisource AC,[b] Glucerna,[a] Glytrol[b]; Impact,[b] Pivot[a]; Peptamen Bariatric[b] Vital High Protein[a]
Modular	Need to modify a single nutrient (carbohydrate, protein, fat)	Beneprotein,[a] Benecalorie,[b] Promod,[a] Glutasolve,[b] Arginaid,[b] MCT oil[b]

[a]Nestle Health Sciences.
[b]Abbott Nutrition.

stomach. Nausea, vomiting, abdominal pain, and distension can develop in conjunction with this feeding route. This feeding method can be used only with gastric tubes and is primarily applied to patients who are stable and patients receiving enteral nutrition support at home.

Intermittent feedings are also administered several times per day and infused over at least 30 minutes. Feedings can be given only into the gastric cavity. Intermittent feedings are associated with the same problems as bolus feedings.

Continuous drip infusion provides a constant, steady flow of formula at a predetermined rate for a set period, generally 12 to 24 hours per day. Drip regulators roll clamps or pumps are used to control rates. Because the small bowel lacks storage capacity, feedings delivered beyond the pylorus must be provided by the continuous drip method. This method is preferred for critically ill patients because it is associated with reductions in gastric residual volume, abdominal distention, gastroesophageal reflux, and pulmonary aspiration.[53]

Trophic feeding is the practice of feeding minimal amounts (10 to 30 mL/h) of enteral nutrition with the primary goal to maintain GI function and integrity. Studies in mechanically ventilated patients with respiratory failure or ARDS show that trophic feedings resulted in fewer episodes of GI intolerance but resulted in similar clinical outcomes compared to early advancement to full enteral feedings.[54]

Enteral Formula Selection

Selection of an enteral formula depends on the patient's medical and surgical state, GI function, energy and nutrient needs, and route of administration. There are eight broad categories of enteral formulas: oral supplements, blenderized, whole-protein lactose-free, fiber containing, nutrient-dense, elemental, disease-specific, and modular. Table 23.4 describes the indications for the various enteral formulas and lists examples of commercial preparations.

Complications of Enteral Therapy

Complications associated with enteral nutrition are categorized as GI, mechanical, or metabolic. These may be avoided by careful selection of formulas, proper administration, and consistent patient monitoring.

Pulmonary aspiration is of significant concern in a critically ill patient with respiratory disease. Aspiration can occur because of one or more of the following factors: if the patient is lying flat, has a depressed gag reflux or vocal cord dysfunction, has delayed gastric emptying, or has improper tube placement. The incidence of pulmonary aspiration varies depending on the patient population and technique used to identify aspiration in the tube-fed patient. The three following practices have been proven to minimize aspiration risk[49]: (1) raise the head of the bed at least 30 degrees, (2) use of bowel motility agents such as metoclopramide, and (3) use post pyloric feeding with the continuous drip method in patients at risk for gastric atony or gastroesophageal reflux. Tube placement always should be verified by x-ray examination before feeding. Pulmonary aspiration has not been proved to be a result of high gastric residual volumes.[55]

Aggressive suctioning of oropharyngeal secretions can help prevent aspiration. The greatest risk is in patients with endotracheal tubes. Endotracheal tubes increase aspiration risk because they alter sensation, impair glottic closure, increase secretion volume, and act as "wicks" to allow secretions to enter the airway.[56] The use of special endotracheal tubes that provide continuous, low-level suctioning of subglottic secretions reduce the micro aspiration common in tube-fed patients.[41] The use of blue dye to detect aspiration is no longer a standard practice because of numerous problems, including a US Food and Drug Administration Public Health Advisory issued in 2003. Blue discoloration of body parts and fluids followed by refractory hypotension, metabolic acidosis, and death were reported in some patients receiving blue food dye.[42]

The routes of nutritional administration can be either enteral or parenteral. The preferred route is enteral. If a patient is intubated and cannot take food by mouth, enteral tube feeding is instituted. The last resort, when all other attempts at feeding are unsuccessful or not recommended, is **parenteral nutrition (PN)**. PN is the feeding of patients by direct infusion of nutrients into either a peripheral or a central vein. There is a reluctance to feed

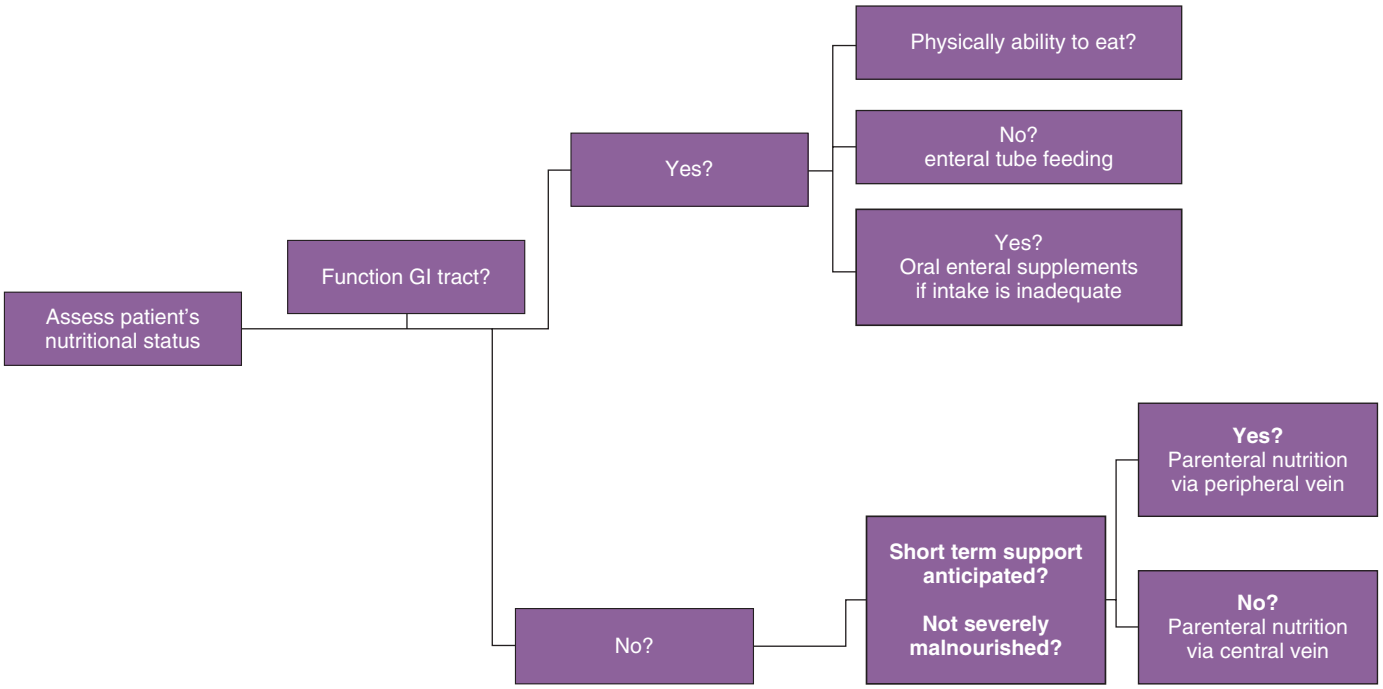

Fig. 23.4 Nutrition support decision tree.

patients by PN because it is not as efficient as the enteral route, it is expensive, and there are increased risks for complications such as infection. Fig. 23.4 outlines the nutrition support decision tree that the RT may use to assess and understand the most appropriate mode of nutrition intervention.

Parenteral Nutrition Support

When it is impossible to provide nutrition support through the GI tract, intravenous or PN support may be needed. PN support is administered through a peripheral or central vein. Ideally, the vascular access line should be restricted to nutrition use and maintained as a sterile route. Because the volume and concentration of nutrients given through a small vein are limited, peripheral PN is considered only for short-term support. Mechanical, infectious, and metabolic complications have been reported in patients fed parenterally.[57]

NUTRITION SUPPORT IN SPECIFIC CIRCUMSTANCES

Details on the appropriate nutrition support provided to the various types of patients seen by RTs are beyond the scope of this chapter. This section emphasizes key points related to nutrition support and management of the most common conditions encountered by practitioners.

General Guidelines for Critically Ill Patients

The general goal of nutrition support in critically ill patients is to provide the energy and protein necessary to meet metabolic demands and to preserve lean body mass. Nutritional support is also an important therapy in critical illness because it attenuates the metabolic response to stress, prevents oxidative cellular injury, and modulates the immune response. Nutritional modulation of the stress response includes early enteral nutrition, appropriate macronutrient and micronutrient delivery, and meticulous glycemic control.[54]

Table 23.5 outlines the general guidelines recommended to achieve these goals.[48,49]

Systemic Inflammatory Response Syndrome

The *systemic inflammatory response syndrome (SIRS)* underlies many critical illnesses, including *sepsis* and *acute respiratory distress syndrome (ARDS)*. Metabolism in systemic inflammatory response syndrome is characterized by increased total caloric requirements, hyperglycemia, triglyceride intolerance, increased net protein catabolism, and increased macronutrient and micronutrient requirements.[40]

Micronutrient requirements also are increased in SIRS. Because of the potential high losses of potassium, zinc, magnesium, calcium, and phosphorus, serum levels of these minerals need to be closely monitored and maintained within the normal range.[40]

Mechanical Ventilation

Adequate nutrition support is crucial for ventilator-dependent patients. During acute illness, proper nutrition helps prevent the loss of lean body mass. After the resolution of the acute phase of illness, good nutrition helps the muscles regain strength and improves the likelihood of successful liberation from mechanical ventilation.[22]

For most patients requiring ventilatory support, following the guidelines provided in Table 23.5 is generally sufficient. As always, care must be taken to avoid overfeeding and the increased ventilatory demands that follow. Patients with COPD present a special situation, in terms of both nutrition needs and ventilatory support. More details regarding these patients are provided in the next section.

TABLE 23.5 General Nutrition Guidelines for Chronically Critically Ill Patients

Category	Guideline
Route of delivery	Enteral nutrition is preferred when the gut is functional Start 24–48 h after resuscitation If gut is not functional, consider starting parenteral nutrition If enteral nutrition cannot provide goal within 7–10 days, consider starting parenteral nutrition
Energy need	Indirect calorimetry should be used when available for estimation of energy goal Target is 65% of goal within the first week Hypocaloric feeding recommended for obese (11–14 kcal/kg)
Protein	Provide supplemental protein to achieve 1.2–2.0 g/kg/day; 2.0–2.5 g/kg/day for obese
Glycemic control	An intensive insulin therapy protocol should be in place Goal: 110–150 mg/dL
Micronutrients	Adequate vitamins and minerals such as vitamins A, B_6, C, E; potassium; magnesium; zinc; iron; selenium; phosphate
Fluid	Approximately 1 mL/kcal
Specialized nutrients	Glutamine (may improve nitrogen stores), arginine (may improve immune system in surgical patients), and omega-3 fatty acids (may reduce inflammatory processes in ARDS/ALI)

ALI, Acute lung injury; *ARDS,* acute respiratory distress syndrome.

MINI CLINI

Nutrition Support

Mrs. Reid is a 46-year-old woman who was diagnosed with Crohn disease 2 years ago. She was recently admitted to the hospital with an exacerbation of her Crohn disease—acute respiratory failure due to tracheobronchial involvement. She was severely malnourished and was found to have complete bowel obstruction with multiple adhesions. She is 5′4″ tall and weighs 108 pounds, with a usual weight of 122 lbs. She is scheduled for surgery and undergoes a small bowel resection to remove the diseased bowel and create a temporary ileostomy. Following surgery, she remains ventilator dependent, and a central line catheter placed to initiate total parenteral nutrition (TPN) with intralipids.

Discussion

1. Discuss Mrs. Reid's percent of weight loss and why was the patient started on TPN rather than enteral feedings or peripheral parenteral nutrition (PPN)?
2. Why is it important for the parenteral feedings to be initiated at a slowly administered infusion rate with close monitoring of the patient's electrolyte levels?

1. Using this simple calculation, you can assess that the patient has lost 11.4% of her usual body weight, which places her at significant risk for complications of malnutrition.

$$\text{Percent weight loss} = \frac{\text{usual weight} - \text{actual weight}}{\text{usual weight}} \times 100$$
$$= 122 - 108 \times 100 = 11.4\%$$

This patient cannot be given enteral feedings because her GI tract cannot be used at this time, due to exacerbation of Crohn disease, and her nutritional needs are too great for PPN. The healthcare team will need to work together to prevent complications related to TPN by using aseptic techniques when inserting the catheters or when changing tubing or a dressing that covers the catheter site; observe for unusual bleeding, wet dressings, and signs of infection (such as redness or swelling, around the catheter site), and unexplained fever. Routine inspections of equipment and monitoring of patient's symptoms will help to minimize the complications of catheter use.

Patients who are severely malnourished and who are fed too quickly may develop refeeding syndrome, which is characterized by fluid imbalances and hyperglycemia and in this case, worsening respiratory failure.

Nutrition support alone is insufficient to ensure liberation from mechanical ventilation of ventilator-dependent patients. For these patients, appropriate nutrition may need to be combined with a tailored exercise program designed to strengthen and retrain muscles.

Chronic Obstructive Pulmonary Disease

Malnutrition is common in patients with COPD and can occur in 30% to 60% of inpatients and 10% to 45% of outpatients.[58] Progressive weight loss from malnutrition is common in patients with COPD and appears to have two causes: (1) prolonged periods of insufficient caloric intake, coupled with (2) increased nutritional needs resulting from increased metabolism demand associated with chronic disease. Both malnutrition and low body weight seem to be factors associated with a poor prognosis.[59]

The degree of weight loss generally correlates with deterioration of pulmonary function values. COPD can create a cycle in which respiratory dysfunction promotes weight loss and weight loss further hinders respiratory function.[41] Fig. 23.5 illustrates the cycle.

Factors contributing to poor intake include fatigue, shortness of breath, frequent coughing, early fullness because of pressure on the abdominal cavity, increased dyspnea during eating, side effects from medications (nausea, vomiting, diarrhea, dry mouth, taste changes), and depression. The increased metabolic rate is due to the added effort to breathe and frequent respiratory infections, both of which increase calorie and fluid needs.

The goal is to increase nutrient intake carefully without overfeeding. Cachexic patients with COPD should be refed cautiously.[53] Functional capacity and the patient's overall health status may improve with an anabolic stimulus, such as exercise, along with nutrition supplementation.[60]

In patients with COPD, satisfactory conventional macronutrient allocations are 15% to 20% as protein, 50% to 60% as carbohydrates, and 20% to 30% as fat. Specialized nutrition formulation consisting of high fat and reduced carbohydrates have been marketed for patients with COPD; however, there is little evidence to support its use.[58,61] As previously stated, setting an appropriate total calorie load is more important than fine-tuning the ratio of carbohydrates to fat.

Given the positive link between dietary intake and knowledge of diet and health, effective patient education is crucial. Patients

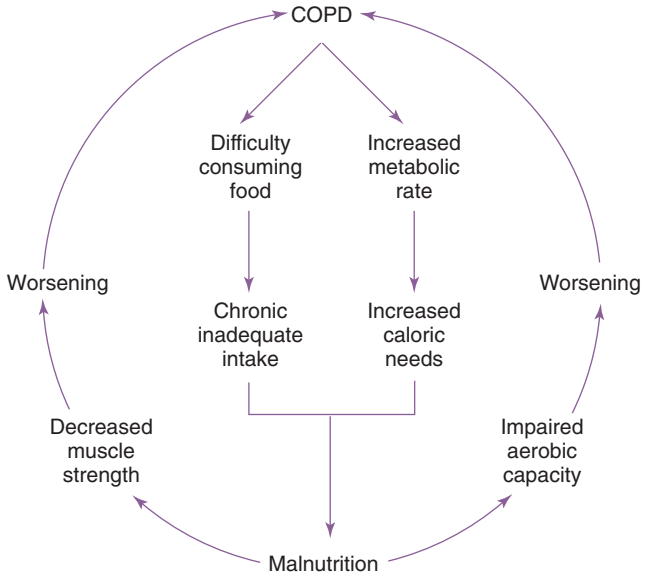

Fig. 23.5 The vicious cycle of respiratory impairment and malnutrition in chronic obstructive pulmonary disease *(COPD)*.

BOX 23.13 Nutrition Support for Patients With Pulmonary Disease

- Perform a complete nutrition assessment.
- Evaluate energy needs and provide an appropriate amount (do not overfeed or underfeed).
- Ensure protein balance.
- Monitor fluids and electrolytes, especially phosphorus.
- Evaluate vitamin and mineral status as indicated.

should be taught to select easy-to-consume, calorically dense foods. Emphasis should be placed on small, frequent feedings, and encourage use of high-calorie, high-protein nutrition supplements. Other considerations in providing nutrition support to patients with COPD are listed in Box 23.13.[60,62-64]

When patients with COPD are hospitalized for ventilatory failure, the clinical outcome is affected by nutrition support. Patients who receive adequate nutrition support are more readily weaned from mechanical ventilation than patients with diets deficient in protein and energy.

Asthma

Because breathing and eating are mutually exclusive, feeding should generally be avoided during severe asthma attacks. However, nutrient-dense, small meals high in quality protein, calories, vitamins, and minerals are recommended during prolonged, mild asthma attacks. Foods identified as allergens (most often milk, eggs, seafood, and fish) should be avoided. Fluid intake should be generous, unless contraindicated. Saturated fats may aggravate the airway, whereas omega-3 fatty acids may be beneficial; these are available in walnuts and flaxseed if the patient is allergic to fish.[62]

Cystic Fibrosis

Exocrine gland dysfunction associated with cystic fibrosis causes chronic lung disease with recurrent infections. The same disturbance causes pancreatic insufficiency. Metabolic problems in patients with cystic fibrosis are similar to metabolic problems in patients with COPD, with reduced intake and increased metabolic needs. However, the associated pancreatic insufficiency with cystic fibrosis also causes malabsorption of all nutrients, especially fat. The administration of pancreatic enzyme supplements with meals enhances absorption but requires trial and error and intense education on how to balance the amount of food and the intake of enzymes. In addition, the time spent in various treatment programs reduces the ability to consume small frequent feedings.

The three goals of nutrition management in cystic fibrosis are to (1) maximize nutrition intake through calorically dense foods, (2) balance intake with pancreatic enzymes to maximize absorption, and (3) provide a nutrition plan that meets the patient's changing clinical and psychosocial status.[63] Use of calorically dense foods and nutrition supplements consumed throughout the day has proved helpful in achieving weight gain.[63] Because of the malabsorption of micronutrients, vitamin and mineral supplementation is encouraged, especially of fat-soluble vitamins.[63] Helping patients with cystic fibrosis achieve optimal nutritional health may minimize the decline in pulmonary function and improve their quality of life.[4,14,65]

RULE OF THUMB Patients with cystic fibrosis tend to have a deficiency of enzymes produced in the pancreas and need for the digestion of fats. As a result, most patients with cystic fibrosis need to take digestive enzyme supplements to minimize the likelihood of a certain type of malnutrition.

MINI CLINI

Methods to Increase Nutrient Intake in Chronic Obstructive Pulmonary Disease

Problem

An 82-year-old woman with known history of COPD has been hospitalized for several days and treated with multiple inhalers and nebulizers. She lost 12 pounds in the last month. She presents with muscle wasting, sparse hair, dry and cracked lips and skin. She reports decrease in oral intake because of shortness of breath and decreased appetite satiety. The dietitian receives a nutrition consult to evaluate the patient's nutrition status and provides nutrition counseling to prevent further weight loss.

Discussion

List sample foods and potential strategies the dietitian reviewed with the patient that the RT can reinforce with the patient.

- Dried fruits, nuts, popsicles, milkshakes
- Whole milk or skim milk powder added to milk, soup, gravies
- Nutrition supplements
- Puddings, custards, yogurt, ice cream
- Cream soups
- Add butter or oil or cheese to vegetables, soups, mashed potatoes, and rice
- Casseroles and egg dishes with sauces and gravies
- Peanut butter or other nut butters, spread on bananas, celery, crackers, apple slices, breads

SUMMARY CHECKLIST

- Nutrition assessment is the basis for developing a nutrition care plan.
- The components of a nutrition assessment include dietary history, anthropometry, biochemical indicators, nutrition-focused physical assessment, and client history.
- BMI is a comparison of weight to height used to determine underweight, healthy weight, overweight, obesity, or morbid obesity.
- Classifications of undernutrition, called *protein-energy malnutrition*, include kwashiorkor, marasmus, and a combination of the two (lack of circulating protein, starvation, and a mixture of the two).
- Laboratory values of albumin, transferrin, transthyretin, and retinal-binding protein may indicate malnutrition. C Reactive Protein may be elevated during acute illness, indicating an inflammatory response and causing low values of serum proteins.
- The Creatinine-Height Index reflects skeletal muscle mass.
- Nitrogen balance compares protein intake to nitrogen excretion in the urine.
- Observable signs in hair, eyes, lips, mouth and gums, skin, and nails may indicate malnutrition.
- REE may be determined by the predictive equations or indirect calorimetry.
- Estimation of total caloric need involves multiplying the REE by a factor that accounts for activity and stressors.
- Indirect calorimetry involves measurement of whole-body $\dot{V}O_2$, $\dot{V}CO_2$, and RQ; results are used to assess a patient's metabolic state, determine nutrition needs, or assess response to nutrition therapy.
- An RQ value greater than 1.00 indicates overfeeding and the need to decrease total calories; RQ between the ranges of 0.67 to 1.3 should be used as an indicator of test validity.
- Malnutrition is a state of impaired metabolism in which the intake of essential nutrients is less than the body's needs; marasmus is malnutrition associated with inadequate nutrient intake (starvation), and kwashiorkor is the hypercatabolic form.
- Malnutrition can affect the respiratory system by causing loss of respiratory muscle mass and contractility, decreased ventilatory drive, impaired immune response, and alterations in lung parenchymal structure.
- Approximately one-third of all patients with acute respiratory failure have malnutrition, mainly the hypercatabolic form; these patients are prone to hypercapnia, can be difficult to liberate from ventilatory support, and have higher mortality rates than patients with a normal nutrition status.
- In chronic lung disease, the combined effect of increased energy expenditure (due to increased work of breathing) and inadequate caloric intake contributes to a marasmus-type malnutrition.
- The primary goal of nutrition support is to maintain or restore lean body (skeletal muscle) mass by: (1) meeting the overall energy needs of the patient, and (2) providing the appropriate combination of macronutrients (protein, carbohydrate, and fat) and micronutrients (vitamins and minerals). Nutrition support also attenuates the metabolic response to stress, prevents oxidative cellular injury, and modulates the immune response.
- For most patients, a balance of 20% of daily calorie needs from protein, 50% to 60% from simple carbohydrate, and 20% to 30% from fat is adequate.
- Nutrients can be supplied enterally (oral and tube feeding) or parenterally (peripheral or central venous alimentation); the enteral route should be used whenever possible.
- The likelihood of aspiration during tube feedings can be minimized by raising the head of the bed at least 30 degrees, use of motility agents, and delivering the feeding beyond the pylorus using the continuous drip method.
- Nutrition support should be individualized according to patient needs and condition or disease process; accepted guidelines for the systemic inflammatory response syndrome (SIRS), COPD, mechanical ventilation, asthma, and cystic fibrosis should be followed.

Pulmonary Infections

Sarah A. Longworth and Steven K. Schmitt

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- State the frequency and economic impact of pneumonia in the United States
- Discuss the current classification scheme for pneumonia and define hospital-acquired pneumonia, ventilator-associated pneumonia, and ventilator-associated events
- Recognize the pathophysiology and common causes of lower respiratory tract infections in specific clinical settings
- List the common microbiologic organisms responsible for community-acquired and nosocomial pneumonias
- Describe the clinical and radiographic findings seen in patients with pneumonia
- Describe risk factors associated with increased morbidity and mortality in patients with pneumonia
- Understand what a Gram stain is and what it can reveal about the potential cause of a patient's pneumonia
- State the criteria used to identify an adequate sputum sample for Gram stain and culture
- Describe the techniques used to identify the organism responsible for nosocomial pneumonia
- List the latest recommendations regarding empiric and pathogen-specific antibiotic regimens used to treat various types of pneumonia and the role of inhaled antibiotics in the treatment of these conditions
- Discuss strategies to prevent pneumonia
- Describe how the respiratory therapist aids in diagnosing and managing patients with suspected pneumonia

CHAPTER OUTLINE

KEY TERMS

antibiotic therapy
atypical pathogens
community-acquired pneumonia
fomites
hospital-acquired pneumonia
Hospital Readmission Reduction Program (HRRP)
lower respiratory tract infection
nosocomial pneumonia
pneumonia
tuberculosis
ventilator-associated events
ventilator-associated pneumonia

Infection involving the lungs is termed **pneumonia** or **lower respiratory tract infection** (LRTI) and is a common clinical problem in respiratory care practice. Today, pneumonia remains a major cause of morbidity and mortality in the United States and worldwide. Each year, 5 million people die from pneumonia worldwide. Five million cases of pneumonia occur annually in the United States, and 1.1 million require hospitalization.[1] Pneumonia is the eighth leading cause of death in the United States and the leading cause of infection-related mortality.[2]

In addition, pneumonia is one of six conditions for which hospitals may be penalized for excessive short-term (30-day) readmissions under the **Hospital Readmission Reduction Program (HRRP)** of the US Centers for Medicare and Medicaid Services (CMS). As a result, an understanding of the classification, pathogenesis, clinical manifestations, and treatment of pneumonia is important to clinicians and health care organizations to help design and implement an effective care plan for these patients.

CLASSIFICATION

Pneumonia can be classified based on the clinical setting in which it occurs (Table 24.1). This classification is useful because it predicts the likely organism and guides empiric antimicrobial therapy while a definitive microbiologic diagnosis is being awaited. The term *empiric therapy* refers to treatment that is started based on the most likely pathogen when the specific organism responsible is still unknown.

Community-acquired pneumonia (CAP) can be divided into two types—acute and chronic—based on its clinical presentation. *Acute* pneumonia presents suddenly over a few hours to several days. *Chronic* pneumonia develops more gradually, with worsening symptoms over days, weeks, or months.

Pneumonia acquired in health care settings is often caused by different microorganisms from those that cause CAP. Previously termed **nosocomial pneumonia**, this clinical entity has been further classified as **hospital-acquired pneumonia** (HAP) and **ventilator-associated pneumonia** (VAP). The 2016 Infectious Disease Society of America (IDSA)/American Thoracic Society (ATS) guidelines define HAP as a LRTI that develops more than 48 hours after admission and does not appear to be incubating at the time of admission. VAP is defined as a LRTI that develops more than 48 to 72 hours after endotracheal intubation.[3] Older guidelines included the category of health care–associated pneumonia (HCAP) to identify patients thought to be at risk for multidrug-resistant (MDR) pathogens coming from the community setting; HCAP was defined as pneumonia occurring in any patient hospitalized for 2 or more days in the previous 90 days in an acute care setting or who in the previous 30 days had resided in a long-term-care or nursing facility; attended a hospital or hemodialysis clinic; or received intravenous antibiotics, chemotherapy, or wound care.[4] This entity was not included in the updated guidelines because there is increasing evidence that many patients with HCAP are not truly at high risk for MDR pathogens and treating them for such does not improve outcomes.[5-7]

HAP and VAP are frequent complications of clinical care. Together, they are the most common hospital-acquired infections in the United States, accounting for 22% of all such infections.[8] Approximately 10% of patients requiring ventilation develop VAP,[9] which has an attributable mortality of 13%.[10] In two studies, VAP prolonged the length of mechanical ventilation by 7.6 to 11.5 days and prolonged hospitalization by 11.5 to 13.1 days,[11,12] with an average incremental per-patient cost of $40,000.[12] In selected populations, such as patients in the intensive care unit (ICU) and bone marrow transplant recipients, the crude mortality rate from HAP may approach 30% to 70%, with an attributable mortality of 33% to 50%. Certain microorganisms, such as *Pseudomonas aeruginosa* and *Acinetobacter* species, are associated with higher rates of mortality.[13]

TABLE 24.1 Classification and Possible Causes of Pneumonia

Classification	Likely Organisms
Community-Acquired: Acute	
Typical	*Streptococcus pneumoniae*
	Haemophilus influenzae
	Moraxella catarrhalis
	Staphylococcus aureus
Atypical	*Legionella pneumophila*
	Chlamydophila pneumoniae
	Mycoplasma pneumoniae
	Coxiella burnetii
	Respiratory viruses
Community-acquired: Chronic	*Mycobacterium tuberculosis*
	Histoplasma capsulatum
	Blastomycosis dermatitidis
	Coccidioides immitis
Immunocompromised host	*Pneumocystis jirovecii*
	Cytomegalovirus
	Aspergillus species
	Cryptococcus neoformans
	Reactivation tuberculosis or histoplasmosis
Nosocomial	
Aspiration	Mixed aerobes and anaerobes, gram-negative bacilli
Hospital-acquired	Mixed aerobic and anaerobic mouth flora
	S. aureus
	Enteric gram-negative bacilli
	Influenza and other respiratory viruses
	Mycobacterium tuberculosis
Ventilator-associated	*Pseudomonas aeruginosa*
	Acinetobacter species
	Enterobacter species
	Klebsiella species
	Stenotrophomonas maltophilia
	S. aureus

PATHOGENESIS

Six mechanisms may contribute to the development of pneumonia (Table 24.2). Knowledge of these mechanisms is important to both the understanding of the various disease processes and

TABLE 24.2 Pathogenesis of Pneumonia

Mechanism of Disease	Examples of Specific Infections
Inhalation of aerosolized infectious particles	Tuberculosis Histoplasmosis Cryptococcosis Blastomycosis Coccidioidomycosis Q fever Legionellosis
Aspiration of organisms colonizing the oropharynx	Community-acquired bacterial pneumonia Aspiration pneumonia Hospital-acquired pneumonia Ventilator-associated pneumonia
Direct inoculation of organisms into the lower airway	Hospital-acquired pneumonia Ventilator-associated pneumonia
Spread of infection to the lungs from adjacent structures	Mixed anaerobic and aerobic pneumonia from subdiaphragmatic abscess Amebic pneumonia from rupture of amebic liver abscess into the lung
Spread of infection to the lung through the blood	*Staphylococcus aureus* pneumonia arising from right-sided bacterial endocarditis Parasitic pneumonia: strongyloidiasis, ascariasis, hookworm
Reactivation of latent infection, usually in the setting of immunosuppression	*Pneumocystis jiroveci* pneumonia Reactivation tuberculosis Cytomegalovirus

MINI CLINI

The Gram Stain: What It Is and What It Reveals

Problem

A 32-year-old male, an unrestrained driver in motor vehicle accident, sustained head trauma leading to an intracerebral hemorrhage requiring surgical evacuation. He has been mechanically ventilated in the ICU for 7 days. He now develops fever, increasing respiratory secretions, and a new right-lower-lobe infiltrate on chest x-ray. A tracheal aspirate is sent for Gram stain, and culture. The stain yields moderate gram-negative rods (GNR) and many white blood cells (WBCs); culture is pending.

Discussion

Gram staining of clinical specimens helps to guide empiric clinical management of bacterial infections while definitive culture data are being awaited. The technique differentiates between various types of bacteria based on the biochemical properties of their cell walls. A clinical specimen is prepared by heat fixation, staining with crystal violet (purple) dye, decolorization, and counterstaining with safranin (pink) dye. Gram-positive bacteria (e.g., staphylococci and streptococci) retain crystal violet and appear purple with staining; gram-negative bacteria (e.g., *Pseudomonas aeruginosa, Acinetobacter baumanii*) do not retain crystal violet but take up safranin counterstain and thus appear pink. Visualization of the bacteria allows for characterization of their morphology ("cocci" [round] or "rods") and arrangement ("chains" or "clusters") as well as semiquantification of the number of organisms present. Based on gram-stain results, clinicians can make an educated guess regarding likely pathogens and select antibiotics accordingly.

RULE OF THUMB Prevent VAP using the following "VAP bundle"[14]:

- Use noninvasive positive-pressure ventilation when possible.
- Minimize sedation and interrupt it daily.
- Assess readiness to extubate daily.
- Perform spontaneous breathing trials with sedation turned off.
- Facilitate early mobility.
- Utilize endotracheal tubes with subglottic secretion drainage ports for patients expected to require more than 48 to 72 h of mechanical ventilation.
- Change the ventilator circuit only if it is visibly soiled or malfunctioning.
- Elevate the head of the bed to 30 or 45 degrees.

the formulation of effective strategies to minimize nosocomial spread.

Inhalation of infectious particles is a common route of inoculation; this is how pulmonary tuberculosis is acquired and it justifies the policy of respiratory isolation for patients with suspected or proved tuberculosis who are coughing.

Aspiration of oropharyngeal secretions is the second mechanism that may contribute to the development of LRTI. Healthy individuals may aspirate periodically, especially during sleep. Aspiration of even a small volume of oropharyngeal secretions, which can be colonized with potential pathogens such as *Streptococcus pneumoniae* and *Haemophilus influenzae,* may contribute to development of CAP. Certain patient populations are at risk for large-volume aspiration, such as those with impaired gag reflexes from narcotic use, alcohol intoxication, or prior stroke. Aspiration may also occur after a seizure, cardiac arrest, or syncope. Aspiration seems to be the major mechanism responsible for the development of some types of mixed aerobic and anaerobic, gram-negative, and staphylococcal HAPs. In intubated patients, chronic aspiration of colonized secretions through a tracheal cuff has been linked to the subsequent occurrence of pneumonia.

The Society for Healthcare Epidemiology of America (SHEA) and IDSA have created guideline recommendations to minimize risk of VAP,[14] which many institutions have incorporated into a "VAP bundle"; many of these recommendations aim to minimize ventilation duration and risk of aspiration.

Direct inoculation of microorganisms into the lower airway is a less common cause of pneumonia. In mechanically ventilated patients who undergo frequent suctioning of lower airway secretions, passage of a suction catheter through the endotracheal tube can dislodge biofilm and result in inoculation of colonizing organisms into the airways, leading to the development of VAP.

Direct spread of microorganisms to the lungs or pleural space from adjacent areas of infection, such as a liver abscess beneath the diaphragm, is an infrequent cause of pneumonia. This may occur in patients with amebic liver abscesses when rupture of the abscess through the diaphragm leads to the development of pulmonary infection or empyema.

Hematogenous dissemination is the spread of infection through the bloodstream from a remote site; it is an uncommon cause of pneumonia. It may occur in the setting of right-sided bacterial endocarditis, in which fragments of an infected heart valve break off and spread through the pulmonary arteries to the lungs, producing either pneumonia or septic pulmonary infarcts (areas

of dead lung tissue). Certain parasitic pneumonias—including strongyloidiasis, ascariasis, and hookworm—arise through hematogenous dissemination. In such cases, migrating parasitic larvae travel to the lungs through the bloodstream from remote sites of infection, such as the skin or the gastrointestinal (GI) tract.

Pneumonia may develop when a latent infection, acquired earlier in life, is reactivated. This may occur for no apparent reason, as is often the case for reactivation pulmonary tuberculosis. However, reactivation frequently occurs in the setting of a decrease in immune function, as is the case with *Pneumocystis jiroveci* (previously called *Pneumocystis carinii*) pneumonia. In developed countries, most healthy individuals have acquired *P. jiroveci* by age 3 years and show evidence of prior infection on blood tests. The organism remains dormant in the lung but may reactivate later in life and produce pneumonia in individuals with decreased cell-mediated immunity, such as those with HIV infection or patients receiving immunosuppressive therapy such as chemotherapy or high-dose steroids.

MICROBIOLOGY

The microbiology of CAP and HAP/VAP has been studied extensively. Knowledge of which organisms are most commonly associated with pneumonia in different settings is essential, as it guides the diagnostic evaluation and the selection of empiric antimicrobial therapy.

Historically, bacteria that cause CAP have been divided into two groups "typical" and "atypical" pathogens (see Table 24.1). Typical organisms include *Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus*, *Streptococcus* species, *Moraxella catarrhalis,* and both anaerobic and aerobic gram-negative bacteria. **Atypical pathogens** include *Legionell*a species, *Mycoplasma pneumoniae, Chlamydophila pneumoniae*, and *Chlamydophila psittaci.* Historically, these pathogens were often not identified in clinical practice because—with exception of *Legionella* species—there were no widely available specific, rapid, or standardized tests to detect them. However, as molecular diagnostic techniques such as polymerase chain reaction (PCR) assays have become more widespread, these organisms are detected more frequently. Unfortunately, historical, physical examination, and laboratory findings have not proven helpful in distinguishing between infections due to typical versus atypical pathogens.

In most studies, *S. pneumoniae,* also called the pneumococcus, is the most commonly identified cause of CAP. In the preantibiotic era, this pathogen was responsible for more than 75% of cases[15,16]; however, more recent studies have isolated this organism in only 5% to 15% of cases in the United States.[17,18] This observed decline in likely related to a decrease in cigarette smoking as well as the pneumococcal vaccination of both children and adults, leading to "herd immunity."[19-22] Similarly, there has been a dramatic decrease in the incidence of *H. influenzae* pneumonia since the introduction of the type B *H. influenzae* (also known as *Hib*) vaccine in the 1980s.[23] In addition, there has been increasing recognition that respiratory viruses are common causes of CAP, either alone or as a coinfection with bacteria. With the introduction of molecular methods, respiratory viruses are detected in approximately one-third of cases of CAP in adults.[17,24-26] Atypical bacteria, primarily *Legionella* species and *M. pneumoniae*, account for 3% to 15% of patients with CAP requiring hospitalization.[17,24]

RULE OF THUMB *S. pneumoniae* is the most common cause of CAP.

Severity of illness and site of care also inform the microbiology of CAP. Among patients treated in the outpatient and non-ICU inpatient setting, *S. pneumoniae, M. pneumoniae,* and respiratory viruses are most common.[27,28] However, among patients ill enough to require ICU admission, *Legionella* species, gram-negative bacilli, *S. aureus*, and the pneumococcus are disproportionately more common.[17,24,29] Mixed aerobic and anaerobic aspiration pneumonia may account for 10% of cases. This cause of pneumonia should be considered for nursing home residents and for individuals with impaired gag reflexes or recent loss of consciousness.

Occasionally outbreaks of less common pathogens occur, both locally and globally; when this happens, these pathogens must be considered among patients presenting with CAP. For instance, atypical pneumonias due to endemic fungi such as *Histoplasma capsulatum* (central river valleys), *Blastomyces dermatiditis* (upper Midwest), and *Coccidioides immitis* (desert Southwest) are occasionally seen in the appropriate geographic settings. *Middle East respiratory syndrome* (MERS) has arisen as a global health concern. First described in Saudi Arabia in 2012, this coronavirus is found within the Arabian Peninsula and causes a severe respiratory illness with a 30% mortality rate. The first two cases imported to the United States were confirmed in 2014, both in travelers from Saudi Arabia.[30]

In most published series, no microbiologic diagnosis is established in 50% of patients. This is due to many factors, including the following:

- Inability of many patients to produce sputum
- Acquiring a sputum specimen after antibiotics have already been started
- Failure to perform diagnostic blood test routinely in all patients
- Failure to consider, or until recently—be able to identify—certain pathogens, including respiratory viruses, many of the atypical pathogens, and anaerobes

The common microbial agents producing HAP and VAP are summarized in Table 24.1; they include gram-negative bacilli, *S. aureus, Legionella* species, and occasionally respiratory viruses such as influenza or respiratory syncytial virus. These viruses are prevalent during the winter months, when they circulate in the community and are brought into the hospital by health care workers, visitors, or patients.

The relative frequencies and susceptibilities of the nosocomial pathogens that cause HAP may vary considerably from one institution to another. Knowledge of which organisms are most common within one's own institution and community, along with their drug-sensitivity profiles, has important implications with regard to selecting the best **antibiotic therapy,** the formulation of infection control policies, the investigation of potential outbreaks, and the selection of antimicrobial agents for the hospital formulary. For example, patients who develop severe VAP in ICUs with a high prevalence of carbapenem (a class of

MINI CLINI

Distinguishing Between Different Types of Nosocomial Pneumonia

Problem

A 52-year-old man with a history of severe low back pain is admitted to the hospital with a GI bleed due to the excessive use of nonsteroidal antiinflammatory drugs (NSAIDs, e.g., ibuprofen). He had not seen a doctor in 5 years. His presenting symptoms include epigastric abdominal pain, black stools, and dizziness with standing. Admission hemoglobin is 5.2 g/dL; WBCs are is 6.2 $\times$ 10^9/L. Red blood cells (RBCs) are transfused and he undergoes upper GI endoscopy, which reveals a large bleeding duodenal ulcer. Three days into his admission, the patient develops a fever to 40.2°C, shortness of breath, and cough. Laboratory testing reveals a WBC count of 16.8 $\times$ 10^9. Chest x-ray shows a patchy infiltrate in the right lower lobe. What type of pneumonia does this patient have? How might this infection have developed?

Discussion

The patient has HAP because he did not have any evidence of pneumonia at the time of admission and developed his infection more than 48 h into his hospital stay. He may have developed pneumonia due to the inhalation of infectious particles through exposure to patients or health care providers who have come to work despite having a respiratory illness. More likely, he aspirated oropharyngeal or gastric secretions during his upper endoscopy procedure or during a vomiting episode. Empiric antimicrobial coverage should target mixed aerobic and anaerobic mouth flora, *S. aureus,* enteric gram-negative bacilli, and potentially influenza, depending on the season.

antibiotics) resistance among gram-negative organisms such as *Klebsiella pneumoniae* and *Acinetobacter baumannii* may warrant empiric antimicrobial therapy for these organisms pending culture information.

Nosocomial pathogens capable of producing HAP can be transmitted directly from one patient to another, as in the case for tuberculosis. However, transmission from health care workers (including respiratory therapists [RTs]), contaminated equipment, or **fomites** (objects capable of transmitting infection through physical contact with them) is more common, especially for gram-negative bacilli, *S. aureus,* and viruses. The RT has an important role to play in preventing the transmission and development of nosocomial pneumonia. Handwashing and appropriate contact precautions, including disinfecting stethoscopes and nondisposable diagnostic and therapeutic equipment, are very important.

CLINICAL MANIFESTATIONS

Patients with CAP typically have fever and respiratory symptoms such as cough, sputum production, pleuritic chest pain, and dyspnea. Patients may also complain of hoarseness, sore throat, headache, and diarrhea. Fever, cough, and sputum production may occur in other illnesses as well, such as acute bronchitis or exacerbations of chronic bronchitis.

The clinical presentation of CAP in elderly patients warrants special mention because it may be subtle. Older individuals with pneumonia may not have a fever or cough and may simply present with shortness of breath, confusion, worsening congestive heart failure (CHF), or failure to thrive.

TABLE 24.3 Radiographic Patterns Produced by Pathogens in Community-Acquired Pneumonia

Pattern	Pathogens
Lobar consolidation	Bacterial
Bronchopneumonia	Bacterial
Pleural effusion	Bacterial
	Inhalation anthrax
Interstitial infiltrates	Viruses
	Pneumocytis jiroveci
Cavities	Mycobacteria
	Fungi
	Nocardia species
	Staphylococcus aureus
	Gram-negative bacilli
	Polymicrobial aerobic and anaerobic lung abscess
	P. jiroveci (rare)
Mediastinal widening without infiltrates	Inhalation anthrax
Rapidly progressive multilobar	*Legionella* species
	Streptococcus pneumoniae
	Endobronchial tuberculosis

HAP and VAP often present with a new onset of fever, elevated WBCs (leukocytosis), new sputum production (if not intubated), purulent endotracheal secretions (if intubated), and a new pulmonary infiltrate. Nonintubated patients may have a recent history of vomiting, seizure, or syncope during which aspiration of oropharyngeal or gastric secretions may have occurred. The diagnosis of HAP and VAP can be extremely difficult to make in patients with preexisting abnormalities on the chest x-ray, such as CHF or acute respiratory distress syndrome (ARDS). In mechanically ventilated patients, purulent tracheobronchitis (in which the airway but not the lung parenchyma is infected) may be accompanied by fever; in these as well as in patients with preexisting abnormalities on chest x-ray, the distinction between bronchitis and pneumonia can be especially difficult.

CHEST X-RAY

In patients with a compatible clinical syndrome, the diagnosis of CAP is established by the presence of a new pulmonary infiltrate on chest x-ray. Not all healthy outpatients with suspected pneumonia require a chest x-ray, and physicians may choose not to obtain one and instead to treat empirically for CAP in individuals with mild illnesses who are at low risk for complications.

Also, a normal chest x-ray does not exclude the diagnosis of pneumonia. The chest x-ray may be normal in patients with early infection, dehydration, or *P. jiroveci* infection. The pattern of chest x-ray abnormality is not diagnostic of the causative agent, although specific radiographic findings should suggest a specific microbial differential diagnosis (Table 24.3) (see Chapter 21).

Consolidation involving an entire lobe is called *lobar consolidation* (Fig. 24.1), whereas *bronchopneumonia* refers to the presence of a patchy infiltrate surrounding one or more bronchi without opacification of an entire lobe. Both radiographic patterns

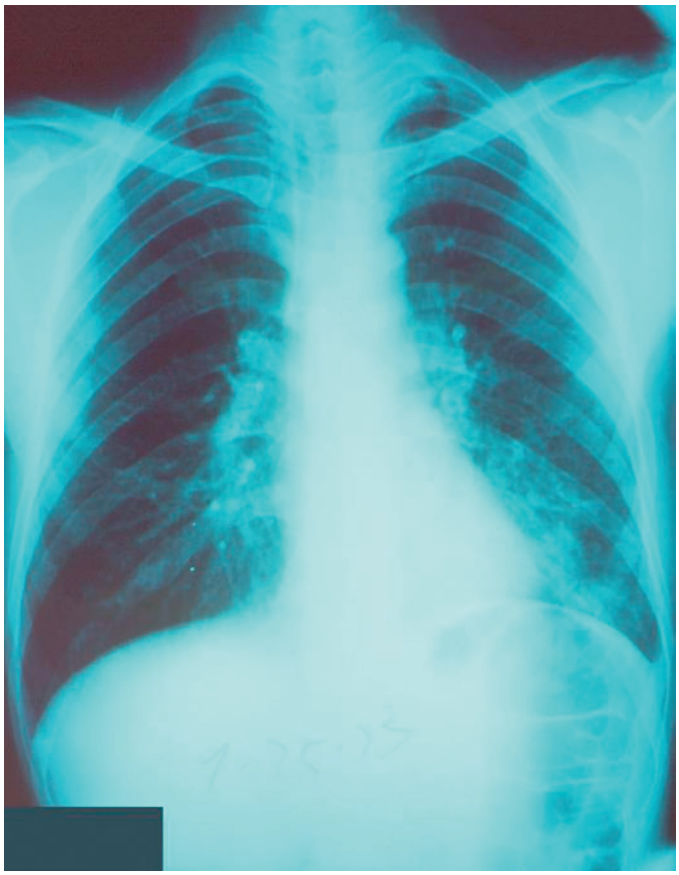

Fig. 24.1 Lobar pneumonia caused by *Streptococcus pneumoniae.* A 36-year-old previously healthy woman presents with an abrupt onset of fevers and shaking chills, cough productive of yellow sputum, and right-sided pleuritic chest pain. Chest x-ray reveals lobar consolidation. Sputum culture yields *S. pneumoniae.*

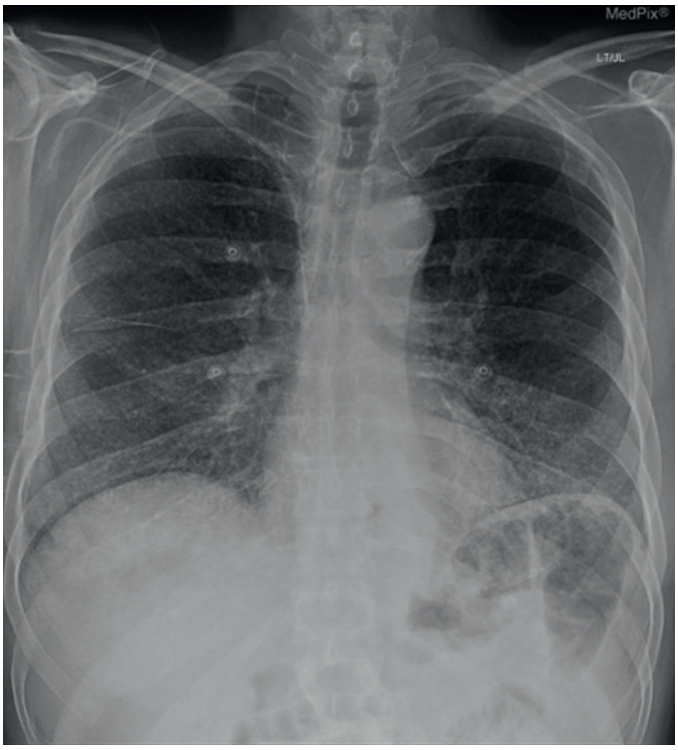

Fig. 24.2 *Pneumocystis jiroveci* pneumonia (PJP). A 23-year-old male intravenous drug user presents with a history of 2 weeks of dyspnea on exertion, nonproductive cough, and fevers to 40.4°C. The chest x-ray shows an interstitial infiltrate. HIV antibody test is positive, serum beta-D glucan level is elevated, and bronchoalveolar lavage *P. jiroveci* polymerase chain reaction is positive. The interstitial infiltrate in a "bat-wing" distribution is classic for PJP.

suggest the presence of a bacterial pathogen. Pleural effusions are common in patients with bacterial pneumonia and uncommon in patients with viral, *P. jiroveci, C. pneumoniae,* or fungal pneumonia. Pleural effusions are seen in approximately 10% of patients with *M. pneumoniae* and *Legionella* pneumonia and occur occasionally in patients with reactivation pulmonary tuberculosis. Interstitial infiltrates (Fig. 24.2), especially if diffuse, suggest viral disease, *P. jiroveci,* or miliary tuberculosis in patients with CAP. Cavitary infiltrates (Fig. 24.3) are seen in reactivation pulmonary tuberculosis; fungal pneumonias such as histoplasmosis, blastomycosis, and aspergillosis; nocardiosis; bacterial lung abscess; and, rarely, *P. jiroveci* pneumonia. Patients with severe staphylococcal or gram-negative pneumonias may develop small cavities called *pneumatoceles. Legionella* species should be considered in sicker patients with pneumonia of a single lobe, which quickly spreads to involve multiple lobes over 24 to 48 hours.

The chest x-ray may be helpful in diagnosing HAP in nonintubated patients with a suspected aspiration event and a previously normal chest x-ray. In such cases, development of a new infiltrate may confirm the clinical suspicion of aspiration pneumonia. The chest x-ray is often less helpful in the diagnosis of VAP because mechanically ventilated patients may have other reasons for radiographic abnormalities, such as ARDS, CHF, pulmonary thromboembolism, alveolar hemorrhage, or atelectasis. In these

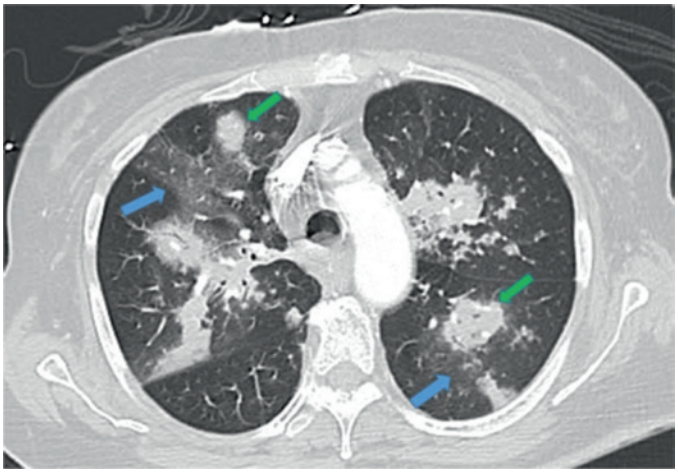

Fig. 24.3 Cavitary nodular pneumonia caused by *Aspergillus.* A 34-year-old woman undergoing induction chemotherapy for newly diagnosed acute myeloid leukemia presents with persistent neutropenic fevers and cough productive of scant he moptysis. Sputum cultures are negative, but serum galactomannan antigen is markedly elevated, highly suggestive of *Aspergillus* infection. Computed tomography reveals multicentric cavitary nodules, some of which have a halo of ground-glass opacity. These findings are classic for invasive pulmonary aspergillosis.

patients it can be difficult to confirm the diagnosis of a new nosocomial LRTI. A clinical diagnosis of pneumonia—defined as the presence of fever, purulent respiratory secretions, new leukocytosis, and a new pulmonary infiltrate—is sensitive but not specific for diagnosing VAP. Other strategies to diagnose VAP more accurately have been investigated.

RISK FACTORS FOR MORTALITY AND ASSESSING THE NEED FOR HOSPITALIZATION

An important first step in management is determining whether a patient with CAP requires admission to the hospital. Severity of illness and risk of death are the most important factors in making this decision, and much research has been devoted to identifying risk factors for poor outcomes among patients with CAP.[31-35] Risk factors predicting a high risk for death are summarized in Box 24.1. However, other factors must be also be considered, including the patient's ability to maintain oral intake, likelihood of medication adherence, history of mental illness, cognitive or functional impairment, active substance abuse, and living circumstances (e.g., homelessness or limited access to health care services should he or she worsen).

Because some variables are not known at the time a patient seeks treatment for pneumonia, such as the causative agent and whether bacteremia is present, more recent studies have evaluated the risk for death by using clinical and laboratory data that are readily available at the time of the initial evaluation. The Pneumonia Severity Index (PSI) is a clinical prediction tool that has been shown to effectively identify patients at low and high risk for death at 30 days following a CAP diagnosis.[31] The algorithm uses demographic, clinical, and laboratory data available at presentation to stratify the risk for death and the criteria for hospitalization in outpatient groups. Points are assigned for the presence of numerous variables, and cumulative point scores are used to stratify patients into one of five risk groups with predictable mortality rates (Tables 24.4 and 24.5). In this model, which has been validated in large prospective cohorts of patients, those at the lowest risk for death fall into groups I and II. In most instances, these patients may be treated successfully as outpatients unless they are hypoxemic, vomiting and unable to take oral antibiotics, noncompliant, or immunocompromised.

Due to the complexity of the PSI, many practitioners prefer a simpler stratification system, called CURB-65, whose name is derived from the following five variables:

- **C**onfusion
- **U**rea (blood urea nitrogen) greater than 20 mg/dL
- **R**espiratory rate ≥30 breaths/min
- **B**lood pressure ([BP] systolic <90 mm Hg or diastolic <60 mm Hg)
- Age **65** years or greater

Using this risk prediction model, patients with one or two risk criteria can be treated as outpatients, those with two criteria should be treated on general hospital wards, and those with three or more criteria should be admitted to the ICU.[36]

Many studies have also examined risk factors for developing HAP and VAP, which in broad terms can be divided into (1) factors that interfere with host defense and (2) factors that encourage exposure to large numbers of bacteria.[13] Examples of factors that interfere with host defense include the following:

- Underlying illnesses such as diabetes mellitus, malignancy, chronic heart and lung disease, and renal failure
- Critical illnesses such as sepsis and ARDS
- Therapeutic interventions such as endotracheal intubation, tracheostomy, and administration of medications such as sedatives and corticosteroids

Factors that promote exposure of the lung to pathogenic microorganisms include the following:

- Use of endotracheal or nasogastric tubes
- Contaminated ventilator equipment or water supplies
- Prior antibiotic therapy
- Neutralization of gastric pH

BOX 24.1 Risk Factors for Mortality in Community-Acquired Pneumonia

I. Patient variables
  A. Age above 50 years
  B. Male sex
  C. Comorbid illnesses
    1. Cerebrovascular disease
    2. Cancer
    3. Congestive heart failure
    4. Renal disease
    5. Liver disease
    6. Immunosuppression
    7. Alcoholism
    8. Diabetes mellitus
    9. Chronic lung disease
II. Clinical parameters at presentation
  A. Altered mentation
  B. Systolic hypotension <90 mm Hg
  C. Tachypnea >30 breaths/min
  D. Hypothermia (temperature <35°C)
  E. Fever (temperature >40°C)
  F. Pulse rate >125 beats/min
  G. Extrapulmonary site of infection
III. Laboratory and radiographic findings at presentation
  A. Arterial pH <7.35
  B. Blood urea nitrogen >30 mg/dL
  C. Serum sodium <130 mmol/L
  D. Glucose >250 mg/dL
  E. Hematocrit <30%
  F. Hypoxia (PaO_2 <60 mm Hg) or hypercarbia (PCO_2 >50 mm Hg) on room air
  G. White blood cell count $<4 \times 10^9$/L, $>30 \times 10^9$/L, or an absolute neutrophil count $<1 \times 10^9$
  H. Multilobar infiltrate
  I. Bacteremia
  J. Pleural effusion
  K. High-risk cause
    1. Gram-negative bacilli
    2. *Staphylococcus aureus*
    3. Postobstructive pneumonia
    4. Aspiration

From Fine MJ, Smith MA, Carson CA, et al: Prognosis and outcomes of patients with community-acquired pneumonia: a meta-analysis, *JAMA* 275:134–41, 1996.

TABLE 24.4 Pneumonia Severity Index Scoring System for Stratifying Risk of 30-Day Mortality in Adults With Community-Acquired Pneumonia

Variable	Points Assigned
Age	
Men	Age (years)
Women	Age (years) –10
Nursing home resident	+10
Comorbid illnesses	
Cancer	+30
Liver disease	+20
Kidney disease	+10
Cerebrovascular disease	+10
Congestive heart failure	+10
Physical findings	
Altered mentation	+20
Tachypnea >30 breaths/min	+20
Systolic hypotension <90 mm Hg	+20
Temperature <35°C or >40°C	+15
Heart rate >125 beats/min	+10
Laboratory and radiographic findings	
Acidemia (arterial pH <7.35)	+30
Azotemia (blood urea nitrogen >30 mg/dL)	+20
Hyponatremia (sodium <130 mmol/L)	+20
Hypoxia (PaO_2 <60 mm Hg)	+10
Hyperglycemia (glucose >250 mg/dL)	+10
Anemia (hematocrit <30%)	+10
Pleural effusion	+10

NOTE: Plus sign (+) denotes adding points; minus sign (–) denotes subtracting points (e.g., for women, points assigned equal age in years –10).
Modified from Fine MJ, Auble TE, Yealy DM, et al: A prediction rule to identify low-risk patients with community-acquired pneumonia, *N Engl J Med* 336:243–50, 1997.

TABLE 24.5 Risk Class Mortality Rates Using Pneumonia Severity Index Scoring System in Patients With Community-Acquired Pneumonia

Risk Class (Cumulative Point Score)	Mortality Rate (%)
I	0.1
II (≤70)	0.6
III (71–90)	2.8
IV (91–130)	8.2
V (>130)	29.2

NOTE: Patients in risk class I are below 50 years old and lack existing illness or physical findings listed in Table 24.4. Points are assigned to patients in risk classes II and higher.
Modified from Fine MJ, Auble TE, Yealy DM, et al: A prediction rule to identify low-risk patients with community-acquired pneumonia, *N Engl J Med* 336:243–50, 1997.

Although many studies have emphasized the substantial mortality rate (20% to 50%) for patients who develop HAP or VAP, few studies have examined the specific risk factors associated with mortality in hospital-acquired LRTI. For nonventilated patients, risk factors for mortality include bilateral infiltrates, respiratory failure, and infection with high-risk organisms.[37,38] In mechanically ventilated patients, factors associated with fatal outcome include the following[3,38,39]:

- Infection with high-risk organisms such as *P. aeruginosa*, *Acinetobacter* species, and *Stenotrophomonas maltophilia*
- Multisystem organ failure
- Nonsurgical diagnosis
- Therapy with antacids or histamine-2 (H_2)–receptor antagonists
- Transfer from another hospital or ward
- Renal failure
- Prolonged mechanical ventilation
- Coma or shock
- Inappropriate antibiotic therapy
- Hospitalization in a noncardiac ICU

MINI CLINI

Estimating Risk of Death From Pneumonia and Triaging Care

Problem

The RT is called to the emergency department to perform an arterial blood gas analysis on a 70-year-old woman with confusion and shortness of breath who is brought in by her husband. Her history is notable for diabetes mellitus, hypertension, and a recent stroke, which has resulted in left-sided weakness. The emergency physician ordered a chest x-ray, which showed a right lower lobe infiltrate and a right pleural effusion.

On physical examination, the patient is very sleepy. Her vital signs are temperature 35°C, blood pressure 85/50 mm Hg, heart rate 130 beats/min, and respiratory rate 24 breaths/min. Laboratory testing reveals the following:

- Peripheral WBCs, 3000/mm^3
- Blood urea nitrogen, 18 mg/dL
- Creatinine, 1.4 mg/dL
- Hematocrit, 31%
- Blood glucose, 262 mg/dL

The RT collects the arterial blood gas on room air, which shows a pH of 7.30; PaO_2, 58 mm Hg; and PCO_2, 25 mm Hg. Should the patient be admitted to the hospital or can she be discharged home? What risk factors does she have for death from pneumonia in the next 30 days?

Discussion

Using CURB-65 as a tool,[36] she meets 3 of the 5 criteria: confusion, low blood pressure (systolic BP <90 mm Hg, diastolic BP <60 mm Hg), and age ≥65 years. She should be admitted to the hospital and consideration should be given to placing her in the ICU. She also has many risk factors that place her at considerable risk of death (see Box 24.1), including: age greater than 50 years, cerebrovascular disease, diabetes mellitus, altered mentation, hypotension, tachycardia, acidemia, hyperglycemia, PaO_2, below 60 mm Hg, leukopenia, and a pleural effusion.

DIAGNOSTIC STUDIES

Community-Acquired Pneumonia

Many patients with CAP who are treated as outpatients never have a microbiologic diagnosis established. Many are treated based on the history and examination findings, with or without a chest x-ray to confirm the presence of an infiltrate. Patients who are sick enough to warrant hospitalization or consideration of hospitalization should undergo appropriate studies to stratify

BOX 24.2 Recommended Tests for Adults With Community-Acquired Pneumonia Warranting Consideration of Hospitalization

- Chest x-ray
- Complete blood count
- Blood chemistries
  - Glucose
  - Serum sodium
  - Blood urea nitrogen
- Arterial blood gas
- Sputum Gram stain and culture
- Additional sputum studies as clinically indicated
  - Acid-fast stain and culture for mycobacteria
  - Fungal stain and culture
  - Direct fluorescent antibody stain or polymerase chain reaction (PCR) for *Legionella* species
  - Stain, direct fluorescent antibody (DFA), or PCR for *Pneumocystis jiroveci*
- Blood cultures
- Pleural fluid analysis if sizable effusion is present
  - Cell count with differential
  - Glucose, protein, and lactate dehydrogenase
  - pH
  - Gram stain and routine aerobic and anaerobic culture
  - Fungal stain and culture
  - Acid-fast stain and culture for mycobacteria
- Additional other studies as clinically indicated
  - *Legionella* urinary antigen
  - Pneumococcal urinary antigen
  - Acute and convalescent sera for *Mycoplasma pneumoniae, Legionella* species, and *Chlamydophila pneumoniae*
  - Fungal serologies and/or antigen testing
  - HIV test for individuals 15 to 65 years old or for those engaging in high-risk behavior

risk for mortality and establish a microbiologic diagnosis (Box 24.2). Complete blood count (CBC), blood glucose, serum sodium, and blood urea nitrogen are all necessary to calculate a point score for estimating mortality risk. An arterial blood gas analysis is used to detect the presence of hypoxemia and acidemia, which indicate more serious illness.

The value of Gram stain and culture of expectorated sputum has been debated for years.[40] Many patients lack a productive cough, making collection of an adequate specimen difficult. Prior antibiotic therapy reduces the yield from both tests. However, sputum culture is positive in more than 80% of cases of pneumococcal pneumonia if a good-quality specimen can be obtained before or within 6 to 12 hours of antibiotic initiation.[41] In addition, finding of a predominant organism on Gram stain in an properly collected specimen can be very helpful in selecting appropriate antibiotic therapy.[42]

RULE OF THUMB A routine sputum culture can be interpreted only within the context of the sputum Gram stain. When many skin cells from the cheek (epithelial cells) are present or when no inflammatory cells are present in the Gram stain in patients who have adequate numbers of WBCs (i.e., are non-neutropenic), the culture result may be misleading.

TABLE 24.6 Sputum Culture Testing for Diagnosing Community-Acquired Pneumonia

Test	Suspected Pathogen
Gram stain, aerobic (routine) culture	Bacteria
Anaerobic culture	Anaerobes, *Actinomyces*
Fungal (Potassium hydroxide, Grocott) stain and culture	*Aspergillus, Histoplasma, Blastomyces, Coccidiomycosis, Cryptococcus*, etc.
Acid-fast bacilli (AFB) stain and culture	Tuberculosis and Nontuberculous Mycobacteria (NTM) species
Respiratory virus polymerase chain reaction (PCR) panel	Influenza, parainfluenza, respiratory syncytial virus, rhinovirus, adenovirus, human metapneumovirus, coronavirus
Legionella PCR	Legionella (L1 serotype and others)
Pneumocystis jiroveci PCR and direct fluorescent antibody (DFA), silver or toluidine blue stains	*P. jiroveci*

The RT has an important role in collecting an appropriate specimen of expectorated sputum. Ideally, the specimen should be obtained prior to starting antibiotics. Patients should be advised to rid their mouths of contaminating saliva by rinsing with water or spitting and then to expectorate a specimen from deep within the tracheobronchial tree into a sterile collection container. Prompt transportation of the specimen to the laboratory is essential and improves the diagnostic yield from culture.[43] Most microbiology laboratories screen the adequacy of the specimen; a satisfactory specimen contains more than 25 leukocytes and fewer than 10 squamous epithelial cells per high-power field on Gram stain.[44] In routine sputum culture, finding bacteria such as *S. pneumoniae* and *H. influenzae* must be interpreted within the context of the Gram stain because these organisms can colonize the oral cavity and their presence in culture may not signify true LRTI.

RULE OF THUMB The presence of *Candida* species on sputum smear or culture is almost never clinically significant.

Other stains and cultures of expectorated sputum should be obtained as dictated by the clinical circumstance, when management would be changed, or for purposes of tracking unusual or resistant organisms in an institution or population. Table 24.6 describes additional testing that can be sent depending on what pathogens are suspected.

Sputum induction can be a useful procedure for patients who have difficulty producing sputum spontaneously. The RT plays an equally important role in making sure that this procedure is done correctly. Patients with underlying lung disease (such as asthma or emphysema) should receive pretreatment with a fast-acting bronchodilator, such as albuterol, to prevent bronchospasm. The patient then inhales nebulized hypertonic saline, which irritates the airways and promotes the production of thin, watery mucus. The patient should then be instructed to perform huff coughs followed by a vigorous cough, which will enable the collection of any secretions that are in the airways. The

secretions may seem thin; it is important to label the sample as "induced sputum" so that it will not be discarded by the laboratory as an inadequate specimen.

RULE OF THUMB Occasionally it is very important to make a microbiologic diagnosis (e.g., of tuberculosis, *P. jiroveci*), for both treatment and infection control purposes. For patients who cannot produce sputum, induced sputum can be a valuable tool that allows patients to avoid the risks associated with bronchoscopy.

Blood cultures should be obtained in hospitalized patients with CAP and may be helpful in establishing the diagnosis in patients with typical bacterial pathogens. Blood cultures are positive in approximately 20% to 25% of inpatients with pneumococcal pneumonia but in fewer cases of pneumonia due to *H. influenzae* or *P. aeruginosa*.[45] Blood cultures are usually positive in cases of *S. aureus* pneumonia that develop by hematogenous spread; however, they are positive in only about 25% of cases where inhalation or aspiration is the suspected mechanism of acquisition.[46] Blood cultures are not helpful in patients with legionellosis, *M. pneumoniae, C. pneumoniae, P. jiroveci,* or viral infections.

Approximately 30% to 50% of cases of CAP are accompanied by a pleural effusion (so-called parapneumonic effusion). In this situation, the fluid itself is not infected but instead forms as a result of inflammation in the adjacent lung. However, empyema, or infection of the pleural space, can also complicate CAP. Thoracentesis is indicated for patients with large pleural effusions and those with smaller effusions who fail to respond to therapy or for whom the microbiologic diagnosis is not established. Pleural fluid should be tested for cell count, glucose, protein, pH, lactate dehydrogenase, gram staining and stains for acid-fast bacilli, and routine (aerobic), anaerobic, and mycobacterial cultures. Pleural effusions with a fluid pH less than 7.20, a positive Gram stain or culture, or fluid that appear grossly purulent on inspection require tube thoracostomy for drainage (see Chapter 27).[47]

Other studies may be helpful in establishing a microbiologic diagnosis in the appropriate clinical setting. *L. pneumophila* serogroup 1 accounts for 70% to 80% of cases of Legionnaire's disease.[48] The urinary antigen test for *L. pneumophila* serogroup 1 is a sensitive and rapid test and usually becomes positive within 3 days of illness onset. *Legionella* PCR testing is also available and highly sensitive; it has the advantage of detecting non–serogroup 1 *Legionella* species.

Serologic tests for immunoglobulin M (IgM) and IgG antibodies to *M. pneumoniae, Legionella* species, or *C. pneumoniae* are rarely helpful during the initial stages of pneumonia, but convalescent titers (i.e., drawn after recovery) 3 to 4 weeks later may permit a retrospective microbiologic diagnosis by showing a fourfold increase in IgG titer or the development of IgM antibody against a specific pathogen. Acute sera should be analyzed in patients who are critically ill with pneumonia and for whom the microbiologic diagnosis is unavailable. Fungal serologic findings are occasionally helpful in supporting the diagnosis of blastomycosis, histoplasmosis, or coccidioidomycosis pending culture isolation of the organism.

Fungal antigen assays are increasingly being used in settings where there is a high clinical suspicion for invasive fungal infection. Invasive aspergillosis is an important cause of pneumonia in immunocompromised hosts, particularly in those with prolonged neutropenia. Galactomannan is a polysaccharide that is a major constituent of *Aspergillus* cell walls. Galactomannan antigen testing is 71% sensitive and 89% specific for *Aspergillus* infection.[49] Similarly, 1,3-β-D-glucan is a cell wall component of many fungi, and levels of this molecule are elevated in many types of invasive fungal infection, including those with *Aspergillus, P. jirovecii*, *H. capsulatum*, and *C. immitis*. β-D glucan assays have a sensitivity of 77% and specificity of 85% for invasive fungal infection.[50] Both of these assays, however, have limitations.[50]

HIV testing should be performed in patients presenting with CAP, since infection with certain pathogens—such as *S. pneumoniae, H. influenzae,* and *P. jiroveci*—occur more often in patients with HIV infection, particularly in those with advanced disease, than in the average population.[51-53] In addition, nearly 15% of patients with HIV are unaware of their diagnosis, so every encounter with health care should be considered an opportunity to identify this population.[54]

Molecular techniques, such as DNA probes and PCR, are increasingly being used in clinical practice. These tests are highly sensitive and can be performed quickly, with a turnaround time of 2 to 3 hours in large hospital laboratories. Such testing allows for a rapid diagnosis, which has important implications for management decisions. Assays for specific organisms such as *M. pneumoniae* or *M. tuberculosis* have been developed. In addition, the generation of respiratory viral PCR panels has allowed for simultaneous testing for multiple viral pathogens, such as influenza, parainfluenza, and respiratory syncytial virus. These assays can be performed on both nasopharyngeal swabs and bronchoalveolar lavage (BAL) fluid, depending on the clinical circumstance.

Flexible bronchoscopy is usually reserved for severe cases of CAP, for immunocompromised individuals in whom opportunistic pathogens must be excluded, or for cases in which *P. jirovecii* infection is suspected. The yield from flexible bronchoscopy in patients with bacterial pneumonia is higher if it is performed before starting antibiotic therapy. Open lung biopsy is rarely indicated for patients with CAP.

Hospital-Acquired Pneumonia, Ventilator-Associated Pneumonia, and Ventilator-Associated Events

In an effort to better monitor and hopefully reduce ventilator-associated complications including VAPs, the Centers for Disease Control (CDC) Healthcare Safety Network implemented a **ventilator-associated events** (VAE) surveillance program in 2013. Its three-tier surveillance definition uses objective, readily available data to identify complications.[56] See Box 24.3 for definitions. These criteria were formulated for purposes of surveillance and quality improvement at the population level and not to aid clinically in diagnosis and treatment decisions. In the future, they may be utilized to inform reimbursement decisions. Interestingly, one study found that less than one-third of VAPs are identified

MINI CLINI

Importance of Clinical Setting for Determining the Cause of Pneumonia

Problem

You are caring for a 32-year-old man admitted to the hospital 24 h earlier with fever, shaking chills, and a new left-lower-lobe infiltrate. His WBCs on admission were 3500/mm^3, with 96% neutrophils and 4% lymphocytes. A sputum Gram stain showed many polymorphonuclear leukocytes and lancet-shaped gram-positive diplococci. Blood cultures have grown *S. pneumoniae* at 24 h. He remained febrile 24 h into therapy with penicillin G. While checking pulse oximetry, the RT notes that the patient is emaciated and that there are multiple needle tracks on each forearm. The patient admits that he uses intravenous heroin. What other tests are indicated?

Discussion

This patient, who is an intravenous drug user, has bacteremic pneumococcal pneumonia. These findings, along with the presence of cachexia and leukopenia with lymphopenia, should suggest the possibility of underlying HIV infection. An HIV test is indicated and should be performed after the patient's consent is obtained.

Both pneumococcal and *H. influenzae* pneumonia occur with higher frequency in HIV-infected individuals than in the general population. Occasionally an HIV-infected patient has his or her first contact with the health care system as a result of one of these infections. New guidelines recommend that all average-risk individuals ages 15 to 65 undergo testing for HIV once in their lives and persons at higher risk for HIV infection undergo more frequent testing.[55]

by the VAE criteria and that most VAPs are nonpreventable events,[57] suggesting that these definitions may not be useful tools in the clinical arena.

RULE OF THUMB The CDC's VAE definitions were designed to aid in surveillance and quality improvement and should not be used to guide patient management.

The accurate diagnosis of nosocomial pneumonia is challenging and has been the subject of intense investigation. Many techniques have been extensively evaluated (Box 24.4); however, none is perfect. The 2016 IDSA/ATS guidelines for the management of HAP and VAP recommend a *clinical diagnosis*, which is defined as the following: development of a new infiltrate on chest x-ray and decline in oxygenation in the setting of fever, purulent sputum, and leukocytosis in a hospitalized patient.[3] A clinical diagnosis lacks specificity because many other causes of pulmonary infiltrates exist in hospitalized patients, especially in patients on mechanical ventilation. In addition, hospitalized patients' airways can become colonized with gram-negative bacilli and staphylococci even in the absence of pneumonia. For this reason, the isolation of these organisms from sputum culture correlates poorly with the presence or absence of pneumonia.

Direct visualization of the lower airway by bronchoscopy in ventilated patients is sometimes helpful to support the diagnosis of VAP. In one study, the presence of distal purulent secretions, persistence of secretions surging from distal bronchi during exhalation, and a decrease in the PaO_2/FiO_2 ratio to less than 50 were independently associated with the presence of pneumonia.

BOX 24.3 Centers for Disease Control Definitions of Ventilator-Associated Events

Ventilator-associated condition (VAC)—Period of sustained respiratory deterioration, defined as a change in positive end-expiratory pressure (PEEP) ≥3 cm H_2O *or* FiO_2 ≥0.2 for 2 days following a sustained period of stability or improvement on the ventilator for 2 days or more.

Infection-related ventilator-associated complication (IVAC)—VAC accompanied by abnormal temperature (<36°C or >38°C) or white blood cell count (≤4000 or ≥12,000/mm^3) requiring initiation of new antibiotics that are continued for at least 4 days.

Possible and probable ventilator-associated pneumonia (VAP)—IVAC with laboratory and/or microbiologic evidence of respiratory infection.

- Possible VAP—Gram stain evidence of purulent pulmonary secretions or a sputum culture positive for pulmonary pathogen in a patient with IVAC
- Probable VAP
  - Purulent respiratory secretions *and* one of the following:
    - Positive culture of endotracheal aspirate ≥ 10^5 CFU/mL or equivalent semiquantitative result
    - Positive culture of bronchoalveolar lavage ≥ 10^4 CFU/mL or equivalent semiquantitative result
    - Positive culture of lung tissue ≥ 10^4 CFU/mL or equivalent semiquantitative result
    - Positive culture of protected specimen brush ≥ 10^3CFU/mL or equivalent semiquantitative result
  - OR one of the following (without requirement for purulent respiratory secretions):
    - Positive pleural fluid culture (specimen obtained during thoracentesis or initial placement of chest tube, not from indwelling chest tube)
    - Positive lung histopathology
    - Positive diagnostic test for *Legionella* species
    - Positive diagnostic test on respiratory secretions for influenza, respiratory syncytial virus, adenovirus, parainfluenza, rhinovirus, human metapneumovirus, or coronavirus

Modified from Centers for Disease Control and Prevention: Surveillance for Ventilator-associated Events, <http://www.cdc.gov/nhsn/acute-care-hospital/vae/>, Accessed June 2018.

BOX 24.4 Techniques for Diagnosing Nosocomial Pneumonia

- Clinical diagnosis
- Direct visualization of the airway by bronchoscopy
- Quantitative or semiquantitative cultures of
  - Endotracheal aspirates
  - Protected specimen brush (PSB) bronchoscopy specimens
  - Bronchoalveolar lavage (BAL) specimens
  - PSB or BAL specimens plus microscopic examination of recovered cells (cytology)
- Respiratory therapist (RT)–directed mini-BAL
- Transthoracic fine-needle aspiration

The presence of two of three of these factors had a sensitivity of 78% in diagnosing nosocomial pneumonia; these factors were absent 89% of the time when there was no pneumonia (89% specific).[58]

Quantitative and semiquantitative cultures of sputum cultures are often utilized to try to increase the specificity of culture results. Different studies have used various breakpoints for

quantitative cultures, ranging from 10^3 to 10^7 colony-forming units (CFU) per milliliter of respiratory secretions; a breakpoint of 10^6 CFU/mL appears to perform best, with a sensitivity of 68% to 82% and specificity of 84% to 96%.[59,60] When a semiquantitative approach is being used, the number of microorganism isolated is reported as rare, few, moderate, or many.

Respiratory secretions can be obtained in a number of different ways, each of which has its advantages and disadvantages. When a patient is able to expectorate sputum, a sample should be obtained noninvasively. In an intubated patient, a tracheal aspirate can also easily be obtained. Several invasive techniques are also available, though they require that the patient be intubated. BAL, in which a lung segment is lavaged with sterile saline through the bronchoscope and recovered fluid is cultured (see Chapter 22), has been studied extensively as a tool for diagnosing nosocomial pneumonia and has sensitivity of 47% to 66% and specificity of 71% to 88%.[61-64] One advantage of this approach is that the specific affected area of the lung can be visualized and sampled. However, a limitation is the potential for upper airway contamination of the specimen. A way to minimize this risk is to use a protected specimen brush (PSB), which makes use of a special double-catheter brush system; however, the sample obtained is smaller than that derived with other methods, leading to a lower sensitivity with this approach. RTs can also perform a mini-BAL (see Chapter 22), also known as a blind BAL or nonbronchoscopic BAL, in which a telescoping catheter is inserted into the lungs without visual guidance; a sample is then lavaged and sent for culture. The sensitivity and specificity of this approach is similar that of a traditional BAL.[65,66]

The 2016 IDSA/ATS VAP and HAP guidelines recommend noninvasive sampling (i.e., expectorated sputum and tracheal aspirate) with semiquantitative cultures over other methods when possible. This recommendation is based on evidence suggesting that outcomes are similar regardless of how specimens are obtained and how microbial growth is quantified. Noninvasive sampling can be completed more quickly, with fewer complications and resources. Similarly, semiquantitative cultures can be done more rapidly than quantitative cultures, with fewer laboratory resources and less expertise. Therefore these approaches are preferred.[3]

ANTIMICROBIAL THERAPY

Community-Acquired Pneumonia

The selection of antibiotic therapy for patients with CAP should be guided by several considerations, including the age of the patient, severity of the illness, presence of risk factors for specific organisms, and results of initial diagnostic studies. Pathogen-specific therapy should be used when clinical circumstances and initial evaluation strongly suggest the microbiologic diagnosis or when cultures or other studies confirm the cause. In many instances, initial studies fail to establish a diagnosis and empiric therapy must be started. Major classes of antibiotics used to treat pneumonia are listed in Table 24.7. Consensus guidelines for therapy have been published by ATS and IDSA (Table 24.8).[67] Therapy initiated within 4 hours of hospital admission has been associated with improved survival.[68]

For hospitalized patients, empiric treatment varies with the severity of illness. Patients from the regular ward who are stable

TABLE 24.7 Major Classes of Antibiotics Used in the Treatment of Pneumonia

Antibiotic Class	Representative Drugs
Penicillins	Penicillin G, ampicillin
Semisynthetic penicillins	Oxacillin, nafcillin
First-generation cephalosporins	Cefazolin
Second-generation cephalosporins	Cefuroxime
Third-generation cephalosporins	Cefotaxime, ceftriaxone, cefpodoxime
Antipseudomonal cephalosporins	Ceftazidime, cefepime
Carbapenems	Imipenem, meropenem, ertapenem
Monobactams (for penicillin and cephalosporin-allergic patients)	Aztreonam
β-lactam/β-lactamase inhibitor combinations	Ticarcillin/clavulanate, piperacillin/tazobactam, ampicillin/sulbactam
Fluoroquinolones	Levofloxacin, moxifloxacin, gemifloxacin
Macrolides	Clarithromycin, azithromycin
Tetracyclines	Doxycycline, minocycline
Aminoglycosides	Amikacin, tobramycin, gentamicin
Glycopeptides	Vancomycin
Oxazolidinones	Linezolid

TABLE 24.8 Empiric Regimens for Treatment of Hospitalized Adults With Community-Acquired Pneumonia

Patient Group	Likely Pathogens	Empiric Regimens
Hospitalized on ward	*Streptococcus pneumoniae, Haemophilus influenzae, Chlamydophila pneumoniae, Staphylococcus aureus, Mycoplasma pneumoniae,* anaerobes, viruses	Fluoroquinolone alone or β-lactam (cefotaxime, ceftriaxone, ampicillin, ertapenem) and macrolide
Critically ill, in intensive care unit (ICU)	*S. pneumoniae, Legionella* species, *S. aureus,* gram-negative bacilli, *M. pneumoniae, C. pneumoniae*	If *Pseudomonas aeruginosa* and methicillin-resistant *S. aureus* (MRSA) unlikely: beta-lactam (cefotaxime, ceftriaxone, ampicillin-sulbactam) plus either azithromycin or a fluoroquinolone If *P. aeruginosa* possible: intravenous antipseudomonal β-lactam (piperacillin-tazobactam, cefepime, imipenem, meropenem) plus fluoroquinolone or macrolide +/– aminoglycoside If MRSA possible, regimen already mentioned plus vancomycin

Modified from Mandell MA, Wunderink RG, Anzueto A, et al: Infectious Disease Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults, *Clin Infect Dis* 44:S27–S72, 2007.

TABLE 24.9 Pathogen-Specific Treatment Recommendations for Adults With Community-Acquired Pneumonia: Infectious Disease Society of America Guidelines

Pathogen	Recommended Regimen
Streptococcus pneumoniae	
Penicillin susceptible	Penicillin G or amoxicillin
Penicillin resistant	Ceftriaxone, cefotaxime, fluoroquinolone, or vancomycin
Haemophilus influenzae	Second- or third-generation cephalosporin, azithromycin, or TMP-SMX
Legionella species	Macrolide ± rifampin or fluoroquinolone alone
Mycoplasma pneumoniae	Macrolide or doxycycline
Chlamydophila pneumoniae	Macrolide or doxycycline
Staphylococcus aureus	
Methicillin susceptible	Semisynthetic penicillin ± rifampin or gentamicin
Methicillin resistant	Vancomycin or linezolid
Enterobacteriaceae	Third-generation cephalosporin ± aminoglycoside or carbapenem
Pseudomonas aeruginosa	Antipseudomonal beta lactam or carbapenem ± aminoglycoside
Influenza with suspected secondary pneumococcal or staphylococcal infection	Neuraminidase inhibitor (oseltamivir or zanamivir) and vancomycin or linezolid
Pneumocystis jiroveci	TMP-SMX (first line) Alternatives: Mild-moderate: atovaquone, clindamycin, and primaquine, or trimethoprim and dapsone Severe: intravenous pentamidine

TMP-SMX, trimethoprim-sulfamethoxazole.
Modified from Mandell MA, Wunderink RG, Anzueto A, et al: Infectious Disease Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults, *Clin Infect Dis* 44:S27–S72, 2007.

are treated differently from those ill enough to require ICU admission. See Table 24.8 for ATS/IDSA recommendations regarding empiric therapy regimens. For patients requiring ICU admission, consideration must be given to upfront empiric coverage of *Pseudomonas* and methicillin-resistant *S. aureus* (MRSA), as these pathogens often cause more serious infection.

Once a microbiologic diagnosis has been established, the antimicrobial regimen should be tailored to the isolated pathogen. Pathogen-specific treatment recommendations from the IDSA and ATS are summarized in Table 24.9. The narrowest-spectrum agent should be used whenever possible.

The duration of therapy for CAP is guided by the specific pathogen and the patient's clinical course. Recommendations have evolved from the traditional 14 days to a minimum of 5 days of therapy with clinical stability. Exceptions include Legionnaire's disease, *Pseudomonas* or *S. aureus* pneumonia, for which a minimum of 2 weeks of therapy is recommended. Older individuals and patients with comorbidities may also require longer courses of treatment. When fever has resolved and patients begin to improve clinically, oral therapy may be used to complete the

MINI CLINI

Evaluating Persistent Fever in Pneumonia

Problem

You are caring for a 68-year-old man admitted 1 week ago with bacteremic *S. pneumoniae* pneumonia. His admitting chest x-ray showed right-lower-lobe consolidation and a large right pleural effusion. He has a history of chronic obstructive pulmonary disease (COPD) and reports a 100 pack-year smoking history. He was treated initially with ceftriaxone and azithromycin until his blood cultures became positive. The organism was susceptible to penicillin, to which he was switched. Despite treatment, the patient has remained persistently febrile (39°C) and his chest x-ray has not shown improvement. Why is he not responding to therapy?

Discussion

Patients with CAP who have comorbid illnesses such as alcoholism or COPD may recover more slowly than healthy individuals despite appropriate therapy. Nevertheless, persistent fever 7 days into optimal treatment should prompt several considerations.

The two most likely concerns for this patient are (1) an undrained empyema and (2) an obstructing endobronchial malignancy, given his substantial smoking history. Other less likely considerations are drug fever; a new nosocomial infection; a missed pathogen that is not responsive to penicillin, contributing to his pneumonia; or a deep venous thrombosis resulting from bed rest.

The next step should be to repeat the history and physical examination. If these do not reveal a cause of the persistent fever, a thoracentesis should be performed to exclude empyema. If thoracentesis findings are negative, further investigation looking for an endobronchial-obstructing lesion with bronchoscopy should be considered.

treatment course. Failure of the patient's temperature to normalize within 4 or 5 days suggests a missed pathogen, a metastatic or closed-space infection (e.g., empyema), drug fever, or the presence of an obstructing endobronchial lesion. Empyema should be treated with tube thoracostomy (see Chapter 27). Abnormal findings on physical examination may persist beyond 1 week in 20% to 40% of patients despite clinical improvement. By 1 month, radiographic resolution occurs in 90% of individuals under 50 years of age.[69] After 1 month, radiographic abnormalities may persist in 70% of cases involving older individuals or in patients with significant underlying illnesses.[69]

RULE OF THUMB Empyema should be ruled out in patients with CAP and a large pleural effusion who fail to respond to therapy. Patients with CAP often get better before the chest x-ray shows any improvement.

Hospital-Acquired Pneumonia and Ventilator-Associated Pneumonia

Empiric and definitive therapy of nosocomial pneumonia is determined by institution-specific data regarding the most common organisms and their antibiotic susceptibility profiles and by patient-specific risk factors. Although general guidelines have been published,[3] the importance of local data cannot be overemphasized because there is great variation across regions and health care facilities regarding the prevalence and susceptibility profiles of specific pathogens.

Generally, in-hospital aspiration should be treated with a regimen that provides coverage against anaerobes and gram-negative bacilli, such as a beta-lactam/beta-lactamase inhibitor combination or clindamycin with a third-generation cephalosporin. If aspiration is not suspected, empiric coverage of *P. aeruginosa* and MRSA is usually recommended while additional culture data are being awaited. In critically ill patients, two agents with antipseudomonal coverage—usually an antipseudomonal beta lactam and an aminoglycoside—are used upfront due to concerns for possible drug resistance. If nosocomial legionellosis is present within an institution, a macrolide may be added to the empiric regimen. Although vancomycin has been the traditional drug of choice for MRSA pneumonia, evolving data suggest that linezolid may be better than vancomycin for this purpose. In a randomized controlled trial of vancomycin versus linezolid for treatment of MRSA pneumonia, clinical resolution of pneumonia occurred more frequently in patients treated with linezolid, but there was no difference in 60-day mortality between the two groups.[70] For VAP, empiric coverage may be targeted at organisms known to colonize the patient's oropharynx or pathogens that are present in the ICU.

As in the case of CAP, the duration of therapy for cases of nosocomial pneumonia is dictated by the clinical course. A study comparing 8 days versus 15 days of therapy in patients with VAP found comparable outcomes with both durations of therapy, although the rate of relapse was slightly higher in patients with *Pseudomonas* or *Acinetobacter* infections.[71] More prolonged courses of therapy may be required in patients who are slow to respond but are associated with a greater risk of new colonization with other organisms and the emergence of drug resistance. Failure of the patient to improve should prompt the following considerations: the presence of an occult empyema; an unrecognized pathogen; a new, unrelated nosocomial infection; or other noninfectious causes of fever common in the ICU, such as deep venous thrombosis, drug fever, occult pancreatitis, or acalculous cholecystitis (gallbladder inflammation without gallstones).

Inhaled Antibiotics

Inhaled antibiotics are sometimes used as an adjunctive therapy for patients with *P. aeruginosa* and other MDR gram-negative infections of the lower respiratory tract. The rationale for their use is maximal drug delivery to the site of infection while simultaneously limiting potential for systemic side effects. Inhaled forms of tobramycin, aztreonam, and colistin are currently approved by the US Food and Drug Administration (FDA) for use in patients with cystic fibrosis (CF), although they are often used in other settings of lower respiratory tract infections, such as non-CF bronchiectasis, VAP, COPD, mycobacterial disease, and following lung transplantation. In addition, injectable forms of gentamicin, amikacin, and ceftazidime can be nebulized "off-label" for similar indications. The 2016 ATS/IDSA HAP guidelines recommend use of both inhaled and systemic antibiotics for patients with VAP due to gram-negative bacilli that are susceptible only to aminoglycosides or colistin.[3] It must be acknowledged, however, that data to strongly support their use are lacking. Two randomized controlled trials evaluating nebulized antibiotics as an alternative or adjunctive agent to intravenous antibiotics in VAP demonstrated improved microbiologic outcomes but no impact on clinical or radiographic responses.[72,73] There are several risks associated with their use that must be considered. Bronchospasm is common and bronchodilators are often routinely administered before dosing in order to offset this side effect. Altered taste and throat irritation can also occur. Though rare, systemic absorption of inhaled agents can occur and lead to toxicity, particularly ototoxicity (hearing loss, vertigo, and ringing in the ears) and nephrotoxicity with inhaled aminoglycosides and colistin. Use of these agents also poses the risk of developing drug resistance, potentially limiting future treatment options.[74]

The RT has an important role in diagnosing and managing patients with CAP and nosocomial pneumonia. It is essential to help patients clear infected secretions and maintain adequate oxygenation. The usefulness of chest physiotherapy in the treatment of pneumonia is still unproved but some patients seem to benefit from it.

PREVENTION

Community-Acquired Pneumonia

Preventive strategies for CAP have focused on immunizing high-risk individuals against influenza and *S. pneumoniae.* Influenza is a risk factor for the subsequent development of CAP during the fall and winter months. In 2010, the Advisory Committee on Immunization Practices (ACIP) expanded its recommendation for influenza vaccination to include all individuals above 6 months of age.[75] Immunization is particularly important for individuals above 60 years (because it reduces the incidence of illness for this age group by half[76]) and for those with chronic lung or heart disease in whom the morbidity of influenza may be substantial. Studies suggest that widespread immunization of healthy working adults is cost-effective because the number of sick days taken and the number of visits to a physician are reduced.[77] Health care workers, including RTs, should be immunized annually to prevent transmission of influenza to patients.

Two pneumococcal vaccines are currently available: Pneumovax23 (which contains polysaccharides, or sugars present on the surface of the bacteria, of 23 different serotypes) and Prevnar13 (a conjugate vaccine in which the surface sugars from 13 different serotypes are linked to proteins to stimulate a stronger immune response). Vaccination is indicated for all individuals above 65 years of age and for individuals above 2 years who have functional or anatomic asplenia (i.e., lack of a spleen). Vaccination is also indicated in patients with chronic illnesses that have been associated with a higher risk of pneumococcal infection: CHF, chronic lung disease, chronic liver disease, current tobacco use, alcoholism, diabetes mellitus, cerebrospinal fluid leaks, cochlear implants, or conditions characterized by impaired immunity.[78] Routine pneumococcal vaccination of all health care workers is not currently recommended; health care workers who possess one of the specific indications for vaccination outlined previously should be immunized.

Immunity against *Bordetella pertussis* fades over time, leading to transmission from older adults to other adults and infants. In order to boost immunity among those at risk, the ACIP has recommended that the tetanus-diphtheria-acellular pertussis

TABLE 24.10 Strategies for the Prevention of Nosocomial Pneumonia

Strategy	Efficacy
Handwashing	Probably effective
Isolation of patients with resistant organisms	Probably effective
Infection control and surveillance	Probably effective
Enteral feeding rather than total parenteral nutrition	Possibly effective
Semierect position	Possibly effective
Sucralfate for bleeding prophylaxis	Possibly effective
Careful handling of respiratory therapy equipment	Possibly effective
Subglottic secretion aspiration	Possibly effective
Selective digestive decontamination	Unproved efficacy
Topical tracheobronchial antibiotics	Unproved efficacy

(Tdap) vaccine replace a tetanus-diphtheria (Td) vaccine booster in adults; these vaccinations are typically given every 10 years.[79]

Hospital-Acquired Pneumonia and Ventilator-Associated Pneumonia

The prevention of nosocomial pneumonia has been intensely studied over the past 30 years. Table 24.10 summarizes currently available strategies and their relative efficacy. No preventive strategy is uniformly effective. Many institutions now employ a "ventilator bundle" including several of these measures (see "Ventilator-Associated Pneumonia Bundle Rule of Thumb," earlier).

Handwashing is an important but frequently overlooked measure that can reduce nosocomial spread of infection. Handwashing is important even if gloves are worn; gloves should be changed between patients because they easily become contaminated with bacteria. In addition, other potential fomites such as stethoscopes, pens, and hard copy or mobile devices used for ventilator patient checks and charting medical record entry should be properly disinfected.

Infection control surveillance to detect outbreaks of nosocomial pneumonia with specific pathogens and to monitor antibiotic resistance patterns is important. Isolation and caring for infected patients in the same place can limit the scope and duration of outbreaks, especially in ICUs.

In patients requiring nutritional support, the use of enteral feeding via jejunostomy has been associated with a lower risk for nosocomial pneumonia than the use of total parenteral nutrition.[80] In addition, patients who are fed enterally (i.e., using the gut to feed) have a lower incidence of pneumonia if kept semierect rather than recumbent.[81] Interestingly, GI bleeding prophylaxis with sucralfate is associated with a lower risk for pneumonia compared with H_2-blockers or proton pump inhibitors (PPIs); the mechanism is unclear, but the drug itself may have antibacterial activity.[82,83] Careful handling of respiratory therapy equipment may reduce the risk for LRTI in ventilated patients. Condensate within the tubing may be colonized with bacteria and should be drained away from the patient because passage of this material into the airway may encourage colonization with nosocomial pathogens. Drainage of subglottic secretions may decrease the incidence of VAP but does not appear to affect mortality, length of ICU stay or mechanical ventilation, or antibiotic use.[84] Decontamination of the digestive tract with nonabsorbable antibiotics reduces the risk of HAP and VAP, but this practice is not routinely used due to the risk of prompting antimicrobial resistance.[85,86]

TUBERCULOSIS

Tuberculosis, caused by *Mycobacterium tuberculosis,* can sometimes mimic CAP and poses special management challenges for the RT. Knowledge of the epidemiology, clinical manifestations, diagnosis, infection control management, and treatment of patients with suspected or proved tuberculosis is essential.

Epidemiology

The epidemiology of tuberculosis in the United States has changed over the past 25 years. After the introduction of effective drugs to treat tuberculosis in the 1950s, the incidence of tuberculosis steadily declined. Tuberculosis increasingly became a disease affecting elderly patients, and most cases represented reactivation of old latent disease. With the emergence of the AIDS epidemic in the early 1980s, there was an increase in the incidence of tuberculosis in the United States and worldwide between 1985 and 1992. Thankfully the incidence has decreased since then. This resurgence was accompanied by dramatic shifts in the patients at risk and the clinical manifestations of the disease. MDR tuberculosis, defined as resistance to both isoniazid and rifampin, emerged as a major public health problem in some populations. Compared with the pre-AIDS era, tuberculosis now more often occurs in younger individuals with HIV infection, especially inner-city minority populations with a history of injecting drugs. Foreign-born nationals residing in the United States have accounted for half of the cases of TB reported annually in recent years.

Tuberculosis has increasingly become a disease affecting individuals of lower socioeconomic status—those in whom homelessness or crowded living conditions, poor access to health care, and unemployment have contributed to the persistence of the disease. Other risk factors include the presence of hematologic malignancies, head and neck cancer, and the receipt of medications such as corticosteroids and tumor necrosis factor α (TNF-α) antagonists.[87-89]

Pathophysiology and Clinical Manifestations

Tuberculosis is acquired by inhaling airborne droplets containing *M. tuberculosis,* and the lungs are the major site of infection. Microorganism-laden droplets are deposited in the terminal airways and cause a host immune response. Most exposed individuals successfully contain the infection and remain asymptomatic, although they remain at risk for reactivation of infection later in life, especially if they become immunosuppressed.

Patients with tuberculosis can present with pulmonary or extrapulmonary manifestations. The major syndromes of pulmonary tuberculosis include primary infection, reactivation, and endobronchial tuberculosis and tuberculoma.

Primary Tuberculosis

Symptomatic primary tuberculosis occurs in a few individuals shortly after exposure. Primary tuberculous pneumonia occurs

more often in children and HIV-infected individuals than in other populations. Fever is the most common symptom and occurs in 70% of patients; it persists for 14 to 21 days on average.[90] Chest pain and cough occur in a minority of patients. Chest x-ray shows hilar lymphadenopathy in 65%, pleural effusion in 33%, and an infiltrate in approximately 25%. Diagnosis may be difficult given the infrequency of cough and a pulmonary infiltrate.

Reactivation Tuberculosis

Reactivation tuberculosis develops months to years after initial infection and may occur spontaneously or in the setting of immunosuppression. In individuals without HIV infection, reactivation disease accounts for 90% of cases of tuberculosis. The most common symptoms include fever, cough, night sweats, and weight loss. Sputum production increases as the infection progresses and is occasionally accompanied by hemoptysis, which is seldom massive. Older patients may present with a more indolent illness in which fever and night sweats are absent. Physical examination is often unrevealing. Chest x-ray shows upper lobe disease in 80% to 90% of patients, and cavities are present in 20% to 40%.

Endobronchial Tuberculosis and Tuberculomas

Endobronchial tuberculosis involves the airways and may occur in both primary and reactivation tuberculosis. In primary tuberculosis, hilar nodal enlargement may impinge on the bronchi, resulting in compression and ultimately ulceration. In patients with reactivation disease, endobronchial involvement may occur as a result of direct extension from the parenchyma or pooling of secretions from upper lobe cavities in the dependent distal airways. Symptoms of endobronchial tuberculosis include a barking cough in two-thirds of patients, sputum production, wheezing, and hemoptysis. Exam often reveals wheezing. Chest x-ray frequently shows an upper lobe cavitary infiltrate with a lower lobe infiltrate on the same side. Extensive endobronchial disease may produce bronchiectasis.

Tuberculomas are rounded solitary mass lesions and may occur in primary or reactivation tuberculosis. They are often asymptomatic and may mimic malignancy. Tuberculoma is in the differential diagnosis of solitary pulmonary nodule and may be difficult to diagnose without biopsy or excision because expectorated sputum in patients with tuberculoma rarely shows *M. tuberculosis* on smear or culture.

Complications

Complications of pulmonary tuberculosis include tuberculous empyema, bronchiectasis, extensive pulmonary parenchymal destruction, spontaneous pneumothorax, and massive hemoptysis from rupture of a Rasmussen aneurysm in the wall of a cavity.

Extrapulmonary Tuberculosis

Extrapulmonary tuberculosis is defined as spread of *M. tuberculosis* infection beyond the lung and may involve virtually any organ. The central nervous system, musculoskeletal system, genitourinary tract, and lymph nodes (scrofula) are the most common sites of extrapulmonary tuberculosis. HIV-infected patients may develop rapidly progressive primary infection and present with both pulmonary and extrapulmonary disease. In patients with advanced AIDS, tuberculosis may manifest as disseminated disease with involvement of multiple organs, including lymph nodes, bone marrow, liver, and spleen. Symptoms in this setting include high fevers, sweats, and progressive weight loss. Findings on examination may include fever, wasting, and enlargement of the spleen and liver. Laboratory testing may show pancytopenia (decreased cell counts) and advanced immunodeficiency. Imaging studies often show mediastinal and abdominal lymphadenopathy and hepatosplenomegaly.

Diagnosis

The history is important in diagnosing and managing patients with suspected tuberculosis. In addition to asking about the patient's symptoms, the clinician should inquire about any history of tuberculosis, the presence of risk factors for acquiring tuberculosis and/or HIV infection, any history of travel, as well as potential contacts with individuals with known or suspected tuberculosis. The patient should be asked whether he or she has been previously treated, the drugs chosen, duration of treatment, and adherence to therapy. Risk factors for drug-resistant tuberculosis should be sought, which include prior treatment for tuberculosis, exposure to individuals with known drug-resistant disease or those with active tuberculosis who have been previously treated, travel to parts of the world with a high prevalence of drug resistance, or exposure to individuals with active tuberculosis from those areas.

The gold standard for diagnosing tuberculosis is culture isolation of the organism. The major disadvantage of culture is that *M. tuberculosis* may take 4 to 6 weeks to grow, thereby delaying diagnosis. Acid-fast staining of expectorated sputum, bronchoscopic specimens, and other body fluids or tissues is usually performed. In patients with pulmonary tuberculosis, it is estimated that 10^4 organisms per milliliter are required for the smear to be positive. Acid-fast smears are less sensitive than culture for detecting disease, and the presence of acid-fast bacilli on a smear does not prove the diagnosis of *M. tuberculosis* because nontuberculous mycobacteria (NTM) can produce disease in selected populations. More rapid diagnostic techniques for identifying *M. tuberculosis* in clinical specimens and for confirming the identity of the organism in culture are available in some centers. These techniques include nucleic acid amplification, nucleic acid probes, PCR genomic analysis, and molecular tests for chromosomal mutations associated with drug resistance.

A five-tuberculin-unit purified protein derivative (5 TU PPD) skin test or interferon-gamma release assay (IGRA) may be performed in individuals with suspected tuberculosis. Both tests evaluate for cell-mediated immunity to tuberculosis in individuals with prior exposure to the organism. A PPD consists of intradermal injection of tuberculin material, which stimulates a delayed-type hypersensitivity response mediated by T cells and causes skin induration within 48 to 72 hours. False-positive results can occur in patients with prior bacille Calmette-Guérin (BCG) vaccination or infection with NTM species. IGRAs are blood tests that measure T-cell release of the cytokine interferon-gamma after stimulation by antigens unique to *M. tuberculosis*. IGRAs

are unaffected by BCG vaccination status and most NTM infections (except *Mycobacterium marinum* and *Mycobacterium kansasii*) and require only a single patient encounter, all of which are advantages over the PPD.[91] Both tests become positive 3 to 8 weeks after infection. A positive skin test or IGRA supports the diagnosis in the appropriate clinical setting, but a negative result does not exclude the diagnosis. Patients with HIV infection, other causes of immunodeficiency, advanced age, or other comorbidities may be anergic and unable to mount either a positive skin test or IGRA result.[91,92]

Precautions

Patients hospitalized with suspected or proved active pulmonary tuberculosis should be placed in respiratory isolation in private negative pressure airflow rooms because they pose a risk for transmitting infection to others by coughing up aerosolized droplets containing *M. tuberculosis*. Individuals entering the patient's room should wear fit-tested National Institute for Occupational Safety and Health–approved N-95 or higher masks or respirators. A surgical mask should be placed on a patient with suspected or proven active pulmonary tuberculosis during transport outside the negative-pressure room.

RULE OF THUMB In order to minimize the risk of spread to others, patients with suspected or proven pulmonary tuberculosis should be placed on airborne isolation in negative-pressure-airflow rooms, and N-95 masks should be worn by all individuals entering the room. Patients must remain in isolation until sputum acid fast bacilli (AFB, especially *Mycobacterium* tuberculosis) smears return negative.

Treatment

Treatment recommendations for tuberculosis have been published by the ATS, the CDC, and the IDSA.[93] The goals of therapy are to cure the patient and prevent transmission of *M. tuberculosis* to others. Treatment must address clinical and social issues and should be customized to the patient's circumstance. At the outset, daily observed therapy (DOT) should be part of the treatment program; this consists of observing the patient taking the antituberculous medications. Treatment programs that use comprehensive case management and DOT have a higher rate of successful completion of therapy than other treatment strategies. Social service support, housing assistance, and treatment for substance abuse may be required for selected individuals with tuberculosis and should be part of the treatment plan. Patients with tuberculosis must be promptly reported to the local department of public health so that contact tracing can be performed. This includes identifying, if possible, the index case from whom the patient has contracted the infection and identifying close personal contacts to whom the patient may have transmitted *M. tuberculosis*.

Isoniazid, rifampin, pyrazinamide, and ethambutol are first-line antituberculous medications. Pending antimicrobial susceptibility results, treatment with four drugs is recommended. In patients with drug-susceptible pulmonary tuberculosis, many 6- to 9-month treatment regimens have been shown to be effective, as outlined in guidelines by the ATS, CDC, and IDSA.[93] Patients with MDR tuberculosis require more prolonged courses of therapy with multidrug regimens.

ROLE OF THE RESPIRATORY THERAPIST IN PULMONARY INFECTIONS

The RT plays a key role in managing patients with pulmonary infections, including helping to diagnose and treat the illnesses. Diagnostically, RTs participate in collecting sputum specimens or assisting physicians during bronchoscopy. In some settings, RTs may perform mini-BAL.

RTs often administer chest physiotherapy when indicated, as in patients with bronchiectasis and CF. They may also be involved in counseling patients in other clearance techniques, such as autogenic drainage and positive expiratory pressure (PEP) therapy. RTs also play key roles in modeling optimal infection control and prevention practices (e.g., handwashing, implementing and complying with respiratory precautions, vaccination) and in advising patients about preventive interventions, such as influenza, pneumococcal, and Tdap vaccines.

SUMMARY CHECKLIST

- CAP and nosocomial pneumonia are common and important clinical problems with significant morbidity and mortality.
- *S. pneumoniae* remains the most common cause of CAP. Gram-negative bacilli and *S. aureus* are the most common causes of nosocomial pneumonia, but their relative incidence and antimicrobial susceptibility profiles may vary across institutions.
- The mortality risk can be estimated at presentation for most patients with CAP, which helps in determining the need for hospitalization.
- Routine sputum cultures for patients with CAP must be interpreted within the context of the sputum Gram stain, which provides valuable information regarding the adequacy of the specimen and the predominance of potential pathogens.
- The accurate diagnosis of nosocomial pneumonia remains a challenge; none of the diagnostic methods currently available is completely reliable.
- The VAE surveillance program was instituted to monitor and reduce ventilator-associated complications, including VAP, but is not being used clinically at this time.
- Guidelines exist for the treatment of CAP and nosocomial pneumonia. When possible, pathogen-specific antibiotic therapy should be used.
- Inhaled antibiotics may play an adjunctive role in the treatment of pneumonia due to multidrug-resistant organisms
- Immunizing high-risk individuals against influenza and *S. pneumoniae* is the major strategy in preventing CAP.
- Strategies for preventing nosocomial pneumonia are not uniformly effective.
- Pulmonary tuberculosis may mimic CAP; the recognition and appropriate isolation, diagnostic evaluation, and management of individuals with possible pulmonary tuberculosis are essential.
- The RT can help to prevent nosocomial pneumonia by paying careful attention to basic infection control procedures such as handwashing.

Obstructive Lung Disease: Chronic Obstructive Pulmonary Disease (COPD), Asthma, and Related Diseases

Amy Attaway, Umur Hatipoğlu, and James K. Stoller

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- State definitions of chronic obstructive pulmonary disease (COPD), asthma, and bronchiectasis.
- Understand the major risk factors associated with COPD.
- Identify the common signs and symptoms associated with COPD.
- Describe a treatment plan for a patient with stable COPD and for a patient with an acute exacerbation of COPD.
- State the typical clinical presentation of a patient with asthma.
- Be able to differentiate between asthma and COPD.
- Describe a treatment plan for a patient with stable asthma and for a patient with an acute exacerbation of asthma.
- Understand the causes of bronchiectasis.
- Describe the treatment currently available for patients with bronchiectasis.

CHAPTER OUTLINE

KEY TERMS

acute exacerbation of COPD
airway hyperresponsiveness
airway inflammation
airway obstruction
alpha-1 antitrypsin deficiency
asthma
asthma-COPD overlap syndrome
bronchiectasis
bronchodilator
bronchospasm
chronic bronchitis
cystic fibrosis
emphysema
noninvasive ventilation
supplemental oxygen

The category of obstructive lung diseases is broad and includes chronic obstructive pulmonary disease (COPD) and **asthma** as the most common diseases and **bronchiectasis** and **cystic fibrosis** as less common forms. Airflow obstruction may also be a feature of other diseases such as sarcoidosis and congestive heart failure. This chapter reviews the major obstructive lung diseases, emphasizing their defining features, epidemiology, pathophysiology, clinical signs and symptoms, prognosis, and management. Cystic fibrosis is discussed in Chapter 35.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Overview and Definitions

The term *COPD* refers to a disease state characterized by the presence of airflow obstruction that does not reverse completely after **bronchodilator** treatment. Current guidelines by the American Thoracic Society (ATS) and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines recommend the use of the term *COPD* to encompass both chronic

bronchitis and emphysema. The GOLD guidelines define COPD as follows:

COPD is a common, preventable, and treatable disease characterized by persistent respiratory symptoms and airflow limitation caused by airway and/or alveolar abnormalities, usually caused by significant exposure to noxious particles or gases. The chronic airflow limitation that is characteristic of COPD is caused by a mixture of small airways disease (e.g., obstructive bronchiolitis) and parenchymal destruction (emphysema), the relative contributions of which vary from person to person.[1] The spectrum of COPD is shown in Fig. 25.1, which presents a Venn diagram representing the major components of COPD—chronic bronchitis and emphysema. Although asthma is no longer conventionally considered to be part of the spectrum of COPD, the diagram shows that there is overlap between asthma and COPD. In actual practice, it may not be possible to distinguish between individuals with a history of asthma but with incompletely reversible airflow obstruction and individuals with COPD. Recently, this overlap has been recognized with the term "asthma-COPD overlap" syndrome (ACOS).

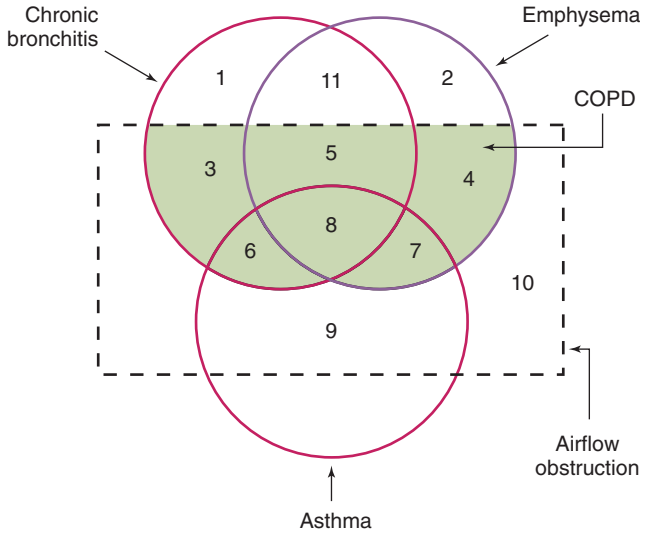

Fig. 25.1 Schema of Chronic Obstructive Pulmonary Disease *(COPD).* This nonproportional Venn diagram shows subsets of patients with chronic bronchitis, emphysema, and asthma. The subsets constituting COPD are *shaded.* Subset areas are not proportional to actual relative subset sizes. Asthma is by definition associated with reversible airflow obstruction, although in variant asthma special maneuvers may be necessary to make the obstruction evident. Patients with asthma whose airflow obstruction is completely reversible *(subset 9)* are not considered to have COPD. Owing to the fact that in many cases it is virtually impossible to differentiate patients with asthma whose airflow obstruction does not remit completely from patients with chronic bronchitis and emphysema who have partially reversible airflow obstruction with airway hyperreactivity, patients with unremitting asthma are classified as having COPD *(subsets 6, 7, and 8).* Chronic bronchitis and emphysema with airflow obstruction usually occur together *(subset 5),* and some patients may have asthma associated with these two disorders *(subset 8).* Individuals with asthma who are exposed to chronic irritation, as from cigarette smoke, may develop a chronic, productive cough, a feature of chronic bronchitis *(subset 6).* Such patients are often referred to as having *asthmatic bronchitis* or the *asthmatic form of COPD.* Individuals with chronic bronchitis or emphysema without airflow obstruction *(subsets 1, 2, and 11)* are not classified as having COPD. Patients with airway obstruction caused by diseases with a known cause or specific pathologic process, such as cystic fibrosis or obliterative bronchiolitis *(subset 10),* are not included in this definition.

The two major diseases that make up COPD—emphysema and chronic bronchitis—are defined in different ways. **Emphysema** is defined in anatomic terms as a condition characterized by abnormal, permanent enlargement of the airspaces beyond the terminal bronchiole, accompanied by destruction of the walls of the airspaces and loss of elastance. **Chronic bronchitis** is defined in clinical terms as a condition in which chronic productive cough is present for at least 3 months per year for at least 2 consecutive years. The definition specifies further that other causes of chronic cough (e.g., gastroesophageal reflux, asthma, and postnasal drip) have been excluded. Fig. 25.1 shows considerable overlap between chronic bronchitis and emphysema and some overlap with asthma—that is, when airflow obstruction is not completely reversible after bronchodilator therapy. Fig. 25.1 also shows that chronic bronchitis and emphysema can occur without airflow obstruction, although the clinical significance of these diseases usually comes from obstruction to airflow.

Epidemiology

COPD is one of the most frequent causes of morbidity and mortality worldwide.[2] The World Health Organization predicts that COPD will become the fifth most prevalent disease in the world and the third leading cause of worldwide mortality by 2030. In the United States, COPD is currently the third leading cause of death[3]; it is responsible for 143,560 deaths in 2015.[4] Estimates suggest that 30 million Americans are affected, although only 15 million U.S. adults have been diagnosed.[4-7] Prevalence by state in the United States ranges from 3.9% to 9.3%.[5] Data from the National Health and Nutrition Examination Survey (NHANES) suggest that among adults 25 to 75 years old in the United States, mild COPD (defined as forced expiratory volume in 1 second [FEV_1]/forced vital capacity [FVC] <70%, and FEV_1 >80% predicted) occurs in 6.9% and moderate COPD (defined as FEV_1/FVC <70% and FEV_1 ≤80% predicted) occurs in 6.6%.[2] COPD prevalence increases with aging, with a fivefold increased risk for adults older than 65 years compared with adults younger than 40 years, and some studies estimate a prevalence of 20% to 30% in adults older than 70 years.[8]

COPD has recently become more prevalent in women. Starting in the year 2000, COPD was responsible for the deaths of more women than men, and by 2009 women accounted for 53% of all COPD deaths in the United States.[9]

The growing health burden from COPD is caused in part by the aging of the population but mainly by the continued use of tobacco. Also, COPD is one of the conditions for which hospitals may be financially penalized for excessive short-term readmission rates under the federal government's Hospital Readmission Reduction Program (HRRP).[10]

Risk Factors and Pathophysiology

Although many risk factors exist for COPD (Box 25.1), in the United States the two most common are *cigarette smoking* (which has been estimated to account for 80% to 90% of all COPD-related deaths) and *alpha-1 antitrypsin (AAT) deficiency.*[11] Worldwide, exposure to biomass fuels (like cooking with wood or

BOX 25.1 Causes of Chronic Obstructive Pulmonary Disease[a]

Common Causes

- Cigarette smoking
- AAT deficiency
- Outdoor air pollution
- Long-standing asthma
- Biomass and occupational exposure (e.g., chronic exposure to wood smoke with poorly ventilated indoor cooking)

Less Common Causes

- Hypocomplementemic urticarial vasculitis
- Intravenous methylphenidate (Ritalin) abuse
- Ehlers-Danlos syndrome
- Marfan syndrome
- Cutix laxa
- Menke syndrome
- Salla disease[b]
- Alpha-1 antichymotrypsin deficiency[b]
- Human immunodeficiency virus infection (emphysema-like illness)

[a]Multiple causes (e.g., cigarette smoking and alpha-1 antitrypsin deficiency) may coexist in a single patient.
[b]Putative cause; firm evidence is unavailable.
AAT, Alpha-1 antitrypsin.

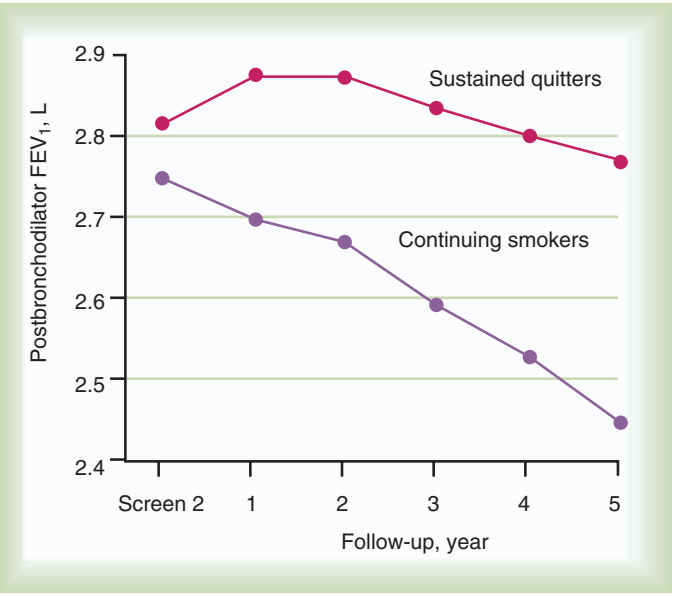

Fig. 25.2 Mean post-bronchodilator forced expiratory volume in 1 *(FEV_1)* for participants in the smoking intervention and placebo groups who were sustained quitters *(red circles)* and continuing smokers *(purple circles).* The two curves diverge sharply after baseline. (From Anthonisen SR, Connett JE, Kiley JP, et al: Effects of smoking intervention and the use of an anticholinergic bronchodilator on the rate of decline of FEV_1: the Lung Health Study. *JAMA* 272:1497–1504, 1994.)

natural product-burning stoves in enclosed spaces) also accounts for a major disease burden.[12]

Evidence linking cigarette smoking to the development of COPD is strong and includes the following:

- Symptoms of COPD (e.g., chronic cough and phlegm production) are more common in smokers than in nonsmokers.
- Impaired lung function with evidence of an obstructive pattern of lung dysfunction is more common in smokers than in nonsmokers.
- Pathologic changes of airflow obstruction and chronic bronchitis are evident in the lungs of smokers.
- So-called *susceptible smokers,* who represent approximately 15% of all cigarette smokers, experience more rapid rates of decline of lung function than nonsmokers.

Information from the Lung Health Study (Fig. 25.2) highlighted the accelerated rate of decrease of FEV_1 in smokers compared with former smokers who have achieved sustained quitting.[13,14] Overall, the strength of evidence implicating cigarette smoking as a cause of COPD has allowed the U.S. Surgeon General to conclude, "Cigarette smoking is the major cause of chronic obstructive lung disease in the United States for both men and women. The contribution of cigarette smoking to chronic obstructive lung disease morbidity and mortality far outweighs all other factors."[15]

As the second well-recognized cause of emphysema, AAT deficiency, sometimes called *genetic emphysema* or *α-1 antiprotease deficiency,* is a condition that features a reduced amount of the protein AAT, which may result in the early onset of emphysema and which is inherited as a so-called *autosomal codominant condition*. AAT deficiency accounts for 2% to 3% of all cases of COPD and affects 100,000 Americans but is under-recognized by health care providers.[16,17] Respiratory therapists (RTs) should be aware of AAT deficiency and suspect it in all patients with signs and symptoms of emphysema and especially in those without risk factors such as smoking.

Identifying individuals with AAT deficiency is simple, often requiring only a blood test of the serum AAT level. Importantly, RTs can contribute to detecting individuals with AAT deficiency (e.g., by suggesting or offering testing when airflow obstruction is diagnosed in the pulmonary function laboratory by an RT performing the test and by making patients aware of available free, home-based testing kits) (see http://www.alpha-1foundation.org). Several observations suggest the importance of detection: (1) first-degree relatives (e.g., siblings, parents, and children) may also be affected but unaware of their risk; (2) early detection allows appropriate monitoring and therapy, including the very important step of smoking cessation; and (3) for individuals with established emphysema, consideration can be given to available specific therapy, called *intravenous augmentation therapy* (which is the administration of purified AAT intravenously to individuals with severe deficiency of AAT). The risk for developing emphysema for individuals with AAT deficiency increases as the serum AAT level decreases to less than 11 µmol/L or less than approximately 57 mg/dL (with normal serum levels generally 100 to 220 mg/dL); these levels in serum define the so-called *protective threshold value,* which is the serum level below which the risk for emphysema is felt to increase. Cigarette smoking markedly accelerates the rate of emphysema progression in individuals with AAT deficiency.[18]

Study of AAT deficiency has helped formulate the protease-antiprotease hypothesis of emphysema.[18,19] In this explanatory model (Fig. 25.3), lung elastin, a major structural protein that supports the alveolar walls of the lung, is normally protected by

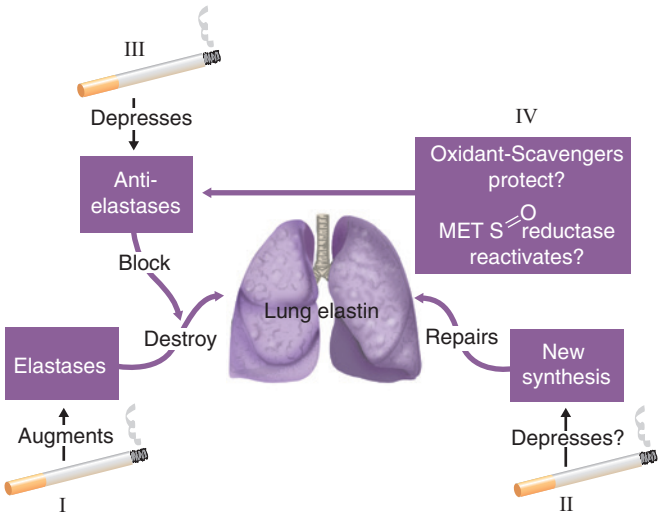

Fig. 25.3 Proposed Biochemical Links Between Cigarette Smoking and the Pathogenesis of Emphysema. *(I)* Smoking recruits monocytes, macrophages, and (through macrophage chemotactic factors) polymorphonuclear neutrophils to the lung, elevating the connective tissue "burden" of elastolytic serine and metalloproteases. *(III)* At the same time, oxidants in smoke plus oxidants produced by smoke-stimulated lung phagocytes (and oxidizing products of chemical interactions between these two) inactivate bronchial mucus proteinase inhibitor and alpha-1 antitrypsin, the latter representing the major antielastase "shield" of the respiratory units. *(III)* Other, unidentified water-soluble, gas-phase components of cigarette smoke (cyanide, copper chelators) inhibit lysyl oxidase–catalyzed oxidative deamination of epsilon-amino groups in tropoelastin and block formation of desmosine and presumably other cross-links during elastin synthesis, decreasing connective tissue repair. *(IV)* Antioxidants (ceruloplasmin, methionine-sulfoxide-reductase) may protect or reactivate elastase inhibitors, and other unidentified factors may modulate the chemical lesions induced in the lung by smoking to influence the risk for developing COPD. (Modified from Janoff A, Carp H, Laurent P, et al: The role of oxidative processes in emphysema. *Am Rev Respir Dis* 127[Suppl]:S31, 1983.)

AAT, a protein that defends the lung against tissue destruction by neutrophil elastase. Neutrophil elastase is a protein contained within a category of white blood cells called *neutrophils* that is released when neutrophils are attracted to the lung during inflammation (like smoking) or infection. Under normal circumstances of an adequate amount of AAT, neutrophil elastase is counteracted so as not to digest lung elastin; however, with severe deficiency of AAT (i.e., when serum levels decrease below the "protective threshold" serum value of 11 µmol/L, or 57 mg/dL), neutrophil elastase may go unchecked, causing breakdown of elastin and of alveolar walls.

COPD may also occur without active cigarette smoking or AAT deficiency (see Box 25.1).[20,21] Factors such as passive smoking, air pollution, occupational exposure, and airway hyperresponsiveness (AHR) may contribute to airflow obstruction that is not reversible.

The pathophysiologic mechanisms of airflow obstruction in COPD include inflammation and obstruction of small airways (<2 mm in diameter); loss of elasticity, which keeps small airways open when elastin is destroyed in emphysema; and active **bronchospasm**. Although traditionally considered to be characteristic of asthma, some reversibility of airflow obstruction has been

Fig. 25.4 Posteroanterior Plain Chest X-ray in a Patient With Severe Deficiency of Alpha-1 Antitrypsin and Emphysema. Note that the emphysematous changes (hyperlucency) are more pronounced at the lung bases than at the apexes.

observed in up to two-thirds of patients with COPD when tested multiple times with inhaled bronchodilators.[22]

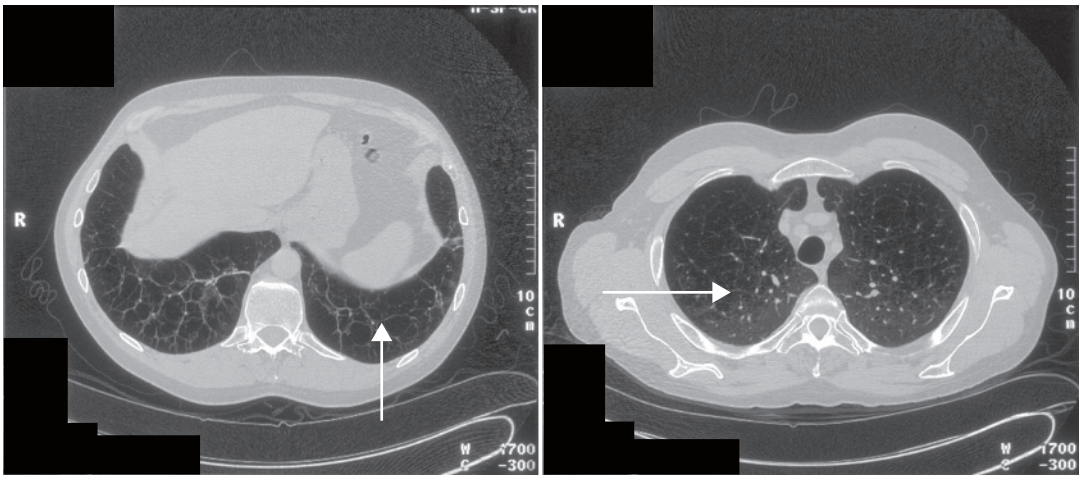
RULE OF THUMB When COPD occurs in a non-smoker, a young person, an individual with a family history of liver or lung disease, or an individual with emphysematous changes more pronounced at the lung bases than apexes on a chest radiograph (Fig. 25.4) or chest computed tomography (CT) (Fig. 25.5), AAT deficiency should be especially suspected. Still, guidelines suggest that *all* adult, symptomatic patients with COPD should be tested for AAT deficiency. RTs can play a key role in diagnosing AAT deficiency.

Clinical Signs and Symptoms

Common symptoms of COPD include cough, phlegm production, wheezing, and shortness of breath, typically on exertion. Dyspnea is often slow but progressive in onset and occurs later in the course of the disease, characteristically in the late sixth or seventh decade of life. A notable exception is AAT deficiency, in which dyspnea characteristically begins sooner (mean age is approximately 45 years).[11]

Table 25.1 reviews the characteristic features of emphysema and chronic bronchitis and emphasizes traits that should especially suggest the possibility of AAT deficiency, including early onset of emphysema, emphysema in a nonsmoker, a family history of emphysema, or emphysema with a chest x-ray (see Fig. 25.4) or CT (see Fig. 25.5), in which emphysematous changes are more pronounced at the lung bases than at the apexes (so-called *basilar hyperlucency*).[11,18]

Physical examination of the chest early on in a patient with COPD may reveal wheezing or diminished breath sounds. Later, signs of hyperinflation may be evident—that is, increased anteroposterior diameter of the chest (sometimes called a *barrel chest*), diaphragm flattening, and dimpling inward of the chest wall at the level of the diaphragm on inspiration (called the *Hoover sign*). Other late signs of COPD include use of accessory muscles of respiration (e.g., sternocleidomastoid), leg edema from cor pulmonale (also known as the right-sided heart failure that can develop



A B

Fig. 25.5 Computed Tomography Chest Image From an Individual With Severe Deficiency of Alpha-1 Antitrypsin. Note the changes of emphysema *(arrows)* are more pronounced in the lung bases (B) than in the lung apexes (A).

TABLE 25.1 Clinical Features of Chronic Obstructive Pulmonary Disease: Distinctions Between Chronic Bronchitis and Emphysema, With Emphasis on Distinguishing Features of Alpha-1 Antitrypsin Deficiency

Features	Chronic Bronchitis	Emphysema	Severe Alpha-1 Antitrypsin Deficiency
Symptoms and Signs			
Chronic cough, phlegm	Common	Less common	Less common, but may be present
Dyspnea on exertion	Less common	Common	Common
Cor pulmonale	Present (often with multiple exacerbations)	Present (but often in end-stage emphysema)	Present (but often in end-stage emphysema)
Age of patient at symptom onset	6th–7th decade	6th–7th decade	4th–5th decade (although late onset is possible)
Family history of COPD	Possible but not characteristic	Possible but not characteristic	Common in parents, children, and siblings
History of cigarette smoking	Present, often heavy	Present, often heavy	May be present, but COPD can occur in the absence of smoking
Physiologic Function			
Airflow (FEV_1, FEV_1/FVC)	Decreased	Decreased	Decreased
Lung volumes, residual volume	Normal	Increased, suggesting air trapping	Increased
Gas exchange, diffusion PaO_2	Often decreased	Often preserved until advanced stage	Often preserved until advanced stage
$PaCO_2$	May be increased	Often preserved until advanced disease, then elevated	Often preserved until advanced disease, then elevated
Diffusion capacity	Often normal	Decreased	Decreased
Static lung compliance	Normal	Increased	Increased
Chest radiograph	"Dirty lungs" with peribronchial cuffing, suggesting thickened bronchial walls	Hyperinflation, with evidence of emphysema; greater at lung apex than at lung base	Hyperinflation, with evidence of emphysema; frequently greater at lung base than at lung apex (basilar hyperlucency)

FEV_1, Forced expiratory volume in 1; *FVC*, forced vital capacity; *COPD*, chronic obstructive pulmonary disease.

from lung disease), mental status changes caused by hypoxemia or hypercapnia (especially in acute exacerbations of chronic, severe disease), or asterixis (i.e., involuntary flapping of the hands when held in an extended position, as in "stopping traffic").

RULE OF THUMB In patients with COPD, $PaCO_2$ is usually preserved until airflow obstruction is severe (i.e., FEV_1 <1 L), which is when $PaCO_2$ may characteristically increase.

RULE OF THUMB Digital clubbing is **not** caused by COPD alone, even if hypoxemia is present. Clubbing in a patient with COPD warrants consideration of another cause (e.g., bronchogenic cancer, bronchiectasis, interstitial lung disease, liver disease, inflammatory bowel disease, cystic fibrosis).

Management

In managing patients with chronic, stable COPD, the following goals must guide the clinician[1,23]:

- Establish the diagnosis of COPD.
- Optimize lung function.
- Maximize the patient's ability to perform daily activities.
- Simplify the medical treatment program as much as possible.
- Prevent infection, including vaccinations.
- Avoid exacerbations of COPD.
- Prolong survival.

In managing an **acute exacerbation of COPD**, additional considerations are to reestablish the patient to baseline status as quickly and with as little morbidity and mortality as possible.[24,25] Each of the treatments discussed in this section is considered in regard to these goals, recognizing differences in management between patients with chronic, stable COPD versus an acute exacerbation of COPD.

Establishing the Diagnosis

Although many diseases can give rise to obstructive lung disease, including some unusual entities such as chronic eosinophilic pneumonia, bronchiectasis, and allergic bronchopulmonary aspergillosis, the major challenge facing the clinician who encounters a patient with airflow obstruction is to distinguish COPD (i.e., emphysema or chronic bronchitis or both) from asthma. Distinguishing asthma from COPD may be very difficult in practice. This difficulty has been recognized by naming an overlap syndrome called the "ACOS". While definitive criteria for this syndrome are not yet agreed upon, patients are generally ≥35 years and have evidence for chronic persistent airflow limitation, that is, COPD with a smoking history of at least 10 pack years. For those patients who already have a diagnosis of asthma, a positive bronchodilator response (FEV_1 ≥12% and ≥200 mL increase after bronchodilator use), diurnal variability of peak expiratory flow or elevated exhaled nitric oxide levels (i.e., ≥50 ppb) are considered diagnostic of ACOS. For those who do not have a current diagnosis of asthma, prominent fluctuation in symptom burden, a vigorous bronchodilator response (usually an increase of 15% and ≥ 400 mL in FEV_1 after bronchodilator) and the presence of eosinophilia in blood (≥300 cells/mcl) suggest the presence of ACOS. Clinicians may consider allergy evaluation and treatment, use of inhaled corticosteroids, and even biological drugs typically used for asthma for patients with ACOS.[26]

After the diagnosis of COPD is established, another issue is whether the patient has an underlying predisposition to COPD, such as AAT deficiency or other cause listed in Box 25.1.[20,21] Underlying causes are present in fewer than 5% of patients with COPD, with AAT deficiency being the most common (2% to 3% of all patients with COPD in the United States).

Optimizing Lung Function

Stable Chronic Obstructive Pulmonary Disease

Although airflow obstruction from emphysema itself is irreversible, most (up to two-thirds) patients with stable COPD exhibit a reversible component of airflow obstruction, defined as a 12% and 200 mL increase in post-bronchodilator FEV_1 or FVC or both. For this reason, as shown in an algorithm developed by GOLD (Fig. 25.6),[1,22,25,26,34,35] bronchodilator therapy is recommended for patients with COPD.

MINI CLINI

Distinguishing Asthma From Chronic Obstructive Pulmonary Disease

Problem

You are asked to see a new patient in clinic with a history of asthma. The patient is a 60-year-old female who is a current smoker of 50 pack years. She notes a chronic productive cough and persistent shortness of breath, but denies nighttime wakening. She states her symptoms began later in life and denies a childhood history of asthma. Her pulmonary function test (PFT) reveals an FEV_1/FVC ratio <70% and FEV_1 noted to be 55% with no significant bronchodilator response. Review of records show an FEV_1 of 60% when she had spirometry performed 4 years prior. How would you characterize the patient's airflow obstruction based on her spirometry, history, and clinical symptoms?

Discussion

Distinguishing asthma versus COPD has been the topic of several clinical practice guidelines. A questionnaire that incorporated age of onset, smoking history, atopy status (i.e., the tendency to develop allergic diseases), and cough quality was able to correctly identify asthma versus COPD in 87.4% of cases.[27] Another questionnaire to help distinguish COPD included age, pack-years, worsening cough, breathing-related disability or hospitalization, phlegm quantity, and worsening dyspnea, demonstrating COPD with a sensitivity of 72% and a specificity of 82.7%.[28]

In some instances asthma and COPD cannot be distinguished owing to significant overlap of symptoms, which is a term known as ACOS. In one of the questionnaires mentioned above, a score designated as overlap between asthma and COPD represented 20% of the population studied. Another recent study showed ACOS criteria to be present in 15% of a COPD cohort.[27,29,30]

Asthma	COPD
Onset early in life (often childhood)	Onset in mid-life
Symptoms vary from day to day	Symptoms slowly progressive
Symptoms at night/early morning	Long history of tobacco smoking
Allergy, rhinitis, and/or eczema sometimes present	Dyspnea largely owing to exertion
Family history of asthma usually present	Presence of comorbidities
Largely reversible airflow limitation	Largely irreversible airflow limitation

Adapted from the Global Initiative for Chronic Obstructive Lung Disease.[1]

While the patient described in the example above gives a medical history of asthma, her history, symptoms, and the results of her breathing tests suggest she is more likely to have COPD.

Bronchodilators produce smooth muscle relaxation, resulting in improved airflow obstruction, improved symptoms and exercise tolerance, and decrease in the frequency and severity of exacerbations, but they do not enhance survival. The results of the Lung Health Study,[22] which compared the effects of inhaled ipratropium bromide (two puffs four times daily) with placebo in patients with mild, stable COPD, showed that regular, long-term use of ipratropium did not change the rate of decline of lung function but offered a one-time, small increase in FEV_1. More recently, a study of tiotropium for mild to moderate COPD showed a higher FEV_1 than placebo at 24 months and decreased the rate of decline in FEV_1, suggesting that earlier use of bronchodilators may lead to some improvement of obstruction over time.[36]

MINI CLINI

Determining the Severity of Chronic Obstructive Pulmonary Disease

Problem

You are asked to see a new patient in clinic who was recently discharged from the hospital with a COPD exacerbation. The patient describes being hospitalized at least twice per year because of lung problems and complains of severe dyspnea when walking up a hill. Spirometry showed an FEV_1 of 40% predicted after bronchodilator. How do you characterize the severity of COPD in this patient?

Discussion

The GOLD has created a classification system based on the severity of airflow obstruction measured by post-bronchodilator FEV_1.[1] According to this staging system, severity of COPD is graded based on the degree of airflow obstruction into one of the following four stages:

Stage	Description
I	Patients with FEV_1/FVC <70% and FEV_1 >80% predicted
II	Patients with FEV_1/FVC <70% and FEV_1 50%–79% predicted
III	Patients with FEV_1/FVC <70% and FEV_1 30%–49% predicted
IV	Patients with FEV_1/FVC <70% and FEV_1 <30% or FEV_1 <50% predicted plus chronic respiratory failure

The original GOLD guidelines from 2001 were revised in 2011 to include symptoms and exacerbation history and, in the 2017 version of the GOLD guidelines, COPD severity is graded first by post-bronchodilator FEV_1 strata (previously mentioned) and then by a letter combination (A to D) that characterizes the patient's symptoms (based on the Modified Medical Research Council [mMRC] and the COPD Assessment Test [CAT, see later) and frequency of COPD exacerbations, as follows[31]:

A = Low risk, low symptom burden
- Low symptom burden (mMRC score of 0 to 1 OR CAT score <10) AND
- Low exacerbation rate (0 to 1/year, not leading to hospitalization)

B = Low risk, higher symptom burden
- Higher symptom burden (mMRC score of ≥2 OR CAT of ≥10) AND
- Low exacerbation rate (0 to 1/year, not leading to hospitalization)

C = High risk, low symptom burden
- Low symptom burden (mMRC score of 0 to 1 OR CAT score <10) AND
- High exacerbation rate (≥2/year or at least 1 exacerbation leading to hospitalization)

D = High risk, higher symptom burden
- Higher symptom burden (mMRC score of ≥2 OR CAT of ≥10) AND
- High exacerbation rate (≥2/year or at least 1 exacerbation leading to hospitalization)

The new classification categorizes patients first by spirometric features and then adds severity of symptoms and exacerbation history to refine risk. As mentioned above, this system uses two different scales to define symptom burden–the modified Medical Research Council questionnaire (mMRC)[32] and the CAT.[33]

mMRC

0: Dyspnea with strenuous exercise
1: Dyspnea when hurrying on the level or walking up a slight hill
2: Walks slower than most people on the level, stops after a mile or so, or stops after 15 min of walking at own pace
3: Stops for breath after walking 100 yards or after a few minutes of level ground
4: Too breathless to leave the house or breathless when undressing

CAT

- Cough (none to all the time): Total 0–5
- Phlegm (mucus) in my chest: Total 0–5 (none to severe)
- Chest tightness: Total 0–5 (none to severe)
- Dyspnea walking flight of stairs: Total 0–5 (none to severe)
- Limitation for home activities: Total 0–5 (none to severe)
- Confident leaving home despite lung condition: Total 0–5 (very confident to nonconfident)
- Sleep quality: Total 0–5 (sound sleep to no sleep because of lung condition)
- Energy: Total 0–5 (full energy to none)

Both anticholinergic and adrenergic (β agonist) bronchodilators can improve airflow in patients with COPD, although some clinicians favor an inhaled anticholinergic medication (e.g., ipratropium bromide or tiotropium[34,35]) as first-line therapy (see Fig. 25.6).

The GOLD guidelines[1] recommend the use of short-acting β-adrenergic agents (≤6 hours) for symptomatic management of all patients with COPD. Also, the use of a long-acting β agonist (e.g., salmeterol) or a long-acting anticholinergic drug (e.g., tiotropium) can lessen the frequency of acute exacerbations of COPD.[35]

Other treatment options to optimize lung function include administering corticosteroids. Chronic oral steroids are rarely recommended for patients with stable COPD, but are used commonly to treat acute exacerbations of COPD (see later).[37,38] Results of several major clinical trials (e.g., Lung Health Study II, Euroscop, Inhaled Steroids in Obstructive Lung Disease [ISOLDE] study, and Copenhagen City Study, but not another trial, Towards a Revolution in COPD Health [TORCH] study) agree that inhaled corticosteroids do not significantly change the rate of decline of FEV_1 in patients with COPD, although their use is associated with a decreased frequency of acute exacerbations.[39-42]

Studies of combined salmeterol and fluticasone versus placebo in patients with COPD suggest that adding an inhaled corticosteroid (fluticasone) to the long-acting β agonist (salmeterol) can reduce the frequency of acute exacerbations of COPD but does not improve survival.[39,40] The finding of a higher rate of pneumonia in inhaled corticosteroid users is concerning. Overall, the GOLD guidelines[1] recommend use of inhaled corticosteroids in patients with significant symptoms and history of recurrent exacerbations (three episodes in the last 3 years).

Treatment with a methylxanthine (like theophylline) offers little additional bronchodilation in patients using inhaled bronchodilators and is generally reserved for the few patients with debilitating symptoms from stable COPD despite maximal conventional therapy. Research has shown lessened dyspnea in methylxanthine recipients despite a lack of measurable increases in airflow.[43] Side effects of methylxanthines include anxiety, jitteriness (tremulousness), nausea, cardiac arrhythmias, and seizures. To minimize the chance of toxicity, current recommendations suggest maintaining serum theophylline levels at 8 to 10 mcg/mL.

In patients with frequent exacerbations of COPD, drugs to minimize the risk of exacerbation should be considered (see later).

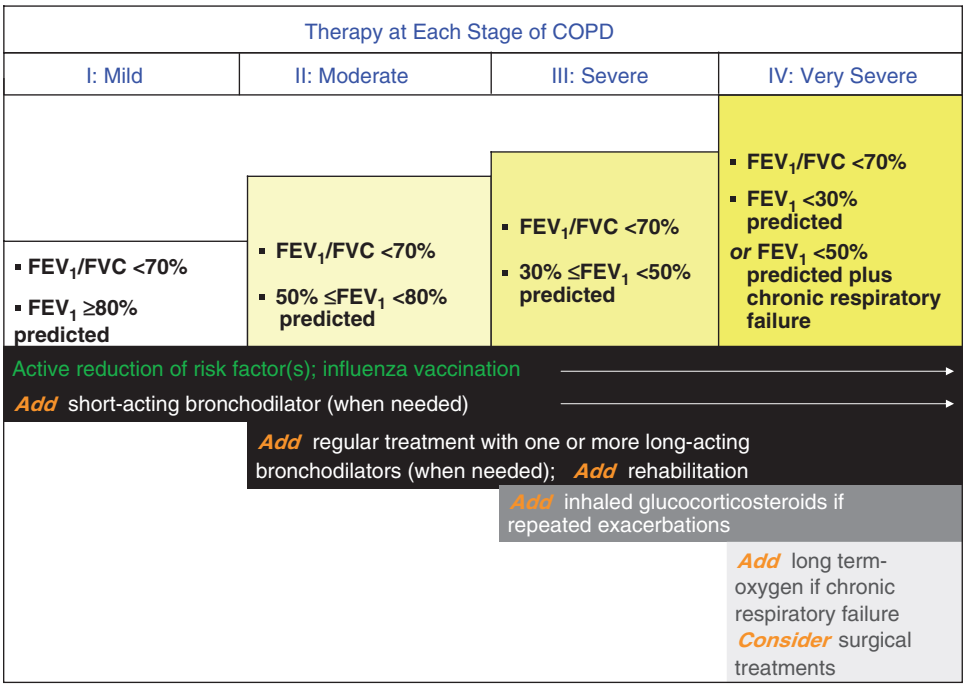


Fig. 25.6 Initial pharmacologic management of chronic obstructive pulmonary disease (COPD). *FEV_1*, Forced expiratory volume in 1; *FVC,* forced vital capacity. (From The Global Strategy for the Diagnosis, Management and Prevention of COPD: *Global Initiative for Chronic Obstructive Lung Disease [GOLD]*, 2018. http://www.goldcopd.com. Accessed May 22, 2018.)

In addition to drug therapy for COPD, non-invasive ventilation is being increasingly offered to patients with chronic hypercapnia accompanying stable COPD, with mixed data regarding effectiveness (see later and Chapter 50).

Acute Exacerbation of Chronic Obstructive Pulmonary Disease

Strategies for improving lung function during acute exacerbations of COPD generally include inhaled bronchodilators (especially β-2 agonists), antibiotics, and systemic corticosteroids. Owing to their rapid onset of action and efficacy, short-acting β-2 agonists are first-line therapy for patients with COPD exacerbation. Inhaled β-2 agonists are frequently administered through a nebulizer, although metered dose inhaler devices may have equal efficacy if administered appropriately.[1] A common practice is to administer 2.5 mg of albuterol by nebulizer every 1 to 4 hours as needed. Higher doses of albuterol (i.e., 5 mg) do not produce further improvement in pulmonary function and may cause cardiac side effects (like tachycardia).[44] Similarly, continuous nebulization of short-acting β-2 agonists in patients with COPD exacerbation is not recommended.

In addition to inhaled bronchodilator therapy, short-term systemic corticosteroids are recommended to reduce inflammation and improve lung function. An early randomized, controlled trial of intravenous methylprednisolone for patients with acute exacerbations showed accelerated improvement in FEV_1 within 72 hours.[45] Larger, more recent trials have confirmed the benefits of systemic corticosteroids in acute exacerbations and have shown that short-term oral courses (i.e., approximately 2 weeks) are as effective as longer courses (i.e., 8 weeks) with fewer adverse steroid effects.[46] More recent data show that for COPD patients with exacerbations presenting to the emergency room, 5 days of oral prednisone (40 mg/day) is as effective as 14 days of oral prednisone.[47]

For patients with acute exacerbations characterized by purulent phlegm, oral antibiotics (e.g., trimethoprim-sulfamethoxazole, amoxicillin, or doxycycline) administered for 7 to 10 days have produced accelerated improvement of peak flow rates compared with placebo recipients.[24,48,49] Owing to the risk of being infected with more virulent bacteria (e.g., *Pseudomonas aeruginosa*), patients who have severe COPD and an exacerbation may benefit from broader spectrum antibiotics, such as fluoroquinolones or aminoglycosides. Chapter 24 describes antibiotic therapy for these patients in more detail.

Finally, important elements of managing an acute exacerbation of COPD caused by purulent bronchitis include supplemental oxygen (O_2) to maintain arterial saturation 88% to 94%, inhaled bronchodilators, oral antibiotics, and a brief course of systemic corticosteroids.[24]

For patients with hypercapnia and acute respiratory acidemia accompanying an acute exacerbation of COPD, the clinician must also decide whether to provide ventilatory assistance. Although intubation and mechanical ventilation had historically been the preferred approach, more recent studies suggest that noninvasive positive pressure ventilation (see Chapters 46 and 50) can be an effective and the preferred alternative for patients with acute exacerbations of COPD.[50] Specifically, based on studies that show that noninvasive positive pressure ventilation can shorten intensive care unit (ICU) stay and avoid the need for intubation, the American Association for Respiratory Care

(AARC) consensus conference and guidelines on **noninvasive ventilation** from other official societies have endorsed use of noninvasive ventilation for such patients (unless a contraindication to noninvasive ventilation is present, see Chapter 50).[51,52]

Maximizing Functional Status

In symptomatic patients with stable COPD, maximizing their ability to perform activities of daily living is a priority. Pharmacologic treatments to maximize functional status include administration of bronchodilators to enhance lung function as much as possible, based on data that such drugs can lessen dyspnea and improve functional status ratings even though airflow is not increased.[2]

Comprehensive pulmonary rehabilitation is another important treatment for patients with COPD that has the goal of improving patients' ability to function.[53] As discussed in Chapter 56, pulmonary rehabilitation is a multidisciplinary intervention that consists of lower and upper extremity exercise conditioning, breathing retraining, education, and psychosocial support. Research suggests that although pulmonary rehabilitation does not improve lung function or survival, pulmonary rehabilitation results in decreased dyspnea perception, improved health-related quality of life, fewer days of hospitalization, and decreased health care usage. Pulmonary rehabilitation can be helpful in the early identification of COPD patients whose clinical status is deteriorating, so they can be quickly treated and the likelihood of hospital readmission reduced.[54,55]

Preventing Progression of Chronic Obstructive Pulmonary Disease and Acute Exacerbations, and Enhancing Survival

Cigarette smoking is widely recognized as the major risk factor for accelerating airflow obstruction in smokers. Although some individuals can continue to experience accelerated loss of lung function even after stopping smoking, smoking cessation can often slow the rate of decline of FEV_1 and restore the rate of lung decline to that seen in non-smokers.

Follow-up data from the Lung Health Study[13] confirm that a comprehensive smoking cessation program (including instruction, group counseling, and nicotine replacement therapy) can achieve sustained smoking cessation in 22% of participants and that the rate of annual FEV_1 decline in these sustained nonsmokers was significantly less than it was for continuing smokers, even over 11 years of follow-up.[14] Participation in aggressive smoking cessation can enhance survival rates in patients with COPD.[14]

Critical elements in achieving successful smoking cessation include identifying "teachable moments" (i.e., during episodes of illness in which smoking can be identified as a contributing factor[56]), identifying the role of smoking in adverse health outcomes, negotiating a "quit date," and providing frequent follow-up reminders from health care providers.[57] A helpful strategy during counseling is to use the five *A*s of smoking cessation[1]:

*A*sk if they are smoking
*A*dvise to quit
*A*ssess willingness to quit
*A*ssist by providing a plan
*A*rrange a follow-up

In this regard, the RT, who sees the patient frequently, has a special responsibility to provide frequent, constructive reminders about how very important it is to stop smoking.[58]

Among available treatments for COPD, **supplemental oxygen** is important because, similar to smoking cessation and lung volume reduction surgery (LVRS) in selected individuals, it can prolong survival in appropriate candidates.[59-62] Box 25.2 reviews the indications for supplemental O_2, and Fig. 25.7 shows the results of the American Nocturnal Oxygen Therapy Trial[59] and the British Medical Research Council trial of domiciliary O_2 (1980 to 1981).[60,61] Survival was improved when eligible patients used supplemental O_2 for as close to 24 hours as possible; survival improved less for patients using O_2 only 15 hours per day. No survival benefit was observed when O_2 was used during sleeping hours only. Patients should be assessed for supplemental O_2 use only after receiving optimal bronchodilator therapy because one-third of potential O_2 candidates can experience sufficient improvement with aggressive bronchodilation to avoid the need for

MINI CLINI

Recognizing and Managing an Acute Exacerbation of Chronic Obstructive Pulmonary Disease

Problem

A 70-year-old man with long-standing COPD is admitted to the hospital with an acute exacerbation. On physical examination, he is not dehydrated and examination shows diminished breath sounds bilaterally without wheezing. Pertinent laboratory values show a hematocrit of 54% (normal is 40% to 47%). An arterial blood gas (ABG) analysis performed with the patient on room air showed the following:

PaO_2 = 47 mm Hg
PCO_2 = 67 mm Hg
pH = 7.30
HCO_3^- = 34 mEq/L

How do you describe his current status, what do his current laboratory values suggest about his long-term gas exchange status, and what treatment should be considered?

Solution

The patient has an acute exacerbation of COPD. The acidemia (pH 7.30) on his ABG analysis suggests an acute increase in PCO_2 superimposed on chronic hypercapnia, which is suggested by the elevated serum bicarbonate (HCO_3^-), indicating renal compensation for chronic respiratory acidosis. Although his current hypoxemia may be caused by worsened gas exchange accompanying the current flare-up of COPD, his elevated hematocrit, in the absence of dehydration and consequent hemoconcentration, suggests chronic hypoxemia and secondary erythrocytosis. The goal of therapy is to restore his gas exchange to baseline and to avoid invasive or high-risk interventions, while optimizing survival.

To achieve these goals, treatment consists of aggressive use of bronchodilators, intravenous corticosteroids, supplemental O_2, and antibiotics (if there is evidence of acute lung infection, either bronchitis or pneumonia). In view of the patient's acute chronic respiratory acidemia, ventilatory support is indicated. As shown by several randomized, controlled trials, noninvasive positive pressure ventilation is an effective alternative to intubation.

BOX 25.2 Indications for Long-Term Oxygen Therapy

I. Continuous O_2
   A. Resting PaO_2 ≤55 mm Hg
   B. Resting PaO_2 56–59 mm Hg or SaO_2 89% in the presence of any of the following:
      1. Dependent edema, suggesting congestive heart failure
      2. P pulmonale on the electrocardiogram (P wave >3 mm in standard lead II, III, or aV_F)
      3. Erythrocytosis (hematocrit >56%)
         a. Reimbursable only with additional documentation justifying O_2 prescription and a summary of more conservative therapy that has failed

Modified from Tarpy SP, Celli BR: Long-term oxygen therapy. *N Engl J Med* 333:710–714, 1995.

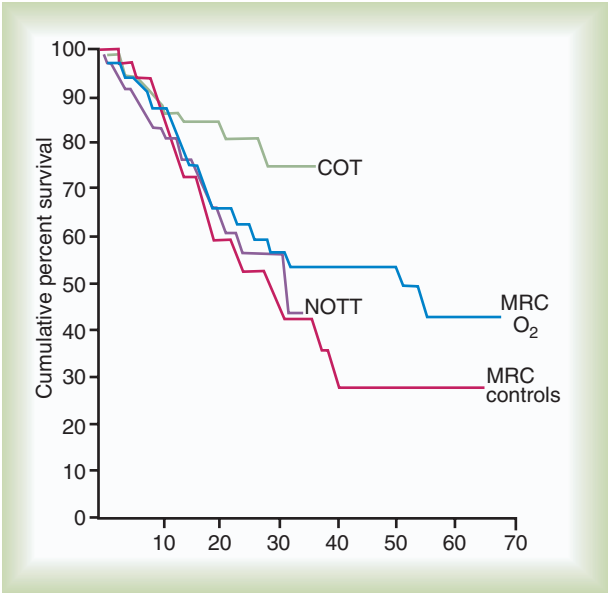

Fig. 25.7 Cumulative Percent Survival of Patients in the Nocturnal Oxygen Therapy Trial *(NOTT)* and Medical Research Council *(MRC)* Controlled Trials of Long-Term Domiciliary O_2 Therapy for Men Older Than 70 Years. MRC control subjects *(red line)* received no O_2. NOTT subjects *(purple line)* received O_2 for 12 hours in the 24-hour day, including the sleeping hours. MRC O_2 subjects *(blue line)* received O_2 for 15 hours in the 24-hour day, including the sleeping hours, and continuous O_2 therapy *(COT)* subjects *(green line)* received O_2 for 24 hours in the 24-hour day (on average, 19 hours). (Modified from Flenley DC: Long-term oxygen therapy. *Chest* 87:99–193, 1985.)

long-term supplemental O_2. Also, patients prescribed to receive supplemental O_2 during acute exacerbations should be reassessed several months later to determine whether they continue to need supplemental O_2.[63] RTs can play a key role in ensuring compliance with this recommendation and optimizing O_2 therapy.[64,65] Newer data from the Long-Term Oxygen Treatment Trial (LOTT)[66] address the role of supplemental O_2 in COPD patients with moderate resting hypoxemia (defined as SpO_2 at rest on room air of 89% to 93%) or with resting normoxemia but desaturation (to below SpO_2 of 90% for ≥ 10 seconds). In these patients randomized to supplemental O_2 (either 24 hours a day for those with moderate resting hypoxemia or with activity and sleep in those with exercise desaturation only), O_2 use neither showed benefit in decreasing time to death or first hospitalization nor in the rate of hospitalization, COPD exacerbation, COPD-related hospitalization, or various quality of life measures. In the light of the results of the LOTT trial, supplemental O_2 as close to 24 hours a day as possible remains indicated for COPD patients with severe resting hypoxemia (i.e., room air resting SpO_2 < 88%, PaO_2 < 55 mm Hg, or PaO_2 ≤59 mm Hg with cor pulmonale or polycythemia), but the indication for prescribing supplemental O_2 for those COPD patients with moderate resting hypoxemia or resting desaturation is weaker. Such treatment, if offered, should be individualized and continued only if there is clear subjective benefit to the patient.

BOX 25.3 Indications for 23-Valent Pneumococcal Vaccine Administration

Vaccination is recommended for the following adults:
- Adults age 65 years and older and adults of all ages with long-term illnesses that are associated with a high risk for contracting pneumococcal disease, including heart or lung diseases, diabetes, alcoholism, cirrhosis, or cerebrospinal fluid leaks
- Adults with diseases or conditions that lower the body's resistance to infections, including abnormal function of the spleen or removed spleen, Hodgkin disease, lymphoma, multiple myeloma, kidney failure, nephrotic syndrome, or organ transplantation, and adults who are taking drugs that lower the body's resistance to infections
- Adults with human immunodeficiency virus infection and acquired immunodeficiency syndrome (HIV/AIDS), with or without symptoms

Revaccination should be considered for the following groups:
- Individuals at the highest risk for fatal pneumococcal infection, such as individuals with abnormal function or removal of the spleen, who received the original pneumococcal vaccination (from 1979 to 1983) or who received the current vaccine (1983 to present) 6 years ago or longer
- Individuals shown to lose protection rapidly (e.g., individuals with nephrotic syndrome, kidney failure, or transplants), who received the current vaccine 6 years ago or longer
- Children 10 years old or younger with nephrotic syndrome, abnormal function or removal of the spleen, or sickle cell anemia, who received the vaccine 3–5 years ago
- Adults age ≥65 should also receive the 13-valent pneumococcal vaccine (Prevnar) followed 6–12 months later by the 23-valent vaccine (e.g., Pneumovax)

Finally, preventive strategies such as pneumococcal and annual influenza vaccinations, and other strict infection control practices such as avoiding contact with others who are sick, are recommended for all patients with chronic debilitating conditions such as COPD.[65] Specific indications for pneumococcal vaccination are presented in Box 25.3. Recommendations for those age 65 or older also include a 13-valent pneumococcal vaccine in addition to the existing 23-valent pneumococcal vaccine.

Other measures to prevent exacerbations of COPD include use of long-acting anticholinergic agents (e.g., tiotropium, aclidinium, umeclidinium), inhaled corticosteroids, especially in combination with long-acting β agonists, macrolide antibiotics (e.g., erythromycin and azithromycin),[67] phosphodiesterase-4 inhibition with roflumilast,[68] and antioxidants such as oral N-acetylcysteine.[69]

Noninvasive ventilation may offer a benefit to patients with chronic ventilatory failure accompanying COPD. When intensive noninvasive ventilation (titrated to lower $PaCO_2$, IPAP 22 to 24 cm H_2O, applied for at least 6 hours of the day) was instituted for patients with chronic hypercapnic respiratory failure owing to COPD, improved quality of life, reduced exacerbations and reduced mortality and readmissions were noted in two randomized control trials.[70,71] In another study, similar noninvasive ventilation regimen did not produce similar benefits when COPD patients were recruited at the time of an inpatient admission for hypercapnic respiratory failure.[72] Of note, 25% of those patients attained normal carbon dioxide levels after 3 months, suggesting the recruitment of a less severe group of patients for that trial.

Additional Therapies

Additional therapies for individuals with end-stage COPD include lung transplantation[73] and LVRS,[74-76] in which small portions of emphysematous lung are removed to reduce hyperinflation and improve lung mechanics of the remaining tissue. COPD is the most common current indication for lung transplantation. Lung transplantation is a consideration for patients with severe airflow obstruction (i.e., FEV_1 <20% predicted and a Body-mass index, Obstruction, Dyspnea, and Exercise [BODE] index >7 who are younger than 70 years old, and who are psychologically suitable and motivated). Double lung transplantation is preferred; nevertheless, because the supply of donor lungs to transplant is less than the number of patients needing lung transplantation, single-lung transplantation is also frequently performed. Although lung transplantation may be associated with significantly improved quality of life and functional status, major risks include rejection (manifested as bronchiolitis obliterans and progressive, debilitating airflow obstruction), infection with unusual opportunistic organisms, and death from these and other complications. The 5-year actuarial survival rate after lung transplantation in patients with COPD is approximately 54%[73] (Fig. 25.8).

LVRS has regained popularity after initial experiences were reported in 1957.[74] Study results of LVRS, including the large National Emphysema Treatment Trial, indicate that in selected subsets of patients with COPD (i.e., patients with heterogeneous emphysema that is upper lobe–predominant and who have low exercise capacity after pulmonary rehabilitation), LVRS can prolong survival, improve quality of life, and increase exercise capacity.[75,76] LVRS should not be considered in individuals with very severe COPD (i.e., characterized by FEV_1 <20% predicted with either a homogeneous pattern of emphysema or a diffusing capacity <20% predicted), because the mortality rate associated with LVRS in these patients is higher than in medically treated patients.[77]

Nonsurgical bronchoscopic techniques to achieve lung volume reduction have been developed in an attempt to reduce morbidity, mortality and cost. With the use of the bronchoscope,

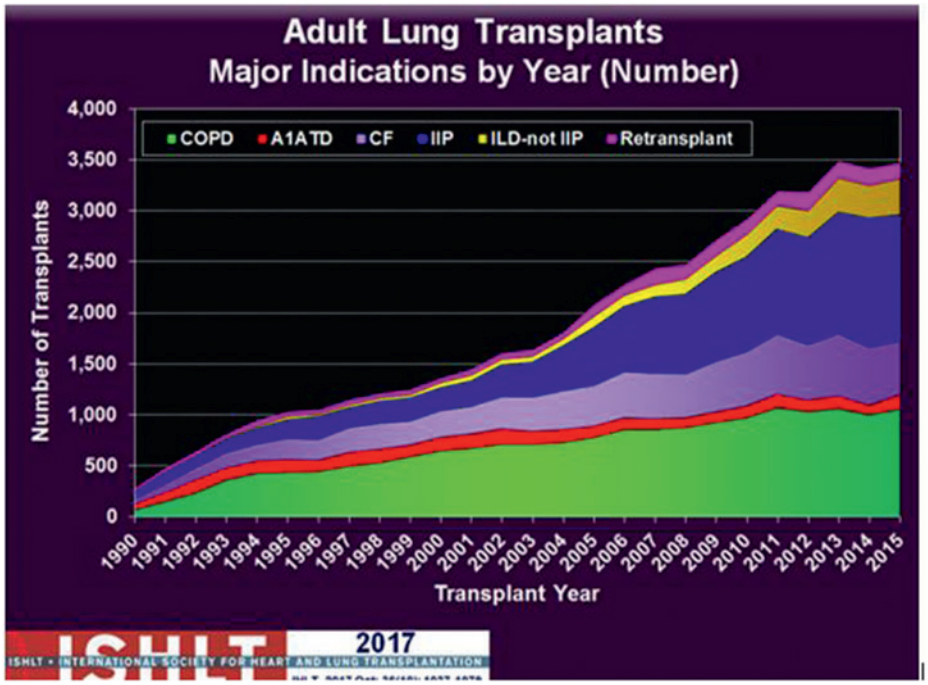

Fig. 25.8 Adult Recipient Kaplan-Meier Survival by Diagnosis (Transplants: January 1990 to June 2015). The overall survival rate of patients with alpha-1 antitrypsin deficiency is significantly higher than the survival rate of patients with chronic obstructive pulmonary disease *(COPD)* and interstitial lung disease *(ILD)*, which includes idiopathic pulmonary fibrosis (IPF). Similarly, the overall survival rate of patients with COPD is higher than the survival rate of patients with idiopathic pulmonary fibrosis. *AATD,* alpha-1 antitrypsin deficiency associated COPD; *COPD,* non-AATD associated COPD; *CF,* cystic fibrosis; IPAH, idiopathic pulmonary arterial hypertension. (From Yusen RD, Christie JD, Edwards LB, et al: *30th official adult lung and heart-lung transplant report, 2015 in the Registry of the International Society for Heart and Lung Transplantation*. http://www.ishlt.org. Accessed May 22nd 2018.)

deployment of unidirectional endobronchial valves or coils into the airways results in collapse of the targeted lung parenchyma.[78-82] Neither of these interventions are currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of emphysema in the United States. Updated GOLD guidelines recommend their consideration (where approved outside the United States) for the purpose of improving exercise tolerance, health status, and lung function at 6 to 12 months after treatment, although no mortality benefit has been shown in any studies.[1]

Finally, for patients with AAT deficiency and established COPD, so-called *intravenous augmentation* with a purified preparation of AAT from human blood donors is recommended.[18] The best available evidence[83-86] suggests that for individuals with severe AAT deficiency and moderate degrees of airflow obstruction (i.e., FEV_1 35% to 60% predicted), weekly augmentation therapy may be associated with a slower rate of decline of lung function, a slower rate of loss of lung density on chest CT, and improved survival. Difficulties with intravenous augmentation therapy include the substantial expense (approximately $100,000 per year); the inconvenience of frequent intravenous infusions for life; and the infusion itself, which poses a theoretical risk for transmitting a blood-borne infection. Despite these drawbacks, the facts that augmentation therapy may slow the rate of FEV_1 decline, slows the rate of CT lung density loss, and is currently the only specific therapy for AAT deficiency have led to its endorsement in official guidelines from the ATS, the European Respiratory Society (ERS), and the Canadian Thoracic Society.[18,87]

ASTHMA

Definition

Asthma is a clinical syndrome characterized by **airway obstruction,** which is partially or completely reversible either spontaneously or with treatment; **airway inflammation;** and **airway hyperresponsiveness** (AHR) to various stimuli.[88-90] Past definitions of asthma emphasized AHR and reversible obstruction; however, newer and more accurate definitions of asthma focus on asthma as a primary inflammatory disease of the airways, with clinical manifestations of increased airway hyperreactivity and airflow obstruction caused by the inflammation.

Incidence

Asthma is a chronic illness that has been increasing in prevalence in the United States since 1980. The number of people with asthma in the United States grew from 20 million in 2001 to 25 million in 2010 (8% of the U.S. population). According to data from the National Health Interview Survey performed by the Centers for Disease Control and Prevention in 2016, 20.4 million adults and 6.1 million children (8.3% of American children) reported having asthma. Asthma accounted for 1.7 million emergency room visits in 2015.[91] Asthma also accounted for 11 million outpatient visits in 2014, and approximately 3500 deaths in 2016.[92,93] An analysis from 1999 to 2016 showed that asthma mortality significantly decreased, which was felt to be the result of an improvement in asthma management and prevention measures.[94,95]

A study from 2011 to 2016 showed that among the 6.8% of working adults with asthma, 44.7% had experienced an asthma attack and 9.9% had an asthma-related emergency room visit. The highest prevalence was in the healthcare and social assistance industry (8.8%).[96]

Etiology and Pathogenesis

In the genetically susceptible host, allergens, respiratory infections, certain occupational and environmental exposures, and many unknown hosts or environmental stimuli can produce the full spectrum of asthma, with persistent airway inflammation, bronchial hyperreactivity, and consequent airflow obstruction. When inflammation and bronchial hyperreactivity are present, asthma can be triggered by additional factors, including exercise; inhalation of cold, dry air; hyperventilation; cigarette smoke; physical or emotional stress; inhalation of irritants; and pharmacologic agents, such as methacholine and histamine.[97-99]

When a patient with asthma inhales an allergen to which he or she is sensitized, the antigen cross-links to specific immunoglobulin E (IgE) molecules attached to the surface of mast cells in the bronchial mucosa and submucosa. The mast cells degranulate rapidly (within 30 minutes), releasing multiple mediators including leukotrienes (previously known as *slow-reacting substance of anaphylaxis* [SRS-A]), histamine, prostaglandins, platelet-activating factor, and other mediators. These mediators lead to smooth muscle contraction, vascular congestion, and leakage, resulting in airflow obstruction, which can be assessed clinically as a decline in FEV_1 or *peak expiratory flow rate* (PEFR) (Figs. 25.9 and 25.10). This is the *early (acute) asthmatic response*, which is an immediate hypersensitivity reaction that usually subsides in approximately 30 to 60 minutes. In approximately 50% of asthmatic patients, however, airflow obstruction recurs in 3 to 8 hours.[99] This *late asthmatic response* is usually more severe and lasts longer than the early asthmatic response (see Fig. 25.10).[100] The late asthmatic response is characterized by increasing influx and activation of inflammatory cells such as mast cells, eosinophils, and lymphocytes.[100,101]

Clinical Presentation and Diagnosis

The diagnosis of asthma requires a two-pronged approach of clinical assessment supported by laboratory evaluation. Because no single measurement can absolutely establish the diagnosis, and physical examination can be entirely normal between episodes, the history plays a key role in suggesting, and later establishing, the diagnosis of asthma. The classic symptoms of asthma are episodic wheezing, shortness of breath, chest tightness, and cough. The absence of wheezing does not exclude asthma, and sometimes a cough can be the only manifestation. Not all wheezing is due to asthma, however. Partial obstruction of the upper airway by tumors, laryngospasm, aspirated foreign objects, tracheal stenosis, fluid from left (congestive) heart failure or functional laryngospasm (vocal cord dysfunction) can mimic the wheezing of asthma.

Confirmation of the diagnosis of asthma requires demonstration of a component of reversible airflow obstruction. PFTs may be normal in asymptomatic patients with asthma, but more commonly they reveal some degree of airway obstruction

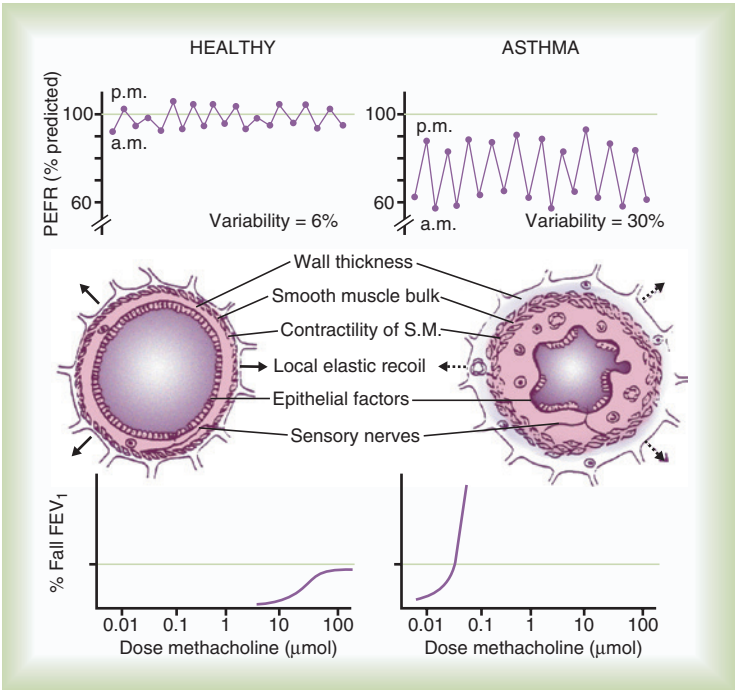

Fig. 25.9 Inflammation in Asthma. Cross sections of an airway from a healthy individual and a patient with asthma are shown. Multiple cells and multiple mediators are involved in asthma. Inflammatory cells, such as mast cells, eosinophils, lymphocytes, and macrophages, release a variety of chemical mediators, such as histamine, prostaglandins, and leukotrienes. These mediators result in increased wall thickness, airway smooth muscle hypertrophy and constriction, epithelial sloughing, mucus hypersecretion, mucosal edema, and stimulation of nerve endings. *Top,* Daily variability in peak airflow measurements. The normal increase in smooth muscle tone in the early morning, which causes airway narrowing in healthy individuals, is more exaggerated in asthmatics. *Bottom,* Dose-response curves to methacholine. *FEV_1*, forced expiratory volume in 1; *PEFR*, peak expiratory flow rate. (Modified from Woolcock AJ: Asthma. In: Murray JF, Nadel JA, editors: *Textbook of Respiratory Medicine*, Philadelphia, 1994, Saunders.)

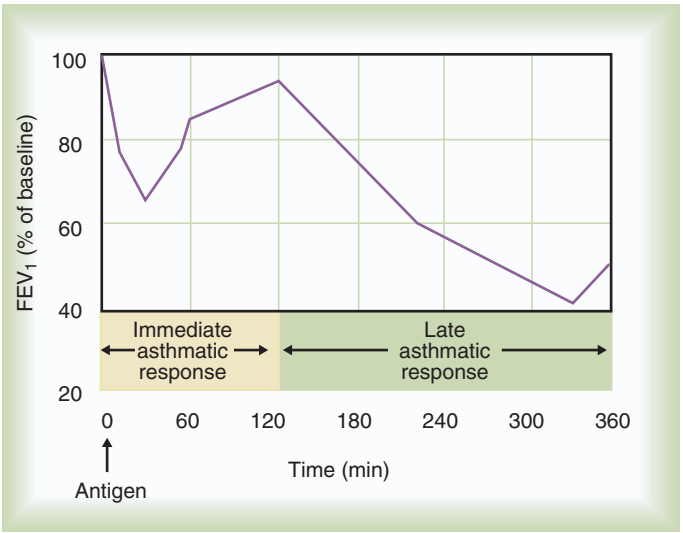

Fig. 25.10 Early and Late Asthmatic Responses. When a person with asthma is exposed to an allergen to which he or she is sensitized, the challenge results in a biphasic decline in respiratory function. An early asthmatic response occurs within minutes and usually subsides within 2 hours. In approximately half of asthmatic patients, a late asthmatic response occurs within 3 to 8 hours and may last for 24 hours or longer. *FEV_1*, Forced expiratory volume in 1. (Modified from Wiedemann HP, Kavuru MS: *Diagnosis and management of asthma*, Caddo, OK, 1994, Professional Communications.)

manifested by a decreased FEV_1 and FEV_1/FVC ratio. By convention, improvement in the FEV_1 by at least 12% and 200 mL after administration of a short-acting bronchodilator is considered evidence of reversibility. Spontaneous variation in self-recorded PEFR by 15% or more can also provide evidence of reversibility of airway obstruction. Elevated values of exhaled nitric oxide can also be used to support the diagnosis of asthma when eosinophilic inflammation is present.[102]

Patients with asthma evaluated in a symptom-free period may have a normal chest x-ray and normal PFTs. Under these circumstances, provocative testing can be used to induce airway obstruction. Bronchoprovocation is a well-established method to detect and quantify AHR. Pharmacologic agents, including acetylcholine, methacholine, histamine, cysteinyl leukotrienes, and prostaglandins, and physical stimuli such as exercise and isocapnic hyperventilation with cold, dry air have been used to detect, quantify, and characterize nonspecific AHR in asthma.

The most commonly used stimulus for bronchoprovocation is methacholine. The generally accepted criterion for hyperresponsiveness is a decrease in FEV_1 by 20% or more below the baseline value after inhalation of methacholine.

Elevated IgE levels and eosinophilia may be present in patients with asthma, but their presence is not specific and their absence does not exclude asthma, making them less useful for the diagnosis.[94-96] Although ABG analysis is not helpful or necessary

MINI CLINI

Recognizing Severity of Asthma

Problem

A 20-year-old woman with a diagnosis of asthma is seen in the outpatient clinic for increased dyspnea with exertion requiring daily use of short-acting bronchodilators. The patient complains of difficulty attending classes in college and wakes up a couple of times a week feeling short of breath. She describes two visits to the emergency department in the last 12 months because of asthma, requiring use of corticosteroids for a short period. Physical examination shows normal breath sounds bilaterally without wheezing. Spirometry shows FEV_1 of 78% predicted with FEV_1/FVC of 75%. How do you describe the severity of her asthma?

Solution

Classification of asthma severity is based on a combination of symptoms, medication requirements, and lung function. Although this patient has a spirometry consistent with mild airflow obstruction, her asthma is classified as moderately persistent because of the presence of daily symptoms, daily use of short-acting bronchodilators, frequent nighttime awakenings, limitation with normal activities, and history of exacerbations (see the following table).

Classification of Asthma Severity (Youths ≤12 Years of Age and Adults)

			PERSISTENT		
Components of Severity		**Intermittent**	**Mild**	**Moderate**	**Severe**
Impairment	Symptoms	≤2 days/wk	>2 days/wk but not daily	Daily	Throughout the day
FEV_1/FVC:	Nighttime awakenings	≤2 times/mo	3–4 times/mo	>1 time/wk but not nightly	Often 7 times/wk
18–19 years, 85%	Short-acting β-2 agonist use for	≤2 days/wk	>2 days/wk but not >1	Daily	Several times per day
20–39 years, 80%	symptom control (not prevention of		time/day		
40–59 years, 75%	exercise-induced bronchospasm)				
60–80 years, 60%	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	Normal FEV_1 between exacerbations	FEV_1 ≥80% predicted	FEV_1 ≥60% but <80% predicted	FEV_1 ≥60% predicted
			FEV_1/FVC normal	FEV_1/FVC reduced >5%	FEV_1/FVC reduced >5%
		FEV_1 >80% predicted			
		FEV_1/FVC normal			
		0–1/year	≥2/year		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category.			
Risk	Exacerbations requiring oral systemic corticosteroids	Relative annual risk for exacerbations may be related to FEV_1.			

in diagnosing asthma, it can be helpful in assessing the severity of an acute asthma attack.

A patient experiencing an acute asthma attack usually has a low $PaCO_2$ as a result of hyperventilation. A normal $PaCO_2$ in such a situation is concerning because it indicates a severe attack and potential impending respiratory failure.

Management

The goal of asthma management is to maintain a high quality of life for the patient, uninterrupted by asthma symptoms, side effects from medications, or limitations on the job or during exercise. This goal can be accomplished by preventing acute exacerbations, with their potential mortality and morbidity, or by returning the patient to a stable baseline when exacerbations occur. Asthma management relies on the following four important components recommended by the National Asthma Education Program (NAEP) expert panel[94]:

1. Objective measurements and monitoring of lung function
2. Pharmacologic therapy
3. Environmental control
4. Patient education

Table 25.2 outlines the stepwise approach currently recommended for long-term management of asthma. This approach provides a framework for adjusting the dose of medication based on the severity of asthma in any patient at a particular time. This approach also takes into consideration the fact that asthma is a chronic and dynamic disease, which needs optimum control. Control of asthma is defined as minimal to no chronic diurnal or nocturnal symptoms, infrequent exacerbations, minimal to no need for β-2 agonists, no limitation to exercise activity, PEFR or FEV_1 greater than 80% predicted with less than 20% diurnal variation, and minimal to no adverse effects of medication.[94-96]

Objective Measurement and Monitoring

Objective measurement of lung function is particularly important in asthma because subjective measures, such as patient reports of the degree of dyspnea and physical examination findings, often do not correlate with the variability and severity of airflow obstruction. Spirometry is recommended as part of the initial assessment of all patients being evaluated for asthma and periodically thereafter as needed.

Either spirometry or PEFR measurement can be used to assess response to therapy in the outpatient setting, emergency department, or hospital. NAEP guidelines also recommend that home PEFR measurement be used for patients with moderate to severe asthma.

When patients learn how to take PEFR measurements at home, the clinician is better able to recommend effective treatment.

TABLE 25.2 Stepwise Approach to Long-Term Management of Asthma Based on Severity

Severity[a]	Clinical Features Before Treatment[b]	PEFR or FEV_1	Long-Term Preventive Medications	Quick Relief Medications
Step 4				
Severe persistent	Continuous symptoms	≤60% predicted	Inhaled corticosteroids ≥800–2000 mcg/day	Inhaled β-2 agonist as needed for symptoms
Red zone	Frequent exacerbations Nocturnal symptoms Symptoms limit activity	>30% variability	Long-acting bronchodilator[c] Oral corticosteroids	
Step 3				
Moderate persistent	Daily symptoms	>60%–<80% predicted	Inhaled corticosteroids ≥800–2000 mcg/day	Inhaled β-2 agonist as needed for symptoms, not to exceed 3–4 times per day
Yellow zone	Exacerbations affect activity and sleep Nocturnal symptoms more than once per week Daily use of short-acting β-2 agonist	>30% variability	Long-acting bronchodilator,[c] especially for nocturnal symptoms	
Step 2				
Mild persistent	Symptoms at least once per week but less than once per day	≥80% predicted	Inhaled corticosteroid, 200–500 mcg/day	Inhaled β-2 agonist as needed for symptoms, not to exceed 3–4 times per day
Yellow zone	Exacerbations may affect activity or sleep Nocturnal symptoms more than twice per month	20%–30% variability	Long-acting bronchodilator[c] for nocturnal symptoms	
Step 1				
Intermittent	Intermittent symptoms less than once per week	≥80% predicted	None needed	Inhaled β-2 agonist needed for symptoms but less than once per week
Green zone	Nocturnal symptoms not more than twice per month Asymptomatic with normal lung function between exacerbations	<20% variability		Inhaled β-2 agonist before exercise or exposure to allergen

[a]*Step-down:* Review treatment every 3–6 months. If control is sustained for at least 3 months, consider a gradual stepwise reduction in treatment. *Step-up:* If control is not achieved, consider step-up, but first review patient medication technique, compliance, and environmental control.
[b]The presence of one of the features of severity is sufficient to place a patient in that category.
[c]Long-acting β-2 agonist.
FEV_1, Forced expiratory volume in 1; *PEFR*, peak expiratory flow rate.
Modified from National Asthma Education and Prevention Program: Expert panel report 3 (EPR-3): guidelines for the diagnosis and management of asthma—summary report 2007. *J Allergy Clin Immunol* 120(Suppl):S94–S138, 2007.

Though somewhat effort-dependent, daily monitoring of PEFR helps detect early stages of airway obstruction. All PEFR measurements are compared with the patient's personal best value, which can be established during a 2- to 3-week asymptomatic period when the patient is being treated optimally.[94-96]

To help patients understand home PEFR monitoring, a zonal system corresponding to the traffic light system may be helpful (see Table 25.2). A PEFR measurement of 80% to 100% of the personal best is considered to be in the *green zone*. No asthma symptoms are present, and maintenance medications can be continued or tapered. A PEFR in the 60% to 80% range of the personal best is in the *yellow zone* and may indicate an acute exacerbation and requires a temporary step-up in treatment. A PEFR less than 60% of the personal best is in the *red zone* and signals a medical alert, requiring immediate medical attention if the patient does not return to the yellow zone or green zone with bronchodilator use.[90]

Pharmacotherapy

Pharmacotherapy for asthma is detailed in Chapters 36 and 40; however, the foundation for such therapy includes antiinflammatory agents such as corticosteroids that suppress the primary disease process and its resultant airway hyperreactivity.[105] Bronchodilators such as β-2–adrenergic agonists and anticholinergics relieve asthma symptoms. Owing to the fact that asthma is a disease of the airways, inhalation therapy is preferred to oral or other systemic therapy. Inhaled therapy using metered dose inhalers or dry powder inhalers allows high concentration of the medication to be delivered directly to the airways, resulting in fewer systemic side effects. Spacer devices can be used to

MINI CLINI

Asthma Management

Problem

You are asked to see a new patient in clinic with a history of asthma. The patient is a 22-year old female who presents 4 weeks after a visit to the emergency room owing to an asthma exacerbation. She completed a course of oral corticosteroids and reports her symptoms have improved but she continues to have nighttime awakenings 2 times a week as well as having to use a short-acting β agonist daily. She is not currently on a maintenance inhaler. Further questioning reveals that she recently started working at a florist and she has 1 cat and 1 dog.

Discussion

Based on the patient's clinical symptoms she is classified as moderate persistent asthma (see Table 25.2), which warrants maintenance inhaler therapy. Initial pharmacologic therapy can include a low-dose inhaled corticosteroid plus a long acting β agonist, leukotriene receptor antagonist, or theophylline, or medium-dose inhaled corticosteroid (see Table 25.2).

The patient should also be assessed for inhaler technique, as well as undergo asthma education and peak flow monitoring. Adherence should be assessed because on average most asthma patients have an adherence of 22% to 63% for their maintenance inhalers.[103] Assessment for environmental control is important because the patient describes having pets as well as a possible occupational exposure. The patient should be assessed for allergies and comorbid atopic diseases such as allergic rhinitis. She should monitor peak flows in her home as well as at her job to assess for occupational asthma.

MINI CLINI

Diagnosis of Wheezing

Problem

You are asked to see a patient with a history of wheezing. The patient notes that the wheezing has been continuous, has been present for several months, and has not responded to bronchodilator medications, including systemic corticosteroids and various inhaled bronchodilators.

Solution

The patient has either refractory asthma or a condition mimicking asthma. The aphorism "all that wheezes is not asthma" applies here, and the clinician should suspect alternative diagnoses. Features that are atypical for asthma in this patient are the continuous nature of the wheezing and its complete refractoriness to medication. With this in mind, consideration of other "wheezy" disorders should include abnormalities of the upper airway. Specifically, tracheal stenosis or fixed upper airway obstruction (e.g., caused by tracheal tumors) could account for the patient's symptoms. Another condition that mimics asthma is vocal cord dysfunction. Characteristically, vocal cord dysfunction causes stridor with convergence of the vocal cords on inspiration (a paradoxical response); however, vocal cord dysfunction can also cause expiratory wheezing, with closure of the vocal cords on expiration. Further assessment of this patient might include a flow-volume loop or a flexible bronchoscopic examination of the upper airway, observing both the vocal cords and the trachea to the level of the main stem bronchi.

Another important disease that can mimic asthma is congestive heart failure (CHF), which has been known to cause "cardiac wheezing." Distinguishing heart failure from asthma can be challenging because patients with CHF may not only wheeze but also exhibit transient AHR. Patients with severe CHF have abnormalities on their PFT as well, such as restrictive defects, obstruction, or inspiratory muscle weakness.[104] To distinguish between asthma and CHF, a simple physical examination (e.g., looking for rales that would suggest CHF, edema) and a chest x-ray (which might show cardiomegaly or pleural effusions in CHF), or lack of improvement from bronchodilator therapy, are ways to help the clinician distinguish CHF from asthma.

improve delivery of inhaled medication, but training and coordination are still required for patients using metered dose inhalers. Table 25.3 lists commonly used medications in the treatment of asthma. See Chapter 36 for more details on pharmacotherapy and Table 25.4 for a summary of common medications in asthma.

Anti–Immunoglobulin E Therapy

IgE plays a key role in the pathogenesis of asthma, and many asthmatic patients have elevated levels of IgE.[113] Corticosteroids do not inhibit synthesis of IgE by activated lymphocytes. Omalizumab, an antibody that binds IgE and blocks its biologic effects, has been approved by the FDA for patients with a history of perennial allergy and with moderate to severe asthma that is poorly controlled with inhaled corticosteroids.[114] Studies have shown that treatment with omalizumab allows reduction of the dose of inhaled glucocorticoids required to control symptoms and also a decrease in the number of asthma exacerbation episodes.[115] For this reason, the NAEP asthma guidelines recommend that omalizumab should be considered as adjunctive therapy for patients with severe persistent asthma.[94]

Anti-Interleukin 5 Therapy

IL-5 is a cytokine that promotes eosinophilic inflammation of the airway. There are three approved agents that target IL-5 or its receptor to reduce the impact of IL-5: mepolizumab and reslizumab (anti-IL-5 monoclonal antibodies) and benralizumab (an anti-IL-5 receptor α antibody). Mepolizumab has been shown to decrease oral corticosteroid use and reduce exacerbations in patients with severe persistent asthma and an eosinophilic phenotype (i.e., asthma characterized by a high peripheral eosinophil count on blood testing). Currently, mepolizumab is FDA-approved for add-on maintenance treatment of severe persistent asthma, and the NICE (National Institute for Health and Care Excellence) guidelines recommend a threshold eosinophil count of >300/μL for its use. Reslizumab is also approved by the FDA as add-on maintenance treatment for severe eosinophilic asthma (eosinophil count >400/μL).[116-122]

Benralizumab is FDA-approved as add-on for severe eosinophilic asthma (>300/μL) as well. Benralizumab works in a slightly different way than the other two drugs, in that it blocks the IL-5 receptor on immune cells and is considered to be more effective in lowering the number of eosinophils. Benralizumab has also been shown to reduce asthma exacerbations.[123,124]

Emergency Department and Hospital Management of Asthma

Emergency management of acute asthma should include early and frequent administration of aerosolized β-2 agonists and therapy with systemic corticosteroids. Frequent assessment for response with PEFR should be performed. The NAEP guidelines recommend that only selective β-2 agonists (i.e., albuterol, levalbuterol, pirbuterol) should be used in high doses to avoid cardiotoxicity.[94]

TABLE 25.3 Medications Commonly Used in the Treatment of Asthma or Chronic Obstructive Pulmonary Disease

Medication	Trade Names	Available Preparations	Usual Dosage	Comment
Inhaled Corticosteroids (Single Medication)				
Beclomethasone	Qvar	MDI 40, 80 mcg/inh 120 inh/unit	40–320 mcg bid	
Budesonide	Pulmicort Flexhaler	DPI 90, 180 mcg/inh, 120 inh/unit	360–720 mcg bid	
	Pulmicort Nebulizer	0.25, 0.5, 1 mg/2 mL single-dose ampules	0.5–2 mg bid	
Ciclesonide	Alvesco	MDI 80, 160 mcg/inh, 60 inh/unit	80–320 mcg bid	
Flunisolide	Aerospan	MDI 80 mcg/inh, 120 inh/unit	160–320 mcg bid	
Fluticasone furoate	Arnuity	DPI 100, 200 mcg/inh, 30 inh/unit	100–200 mcg daily	
Fluticasone propionate	Flovent diskus	DPI 50, 100, 250 mcg/blister, 60 inh/unit	100–1000 mcg bid	
	Flovent MDI	MDI 44, 110, 220 mcg/inh, 120 inh/unit	88–880 mcg bid	
	ArmonAir Respiclick	DPI 55, 113, 232 mcg/inh, 60 inh/unit	55–232 mcg bid	
Mometasone furoate	Asmanex MDI	MDI 100, 200 mcg/inh, 120 inh/unit	200–400 mcg bid	
	Asmanex Twisthaler	DPI 110, 220 mcg/inh, 30, 60, 120 inh/unit	220–880 mcg once/day in evening or 220 mcg bid	
Inhaled Corticosteroids (Combined Medication)				
Budesonide and formoterol	Symbicort	MDI 80,160 mcg/4.5 mcg/inh 60, 120 inh/unit	2 inh bid	
Fluticasone furoate and vilanterol	Breo Ellipta	DPI 100, 200 mcg/25 mcg/inh 30 inh/unit	1 inh daily	
Fluticasone propionate and salmeterol	Advair diskus	DPI 100, 250, 500 mcg/50 mcg/blister, 60 inh/unit	1 inh bid	
	Advair HFA		2 inh bid	
	AirDuo Respiclick	MDI 45, 115, 230 mcg/21 mcg/inh 60, 120 inh/unit	1 inh bid	
		DPI 55, 113, 232 mcg/14 mcg/inh, 60 inh/unit		
Mometasone and formoterol	Dulera	MDI 100, 200 mcg/ 5 mcg/inh 60, 120 inh/unit	2 inh bid	
Systemic Corticosteroids				
Prednisone	Many	Tablets 1, 5, 20, 50 mg	5–50 mg/day	
Methylprednisolone	Medrol	Tablets 2, 4, 8, 16, 24, 32 mg	4–48 mg/day	
	Solu-Medrol	IV 40, 125, 500, 1000 mg	1–2 mg/kg q4–6h	
Hydrocortisone	Solu-Cortef	IV 100, 250, 500, 1000 mg	4 mg/kg q4–6h	
Short Acting β-2 Agonists (SABAs)				
Albuterol				
	ProAir HFA	MDI 90 mcg/inh, 200 inh/unit	1–2 inh q4–6h prn

	Bricanyl	Tablets 2.5, 5 mg	2.5–5 mg tid, maximum 15 mg/day	
		Solution 1 mg/mL	0.25 mg subcutaneously q15–30 min	

TABLE 25.3 MedicationsCommonly Used in the Treatment of Asthma or Chronic Obstructive Pulmonary Disease—*cont'd*

Medication	Trade Names	Available Preparations	Usual Dosage	Comment
Short-Acting β-2 Agonists/Short-Acting Antimuscarinic Combination (SABA/SAMA)				
Albuterol and ipratropium	Combivent Respimat Nebulizer	Respimat 100 mcg/20 mcg/inh, 120 inh/unit 2.5 mg/0.5 mg/3 mL solution	1 inh q6h prn 2.5/0.5 mg q6h as needed	
Long-Acting β-2 Agonists (LABAs)				
Arformoterol	Brovana	Solution 15 mcg/mL	15 mcg inhaled bid	
Formoterol	Perforomist Nebulizer	20 mcg/2 mL solution	20 mcg bid	
Indacaterol	Arcapta Neohaler	DPI 75 mcg/capsule, 30 inh/unit	1 inh daily	Not indicated in patients with asthma.
Olodaterol	Striverdi Respimat	Respimat 2.5 mcg/inh, 60 inh/unit	2 inh daily	
Salmeterol	Serevent Diskus	DPI 50 mcg/blister 28, 60 inh/unit	1 inh bid	
Short-Acting Antimuscarinic agents (SAMAs)				
Ipratropium bromide	Atrovent HFA Nebulizer	MDI 17 mcg/inh, 200 inh/unit 200 mcg/mL, 0.5 mg/2.5 mL vial	2 inh q6h prn 0.5 mg q6h prn	
Long-Acting Antimuscarinic Agents (LABAs)				
Aclidinium	Tudorza pressair	DPI 400 mcg/inh 30,60 inh/unit	1 inh/bid	M_2/M_3 muscarinic antagonist. Only approved for COPD.
Tiotropium	Spiriva Handihaler Spiriva Respimat	DPI 18 mcg/capsule 30, 90 inh/unit Respimat 2.5 mcg/inh 60 inh/unit	18 mcg daily (two inh of the contents of one capsule) 2 inh daily	
Umeclidinium	Incruse Ellipta	DPI 62.5 mcg/inh 30 inh/unit	1 inh daily	
Long-Acting Antimuscarinic Agent / Long-Acting β 2 Agonist Combination (LAMA/LABA)				
Glycopyrrolate and formoterol fumarate	Bevespi aerosphere	MDI 9 mcg/4.8 mcg/inh	2 inh bid	Not approved for patients with asthma.
Glycopyrrolate and indacaterol	Utibron Neohaler	DPI 15.6 mcg/27.5 mcg/capsule 60 inh/unit	1 inh bid	Not approved for patients with asthma.
Tiotropium and olodaterol	Stiolto Respimat	Respimat 2.5 mcg/2.5 mcg/inh, 60 inh/unit	2 inh daily	Not approved for patients with asthma.
Umeclidinium and vilanterol	Anoro Ellipta	DPI 62.5 mcg/25 mcg/inh, 30 inh/unit	1 inh daily	Not approved for patients with asthma.
Combined Medication (Anticholinergic + Long Acting β Agonist + Inhaled Corticosteroid)				
Fluticasone furoate and umeclidium and vilanterol	Trelegy Ellipta	DPI 100 mcg/62.5 mcg/25 mcg/inh	1 inh once/day	Not approved for asthma.
Methylxanthines				
Aminophylline		IV Tablets or capsules	Load 5–6 mg/kg, maintenance 0.5–0.9 mg/kg/h	
Theophylline	Theo-Dur Slo-bid Theovent Uniphyl (immediate or sustained release)		300–1200 mg/day divided q6–8h For immediate and q12–24h For sustained

TABLE 25.3 MedicationsCommonly Used in the Treatment of Asthma or Chronic Obstructive Pulmonary Disease—*cont'd*

Medication	Trade Names	Available Preparations	Usual Dosage	Comment
Leukotriene Inhibitors				
Zafirlukast	Accolate	Tablets 20 mg	20 mg bid	
Zileuton	Zyflo	Tablets 600 mg	600 mg qid	
Montelukast	Singulair	Tablets 10 mg	10 mg daily	
Other				
Roflumilast	Daliresp	Tablets 500 mcg	500 mcg/day 250 mcg/day for the first 4 weeks is FDA approved because it is shown to decrease rates of discontinuing the medication owing to side effects.	PDE-4 inhibitor. Primary use prevention of COPD exacerbations, not indicated for acute bronchospasm or asthma.
Azithromycin	Zithromax	Tablets 250 mg, 500 mg	250 mg/day	Macrolide antibiotic associated with reduction in number of COPD exacerbations.[a]
N-Acetylcysteine (NAC)	Mucomyst	Tablets 300 mg, 600 mg	1200 mg/day	High-dose NAC is associated with decrease in exacerbation frequency in patients COPD.[b]
Omalizumab	Xolair	150 mg/5 mL	150–375 mg subcutaneously every month	Anti-IgE therapy only approved for patients with moderate to severe asthma
Mepolizumab	Nucala	100 mg SC	100 mcg subcutaneously (SC) every 4 weeks	Anti-IL-5 therapy for severe asthma with eosinophilic phenotype
Reslizumab	Cinqair	3 mg/kg IV	3 mg/kg IV every 4 weeks	Anti-IL-5 therapy for severe asthma with eosinophilic phenotype
Benralizumab	Fasenra	30 mg SC	30 mg SC start every 4 weeks × 3 doses then every 8 weeks	Anti-IL-5 receptor α antibody for severe asthma with eosinophilic phenotype

Hospital and ICU care for patients with asthma should be aggressive. The goal is to decrease mortality and morbidity and to return the patient to preadmission stability and function as quickly as possible. Management includes supplemental O_2, as needed for hypoxemia periodic or short-term continuous administration of high doses of aerosolized β-2 agonists (limited only by tachycardia or tremor), high-dose parenteral corticosteroids (>0.5 to 1 mg/kg per day), and antibiotics if there is evidence of infection. Sedatives and hypnotics should be avoided. Symptoms, PEFR, and ABGs should be monitored.

For status asthmaticus, heliox (mixture of helium and O_2) can be combined with bronchodilator therapy. A pediatric study showed improved clinical asthma scores with this mixture, although the rates of emergency department discharge versus pediatric ICU admission were not significantly different.[125] As detailed in Chapters 6 and 42, the driving pressure is lowered in the large airways when a low density gas mixture is used, such as helium. Heliox-powered nebulization improves aerosol deposition owing to a reduction in turbulence, and the low density of helium allows the gas flow to be increased from 6 L/min to 10 to 12 L/min.

Patients with severe asthma and respiratory failure (hypoxemia, hypercapnia, increased work of breathing) need ventilatory support and present special challenges. Mortality rates for these patients can reach 22%, and complications are common, especially barotrauma. These complications can be minimized by reducing plateau pressure to <28 cm H_2O and driving pressure to <15 cm H_2O and by using small tidal volumes, allowing "permissive hypercapnia" if necessary.

Intravenous magnesium sulfate has bronchodilating properties and has been shown to improve pulmonary function in patients with severe asthma.[126] Other adjunctive therapies for status asthmaticus include inhalational anesthetic agents like isoflurane or halothane, which are known to bronchodilate, although these have never been evaluated in randomized clinical trials.[127]

TABLE 25.4 Summary of Common Medications Used in Asthma

Medication	Mechanism	Adverse Reactions/Side Effects
Inhaled corticosteroids (ICS)	First line for moderate persistent asthma. Act on various components of the inflammatory response in asthma. Decrease bronchial hyperreactivity and airflow obstruction. Reduce symptoms and mortality from asthma.[105]	Long-term high-dose ICS have fewer side effects than oral corticosteroids. Side effects like oropharyngeal candidiasis and dysphonia and controllable with spacer and rinsing the mouth after each treatment. Other side effects include skin bruising, increased risk for glaucoma and cataracts.
Oral corticosteroids	Effective to reduce the severity and duration of an asthma exacerbation, decrease emergency room visits and hospitalization, and reduce mortality.[105] Should be avoided as a long-term therapy owing to risk of side effects. If giving long-term, can consider antibiotic prophylaxis.	Skin bruising, risk for glaucoma and cataracts, osteoporosis, adrenal suppression, immunosuppression.
Leukotriene inhibitors (montelukast, zafirlukast, zileuton)	Mediators of inflammation and bronchoconstriction that play a role in the pathogenesis of asthma. Are all modestly effective for maintenance of mild to moderate asthma, but do not cause bronchodilation. Helps to reduce ICS dose especially in the treatment of children.[106,107]	Headaches, hypersensitivity reaction, influenza-like syndrome. May cause or "unmask" the diagnosis of eosinophilic granulomatosis with polyangiitis.[108]
β-2 adrenergic agonists	The most rapid and effective bronchodilators for treating acute bronchospasm, and can be given prophylactically for bronchoconstrictor challenges like exercise. They act by attaching to β receptors and cause smooth muscle relaxation and block mediator release from mast cells.	Do not prevent the late asthmatic response. Long-acting should not be used alone for maintenance therapy and must be combined with an ICS owing to concern for increased risk of death,[94-96,109-111] although short-acting β agonists remain safe.[101,103,105]
Methylxanthines (theophylline)	Added to long-term asthma management therapy and may be helpful in controlling nocturnal symptoms.	Efficacy limited by side effects of nausea, vomiting, headache, insomnia, seizures, and cardiac arrhythmias. Toxicity increases with blood levels greater than 15 mcg/mL. Levels of 8–10 mcg/mL are adequate for long-term therapy and associated with fewer side effects. Conditions that increase levels include acute viral infections, cardiac failure, hepatic disease, and use of medications like erythromycin or cimetidine. In these cases, the maintenance dose should be halved and blood levels monitored. Conditions that decrease levels include cigarette smoking and medications that increase hepatic clearance, like phenobarbital.[94-96]
Short-acting antimuscarinic agents (ipratropium)	Bronchodilates by reduction of intrinsic vagal tone and blocking vagal reflex. Adds bronchodilator affect to β 2 agonists and useful for treating cough-variant asthma.	Does not stabilize mast cells or prevent mediator release. Less potent of a bronchodilator than β 2 agonist.
Long-acting antimuscarinic agents (tiotropium)	Been shown to enhance asthma control (e.g., improved peak expiratory flow, increased FEV_1, and improved symptoms) when added to an inhaled corticosteroid compared with doubling the inhaled steroid dose.[112]	

FEV_1, Forced expiratory volume in 1.

When asthma control is achieved, hospital discharge criteria include not needing supplemental O_2; having a PaO_2 greater than 60 mm Hg and a stable PEFR or FEV_1, with values close to the patient's best or >70% of predicted; feeling that asthma symptoms are returning to preadmission levels and are not occurring at night; and 12- to 24-hour stability on discharge medications.[94-96]

RULE OF THUMB In a patient presenting with an acute asthma attack, $PaCO_2$ is usually low because of hyperventilation. A normal $PaCO_2$ in this situation indicates a severe attack and potential impending respiratory failure.

Bronchial Thermoplasty

Bronchial thermoplasty is an approved addition to treatment options for adults whose asthma remains uncontrolled despite use of inhaled steroids and long-acting β agonists.[128] Bronchial thermoplasty is a procedure in which a probe is introduced into the central airways through a bronchoscope and heat is applied (through radiofrequency waves) to airways of 3 to 10 mm diameter with the goal to reduce the airway smooth muscle mass, reducing the ability of the airways to constrict. Studies have shown that bronchial thermoplasty, in selected patients with documented airway hyperreactivity and FEV_1 >60%, improves asthma-specific quality of life and reduces the number of severe asthma exacerbation episodes and emergency department visits.[129,130] Moreover, data suggest that these effects are long-lasting (approximately 5 years) with regard to both asthma control (based on maintained reduction in severe exacerbations and emergency department visits for respiratory symptoms) and safety.[131] Bronchial thermoplasty was approved for use by the FDA in 2010. Bronchial thermoplasty is performed in specialized centers and a registry is maintained to understand the outcomes of patients who underwent this novel procedure.[132]

MINI CLINI

Assessing the Severity of an Acute Asthma Attack

Problem

You have just obtained an ABG analysis on a patient who sought treatment at the emergency department for an acute attack of asthma. How would the ABG analysis help you assess the severity of the attack?

Solution

In the early stages of an asthma attack, the ABG analysis shows a low $PaCO_2$ caused by hyperventilation. As the asthma attack progresses and the FEV_1 decreases to <25% of predicted, the $PaCO_2$ returns to normal. When the FEV_1 decreases to <15% of predicted, carbon dioxide retention begins to occur. Changes in the pH reflect changes in the $PaCO_2$ level. The following table summarizes the ABG abnormalities based on the severity of an asthma attack:

Asthma Attack Severity	Stage	PaO_2	$PaCO_2$	pH
Mild	I	Normal	Decreased	Increased
Moderate	II	Decreased	Decreased	Increased
Severe	III	Decreased	Normal	Normal
Very severe (respiratory failure)	IV	Decreased	Increased	Decreased

Immunotherapy

Immunotherapy (called "allergy shots" by patients) is based on the theoretical rationale that part of the immunologic response to an administered allergen is the production of an IgG-specific antibody to the allergen injected. This newly generated IgG does not affix to most cells but can react with the allergen diffusing into the tissues and "neutralize" it. Although immunotherapy is acceptable in the treatment of allergic rhinitis, its use in the treatment of asthma is not standardized and remains controversial; however, a meta-analysis of 88 randomized controlled trials of injection allergen immunotherapy for asthma reported that immunotherapy is effective, with evidence of significant reductions in asthma medications and symptoms and a reduction in the degree of bronchial hyperreactivity.[133]

Environmental Control

The association between asthma and allergy has long been recognized. Among patients with asthma, 75% to 85% are reported to have positive immediate skin test reaction to common inhalant allergens. A thorough history is essential to diagnosing whether a patient's asthma has an allergic component and determining the relationship between exposure to an allergen and the occurrence of symptoms. Skin tests are more helpful for excluding an allergen as a cause of asthma symptoms because clinical sensitivity to an aeroallergen is rare in the absence of a positive skin test, whereas many positive skin tests do not have clinical relevance.

To prevent allergic reactions in patients with asthma, environmental control measures to reduce exposure to indoor and outdoor allergens and irritants are essential. Patients should be advised to avoid outdoor antigens, primarily ragweed, grass, pollens, and molds. Exposure to outdoor allergens is best reduced by staying indoors with the windows closed, in an air-conditioned environment, particularly during the midday and afternoon, when pollen and some mold counts are highest. Patients who are allergic to indoor allergens, primarily house-dust components and indoor molds, should take steps to eliminate these allergens from the home environment (e.g., single-room air purifier). All warm-blooded pets, including small rodents and birds, should be removed from the house because they produce dander, urine, and saliva that can cause allergic reactions. House-dust mites depend on atmospheric moisture and human dander for survival. Essential house-dust mite control measures include encasing mattresses and pillows in airtight covers, washing the bedding in water of 130°F weekly, avoiding sleeping on upholstered furniture, and removing carpets that are laid on concrete.

Additional helpful control measures include reducing the indoor humidity to less than 50%, removing carpets from the bedroom, and using chemical agents to kill mites. Indoor air-cleaning devices, especially high-efficiency particulate air/aerosol filters, may be useful, but they cannot substitute for controlling the allergen source. Humidifiers are potentially harmful because they can harbor and aerosolize mold spores, and the increased humidity they generate may encourage production of both mold and house-dust mites.[94-96]

Patient Education

With close back-up by the informed physician, RT, or nurse, much of the day-to-day responsibility for managing asthma falls on the patient and the patient's family. Patient education is a powerful motivational tool, helping patients attain the skills and gain the confidence to control their asthma. Patient education involves helping patients understand asthma and learning and practicing the skills necessary to manage it. Patient education includes providing information; developing a partnership with the patient; involving the patient in decision-making; and demonstrating and observing asthma management practices such as the proper use of inhalers, nebulizers, and peak flowmeters.[109]

Special Considerations in Asthma Management

Special considerations in treating asthma (e.g., during pregnancy, with gastroesophageal reflux) are summarized in Table 25.5. Other occupational causes of asthma are listed in Table 25.6.

BRONCHIECTASIS

Clinical Presentation

Bronchiectasis refers to the abnormal, irreversible dilation of the bronchi caused by destructive and inflammatory changes in the airway walls. Bronchiectasis has the following three major anatomic patterns[138]:

1. *Cylindrical bronchiectasis:* Airway wall is regularly and uniformly dilated
2. *Varicose bronchiectasis:* Irregular pattern, with alternating areas of constriction and dilation
3. *Cystic bronchiectasis:* Progressive, distal enlargement of the airways, resulting in saclike dilations

Bronchiectasis is thought to result from damage to the bronchial wall by chronic inflammation. Predisposing conditions are listed in Box 25.4.

TABLE 25.5 Special Types of Asthma and Comorbidities/Situations Associated With Asthma

Type	Definition	Management
Exercise-induced asthma	Common in asthmatics especially after participation in outdoor activities with cold weather. May be related to heat loss from the airways.[100]	Prophylactic use of a short-acting β agonist.[134,135] Can consider adding a leukotriene inhibitor.[94,95]
Occupational asthma	2%–5% of all asthma episodes may be caused by exposure to a specific sensitizing agent in the workplace. Defined as variable airflow limitation or AHR caused by causes and conditions attributable to the work environment and not to stimuli encountered outside the workplace. Toluene diisocyanate is the most common cause of occupational asthma and is the best studied. Other causes of occupational asthma are listed in Table 25.6.	The treatment of occupational asthma is identical to treatment of other types of asthma; however, early diagnosis is important and in environmental control with cessation of exposure is key. Complete elimination of exposure is usually necessary because once sensitization has occurred, bronchoconstriction can be triggered by minimal subsequent exposure.[95,100]
Cough-variant asthma	Coughing may be the only complaint of patients with asthma. In such patients, the cough may be relieved by a bronchodilator or by avoiding inhaled allergens. If bronchospasm is not present at the time of examination and spirometry is normal (which is often the case), the diagnosis can be confirmed by showing reversible airway obstruction by a methacholine challenge test or suggested by elevated levels of exhaled NO.[102]	Ipratropium bromide may be particularly helpful in the treatment of cough-variant asthma. Otherwise, treatment is the same as other types of asthma.
Nocturnal asthma	Also known as nighttime asthma, which is a characteristic problem in poorly controlled asthma and is reported by more than two-thirds of patients who receive treatment that is less than ideal. Likely is caused by the known physiologic decrease in the airway tone during sleep, which has been attributed to variation in catecholamine and cortisol secretion. Aspiration of gastric acid may also play a role in some patients with increased symptoms at night.	After ensuring adequate antiinflammatory therapy, medications should be focused toward the night and especially the early morning hours, when the airway tone is lowest. Sustained-release theophylline and long-acting β-2 agonists such as salmeterol are particularly helpful for controlling nocturnal asthma symptoms.[94] Addition of a proton pump inhibitor medication such as esomeprazole has not been shown to enhance asthma control.[136]
Aspirin sensitivity	At least 5% of adults with asthma experience severe and even fatal exacerbation of asthma after taking aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs). Many of these patients have nasal polyps, although the relationship is not causal. The presumed mechanism is the inhibition of the cyclooxygenase pathway by aspirin and NSAIDs, with shunting of arachidonic acid into the 5-lipoxygenase pathway, causing overproduction of bronchoconstrictor leukotrienes.	Individuals with asthma should avoid aspirin and nonsteroidal antiinflammatory drugs (NSAIDs, e.g., ibuprofen) and instead use alternatives such as acetaminophen. Patients should be informed that many over-the-counter medications contain aspirin and should be avoided as well.[94,100]
Asthma during pregnancy	During pregnancy, one-third of patients have worse control of their asthma, one-third have better control, and one-third are unchanged. The potential threat of adverse effects from asthma medications is far outweighed by the danger of uncontrolled asthma to the fetus and mother. Poorly controlled asthma during pregnancy can cause increased pre-eclampsia, perinatal mortality, increased prematurity, and low birth weight.	Patients should be counseled about the importance of continuing their medication to maintain good asthma control during pregnancy because several studies have shown that pregnant mothers tend to reduce their asthma medications during pregnancy. β-2 agonists, inhaled or oral corticosteroids can be used during pregnancy without significant risk for fetal abnormalities.[137]
Gastro-esophageal Reflux	The relationship between asthma and gastroesophageal reflux is controversial, although reflux is nearly three times more prevalent in patients with asthma than in persons without asthma. Presumably, acid reflux into the esophagus causes vagal stimulation, resulting in a reflex increase in bronchial tone in patients with asthma.	Patients should be counseled on lifestyle modifications to improve their reflux as well as consider elevating the head of their bed at night. Routine addition of a proton pump inhibitor to an asthma regimen has not been shown to enhance asthma control significantly.[136]
Sinusitis	Acute sinusitis and chronic sinusitis have been related to exacerbations and poor control of asthma by causing postnasal drip and interfering with nasal patency.	A limited CT scan of the sinuses can be considered for patients with uncontrolled asthma. If sinusitis is present, therapy with antibiotics for 2–3 weeks, nasal decongestants, and nasal corticosteroid inhalers may help improve asthma control.[94,100]
Surgery	Patients with asthma are predisposed to respiratory complications after surgery, including respiratory arrest during induction of anesthesia, hypoxemia and possible hypercapnia, impaired effectiveness of cough, atelectasis, and respiratory infection. The likelihood of these complications depends on the severity of the patient's airway hyperreactivity, the degree of airflow obstruction, and the amount of excess airway secretions at the time of surgery.	Optimizing the patient's lung function before surgery, including the administration of perioperative corticosteroids, is an important strategy for minimizing perioperative complications.[94,100]

AHR, Airway hyperresponsiveness.

TABLE 25.6 Occupational Causes of Asthma

Occupation or Industry	Agent
Laboratory animal workers, veterinarians	Animals (dander, urine protein)
Food processing	Shellfish, egg proteins, pancreatic enzymes
Dairy farming	Storage mites
Poultry farming	Poultry mites, droppings, feathers
Detergent manufacturing	*Bacillus subtilis* enzymes
Baking	Flour
Sawmill workers, carpentry	Wood dust (western red cedar, oak, mahogany, zebrawood, redwood)
Nursing	Psyllium
Refining	Platinum salts
Plating	Nickel salts
Stainless steel welding	Chromium salts
Cosmetology	Persulfate
Refinery workers	Vanadium
Rubber processing	Formaldehyde, ethylenediamine
Plastics industry	Toluene diisocyanate, trimellitic anhydride

BOX 25.4 Causes of Bronchiectasis

Local Bronchiectasis
- Foreign body
- Benign airway tumor (e.g., adenoma)
- Bronchial compression by surrounding lymph nodes (e.g., middle lobe syndrome)

Diffuse Bronchiectasis
- Cystic fibrosis
- Ciliary dyskinesia disorders (e.g., Kartagener syndrome, Young syndrome)
- Hypogammaglobulinemia
- Alpha-1 antitrypsin deficiency
- Allergic bronchopulmonary aspergillosis
- Rheumatoid arthritis
- Sjogren syndrome
- Serious childhood lung infection (e.g., from whooping cough, measles, or influenza)

Evaluation

The hallmark of bronchiectasis is the chronic production of large quantities of purulent sputum, often following repeated respiratory infections such as those associated with cystic fibrosis. Dyspnea is variable and depends on the extent of involvement and the underlying disease. Hemoptysis occurs frequently and is usually mild, but severe hemoptysis can be seen. Radiographic studies confirm the diagnosis by showing airway dilation. A chest x-ray may show cystic spaces and tram tracks (thin parallel lines representing the airway walls). CT is the diagnostic standard for bronchiectasis; the diagnosis of bronchiectasis is established when the diameter of the bronchus exceeds the diameter of the adjacent pulmonary artery branch.[139] Owing to the fact that reversible airway changes consistent with bronchiectasis can follow pneumonia, CT should be deferred for 6 to 8 weeks after pneumonia resolves. Only then can a diagnosis of bronchiectasis be made with confidence.

Management

Antibiotics and bronchopulmonary hygiene are the mainstays of bronchiectasis management. Antibiotics can be given as needed or following a regularly scheduled regimen. Sputum cultures may be helpful in guiding antibiotic choice. Inhaled aminoglycosides may be a useful option for patients with chronic colonization by *P. aeruginosa*. Additionally, inhaled fluoroquinolones (e.g., ciprofloxacin) are currently being evaluated in patients with cystic fibrosis and non-cystic fibrosis bronchiectasis.[140] Infection by *P. aeruginosa* in patients with bronchiectasis is a marker of severity but is not linked to accelerated decline in pulmonary function.[141] Secretions can be cleared by chest physiotherapy with postural drainage, cough maneuvers, and humidification. While high-frequency chest wall oscillation vest therapy is standard of care for cystic fibrosis (CF), it has also shown some benefit in small studies of non-CF bronchiectasis for improving symptoms of breathlessness, cough and ease of sputum expectoration; some, but not all, studies have shown an improvement in FEV_1 as well. Typically, the vest treatment—which produces high-frequency, small-volume oscillations in the airways that help mobilize secretions—is given for 20 to 30 minutes twice a day.

Inhaled bronchodilators may be helpful in some patients because accompanying airflow obstruction is common, and β agonists like albuterol and salmeterol improve mucociliary clearance.[138,142] Inhaled hyperosmolar saline or mannitol may be helpful in clearing secretion in patients with bronchiectasis. A literature review concluded that dry powder mannitol improves tracheobronchial clearance in patients with bronchiectasis, patients with cystic fibrosis, those with asthma, and normal individuals.[143] Hypertonic saline has been studied to a limited extent in bronchiectasis and may be helpful. In cases that are complicated by massive hemoptysis, embolization of the bleeding bronchial artery may be helpful. Surgical resection should be reserved for the few patients with localized areas of bronchiectasis who develop massive hemoptysis or who are severely symptomatic despite appropriate medical therapy.[144-146]

ROLE OF THE RESPIRATORY THERAPIST IN OBSTRUCTIVE LUNG DISEASE

RTs play key roles in all aspects of managing patients with obstructive lung diseases; they are involved in diagnosis, acute treatment, and follow-up and monitoring. In diagnosing obstructive lung diseases, RTs often perform the lung function testing that indicates the presence of airflow obstruction that is essential for diagnosis. Because of their close involvement with patients, RTs also play important roles in recognizing clinical features such as the presence of copious secretions, hemoptysis, or other findings that may eventually lead to a confirmed diagnosis of bronchiectasis, asthma, or COPD.[147] RTs have been shown specifically to enhance the diagnosis of **alpha-1 antitrypsin deficiency** by informing patients in the Pulmonary Function Laboratory with fixed airflow obstruction or COPD patients in rehabilitation about the recommendation to be tested and the means to do so. In the current environment of value-based care in which all

healthcare providers must function at the "top of their license," RTs are increasingly at the front line of diagnosis and may be the first healthcare provider that patients see in evaluation for dyspnea.[148]

In acute management, hospital-based RTs often administer medications and therapies to patients with acute exacerbations of asthma or COPD. Examples include the delivery of bronchodilators in small-volume nebulizers, administration of chest physiotherapy in the management of bronchiectasis, and setup of supplemental O_2. For patients with severe exacerbations, ICU management of arterial lines, blood gases, and mechanical ventilation (with both noninvasive and conventional mechanical ventilation) usually involves RTs in key management roles. In managing patients with bronchiectasis, RTs are pivotal in administering chest physiotherapy and instructing in the use of flutter valves and percussive vests that may be critical parts of acute management.

Finally, in follow-up of patients with obstructive lung diseases, RTs are involved in counseling (e.g., smoking cessation, medication management), administering pulmonary rehabilitation programs, and certifying and recertifying long-term supplemental O_2 therapy. RTs working in home care may conduct home visits to patients and set up and adjust equipment in the home. This description of activities of the RT in care of the patient with obstructive lung disease demonstrate that RTs are indispensable caregivers for patients with asthma, COPD, and bronchiectasis and that the care of patients with obstructive lung diseases constitutes a major component of RTs' activities.

SUMMARY CHECKLIST

- The spectrum of obstructive lung diseases includes COPD (consisting of emphysema and chronic bronchitis), asthma, and bronchiectasis. Airflow obstruction may be a feature of other lung diseases as well, such as sarcoidosis, and congestive heart failure.
- COPD features persistent airflow obstruction despite therapy.
- Classically, asthma causes airway obstruction that is fully reversible with therapy and features symptoms such as episodic wheezing, shortness of breath, chest tightness, and cough.
- Bronchiectasis features permanent dilation of bronchi or bronchioles on chest imaging (often chest CT) and may result from various causes (e.g., childhood lung infection, cystic fibrosis, hypogammaglobulinemia).
- Major risk factors for COPD include cigarette smoking, chronic exposure to noxious fumes (e.g., cooking with biomass fuels in enclosed spaces), and genetic factors, the best characterized of which is AAT deficiency.
- The most common symptom of patients with COPD is dyspnea. Cough, chronic phlegm production, and wheezing may also be present.
- Goals in treating COPD are to improve airflow, maximize the patient's functional status, reduce symptoms, avoid exacerbations, and prolong the patient's survival as possible.
- Important treatments for COPD include inhaled bronchodilators, inhaled corticosteroids, supplemental O_2 when indicated, pulmonary rehabilitation, and preventive vaccinations (e.g., against influenza and pneumococcus). Lung transplantation and LVRS are also available for specific subsets of patients with advanced disease.
- The goal of stable asthma management is to maintain a high quality of life for the patient, uninterrupted by asthma symptoms, side effects from medications, or limitations on the job or during exercise. This goal can be accomplished by objective measurements and monitoring lung function, pharmacologic therapy, environmental control, and patient education.
- The goals of emergency management of acute asthma are to decrease mortality and morbidity and to return the patient to preadmission stability and function as quickly as possible. These goals are accomplished by supplemental O_2 and frequent administration of high doses of aerosolized β-2 agonists, high-dose parenteral corticosteroids, and antibiotics if there is evidence of infection.
- The hallmark of bronchiectasis is the chronic production of large quantities of purulent sputum. Dyspnea is variable and depends on the extent of involvement and the underlying disease. Antibiotics and bronchopulmonary hygiene are important treatments.

Interstitial Lung Disease

Jeffrey T. Chapman and Jason Bordelon

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Organize and distinguish among the interstitial lung diseases (ILDs).
- Understand that some ILDs have specific causes while most patients will have ILD from an unknown cause leading to a specific pattern of injury.
- Interpret symptoms, examination signs, and pulmonary function test results in ILD.
- Describe radiographic patterns and how they can diagnose some ILDs.
- List causes, exposures, or pathologic characteristics associated with selected ILDs.
- Know in which patients and how to manage ILD with nonspecific therapies.
- Understand which patients should be treated with therapy specific to the type of ILD.
- Understand end-of-life issues with ILDs.

CHAPTER OUTLINE

KEY TERMS

asbestosis
connective tissue disease
corticosteroids
hypersensitivity pneumonitis
idiopathic pulmonary fibrosis
interstitial lung disease
lymphangioleiomyomatosis
occupational interstitial lung disease
organizing pneumonia
pulmonary Langerhans cell histiocytosis
sarcoidosis
silicosis

Interstitial lung disease (ILD) refers to a broad category of lung diseases rather than a specific disease process.[1,2] This category includes illnesses affecting the lung parenchyma with different causes, treatments, and prognoses. These disease processes are grouped together because of similarities in their clinical presentations, appearance on chest x-ray and computed tomography (CT), and physiology.

An organizational scheme is presented in Fig. 26.1. In evaluating patients with an ILD, diseases with known causes or associations, such as diseases related to specific exposures, diseases associated with systemic conditions, and diseases with a known genetic basis must be considered first. However, most patients are classified with an ILD of unknown cause, the so-called *idiopathic interstitial diseases*. Their disorder is classified by pathologic pattern. Using this organizational scheme to guide a careful and complete history, one is able to understand the disease processes and work efficiently toward an accurate diagnosis and treatment.

The histologic abnormalities of the ILDs involve the pulmonary interstitium to a greater extent than the alveolar spaces or airways. Fig. 26.2 illustrates the components of the normal

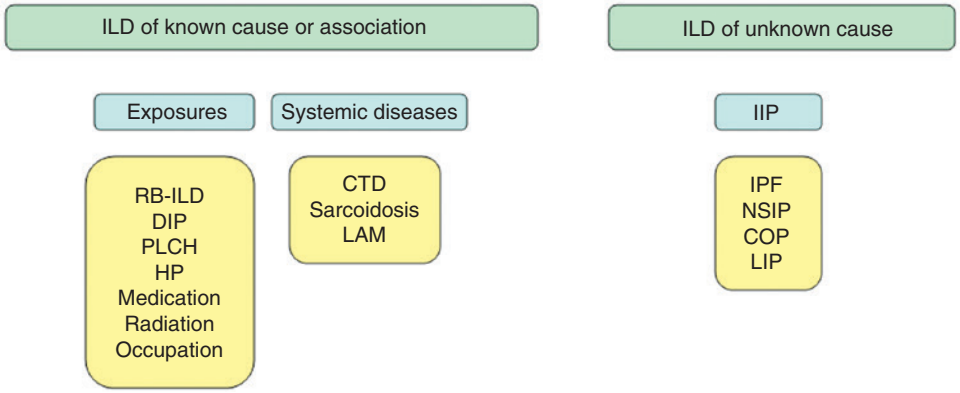

Fig. 26.1 Current Organization of Interstitial Lung Disease *(ILD). Fig. 26.2 (A) Diagram of the pulmonary parenchyma shows the respiratory bronchiole, alveolar duct, and alveolar sacs. (B) The constituents of the interstitial space, including type I and type II alveolar epithelial cells, a capillary with vascular endothelial cells and erythrocytes in transit, resident macrophages, interstitial fibroblasts, and matrix substance.

pulmonary parenchyma. The interstitium is the area between the capillaries and the alveolar space. In the normal state, this space allows close contact between gas and capillaries with minimal connective tissue matrix, fibroblasts, and inflammatory cells such as macrophages. The interstitium supports the delicate relationship between the alveoli and capillaries, allowing for efficient gas exchange. After an injury, the lung must respond to the damage and repair itself. If the exposure or injury persists or if the injury repair process is imperfect, the lung may be permanently damaged with abnormal interstitial tissue replacing the normal capillaries, alveoli, and healthy interstitium.

These pathologic abnormalities can lead to impairment in lung function. Gas exchange is impaired due to $\dot{V}/\dot{Q}$ mismatching, shunt, and decreased diffusion across the abnormal interstitium. The work of breathing in patients with ILD is increased because of decreased lung compliance. Together, these impairments cause exercise intolerance, seen in all ILDs. If the injury that causes the ILD or the abnormal repair from injury is not halted, progressive tissue damage occurs, leading to worsening disability and possibly death.

CHARACTERISTICS OF INTERSTITIAL LUNG DISEASE

Clinical Signs and Symptoms

Many ILDs have similar clinical features and are not easily distinguished based on history or examination. Symptoms are generally limited to the respiratory tract. However, extrapulmonary symptoms should not be ignored because they may point to an ILD associated with a systemic diagnosis. Exertional breathlessness (dyspnea) and a nonproductive cough are the most common reasons that patients with ILD seek medical attention. Other respiratory symptoms, such as sputum production, hemoptysis, pneumothorax, or wheezing, can occur and may suggest specific diseases (Table 26.1). If the patient also has prominent extrapulmonary symptoms, such as myalgia, arthralgia, sclerodactyly (tightening of the skin over the fingers), gastroesophageal reflux, or Raynaud phenomenon (discoloration of the digits, often initially with a white color because of spasm of the arteries that supply the digits), ILD resulting from underlying **connective tissue disease** may be present (Table 26.2).

TABLE 26.1 Unusual Pulmonary Findings and Likely Diagnosis

Pulmonary Findings	Disease	Frequency
Hemoptysis	LAM	Rare
Chyloptysis (coughing up chyle)	LAM	Rare
Pneumothorax	LAM, BHD	Common
Wheeze	Sarcoidosis, LAM	Common
Chylous pleural effusion	LAM	Common
Exudative pleural effusion	RA	Common

BHD, Birt-Hogg-Dubé syndrome; *LAM,* lymphangioleiomyomatosis; *RA,* rheumatoid arthritis.

Physical Examination

Many patients with ILD have bilateral fine inspiratory crackles, which usually are most prominent at the lung bases. However, some diseases, such as sarcoidosis and lymphangioleiomyomatosis (LAM), may manifest with only decreased breath sounds without abnormal breath sounds despite markedly abnormal chest imaging. Expiratory wheezing is uncommon in ILD and its presence suggests either airway involvement as part of the primary disease process (LAM, sarcoidosis, respiratory bronchiolitis–associated interstitial lung disease [RB-ILD], desquamative interstitial pneumonitis [DIP], pulmonary Langerhans cell histiocytosis [PLCH]) or concomitant airways disease, such as emphysema or asthma. Signs of pulmonary arterial hypertension with right ventricular dysfunction, such as lower extremity edema or jugular venous distension, may occur late in the course of any ILD. Examination also may show features of an underlying connective tissue disease, including synovitis, joint deformities, or skin rash.

Radiographic Features

ILDs manifest as abnormal lung parenchyma that casts abnormal radiographic shadows. For most ILDs, the chest x-ray shows reduced lung volumes with bilateral reticular or reticulonodular opacities. However, the chest x-ray has limited value because the three-dimensional abnormalities are shown in two dimensions from which depth cannot be determined. High-resolution cross-sectional imaging using CT provides detailed images representing pulmonary pathology.[3] High-resolution CT images allow

TABLE 26.2 Extrapulmonary Findings and Likely Diagnosis

Extrapulmonary Findings	Disease	Frequency
Raynaud phenomenon	All CTD	Common
Arthralgia	All CTD	Common
Myalgia	Polymyositis	Common
Large muscle weakness	Polymyositis	Common
Sclerodactyly	Scleroderma	Common
Rheumatoid skin nodules	RA	Rare
Fingertip fissures	Antisynthetase syndrome	Common
Dorsal hand rash	Dermatomyositis	Common
Facial rash	Dermatomyositis	Common
Exudative pleural effusion	RA	Common
Shawl distribution skin nodules	TSC	Common
"Pencil eraser" facial skin nodules	BHD	Common
Central nervous system benign cortical tuber	TSC	Common
Abdominal angiomyolipoma	LAM	Common
Renal cancer	BHD	Common
Cardiomyopathy	Sarcoidosis, polymyositis	Rare
Cardiac conduction block	Sarcoidosis	Rare
Violaceous facial skin nodules	Sarcoidosis	Common
Subcutaneous nodules	Sarcoidosis	Common
Cranial neuropathy	Sarcoidosis	Rare
Small fiber neuropathy	Sarcoidosis	Rare

noninvasive evaluation of ILDs and are a key element in making a confident diagnosis and managing ILD.[4]

The most important pattern to recognize on chest x-rays and high-resolution CT images is usual interstitial pneumonitis (UIP), the pathologic pattern of injury seen in the disease idiopathic pulmonary fibrosis (IPF). The chest x-ray (Fig. 26.3A) and high-resolution CT images (see Fig. 26.3B) in UIP typically show increased attenuation, whiteness, which is bilateral, patchy (abnormal areas separated by normal lung), peripheral (abnormal pleural edges), and basilar (affecting the lower parts of the lung predominantly). Frequently, the abnormal fibrosis leads to so-called honeycomb cysts at the edges of the most abnormal lung and bronchiectasis where the airways are dilated to a larger size than the accompanying pulmonary artery. Honeycomb cysts are so named because they look like a honeycomb, with thick walls surrounding air. Faint ground-glass abnormalities, which are increased whiteness of the lung tissue without distortion of the underlying blood vessels or bronchi, are absent or minimal in UIP. Pleural disease, air trapping, micronodules, and significant lymphadenopathy are not seen, although two-thirds of patients with UIP can have mild mediastinal adenopathy.[5]

RULE OF THUMB In patients with spontaneous pneumothorax and interstitial infiltrates, LAM or PLCH should be considered.

In contrast to UIP, cellular nonspecific interstitial pneumonitis (NSIP) is a pattern of injury dominated by inflammation and has imaging findings distinct from those with UIP. Ground-glass attenuation (patchy fine whiteness in the CT images) predominates.

RULE OF THUMB Calcification along the pleura on a chest x-ray suggests previous exposure to asbestos. Although such calcified areas (called *plaques*) do not cause symptoms or physiologic abnormality, they can provide a clue that the cause of ILD is asbestos exposure.

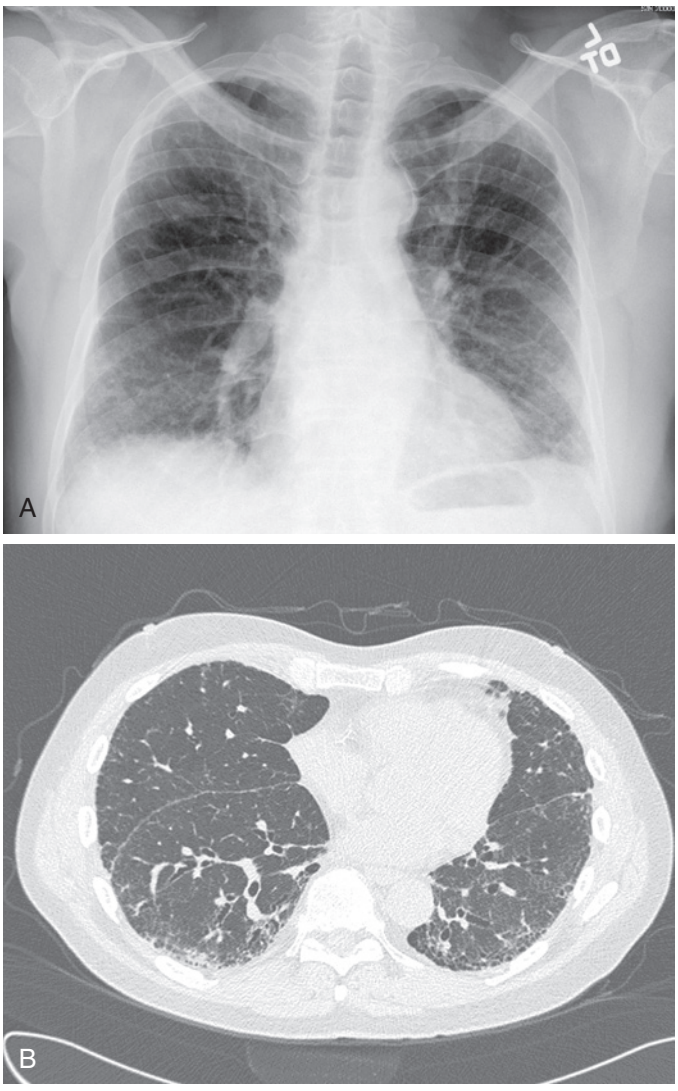

Fig. 26.3 (A) Posteroanterior chest x-ray showing the characteristic features of idiopathic pulmonary fibrosis, a common interstitial lung disease. Notice the bilateral lower zone reticulonodular infiltrates and the loss of lung volume in the lower lobes. (B) Chest computed tomography image shows the peripheral nature of the fibrosis.

Physiologic Features

Similar to the radiographic findings, specific ILDs can vary considerably regarding the degree of physiologic abnormalities. However, a restrictive physiologic impairment is the most common finding.[6] With this restrictive pattern, both forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) are diminished, and the FEV_1/FVC ratio is preserved or even above normal. Lung volumes are reduced, as is the diffusing capacity of the lung for carbon monoxide (DLCO). This reduction in diffusing capacity reflects a pathologic disturbance of the alveolar-capillary interface, reflecting the abnormality in the interstitium of the lung.

In almost all ILDs, the lungs have reduced compliance and require above normal transpleural pressures to ventilate (Fig. 26.4). This lack of compliance results in small lung volumes and

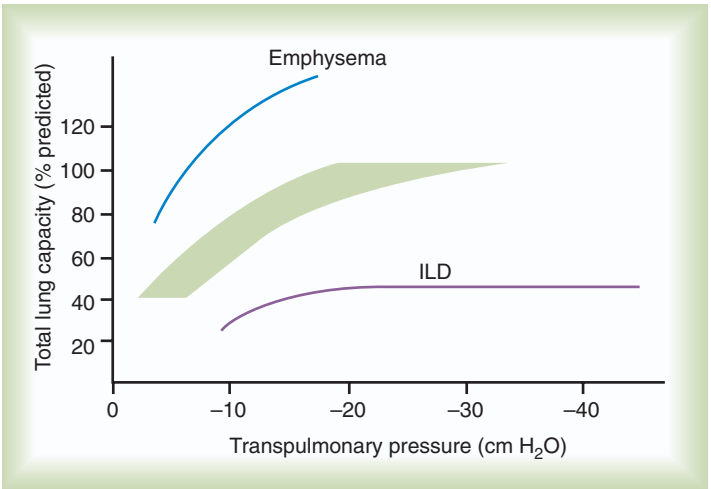

Fig. 26.4 **Static Pressure-Volume Curve.** The compliance characteristics of the lung are illustrated with a plot of lung volume against the corresponding transthoracic pressure measured during static (i.e., no flow) conditions. The *shaded area* represents the range of values expected with a normally compliant lung. The line labeled *ILD* represents an example of a patient with interstitial lung disease *(ILD)*. At any particular lung volume, the transthoracic pressure is greater than expected. For comparison, the line labeled *Emphysema* shows the compliance characteristics of patients with emphysema.

increased work of breathing, and increased driving pressures if mechanical ventilation is required.

Rarely, a pattern of physiologic obstruction may be seen. This obstruction can be the result of the primary disease process (e.g., LAM, PLCH, or sarcoidosis in some patients) or accompanying emphysema or asthma.[7] If ILD develops in a patient with significant emphysema (a condition called "combined pulmonary fibrosis with emphysema" [CPFE]), the opposing physiologic effects of the two disease processes (i.e., restriction for the ILD and obstruction from the emphysema) may result in deceptively normal spirometry and lung volume measurements and apparently normally compliant lungs. For example, emphysema might cause lung volumes to increase, whereas the restriction would be reflected by decreased lung volumes. The net effect of both processes in the same patient could be a normal lung volume. However, because both emphysema and ILD result in impaired gas exchange, the DLCO is significantly decreased.

RULE OF THUMB Among smokers with IPF, normal spirometry and lung volumes with reduced DLCO suggest the presence of coexisting emphysema. Consider CPFE in this situation.

SELECTED SPECIFIC TYPES OF INTERSTITIAL LUNG DISEASE AND THERAPIES

Exposure-Related Disease

Tobacco-Associated Lung Disease

Although the association of first-hand tobacco smoke and obstructive lung disease is common and well known, tobacco smoke is also an avoidable cause of ILD. Although the association is rarer than with obstructive lung disease, first-hand tobacco smoke inhalation can lead to three types of ILD in susceptible individuals: (1) RB-ILD, (2) DIP, and (3) PLCH. The first two disorders manifest as overly abundant macrophages in the lung in reaction to tobacco smoke. In RB-ILD, macrophages accumulate in the respiratory bronchioles leading to bronchiolar remodeling and fibrosis of adjacent alveoli. As expected for a disease with combined airway and alveolar injury, pulmonary function testing reveals mixed restriction and obstruction with air trapping. High-resolution CT images show this mixed pathologic location with indistinct centrilobular nodules (Fig. 26.5). In DIP, the increased macrophages fill the alveoli, manifesting as restrictive impairment on pulmonary function testing and diffuse ground-glass attenuation on high-resolution CT imaging (Fig. 26.6).

Pulmonary Langerhans cell histiocytosis (PLCH) is the third interstitial manifestation of tobacco smoke. Increased numbers of polyclonal macrophages are accompanied by fibroblasts and eosinophils in nodules concentrated around small airways. These nodules are star-shaped (or stellate) and destroy adjacent lung tissue, leading to the classic high-resolution CT image of stellate nodules associated with cysts, as seen in Fig. 26.7. Although adult smoking-associated PLCH is pathologically similar to childhood Langerhans cell histiocytosis, the adult form does not involve bone and has not proved to respond to chemotherapy as the childhood form does. The relationship of these two disorders has yet to be defined.

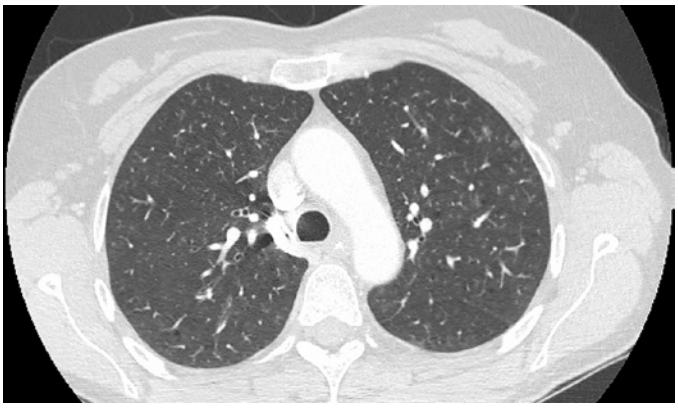

Fig. 26.5 Respiratory Bronchiolitis–Associated Interstitial Lung Disease (RB-ILD). There are numerous indistinct centrilobular nodules. Air trapping can be seen in RB-ILD but is not present in this case.

Fig. 26.6 Desquamative Interstitial Pneumonitis. Note the diffuse ground-glass attenuation.

In each of these three diseases, the primary treatment is stopping smoking completely. With abstinence from smoking, most patients either minimally improve or remain stable,[8] but a few progressively worsen, sometimes to the point of needing lung transplantation. The use of immunosuppressive medications is generally not effective.[9]

Drug-Related and Radiation-Related Disease

Many drugs have been associated with pulmonary complications of various types, including interstitial inflammation and fibrosis, bronchospasm, pulmonary edema, and pleural effusions. Drugs from many different therapeutic classes can cause ILD, most commonly chemotherapeutic agents, antibiotics, antiarrhythmic drugs, and immunosuppressive agents (Box 26.1). Treatment is avoidance of further exposure and systemic corticosteroids in markedly impaired or declining patients.

RULE OF THUMB Exposure to the chemotherapeutic agent bleomycin can lead to interstitial lung disease and is accentuated by exposure to increased fractional inspired oxygen (FiO_2), even months after last drug exposure. Thus supplemental oxygen (O_2) should be used only if absolutely necessary for patients with bleomycin-induced ILD.[10]

Fig. 26.7 Pulmonary Langerhans Cell Histiocytosis. Note the left upper lobe cysts and indistinct stellate-shaped nodule around an airway, which will become a cyst.

BOX 26.1 Drugs Associated With the Development of Interstitial Lung Disease

Antibiotics
- Nitrofurantoin
- Sulfasalazine

Antiinflammatory Agents
- Leflunomide
- Methotrexate
- Etanercept
- Infliximab

Cardiovascular Agents
- Amiodarone
- Tocainide

Chemotherapeutic Agents
- Bleomycin
- Mitomycin C
- Busulfan
- Cyclophosphamide
- Chlorambucil
- Melphalan
- Methotrexate
- Etoposide
- Vinblastine
- Imatinib

Drugs Used in an Illegal Way
- Heroin
- Methadone
- Talc as an intravenous drug contaminant

Exposure to therapeutic radiation used to treat cancer may result in ILD. Patients presenting within 6 months of radiation therapy generally have ground-glass abnormalities thought to represent acute inflammation. The ground-glass abnormalities can occur in both radiation-exposed tissue and unexposed tissue. Short-term systemic corticosteroid treatment can improve lung function. In contrast, radiographic abnormalities that develop more than 6 months after therapy typically appear as densely fibrotic tissue. On CT scan, a straight line indicating the margin

Fig. 26.8 High-resolution computed tomography slice shows dense fibrosis with a non-anatomic straight line boundary.

of radiation is frequently evident, as seen in Fig. 26.8. These patients do not improve with corticosteroid therapy and treatment is supportive.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HP) is a cell-mediated immune reaction to inhaled antigens in susceptible persons.[11] Patients must be sensitized by an initial exposure, with re-exposure leading to either an acute or chronic HP. Patients with acute HP present to medical attention with a few days of shortness of breath, chest pain, fever, chills, malaise, and a cough that may be productive of purulent sputum. Patients who are chronically exposed to low levels of inhaled antigens may develop subtle interstitial inflammatory reactions in the lung that do not result in noticeable symptoms for months to years and can present with severe, impairing disease, which can be very difficult to distinguish from IPF.

Common organic antigens known to cause HP include bacteria and fungi, which may be found in moldy hay (farmer's lung) or in the home environment, in particular, in association with central humidification systems (humidifier lung), indoor hot tubs, and animal proteins (e.g., bird breeder's lung). Inorganic antigens from vaporized paints and plastics also can lead to HP. Many established antigens are listed in Table 26.3, along with the typical source of exposure and the associated syndrome.

Because the relationship between exposure and lung disease may not be obvious, a careful systematic occupational, environmental, and avocational history is crucial. Elements that strongly suggest a diagnosis of HP are exposure to an appropriate antigen and the correct timing of symptom onset to the exposure. Blood samples may be obtained to determine whether there has been an antibody response to certain antigens associated with HP (serum precipitins). However, the presence of such antibodies cannot establish the diagnosis of HP because many individuals develop antibodies in the absence of disease. Likewise, the absence of detectable antibodies does not rule out the diagnosis of HP because the culprit may be an antigen that is not included in the blood test panel that is analyzed.[12]

Specific therapies for HP are strict antigen avoidance and immunosuppression with corticosteroids in patients with

TABLE 26.3 Causes of Hypersensitivity Pneumonitis

Antigen	Exposure	Syndrome
Bacteria		
Thermophilic Bacteria		
Saccharopolyspora rectivirgula	Moldy hay	Farmer's lung
Thermoactinomyces vulgaris	Moldy sugarcane	Bagassosis
Thermoactinomyces sacchari	Mushroom compost	Mushroom worker's lung
Thermoactinomyces candidus	Heated water reservoirs	Humidifier lung Air conditioner lung
Nonthermophilic Bacteria		
Bacillus subtilis, Bacillus cereus	Water, detergent	Humidifier lung Washing powder lung
Fungi		
Aspergillus species	Moldy hay	Farmer's lung
Aspergillus clavatus	Barley	Malt worker's lung
Penicillium casei, Penicillium roqueforti	Cheese	Cheese washer's lung
Alternaria species	Wood pulp	Woodworker's lung
Merulius lacrymans	Rotten wood	Dry rot lung
Penicillium frequentans	Cork dust	Suberosis
Aureobasidium pullulans	Water	Humidifier lung
Cladosporium species	Hot tub mists	Hot tub HP*
Trichosporon cutaneum	Damp wood and mats	Japanese summer-type HP
Animal Proteins		
Avian proteins	Bird droppings, feathers	Bird-breeder's lung
Urine, serum, pelts	Rats, gerbils	Animal handler's lung
Chemicals		
Isocyanates, trimellitic anhydride	Paints, resins, plastics	Chemical worker's lung
Copper sulfate	Bordeaux mixture	Vineyard sprayer's lung
Phthalic anhydride	Heated epoxy resin	Epoxy resin lung

HP, Hypersensitivity pneumonitis.

symptomatic or physiologically impairing disease. In acute HP, corticosteroids seem to hasten recovery but do not improve ultimate lung function.[13] Patients with chronic HP, those with fibrosis on CT scan have a shorter survival and the benefit of long-term immunosuppression is unknown.[14]

Occupational Disease

The three most common types of **occupational interstitial lung disease** are **asbestosis**, chronic **silicosis**, and coal workers' pneumoconiosis. Awareness of the associated risk and reduction in exposure has greatly reduced the frequency of these diseases. However, they remain common in developing countries and among emigrants from these countries.

Predictable clinical and radiographic abnormalities occur in susceptible patients who have been exposed to asbestos.[15] These abnormalities include pleural changes (plaques, fibrosis, effusions, atelectasis, and mesothelioma) and parenchymal scarring and lung cancer.

RULE OF THUMB Asbestos exposure alone increases the risk for lung cancer minimally (1.5 to 3.0 times). However, asbestos exposure and cigarette smoking act synergistically to increase greatly the risk for cancer.

Asbestos exposure also may result in benign asbestos pleural effusions or an entity known as *rounded atelectasis*. Benign asbestos pleural effusions characteristically appear many years after initial exposure to asbestos (e.g., 10 to 20 years) and may be asymptomatic or may be associated with acute chest pain, fever, and dyspnea. Benign asbestos pleural effusions usually resolve on their own, but may recur. Treatment is drainage to reduce symptoms. Rounded atelectasis typically manifests as a pleural-based parenchymal mass that may be mistaken for cancer. The characteristic CT features, such as local volume loss, pleural thickening, and the "comet tail" appearance of bronchi and vessels curving into the lesion, help distinguish rounded atelectasis from carcinoma.

The term *asbestos-related pulmonary disease* encompasses all of these entities, whereas *asbestosis* is reserved for patients who have evidence of parenchymal fibrosis from asbestos exposure. Most patients with asbestosis have had considerable airborne asbestos exposure for many years (i.e., usually >20 years) before the lung disease becomes apparent. Exposure frequently is associated with occupations such as shipbuilding or insulation work. Patients report very slowly progressive dyspnea on exertion[16] and have crackles on lung examination. Physiologic testing shows restrictive impairment with a reduced DLCO. The chest x-ray shows bilateral lower zone reticulonodular infiltrates similar to infiltrates seen in IPF. With an appropriate exposure history, the presence of radiographic pleural plaques or rounded atelectasis indicates asbestos as the likely cause of ILD, although neither history nor radiographic findings are required for establishing the diagnosis. Surgical lung biopsy and finding so-called asbestos bodies can establish a definitive diagnosis, but surgical biopsy is infrequently performed due to the age and frailty of these patients. No medical therapy has been shown to improve or decrease progression of asbestosis. Severe impairment typically occurs 30 to 40 years after exposure, making almost all patients ineligible for lung transplantation because of advanced age. Management of asbestosis is supportive.

Chronic silicosis results from chronic exposure to inhaled silica particles. Occupations that commonly involve exposure to silica include mining, tunneling, sandblasting, and foundry work. The chest x-ray shows upper lung zone–predominant abnormalities characterized by multiple small nodular opacities in the central lung tissue. These nodules (simple silicosis) are asymptomatic and may never progress or cause symptoms. However, in susceptible individuals, the nodules coalesce into large midlung zone masses known as *progressive massive fibrosis*. Some patients with abnormal chest x-rays report few, if any, symptoms and may have normal lung examination and pulmonary function testing. Many patients are impaired and have mixed restrictive and obstructive impairment with reduced diffusion capacity. The physiologic impairment may remain stable or, if progressive,

massive fibrosis occurs, may progress even without continued exposure. Symptoms are typically exertional dyspnea and variable mucus production.

Patients with silicosis are at increased risk for lung cancer, and the risk is increased when combined with exposure to tobacco smoke, diesel exhaust, or radon gas. Patients with silicosis develop active tuberculosis 2 to 30 times more frequently than those without silicosis.[17] This association is especially important in populations with a high frequency of human immunodeficiency virus infection, which markedly increases the risk for silicosis-associated active tuberculosis.

Coal workers' pneumoconiosis develops as the result of chronic inhalation of coal dust. In the past, it was assumed that silica dust was responsible for the pulmonary disease seen among coal miners because the clinical and radiographic features are quite similar to those of chronic silicosis. However, it is now recognized that coal workers' pneumoconiosis and silicosis are the result of different exposures. Simple coal workers' pneumoconiosis, characterized by multiple small nodular opacities on the chest x-ray, is asymptomatic. Cough and shortness of breath do not develop unless the disease progresses to progressive massive fibrosis similar to that seen in silicosis.

There are no proven therapies for either silicosis or coal workers' pneumoconiosis other than eliminating future exposure. In patients with significant obstructive impairment or mucus production, inhaled bronchodilators and **corticosteroids** may relieve some symptoms. Exacerbations can be frequent and are treated with antibiotics and systemic corticosteroids.

Interstitial Lung Disease Associated With a Systemic Disease

Connective Tissue Disease

ILD is a well-known complication of connective tissue diseases.[18] The most commonly implicated disorders are scleroderma, rheumatoid arthritis, Sjögren syndrome, polymyositis/dermatomyositis, and systemic lupus erythematosus.

In any of these disorders, pulmonary involvement may remain undetected until significant impairment is present, because these patients may be inactive owing to the underlying connective tissue disease. In addition, severity of the pulmonary and nonpulmonary manifestations do not always correlate. In some instances, the lung disease may overshadow or may occur earlier than other symptoms of the systemic disease. Dyspnea and cough, as with all ILDs, are the most common symptoms. On chest examination, crackles or wheezing are typically found. Lung physiology is usually restrictive with decreased DLCO but may be obstructive especially with Sjögren syndrome owing to collections of lymphocytes in bronchioles.

High-resolution CT findings are variable and range from normal to ground-glass abnormalities, to reticular and fibrotic changes.[19] The pathologic pattern of injury with these diseases is equally diverse and correlates with the high-resolution CT findings. Inflammatory injury patterns are most commonly seen, such as NSIP and organizing pneumonia. The NSIP inflammatory injury pattern appears as ground-glass abnormalities on high-resolution CT scan, whereas organizing pneumonia is shown by patchy consolidated lung with air bronchograms. Both of these pathologic patterns can improve with aggressive immunosuppression. At the other end of the pathologic response spectrum is fibrotic injury, which manifests as UIP and shows reticular fibrotic opacities and honeycomb cystic changes on high-resolution CT scan. These abnormalities typically do not improve with immunosuppression, although long-term controlled studies are lacking.

Specific treatment of connective tissue disease–associated ILD must be individualized. Patients with evidence of extrapulmonary inflammation, an inflammatory pathologic pattern such as NSIP or organizing pneumonia on high-resolution CT or biopsy, or rapidly progressive symptoms, are usually treated with prolonged immunosuppressive agents such as cyclophosphamide, azathioprine, mycophenolate, or tacrolimus.[20,21]

The Scleroderma Lung Study showed that one year of oral cyclophosphamide modestly improved lung function compared with modest decline in the placebo group.[22] However, after 1 year off immunosuppressive therapy, the patients treated with cyclophosphamide worsened and were indistinguishable from the untreated patients.[23] Owing to significant side effects with cyclophosphamide, the Scleroderma Lung Study II was performed comparing 1 year of cyclophosphamide followed by 1 year of placebo to 2 years of mycophenolate. Both groups demonstrated significant and equal benefit.[24] Owing to less side effects, mycophenolate is now the treatment of choice for scleroderma-related ILD.

Polymyositis-associated ILD is being increasingly recognized as a common disease entity. Patients usually present with "mechanic's hands," consisting of thickened skin and painful fingertip fissures, and 50% have Jo-1 antibodies on antinuclear antibody testing. Lung pathologic results typically show fibrotic NSIP or organizing pneumonia. As would be expected with these inflammatory patterns of injury, patients usually benefit from immunosuppression.

Sarcoidosis

Sarcoidosis is an idiopathic (of unknown cause) multisystem inflammatory disorder that commonly involves the lung.[25] It is the most common ILD in the United States. The tissue inflammation that occurs in sarcoidosis has a characteristic pattern in which the inflammatory cells collect in microscopic nodules called *granulomas*. In contrast to IPF, sarcoidosis is more common among young adults than among older adults. Sarcoidosis often follows a benign course of inflammation without symptoms or long-term consequences that spontaneously improves.

The most common manifestation of sarcoidosis is asymptomatic hilar adenopathy. Less frequently, the chest x-ray shows parenchymal opacities in the midlung zone that may be nodular, reticulonodular, or alveolar. When symptoms occur, cough, chest pain, dyspnea, and wheezing are most common. Pulmonary physiology may be normal, restrictive, obstructive, or mixed, all with reduced DLCO. Obstructive impairment may be related to endobronchial granulomatous inflammation or scarring.[26]

Corticosteroids are commonly used to treat sarcoidosis, but treatment usually is reserved for patients with marked symptoms or physiologic impairment attributable to the disease.[27] Although corticosteroids almost always reduce active sarcoid inflammation, long-term side effects should limit the duration of steroid

treatment. For patients requiring long-term immunosuppression, alternative immunosuppressive agents should be used.[28] Involvement of other organs that may require corticosteroid therapy include cardiac involvement, uveitis, and peripheral or central nervous system involvement with cranial nerve abnormalities. Disease activity is difficult to detect in many patients. Serum angiotensin-converting enzyme levels and gallium scans are not well correlated with disease activity, and their routine use is discouraged.[29]

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is a rare disorder of abnormal smooth muscle tissue proliferating around small airways and leading to severe obstruction and destruction of alveoli with resultant thin-walled cyst formation.[30] All patients are women, although both men and women with tuberous sclerosis complex can develop lung pathologic findings identical to those of LAM that is called *tuberous sclerosis complex LAM*. This peculiar pathologic process is caused by abnormalities in the *TSC-2* gene.[31]

Dyspnea on exertion and an obstructive ventilatory impairment with reduced DLCO is almost always present, except in very early disease. Disease progression is variable; some women have steadily worsening lung function during midlife, whereas some elderly women experience extremely slow decline over many years. Risk factors for worsening lung function include a significant bronchodilator response and possibly pregnancy. Other important disease manifestations include pneumothorax from a ruptured subpleural cyst. Unilateral or, less commonly, bilateral chylothorax is seen in about one-third of patients. This results from lymphatic obstruction by abnormal smooth muscle tissue. Treatment with a low-fat diet or blocking gut fat absorption is usually ineffective, and pleurodesis (i.e., sealing the pleural space by instilling an irritant solution to cause the visceral and parietal pleura to stick together [Chapter 27]) is required. Pleurodesis does not preclude subsequent lung transplantation.

Sirolimus, which blocks the abnormal *TSC-2* gene and inhibits LAM cell proliferation, has recently been shown to stabilize lung function in comparison with placebo and has become standard therapy in LAM patients with abnormal lung function.[32] Additional treatment is with inhaled bronchodilators and inhaled corticosteroids while selected patients may ultimately require lung transplantation.

Interstitial Lung Disease of Unknown Cause

Idiopathic Interstitial Pneumonias

Despite a careful history, physical examination, and high-resolution CT scan, most patients are not found to have an exposure or systemic illness as a cause of ILD. These patients have a disorder isolated to the lung termed *idiopathic interstitial pneumonia (IIP)*. Prognosis and potential therapies are completely dependent on the type of pathologic pattern of IIP.

Idiopathic pulmonary fibrosis. **Idiopathic pulmonary fibrosis** (IPF) is the most common IIP and is a progressive fibrotic disease isolated to the lung.[33] Although the precise cause of IPF is unknown, studies have demonstrated that susceptible individuals have lung injury from diverse causes, such as metal dust, farming dust, tobacco smoke, subclinical gastric aspiration, and mechanical stress from abnormal surfactant proteins that lead to abnormal lung healing and progressive fibrosis.[34] Most patients are older than 60 years, and IPF is extremely unusual in persons younger than 40 years. Patients present with chronic cough and exertional dyspnea, and high-resolution CT suggests a fibrotic process.

The diagnosis of IPF is made by noting a lack of exposure or systemic disease known to cause ILD and determining UIP as the pathologic pattern of injury. The diagnosis of UIP is made when high-resolution CT shows bilateral and basilar-predominant peripheral reticular fibrosis and honeycomb cystic change with absence of significant ground-glass abnormalities, micronodules, and air trapping. Without these classic findings, a surgical lung biopsy is needed for diagnosis.[35,36] Patients who do not have IPF can have UIP on surgical lung biopsy (e.g., connective tissue disease), so this pattern of injury and repair is not unique to IPF.

Most patients die as a result of progressive fibrotic lung disease within 4 years of diagnosis. Data show that approximately half of patients die with gradually progressive disease over several years.[37] The other half experience stable lung function or minimal decline for months to years and then have sudden worsening over a few weeks or months, leading to death.[38]

RULE OF THUMB In IPF severity of dyspnea, restrictive physiologic defect, DLCO impairment, degree of pulmonary arterial hypertension degree of fibrosis on high-resolution CT, and SaO_2 desaturation on exertion predict a higher risk of death.[39] Serial parameters that predict poor survival include worsening dyspnea, FVC, and DLCO.

Specific treatment for IPF is now available after decades of IPF trials showing no benefit with aggressive immunosuppression[40-42] and various other drugs (e.g., interferon γ,[43] etanercept,[44] bosentan, macitentan, ambrisentan, sildenafil,[45] imatinib,[46] warfarin, *N*-acetylcysteine,[47] and azathioprine in combination with both oral corticosteroids and *N*-acetylcysteine).[48] Pirfenidone and nintedanib, both molecules with multiple antifibrotic properties, have been shown to slow disease progression in patients with IPF.[49,50] Either of these two drugs should be offered to all patients who have an established diagnosis of IPF as long as side effects are tolerable, since the medications do not improve lung function or halt lung function decline.

Studies have demonstrated coexisting pulmonary arterial hypertension in IPF, leading to worse exercise intolerance and increased mortality.[51,52] Significant pulmonary arterial hypertension is suggested in patients with markedly reduced diffusion capacity but relatively preserved FVC. Medications that benefit pulmonary arterial hypertension such as bosentan and sildenafil have not proved beneficial for IPF either with or without pulmonary arterial hypertension.[53,54]

Nonspecific interstitial pneumonia. NSIP is an IIP with diffuse inflammation seen on surgical lung biopsy.[55] Patients are on average 7 to 10 years younger than patients with IPF, but considerable overlap exists. The degree of accompanying interstitial fibrosis varies. The most common presentation of NSIP is fibrotic NSIP. This type involves fibrosis and inflammation. Cellular NSIP is less common. Patients present with chronic or subacute cough and

dyspnea. High-resolution CT shows predominant ground-glass abnormalities in cellular NSIP and both ground-glass abnormalities and fibrotic changes in fibrotic NSIP. Given that there is significant clinical and radiographic overlap between fibrotic NSIP and IPF, surgical lung biopsy is frequently required to distinguish these two entities, such as when elements of classic UIP are not present on high-resolution CT images.

The prognosis is much better for NSIP than IPF, with most patients surviving 7 to 10 years. Immunosuppression with oral corticosteroids and cytotoxic immunosuppressive agents is the primary therapy. Type and duration of therapy are guided by disease activity and degree of inflammation on biopsy and ground-glass abnormalities on high-resolution CT. Pathologic NSIP is found frequently as an IIP and is the most common pattern of injury seen in connective tissue disease–associated ILD. Owing to this frequent association, many authors consider NSIP a connective tissue disease isolated to the lung.[56,57]

Organizing pneumonia. **Organizing pneumonia** (OP) is the newer, revised term for *bronchiolitis obliterans organizing pneumonia*. The term *cryptogenic organizing pneumonia* is used when this pattern of injury occurs as an IIP, and it is termed *organizing pneumonia* when found in the setting of connective tissue disease. Patients with organizing pneumonia are typically younger than patients with IPF and present with acute or subacute dyspnea and cough. Approximately one-third describe a preceding viral illness. However, no other risk factors are known. High-resolution CT shows alveolar filling with air bronchograms mimicking acute pneumonia, and the patient with classic organizing pneumonia presents after having failed to improve despite several courses of antibiotics. Diagnosis usually requires surgical lung biopsy, especially if the clinical and radiographic features are uncertain because small areas of organizing pneumonia can be seen in various inflammatory and fibrotic disorders on transbronchial lung biopsy. Surgical lung biopsy specimens show young fibroblasts within the alveoli that are presumably recovering from an injury. The alveolar basement membrane is intact, allowing for significant recovery if the inflammation or injury can be suppressed.

Most patients improve with oral corticosteroids (0.5 to 1 mg/kg for 6 to 12 weeks). However, many patients have recurrence after corticosteroid withdrawal and require long-term immunosuppressive agents.

Lymphocytic Interstitial Pneumonia

Lymphocytic interstitial pneumonia is a rare disorder of polyclonal lymphocyte aggregates that accumulate diffusely in the interstitium.[58] The diagnosis almost always requires surgical lung biopsy. Patients are typically younger than patients with IPF and present with subacute dyspnea and cough. Pulmonary function testing may show a mixed picture, and high-resolution CT typically shows diffuse ground-glass attenuation with variable amounts of fibrosis. Most patients respond well to oral corticosteroids, with a few requiring long-term immunosuppression. Lymphocytic interstitial pneumonia is frequently associated with connective tissue diseases, especially Sjögren syndrome, and with immunodeficiency, and these possibilities should be investigated in all patients with lymphocytic interstitial pneumonia.

MINI CLINI

Clinical Deterioration in a Patient With Interstitial Lung Disease

Problem

A 50-year-old man with fibrotic NSIP is being treated with oral corticosteroids and cyclophosphamide. After 6 months of therapy, he begins to report progressive breathlessness. Why is this occurring?

Solution

Many ILDs follow a gradually progressive course to end-stage disease and death. The available treatments may result in temporary improvement or slow progression of the disease. These treatments seldom are curative, however. Progressive symptoms (exertional dyspnea or cough) in a patient being treated for ILD often, although not always, indicates disease progression.

The following possibilities must be considered and separated from progression of the disease:

1. *Superimposed infection:* Immunosuppressive agents used in the management of some ILDs increase the risk for infection in the lung and elsewhere. Common bacteria or uncommon opportunistic infections may be responsible. Pneumonia may be difficult to detect radiographically because of preexisting radiographic abnormalities, and bronchoscopy with bronchoalveolar lavage and transbronchial lung biopsy may be needed.
2. *Drug reaction:* Almost all medications used to treat ILD have been reported to be capable of causing an adverse pulmonary reaction. Some medications, such as methotrexate, have been described to result in pulmonary reactions in 5% to 10% of users. An adverse drug reaction should be considered in all patients with ILD who are being actively treated, particularly if there is a clear temporal relationship between starting the medication and the new or progressive respiratory symptoms.
3. *Steroid-related muscle weakness.* This is a less common complication of corticosteroid therapy and can cause exercise intolerance that can be difficult to separate from progression of the underlying lung disease. Steroid-related muscle weakness (steroid myopathy) is difficult to diagnose because the weakness can result in worsening of the underlying restrictive physiologic defect. When proximal muscle weakness occurs in combination with progressive respiratory symptoms, the possibility of steroid myopathy should be considered. A greater than 20% drop in the FVC in the supine position compared with the sitting position suggests bilateral diaphragmatic dysfunction.
4. *Pulmonary embolism:* Inactivity as a result of disease-related physiologic impairment and right ventricular dysfunction may be a risk factor for thromboembolic disease. A sudden decline in respiratory status, sometimes associated with pleuritic chest pain, should raise the possibility of acute pulmonary embolism.
5. *Lung carcinoma:* Patients with pulmonary fibrosis have an increased risk for lung cancer, and the development of lung cancer can contribute to clinical decline.

TABLE 26.4 Nonspecific Therapies for Interstitial Lung Disease

Therapy	Details
Supplemental oxygen	Continuous rather than pulsed delivery of O_2 is preferred because the desaturation with activity seen in most patients is not corrected with pulse therapy, and pulse units vary greatly in the amount of O_2 delivered.[61] For other modes of supplemental oxygen delivery, see Chapter 42.
Pulmonary rehabilitation and exercise therapy	Pulmonary rehabilitation improves physical activity quality of life in patients with ILD. Pulmonary rehabilitation should be continued as monitored exercise therapy as when exercise is stopped the gains dissipate over a few months.[62]
Vaccinations and infection avoidance	All ILD should receive the pneumococcal vaccine per U.S. Centers for Disease Control and Prevention guidelines and a yearly influenza virus vaccine. Additionally, we recommend that patients practice good hand hygiene (frequent handwashing). We do not recommend use of masks or special antibacterial products. Patients treated with prednisone in doses greater than 15 mg daily or with a steroid-sparing immunosuppressant should receive Pneumocystis prophylaxis (e.g., with oral trimethoprim-sulfamethoxazole, inhaled pentamidine, etc.).
Gastroesophageal reflux prevention	GERD is found in many patients with ILD and symptoms of GERD should be actively sought. If present, GERD should be treated, and although only studied in IPF, treatment of GERD is associated with lower IPF-related mortality.[63]
Lung transplantation	The only therapy shown to prolong life in patients with end-stage, particularly fibrotic, ILD is lung transplantation.[64] Transplantation has been performed successfully in the management of most ILDs. A recommendation for lung transplantation must consider the significant risk of dying after lung transplantation at 1 year (10%–25%) and 5 years (50%–60%). Many patients with ILD are older than the upper age limit of "physiologic" age 65, though lung transplantation is being offered to older individuals at some centers.
End of life care	Palliative care should be provided, ideally in the patient's home when the patient with ILD deteriorates and reversible causes such as infection or PE are unlikely.[65]

GERD, Gastroesophageal reflux disease; *ILD,* interstitial lung disease; *IPF,* idiopathic pulmonary fibrosis; *PE,* pulmonary embolism.

MINI CLINI

Tobacco Use and Interstitial Lung Disease

Problem

A 30-year-old woman has ILD and is a current smoker. She is concerned that quitting on her own is too difficult and comments that tobacco use is associated with emphysema, not with scarring. Should she be encouraged to quit smoking? Why or why not?

Solution

Yes! Although the association between tobacco use and COPD is well known, the relationship with ILD is less well-appreciated. Smoking is a risk factor for the development of IPF but not the sole cause. However, the IIPs of DIP, RB-ILD, and PLCH have a strong association with cigarette smoking.

6. *Atherosclerotic vascular disease:* Many patients with ILD have independent risk factors for atherosclerotic vascular disease. They may have an unrelated cardiac disease, such as coronary artery disease, left ventricular dysfunction, or valvular disease, which can be mistaken for a worsening of the pulmonary process.

Each of the possible explanations for the patient's breathlessness should be considered before concluding that progression of the ILD is the cause of worsened dyspnea.

NONSPECIFIC THERAPIES

Several therapies should be considered in all types of ILD depending upon the patient's degree of impairment and physiology and these are listed in Table 26.4.

Almost all patients with DIP, RB-ILD, and PLCH are current or former tobacco smokers. As with other toxic exposures, complete avoidance of all smoke is important for these patients. In RB-ILD and PLCH, physiologic stabilization and occasionally even improvement can occur after stopping smoking. In DIP, the benefits of smoking cessation are unclear.

In addition to having concerns about these specific disease considerations, patients with ILD of any type cannot afford to risk developing additional, smoking-related cardiorespiratory impairment. The patient should be strongly encouraged to stop smoking.

SUMMARY

The entities grouped as ILDs are a diverse group of illnesses of varied cause, treatment, and prognosis. These diseases generally manifest as chronic, progressive dyspnea on exertion and cough. Findings on examination are often limited to the chest in the form of fine, inspiratory crackles. The most common finding on chest x-ray is diffuse reticular or reticulonodular infiltrates with reduced lung volumes. Pulmonary function testing usually reveals restrictive physiology and decreased diffusion capacity; however, other patterns can be seen. Therapy depends on the underlying disease and may consist of immunosuppressive drugs and the avoidance of disease-inducing exposures.

ROLE OF THE RESPIRATORY THERAPIST IN INTERSTITIAL LUNG DISEASE

- The respiratory therapist (RT) sees patients with ILD in one of two settings—as an outpatient or when the patient is hospitalized. RTs assess and treat outpatients in several manners. In the role of pulmonary function technician, the RT assesses disease burden and serial changes in lung function. At the initial evaluation, the RT needs to provide accurate spirometry, lung volume, and DLCO, along with 6-minute walk distance

and saturation, because these measures have important prognostic value. At subsequent visits, serial changes in these parameters are important to assess a patient's response to therapy or disease progression. Besides having important prognostic values, changes in lung function over time help determine whether to continue therapy or refer eligible patients for lung transplantation.

- RTs determine supplemental O_2 requirements at rest and with exertion and recommend the appropriate delivery amount, mode, and source of O_2. Also, RTs typically perform outpatient pulmonary rehabilitation, which can benefit many patients with ILD. RTs also may administer inhaled pentamidine, which is used to prevent *Pneumocystis jirovecii* infection in patients receiving immunosuppressive drugs for an ILD.
- The needs of patients with ILD change when admitted to the hospital. The RT plays a crucial role in assessing supplemental O_2 needs and delivering O_2 by the proper mode (nasal cannula, face mask, high-flow O_2 with non-rebreathing face mask, or intubation and mechanical ventilation). If obstructive impairment is suspected, the RT can recommend and deliver the appropriate bronchodilators or inhaled corticosteroids. Owing to the tenuous nature of these patients, careful monitoring by the RT of patients with ILD is required to prevent hypoxemia and its acute complications.
- Patients with ILD can progress to having severely impaired lung function and require mechanical ventilation for survival. In partnership with the other members of the patient care team, the RT must understand the treatment goals of the patient and must assess whether mechanical ventilation is indicated. Most patients with severe ILD will not meaningfully benefit from mechanical ventilation as it will only prolong the course of dying. However, in select cases, patients who are awaiting lung transplantation or who have a potentially reversible process, mechanical ventilation may bridge survival until lung transplantation or lung improvement.[59] The RT must be aware of the need for reduced tidal volumes, the potential lung injury that is associated with ventilation with large tidal volumes, and the potential need for elevated pressures to drive adequate ventilation because of decreased compliance.
- Patients who are awaiting lung transplantation or who develop severe primary graft dysfunction shortly after transplantation are candidates for extracorporeal membranous oxygenation (ECMO). Ideally, candidates for ECMO should be younger, have no significant comorbidities, and already be listed for lung transplantation or have no significant contraindications to quick listing.[60] While on ECMO, the lung should be rested as much as possible to prevent worsening ILD, and if possible the patient should be ambulated.

SUMMARY CHECKLIST

- ILDs are a diverse group of illnesses that can be organized into groups based on related causes.
- These diseases generally cause chronic, progressive dyspnea on exertion and cough.
- Findings on examination are often limited to the chest in the form of fine, inspiratory crackles.
- The most common chest x-ray finding is diffuse reticular or reticulonodular infiltrates with reduced lung volumes.
- Pulmonary function testing usually reveals restrictive physiology and decreased diffusion capacity; however, other patterns can be seen.
- Causes of the ILDs are diverse but are most frequently from exposure (tobacco, hypersensitivity pneumonitis antigens, silica, asbestos), autoimmune dysfunction (sarcoidosis, connective tissue disease associated), and abnormal injury healing (IPF).
- Treatment for IPF is now available with pirfenidone and nintedanib, both of which reduce the decline in lung function.
- Non-specific treatment may be considered in all ILD patients (e.g., supplemental O_2, pulmonary rehabilitation), but specific ILD treatment depends on the underlying disease and may consist of antifibrotic drugs for fibrotic disorders, immunosuppressive drugs for immune mediated disorders, and avoidance of disease-inducing exposures.

Pleural Diseases[a]

Joseph Cicenia

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the anatomy and function of the visceral and parietal pleura.
- Describe how pleural effusions occur and the difference between transudative and exudative effusions.
- Identify common causes of transudative and exudative pleural effusions.
- Write definitions of chylothorax, hemothorax, and pneumothorax.
- Describe the impact of moderate to large pleural effusions on lung function.
- State the role of the chest x-ray in recognizing pleural effusions.
- State the purpose of thoracentesis and the potential complications.
- Identify the definitions of spontaneous, secondary, and tension pneumothorax.
- Describe the diagnosis and treatment of pneumothorax, including the use and function of chest tubes and three bottle collection systems.

CHAPTER OUTLINE

KEY TERMS

alveolopleural fistula
bronchopleural fistula
chest tube
chyle
chylothorax
empyema
exudative pleural effusion
hemothorax
parietal pleura
pleural effusion
pleurisy
pleurodesis
pneumothorax
primary spontaneous pneumothorax
re-expansion pulmonary edema
secondary spontaneous pneumothorax
stomata
tension pneumothorax
thoracentesis
transudative pleural effusion
visceral pleura

A wide variety of pleural diseases affect respiratory function. An understanding of pleural anatomy, physiology, and pathology is essential for the respiratory therapist (RT) to deliver effective respiratory care. This chapter focuses on the two major diseases that occur in the pleural space: pleural effusion and **pneumothorax**.

[a]With acknowledgement and appreciation of Dr. Charlie Strange for his authoring of this chapter in earlier editions of this book.

THE PLEURAL SPACE

The pleura is a thin membrane that lines the lung itself, the inside of the chest wall, the diaphragm, and the mediastinum (Fig. 27.1). The pleural is divided into two regions: the **visceral pleura** covers the lung parenchyma (including within the interlobar fissures) and the **parietal pleura** covers the inside of the thoracic cavity. The two pleural surfaces meet at the lung root, located at the hilum (Fig. 27.2). Differentiation of the pleural surfaces is important, because each has its own unique physiologic

properties and anatomy. A small amount of fluid, known as the pleural fluid, typically floats freely within the space between the visceral and parietal pleura. It is thought that this thin layer of fluid serves as lubricant to allow the lung to slide freely along the chest wall during breathing. The space where the fluid circulates is called the pleural space, and it is considered a "potential space" such that it can accommodate large amounts of fluid, which can occur in disease states. Normally, the right and left pleural spaces do not communicate, as they are completely separated by the mediastinum.

The parietal pleura can be further subdivided into the regions it covers, including the rib surface (costal pleura), the diaphragm (diaphragmatic pleura), and the mediastinum (mediastinal pleura). Within the parietal pleura there are capillaries and lymphatic channels called *stomas*, and the parietal pleura is relatively thin compared with the visceral pleura. The parietal pleura is also richly innervated by sensory nerves, which originate in different areas depending on the area of pleura. Intercostal nerves supply the costal pleura, whereas the diaphragmatic pleural is supplied by the phrenic nerve. Thus stimulation of the diaphragmatic pleura will cause pain referred to the shoulder, whereas stimulation of costal pleural nerves will cause pain in the chest wall along the distribution of the corresponding costal nerve.

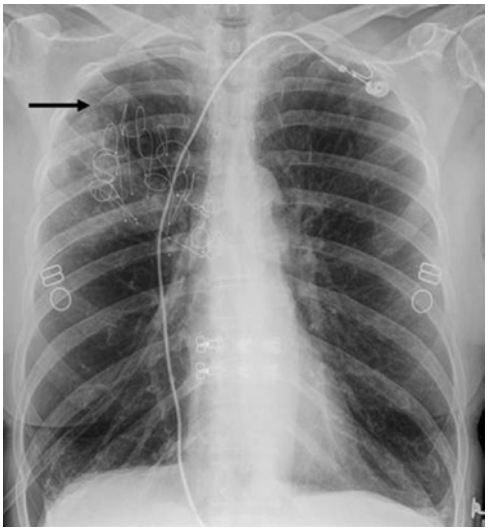

Fig. 27.1 The presence of a pneumothorax is diagnosed by identification of a pleural line *(arrow),* in this case after bronchoscopic placement of lung volume reduction coils. A hydropneumothorax requires identification of both a pleural line *(arrow)* and the air-fluid interface of pleural fluid that causes a straight line in the chest. A high-quality monitor is needed to optimally detect the pleura.

The visceral pleura is relatively thick, almost 2 to 3 times the thickness of the parietal pleura. The visceral pleura also has blood vessels running through it but no lymphatic stomas. Furthermore, the visceral pleura have a thick layer of connective tissue separating it from the lung. These differences in thickness impact fluid generation and drainage, with most of this occurring in the parietal pleura. The visceral pleura has no sensory innervation and thus can be manipulated without causing any pain.

The average person has approximately 8 mL of pleural fluid per hemithorax.[1] It is estimated that this pleural fluid has a total protein concentration similar to that of interstitial fluid elsewhere in the body: between 1.3 and 1.4 g/dL.[2]

The pleural space is under negative pressure except during forced expiration. This is an important concept, because if the pleural space pressure was positive, the lungs would collapse. The intact thoracic rib cage provides elastic recoil pressure outward, whereas the intrinsic recoil pressure of the lung is inward toward the lung hilum. The diaphragm further decreases the intrapleural pressure below atmospheric pressure to allow inspiration to occur. The overall contribution of each results in a normal pressure within the pleural space between 0 and −5 cm H_2O. In an upright person, the pressure is more negative at the top of the lung than at the bottom of the lung because of the weight of the lung and the effects of gravity. An important effect of the negatively pressurized pleural space is that fluid can move into the pleural space from adjacent sites when a communication is present.

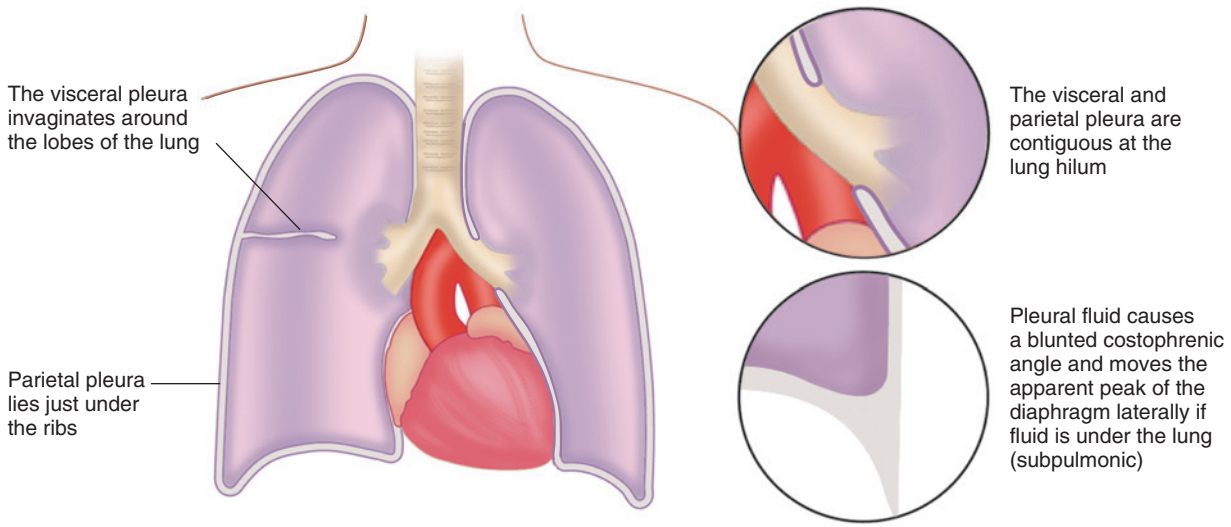

Fig. 27.2 Anatomy of the pleura.

PLEURAL EFFUSIONS

Any abnormal amount of pleural fluid in the pleural space is called a **pleural effusion**. The many causes of pleural effusion are categorized according to the factor that causes it and the content of the fluid.[3] Pleural fluid will accumulate in the pleural space when fluid formation overcomes the ability to drain the fluid.

Pleural fluid is normally produced from capillaries within the parietal pleura, and exits the pleural space through lymphatic **stomata**. The lymphatic stomata have a larger capacity to remove fluid compared to the normal rate of production, by almost 20 times. Normal production occurs at 0.01 mL/kg/h, and removal capacity is 0.20 mL/kg/h. Any process that results in alterations of production, removal, or both will result in a pleural effusion. Since parietal pleural stomata connect with intercostal lymphatic vessels under the ribs that drain posteriorly into the mediastinum, any process that impairs flow into the mediastinum will cause removal capacity to go down. Once in the mediastinum, these lymphatic vessels enter lymph nodes before draining into the thoracic duct, a large lymphatic channel within the chest, which empties into the left subclavian vein. Abnormalities along this path will also result in diminished fluid removal from the pleural space. Since pleural fluid arises from capillaries within the pleural membranes, any process that favors translocation across those capillaries into the pleural space will increase fluid formation, and if this is to a point that overwhelms the capacity for removal, a pleural effusion will also occur.

Transudative Effusions

Any pleural effusion that forms when the pleural space is intact is called a **transudative pleural effusion**. These generally occur due to systemic factors, and not due to factors impacting the pleura directly. Several pleural fluid testing schemes have sought to help identify a transudate by comparing values of the fluid to corresponding values in the serum. A pleural fluid total protein concentration less than 50% of the serum total protein level and lactate dehydrogenase (LDH) values in the pleural fluid less than 60% of the serum value indicate the presence of a so-called transudative pleural effusion. In the absence of serum values, an absolute pleural fluid LDH level less than two-thirds normal for serum suggests the presence of a transudate. These tests are best known as "Light criteria."[4] It should be remembered, however, that the designation of a transudate is contingent upon its cause not its corresponding lab values.

The classification system listed in Box 27.1 is not perfect, and refinements continue to be proposed. For practical purposes, the laboratory values used to assess the cause of a pleural effusion help narrow the possible causes of pleural fluid formation.

Transudative pleural effusions form when hydrostatic and oncotic pressures are abnormal (Fig. 27.3).[5] The list of diseases that cause transudative pleural effusions is short. Therefore, these diseases, listed as follows, remain relatively easy to diagnose.

Congestive Heart Failure

Elevation of pressure in the left atrium and pulmonary veins is the defining feature of *congestive heart failure* (CHF). Elevation

BOX 27.1 Causes of Pleural Effusion

Transudative pleural effusion
- Congestive heart failure
- Cirrhosis
- Nephrotic syndrome
- Hypoalbuminemia
- Lymphatic obstruction
- Peritoneal dialysis
- Atelectasis
- Central venous catheter in pleural space
- Urinothorax

Exudative pleural effusion—neoplastic disease
- Carcinoma
- Lymphoma
- Mesothelioma

Exudative pleural effusion—infectious disease
- Bacterial infection
- Tuberculosis
- Fungal infection
- Paragonimiasis
- Viral pleurisy

Exudative pleural effusion—pulmonary embolism and gastrointestinal disease
- Pancreatic disease
- Intraabdominal abscess
- Splenic infarction
- Esophageal perforation
- Abdominal surgery
- Endoscopic variceal sclerotherapy

Exudative pleural effusion—collagen vascular disease
- Rheumatoid pleurisy
- Systemic lupus erythematosus
- Drug-induced lupus
- Immunoblastic lymphadenopathy
- Sjögren syndrome
- Familial Mediterranean fever
- Churg-Strauss syndrome (eosinophilic granulomatosis with polyangiitis)
- Granulomatosis with polyangiitis (formerly called *Wegener granulomatosis*)

Exudative pleural effusion—drug-induced pleural disease
- Nitrofurantoin
- Minoxidil
- Dantrolene
- Methysergide
- Bromocriptine
- Amiodarone
- Procarbazine, bleomycin, mitomycin
- Methotrexate

Miscellaneous diseases and conditions
- Benign asbestos pleural effusion
- Post-cardiac injury syndrome (Dressler syndrome)
- Meigs syndrome
- Yellow nail syndrome
- Sarcoidosis
- Pericardial disease
- Fetal pleural effusion
- Uremic pleural effusion
- Trapped lung
- Radiation pleurisy
- Amyloidosis

Electrical burns

Hemothorax

Chylothorax

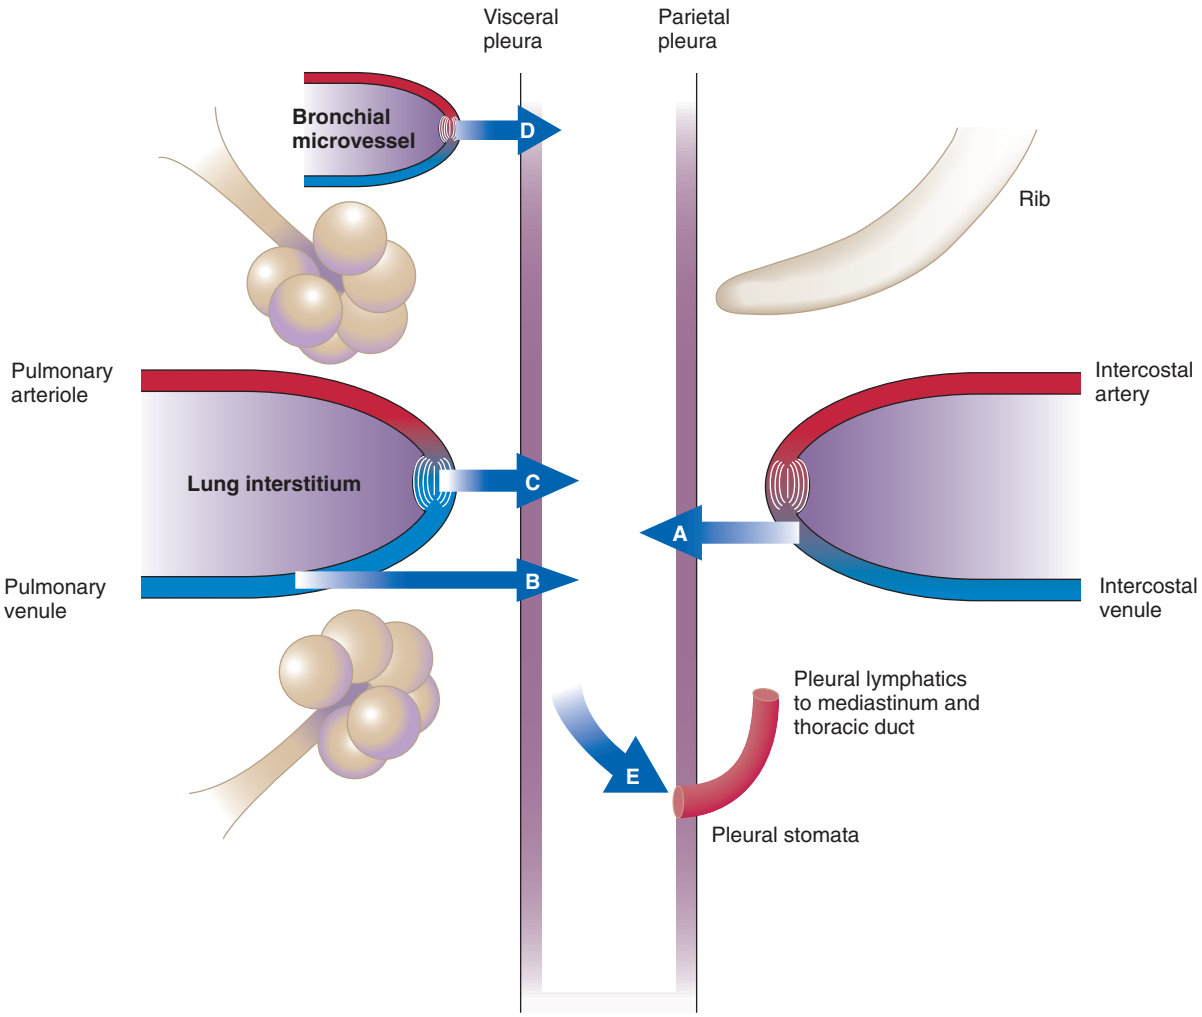

Fig. 27.3 Pleural fluid formation requires both excess fluid formation and decreased elimination. In diseases such as pulmonary arterial hypertension, in which right-sided heart pressure is increased and systemic veins, such as the intercostal veins *(A)*, are pressurized, pleural fluid does not form because pleural fluid formation is not increased and lymphatic drainage remains intact. However, when left ventricular failure causes pulmonary venule pressure *(B)* to increase, the addition of interstitial lung water overwhelms the drainage and produces a transudative pleural effusion. Injury to the capillaries *(C)*, as in pneumonia or acute respiratory distress syndrome, causes fluid to leak into the lung interstitium and pleural space at increased rates. Under these conditions, fibrin can occlude the pleural lymphatic vessels *(E)* and cause fluid to accumulate. The bronchial microvessels *(D)* supply the pleura with blood and likely participate to some extent in production of pleural fluid.

of pulmonary venous pressure increases the amount of interstitial fluid in the lung. In severe cases, flooding of the alveoli causes pulmonary edema, but in less severe cases, interstitial lung water increases and decompresses into the pleural space. Because systemic venous pressure also is elevated, there is limited capability to remove pleural fluid through the intercostal veins. Therefore, pleural fluid must be predominantly removed by the lymphatic vessels. Pleural effusions result when the capacity of pleural lymphatic drainage is overwhelmed.[6]

CHF is the most common cause of pleural effusions in clinical practice. The effusions can be massive, filling the entire hemithorax and compressing the lung. More commonly, they are small and bilateral. When pleural effusions from CHF are unilateral, they are twice as commonly on the right side as on the left; thus an isolated left pleural effusion resulting from CHF is unusual, and the occurrence of a unilateral left pleural effusion should cause suspicion of causes other than CHF. The effusions of CHF are rarely drained because outcome is heavily influenced by successful management of the underlying CHF, which also clears the effusions.[7]

RULE OF THUMB Pleural effusions associated with congestive heart failure are usually bilateral, but when unilateral, they are twice as commonly right-sided as unilaterally left-sided.

Nephrotic Syndrome

In *nephrotic syndrome* (also known as *nephrosis*), the kidneys leak more than 3 g of protein per day into the urine. Because

patients become protein depleted, there is insufficient oncotic pressure within the blood to hold appropriate amounts of fluid within the blood vessels. These patients become edematous, and fluid leaks into the lung interstitium and pleural space. Effusions are common in nephrotic syndrome. It is thought that nephrotic syndrome is a risk factor for venous thromboembolism, so pulmonary embolism should be considered in these patients as a cause of the pleural effusion if the clinical situation warrants.

Hypoalbuminemia

Hypoalbuminemia is caused by a variety of debilitating diseases, such as AIDS and chronic liver disease. Pleural effusions rarely form until the serum albumin level is less than 1.8 g/dL. The mechanism of formation of pleural fluid is identical to that of nephrotic syndrome. Low protein levels in the blood allow fluid to leak into interstitial tissues and the pleural space.

Liver Disease

End-stage liver disease causes transudative fluid to accumulate in the abdomen. This fluid is called *ascites*. Because the pleural space is under negative pressure during inspiration and because ascitic fluid often is under positive pressure, any small defect in the diaphragm can draw ascitic fluid into the pleural space to form what is called a *hepatic hydrothorax*.

All ascitic fluid can end up in the chest because of the pressure gradient, and true ascites can be absent. This condition often is quite difficult to manage except with methods that limit ascites formation, such as sodium restriction and diuretics. Excessive pleural fluid is present in approximately 6% of patients with ascites, and 70% of these fluid collections are on the right side.[8]

Atelectasis

When segments of the lung collapse, intrapleural pressure becomes more negative and can produce small effusions. With relief of bronchial obstruction and postoperative pain, these effusions may go away.

Lymphatic Obstruction

Lymphatic obstruction within the mediastinum causes poor pleural fluid removal from the pleural space, although the pleural space is otherwise normal. The most common condition that causes this abnormality is cancer that metastasizes to the mediastinal lymph nodes or that obstructs the pulmonary veins. This condition should be differentiated from a true malignant pleural effusion, defined as having actual cancer cells within the pleural space.

Rare Causes of Transudative Pleural Effusion

There are other rare causes of transudative pleural effusions. Urinothorax occurs after rupture of the ureter, causing a urine leak into the retroperitoneal space that refluxes into the chest. The pleural fluid in urinothorax has a low pH. A central venous line that is inappropriately placed into the pleural space can put large amounts of transudative fluid into the pleural space before this abnormality is recognized. The level of glucose in the pleural fluid can be very elevated if there is glucose in the intravenous solution that is being administered.

Exudative Effusions

In contrast to a transudate, an **exudative pleural effusion** is caused by inflammation in the lung or pleura that results in a direct effect upon the pleura itself. This type of pleural effusion contains more protein and inflammatory cells than does a transudative effusion. Because therapy for pleural effusion depends on the cause, **thoracentesis** often is performed to determine the specific biochemical and cellular characteristics of the pleural effusion. Box 27.1 lists the common causes of exudative pleural effusion. They account for approximately 70% of all pleural effusions.

Parapneumonic Effusion

Pleural effusions form in pneumonia because inflammation in the lung increases interstitial lung water and pleural fluid production. Most effusions are small and resolve with resolution of the bacterial pneumonia.[9] However, if the effusion is not small, it should be sampled via thoracentesis, with appropriate lab studies to determine if the fluid is at risk to become a complicated parapneumonic pleural effusion, in which a more definitive drainage procedure should be done.[10] Complicated parapneumonic pleural effusion develops when the pleural fluid has a high enough protein content to clot. The clotting causes fibrin strands to span the visceral and parietal pleura. The net result is collection of pleural fluid into different pockets called *loculi* within the pleural cavity. These often cannot be drained by a single **chest tube**.

Progression to **empyema** is marked by the presence of bacteria within the pleural space, seen as pus or bacteria on Gram stain. Empyemas require drainage, usually by chest tube placement or by surgery. Whether complicated parapneumonic effusions require drainage remains controversial, although most physicians perform drainage because some of these effusions can progress to empyema.[10]

Parapneumonic effusions are common causes of persistent fever among intensive care unit (ICU) patients with pneumonia. Sampling by thoracentesis is commonly performed to exclude empyema. Pleural fluid drainage can improve ventilation and dyspnea if the volume of fluid removed is large.[11]

Viral Pleurisy

Viral lung infections (**pleurisy**) can cause pleural inflammation, small pleural effusions, and pain. The effusions may be so small they may be overlooked on a routine chest radiograph, and even when they can be seen, the effusions often are too small to sample. Pleural pain, which is called *pleurodynia*, and which can be the result of many other pleural processes, often is difficult to manage. The typical patient with pleurodynia has shallow respirations; deeper breaths are limited by pain. The subsequent atelectasis can cause hypoxemia caused by shunting.

Tuberculous Pleurisy

In many parts of the world, any lymphocyte-predominant exudative effusion is considered tuberculosis until proved otherwise. Tuberculous pleural effusions occur when an area of prior tuberculosis infection reactivates and ruptures through the visceral pleural surface, causing an exudative inflammatory effusion. The

resultant pleural effusion is an immune reaction to the tuberculosis, rather than an infection of the pleural space per se. Though tuberculous effusions tend to be small to moderate, they may be excessively large and span the entire hemithorax. Tuberculous pleural effusions may resolve spontaneously, often with subsequent progression of the tuberculous infection in the lung.

Although these patients need respiratory isolation, only 25% of them have sputum that subsequently grows *Mycobacterium tuberculosis.* The purified protein derivative (PPD) skin test result is negative in 30% of patients when they come to medical attention but turns positive in 6 to 8 weeks in almost everyone.[12] Though recently serum interferon gamma assays have been used in the diagnosis of latent and active TB, they have no role in the diagnosis of tuberculous effusion.

Diagnosis of tuberculous effusions relies on high suspicion and a characteristic lymphocytic exudative profile of pleural fluid. Definitive diagnosis is usually made through finding a pathologic pattern of granulomas on biopsy of pleural tissue. Recent studies have shown that high levels of pleural fluid adenosine deaminase (ADA) or pleural fluid interferon gamma can also be diagnostic. Definitive diagnosis can also be made by isolation of Mycobacterium tuberculosis from sputum, pleural fluid, or pleural biopsy specimen.[13]

Malignant

Malignant disease is the most common cause of large unilateral pleural effusions among persons older than 60 years. Common cancers that form malignant pleural effusions include lung cancer and breast cancer, although any cancer can metastasize to the pleural surface. The effusions usually are lymphocyte predominant; malignant cells are found during cytologic examination of the pleural fluid.

Some malignant pleural effusions, such as those from lymphoma, respond to therapy for the malignant disease. However, most patients with symptomatic malignant pleural effusions need primary therapy with **pleurodesis** or placement of an indwelling tunneled pleural catheter. Pleurodesis describes the process of fusing the visceral and parietal pleural membranes and is described in more detail later in this chapter. If pleurodesis cannot be achieved, palliation through indwelling tunneled pleural catheters is an option.[14]

Postoperative Effusion

A variety of operations involving the chest or upper abdomen produce pleural fluid.[15] Effusions after cardiac surgery usually are predominant on the left side and tend to be bloody. These effusions are particularly prevalent after a cutdown of the internal mammary artery for coronary artery bypass.

Small transudative pleural effusions are common when there is any atelectasis in the lung. Upper abdominal operations cause inflammation of the diaphragm. The resulting effusion has been termed a *sympathetic* effusion. Lung surgery in which the lung is unable to fill the thoracic cavity leaves a space under negative pressure, which fills with inflammatory pleural fluid. When the lung is unable to fill the space because of small postoperative size or visceral pleural fibrosis, the resulting pleural effusion can never be completely drained because of the "trapped lung."

Chylothorax

The thoracic duct is a lymphatic channel that runs from the abdomen through the mediastinum to enter the left subclavian vein. The thoracic duct collects and transports **chyle** (a milky fluid consisting of fat droplets and lymph) into the central venous system. Disruption of the thoracic duct anywhere along its course can cause leakage of **chyle** into the mediastinum, which then may rupture into the pleural space and cause a **chylothorax**. The most common causes of rupture are malignancy (50%), surgery (20%), and trauma (5%).[16] The thoracic duct courses through the right side of the mediastinum in the lower thoracic cavity before crossing to the left side of the mediastinum at the level of the fourth to sixth thoracic vertebra (T4 to T6). Rupture below this level causes right-sided pleural effusion, whereas rupture above this level causes left-sided pleural effusion containing chyle.

In a patient who has eaten recently, the effusions are milky white as a result of the presence of chylomicrons (microscopic fat particles) absorbed by abdominal lymphatic vessels. In a fasting patient, these effusions usually are yellow, but they may be bloody. Regardless of the color, presence of emulsified fat droplets imparts a milky or glistening appearance to the fluid. When this is seen, specific studies should be done on the fluid to evaluate for chylous effusion. A pleural fluid triglyceride concentration greater than 110 mg/dL confirms the diagnosis of chylothorax.[17] Computed tomography (CT) should be performed to evaluate the cause of the chylothorax.

RULE OF THUMB A value of the triglyceride level in the pleural fluid above 110 mg/dL defines the fluid as a chylous pleural effusion. This should prompt consideration of the causes of chylothorax.

Hemothorax

Hemothorax is the presence of blood in the pleural space. Hemothorax is arbitrarily defined as a pleural fluid hematocrit more than 50% of the serum value. Small amounts of blood in otherwise clear fluid can turn the fluid red, so measurement of the pleural fluid hematocrit is necessary to make this diagnosis.

A hemothorax is seen most commonly after blunt or penetrating chest trauma. Any vein or artery in the thorax can bleed into the pleural space. A chest tube usually is inserted to monitor the rate of bleeding and determine whether the source is arterial or venous.[18]

Connective Tissue Diseases

Pleural effusions are found in a variety of connective tissue diseases, although the effusions usually are small. Effusions caused by inflammation of small blood vessels are the most common chest manifestation of systemic lupus erythematosus (SLE). Pleural effusions often accompany pericardial effusions in SLE and disappear with corticosteroid therapy.

Rheumatoid arthritis produces a characteristic effusion with a very low glucose content and low pH. These effusions can cause visceral pleural fibrosis and a trapped lung.

Uremic Effusion

Uremic pleurisy occurs under the same conditions as uremic pericarditis, which is inflammation of the pericardium (or sac enclosing the heart). The typical patient is undergoing dialysis that is inadequate in duration or frequency. Although the cause of pleural and pericardial inflammation in kidney failure remains unknown, the inflammatory process can take weeks to resolve.

Miscellaneous Causes

Discussion of the other causes of exudative effusions is beyond the scope of this chapter. Nevertheless, thoracentesis that yields findings compatible with any of those in the systemic diseases listed in Box 27.1 can narrow the differential diagnosis.

Physiologic Importance

Mechanics of Ventilation

Pleural effusions cause lung atelectasis because the capacity of the thorax to expand is limited and fluid collapses the lung. Spirometry can show restriction in individuals with pleural effusions. Studies correlating the volume of pleural fluid removed with improvement in forced vital capacity (FVC) show much variability from patient to patient.

RULE OF THUMB The patient's vital capacity improves by approximately one-third of the pleural fluid volume removed. The remainder of the pleural fluid volume causes diaphragmatic compression and chest wall expansion. Some patients have a delay of 24 to 48 hours before the improvement can be seen as atelectasis resolves. Lack of any improvement suggests that lung consolidation or endobronchial obstruction is present. Improvement is less when the underlying disease is acute respiratory distress syndrome (ARDS).

Dyspnea is common with pleural effusions, even when lung mechanics are relatively preserved. The mechanisms remain unknown but are likely associated with abnormalities in gas exchange and respiratory mechanics, impaired diaphragm function, and altered hemodynamics.[19] Dyspnea relief is variable after pleural fluid removal. Some patients have symptomatic relief after removal of small pleural fluid volumes. Others can actually have more dyspnea if the fluid is removed in situations such as trapped lung, in which neural activation may increase with fluid withdrawal.

In rare instances, the pleurae thicken with a disease process sufficient to cause fibrothorax. Technically, fibrothorax is any process that causes fibrosis of the thoracic cage that affects pulmonary function. Fibrothorax can be caused by diseases of the skin (e.g., fibrothorax that occurs, rarely, in scleroderma), soft tissue, bone (e.g., myositis ossificans, a disease in which muscles calcify), or pleura. The causes of pleural thickening significant enough to produce restriction include severe asbestos pleurisy, rheumatoid pleurisy, complicated trauma, cancer, and empyema. Treatment of fibrothorax from a pleural cause requires surgery, which is rarely performed because it is a very difficult operation.

Hypoxemia

Most patients with a pleural effusion have an increased alveolar-arterial (A-a) gradient (see Chapter 12) and a reduced P:F ratio resulting from the pathologic changes in the lung that are causing the effusion (see Chapter 12). Oxygenation can worsen after thoracentesis because changes in ventilation/perfusion ($\dot{V}/\dot{Q}$) matching are not instantaneous. Recovery to baseline PO_2 and subsequent improvement usually occurs a short time after thoracentesis.[19]

Diagnostic Tests

Chest Radiography

The chest x-ray is the most common method of detecting a pleural effusion (see Chapter 21). It is important that, if possible, the chest x-ray be obtained with the patient in an upright position to show a pleural fluid meniscus at the costophrenic angles. Many ICUs have rules that all chest x-rays are taken with patients sitting upright to optimize the value of the test. When the same patient undergoes radiography in the supine position, the effusion is distributed throughout the posterior part of the chest. The chest x-ray shows a generalized haze, which interferes with detecting pulmonary infiltrates and quantifies the amount of fluid in the pleural effusion.

Lateral decubitus chest x-rays (see Chapter 21) are performed by having patients lie on their side with the radiograph taken across the bed or table. This technique can show an effusion as small as 5 mL. This technique is used less often than other tests.

Ultrasonography and Computed Tomography

Pleural fluid can be detected easily with ultrasonography of the chest. Ultrasound can also detect the presence of fibrous strands, or loculations, that have developed in the pleural fluid. The sensitivity of ultrasonography for pleural effusions is high, although ultrasonography is an operator-dependent study. Small portable ultrasound machines with high diagnostic accuracy have become available to localize the presence and location of pleural effusions. Most physicians use them routinely to optimize thoracentesis success.

CT scanning of the chest is the most sensitive study for identifying a pleural effusion. A contrast-enhanced scan is needed to delineate the pleural membrane and differentiate peripheral lung consolidation from pleural fluid. In addition to showing the size and location of a pleural effusion, the chest CT scan often gives information about the underlying lung parenchyma and the primary process causing the effusion.

Thoracentesis

In thoracentesis, pleural fluid is sampled percutaneously by means of inserting a needle into the pleural space (Fig. 27.4). Administering an adequate local anesthetic ensures a painless procedure if care is taken to place lidocaine at the skin insertion site, along the periosteum of the involved rib, and at the parietal pleura, which is richly innervated with sensory nerve fibers. Diagnostic sampling of pleural fluid for cell counts, cultures, chemistries, and cytologic examination usually can be performed with a single syringe and a small needle. Samples for pleural pH should be kept from contact with room air. Pleural fluid drainage with lung re-expansion involves placing a larger catheter into the pleural space.

Thoracentesis involves the following three major risks: (1) intercostal artery laceration, (2) infection, and (3) pneumothorax.[20] Both an artery and a vein course under every rib, and the

vessels become increasingly serpiginous with aging. Ensuring needle passage just over the rib margin makes bleeding during thoracentesis rare.

Because infection can be introduced into the pleural space, maintaining sterility during the procedure is necessary. In some situations, the risk for infection is so high that thoracentesis rarely should be performed. When a lung is surgically removed, the space fills with sterile fluid. An infection introduced into this space usually requires open surgical drainage. Any trapped lung also carries a high risk for empyema because of the inability of the visceral and parietal pleura to meet and contain any infectious process. Needle puncture remains one of the most common causes of pneumothorax (see discussion of pneumothorax later in this chapter).

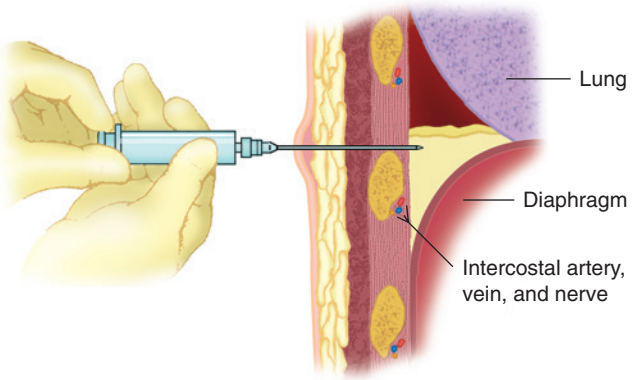

Fig. 27.4 The technique of thoracentesis involves passage of a needle just above the rib. If the needle is placed too low on the chest, the diaphragm or organs below the diaphragm can be punctured. Diagnostic thoracentesis can be performed with small amounts of pleural fluid.

Chest Thoracotomy Tubes

Chest tubes currently are manufactured in a variety of sizes and shapes, from 7 to 40 Fr catheters. Catheter choice is frequently a matter of physician preference. The letter "F" stands for "French," a unit of width of the tube with larger numbers indicating wider tubes. The French size is three times the external diameter for the catheter in millimeters, so that a 6 Fr catheter has a 2 mm external diameter. Larger tubes are less likely to become obstructed and are capable of high airflow rates. Smaller tubes are easier to place over guidewire systems and cause less pain.

RULE OF THUMB The French size indicates three times the diameter of a tube in millimeters. For example, a 6 Fr tube has a 2 mm external diameter.

Intercostal placement is designed for the skin and soft tissue to approximate the tube and prevent air from entering the pleural space from the outside. The chest tube is then connected to a water-sealed chamber, which usually is contained within a commercially marketed three-bottle system that also regulates pleural pressure and is used to measure pleural fluid volume (Fig. 27.5).

RULE OF THUMB Chest tubes are usually removed when the volume of pleural fluid that comes out is less than 50 mL/24 h. To optimize pleural space drainage, chest tubes should not be kinked. Higher volumes suggest that the primary process has not been treated adequately. Daily monitoring of pleural fluid volume requires that the pleural fluid drainage system not be tipped over. Volumes should be recorded in the medical chart and marks made on the pleural drainage system to help determine the best time for chest tube removal.

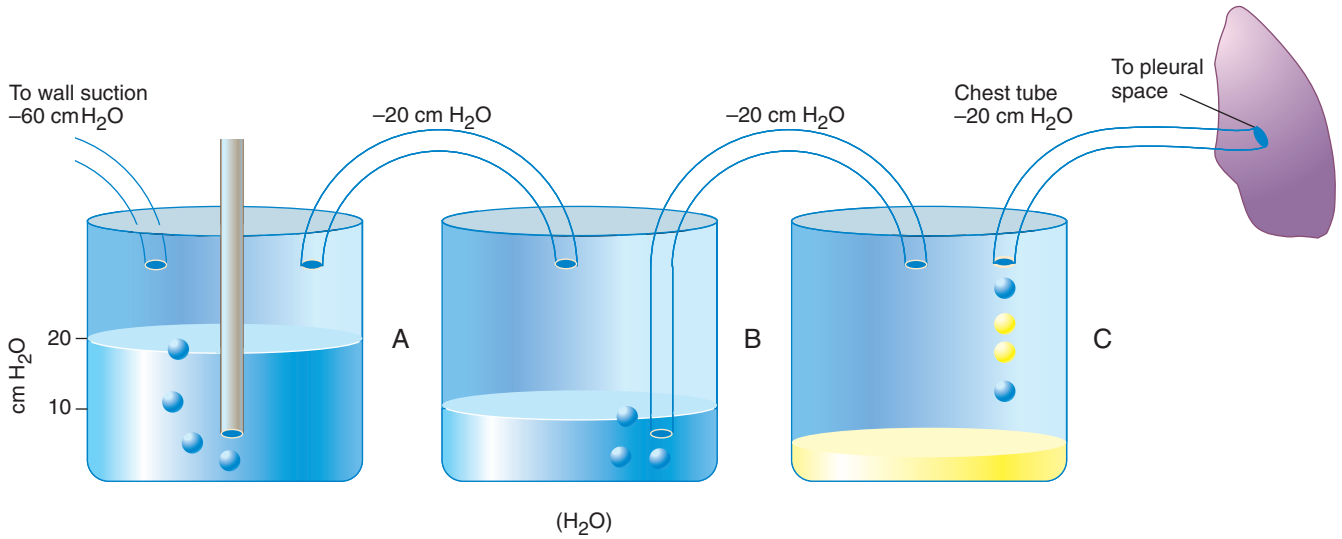

Fig. 27.5 The standard three-bottle system is the basis for all commercial chest tube drainage systems. Pleural fluid and pleural air enter compartment *C*, which serves as a fluid collection trap so that the water-seal fluid volume will not rise (compartment *B*) and create resistance to air escaping the chest. Air cannot be inspired into the chest because of the water in compartment *B*. Open entrainment of room air through a submerged tube in compartment *A* buffers the amount of wall suction applied (–60 cm H_2O) to the height of the water column to standardize the pressure (–20 cm H_2O) transmitted to the chest.

Chest Tube Drainage Systems

Three bottle systems are now integrated into commercially available chest drainage systems that house each of the bottle components into a compact system. These commercial systems will house a water-seal chamber, suction control chamber, and a collection chamber in one container, and all will have a one-way valve that prevents air or fluid from returning into the chest. Commercial systems vary slightly, and the therapist should be aware of each commercial unit's design, set up, and functionality, as determined by the manufacturer. In general, the water seal is usually set at the 2 cm mark, and the suction control component is set at the −20 cm H_2O level (which can be adjusted on many units, if ordered by the physician). The suction control component of the system is what determines the suction level (regardless of the degree of wall suction).

Systems are set up at the bedside using sterile water. The water seal chamber is first filled to the level recommended by the manufacturer. Next, the suction control chamber is filled to the desired level (usually −20 cm H_2O). The drain is then connected to a vacuum (usually wall suction), and suction is increased slowly until bubbling appears in the suction control chamber. Avoid excessive bubbling, as this can result in accelerated evaporation of the water in the chamber, which, in turn, will change the suction pressure. After the chest tube drainage system is set up, the chest tube should be secured to the collection system.

Water levels in the water seal and suction control chambers should be checked daily to ensure that evaporation has not changed volumes significantly. If there is an active air leak, bubbling will be seen in the water seal chamber. Bubbling should only occur during expiration (unless a large air leak is present). If bubbling occurs throughout the respiratory cycle, then the system should be checked for leaks or loose connections.

The chest tube and chest tube system should be checked frequently, looking for tube migration, subcutaneous emphysema, or kinking of the tube. Kinking of the tube can be especially serious because it can result in development of expanding or **tension pneumothorax**. Kinking should be suspected if there are no fluid fluctuations (the fluctuations are known as "tidaling") in the water seal chamber. Another cause of loss of tidaling includes tube occlusion by fluid or clot, or unintended clamping of the tube.

RULE OF THUMB Fluctuation of the water level, known as tidaling, should normally occur in the water seal chamber with respiratory effort. During spontaneous inspiration, the water level should increase, and during spontaneous expiration, it should decrease. However, this should reverse normally if the patient is on mechanical or positive-pressure ventilation. If tidaling does not occur, check for tube kinking, clamping, or occlusion.

As a rule of thumb, the chest tube should only be clamped temporarily (for instance, when changing the chest tube drainage unit). Stripping and milking of the chest tube should also be avoided, as this could create significant negative pressure within the tube; clots should be gently squeezed forward into the chest tube collection unit.

Thoracoscopy

The video-assisted thoracoscope is ideally designed for diagnostic and therapeutic work in the pleural space. Thoracoscopy is generally a procedure done by thoracic surgeons in the operating room, done by placing instruments through ports placed between the ribs such that direct visualization of the pleural space can occur. Typically this will be done utilizing three ports: one for instruments that contain a light source and video camera, one for instruments that could move tissue and lung aside, and one for instruments that can take biopsies. "Medical" thoracoscopy is sometimes performed by those trained in this procedure. This procedure can be performed in a medical procedure room using local anesthesia and conscious sedation. Medical thoracoscopy is reserved for more basic cases and should only be done by highly trained individuals.

Pleurodesis

Pleurodesis is the process of fusing the parietal and visceral pleura by causing a fibrotic reaction that prevents further pleural fluid formation and seals the pleural space. Methods to produce pleurodesis include surgical abrasion of the pleural surface and the application of intrapleural chemicals such as doxycycline, minocycline, and talc. Talc has been applied as a powder suspended in sterile saline solution and injected through the chest tube (talc slurry) or dusted through a thoracoscope (talc insufflation). The success rate of talc pleurodesis, approximately 90%, is higher than that of all alternatives except surgical abrasion.[21,22] Pleurodesis is used most commonly in managing symptomatic pleural effusions caused by cancer.

Although pleurodesis of benign effusions, such as those occurring with CHF, nephrotic syndrome, and idiopathic chylothorax, has been performed successfully, the procedure is discouraged for pleural effusions that are not malignant. Most pleural effusions are best managed by controlling the underlying condition.[23]

Pleuroperitoneal Shunt and Indwelling Catheter

In refractory pleural effusions that cannot be treated adequately with pleurodesis, a small pump (PleurX, CareFusion, San Diego, CA) can be placed subcutaneously and tubes placed in the pleural and peritoneal spaces. The pleuroperitoneal connection has a one-way valve and a pumping mechanism to allow the patient to expel pleural fluid from the negatively pressurized chest to the positively pressurized peritoneum. The pleuroperitoneal shunt is placed as a last resort for refractory pleural effusions for which there is no other treatment.

More commonly, an indwelling catheter is placed into the pleural space and tunneled under the skin to prevent infections. This catheter then exits the skin and has an adapter that hangs outside of the body. The patient or family member then connects this catheter to vacuum bottles that fill with pleural fluid. In this way, pleural fluid can be removed at home for recurrent effusions. If the pleural space is kept dry, a pleurodesis often results, and the catheter can then be removed.[24]

Teaching is facilitated by online resources from the catheter manufacturer that provide reading materials for home use. However, there is no substitute for hands-on training. If a PleurX

MINI CLINI

Indwelling Catheter Care

Problem

A patient with a malignant pleural effusion has an indwelling pleural catheter (PleurX) placed during his hospitalization and is now ready for hospital discharge. The nurse on the ward asks you to assist with discharge planning of the patient with this device.

Solution

The care of an indwelling catheter at home requires the involvement of a dedicated caregiver who needs to be taught about proper catheter care, timing and technique of drainage, and vacuum bottle inventory. There is often one individual in a hospital that is most knowledgeable to provide this teaching. Often, this person is an RT. Note that the brand name of PleurX (Becton Dickinson, Franklin Lakes, NJ) is unique to the first company that advanced this technology and that other catheter systems are also available.

catheter is available on the hospital ward, dedicated time for teaching home care is best done a few days before hospital discharge. This allows the home care provider to have a better comfort level and causes fewer questions after the patient returns home.

One major risk is infection. The risk for infection is sometimes worse than with other wounds, because many of these patients have cancer and may be immunosuppressed by chemotherapy or radiation. Infection can occur at the skin surface or by introducing an infection at the vacuum bottle adapter. The skin wound should be kept covered with a clean dressing, and signs of colored discharge or redness should prompt medical evaluation. A suture is left in place for some time after placement, and a suture abscess should prompt medical evaluation. To prevent introducing bacteria inside the catheter, the adapter should be cleaned before vacuum bottle attachment.

The number of vacuum bottles needed and the timing of drainage is determined by the volume of pleural fluid on previous drainage days. The goal of the catheter is to keep the pleural space dry enough to allow a natural pleurodesis by growth of cancer cells between the parietal and visceral pleura. The other goal is dyspnea relief. Vacuum bottle inventory and access is determined by local resources but should be preplanned.

Ultimately, the management of a PleurX catheter and whether it can be removed is a medical team decision best informed by a diary of pleural fluid volume removal and the patient's medical condition. RTs should know about this device and its care.

PNEUMOTHORAX

Pneumothorax is air in the pleural space. Although air can enter the pleural space from outside the body, as occurs in sucking chest wounds, most cases of pneumothorax occur when disruption of the visceral pleura allows air from the lung to enter the pleural space. Pneumothorax is discussed according to the causative (etiologic) factor because traumatic pneumothorax is managed differently from spontaneous pneumothorax.

Chest pain, which is typically sharp and abrupt, occurs in nearly every patient with pneumothorax. Palpation of the chest wall does not worsen the pain, although respiratory efforts may be difficult. Dyspnea occurs in approximately two-thirds of patients when decreases in vital capacity and PO_2, probably as a result of airway closure at low lung volumes, cause $\dot{V}/\dot{Q}$ defects and shunting. When a spontaneous pneumothorax is evacuated, hypoxemia may persist in some patients.

The following sections describe the diseases that cause pneumothorax and the important treatment differences among them.

Traumatic

Blunt and Penetrating Chest Trauma

Traumatic pneumothorax can be caused by either blunt or penetrating wounds of the thorax. The common causes of penetrating wounds include gunshots and knife punctures. In many cases, penetrating trauma to the chest can be managed conservatively with a chest tube. The clear indications for entering the chest surgically are associated injuries to the intercostal or pulmonary arteries, or injury to the heart or great vessels, with resultant uncontrolled bleeding into the pleural space. In these situations, the pneumothorax becomes secondary.

In blunt trauma to the chest, pneumothorax can be the result of a rib fracture that punctures the lung parenchyma and allows air to leak into the pleural space. For this type of injury, a chest tube is placed, and the rib fractures need no specific therapy. Another common injury is alveolar rupture at the pleural surface, which breaks through the pleural membrane and leaks air directly into the pleural space.

Two special injuries that produce pneumothorax are tracheal fracture and esophageal perforation or rupture. Tracheal fracture results from severe deceleration injury, such as that which may occur in a serious motor vehicle accident (usually a chest against a steering wheel or air bag), and often occurs along with fractures of the anterior aspect of the first through third ribs. In this case, urgent bronchoscopy is appropriate to identify the injury and its location, because tracheal fracture must be corrected surgically. Esophageal rupture is usually the result of trauma; esophageal perforation can be a complication of an upper GI endoscopy. Both injuries can produce an air fluid level in the pleural space. The level of amylase in the pleural fluid is typically elevated from a salivary (not pancreatic) source. Fluid pH may also be low (< 6.0). Patients with esophageal rupture are usually very ill and require urgent endoscopic and/or surgical management.[25]

Large-caliber chest tubes (generally >28 Fr) are placed for trauma-related pneumothoraces to allow exit of blood and blood clots, which can be difficult to remove through small-bore catheters. Chest tubes between 28 and 32 Fr seem to be comparable to larger chest tubes (>36 Fr) in the management of traumatic pneumothorax, with or without concurrent hemothorax.[26] Air leaks from an injured lung can be large. When bleeding is a major component of pleural injury, two chest tubes are used: a posterior chest tube to drain blood that is gravity-dependent and an anterior and apical chest tube to drain air that moves to the lung apex in the absence of pleural disease.

Iatrogenic

Iatrogenic (healthcare provider–caused) pneumothorax is the most common type of traumatic pneumothorax. Common causes are punctures of the lung from needle aspiration lung biopsy, thoracentesis, and central venous catheter placement. Unusual

causes, such as feeding tube placement into the pleural space, also have been recorded. Because the pleural rupture is typically small in the absence of parenchymal lung disease, these lung punctures usually resolve within 24 hours and can be observed without chest tubes as long as serial chest x-rays are obtained. If the pneumothorax enlarges or becomes symptomatic during this time, then a decision to place a chest tube is usually made. Typically, since these air leaks are small (since they are usually from needle sticks), pneumothorax can be treated with smaller percutaneous chest tubes (18 to 24 Fr).

Neonatal

In radiographic series, spontaneous pneumothorax occurs in 1% to 2% of all infants soon after birth.[27] The cause of pneumothorax is likely high transpulmonary pressure during birth coupled with transient bronchial blockade caused by meconium, mucus, or aspiration of blood that can produce transpulmonary pressure gradients as high as 100 cm H_2O.

Recognizing pneumothorax is difficult because breath sounds are transmitted widely through the chest of the neonate. A shift of the heart sounds away from the side of the pneumothorax may provide a clue. Transillumination of the chest with a high-intensity light is used in some centers. Almost all neonates with pneumothorax need a chest tube.

Spontaneous

Spontaneous pneumothorax is defined as any pneumothorax caused by the escape of air into the pleural space without an obvious cause. Spontaneous pneumothoraces are of two types: (1) **primary spontaneous pneumothorax**, in which there is no underlying lung disease, and (2) **secondary spontaneous pneumothorax**, in which underlying lung disease is present.

Primary

Primary spontaneous pneumothorax occurs without underlying lung disease. In a way, this term is a misnomer, because high-resolution CT scans have shown the presence of small subpleural blebs in more than 80% of patients.[28]

Primary spontaneous pneumothorax usually occurs in patients in their late teenage years or early 20s. Patients often are tall, slender, and frequently male, and the lungs and pleural membrane may not have grown at the same pace; the result is airspace enlargement and a thin pleural membrane.

Results of some studies suggest that cigarette smoking is a risk factor in more than 90% of cases of primary spontaneous pneumothorax.[29] The smoking history is typically short, and smoking cessation is recommended.

Secondary

Secondary spontaneous pneumothorax occurs in patients with underlying lung disease. In most cases, the underlying lung disease is chronic obstructive pulmonary disease with some component of emphysema. Pneumothorax also can occur with asthma and cystic fibrosis, usually during an exacerbation of disease.

Interstitial lung diseases in which lung volumes are spared, such as sarcoidosis, bronchiolitis obliterans with organizing pneumonia, Langerhans cell histiocytosis, and lymphangioleiomyomatosis, have a higher incidence than do diseases without any component of obstruction.

Depending on the extent of parenchymal lung disease, pneumothorax in this population can be devastating. A Veterans Affairs cooperative study included 185 patients with secondary spontaneous pneumothorax and monitored them for 5 years.[30] Although only three patients died of pneumothorax, the mortality rate in the series was 43%. Severe underlying lung disease caused most of these deaths. This finding suggested that most pneumothoraces occur in patients with severe lung dysfunction. The degree of dyspnea is out of proportion with the size of pneumothorax in this group of patients because pulmonary reserve is already diminished. Due to diminished pulmonary reserves in these patients, pneumothorax in this cohort of patients should almost always be initially treated with a chest tube. Because the recurrence rate of pneumothorax is high in these patients (up to 50% in 3 years), pleurodesis, either through video-assisted thoracoscopic surgery (VATS) or nonsurgical chemical pleurodesis, is recommended for prevention of recurrent pneumothorax.

Catamenial Pneumothorax

Catamenial pneumothorax occurs in association with menstruation and usually is recurrent and right-sided. The reason for the right-sided predominance is unclear. Many patients have endometriosis on the pleural surface, although it may be impossible to see because of hormonal involution during menses. Once the diagnosis is considered, catamenial pneumothorax is not difficult to manage in that most patients do not have a recurrence if ovulation is suppressed.

Barotrauma disrupts alveoli and allows air to enter the interstitium of the lung. Rupture of the visceral pleura allows air to produce a pneumothorax, or the air can travel along the low-resistance tissue planes of the bronchovascular bundles and through the hilum of the lung to enter the mediastinum. From the mediastinum, air has easy access to the retroperitoneal space, including the scrotum and the neck. The presence of subcutaneous air does not necessarily mean that pneumothorax has occurred, although the risk factors for its development are present.

Air under pressure in the pleural space can enter the subcutaneous tissues through the intercostal incision made for chest tube placement. Subcutaneous air often is seen on a chest x-ray after chest tube placement, but the air rarely spreads unless the chest tube is occluded.

MINI CLINI

Subcutaneous Emphysema

Problem

A patient with ARDS experiences subcutaneous emphysema. How does the clinician determine where the air leak is occurring? Is a pneumothorax always present?

Solution

Subcutaneous emphysema occurs when air enters the soft tissues. Although physical examination reveals subcutaneous bubbles, the patient's family needs to be reassured that the condition is rarely, if ever, physiologically significant. What is important to recognize, however, is that alveolar disruption has occurred, most commonly as the result of barotrauma.

In the absence of pneumothorax, there is no way to determine which lung is causing subcutaneous emphysema. For any deterioration in gas exchange, chest x-rays should be repeated. Because air in the mediastinum can displace the mediastinal parietal pleura, it can be difficult to tell without chest CT whether a small pneumothorax is present. Because patients often are too unstable to be moved, a chest tube sometimes is placed because the potential benefits are greater than the risks.

Complications of Pneumothorax

Tension Pneumothorax

Tension pneumothorax occurs when air in the pleural space exceeds atmospheric pressure. The radiographic appearance includes mediastinal shift to the contralateral side, diaphragmatic depression, and expansion of the ribs. The lung does not necessarily collapse completely if it is involved with a disease process such as ARDS.

Not all patients with radiographic tension have the physiologic changes commonly associated with tension pneumothorax. However, almost all pneumothoraces that occur during mechanical ventilation enlarge if not drained.[31]

As pressure in the thorax increases and mediastinal shift places torsion on the inferior vena cava, venous return to the right side of the heart decreases. Cardiac output decreases, and hypotension with tachycardia results. Hypoxemia occurs as the lung continues to compress because of intrapulmonary shunting through the collapsed lung.

The RT can help make the diagnosis of tension pneumothorax by recognizing these findings, especially in patients at risk. Treatment is emergency decompression of the chest. This procedure usually is done with an 18-gauge intravenous catheter (e.g., Jelco, Smiths Medical, Dublin, OH) inserted just over the second rib on the anterior aspect of the chest in the midclavicular line. Catheter placement should elicit a rush of air through the catheter, and this sign confirms the diagnosis. The blood pressure should recover rapidly, and many other adverse findings often rapidly improve. However, resolution of hypoxemia depends more on complete lung re-expansion and can be delayed. The soft intravenous catheter can be left in place while a more conventional chest tube is inserted. Newer small-gauge percutaneous pneumothorax kits are now available. These kits allow for rapid insertion of small-bore pigtail tubes for the management of pneumothorax, with similar placement over the second rib in the midclavicular line.

RULE OF THUMB Tension pneumothorax is a clinical diagnosis made at the bedside in more than 50% of cases. The clinical signs are diminished breath sounds, hyperresonance to percussion, tachycardia, and hypotension.

RTs are well-positioned to make a timely diagnosis because ventilator alarms, including high-pressure alarms (see Chapter 52) give early warnings.

Re-Expansion Pulmonary Edema

Re-expansion pulmonary edema occurs in a lung that has been rapidly reinflated from low lung volumes, particularly when the pneumothorax has been long-standing or when the pressure gradient across the lung has become high. This might occur when there is endobronchial obstruction from cancer, mucus, or blood.

For many years, it was believed that alveolar edema occurs because intraalveolar pressure becomes negative and pulls fluid from the vasculature. However, the lung fluid has high protein content, a finding that suggests blood vessels have been injured as well.

One of the proposed mechanisms of vascular injury is a phenomenon of reperfusion injury caused by reactive oxygen species. Support for this hypothesis has come from experimental studies that have shown that administering antioxidants before re-expansion decreases the amount of re-expansion pulmonary edema.

Regardless of the cause, lung re-expansion in nonemergency situations should proceed slowly, and transpulmonary pressure should not become excessive. Most physicians who insert a chest tube for a large pneumothorax first place it to the water seal without suction, to allow the air to drain passively and slowly. Making sure that the lung remains expanded when active suction on the chest tube chamber is turned off increases confidence that the initial reason for the pneumothorax has resolved. If the lung is not completely inflated on the subsequent chest x-ray, the chest tube is placed back on suction. Re-expansion pulmonary edema can also occur after drainage of large pleural effusions.

Diagnosis

The diagnosis of pneumothorax is established with chest x-ray or ultrasound. The diagnosis requires a high-quality film to visualize a visceral pleural line. In the ICU, as many as 30% of cases of pneumothorax may be missed on a chest x-ray in retrospect. Impediments to diagnosis include a low-quality chest x-ray or using a computer monitor, supine position of the patient, concomitant presence of mediastinal air, and subpulmonic or mediastinal position of the pneumothorax. Diagnosis is enhanced with additional upright chest x-rays or decubitus views.

The size of a pneumothorax is difficult to assess with a chest x-ray, because a two-dimensional picture is being taken of a three-dimensional thorax. Size can be estimated with volume equations and can be confirmed with CT if needed.

RULE OF THUMB The size of a pneumothorax on a chest x-ray can be estimated with the knowledge that the volume of the lung and thorax is proportional to the cube of their diameters.

For example, on a chest x-ray, the chest measures 8 cm from the spine to the lateral chest wall. A pneumothorax is measured 2 cm from the chest wall:

$$\text{Volume of the lung} = (6\text{ cm})^3 \approx 216\text{ cm}^3$$
$$\text{Volume of the hemithorax} = (8\text{ cm})^3 \approx 512\text{ cm}^3$$
$$\text{Lung size} = 216/512 = 42\%$$
$$\text{Pneumothorax size} \approx 58\%$$

The equation shows the large volume of lung that a pneumothorax can displace despite a "small" distance from the lung to the chest wall. Use of the equation is not as accurate as chest CT because many pneumothoraces collapse asymmetrically.

The diagnosis of pneumothorax by ultrasound occurs when the normal finding of lung sliding is lost. Ultrasound is not capable of judging the size of the pneumothorax because air in the pleural space does not transmit sound waves, and the lung is not seen.

Therapy

Oxygen

Supplemental oxygen should be administered to all patients who have a pneumothorax. Most of the air in a pneumothorax is nitrogen (N) because O_2 is readily absorbed. If an air leak is continuing, supplemental O_2 rather than N leaks into the pleural space. After an air leak has been stopped, administering O_2 decreases the blood and tissue partial pressure of N surrounding the pleural space. Pneumothorax resolution is normally 1.25% of the air per day. O_2 speeds recovery by increasing the gradient of N from the pleural space to the pleural tissues.

Observation

Although there is no high-quality evidence comparing conservative and interventional management of primary spontaneous pneumothorax, several society guidelines and consensus statements recommend observation in patients with small pneumothoraces that are asymptomatic.[32] A small iatrogenic pneumothorax also should be managed with observation. Primary spontaneous pneumothorax often is observed for 4 hours in the emergency department (ED) before discharge to home follow-up care, as long as the pneumothorax is not found to enlarge on serial chest x-rays. Discharged patients should have ready access to emergency care facilities and should be advised to return if they experience any worsened dyspnea or pain.

During observation, it is important to record the respiratory rate and any signs of deteriorating respiratory function, including perception of dyspnea. A decrease in the patient's oxygen saturation can be an early warning of pneumothorax enlargement. Any deterioration indicates that the pneumothorax must be drained.

Simple Aspiration

Simple aspiration can be used in the ED when pneumothorax is first detected. A small catheter is placed into the pleural space, and air is sequentially evacuated with a three-way stopcock until no more air can be removed. If more than 4 L of air is aspirated and no resistance to further aspiration is felt, a chest tube is needed for continuing pleural air leak.

The goal of aspiration is to re-expand the lung. Many patients have a pneumothorax from air leak that subsequently heals between the time of onset and the time that treatment is sought in the ED. Patients with primary spontaneous pneumothorax who undergo simple aspiration for lung re-expansion and who have a stable chest x-ray 4 hours after aspiration can go home without hospital admission.

Chest Tubes

Chest thoracostomy tubes (chest tubes) come in a variety of sizes, from 7 to 40 Fr, and can be connected to a variety of one-way devices (e.g., Heimlich valves) that prevent entry of air into the pleural space from the outside environment. Regardless of chest tube size and the presence of a Heimlich valve or water seal, the effectiveness of chest tube placement for pneumothorax resolution depends more on lung surface healing than on the device used.

Small-bore chest tube. One simple device is a small-bore 7 Fr catheter with a one-way valve apparatus (Heimlich valve) that prevents movement of air back into the chest. Small-bore catheters can be placed with a small skin incision followed by either a guidewire and dilator technique or a trocar to get through the parietal pleura.

All chest tubes used to drain pneumothorax should be directed to the apex of the lung. Small-bore catheters can be placed in the second intercostal space anteriorly in the midclavicular line or laterally in the chest from the fifth through the seventh intercostal space.

It can be difficult to determine whether a Heimlich valve has an ongoing leak unless it is placed to seal underwater. This procedure can be done in the ED by placing the Heimlich valve into a cup of water or by placing it in line with a water-seal chamber to see whether an air leak is continuing after lung expansion. Some newer versions of Heimlich valves have air bladders such that one can visually see one end of the bladder open as air escapes through the valve.

Large-bore chest tube. Large-bore chest tubes usually are connected to a commercial equivalent of a three-bottle system to collect any pleural fluid present, determine whether an air leak is ongoing, and measure intrapleural pressure (Fig. 27.6). Insertion of large-bore catheters can be done percutaneously, using a wire with serial dilators up to the size of the tube being placed; several commercial kits of various sizes are available on the market. Large-bore catheters can also be placed surgically with the use of local anesthetic and blunt dissection of soft tissue down to the parietal pleura.

Dissection should be wide enough to allow insertion of a finger into the pleural space to ensure that no adhesions are holding the lung close to the insertion site and to allow unobstructed entrance of the tube into the pleural space, where it can be directed to the position of choice.

Chest tubes are secured with sutures. The insertion distance should be recorded and be checked on subsequent days to ensure that the chest tube does not migrate outward. Should the most proximal hole in the tube emerge from the skin, air will enter the tube, and it will appear as if the lung is persistently leaking.

Another problem of apparent chest tube leak can occur when the insertion wound is large enough to allow air entry into the pleural space. This usually is accompanied by a sucking sound at the entrance, which can be occluded with petroleum gauze.

A chest x-ray is routinely obtained ideally, including a lateral view to best allow the precise placement of the tube to be visualized. In addition, many chest tubes end up in the major fissure, where their function may be suboptimal.

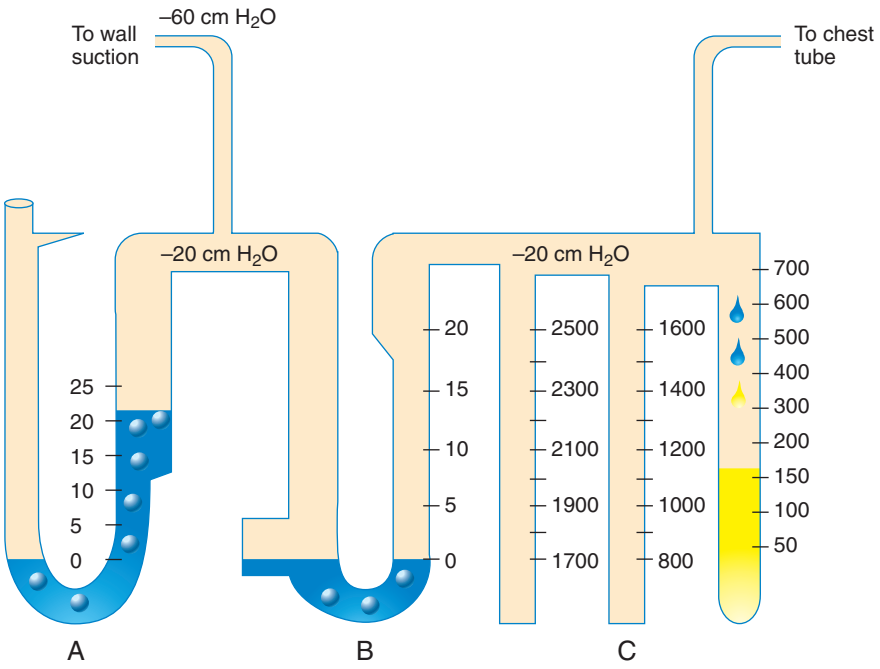

Fig. 27.6 The Pleur-evac chest tube collection system collects fluid in compartment *C* so that it will not spill into the water-seal compartment *B*. A patent chest tube should cause respiratory variation to be seen on the scale adjacent to compartment *B*, which measures intrapleural pressure. Compartment *B* also is the place to see bubbles if an air leak is present. The water level in compartment *A* controls intrapleural pressure and should be adjusted daily.

Chest tube removal remains a highly variable practice. Removal of a chest tube as soon as an air leak visually ceases is associated with a 25% rate of recurrence of pneumothorax. The recurrence rate is near zero when chest tubes are removed 48 hours after the air leak no longer is seen in the water-seal chamber.[32] A common practice of clamping the chest tube, with chest x-rays before and after a 4-hour observation period, can be accompanied by the return of pneumothorax. For this reason, many clinicians discourage clamping the chest tube. If symptoms develop during chest tube clamping, the clamp should be removed immediately and the presence of air leak assessed.

Bronchopleural Fistula

Two terms are used for continuing air leaks from the lung through a chest tube. A **bronchopleural fistula** (BPF) is a large air leak that classically was described after surgery in which the airway was cut. Because some surgeons insist that BPF be reserved for this situation, the term **alveolopleural fistula** has been recently used for large air leaks that come from the lung tissue and that do not heal rapidly. Many patients with persistent air leaks are receiving mechanical ventilation, and positive airway pressures contribute to perpetuating the pleural air.

Because persistent air leaks can leak large quantities of air, more than one chest tube may be used to assure that the visceral pleura is in contact with the chest wall. This maneuver results in tamponade of the site of the air leak and allows pleural healing to occur.

Therapy for BPF involves meticulous monitoring of tidal volume, airway pressures, and positive end-expiratory pressure (PEEP); avoidance of auto-PEEP; and consideration of bronchoscopic closure or thoracoscopic surgery.[33]

Pleurodesis

Patients who have had one pneumothorax are more likely than the general population to have a second. The recurrence rate is greater than 30% among patients with primary spontaneous pneumothorax and approximately 40% among patients with secondary spontaneous pneumothorax. These high recurrence rates indicate that preventing a recurrent pneumothorax should be a priority, particularly for patients in whom pneumothorax may be life-threatening. Preventing recurrence involves producing adhesions between the parietal and the visceral pleurae in the involved area and is termed *pleurodesis*.

The most noninvasive approaches to pleurodesis involve chemical sclerosis of the pleural space through the chest tube once the pleural air leak has stopped. The two most common preparations used for pleurodesis currently in the United States include 500 mg of doxycycline or 5 g of talc mixed into a 50-mL syringe of sterile saline solution. The agent is injected through the chest tube into the pleural space. Then the chest tube is clamped for 2 hours before drainage is allowed.

More invasive methods have included thoracoscopy with pleural poudrage (blowing talc onto the pleural surface under direct visualization), pleural abrasion through a thoracoscope, and thoracotomy with pleurectomy (removing the pleural surface to ensure lung adhesion). Recent guidelines have suggested that surgical pleurodesis is superior to talc slurry instillation through a chest tube for spontaneous pneumothorax management,

MINI CLINI

Alveolopleural Fistula

Problem

Pneumothorax develops in a patient undergoing mechanical ventilation for pneumonia. A 20 Fr chest tube is placed, and the lung fails to re-expand, although a large amount of air is passing through the water-seal chamber. The patient's minute ventilation is 20 L/min to keep gas exchange stable. What is the problem?

Solution

The problem is an alveolopleural fistula caused by a large hole in the pleura that is difficult to manage. The lung surface of patients with underlying emphysema can contain large bullae that do not heal readily once ruptured. Large pleural holes also can develop in patients with necrotizing pneumonia and those who have undergone surgery on the lung.

with slurry reserved only for those who are not surgical candidates.[34]

Because the diseases that produce pneumothorax often involve both lungs, patients may experience sequential events in opposite lungs. In this situation, median sternotomy with bilateral abrasion or pleurectomy can be performed, particularly for patients at considerable risk for developing a pneumothorax, such as divers and aviators.

The Fanning equation tells us that humidified airflow through a chest tube is proportional to the chest tube radius to the fifth power. Therefore, the chest tube radius is the most important determinant of maximal airflow. Airflow through large air leaks has been measured as high as 16 L/min, a volume impossible to remove through a chest tube smaller than 24 Fr, regardless of the amount of pressure applied.

This patient should receive a second, larger chest tube. The seal of the chest tube at the skin surface should be inspected to ensure that no air is entering the body from the outside. The position of both chest tubes should be confirmed either by x-ray examination or by hand to ensure the tubes are in the pleural space. Once the lung is expanded, the minute ventilation should decrease because effective alveolar ventilation will be improved.

Flow through stopcocks and chest tube collection devices is governed by the same considerations as chest tube size. The manufacturer of the chest tube collection device that is used in your hospital will have the resistance figures necessary to ensure that 16 L/min of airflow can be accommodated.

The following simple calculations suggest that the excess difference in returned V_T (450 to 300 mL or 150 mL) is due to air passing through the BPF:

30 breaths/min
(150 mL differential = 4.5 L of pleural ventilation)

One other problem is that large amounts of carbon dioxide (CO_2; up to 20%) may be removed through the chest tube.[35] Removal of CO_2 is beneficial because it allows lower V_T and respiratory rates for any given PCO_2. However, as the BPF closes, CO_2 will no longer be eliminated through the chest tube but only through the endotracheal tube, necessitating higher minute ventilation to maintain CO_2 clearance. This need for higher

MINI CLINI

Measuring a Pleural Air Leak

Problem

Pneumothorax develops in a patient with ARDS, and a chest tube is placed to re-expand the lung. Before the pneumothorax developed, the patient was ventilated easily at a rate of 16 breaths/min (see Chapter 46), which delivered a tidal volume (V_T) of 500 mL, and was exhaling 450 mL (a small difference caused by endotracheal cuff leak and tubing compliance). Since the pneumothorax developed, the patient needs a rate of 30 breaths at the same V_T to keep the $PaCO_2$ level the same. Exhaled V_T is 300 mL. What is the approximate size of this patient's air leak? What ventilation options are appropriate?

Solution

Although research laboratories can measure airflow through a chest tube precisely with a pneumotachometer, clinical care can be provided by estimating the pleural air leak.

MINI CLINI

Management of a Bronchopleural Fistula

Problem

A 40-year-old trauma patient with ARDS cannot be ventilated because of a large (16 L/min) BPF located entirely in the left lung. If surgery is not possible, what ventilatory options would be appropriate?

Solution

Two ventilatory interventions have been attempted for large BPFs. The first is placement of a double-lumen endotracheal tube, which can carry most ventilation and PEEP on the right lung while underventilating the lung with the fistula to aid in its closure.[37] Long-term double-lumen ventilation is difficult because of tenuous tube position, the need for continuous paralysis, difficulty with secretion clearance, and high airway resistance through the small endotracheal tube lumens.

minute ventilation might falsely suggest that ARDS is worsening, when in reality the BPF is closing.

Nevertheless, when the air leak is measured with every ventilatory change, the mode of ventilation that minimizes air leak is the one most likely to allow pleural healing. Breath-by-breath analysis shows the difference between delivered V_T and exhaled V_T and approximates the volume of the pleural leak.

PEEP can be a major cause of large air leaks and should be turned off unless necessary for maintaining PO_2. Because there is no such thing as a true plateau pressure when air is exiting a BPF, V_T should be adjusted to produce the lowest peak airway pressure that can sustain ventilation and oxygenation. Position the patient so that the lung with the air leak is down (i.e., in the bed).[36]

Auto-PEEP can be impossible to measure if the fistula is large and decompressing the airways. Therefore, long expiratory times are preferred. Trials of pressure-controlled and high-frequency jet ventilation are appropriate. In a practical sense, these adjustments are the same ones made to prevent barotrauma in the first place and are limited by the severity of lung injury, which requires more support than would optimally close the air leak.

The second intervention is applying positive pressure to the chest tube. This back pressure increases resistance across the

BPF and allows the remainder of the lung to better ventilate. One simple way to add chest tube resistance is to connect a PEEP valve to the expiratory port of the water-seal chamber.[38] PEEP usually is placed at the same level as the ventilator PEEP. Inspiratory pressures exceed PEEP, and air flows through the chest tube. However, as expiratory pressures equilibrate, PEEP can be held within the lung, allowing the beneficial effects on oxygenation.

Pressurizing the chest tube entails synchronous closure of the chest tube during inspiration and requires specialized equipment that must be set up under controlled conditions.[39] When used in combination with an in-line PEEP valve, BPF flow can be slowed during both inspiration and expiration.

These techniques usually increase the volume of intrapleural air. The net effect on oxygenation requires careful bedside observation, because hypoxemia can worsen with any degree of lung collapse. Tension pneumothorax can also occur, so the patient must be monitored closely.

ROLE OF THE RESPIRATORY THERAPIST IN PLEURAL DISEASES

The RT may play an important role in both the diagnosis and management of pleural disease. Diagnostically, the RT's careful palpation and auscultation of the chest may show the dullness and decreased breath sounds that may prompt suspicion of a pleural effusion and lead the physician to order the imaging studies to confirm the presence of a pleural effusion. The RT who is managing the ventilator is often in the earliest position to appreciate a pneumothorax because the patient's ventilatory function would change when a pneumothorax develops. Furthermore, the RT may be called on to assist in performing a thoracentesis or placing a chest tube. Therapeutically, the RT may be called on to assist in setting up the fluid collection chamber after the chest tube is placed or in performing a talc pleurodesis. This broad spectrum of potential roles for the RT makes knowledge of the diagnosis and management of pleural disease essential for the capable RT.

SUMMARY CHECKLIST

- Pleural effusions form when excess pleural fluid is produced by the lung or chest wall in sufficient quantities to overcome the resorptive capacity of the pleural lymphatic vessels.
- Pleural fluid analysis is the key to understanding the specific cause of any pleural effusion.
- Transudates have a pleural fluid total protein level less than 0.5 and an LDH level less than 0.6 of the respective serum values. Common causes of a transudative effusion include CHF, nephrosis, and cirrhosis.
- Pleural fluid drainage returns approximately one-third of the lung volume as measured by FVC. The other two-thirds of fluid drainage allow the diaphragm to rise and the chest wall to normalize.
- Pneumothorax size is underestimated with a one-dimensional view of the chest. Measurement accuracy requires a three-dimensional perspective.
- The risk factors for pneumothorax and pneumomediastinum are the same. Air ruptures a pleural membrane in pneumothorax, and air passes through the lung hilum in pneumomediastinum.
- Oxygen therapy speeds resolution of all pneumothoraces by improving N absorption.
- Chest tube flow depends on tube size, stopcock size, and collection system resistance.
- Breath-by-breath measurement of an air leak can be approximated by the difference between inspired and expired volumes (in the absence of endotracheal cuff leaks).
- The mode of ventilation that produces the least fistula airflow is the most likely to produce healing.
- Methods to decrease BPF airflow include lowering *tidal volume*, lowering respiratory rate, lowering PEEP, and avoiding auto-PEEP. In more severe cases, positioning the affected lung down, double-lumen tube ventilation, adding PEEP valves to the chest tube, inspiratory chest tube occlusion, or thoracic surgery should be considered.

Pulmonary Vascular Disease

Adriano R. Tonelli and Raed A. Dweik

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- State how many patients develop venous thromboembolism each year.
- Describe how and where thromboemboli originate.
- Describe how pulmonary emboli alter lung and cardiac function.
- Identify the clinical features and electrocardiographic, chest x-ray, and arterial blood gas findings associated with pulmonary embolism (PE).
- Describe how PE is diagnosed and managed.
- Describe the hemodynamic findings associated with pulmonary hypertension (PH).
- Describe the mechanisms responsible for pulmonary arterial hypertension (PAH).
- State who is at risk for the development of PAH.
- Identify the clinical features associated with PAH.
- Identify factors associated with worse outcomes in PAH.
- Describe the treatment used to care for patients with PAH.
- Describe the pathogenesis and management of PH associated with chronic obstructive pulmonary disease.

CHAPTER OUTLINE

KEY TERMS

deep venous thrombosis (DVT)
pulmonary embolism (PE)
pulmonary arterial hypertension (PAH)
pulmonary hypertension (PH)
venous thromboembolism (VTE)
ventilation-perfusion ($\dot{V}/\dot{Q}$) scan

The vessels of the lung can be affected by many conditions, including clots and narrowing of the pulmonary arteries, conditions referred as **pulmonary embolism (PE)** and **pulmonary hypertension (PH)**. PE occurs when a fragment of the thrombus in the venous system travels to pulmonary circulation. The thrombus usually originates in the deep veins of the lower extremities and therefore is called **deep venous thrombosis (DVT)**. **DVT and PE** are grouped in the category named **venous thromboembolism (VTE)**. PH is a term that defines an increase in the pressure in the pulmonary arteries that results from conditions that affect the lung vessels, lung parenchyma, and/or the heart.

This chapter reviews disorders associated with the pulmonary vasculature and predominantly focuses on VTE and **pulmonary arterial hypertension (PAH)**. PAH describes a particular subgroup of patients with PH who have progressive narrowing of the pulmonary arteries that, if left untreated, leads to right heart failure (cor pulmonale) and death.[1]

VENOUS THROMBOEMBOLIC DISEASE

Venous thromboembolism (VTE) is a major national health problem with an annual incidence of 117 cases per 100,000 persons (i.e., DVT at 48 cases per 100,000 and PE at 69 cases per 100,000), a ratio that increases with aging and is higher in males compared to females.[2] VTE is treatable but requires prompt diagnosis and treatment to avoid serious consequences, since

TABLE 28.1 Frequency of Venous Thrombosis in Various Hospitalized Patient Groups

Group	Frequency (%)
Orthopedic (e.g., fractured hip)	54–67
Urologic (e.g., prostatectomy)	25
Surgical patients older than 40 years	28
Gynecologic surgery	18
Cardiovascular surgery (e.g., acute myocardial infarction)	39
Obstetrics	3

From Arroliga AC, Matthay MA, Matthay RA: Pulmonary thromboembolism and other pulmonary vascular diseases. In George RB et al., editors: *Chest medicine: essentials of pulmonary and critical care medicine*, ed 3, Baltimore, 1995, Williams & Wilkins.

one third of deaths from PE occur within 1 hour of the onset of symptoms. In more than 70% of patients who die of PE, the diagnosis is not suspected.[3-5] This underrecognition is supported by the frequent (1.5% to 30%) detection of VTE in routine autopsies of adult patients.[4,6,7]

Patients with undiagnosed PE have a higher mortality rate (approximately 30%)[8] when compared with those in whom the condition was promptly recognized and treated (mortality rate <8% with generally favorable long-term outcome).[9] Therefore, a high index of suspicion to detect the disease is essential, particularly in patients at risk for VTE such as those with multiple injuries, immobilization, or intravascular catheters (Table 28.1). Because clinical findings of VTE are frequently misleading,[10] objective tests are needed to confirm or exclude the diagnosis.

Pathogenesis

PE is a frequent complication of DVT[11]; however, the actual source of PE is found in only half of the patients.[5] PE usually arises from detached portions of venous thrombi that form in deep veins of the lower extremities or pelvis (86%). A small percentage of PE arise from the right-sided heart cavities (3.15%) or from the superior vena cava (3%).[5]

Venous thrombosis can be due to inherited and/or acquired conditions, and in more than 80% of cases, a risk factor can be identified. Conditions that favor thrombus formation include blood that is not moving (*stasis)*, blood that is more likely to clot (hypercoagulable state), and vessel wall abnormalities (factors known as Virchow triad). Causes of blood stasis include local pressure, venous obstruction, immobilization, congestive heart failure, shock and dehydration, varicose veins, and enlargement of the right heart chambers. Several conditions increase the blood coagulability and predispose to VTE (see Table 28.1).[12] The most frequent causes of an inherited hypercoagulable state are the factor V Leiden and prothrombin gene mutations, which together account for 50% to 60% of cases.[13] Meanwhile, the major acquired conditions associated with thrombus formation are recent major surgery, trauma, immobilization, atrial fibrillation, antiphospholipid antibodies, malignancy, myeloproliferative disorders, pregnancy, and use of oral contraceptives.[14] Vessel wall abnormalities are found most often in patients who have sustained trauma or have undergone major surgery. In general, more than one risk factor is responsible for VTE.[15]

Pathology

PE is more frequently observed in the lower lobes of the lung and more commonly in the right rather than in the left lung, a phenomenon related to how pulmonary blood flow is distributed.[6] Embolism to the pulmonary arteries produces pulmonary hemorrhage in the poorly perfused or infarcted lung (i.e., lung that is irreparably damaged because of sustained loss of blood flow) in less than 10% of cases. Infarction due to thromboembolism is less common in the lung than in other tissues because the lung has two blood supplies—namely the pulmonary arterial and the bronchial circulations (see Chapter 9).

At a capillary level, extensive connections exist between the pulmonary and bronchial circulations that prevent serious damage to lung tissue that is deprived of its pulmonary artery supply.[6] Cardiovascular diseases may affect the bronchial circulation, which may lead to lung tissue necrosis when emboli occur. Pulmonary infarction is associated with thromboembolic obstruction of a medium-sized pulmonary artery and generally occurs at the lung bases, where it usually presents as a wedge-shaped opacity on chest images.

RULE OF THUMB PE is a complication of venous thrombosis. Patients with clots in the proximal venous system of the lower and upper extremities are at high risk for developing PE.

Pathophysiology

The sudden obstruction of a pulmonary arterial branch causes a decrease or total cessation of blood flow to the distal area of the lung. This interruption of blood flow can cause respiratory and hemodynamic alterations.[16] The obstruction of the pulmonary artery by a clot increases the alveolar dead space (in which areas of the lung parenchyma are ventilated but not perfused), causes bronchoconstriction, and decreases the production of alveolar surfactant. As a compensatory mechanism, the body increases the total ventilation ($\dot{V}$), which in turn contributes to the sensation of dyspnea that accompanies PE and results in hypocapnia. Further **ventilation-perfusion** ($\dot{V}/\dot{Q}$) mismatching may be caused by bronchoconstriction from hypocapnia, regional hypoxia, and the production of serotonin and histamine.[17]

Not all patients with PE have significant arterial hypoxemia, but the presence of a widened alveolar-arterial oxygen tension gradient and reduced arterial O_2 tension (PaO_2) are common.[18] Hypoxemia develops because of the $\dot{V}/\dot{Q}$ mismatch, intrapulmonary shunt, and in some cases, shock. Shock is caused by marked obstruction of the pulmonary vasculature or by numerous small emboli in the presence of cardiopulmonary disease. In this case, cardiac output decreases, peripheral O_2 extraction increases and the oxygen saturation of the venous blood markedly falls. In patients with elevated right heart pressures, an intracardiac right-to-left shunt may develop through a patent foramen ovale (a cardiac condition present in one-third of the population; see Chapter 10).[16,17] Moreover, the depletion of pulmonary surfactant

as a result of embolic occlusion can lead to atelectasis and intrapulmonary shunt, which also cause hypoxemia.[16,19]

The main consequence of PE is the increased resistance to blood flow caused by obstruction of the pulmonary arterial bed. The hemodynamic impact is determined by the extent of the pulmonary circulation involved (cross-sectional area), the underlying cardiopulmonary reserve, and the neurohumoral response to the embolism. PH develops when 50% or more of the pulmonary vascular bed has been occluded.[16,17] When PH occurs, the right ventricle must work harder to maintain the same flow. This added strain results in dilation and dysfunction of the right ventricle. When the mean pulmonary arterial pressure increases to greater than 40 mm Hg during an acute first PE, the right ventricle fails, and hemodynamic collapse and death occur.[20] Therefore, a massive PE should be suspected any time there is unexplained hypotension accompanied by an elevated central venous pressure (jugular vein distension).[21]

Death from massive PE is the result of cardiovascular collapse rather than respiratory failure. Although the usual course of PE is to resolve rapidly (because the body dissolves the embolism with endogenous fibrinolytic agents), permanent residual disease does occur.[22-24] Overall, fewer than 10% of patients with acute PE have lung perfusion defects after 6 weeks, and approximately 3% to 4% develop long-standing PH (i.e., chronic thromboembolic pulmonary hypertension; CTPH).[25]

Clinical Features

A high index of suspicion is crucial to make the diagnosis of VTE. Unfortunately, no specific signs or symptoms indicate the presence of VTE, and a significant proportion of patients are asymptomatic (32%).[3,26] The physical findings of DVT in the lower extremities include redness and warmth in one-third of patients and swelling and tenderness in three-fourths of patients. In addition to the lack of sensitivity, the physical examination is not specific for diagnosing DVT. For instance, in patients who have swelling above and below the knee, fever, and a history of immobility and cancer, the likelihood of finding DVT is only 42%.[27]

The most frequent symptoms in patients with PE are dyspnea, followed by pleuritic chest pain (sharp pain predominantly during inhalation) and cough (Table 28.2).[28] The onset of dyspnea is usually rapid, within seconds (46%) or minutes (26%) of the PE.[28] Hemoptysis occurs in 13% to 20% of patients. The combination of dyspnea of sudden onset, fainting, and acute chest pain should raise suspicion of PE. In one study, this combination of symptoms was present in 96% of patients with confirmed PE, compared with 59% of patients in whom PE was suspected but not confirmed.[29] In some patients, dyspnea lasts only a few minutes, and this episode may be wrongly dismissed as being trivial.[16,18,29,30] There are no characteristic physical findings of PE. The most frequent physical findings include tachypnea, rales on chest examination, and tachycardia. Other common physical findings include an accentuated pulmonary component of the second heart sound (loud P_2) consistent with PH. Fever may be present in as many as 54% of patients.[18,29,30] Similar to what occurs in the diagnosis of DVT, fewer than 35% of patients in whom PE is clinically suspected actually have it.[3]

TABLE 28.2 Clinical Characteristics in Patients With PE and No Cardiopulmonary Disease

Symptoms	Frequency (%)
Dyspnea at rest or with exercise	73
Pleuritic pain	44
Calf or thigh pain	44
Cough	34
Orthopnea	28
Wheezing	21
Signs	**Frequency (%)**
Tachypnea	54
Tachycardia	24
Rales	18
Decrease breath sounds	17
Loud P2	15
Jugular venous distension	14

From Stein PD, Beemath A, Matta F, et al: Clinical characteristics of patients with acute PE: data from PIOPED II, *Am J Med* 120:871–879, 2007.

Because the clinical features lack specificity and treatment is anticoagulation (which carries risk of bleeding over time), confirming or excluding the diagnosis with appropriate testing is necessary.

Chest X-Ray

The chest x-ray cannot confirm or exclude the presence of PE but is helpful to rule out other life-threatening conditions, such as pneumothorax or pneumonia, which can present in a similar way. In patients with dyspnea, a normal chest x-ray may be a clue to the presence of PE; however, the plain chest x-ray is abnormal in more than 80% of the patients with PE.[31] Some of the abnormalities include enlargement of the right descending pulmonary artery (66%), elevation of the diaphragm (61%), cardiomegaly (55%), and pleural effusion (50%). Patchy radiographic opacities or round nodular lesions next to the pleural surface are present in patients who have pulmonary infarction or atelectasis. Other less common findings noted in 25% to 30% of patients with PE include the *Westermark sign*, in which there is pulmonary hyperlucency caused by a marked reduction in blood flow, and the *Hampton hump*, a pleural-based opacity in the costophrenic angle that represents alveolar hemorrhage from a pulmonary infarction.[29,31,32]

Electrocardiogram

The electrocardiogram (ECG) is helpful to rule out other diagnoses, such as acute myocardial infarction and pericarditis. The ECG is frequently abnormal in patients with PE (87% of the time), but the ECG abnormalities are usually nonspecific; tachycardia and ST-segment depression are the most common.[29] Abnormalities such as depression of the ST segment and T-wave inversion in V_1 and V_2 may be present. An $S_IQ_3T_3$ pattern (S wave in lead D_I and Q wave with negative T wave in D_{III}) is associated with massive PE and is present in 19% of such patients (see Chapter 18).[27]

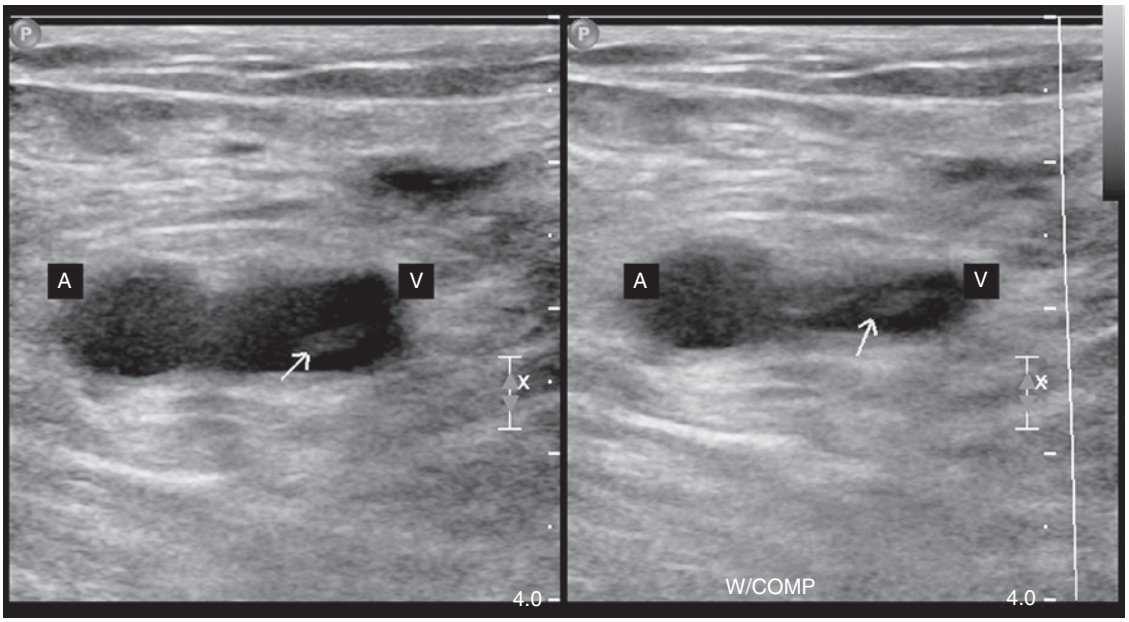

Fig. 28.1 Deep Venous Thrombosis Diagnosed by Ultrasonography. In the left panel, an intraluminal thrombus is visible in the right common femoral vein *(arrow)*. The right panel shows incomplete collapse of the femoral vein due to the presence of a clot. *A,* Femoral artery; *V,* femoral vein.

Arterial Blood Gases

Most patients with acute PE have hypoxemia and hypocapnia,[29] but 15% to 25% of subjects have a PaO_2 greater than 80 mm Hg.[18] Although a widened alveolar-arterial oxygen gradient and a lower PaO_2/FiO_2 ratio are frequently present, a normal alveolar-arterial oxygen gradient is noted in approximately 20% of patients with documented PE.[18,29,33] As such, the arterial blood gases cannot establish or exclude the diagnosis of PE. Massive PE with hypotension and respiratory collapse can result in hypercapnia and respiratory acidosis.

Diagnostic Modalities

The diagnosis of VTE relies on the diagnosis of DVT and/or PE. Importantly, the absence of one condition does not exclude the other.

By-Products of Plasmin Activation

The degradation of fibrin (an essential component of clots) by plasmin releases cross-linked split products called D-dimer, which is a global biomarker of coagulation activation. Low levels of D-dimer are commonly detected; however, higher levels are found in VTE disease. The D-dimer test is particularly useful in the outpatient and emergency department settings for the evaluation of patients with suspected DVT[34] and PE.[35] The D-dimer test has good sensitivity and negative predictive value but poor specificity and positive predictive value. In other words, this test is excellent for ruling out DVT or PE, particularly when the pretest probability for these conditions is low. In fact, a negative D-dimer result is as diagnostically useful as a normal lung scan or duplex ultrasonography for excluding PE or DVT. However, a positive D-dimer determination is insufficient for diagnosing VTE and further investigations are needed.[34-36] In hospitalized patients, D-dimer levels may be elevated as a result of comorbid conditions; therefore an imaging evaluation is preferred in this setting.[35]

Testing for Lower-Extremity Deep Venous Thrombosis

The Wells score is frequently used to evaluate the clinical pretest probability of DVT. This score is calculated using the following clinical parameters: presence of cancer, immobilization, localized tenderness, swelling, edema, previous DVT, superficial collateral veins, and absence of an alternative diagnosis.[37] In cases in which there is a moderate to high pretest probability, compression ultrasonography is commonly used to confirm the diagnosis of DVT.

Compression ultrasonography has proved to be sensitive and specific for diagnosing symptomatic proximal DVT. This noninvasive and portable test is the modality of choice for diagnosing DVT. DVT is diagnosed when deep veins are not compressible and/or have an echogenic filling defect, a free-floating thrombus, or no Doppler flow.[38] Of these, the most reliable DVT sign is the lack of vein compressibility (Fig. 28.1). The sensitivity and specificity of compression ultrasound for detecting a proximal lower-extremity thrombus in symptomatic patients vary between 95% and 100%.[38,39]

Testing for Pulmonary Embolism

Echocardiography can suggest the diagnosis (new or worsening dilation or dysfunction of the right ventricle or right heart thrombus); however, it lacks sensitivity (53%) because echocardiographic findings are usually normal in hemodynamically stable patients. Specificity is better (83%); nevertheless, right ventricular abnormalities could be due to conditions other than PE such as PH.[40] Despite these limitations, echocardiography provides valuable prognostic information to guide treatment decisions.[41,42]

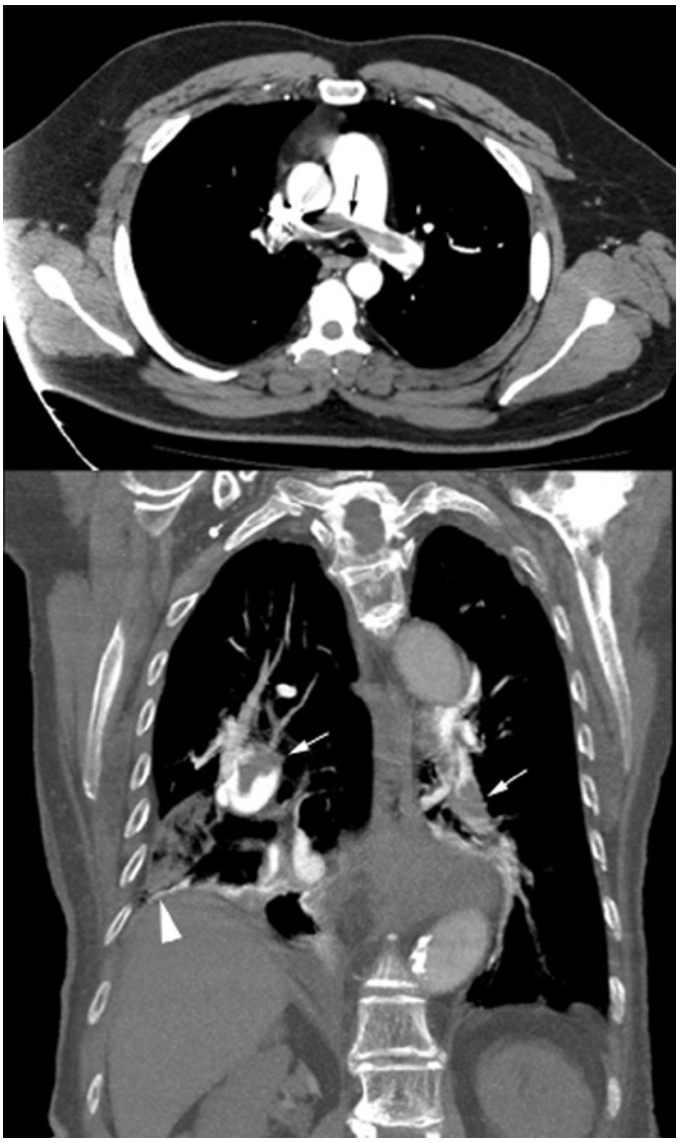

Fig. 28.2 Pulmonary Embolism (PE) Diagnosed by Computed Tomography Angiography. Axial (at the level of the pulmonary artery bifurcation, upper panel) and coronal cuts (just anterior to the thoracic spine, lower panel) showing the presence of PE involving the right and left pulmonary arteries, also known as saddle embolism *(arrows)*. On the coronal cut, there is a wedge-shaped area in the right lower lobe that represents lung infarction *(arrowhead)*.

Computed tomography angiography (CTA; Fig. 28.2) is currently the primary diagnostic modality for diagnosing PE,[43,44] given its high sensitivity and specificity, cost effectiveness, wide availability (particularly on urgent and emergent bases), and benefit of recognizing alternative diagnoses (e.g., pneumonia, pneumothorax).[45,46] The reported sensitivity of CTA ranges from 53% to 100%, and the specificity ranges from 81% to 100%.[44] This variability is due to radiologists' diverse expertise and variable image quality.[47] Studies indicate that CTA scanning detects PEs involving main and lobar emboli. However, this test is generally unable to detect smaller PEs in the distal branches of the pulmonary arteries. Multicenter trials suggest that helical CT scanning is safe to use for ruling out PE, at least in patients with a low or intermediate clinical probability of embolism. The Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) II trial evaluated the accuracy of multidetector CTA alone and combined with venous-phase imaging (CTA-CTV) for the diagnosis of acute PE. Excluding inconclusive studies (6%), the sensitivity of CTA was 83% and the specificity was 96%. The sensitivity increased to 90% when using CTA-CTV. The predictive value of either CTA or CTA-CTV was high with a concordant clinical assessment, but additional testing was necessary when the clinical probability was inconsistent with the imaging results.[44,48] Fig. 28.3 summarizes the diagnostic approach to PE using CTA.

TABLE 28.3 Likelihood of Identifying PE on Pulmonary Angiogram Based on Results of V/Q Lung Scan and Clinical Probability

Scan Interpretation	High Clinical Probability	Intermediate Clinical Probability	Low Clinical Probability
High probability	96%	88%	56%
Intermediate probability	66%	28%	16%
Low probability	40%	16%	4%
Near normal/normal	0%	6%	2%

From Arroliga AC, Matthay MA, Matthay RA: Pulmonary thromboembolism and other pulmonary vascular diseases. In George RB et al., editors: *Chest medicine: essentials of pulmonary and critical care medicine*, ed 3, Baltimore, 1995, Williams & Wilkins.

V̇/Q̇ scanning is in general reserved for patients in whom CTA is contraindicated (i.e., iodine allergy and renal failure) or inconclusive. V̇/Q̇ scanning involves the inhalation of a radiolabeled gas (usually xenon-133 or technetium-99 m) and the intravenous injection of macroaggregated albumin tagged with a gamma-emitting radioisotope (technetium-99m–labeled macroaggregated albumin). The distribution of lung ventilation (V̇) and perfusion (Q̇) is studied, and areas of mismatch where Q̇ is less than V̇ are sought. The presence of mismatches most often indicates PE. In the presence of parenchymal abnormalities, the V̇ defect coincides with the Q̇ defect, and matched abnormalities are found. Matched V̇/Q̇ defects are usually not due to PE. A normal or low probability V̇/Q̇ scan excludes the presence of a clinically significant PE in the context of a low clinical probability of PE.[49,50] An intermediate probability scan is inadequate to confirm or exclude the presence of PE. Better sensitivity and estimation of the PE size can be obtained by using V̇/Q̇ single-photon emission computed tomography (SPECT).[46]

Pulmonary angiography is necessary when a definitive diagnosis of PE cannot be obtained with noninvasive investigations. Pulmonary angiography uses x-ray imaging to expose the contrast dye injected directly into the pulmonary arteries by special catheters. Signs of acute PE include filling defects and cutoffs of the pulmonary arteries. Table 28.3 presents the probability of finding PE with angiography on the basis of results of V̇/Q̇ scan and clinical probability.[51] A definite diagnosis of PE can be established with noninvasive diagnostic tools in more than two-thirds of cases.[52]

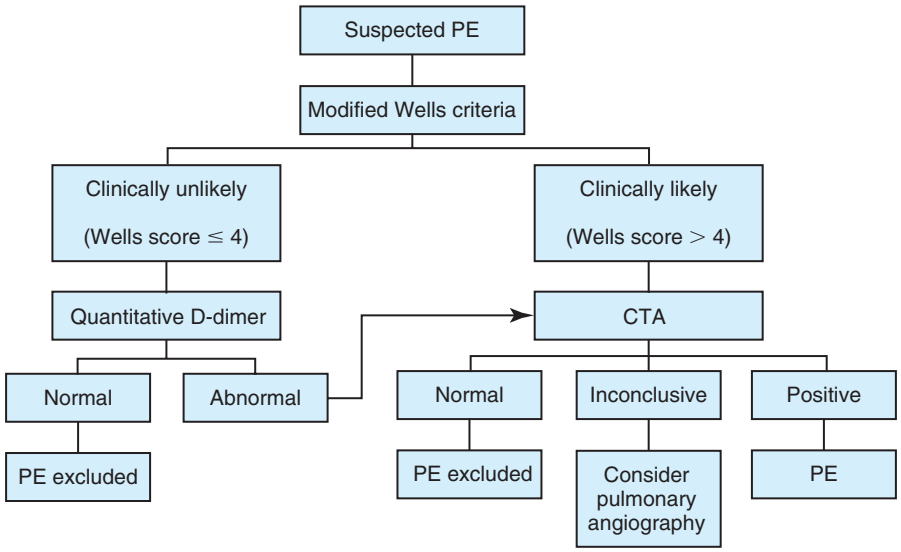

Fig. 28.3 Strategy for Diagnosis of Pulmonary Embolism *(PE)* Using D-Dimer and Computed Tomography Angiography *(CTA).* Diagnosis is based on clinical suspicion (using the Wells modified criteria) and the results of CTA scan. The modified Wells criteria include the following: clinical symptoms of deep venous thrombosis (DVT; 3 points), other diagnoses less likely than PE (3 points), heart rate >100 (1.5 points), immobilization ≥3 days or surgery in previous four weeks (1.5 points), previous DVT/PE (1.5 points), hemoptysis (1 point), and malignancy (1 point). (Modified from van Belle A, Buller HR, Huisman MV, et al: Effectiveness of managing suspected PE using an algorithm combining clinical probability, D-dimer testing, and computed tomography, *JAMA* 295:172–179, 2006.)

MINI CLINI

Respiratory Distress After Hip Replacement

Problem

You are asked to evaluate a 65-year-old man who has undergone right hip replacement. On the third day after surgery, the patient experienced dyspnea and pleuritic chest pain in the right hemithorax. On physical examination, his heart rate is 120 beats/min; respiratory rate is 25 breaths/min; and blood pressure is 120/85 mm Hg. The lungs are clear, and the heart examination does not show any gallops or murmurs. Arterial blood gas measurements on room air show a pH of 7.49; $PaCO_2$, 30 mm Hg; and PO_2, 85 mm Hg. The chest x-ray is unremarkable. What is your differential diagnosis, and how should you treat this patient?

Discussion

The differential diagnosis is extensive and should include an ischemic cardiac event such as an acute myocardial infarction as well as bacterial pneumonia. The type of chest pain is not typical of myocardial infarction. An electrocardiogram is of value because in patients with ST elevation myocardial infarction (STEMI), elevation of the ST segments is distinctive of the acute phase. Other laboratory data include elevation of the creatinine kinase and troponin levels, although these tests may become abnormal after several hours. The normal chest x-ray decreases the likelihood of the presence of pneumonia.

Because of the history of surgery on the right hip, DVT and PE are the most likely diagnoses. The next examinations are duplex ultrasonography of the lower extremities followed by a chest CTA or $\dot{V}/\dot{Q}$ scan. DVT should be sought in patients diagnosed with PE to investigate the origin of the thrombus and assess prognosis, because individuals with PE and coexisting DVT are at increased risk for death.[53] The presence of a "normal" PaO_2 of 85 mm Hg in this patient may be misleading. The wide alveolar-arterial gradient probably is caused by the presence of a pulmonary embolus. The patient should be anticoagulated.

TABLE 28.4 Simplified Pulmonary Embolism Severity Index

	Score[a]
Age > 80 years	1
History of cancer	1
History of chronic cardiopulmonary diseases (i.e., heart failure and/or chronic lung disease)	1
Heart rate of 110 beats/min or above	1
Systolic blood pressure less than 100 mm Hg	1
Arterial oxyhemoglobin saturation less than 90%	1

[a]A score of 0 represents low risk. A score of 1 or more indicates high risk.
The 30-day mortality was 1% in the low-risk group and 11% in the high-risk group.
Modified from Jimenez D, Aujesky D, Moores L, et al.: Simplification of the pulmonary embolism severity index for prognostication in patients with acute symptomatic pulmonary embolism, *Arch Intern Med* 170(15):1383–1389, 2010.

Risk Assessment

The mortality risk of a PE varies among patients, depending on a variety of factors. The mortality risk is higher in patients with PE and high-risk simplified Pulmonary Embolism Severity Index (sPESI) score (Table 28.4),[54] right ventricular dysfunction, elevated N-terminal probrain natriuretic peptide and/or troponin T, and concomitant DVT.[55-57] An online risk calculator that estimates the 30-day mortality after PE is available at www.peprognosis.org.

RULE OF THUMB The risk of death from PE is increased in the elderly and patients with history of cancer, presence of chronic cardiopulmonary disease, tachycardia, hypotension, and hypoxemia.

Treatment

Prophylaxis

Prophylactic therapy reduces the risk of VTE in patients at risk. The frequency of proximal DVT varies from 2% to 4% among general surgical patients undergoing minor surgery to 40% to 80% among patients at the highest risk, such as those who undergo hip or knee surgery.[58] Patients at moderate to high risk include patients admitted to the intensive care units[59,60] and those with acute spinal cord injury, myocardial infarction, ischemic stroke, or other medical conditions, such as obesity, heart failure, renal failure, hypercoagulable states, and history of recurrent VTE.[58] In part because the use of thromboprophylaxis is variable,[58] patients admitted to medical intensive care units develop DVT in 33% of cases.[61] VTE prophylaxis reduces the risk but does not eradicate its occurrence or related mortality in hospitalized patients.[62,63]

Most hospitalized patients who are immobile or have risk factors for VTE, particularly those without an increased risk for bleeding, need pharmacologic thromboprophylaxis. Pharmacologic choices for prophylaxis include low-dose subcutaneous unfractionated heparin, low-molecular-weight heparin (enoxaparin and dalteparin) and the factor Xa inhibitor (fondaparinux).[64-67] Mechanical measures to reduce venous stasis include early ambulation, graduated compression stockings, intermittent pneumatic calf compression devices, and venous foot pumps. Mechanical methods are reserved for patients without risk factors for VTE or who have contraindications to anticoagulant thromboprophylaxis.[68,69] Current prophylactic strategies for DVT and PE are summarized in Table 28.5. VTE prophylaxis is traditionally continued until the patient is ambulatory.[69]

RULE OF THUMB Most hospitalized patients who are immobile need prophylaxis for VTE.

Management of Venous Thromboembolism—Anticoagulation

Unless there is a contraindication (e.g., recent bleeding, head trauma, etc.), anticoagulation is begun when the diagnosis of VTE is first suspected and continued until it is ruled out by appropriate testing. The rationale for this approach is based on the high mortality observed soon after the VTE.

Unfractionated heparin is the time-honored drug treatment, but low-molecular-weight heparin (e.g., enoxaparin, etc.) is widely used.[70] Heparin is an indirect thrombin inhibitor with immediate action that is relatively safe. It forms a complex with antithrombin, inactivating thrombin, factor Xa, and to a lesser extent, factors XIIa, XIa, and IXa. Unfractionated heparin is administered as a bolus followed by a continuous infusion following a normogram to keep an activated partial thromboplastin time (aPTT) greater than 1.5 times the control value.[58,71-73] Low-molecular-weight heparin is administered subcutaneously, once or twice a day, and does not characteristically require blood test monitoring to ensure therapeutic benefit.[70] This agent has been shown to be cost-effective when compared with intravenous heparin therapy. The complications of heparin administration include major bleeding (3.8%) and thrombocytopenia caused by immunoglobulin G antiheparin antibodies (2.5% to 3%). If thrombocytopenia or bleeding occurs, heparin should be discontinued promptly.

There are several oral anticoagulants that are FDA-approved for the treatment of VTE disease. These include antagonists of vitamin K (warfarin) and of factor Xa (rivaroxaban,[74,75] apixaban,[76] edoxaban),[77] as well as direct thrombin inhibitors (dabigatran).[78] Parenteral anticoagulation (i.e., heparin) is given before dabigatran and edoxaban but not before rivaroxaban and apixaban.[67] Parenteral anticoagulation is overlapped with warfarin.[67]

In patients with VTE and no cancer, anticoagulation therapy with dabigatran, rivaroxaban, apixaban, or edoxaban is preferred over warfarin.[67] In patients with VTE and cancer, low-molecular-weight heparin is preferred over other alternatives.[67] Duration of therapy varies between 3 months for provoked VTE (e.g., immobilization post hip surgery) to long-term anticoagulation for recurrent unprovoked VTE or VTE in the setting of active

TABLE 28.5 Thromboembolism Risk and Recommended Thromboprophylaxis in Hospitalized Patients

Risk		DVT Risk Without Prophylaxis	Suggested Option
Low	a) Minor surgery in mobile patient	< 10%	a) No specific prophylaxis
	b) Medical patients fully mobile		b) Early and aggressive ambulation
Moderate	a) For general and abdominal-pelvic surgery	10%–40%	a) LMWH, UF heparin, or fondaparinux
	b) Medical patients, bed rest or sick		b) LMWH, UF heparin, or fondaparinux
	c) High bleeding risk		c) Mechanical prophylaxis
High	a) Hip or knee arthroplasty, major trauma, hip fracture, and spinal cord injury	40%–80%	a) LMWH, fondaparinux, apixaban, dabigatran, rivaroxaban, UF heparin, coumadin (INR 2–3) for a minimum of 10–14 days.
	b) High bleeding risk		b) Mechanical prophylaxis

LMWH, Low-molecular-weight heparin; *UF*, unfractionated. Mechanical prophylaxis includes graduated compression stockings or intermittent pneumatic compression. Recommendations suggest thromboprophylaxis in acutely ill hospitalized patients until they regain mobility.
Modified from Guyatt GH, Akl EA, Crowther M, et al.: Executive summary: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines, *Chest* 141(Suppl 2):7S–47S, 2012.

cancer.[67] Patients with low-risk VTE who have adequate support at home can be treated at home or discharged early from the hospital.[67]

Management of Deep Venous Thrombosis

The role of thrombolytic therapy with streptokinase, urokinase, or tissue plasminogen activator is not well-defined in managing acute DVT. The administration of early thrombolytic therapy decreases the pain and the incidence of postthrombotic syndrome (characterized by persistent pain, swelling, skin discoloration, and/or venous ulceration), but the risks (i.e., bleeding) and benefits of this particular therapy are not well established.[71,79] Thrombolytic therapy may be indicated in patients with massive proximal DVT and risk of limb gangrene.[80] Knowledge of the patient's values and preferences must be used to guide the best decision.[81]

For patients in whom anticoagulation is contraindicated (e.g., because of bleeding risk), placement of a filter in the inferior vena cava (IVC) to prevent embolism of clot to the pulmonary arteries is an option. Another reason for placing an IVC filter is recurrent PE despite adequate anticoagulation or cardiovascular instability (patient would not be able to tolerate another PE). IVC filter placement reduces the risk of PE in the period immediately after insertion but is associated with a higher incidence of recurrent DVT over time.[67]

Management of Pulmonary Embolism

The management of PE depends on the extent and status of the cardiopulmonary system. Therapy with heparin, whether unfractionated or low molecular weight, followed by warfarin or newer anticoagulants, is the treatment of choice. Adequate anticoagulation within the first 24 hours will decrease the risk of recurrent PE, which is associated with higher mortality.[82]

In patients with severe hypoxemia, acute right heart failure,[83] or shock, thrombolytic therapy may be considered for lysis of the emboli.[67] Hemodynamic instability due to massive PE is an accepted indication for thrombolytic therapy and is defined by a systolic blood pressure less than 90 mm Hg or drop of 40 mm Hg or more for more than 15 min or need for vasopressors/inotropic support. Thrombolytic treatment is indicated because these patients have an increased hospital and 90-day mortality.[84-86] Other options in the care of a patient with massive PE, in whom thrombolysis is either contraindicated or unsuccessful, include catheter tip embolectomy (physical removal of the embolism) or surgical pulmonary embolectomy.[67] Because of associated risks, these techniques should be used in centers with appropriate experience.[87]

Patients with an acute PE need supportive measures. Supplemental oxygen should be administered to patients who have hypoxemia. Adequate analgesia should be prescribed for patients who have pain and anxiety. Resuscitation with fluids and vasopressor agents is necessary for patients who develop hypotension and shock.

Prognosis

If left untreated, PE carries an overall mortality rate of 30%.[88] Early death is due to shock and/or a secondary embolic event. Long-term mortality is related to predisposing comorbidities and recurrent PE. Although the mortality from PE has decreased in recent years,[88] the death rate for the first episode of PE among hospitalized patients may be as high as 17.4% at 3 months.[89] Recurrent PE carries a much higher mortality rate, since only a quarter of patients will survive 3 months.[90]

Pulmonary Embolism Response Teams

Because the overall complexity of treating PE has increased over the recent years, several hospitals have created multidisciplinary pulmonary embolism response teams (PERT). Particularly in challenging cases, the PERT can help decide the best interventions for a particular patient—for example, type of anticoagulation, dose, type and route of administration of thrombolysis (intravenous vs. catheter directed), advanced intravascular interventions, surgical embolectomy, placement of inferior vena cava filter, and so on.[91]

PULMONARY HYPERTENSION

PH is defined by an elevation in mean pulmonary arterial pressure ≥25 mm Hg at rest.[92] PH is grouped into five categories, a classification that was last updated in 2013 by the Fifth World Symposium on Pulmonary Hypertension (Table 28.6).[93,94] The importance of the clinical system, besides allowing a better understanding of pathophysiology, is to give a framework for managing and treating different conditions known to cause PH. The first category, namely *PAH*, is characterized by narrowing of small and medium-sized pulmonary arteries,[95] manifested by an elevation in pulmonary arterial pressure associated with high pulmonary vascular resistance (≥3 Wood units) and normal left ventricular filling pressures (pulmonary artery occlusion pressure ≤15 mm Hg).[92,93,96] PAH is associated with several conditions, including collagen vascular disease, congenital heart disease, cirrhosis of the liver, human immunodeficiency virus, and drugs and toxins (diet pills or anorexigens).[93,94] In patients in whom no underlying etiology of PH can be identified, the disease is referred to as idiopathic pulmonary arterial hypertension (IPAH).[97-100]

The most common causes of PH are the ones associated with heart or lung diseases. Heart disease that can cause PH include left ventricular systolic or diastolic dysfunction (heart is not able to pump or relax effectively) and valvular disease. PH due to lung diseases is further divided into several groups: PH associated with chronic obstructive lung disease, interstitial lung disease, other

TABLE 28.6 Simplified Clinical Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension (PAH)
2. Pulmonary hypertension owing to left heart disease
3. Pulmonary hypertension owing to lung diseases and/or hypoxia
4. Chronic thromboembolic pulmonary hypertension (CTEPH)
5. Pulmonary hypertension with unclear multifactorial mechanisms

Modified from Simonneau G, Gatzoulis MA, Adatia I, et al.: Updated clinical classification of pulmonary hypertension, *J Am Coll Cardiol* 62(Suppl 25):D34–41, 2013.

diseases with mixed obstructive and restrictive patterns, sleep breathing disorders, alveolar hypoventilation, chronic exposure to high altitude, and developmental abnormalities.

PH can develop after one or more PE that is not fully reabsorbed. This entity is known as CTEPH.[101] In addition, PH can be associated to or may result from a variety of conditions grouped in PH with unclear or multifactorial mechanisms. A rare type of PH, namely pulmonary venoocclusive disease, is characterized by narrowing of the small pulmonary venules. Although challenging, recognizing pulmonary venoocclusive disease is important, given that the response to PAH-specific treatment is limited and lung transplantation is frequently needed. Patients with pulmonary venoocclusive disease commonly develop pulmonary edema when treated with PH-specific therapies.

Pathogenesis

The initial event of PAH likely involves an insult to the pulmonary endothelium (the cells that line the blood vessel) in patients with certain genetic predispositions.[102-104] This damage to the endothelium alters the balance between vasoconstrictive mediators (such as thromboxane and endothelin-1) and vasodilators such as nitric oxide and prostacyclin, resulting in vasoconstriction. Vasoconstriction might not be the primary event, but it is an important factor in the pathogenesis of PAH.[105-107] In addition to vasoconstriction, there is inflammation, thrombosis, cell proliferation, apoptosis (programmed cell death), and fibrosis, all of which can lead to pulmonary vascular remodeling and irreversible PAH.[108]

As it is for PAH, the mechanisms involved in the development of PH in patients with heart or lung diseases remains unknown. The same holds true for the development of CTEPH after an inadequate resolution of PE, a chronic condition that only occurs in 3% to 4% of patients after an acute PE.[25]

Epidemiology and Clinical Findings

The prevalence of idiopathic and heritable PAH is estimated to be 5 to 15 cases per million adults.[109,110] Overall, PH affects all age groups as well as both genders. Idiopathic and connective tissue disease-associated PAH are more common among women than among men, with a ratio of 3:1. Idiopathic PAH can occur at any age, although it is more common from ages 20 to 50 years. Approximately 7% of all cases of PAH are heritable.

On average, the diagnosis of PAH is delayed for 2 years after the onset of symptoms.[111] The condition frequently is misdiagnosed as asthma, anxiety, or depression because it presents with vague respiratory symptoms. The most common initial symptom is dyspnea (60% of patients). Other common symptoms include chest pain (50% of patients), probably due to a deficit in the oxygen supply to the subendocardial region of the right ventricle or compression of the left main coronary artery, and syncope (passing out; 8% of patients) due to an insufficient cardiac output, predominantly with activities. Less frequent symptoms include cough, hemoptysis, hoarseness (a condition called Ortner syndrome, caused by stretching or trapping of the left recurrent laryngeal nerve by enlarged pulmonary arteries), and Raynaud phenomenon (blanching of the fingers on exposure to cold).

Physical findings associated with PAH include a loud second heart sound and a right-sided third or fourth heart sound. Other common signs are a palpable right ventricular heave and pulmonary and tricuspid regurgitation murmurs. Signs of right ventricular failure such as swelling of the legs (edema), enlargement of the liver (hepatomegaly), and jugular vein distension are common. Cyanosis occurs as a result of low cardiac output or right-to-left shunt in patients with a patent foramen ovale or advanced stages of congenital heart diseases. The chest x-ray shows enlargement of the main and hilar pulmonary arteries, "pruning" (or narrowing) of the peripheral pulmonary arteries, enlargement of the right heart chambers, and pleural effusion,[112] although the chest x-ray may remain normal in 6% of patients.

Diagnosis

The diagnosis of PH is commonly suggested by an echocardiogram, which is the recommended method for screening. However, a definitive diagnosis of PH requires a right heart catheterization showing a mean pulmonary artery pressure of 25 mm Hg or greater. Before proceeding with right heart catheterization, PH guidelines suggest considering whether the patient has a significant heart or lung disease that could explain the degree of PH. Given the high prevalence of pulmonary hemodynamic abnormalities in advanced diseases of the heart and lung, mild degrees of PH are expected and may not need further exploration, particularly since there are no effective specific PAH treatments for PH associated with these conditions.

Results of the right heart catheterization may show pre-, post-, or mixed pre- and postcapillary PH. This division is essential to adequately characterize the pulmonary hemodynamic abnormalities, narrow the potential causes of PH, and guide treatment (Table 28.7).[113] Once the diagnosis of precapillary PH is made with right heart catheterization, PAH is a diagnostic possibility. The recognition of PAH is of great importance, as there are many FDA-approved therapies for this condition.

Other disorders associated with precapillary PH need to be ruled out, such as PH associated with lung disease, CTPH and PH associated with sarcoidosis, sickle cell disease, or other unclear and/or multifactorial mechanisms. This distinction is relevant because PAH-specific therapies are not FDA approved for precapillary PH other than PAH or inoperable or persistent CTPH after pulmonary thromboendarterectomy.[96]

Tests routinely ordered to establish the etiology of PH include blood testing, pulmonary function testing, echocardiogram, $\dot{V}/\dot{Q}$ scan, and pulmonary artery catheterization. Laboratory tests include a complete blood cell count, comprehensive metabolic panel, HIV serology, rheumatologic panel, and liver function tests. Laboratory tests help identify conditions associated with PAH such as systemic sclerosis, systemic lupus erythematosus, and mixed connective tissue. Pulmonary function tests are useful to identify significant restrictive or obstructive airway disease. The most common abnormality on pulmonary function testing in patients with PAH is a low carbon monoxide capacity (DLCO), associated with relatively normal pulmonary mechanics. Arterial blood gases are not routinely done in patients with PAH, but when performed, they frequently reveal mild degrees of hypoxemia and hypocapnia. Gasometric abnormalities are due to

TABLE 28.7 Hemodynamic Types of PH

Definition	Characteristics	Clinical Groups
PH	mPAP ≥25 mm Hg	All
Pre-capillary PH	mPAP ≥25 mm Hg PAOP ≤15 mm Hg	1. Pulmonary arterial hypertension 2. PH due to lung disease 4. Chronic thromboembolic PH 5. PH with unclear and/or multifactorial mechanisms

Data from "2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. The Joint Task Force for the Diagnosis and Treatment of Pulmonary Hypertension of the European Society of Cardiology (ESC) and the European Respiratory Society (ERS)." Nazzareno Galie, Marc Humbert, Jean-Luc Vachiery, Simon Gibbs, Irene Lang, Adam Torbicki, Gerald Simonneau, Andrew Peacock, Anton Vonk Noordegraaf, Maurice Beghetti, Ardeschir Ghofrani, Miguel Angel Gomez Sanchez, Georg Hansmann, Walter Klepetko, Patrizio Lancellotti, Marco Matucci, Theresa McDonagh, Luc A. Pierard, Pedro T. Trindade, Maurizio Zompatori and Marius Hoeper. *Eur Respir J* 46:903–975, 2015. *Eur Respir J* 46(6):1855–1856, 2015.

right-to-left shunt through a patent foramen ovale, decreased mixed venous oxygenation (due to a low cardiac index), and imbalances in the $\dot{V}/\dot{Q}$ match.[114]

The transthoracic echocardiogram may show dilatation of the right ventricle and right atrium, diminished contractility of the right ventricle and tricuspid regurgitation (Fig. 28.4). On certain occasions, the echocardiogram may identify congenital heart diseases such as atrial or ventricular septal defects that can lead to PAH. One especially important noninvasive test is the $\dot{V}/\dot{Q}$ lung scan, which helps rule out CTPH, a mimic of PAH that has different treatment—that is, thromboendarterectomy in those with disease located in the main, lobar, or segmental arteries, or balloon pulmonary angioplasty in those with more distal disease.[115] In patients with PAH, the $\dot{V}/\dot{Q}$ scan may be normal or show only patchy subsegmental perfusion defects. In patients with CTPH, the $\dot{V}/\dot{Q}$ scan reveals segmental perfusion defects; however, confirmation of the suspected pulmonary vascular obstructions with pulmonary angiography is necessary.

Right heart catheterization is required to confirm the diagnosis and determine the presence of vasoreactivity, degree of hemodynamic impairment, and prognosis of patients with PAH (Fig. 28.5). The pulmonary vasoreactivity test is generally performed using inhaled nitric oxide, and a pronounced decrease in mean pulmonary artery pressure during this gas inhalation may support the long-term use of calcium channel blockers as PAH treatment.[116] Patients with severe degrees of PH have worse prognoses. Severe PH is defined hemodynamically as high right atrial pressure and pulmonary vascular resistance, as well as low cardiac index or mixed venous oxygenation (tested in blood obtained from the pulmonary artery).[12,97-100,117]

Management of Pulmonary Hypertension

Pulmonary arterial hypertension can be life threatening and carries a poor prognosis.[1] Without therapy, only 33% of patients are alive 5 years after PAH diagnosis. With treatment, the survival at 5 years is around 65%.[118] There are several markers that indicate a poor prognosis (mortality in the first year after diagnosis higher than 10%) in PAH. These markers include clinical signs of right heart failure, syncope, World Health Organization (WHO) functional class III or IV, 6-minute walk distance less than 165 m, plasma N-terminal prohormone of brain natriuretic peptide greater than 1400 ng/L, cardiopulmonary exercise testing with a peak VO_2 less than 11 mL/min/kg (less than 35% of predicted) and VE/VCO_2 slope of 45 or greater, echocardiography that reveals enlarged right atrium and/or pericardial effusion and right heart catheterization showing a high right atrial pressure (15 mm Hg or above), low cardiac index (less than 2.0 L/min/m^2), or decreased pulmonary artery blood oxygenation (SvO_2; less than 60%).[119]

A risk calculator based on the Registry to Evaluate Early and Long-Term PAH Disease Management (REVEAL) score has proven

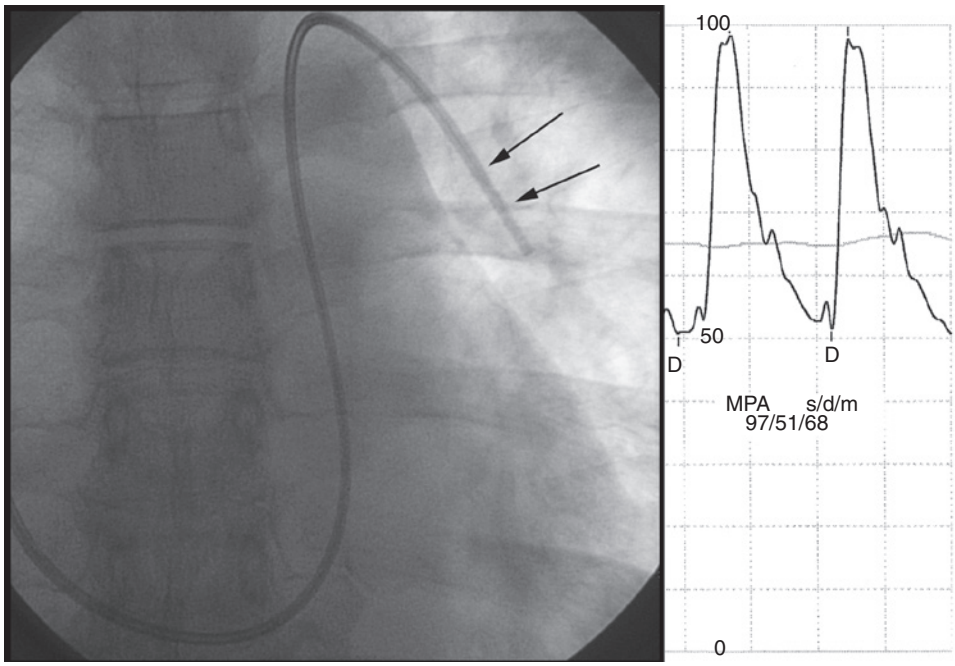

Fig. 28.5 Right Heart Catheterization in Pulmonary Hypertension. On the *left panel,* a pulmonary artery catheter is observed in the left pulmonary artery *(arrows).* On the *right panel,* the corresponding pulmonary artery pressure tracing is shown, confirming the diagnosis of pulmonary hypertension. In this case, the pulmonary artery systolic, diastolic, and mean pressures were 97, 51, and 68 mm Hg, respectively.

of value to predict the prognosis of PAH patients.[120,121] The REVEAL risk score calculator is a composite of 12 elements considered important for outcome including age, gender, WHO functional class, type of PAH, 6-minute walking distance, lung diffusion of carbon monoxide (DLCO), presence of pericardial effusion on echocardiogram, hemodynamic parameters, renal function, and plasma levels of N-terminal prohormone of brain natriuretic peptide.[120,121]

Recent analyses from three PH registries suggest that PAH patients who sustain or achieve a low-risk category[117] during follow-up have better prognosis.[122-124] The lower risk parameters include a WHO functional class I or II, 6-minute walk distance greater than 440 m, plasma N-terminal prohormone of brain natriuretic peptide less than 300 ng/mL, right atrial pressure less than 8 mm Hg, cardiac index of 2.5 L/min/m^2, or greater and SvO_2 above 65%.

RULE OF THUMB Treatment of patients with PAH is focused on achieving the largest number of low-risk parameters, since the more of these, the better the prognosis.

During the past 3 decades, treatment has improved considerably.[96,119,125-130] Current treatment options include using calcium channel blockers, prostanoids, endothelin receptor antagonists, phosphodiesterase-5 inhibitors, and soluble guanylate cyclase stimulators. Based on the results of recent trials, combination therapy either up front (both therapies at the same time) or sequentially (adding a second treatment after a few months of single therapy) is now favored.[96,131-134] A meta-analysis showed that combination therapy in PAH reduces clinical worsening by 38%, predominantly by decreasing nonfatal endpoints.[134] After initiation of PAH therapy, patients are followed every 3 to 6 months with WHO functional class, 6-minute walk distance, plasma N-terminal prohormone of brain natriuretic peptide, and right ventricular function on echocardiography.[96,135] In general, right heart catheterization is repeated when PAH therapies are changed or the patient shows no improvement or worsening.[96] Given that the treatment for PAH is complex and sometimes challenging, it is recommended that these patients are treated at a center with experience in managing this disease.[96]

General Measures

Oral anticoagulation is commonly used in patients with IPAH unless there is a contraindication to anticoagulation[136,137]; however, its benefits are less apparent when added to PAH-specific therapies.[138,139] The role of anticoagulation in other forms of PAH is less clear, and anticoagulation may not be beneficial.[136,139] Supplemental oxygen should be used to maintain oxygen saturation greater than 90%, given than hypoxemia is a major cause of pulmonary vasoconstriction. This is of particular importance in air travel or when staying at places with an altitude above 1000 m. Diuretics are indicated for volume overload, and digoxin might be indicated acutely for patients with refractory right ventricular failure.[129,130] Pregnancy is generally contraindicated in women with PH.

Calcium Channel Blockers

These agents should be considered only in PAH patients who have a definite hemodynamic response to a short-acting vasodilator test during right heart catheterization. Given its very short half-life (seconds) and minimum side effects, inhaled nitric

oxide is routinely used to test the pulmonary vasoreactivity.[116] Nitric oxide is usually administered by mask or nasal cannula at 10–40 parts per million for 2 to 5 minutes.[116] Protocols for using nitric oxide vary by institution. We use 40 ppm of nitric oxide delivered on room air (or the fraction of inspired oxygen needed to keep a pulse oximetry saturation greater than 90%) for 5 minutes. Others use 40 ppm of nitric oxide combined with 100% oxygen. Alternative agents include intravenous epoprostenol, intravenous adenosine, or inhaled iloprost. Unfortunately, only a small fraction of PAH patients qualify for and benefit from long-term therapy with oral calcium channel blockers.[129,130] Patients with PAH other than idiopathic, heritable or anorexigen-induced usually have a negative acute vasodilator testing or, even if the testing is positive, they do not respond to long-term calcium channel blockers.[116]

Prostanoids

Several prostanoids are currently available for treating patients with severe PAH, including epoprostenol, treprostinil, and iloprost. An oral selective IP prostacyclin-receptor agonist (i.e., selexipag) received FDA approval for the treatment of PAH.[133] Epoprostenol is delivered via continuous intravenous infusion, improving exercise capacity, hemodynamic variables, and survival in PAH patients.[140] Common side effects include headache, flushing, jaw pain, diarrhea, nausea, skin rash, and musculoskeletal pain. Catheter-related complications include infection and thrombosis.

Another prostanoid, treprostinil, has a longer half-life and is delivered subcutaneously,[141] intravenously,[142] by inhalation,[143] or by oral delivery. In addition to side effects seen with epoprostenol, patients receiving treprostinil subcutaneously may also experience pain at the infusion site (usually the abdomen). Inhaled treprostinil is administered by using the Tyvaso™ Inhalation System (ultrasonic, pulsed-delivery device). Inhaled treprostinil is started at 3 inhalations, 4 times a day, and if tolerated, the dose is increased by 3 inhalations every 1 to 2 weeks, up to 9 inhalations, 4 times a day. Side effects include cough and throat irritation. Oral treprostinil is associated with gastrointestinal side effects and requires a slow titration.

Oral selexipag reduces disease progression and the risk of hospitalizations for PAH, even when combined with other PAH therapies.[133] Oral selexipag is also associated with gastrointestinal side effects.[96] Iloprost is a prostacyclin analogue that is delivered by inhalation.[144] Due to the relatively short duration of action, iloprost needs to be taken as 1 to 2 inhalations, 6 to 9 times a day. Iloprost is administered using the I-neb AAD system. Common side effects of inhaled prostanoids include cough, flushing, and headache.[125,126,129,130] To avoid treatment interruptions in the event of an equipment malfunction, patients on intravenous or inhaled prostanoids should have easy access to a backup infusion pump or inhalation system, respectively.

Endothelin-Receptor Antagonists

Endothelin antagonists represent another class of medications available for treating PAH. They include bosentan, ambrisentan, and macitentan. Bosentan improves walking distance, hemodynamic variables, and functional class in patients with PAH.[145] The main side effect of bosentan is an asymptomatic increase in hepatic aminotransferase levels, which necessitates monitoring liver function at least monthly in all patients. Ambrisentan[146,147] and macitentan[132] are once-daily medications that do not need monthly hepatic aminotransferase testing. All endothelin receptor antagonists are potent teratogens, and very careful contraception must be observed by patients receiving these medications.

Phosphodiesterase-5 Inhibitors

Sildenafil, a phosphodiesterase type 5 (PDE5) inhibitor, reduces pulmonary arterial pressure and is effective in treating PAH.[127] By inhibiting PDE-5, sildenafil stabilizes cyclic GMP (cGMP, the second messenger of nitric oxide [NO]), allowing a more sustained effect of endogenous NO, which is a practical way of utilizing the NO-cGMP pathway. Tadalafil, a long-acting PDE5 inhibitor that is given once instead of thrice daily like sildenafil, also improves outcomes in PAH.[148,149] These medications are usually well tolerated; rarely, patients can have vision or hearing loss, priapism, and hypotension.

Soluble Guanylate Cyclase Stimulators

Riociguat directly stimulates soluble guanylate cyclase, increasing its sensitivity to nitric oxide. Riociguat is used for the treatment of patients with PAH and CTPH[150] who are not candidates for pulmonary thromboendarterectomy (i.e., surgery to remove clots from the pulmonary artery) or in whom the PH persists or recurs after thromboendarterectomy surgery.[151] This medication is associated with embryo-fetal toxicity; therefore, patients need to follow strict recommendations to avoid pregnancy.

Surgical Therapy

Atrial septostomy. The role of balloon atrial septostomy in treating patients with PAH is uncertain. Septostomy might be of benefit in the setting of severe disease with recurrent syncope and/or right heart failure despite maximal medical therapy. The shunt at the atrial level increases the systemic output and decompresses the right atrium and right ventricle, alleviating signs and symptoms of right heart failure. Balloon atrial septostomy is a high-risk procedure and should be performed only in experienced centers to reduce the procedural risks.[129]

Lung transplantation. Lung transplantation is indicated in individuals with severe PAH refractory to medical therapy.[152] Patients who undergo lung transplantation have an immediate decrease in pulmonary artery pressure and rapid improvement in right heart function.[129] The perioperative mortality of lung transplantation is higher in PAH, but after the immediate postoperative period, patients commonly have an excellent response with dramatic improvements in symptoms and quality of life.[153] Unfortunately, by the time PAH patients are considered for transplantation, they are usually poor candidates due to the comorbidities that accompany PAH.

RULE OF THUMB In patients with shortness of breath who have an unremarkable physical examination, the presence of a low DLCO and normal pulmonary mechanics suggests a pulmonary vascular cause (e.g., PH).

MINI CLINI

Dyspnea and Near-Syncope

Problem

A 35-year-old woman has shortness of breath. She had an episode of near-syncope approximately 6 months ago; a diagnostic evaluation was done, and the results were inconclusive. The physical examination shows a loud second heart sound. A chest x-ray shows cardiomegaly. The forced vital capacity and forced expiratory volume in 1 second are normal, but the DLCO is only 40% of the predicted value. What is the cause of the dyspnea and the low DLCO?

Discussion

This patient could have PH of unknown cause—that is, idiopathic pulmonary artery hypertension (IPAH). She has physical findings consistent with high pressure in the right side of the heart (a loud second heart sound), and she has symptoms that are common in this disorder, such as dyspnea and near-syncope or syncope. The differential diagnosis is broad, but a low DLCO in the presence of normal lung mechanics could indicate an abnormality of the pulmonary vasculature.

Pulmonary Hypertension in Chronic Lung Disease

PH is a frequent complication of chronic obstructive pulmonary disease (see Chapter 25). Approximately 50% of elderly patients with COPD have PH with significant reduction in survival and quality of life. The PH associated with COPD is multifactorial, but chronic hypoxemia is the most important factor. Acute alveolar hypoxia causes a potent pulmonary vasoconstrictive effect. Sustained alveolar hypoxia eventually leads to medial hypertrophy, fibrosis of the intima, and narrowing of the lumen of the pulmonary blood vessels.

Other factors responsible for PH in COPD patients include the loss of vascular surface caused by destruction of lung parenchyma, compression of the vascular bed as a result of hyperinflation, hyperviscosity of the blood due to polycythemia, and left ventricular diastolic dysfunction. The presence of PH in patients with COPD correlates with the severity of the disease. Patients with severe hypoxemia (PaO_2 55 mm Hg or lower) have higher pulmonary artery pressures, although the mean pulmonary artery pressure rarely exceeds 35 to 40 mm Hg.[154-157] Patients with COPD with a mean pulmonary artery pressure higher than 35 to 40 mm Hg have worse prognosis.[158-160]

Oxygen therapy is the main treatment for patients with PH due to COPD. PAH-specific therapies are sometimes used in very selected patients with COPD and severe PH; however, there is a lack of evidence to support their use and concern that pulmonary vasodilators may worsen the $\dot{V}/\dot{Q}$ match and hence worsen oxygenation.

An ECG is the test of choice to assess for the presence of PH. If the echocardiogram is consistent with the diagnosis, pulmonary artery (also known as right heart) catheterization is needed to confirm the diagnosis, determine the severity, and exclude left heart disease. For the diagnosis of IPAH, underlying diseases associated with PAH must be excluded. A normal $\dot{V}/\dot{Q}$ scan and/or pulmonary angiogram exclude chronic thromboembolic disease. A CT scan of the chest and pulmonary function tests is needed to exclude parenchymal lung diseases, and blood serologic tests are essential to screen for connective tissue diseases. A 6-minute walk test helps determine the functional capacity of the patient and assess her response to treatment. Several treatment options are currently available for patients with PH. The best therapeutic option depends on the severity of the disease and whether the patient has pulmonary vasoreactivity with nitric oxide.

ROLE OF THE RESPIRATORY THERAPIST IN PULMONARY VASCULAR DISEASE

Respiratory therapists (RTs) can play a key role in diagnosing and managing individuals with pulmonary vascular disease. The astute RT may help diagnose venous thromboembolism and PH by recognizing signs and symptoms of DVT/PE and PH (e.g., acute onset of dyspnea, pleuritic pain, pedal edema, worsening hypoxemia, hypotension, etc.). Communication with the managing physician to point out these findings and to suggest an adequate workup may prove lifesaving.

Therapists may also play an important role in both preventing and managing pulmonary vascular disease. Ensuring patients' compliance with vascular compression stockings can help prevent PE. Therapists take part in the care for patients with PH, as in administering nitric oxide during a pulmonary vasodilator challenge and managing inhaled therapies that are used to treat PAH (e.g., inhaled iloprost and treprostinil).

KEY POINTS

- Venous thromboembolism (DVT and PE) is an important cause of morbidity and mortality among hospitalized patients.
- Early recognition and treatment of VTE are essential and can be lifesaving. One-third of the deaths caused by PE occur within 1 hour of the symptom onset. The mortality rate in the group of patients with PE that goes undiagnosed is 30%; if the venous thrombosis is recognized and managed, the mortality rate is less than 8%.
- The point of origin of PE is DVT of the lower extremities or pelvis in 86% of cases.
- Most of the time, the clinical presentation of PE and DVT is nonspecific. A high index of suspicion is important to make the diagnosis in patients at risk.
- Prophylactic therapy reduces the risk of venous thromboembolism in patients at risk, but unfortunately, prophylactic therapy is underutilized.
- Pharmacologic choices for prophylaxis include low-dose subcutaneous heparin, warfarin, low-molecular-weight heparin, and novel anticoagulants. Mechanical measures include early ambulation and pneumatic calf compression devices.
- Management of venous thromboembolism includes anticoagulation therapy (heparin, warfarin, and novel anticoagulants).
- IPAH is a rare disease that mainly affects young adults.
- Management of IPAH includes the administration of vasodilators (calcium channel blockers, prostanoids, endothelin receptor antagonists, phosphodiesterase 5 inhibitors, and soluble guanylate cyclase stimulators). Lung transplantation is an option for refractory cases.

Acute Respiratory Distress Syndrome

Matthew C. Exline, Eduardo Mireles-Cabodevila, and Robert Duncan Hite

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Diagnose patients with acute respiratory distress syndrome (ARDS) using currently recommended criteria (Berlin criteria).
- Differentiate normal lung function that prevents pulmonary edema versus common disease mechanisms that lead to pulmonary edema, including nonhydrostatic edema (e.g., ARDS) and hydrostatic pulmonary edema (e.g., congestive heart failure).
- Describe the effect pulmonary edema has on lung function, including gas exchange and lung compliance.
- Identify the histopathologic findings associated with the exudative phase and the fibroproliferative phase of ARDS.
- Describe the common risk factors associated with triggering the onset of ARDS.
- Quantify the impact of ARDS on individual patients (e.g., mortality and morbidity), hospitals, and healthcare systems.
- Describe how mechanical ventilation can cause lung injury and how ventilator-induced lung injury can be avoided.
- Explain importance of tidal volume using lung protective ventilator strategies.
- Describe how ventilator settings (e.g., mode, tidal volume, positive end-expiratory pressure [PEEP], inspiratory time, and respiratory rate) can be adjusted for patients with ARDS.
- Explain the benefits of PEEP in ARDS.
- Describe changes in the pressure-volume curve (P-V curve) in ARDS and implications of lower inflection point (LIP) and upper inflection point (UIP).
- Understand the rationale for "permissive hypercapnia" during ARDS management.
- Explain the indications for conservative fluid management during ARDS.
- Discuss nonventilatory supportive care that can be offered to patients with ARDS, including use of checklists.
- Discuss management strategies for patients with ventilator dyssynchrony, including pharmacologic and nonpharmacologic therapies.
- Describe the use of innovative and alternative strategies for assisting ventilation in ARDS, including modes of mechanical ventilation, prone positioning, neuromuscular blockade (paralytics), extracorporeal support, and other interventions.
- Describe the current status of evidence to support the use of pharmacologic therapies (e.g., nitric oxide, surfactant, corticosteroids) in treating patients with ARDS.

CHAPTER OUTLINE

KEY TERMS

acute hypoxemic respiratory failure
acute lung injury
acute respiratory distress syndrome
airway pressure release ventilation
barotrauma
congestive heart failure
conservative fluid management
driving pressure
extracorporeal carbon dioxide removal
extracorporeal membrane oxygenation
high-frequency ventilation
hydrostatic pulmonary edema
inspiratory-to-expiratory ratio
nonhydrostatic pulmonary edema
lung protective ventilation
multiple organ dysfunction syndrome
permissive hypercapnia
positive end-expiratory pressure
prone positioning
pulmonary edema
ventilator-induced lung injury
volutrauma

Acute hypoxemic respiratory failure may develop in many clinical settings and is a common reason for admission to the intensive care unit (ICU). Acute hypoxemia has several causes. It occurs when oxygen is unable to reach the blood in enough quantity to allow function. This can happen because of abnormalities involving the airway (e.g., tumor, mucous plug), the alveoli (e.g., bacterial or viral pneumonia), the pulmonary vasculature (e.g., pulmonary embolus), and more, as discussed in other chapters. One of the most common causes of acute hypoxemic respiratory failure is abnormal leakage of fluid (pulmonary edema) from the vascular space (i.e., alveolar capillary) into the alveoli. Pulmonary edema was classically described as a manifestation of heart failure, when the hydrostatic pressure in the venous pulmonary capillaries was elevated (leading to leak to the alveoli) due to poor heart performance. Approximately 50 years ago, it was recognized that pulmonary edema can also happen without heart failure (noncardiogenic), a manifestation of alveolar injury.[1] This chapter will focus on understanding the diseases that cause pulmonary edema formation by highlighting one common source of pulmonary edema known as the **acute respiratory distress syndrome** (ARDS).[2,3] In addition, the chapter will explore the clinical syndrome of ARDS, including current management strategies, and the vital role of the respiratory therapist (RT) in helping manage ARDS.

PHYSIOLOGY OF PULMONARY EDEMA

Liquid and Solute Transport in the Lungs

A key component of normal lung function is to maintain a net flux of fluid through the lung parenchyma. For maximal gas exchange, the entire cardiac output passes through the extensive capillary network that surrounds the alveolar airspaces. The walls of the alveolus are separated from the capillary walls by the very thin lung interstitium (Fig. 29.1), which minimizes the distance for gases (i.e., O_2 and CO_2) to diffuse between the airspace and blood. However, this small barrier also needs to hold the fluid from the capillary and lung interstitium from entering the alveolar airspace. There is a normal physiologic amount of fluid that leaks into the alveoli, and a mechanism to clear it, thus keeping a balance. If the balance is broken, pulmonary edema results. In

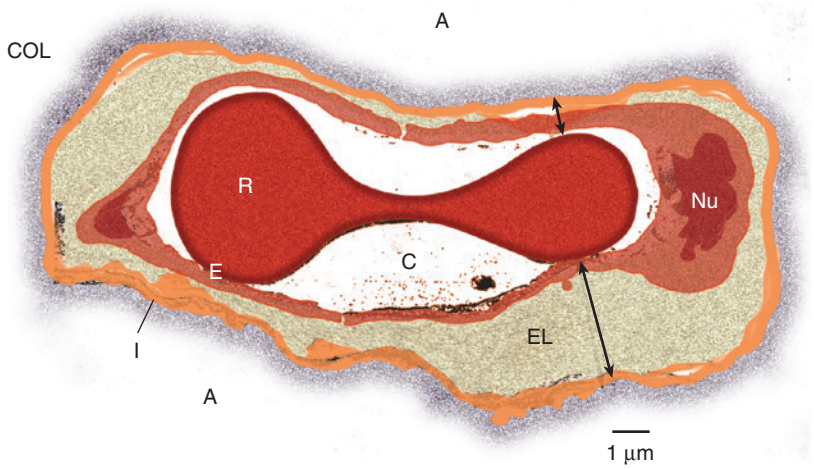

Fig. 29.1 Cross section of an alveolar wall shows the path for O_2 and CO_2 diffusion. The thin side of the alveolar wall barrier *(short double arrow)* consists of type I epithelium *(I)*, interstitium formed by the fused basal laminae of the epithelial and endothelial cells, capillary endothelium *(E)*, plasma in the alveolar capillary *(C)*, and the cytoplasm of the red blood cell (RBC) *(R)*. The thick side of the gas-exchange barrier *(long double arrow)* has an accumulation of elastin *(EL)*, collagen *(COL)*, and matrix that separates the alveolar epithelium from the alveolar capillary endothelium. As long as the RBCs are flowing, O_2 and CO_2 diffusion probably occur across both sides of the air-blood barrier. *A,* Alveolus; *Nu,* nucleus of the capillary endothelial cell. (Human lung surgical specimen, transmission electron photomicrograph.)

MINI CLINI

In a patient with suspected diastolic heart failure, where the left atria will have higher volume and pressures, the pulmonary venous pressure will be elevated, leading to increased hydrostatic pressure and increased alveolar interstitial fluid. When the amount of interstitial fluid is elevated, it can fill the interlobular septal spaces. This is the space separating the lung lobules. When this happens, the normally invisible septal spaces can be seen on a chest x-ray as linear interstitial opacities (known as *Kerley lines*) at the lung periphery (see Fig. 29.4A; see also Chapters 21 and 31 for more detailed discussions).

this chapter, we will summarize only the essential details needed to understand the key concepts of ARDS, whereas more complete details on these principles are provided in Chapters 9 and 10.

Unlike every other organ, the entire cardiac output for the body circulates through the lungs every minute, and the massive surface area of the capillary network provides a low–hydrostatic pressure (5 to 12 mm Hg) for the blood to come into close contact with alveolar gases. The interstitial space between the alveolus and capillary is very thin (<0.5 μm) and separated into two compartments: (1) the relatively stiff *alveolar side* between the capillaries and the alveolar epithelium and (2) the more compliant *nonalveolar side* around the capillary wall (see Fig. 29.1). The physical properties of the interstitium allow absorption of water and solutes. This *interstitial fluid* leads to a hydrostatic pressure, known as interstitial pressure, which is similar to but opposes the hydrostatic pressure in the vascular space. The interstitium, particularly the nonalveolar component, is highly compliant and able to accommodate relatively large increases in fluid volume in the interstitium without significant change in interstitial hydrostatic pressure or leakage of fluid into the alveolar airspace.

The net exchange of fluids between the capillaries and the interstitium of the lungs is determined by the combined influences of hydrostatic and osmotic forces within each compartment. Under normal conditions, a small fraction of fluid normally filters from the capillaries into the interstitial space of the lungs.[4] The lung lymphatic drainage system is the primary system for removing the filtered fluid and protein from the lungs. Drainage is assisted by the presence of a modest pressure gradient within the interstitium (higher pressure near the alveolus than the nonalveolar interstitium and terminal lymphatic vessels), and intrathoracic pressure changes during respiration. Backward flow is prevented by the presence of one-way lymphatic valves, and lymphatic fluid drains ultimately into the superior vena cava via the thoracic duct.[5] Once the capacity of the interstitium to capture fluid is surpassed and the rate of fluid accumulation exceeds the rate of lymphatic drainage, fluid must next begin to accumulate within the alveoli, an entity typically referred to by clinicians as **pulmonary edema**. Although accumulation of interstitial fluid leads to reduced efficiency of gas exchange, the accumulation of intra-alveolar fluid typically results in far more serious impairment of oxygenation and ventilation.

Hydrostatic Versus Nonhydrostatic Edema

The diseases that cause pulmonary edema are typically categorized as either hydrostatic or nonhydrostatic edema. To clarify the distinction between hydrostatic and nonhydrostatic edema, a simple analogy is to consider the intravascular hydrostatic force within the capillary as a body of water and the alveolar barrier as an impermeable dam with pumps that help regulate the water levels behind the dam (Fig. 29.2). Hydrostatic pulmonary edema occurs when the pressure or volume of water exceeds the capacity of the dam's pumps to maintain the water levels. Water then floods the land below the dam (the alveolus in this metaphor). Nonhydrostatic pulmonary edema occurs when the dam is cracked or damaged (the pump still works well) and the water leaks through it onto the land below the dam. It should also be noted that the type or color of water is different in nonhydrostatic edema because the cracks in the dam permit leakage of more sediment, which in patients is composed of serum proteins and inflammatory cells (e.g., neutrophils).

BOX 29.1 Causes of Hydrostatic Pulmonary Edema

Cardiac
- Left ventricular failure
  - Systolic (e.g., myocardial infarction, myocarditis)
  - Diastolic (e.g., left ventricular hypertrophy)
- Valvular heart disease (e.g., aortic, mitral)

Volume Overload
- Excessive fluid administration
- Renal failure
- Hepatic failure
- Hypoalbuminemia (e.g., malnutrition)

Hydrostatic Pulmonary Edema

Hydrostatic pulmonary edema is often also called *cardiogenic pulmonary edema* or **congestive heart failure** (CHF; see Chapter 31) because of its close association with cardiac abnormalities in intravascular hydrostatic pressures that cause edema. Increased hydrostatic pressures in the pulmonary veins lead to increased hydrostatic pressures in the alveolar capillaries that increase fluid leakage out of the capillary. In most patients, elevation of pulmonary venous pressures is caused by increased pressures in left-sided heart pressures (left atrial or left ventricular end-diastolic pressure), which are key characteristics of left-sided CHF, both diastolic and systolic (Box 29.1). In the setting of increased hydrostatic pressure, the endothelial and epithelial barriers remain intact and impermeable to large proteins and molecules. As a result, the fluid that accumulates within the alveoli, when measured from bronchoalveolar lavage (BAL) fluid samples, has characteristics identical to those of normal interstitial fluid, which typically contain minimal cells and low protein levels. In CHF, similar fluid can accumulate in other body spaces (e.g., pleural effusions, peritoneal ascites) for the same reasons and are typically referred to as transudative fluid collections or transudates.

Nonhydrostatic Pulmonary Edema

Nonhydrostatic pulmonary edema, also called *noncardiogenic pulmonary edema*, results from injury to the vascular endothelium

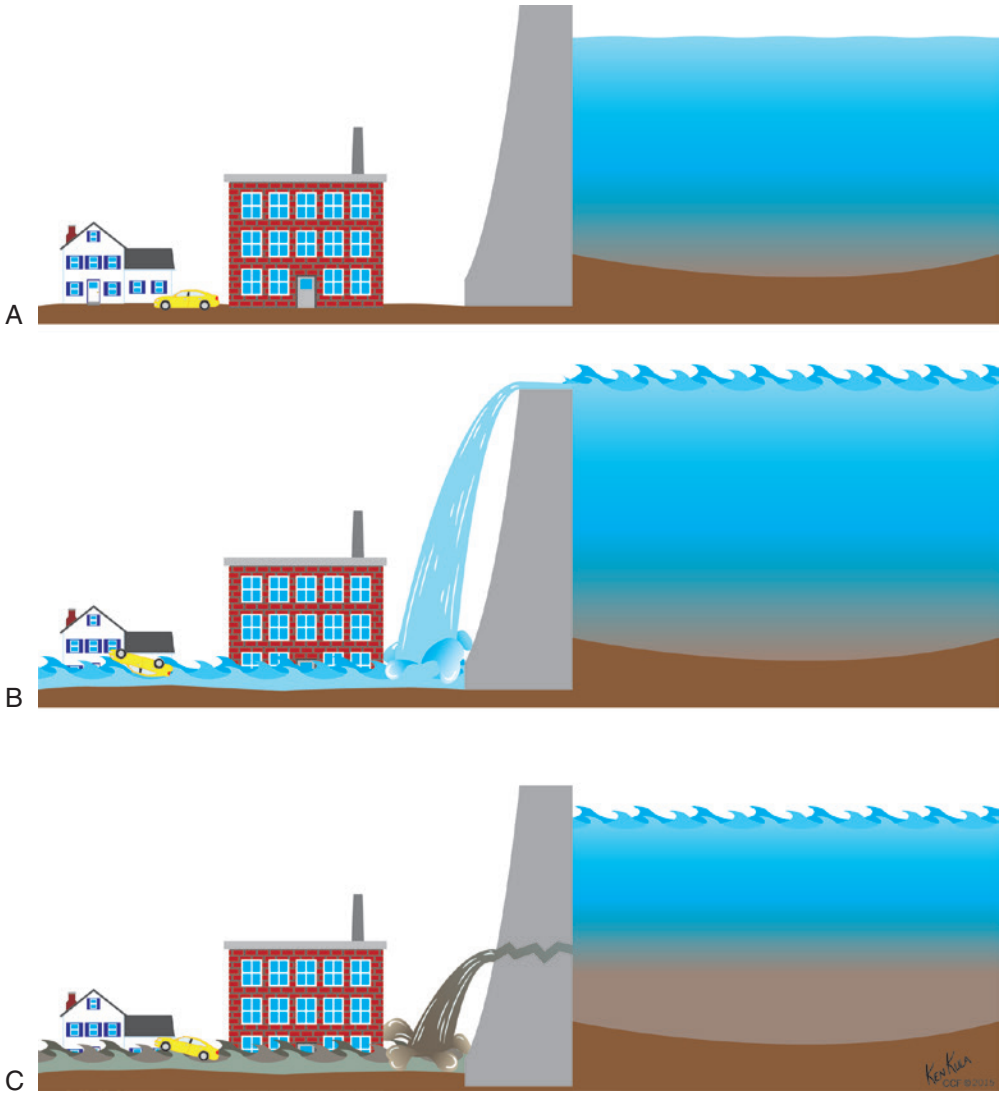

Fig. 29.2 The intact dam (A) represents the normal condition in which oncotic and hydrostatic forces (Starling forces) are balanced, keeping the town dry (where the town represents the alveolar space). (B) The dam remains intact but the water level has risen, overwhelming the dam (i.e., exceeding the forces that resist alveolar flooding) and flooding the town representing the alveoli. This condition resembles hydrostatic pulmonary edema. (C) A crack in the dam (simulating the alveolar-capillary interface) allows water through the dam, flooding the town. Note that the water flooding the town is darker because it contains more sediment and mud from the lake. The condition in (C) simulates the damage to the alveolar-capillary interface that accompanies inflammation in acute respiratory distress syndrome, causing nonhydrostatic pulmonary edema. The muddier water flooding the town (representing the alveolar space) in (C) than in (B) represents the more proteinaceous, inflammatory nature of the fluid that floods the alveoli in nonhydrostatic pulmonary edema.

and/or alveolar epithelium. This injury creates a loss of integrity in the barrier between the vascular and alveolar spaces (like cracks in a dam; see Fig. 29.2). In contrast to hydrostatic pulmonary edema, nonhydrostatic pulmonary edema is associated with increased total lung water despite normal microvascular hydrostatic pressure. All causes of ARDS feature disruption of endothelial and epithelial barriers and typically occur under conditions associated with widespread microvascular injury to the lungs. Vascular endothelial injury in the lungs causes increased permeability and allows fluid to pass from the capillaries into the interstitial space. As protein-rich fluid enters the alveolar interstitium from the vasculature, the osmotic gradient is drastically changed and no longer opposes fluid movement from the capillary into the lung. This process is likely aided both by damage to the normally impermeable alveolar epithelial barrier, which is a key feature of ARDS, and by impaired alveolar fluid clearance in ARDS.[6,7]

Many acute illnesses can lead to the development of ARDS (Box 29.2). Regardless of the cause, ARDS is typically associated with an influx of polymorphonuclear neutrophils, which release inflammatory by-products, such as proteases, phospholipases, and oxygen radicals into the lung.[8,9] These processes lead to

BOX 29.2 Clinical Features of Congestive Heart Failure and Acute Respiratory Distress Syndrome

Features Common to Both

- Symptoms of anxiety, dyspnea, tachypnea
- Decreased compliance and reduced lung volumes
- Hypoxemia (mild to severe), often requiring ventilator assistance
- Chest x-ray shows diffuse alveolar and interstitial infiltrates

Features Favoring CHF

- Suggestive clinical history (see Box 29.1)
- Symmetric pulmonary infiltrates, cardiomegaly, or pleural effusions on chest x-ray (see Fig. 29.2)
- Elevated pulmonary artery catheter wedge pressure (18–30 mm Hg)
- Bronchoalveolar lavage fluid: Low protein and minimally increased cellularity
- Prompt (<12 to 24 h) and lasting response to diuretics and CHF therapy

Features Favoring ARDS

- Clinical history of a risk factor for ARDS (see Box 29.3)
- Asymmetric, peripheral infiltrates on chest radiograph (see Fig. 29.3)
- Bronchoalveolar lavage fluid: Very high protein level and marked cellular influx
- Transient improvement with CHF therapy, but uncommon to significantly improve during initial 12–36 h

ARDS, Acute respiratory distress syndrome; *CHF,* congestive heart failure.

degradation of the endothelial and epithelial barriers and recruit additional neutrophils to continue the inflammatory cascade. In contrast to hydrostatic pulmonary edema, the alveolar fluid that accumulates in ARDS typically demonstrates very high levels of protein, neutrophils, and total cells (Fig. 29.3) and would be comparable to and consistent with exudative pleural fluid collections or exudates (see Chapter 27).

Although neutrophils play a central role in the development of ARDS, multiple pathways lead to the inflammatory cascade in the lung and subsequent loss of alveolar membrane integrity. Other chemical insults (e.g., gastric aspiration), inhalational injury (e.g., of noxious gas such as chlorine), or immunologic pathways (e.g., tumor necrosis factor [TNF] or interleukin-8 [IL-8]) all contribute to the hemodynamic and inflammatory events characteristic of ARDS.[10,11] Sepsis, one of the most common causes of ARDS, features activation of many of these inflammatory pathways. The relative contributions and exact roles of these inflammatory mediators in the pathogenesis of ARDS are not known. Attempts to control the inflammatory response in sepsis and ARDS by blocking specific mediators (e.g., steroids and antibodies to TNF and IL-1) unfortunately have not proved beneficial and are not currently used in the clinical management of patients with ARDS.

It is important to note that acute illnesses associated with the development of ARDS also can lead to widespread systemic organ injury (e.g., renal failure, encephalopathy), which is caused by the same inflammatory pathways leading to vascular injury, local tissue injury, and fluid leak in those organs, as seen in the lungs. This syndrome of diffuse organ impairment is frequently referred to as the **multiple organ dysfunction syndrome** (MODS).[12,13] ARDS is the pulmonary manifestation of MODS, and MODS is a common cause of death in ICUs. In contrast to ARDS, illnesses that lead to hydrostatic pulmonary edema typically do not cause MODS.

Gas Exchange and Lung Mechanics in Pulmonary Edema

Pulmonary edema is characterized by reduced lung and chest wall compliance (restrictive physiology) and refractory hypoxemia. The stiff lung and chest wall lead to increased work of breathing. Patients with pulmonary edema of any cause use a higher fraction (25% to 50%) of their total metabolic output to support their increased work of breathing. If the insult is not reversed, the combination of hypoxemia and increased work of breathing leads to respiratory failure and the need for ventilatory assistance. In most cases the severity of lung dysfunction and hypoxemia is more severe and more prolonged in the nonhydrostatic pulmonary edema of ARDS, when compared with the hydrostatic pulmonary edema caused by CHF (see Chapter 31).

In addition to the replacement of air with fluid in the alveolar spaces, the problems with gas exchange and increased work of breathing seen in ARDS are also caused by the inflammatory nature of the intra-alveolar fluid causing impaired surfactant synthesis, secretion, and function. The resulting surfactant abnormalities lead to increased alveolar collapse (i.e., atelectasis), due to the loss of surfactant's natural effects on lowering surface tension at the air–liquid interface in the alveolus.[14] The negative effects of alveolar consolidation and atelectasis on pulmonary gas exchange are worsened by a loss of the normal vascular response to alveolar hypoxemia. Normally, pulmonary arteries in areas of alveolar hypoxia will constrict as a physiologic response to preserve ventilation/perfusion $\dot{V}/\dot{Q}$ matching. However, in ARDS, this normal vasoconstrictive response is impaired in hypoxic areas; thus nonaerated alveoli receive higher blood flow than needed, which contributes to severe $\dot{V}/\dot{Q}$ mismatching and an intrapulmonary right-to-left shunting of blood flow (leading to hypoxemia).

In summary, pulmonary edema may arise from acute illnesses associated with increased pulmonary venous pressure (hydrostatic pulmonary edema or CHF) or may result from conditions associated with acute injury to the lung, in which the normal barriers to fluid movement within the lungs is disrupted, such as in ARDS. Although CHF and ARDS are distinct disease processes that require very different management strategies, differentiating these two forms of pulmonary edema in patients is frequently challenging because signs and symptoms of both are often very similar. The remainder of this chapter will focus on the distinct characteristics and management approaches for ARDS. In so doing, the reader should gain further ability to understand which characteristics and management approaches are both similar and distinct to CHF.

DEFINITION AND DIAGNOSIS

Early in the 20th century, the clinical problem of respiratory distress shortly after birth was identified in premature infants,

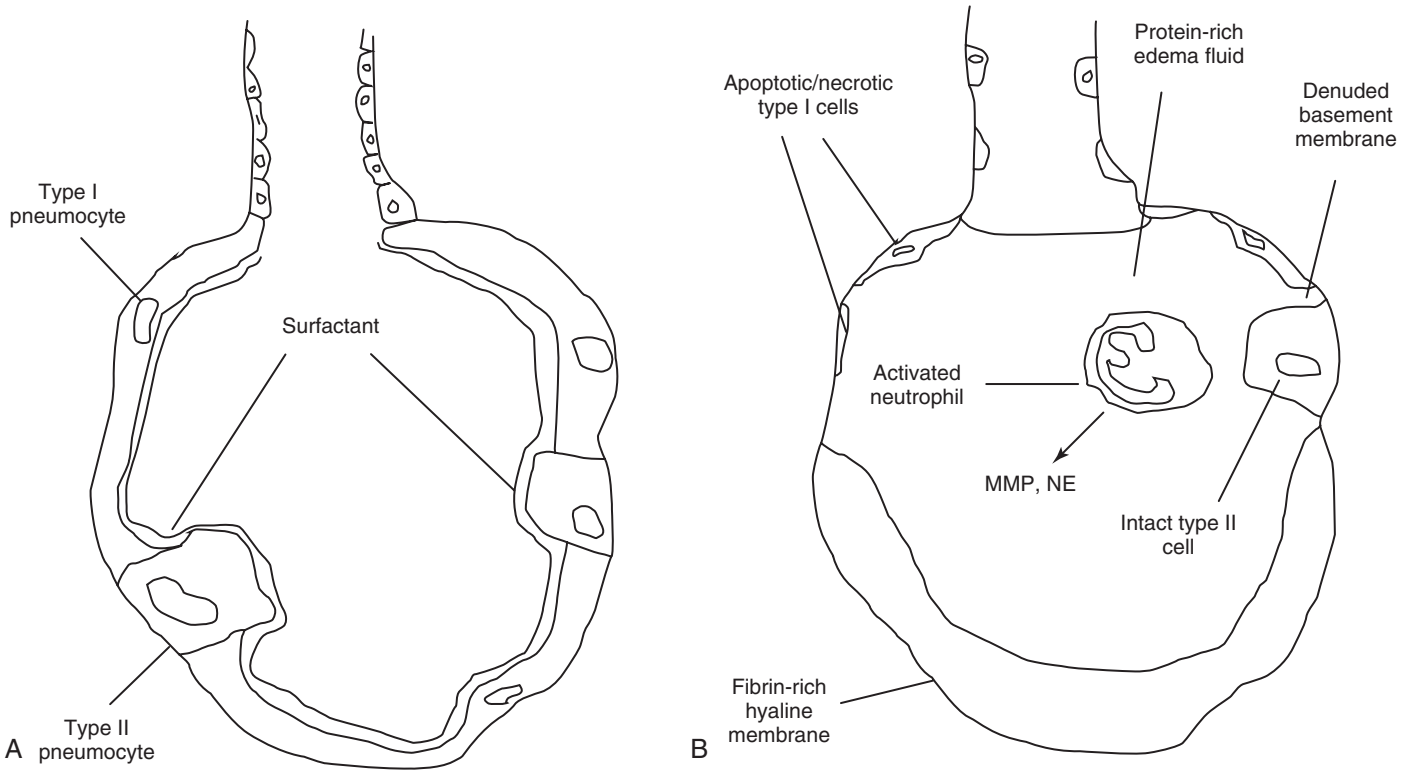

Fig. 29.3 The illustration compares a normal alveolus (A) and an alveolus with acute respiratory distress syndrome (ARDS) (B). The normal alveolus includes intact type I and II pneumocytes along with a layer of surfactant at the air-liquid interface over the epithelium. In ARDS, there is injury and loss of type I cells through apoptosis and necrosis, some preservation of typically dysfunctional type II cells and depletion and inactivation of surfactant. The alveolar lumen becomes filled with protein-rich fluid from leak of serum, activated neutrophils releasing mediators like matrix metalloproteinases *(MMP)* and neutrophil elastases *(NE)*, and leak of serum coagulation factors that form fibrin-rich hyaline membranes lining the alveolar wall. (Modified from Prudhomme JB, Ware LB: Acute lung injury and acute respiratory distress syndrome: mechanisms and potential new therapies, *Drug Discov Today: Dis Mech* 1:123–128, 2004.)

and by mid-century, the principal mechanism for the respiratory distress syndrome (RDS) in neonates was identified as a deficiency of surfactant.[14] Soon thereafter, a similar syndrome was recognized in adults, and the term "adult" respiratory distress syndrome (ARDS) was created.[1] Over the next 25 years, establishing a consistent definition for ARDS was challenging due to its close similarity during the initial clinical presentation of patients with other, more common diseases (e.g., CHF, pneumonia).

Criteria for Clinical Syndrome

In response to these challenges, a consensus definition for the "acute" respiratory distress syndrome (ARDS) was created in 1994 with the collective input of established experts from across Europe and the United States and is commonly referred to as the American-European Consensus Conference (AECC) definition.[15] Because the syndrome of ARDS in children (older than newborns) is not significantly different from that in adults, the AECC definition included all patients beyond newborns and discontinued use of the term *adult* in the title of ARDS. The AECC definition includes five central components: (1) reduced lung compliance, (2) hypoxemia (ratio of $PaO_2/FiO_2 < 300$), (3) bilateral infiltrates on chest radiograph, (4) an acute illness associated with the development of ARDS that can trigger the onset of ARDS, and (5) no evidence of CHF (typically based on direct measurements from an invasive pulmonary artery catheter of vascular filling pressures on the left side of the heart; see Chapter 31). The AECC definition also created the term known as **acute lung injury** (ALI), which shares all characteristics of ARDS except the severity of hypoxemia in ALI is less severe (PaO_2/FiO_2 of <300) as compared with ARDS (PaO_2/FiO_2 of <200). The AECC definition served as the "gold standard" for identifying and enrolling patients with ARDS into clinical trials for almost 20 years. The combination of this consistent definition and enhanced collaboration between investigators around the world led to dramatic discoveries and marked improvements in the outcomes of patients.

In 2012 the definition of ARDS was revised and updated by a new international consensus group that met in Berlin, Germany, in 2011.[16] These updates were made in response to limitations

of the AECC criteria that had been identified. The new criteria included in the revised definition are commonly referred to as the Berlin definition or Berlin Criteria. The key new features of the Berlin Criteria include the following:

1. Discontinuation of the use of the term "acute lung injury" (ALI), which had proven to be nothing more than redundant terminology without adding meaningful value.
2. Creation of three categories for ARDS disease severity (mild, moderate, and severe) based on ranges of PaO_2/FiO_2 ratio and levels of **positive end-expiratory pressure** (PEEP).
3. Inclusion and acceptance of noninvasive techniques to estimate left heart pressures, including echocardiography.
4. Enhanced specificity for interpretation of chest radiographs when determining the presence of bilateral infiltrates or opacities most characteristic of nonhydrostatic pulmonary edema.
5. Greater specificity regarding the time frame by which the development of the disease may still be considered "acute" (<1 week of the triggering condition).

Since its introduction, researchers and clinical trials have primarily used these updated definitions. Although they are not believed to differ dramatically, clinicians and readers should consider the importance and potential impact of these different criteria when comparing the results of research prior to and after creation of the new criteria.

RULE OF THUMB The PaO_2/FiO_2 is calculated using the PaO_2 obtained from an arterial blood gas (ABG) analysis and the FiO_2 at the time the ABG value was obtained. When calculating PaO_2/FiO_2, it is important to remember the difference between a fraction and a percent. In other words, a patient who is receiving 40% supplemental O_2 has a FiO_2 of 0.40 (not 40). As an example, the PaO_2/FiO_2 of a patient on 50% (FiO_2 0.5) whose PaO_2 is 90 mm Hg calculates to be 180. Assuming the patient met the other points of the Berlin Criteria to have acute respiratory distress syndrome (ARDS), the PaO_2/FiO_2 would indicate that the patient has moderate ARDS.

BOX 29.3 Etiologic Risk Factors That Trigger Acute Respiratory Distress Syndrome

Direct Injury
- Pneumonia (viral, bacterial, fungal)
- Gastric aspiration
- Toxic inhalation (phosgene, cocaine, smoke, high concentration of oxygen)
- Near drowning
- Lung contusion

Indirect Injury
- Sepsis and prolonged shock
- Burn injury (chemical or heat induced)
- Multiple trauma
- Transfusions (TRALI)
- Pancreatitis
- Gynecologic causes (abruptio placentae, amniotic embolism, eclampsia)
- Drug effect (e.g., *trans*-retinoic acid for acute leukemia)
- Sickle cell crisis

TRALI, Transfusion-related acute lung injury.

MINI CLINI

After obtaining a careful history and physical exam, the most common and rapidly available test to help differentiate congestive heart failure (CHF) from acute respiratory distress syndrome (ARDS) is a chest radiograph. It is often difficult to distinguish between CHF and ARDS based on the radiographic findings alone. CHF is often associated with cardiomegaly, perihilar infiltrates, and pleural effusions, whereas ARDS is more often associated with the presence of peripheral alveolar infiltrates, air bronchograms, sparing of the costophrenic angles, and normal cardiac size (Fig. 29.4). It must be noted that interpretation of portable chest radiography with patients lying supine in the intensive care unit is more difficult and may reduce the ability to readily identify these unique characteristics. Alveolar infiltrates in both entities can be diffuse and tend to occur in dependent lung zones but tend to form more in a gradient (worsening from anterior to posterior) in ARDS, which can be best seen on computed tomography imaging of the chest in ARDS (Fig. 29.5).

Distinguishing Acute Respiratory Distress Syndrome from Nonhydrostatic Pulmonary Edema in Clinical Practice

Despite the specific details of published definitions for ARDS and nonhydrostatic pulmonary edema, the clinical differentiation of ARDS from hydrostatic pulmonary edema (e.g., caused by CHF or volume overload from either advanced renal or hepatic disease) at the bedside of critically ill patients based on the Berlin Criteria can be challenging, even for experienced clinicians. In Box 29.2, clinical features that are common to both hydrostatic pulmonary edema and ARDS and those that can distinguish each are outlined. Patients presenting with hydrostatic pulmonary edema are much more common than ARDS and should be considered whenever the history or physical examination findings suggest one of the causes of CHF listed in Box 29.3. A clinical history of infection, recent trauma, or risk factors for aspiration may be present in either patient group, but the presence of these risk factors (triggers) favors a diagnosis of ARDS. To emphasize the difficulty in distinguishing the cause of pulmonary edema, many patients with ARDS are older and have preexisting illnesses that also place them at risk for CHF.

Intuitively, invasive measurement of hemodynamic variables using a pulmonary artery catheter (also called right heart catheter or Swan-Ganz catheter) would seem to offer a definitive way to differentiate hydrostatic and nonhydrostatic edema. However, in practice, the measurement of the cardiac output or pulmonary arterial pressure either invasively or noninvasively has not been shown to be essential for diagnosis of ARDS or beneficial in the daily management of ARDS patients.[17] The increasing availability and accuracy of noninvasive assessment of cardiac function by

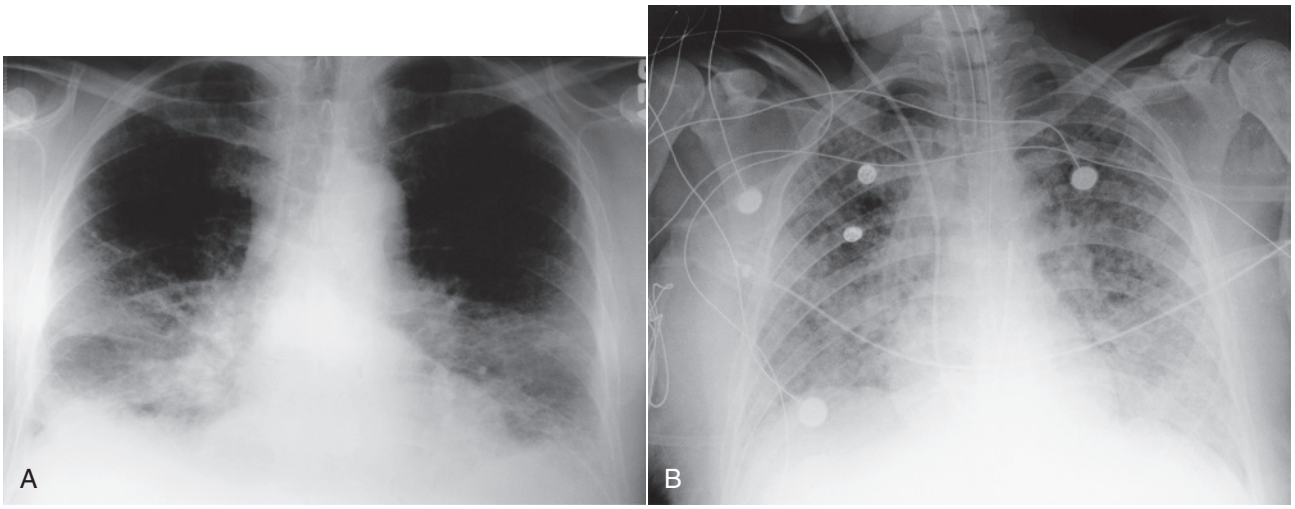

Fig. 29.4 Chest x-rays show the typical radiographic features of congestive heart failure (CHF) and acute respiratory distress syndrome (ARDS). (A) CHF is characterized by cardiomegaly, interstitial infiltrates, bilateral perihilar and basilar alveolar infiltrates, and bilateral pleural effusions, which cause blunting of the costophrenic angles. (B) ARDS is commonly associated with normal cardiac size, diffuse peripheral alveolar infiltrates, and minimal or absent pleural effusions.

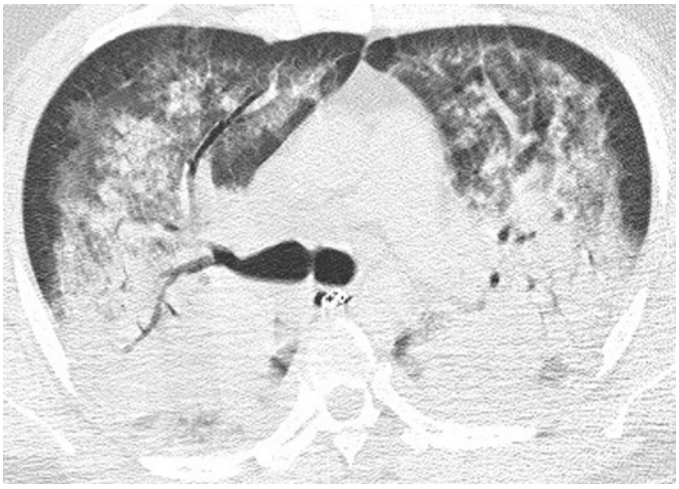

Fig. 29.5 Chest computed tomography image of a patient with bilateral acute respiratory distress syndrome (ARDS). As seen, there is a gradient of infiltrates that worsens progressively from anterior to posterior. The cause of ARDS in this case was indirect due to septic shock from an extrapulmonary (intra-abdominal) source. (From Elicker BM, Jones KT, Naeger DM, et al: Imaging of acute lung injury, *Radiol Clin N Am* 54:1119–1132, 2016.)

MINI CLINI

A careful history and evaluation of the overall clinical presentation often are the most useful means by which congestive heart failure (CHF) and acute respiratory distress syndrome (ARDS) can be initially differentiated in a patient who has refractory hypoxemia and bilateral infiltrates on the chest x-ray. For example, a patient presents to the emergency department with complaints of increased cough and shortness of breath and a low-grade fever (38.2°C). His medical history includes a long history of systolic heart failure (ejection fraction of 20% to 25% on recent echocardiogram). On examination, he has rales noted in both lung bases, engorged neck veins, bilateral lower extremity edema, and bilateral infiltrates with cardiomegaly on chest x-ray. His PaO_2/FiO_2 on 50% FiO_2 is 175. His white blood cell count is within normal range, and he has no other signs of systemic inflammatory response syndrome (SIRS) or other organ failure (e.g., renal, hepatic, central nervous system).

means of echocardiography, when combined with other physical examination features (capillary refill and mottling), can provide reliable information that can effectively guide clinical decision making.

Another potential method of separating CHF from ARDS is based on differences in the composition of the alveolar edema fluid. As described earlier, the inflammatory nature of this exudative fluid with ARDS is reflected by the increased inflammatory cells and serum proteins (versus transudative fluid in CHF), which can both be quantified in fluid obtained from a bronchoscopy with BAL. Collecting BAL is not uncommon in ARDS to provide diagnostic insights regarding respiratory infections that may have served as the initial triggering source for ARDS, but BAL analysis is typically not performed to distinguish hydrostatic pulmonary edema from ARDS.

Based on this presentation, the patient most likely has CHF, despite his fever and a PaO_2/FiO_2 (P/F) ratio less than 200. A brisk response to routine management for CHF (e.g., diuretics, antihypertensives) would be expected and further confirm the diagnosis.

Histopathologic Findings

The changes in the lung tissue in ARDS are typically separated into two phases based on the overall duration of the disease process: (1) the acute exudative phase (1 to 7 days) and (2) the fibroproliferative or also called organizing phase (3 days to weeks).

The exudative phase is characterized by diffuse damage to alveoli and blood vessels and the influx of proteinaceous fluid and inflammatory cells into the interstitium and alveolar spaces. As characterized in Fig. 29.3, there is capillary congestion, intra-alveolar edema, and injury/death of pneumocytes that form the alveolar wall, which includes type I pneumocytes (the predominant structure cells lining the alveoli) and type II pneumocytes (which make and secrete surfactant).[18,19] There is also cellular

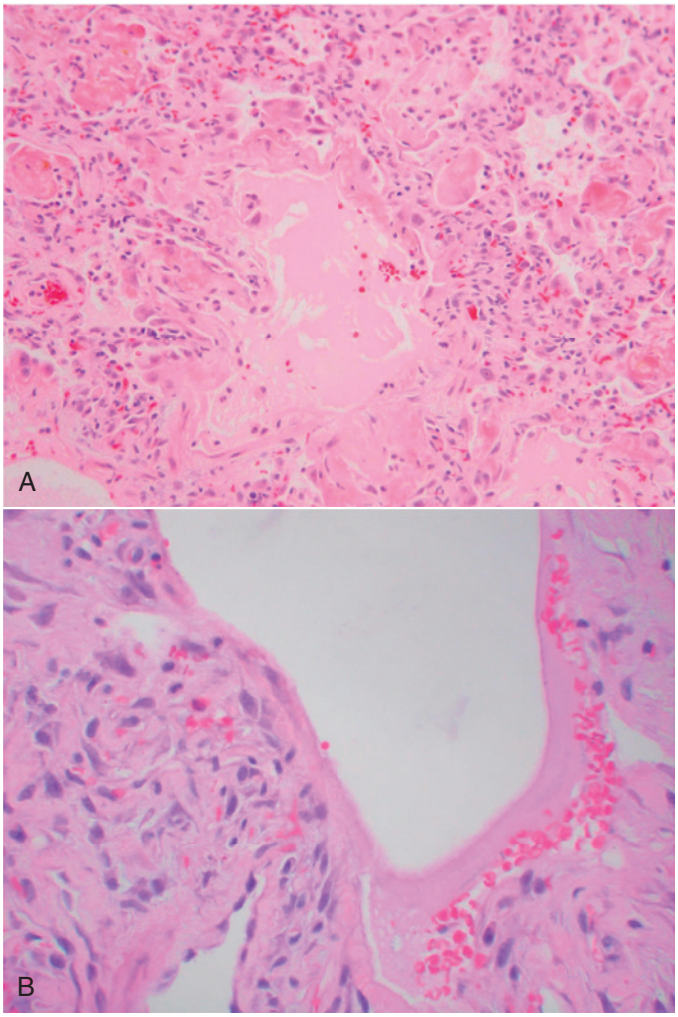

Fig. 29.6 Light microscopic image demonstrating characteristic changes of acute respiratory distress syndrome (ARDS), which are often called diffuse alveolar damage by pathologists. (A) Low magnification demonstrating extensive infiltration of inflammatory cells, thick and edematous alveolar interstitium and intra-alveolar hyaline membranes. (B) Higher magnification to better illustrate the hyaline membrane tightly adherent to the alveolar wall and extravasation of erythrocytes into the interstitium. (From Castro CY: ARDS and diffuse alveolar damage: a pathologist's perspective, *Semin Thorac Cardiovasc Surg* 18:13–19, 2006.)

injury to the lining (endothelium) of the pulmonary capillaries. The alveolar spaces are lined with *hyaline membranes*, which are composed of cellular debris and condensed plasma proteins (Fig. 29.6). As a result, an early name for ARDS was "hyaline membrane disease." When the primary condition that triggered the onset of ARDS is quickly identified and treated, the exudative phase is typically short, lasting only a few days, and is fully reversible, leaving no significant chronic signs of injury to the lung.

After the cause of lung injury is controlled, a process of lung repair begins. On pathologic examination, this appears as an overabundance of alveolar type II pneumocytes and infiltration or proliferation by fibroblasts within the alveolar basement membrane and intra-alveolar spaces. Fibroblasts drive intra-alveolar and interstitial fibrosis. The extent of fibrosis determines the degree of pulmonary disability in patients who survive ARDS. The exact mechanisms controlling lung remodeling in ARDS are not well established but very likely involve by-products of inflammatory cells (e.g., proteases, antiproteases, IL-6) and various growth factors (transforming growth factor [TGF]-α, TGF-β).[20] However, the remodeling process after ARDS is quite variable. Typically, patients have nearly complete normalization of lung compliance and oxygenation 6 to 12 months after the illness, with a persistent slight impairment of the diffusing capacity. However, in a small percentage (5% to 10%) of patients, the architecture of the lung does not fully return to normal and patients can experience chronic respiratory disability related to irreversible pulmonary fibrosis and obliteration of the pulmonary vasculature. The extent of recovery depends on the severity and duration of the initial trigger that led to ARDS and the influence of potential secondary forms of injury that may develop over the patient's complete hospital course. Secondary forms of lung injury include nosocomial infection, O_2 toxicity, and forms of **ventilator-induced lung injury** (VILI), which will be reviewed in detail later in this chapter.

KEY FEATURES

Risk Factors (Triggers) and Host Susceptibility

In the Berlin Criteria, an essential component of ARDS is that the patient must have an associated illness that stimulates an acute inflammatory response that leads to lung injury. These acute illnesses are typically referred to as risk factors or triggers for ARDS.[21,22] It has been proposed that the risk factors for ARDS should be categorized into problems that lead to either direct injury or indirect injury to the lung (see Box 29.3). In this concept, direct injury occurs as the result of triggers that begin in the lung (e.g., pneumonia and aspiration) and create an acute inflammatory reaction, within the lung, that initially leads to injury of the alveolar epithelium and subsequent damage to the interstitium and capillary endothelium injury. Conversely, indirect injury is caused by acute illnesses that begin outside of the lung (e.g., pyelonephritis, trauma or massive hemorrhage) and trigger an acute systemic inflammatory reaction that initially injures the capillary endothelium via circulating inflammatory mediators, which leads to subsequent injury of the interstitium and alveolar epithelium. Some studies suggest that the response of patients to treatment in ARDS may differ depending on whether the initial injury is direct versus indirect. However, thus far, this distinction has not proven to predict response to treatment or other important clinical outcomes.

It is important to recognize that only a minority of patients with risk factors for ARDS ultimately develop the full clinical syndrome. The key factors that determine which patients will develop ARDS are the severity and duration of the risk factor, and variables that lead some patients to be more susceptible. Sepsis is the most common cause, but even among all patients with sepsis, fewer than 20% will develop ARDS. As the severity of sepsis increases, the likelihood of ARDS developing increases dramatically and can exceed 50%. Among direct insults that lead to ARDS, pneumonia is the most common. Pneumonia caused by influenza infection is believed to carry an especially high risk for developing ARDS and a higher severity of ARDS once it develops.[23] As for the susceptibility of the host to develop ARDS,

important variables are increased age (i.e., age >50 years), liver disease, alcoholism, and genetic polymorphisms related to inflammatory mediators (e.g., IL-1, TNF, and surfactant).[24] Evidence suggests that cigarette smoking may also increase susceptibility to ARDS.[25]

One approach to improving outcomes in ARDS is to design studies that advocate starting therapy in advance of ARDS in population at risk. In 2014 the National Institutes of Health (NIH) launched the Prevention and Early Treatment of Acute Lung Injury Network (PETAL), which became the successor to the ARDS Network (1994–2014).[26,27] A priority for their trials and other ARDS clinical trial groups is the focus on patients with acute diseases who are at high risk to progress to ARDS. Methods to better predict patients at high risk have been developed and are continuously being refined as more data from trials become available. The Lung Injury Prediction Score is one such predictive tool and has been used to target preventive measures or therapies on at-risk populations and reduce the incidence of ARDS.[28,29]

Epidemiology and Outcomes

The exact prevalence of ARDS (including ALI) varies depending on the population. The ARDS estimates in the United States (reported in 2005) suggest that each year, there are 75 to 90 cases per population of 100,000 ($PaO_2/FiO_2 \leq 300$), which represents almost 200,000 cases for the entire country. In a recent multicenter, international study (LUNG SAFE),[30] 10% of patients admitted to the ICU had ARDS and 24% of all patients required mechanical ventilation. The prevalence of ARDS severity was 31% mild, 47% moderate, and 23% severe.

The survival of patients with ARDS seems to have changed over time and population.[31] The early mortality rates associated with ARDS between the late 1960s and the early 1990s were very high (i.e., 60% to 80%). Given our ability to maintain respiratory function in ARDS using mechanical ventilation, only a small minority (10% to 15%) of patients with ARDS die from respiratory failure. The most common cause of death in patients with ARDS relates to the original risk factor that triggered ARDS and from the MODS. Fortunately, the mortality rate over the past 20 to 25 years has declined dramatically, with most recent mortality rates typically reported between 20% and 40% and some experience as low as 20%.[32] The implementation of lung protective strategies, recognition, and adjunctive interventions have decreased the incidence. However, recognition of ARDS is poor (40% of cases are missed!) and the implementation of lung protective strategies is not universal. In the latest international study the overall mortality of ARDS while patients were still in the ICU of 35% and overall mortality prior to hospital discharge of 40%. Although the correlation is not as high as bedside clinicians often think, mortality in ARDS is also associated with ARDS severity (lower P/F ratio) with mortality in mild ARDS of approximately 30% to 35% and as high as 45% to 50% in severe ARDS.[30]

Beyond a risk for death, many important morbidities affect survivors of ARDS, including a long period on mechanical ventilation, time in the ICU and hospital, and slow recovery of lung function. Lessening these morbidities has increasingly become the primary target for recent, large ARDS clinical trials. As the duration of the time spent on mechanical ventilation has declined, so has the number of days in the ICU and hospital. However, the recent increasing use of long-term acute care facilities has made these comparisons with early experience more complicated. Recovery of lung function as assessed by pulmonary function tests such as spirometry, diffusion capacity (DLCO), and 6-minute walk test (6MWT) demonstrates that ARDS survivors typically recover more than 80% of lung function over 3 to 12 months.[33] The rate of recovery depends on several variables, including ARDS severity, the original risk factor, patient age, and more. Recovery of vital capacity, expiratory volume, and total lung capacity typically occur earliest, whereas recovery of DLCO and 6MWT is more prolonged.

In addition to outcomes primarily linked with lung function, morbidities are associated with the other aspects of ICU care that are needed in managing ARDS patients (e.g., sedation, delirium, and immobility) that have long-term impact on other organ function, such as muscle strength and cognition. Using a variety of techniques to assess muscular and cognitive function, survivors of ARDS consistently demonstrate prolonged impairments in both for at least 6 to 12 months; however, in some patients, the changes may never reverse. Consequently, increasing attention and urgency has been placed on identifying and using supportive care strategies (e.g., early mobility, minimizing delirium, optimal fluid balance, nutrition) to minimize these morbidities and accelerate recovery.

RULE OF THUMB Although acute respiratory distress syndrome (ARDS) was once considered a diagnosis that carried a high likelihood for death (≥70%), current rates of survival in patients with ARDS are much higher, with more than 50% to 70% surviving. As a result of our ability to provide protective approaches to mechanical ventilation that reduce harm, very few patients with ARDS die from respiratory failure. The severity of patients' hypoxia does correlate with mortality, but transient periods of hypoxemia do not significantly increase the likelihood for death. Most patients who die from mechanical ventilation die from the disease that triggered the ARDS. Accurate early diagnosis and treatment of the disease that triggered ARDS is a key to survival. For the respiratory therapist, this means that even patients with severe hypoxemia must undergo diagnostic tests that require transportation to radiology (e.g., computed tomography scans) or may transiently disrupt their ventilation (e.g., bronchoscopy).

THERAPEUTIC APPROACH

The hallmark of treatment of ARDS is supportive care with mechanical ventilation with disease-specific treatment of the underlying risk factors. Identifying and treating the cause of ARDS is an important step to stop progression of the lung injury. After diagnosis, the care focuses on preventing further injury (lung and other organs) and supporting the body while it recovers. This section presents an overview of the current approach to mechanical ventilation, adjunctive therapies that assist respiratory function, rescue strategies of ventilation, and key principles of nonventilatory support that should be prioritized in the care of patients with ARDS.

As previously mentioned, early efforts to improve outcomes in ARDS were largely unsuccessful due to large variations in definitions of ARDS and management approaches. In response

BOX 29.4 Goals and Priorities for Mechanical Ventilation in Acute Respiratory Distress Syndrome

1. Lung protective strategy
   a. Low tidal volume—using predicted body weight
   b. Low plateau or driving pressure
   c. PEEP titration—minimize derecruitment
2. Goals for gas exchange
   a. Permissive hypercapnia
   b. Avoidance of hyperoxia and hyperoxemia

PEEP, Positive end-expiratory pressure

to this challenge, the NIH launched a multicenter network of investigators and institutions to specifically collaborate on clinical treatment strategies for ARDS, a group that has since been known as the ARDS Network (ARDSNet).[26] It is important to note that the launch of ARDSNet in 1994 coincided with the creation of the original AECC ARDS definition. Several landmark clinical trials by ARDSNet, its successor PETAL Network (2014 to present), and other clinical trial groups have completed trials that demonstrated improvements in patient outcomes, including increased survival.[27] Over this same time, additional study networks focused on ARDS have successfully formed outside the United States, including in Canada, Europe, Australia, and New Zealand, and have provided equally important contributions.

Mechanical Ventilation and Other Respiratory Supportive Care

Mechanical ventilation is the cornerstone of supportive care for patients with ARDS. In general, the three goals of mechanical ventilation are safety, comfort, and liberation from mechanical ventilation. Safety encompasses two main clinical objectives: ensuring gas exchange and preventing further lung injury caused by mechanical ventilation or VILI. Comfort focuses on ensuring synchrony with the ventilator and balancing the work of breathing distribution. Keeping in mind these goals and clinical objectives of ventilation, one can see that some are more important at different stages of ARDS. In the early exudative phase of ARDS, the main goal is to ensure gas exchange and prevent further lung injury. As the disease process resolves and the patient–ventilator interaction and awareness are more important, comfort and liberation become the main goals. This does not mean that each goal is mutually exclusive, but it does help to explain choices about which mode of ventilation to apply to a given patient at a given time. For this chapter, we will review and summarize the key elements of goals for mechanical ventilation that most apply to the care of patients with ARDS (Box 29.4), while more detailed examination and review of the principles and applications of mechanical ventilation are provided later in the book (see Chapters 46 to 49).

Setting Tidal Volume

Although mechanical ventilation provides lifesaving support to patients with ARDS and other forms of acute respiratory failure, mechanical ventilation can be dangerous and can cause VILI. Although there are multiple forms of VILI, the most important

MINI CLINI

Tidal Volume

Tidal volume (V_T) in mechanical ventilation should be kept within a safe range to prevent lung injury. The size of V_T most recommended is 6 (4 to 8) mL/kg of predicted body weight (PBW) (not actual body weight). PBW is determined by knowing a patient's gender and height, and tables with formulas for calculating PBW are readily available. It is important for the respiratory therapist (RT) to accurately calculate each patient's PBW (using their gender and measured or estimated height) when starting mechanical ventilation. For example, a man who is 6 feet tall and weighs 224 lbs. (100 kg) has a PBW of only 70 to 75 kg. Using his PBW and the V_T target of 6 mL/kg, the ventilator should be set for a V_T of 420 to 450 mL. If his actual body weight were incorrectly used, a V_T of 600 mL would have been selected and would be too large and could lead to VILI and increased mortality. Many RTs carry reference cards with safe V_T based on height and sex for rapid reference. The RT should also consider whether the patient has any history of surgical lung resection (e.g., pneumonectomy or lobectomy), which results in smaller predicted lung capacity. For a patient who has undergone pneumonectomy, the selected V_T should be reduced by approximately 50%.

and well-established forms of VILI are volutrauma and barotrauma.[34] ***Barotrauma*** is the rupture of alveolar structures, presumably due to excessive airway pressure, that results in gross leakage of air outside of the lung parenchyma into adjacent tissue spaces (e.g., pneumothorax and pneumomediastinum). ***Volutrauma*** is similarly a form of injury to the alveolar structure; however, rather than a clinically recognizable leak of air, there is microscopic cellular injury to the alveolar and capillary walls, causing them to become leaky. This cellular injury then becomes the trigger for an inflammatory cascade that may trigger or worsen ARDS. The strategy of using a tidal volume (V_T) that avoids volutrauma is commonly referred to as low tidal volume ventilation (LTVV) or ***lung protective ventilation*** (LPV).

In 2000 a landmark clinical trial (the ARMA trial) was completed and published by the ARDS Network using LPV and demonstrated a 22% relative reduction in mortality in patients with ARDS managed with a "low stretch" or low V_T approach. The study compared a strategy of low V_T (6 mL/kg predicted body weight [PBW]) versus a larger V_T of 12 mL/kg PBW, which had been the standard for practice in ICUs across the United States and world for more than 40 years.[35] The survival benefit of low V_T transformed the standards for care of patients with ARDS and is considered one of the most important reasons for the dramatic improvements in mortality and morbidity associated with ARDS over the past 10 to 15 years. More recent trials of mechanical ventilation in patients without ARDS indicate that VILI may happen in any mechanically ventilated patient and that LPV is the preferred approach for choosing a V_T in most clinical settings. These trials include even patients requiring only brief exposures to mechanical ventilation during elective abdominal surgical procedures.[36]

Positive End-Expiratory Pressure

The use and critical importance of PEEP in ARDS were highlighted in the original report of ARDS in adults older than 50 years ago,[1] and over the ensuing years, the effects of PEEP on

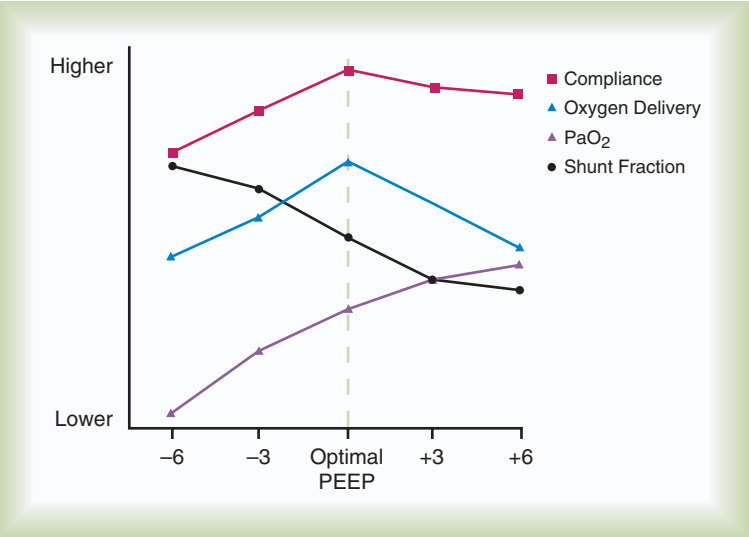

Fig. 29.7 Determination of optimal positive end-expiratory pressure *(PEEP)* from simultaneous measurements of hemodynamic (DO_2), gas exchange (shunt fraction and arterial oxygenation *[PaO_2]*), and physiologic values. Optimal PEEP does not correspond to PEEP associated with optimal pulmonary gas exchange. When adjusting PEEP, the clinician should consider its effects on systemic DO_2 and lung compliance such that systemic organ injury and lung injury are minimized.

lung compliance, oxygenation, and cardiac output have been well characterized. As Fig. 29.7 highlights, the effects of PEEP on lung compliance and oxygen delivery vary based on pressure used and patient-specific factors.

The rationale for using PEEP requires understanding the pressure-volume (P-V) curve of the lung. The P-V relationship can be established for a given patient by measuring lung volume during step increases in airway pressure. The classic P-V curve has an S, or sigmoid, shape (Fig. 29.8). The initial limb has large changes in pressure that are associated with only small increases in volume, the middle limb has the "best" change in pressure per volume, and the final limb again has large pressure changes with smaller increases in volume. Compliance is defined as the relationship between change in volume (ΔV) and change in pressure (ΔP) or ΔV/ΔP, and the middle limb represents the most compliant portion of the curve. The P/V curve also demonstrates a lower inflection point (LIP; point at which the lower limb shifts to the middle limb) and an upper inflection point (UIP; point at which the middle limb shifts to the upper limb). The LIP represents the point at which recruitment (i.e., opening) of alveolar units begins, and typically also the point below which alveolar units close (i.e., collapse or atelectasis) if airway pressure at end expiration drops below. The UIP represents the point beyond which further expansion of alveolar units becomes more difficult and more likely to cause injury from overdistension. From the physiologic standpoint, PEEP reduces lung collapse thereby increasing the amount of aerated lung, a phenomenon often referred to as *recruitment*.[37]

During mechanical ventilation, the goals for titration of PEEP are staying above the LIP to avoid repeated cycles of alveolar collapse. Although creating P-V curves and quantitation of the LIP and UIP can be performed on patients receiving mechanical ventilation, measuring P-V curves is both technically challenging and time consuming and requires patients to be heavily sedated.

MINI CLINI

The pressure-volume relationship is most easily understood by considering the effort required to blow up a party balloon. The start of balloon inflation is often difficult and requires high pressure to get air to enter the balloon. After reaching a certain pressure threshold, inflation becomes easier. At this threshold, the pressure in the balloon has risen above the equivalent of the lung's lower inflection point (LIP) and is now on the steep part of its P-V curve. Eventually, the balloon gets close to maximum inflation and it once again becomes hard to fill it any further, which is its upper inflection point (UIP). Many children have identified that having an adult start blowing up a balloon (getting it beyond the LIP) makes the job easier. This is essentially what positive end-expiratory pressure (PEEP) is doing, keeping the lung open above its LIP with each respiratory cycle, which achieves recruitment of previously deflated lung units and prevention from deflation of open lung units.

Because measurements of LIP and UIP are not done routinely, titration of PEEP is typically performed using estimates from more available daily data of pressure and volume recorded mechanical ventilation.

In ARDS, the challenge of estimating the P-V relationships to determine the "best" PEEP settings is even greater. The P-V curves are flatter and more deviated to the right (see Fig. 29.8), which creates a smaller window for the settings to maximize benefits while avoiding overdistension. It must also be noted that in ARDS, the P-V relationships are highly dynamic and depend on the patient's overall condition, can change rapidly due to fluctuations in the patient's lung compliance (e.g., pneumonia, pulmonary edema), synchrony with mechanical ventilation, and more. Finally, the use of PEEP is further complicated by the potential adverse hemodynamic effect of PEEP to decrease venous return to the right heart. Thus determining PEEP levels in patients with ARDS requires frequent reassessment and adjustments.[38]

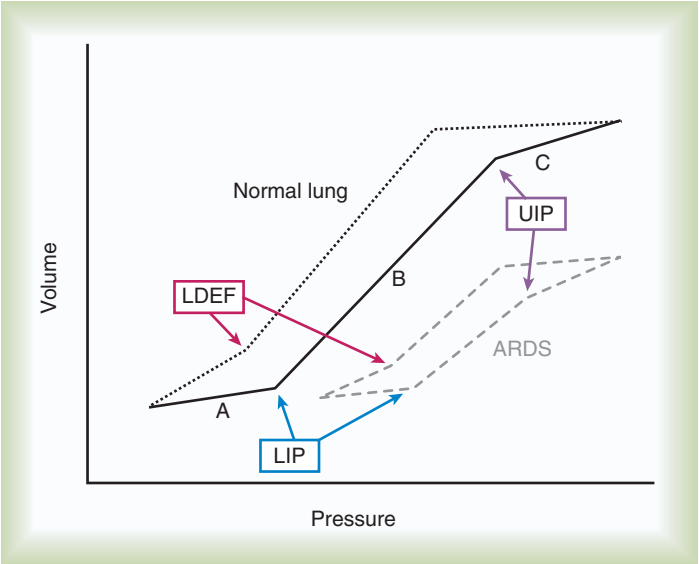

Fig. 29.8 Typical pressure–volume relationships during normal conditions and during acute respiratory distress syndrome *(ARDS)*. At low lung volume, inspiratory pressure increases faster than lung volume *(line A)* owing to high alveolar surface tension. As alveoli open, surface tension decreases, and the pressure required to increase lung volume further decreases *(line B)*. The lower inflection point *(LIP)* occurs between *lines A* and *B* and represents the volume above which most alveolar units are open. The upper inflection point *(UIP)* occurs at near-maximal lung volume and corresponds to the point at which further increases in pressure result in minimal increases in lung volume *(line C)*. Pressure applied above the *UIP* is associated with alveolar distension. During the expiratory phase of the respiratory cycle *(dotted line)*, the lower deflection point *(LDEF)* is the point below which lung volumes slowly decrease (alveolar units collapse). During ARDS *(gray dashed curve)*, pressure-volume relationships change such that higher pressure is needed to maintain alveolar patency, and alveolar distension occurs at lower V_T levels. Near-maximal lung volumes are typically achieved at an inspiratory pressure of approximately 35 cm H_2O in normal conditions and during *ARDS*. Attempts to increase inspiratory pressure to more than 35 cm H_2O provide little additional ventilation and substantially increase the risk for injury to the lungs. During *ARDS*, the *LIP* often occurs at a pressure of 5 to 15 cm H_2O. Positive end expiratory pressure at levels greater than *LIP* may prevent end-expiratory alveolar collapse and reduce lung injury due to alveolar shear stress.

The most reliable method to accurately set PEEP in ARDS remains unknown with some prioritizing oxygenation, lung compliance, or radiographic imaging (computed tomography).[39] A comparison of setting PEEP based on lung mechanics versus oxygenation using tables generated during ARDS Network trials (Fig. 29.9)[40] favored the table approach.[38,41] The majority of trials assessing different levels of PEEP in ARDS do not demonstrate an optimal PEEP strategy; but higher levels of PEEP in more severe disease (P/F ratio <150) may lead to decreased mortality and less use of rescue strategies.[42,43]

RULE OF THUMB Changes in physiologic markers (oxygenation, compliance) take time after changing the level of positive end-expiratory pressure (PEEP). When decreasing PEEP, the changes in physiology become evident early, usually within 5 min. On the other hand, when increasing PEEP, the changes in physiology make take at least 60 min to become fully evident and may continue to change with time.[44]

MINI CLINI

Avoiding Ventilator-Induced Lung Injury

Problem

How can ventilator-induced lung injury (VILI) be minimized in patients with acute respiratory distress syndrome (ARDS) through adjustments of positive end-expiratory pressure (PEEP) and tidal volume (V_T)?

Discussion

Alveolar injury can occur through either shear stress occurs when alveoli collapse during expiration and are reopened as the next V_T is delivered or overdistension, which leads to rupture or tearing of alveolar structures. Patients with ARDS are prone to developing each of these types of VILI due to impaired surfactant and decreased lung compliance. Alveolar collapse at end-expiration (the lower inflection point [LIP] of the P-V curve; see Fig. 29.8) leading to shear stress can be avoided by enough PEEP to keep up above the LIP. Using a smaller V_T (6 mL/kg of predicted body weight [PBW]) then assures that the changes in pressure during tidal ventilation do not exceed the upper inflection point (UIP) and create injury through overdistension. When combined, low tidal volumes and optimized levels of PEEP are the basic elements of lung-protective ventilation (LPV) that minimizes risk for VILI.

Because the recruitment of lung units is a key physiologic benefit of increasing PEEP levels, many investigators and clinicians use transient large increases in PEEP to generate greater recruitment that may be sustained even after return of PEEP levels to their prior levels, and this technique is typically referred to as a *recruitment maneuver*. Although short-term benefits in gas exchange are consistently reported in trials that include recruitment maneuvers, benefits on survival or other longer-term patient outcomes have not been shown. In the ARDS Network ALVEOLI trial, which compared the impact of two different (low versus high) PEEP titration tables, use of recruitment maneuvers was discontinued due to lack of benefit. A more recent multinational study comparing a standard PEEP titration table to patients treated with recruitment maneuvers concluded that use of recruitment maneuvers was harmful and increased mortality.[45]

RULE OF THUMB In most patients with acute respiratory distress syndrome (ARDS), positive end-expiratory pressure (PEEP) levels less than 20 cm H_2O are generally preferred. Levels of PEEP greater than 20 cm H_2O should *not* be routinely used unless the benefits of higher levels of PEEP are supported by objective end points, such as improved lung compliance (see Fig. 29.7) or optimal alveolar recruitment (see Fig. 29.8).

Managing Airway Pressures

Since publication of the ARDSNet ARMA trial (Low V_T), emphasis on RT training for mechanical ventilation in ARDS has focused on early initiation and maintenance of low V_T. However, the approach to mechanical ventilation in ARMA also included goals for maximal *plateau airway pressure* (Pplat; see Chapter 47) of 30 cm H_2O or less in the low V_T group versus 50 cm H_2O or less in the high V_T group. As expected, Pplat was significantly lower in the low V_T group (difference between groups of approximately 8 to 10 cm H_2O) over the first 7 days, whereas differences

Lower PEEP/higher FiO_2

FiO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12

FiO_2	0.7	0.8	0.9	0.9	0.9	1.0
PEEP	14	14	14	16	18	18–24

Higher PEEP/lower FiO_2

FiO_2	0.5	0.5–0.8	0.8	0.9	1.0	1.0
PEEP	18	20	22	22	22	24

Fig. 29.9 Tables for positive end-expiratory pressure *(PEEP)* titration. The tables presented include the low- and high-PEEP titration tables created by the acute respiratory distress syndrome network for landmark clinical trials on mechanical ventilation and frequently used in hospital protocols across the United States. (From ARDS Network website. http://www.ardsnet.org/files/ventilator_protocol_2008-07.pdf.)

in PEEP levels between the groups during the same time were minimal (≤1 cm H_2O) during that same time.[35] As a result, most institutional ventilator protocols for management in ARDS include not only low V_T goals but also goals to maintain Pplat at 30 cm H_2O or less, including lowering V_T when needed.

When considering the most compliant portion of the P/V curve (see Fig. 29.8), it has long been debated whether ventilator goals to achieve inspiration should primarily target a change in volume (ΔV, same as V_T) or a change in pressure (ΔP, also referred to as ***driving pressure***).[46] To calculate driving pressure, it represents the increase in airway pressure during inspiration (level above PEEP) that is not influenced by airway resistance (which affects peak inspiratory pressure but not Pplat) and becomes the difference between Pplat minus PEEP. To address this question, a recent comprehensive analysis used compiled published data on pressure and volume relationships from multiple previously completed clinical trials (>3000 enrolled subjects) including the ARMA trial.[47] The authors concluded that maintaining lower driving pressures (ideally ≤15 cm H_2O) more closely correlated with mortality than maintaining V_T. Although highly provocative and intriguing, no prospective randomized trial has yet been completed to demonstrate that clinicians should adjust practice to prioritize driving pressure over V_T, but future trials are likely to be available soon. In the interim, bedside providers should consider both important and aim to maintain both targets whenever possible.

MINI CLINI

Drive Pressure

Problem

Increasing positive end-expiratory pressure (PEEP) may improve lung recruitment and oxygenation but may also increase the plateau pressure (Pplat), which may indicate the upper inflection point (UIP) of the pressure-volume (P/V) curve is being reached or exceeded and creating risk for VILI from overdistension. How do we know if a patient may need tidal volume (V_T) less than 6 mL/kg predicted body weight (PBW)?

Discussion

Some experts advocate looking at and prioritizing the pressure changes caused by a given V_T in addition to just the V_T. This change in pressure (ΔP) during inspiration is called the driving pressure and is the difference in pressure above PEEP at the end of inspiration (not including the influence of airway resistance). For example, what is the driving pressure in a patient on lung-protective ventilation (LPV) with a PEEP of 10 cm H_2O, receives a V_T = 450 mL that leads to a peak inspiratory pressure of 32 cm H_2O and Pplat of 28 cm H_2O? In this patient, driving pressure is 18 cm H_2O (Pplat – PEEP), which is a level that is higher than desired, and could lead to ventilator-induced lung injury (VILI) and increase mortality. Although not all, some clinicians might attempt to lower V_T and thereby lower ΔP as long as adequate gas exchange targets can be maintained.

Selecting the Mode of Mechanical Ventilation

For decades, experts debated which mode of mechanical ventilation is best for ARDS. Despite extensive efforts, no clear ventilator mode has proven superior, and in practice, clinicians may employ multiple modes to achieve the goals of LPV including V_T, PEEP, Pplat, and ΔP. To further simplify the issue, the mode of ventilation should principally serve the goals of safety (i.e., avoiding VILI) while also ensuring adequate ventilation and oxygenation to maintain the patient's frequently evolving cardiorespiratory and metabolic needs. More complete details outlining mechanical ventilation and the available associated modes are provided in Chapter 46.

Naturally, the mode that most directly achieves the goal of controlling V_T is volume control. In this mode, the clinician sets the V_T (6 mL/kg of PPBW) and the ventilator delivers the target V_T on every breath, whether patient-initiated or not. However, the potential shortcoming to this mode is patient–ventilator dyssynchrony, which may result in patient discomfort, increased work of breathing, increased oxygen consumption, and delivery of large (unsafe) tidal volumes. In response to this limitation,

many ventilator manufacturers have refined volume control modes to use other targeting schemes. For example, on the Maquet Servo-I (Rastatt, Germany), volume control has a dual targeting scheme, which turns into a pressure-controlled breath when the patient initiates a sufficient inspiration. On the Drager Evita XL (Lubeck, Germany), when the Autoflow feature is activated, volume control converts to a pressure control mode with an adaptive targeting scheme.[48,49]

As an alternative to volume control, patients may be placed on a pressure-control mode, the V_T depends on the set inspiratory pressure above PEEP and a set inspiratory time. However, the same limitations noted for volume control can lead to variations in V_T. To improve the safety and utility of pressure control ventilation for LPV, newer ventilators include technologic such as adaptive or intelligent targeting schemes in which the inspiratory pressure is automatically adjusted to achieve a target V_T. Whether these technologic advances lead to advantages that provide improved clinical care for patient–ventilator unknown.[50]

In any ventilator mode, variation in patient effort and dyssynchrony is a challenge. Often this can be resolved with sedation, analgesia, and/or neuromuscular blockade (NMB) to blunt patient respiratory effort. However, the adverse effects of these pharmacologic interventions must be considered and are increasingly recognized as affecting the long-term outcome of ARDS survivors. The therapist, in collaboration with nurses and physicians, should individualize ventilator mode to first maintain LPV principles, followed by balancing between reduction of patient-ventilator dyssynchrony and avoidance of excessive sedation.

Respiratory Rate and Inspiratory Time

ARDS is associated with alveolar consolidation, $\dot{V}/\dot{Q}$ mismatching, increased physiologic shunt, and dead space ventilation. In addition, critically ill patients typically have elevated rates of metabolism and CO_2 production, explaining why patients with ARDS require much higher minute ventilation to maintain $PaCO_2$ in the normal range. The challenge is that we use low V_T to prevent lung injury in ARDS, resulting in the need to increase the ventilator rate to achieve adequate $PaCO_2$ levels. In conventional practice, the respiratory frequency is kept below 35 breaths/min. The concern with faster ventilator rates is that these faster rates will not allow adequate time for exhalation, leading to air trapping (auto-PEEP) and overdistension of the lung, which can eventually worsen oxygenation and reduce cardiac output.[51] Thus, in managing patients with ARDS, the clinician must resist the urge to correct the $PaCO_2$ value to normal. Instead, in the absence of a contraindication to hypercapnia (e.g., elevated intracranial pressure), we allow hypercapnia ("**permissive hypercapnia**") with a goal to maintain the arterial pH at no less than 7.15 to 7.20.[52] Even when $PaCO_2$ rises to a point during which pH may become dangerously low (e.g., pH <7.15), the goal of trying to keep V_T at 6 mL/kg PBW remains. Correction of pH can also be achieved by either pharmacologic supplementation (intravenous [IV] or oral) of bicarbonate or physiologic retention of bicarbonate by the kidneys. In rare instances, extracorporeal removal of CO_2 is considered, and it is discussed later in this chapter.

MINI CLINI

Problem

My patient's carbon dioxide is climbing with lung protective ventilation (LPV). What should I do?

Discussion

The use of a lower tidal volume (V_T) in LPV often will result in worsened gas exchange, with patients demonstrating worsening oxygenation and ventilation, including lower P/F ratios, higher levels of $PaCO_2$, and lower pH. These seemingly adverse effects of LPV on arterial blood gases (ABGs) often create confusion and concern for families and care providers, including respiratory therapists (RTs). However, these changes are not associated with worse overall patient outcomes (e.g., as measured by mortality or time on mechanical ventilation). Quite the contrary, by continuing LPV, the patient's best opportunity for survival is achieved.

Closely related to the ventilator rate is the inspiratory time (Ti), which is the means by which clinicians and RTs adjust the **inspiratory-to-expiratory ratio** (I:E ratio). As discussed earlier, normal I:E is typically 1:≥2. In contrast to intubated patients with obstructive lung diseases (e.g., chronic obstructive pulmonary disease [COPD], asthma) who need I:E rates with even longer expiratory times, patients with acute respiratory distress syndrome (ARDS) have stiffer lungs and require less time for exhalation. As a result, I:E ratios of 1:1 are generally recommended in ARDS, and are achieved by using increasing Ti by decreasing inspiratory flow rates, which often results in desirable reductions of plateau airway pressure (Pplat) and driving pressures to maintain targets for LPV.

It must be remembered that as respiratory rates are increased and Ti is prolonged, risks for air trapping and auto–positive end-expiratory pressure (auto-PEEP) will naturally increase. Diligent monitoring for auto-PEEP during the management of mechanical ventilation in patients with ARDS is essential. Although auto-PEEP (like routine PEEP) may lead to improved oxygenation, when left undetected, auto-PEEP can lead to increased Pplat, alveolar overdistension, and VILI.

Oxygen Titration

Administering high levels of supplemental O_2 (FiO_2) can cause direct lung injury as a result of O_2 toxicity. O_2 toxicity is considered to be time and dose dependent; that is, the longer the exposure and the higher the FiO_2, the worse the injury will be. Although no formal recommendations currently exist, most hospitals have developed protocols and guidelines that instruct RTs to continuously titrate and minimize the FiO_2 and PEEP while targeting SpO_2 between the range of 88% and 96%. This range also happens to be consistent with the range used for delivery of LPV in all ARDS Network trials since ARMA, and most large clinical trials conducted by other clinical trial groups.

In recent years, increasing concern and attention has developed regarding greater focus and priority being placed on the careful titration of oxygen in critically ill patients to minimize potential risks of hypoxia, hyperoxia, and hyperoxemia.[53] Much of the attention for previously unrecognized toxicity from hyperoxemia using conventional approaches oxygen titration originated from

retrospective evidence in the acute and emergency room management of patients with both myocardial infarction and stroke. Recently completed randomized trials have further amplified the concern and strengthened the level of evidence in those settings.[54,55] Likewise, in the more general setting of patients receiving mechanical ventilation (ARDS and otherwise), multiple studies and trials have strengthened the case for targeting lower levels of FiO_2 and maintaining SpO_2 less than 95% to 96%.[56,57]

Adjunctive Strategies to Improve Lung Function

In many patients with ARDS, in particular those with severe hypoxemia (defined as P/F ratio <100 in Berlin Criteria or <120 to 150 in many clinical trials), clinicians often consider additional therapies beyond conventional mechanical ventilation using LPV. In this section, we review a spectrum of therapies that are available and can be added to the care of patients with ARDS as supplemental management while continuing a conventional LPV ventilation approach is presented.

Prone Positioning

The distribution of lung injury in patients with ARDS is heterogenous, and changing the position of the patient can result in improved $\dot{V}/\dot{Q}$ matching within the lungs. Alveolar consolidation in ARDS tends to be most pronounced in the dependent lung zones (posterior regions when patient is lying supine), where blood flow is greatest. For many years, experiments have been conducted with positioning the patient so that aerated lung fields (nondependent lung zones) become dependent by positioning the patient in the prone position (i.e., placing chest and face down, Fig. 29.10). So-called *proning* the patient recalls the old adage to "put the good lung down."[58] The mechanisms by which **prone positioning** improves oxygenation are not fully known. Some proposed mechanisms include improved matching of ventilation with perfusion, increased functional residual capacity, increased cardiac output, more effective drainage of upper and lower airway secretions, and improved diaphragmatic excursion. Ventilation in the supine position causes compressive forces on the dorsal airspaces, resulting in "derecruitment" of lung units, and the phenomenon is reversed by ventilation in the prone position.

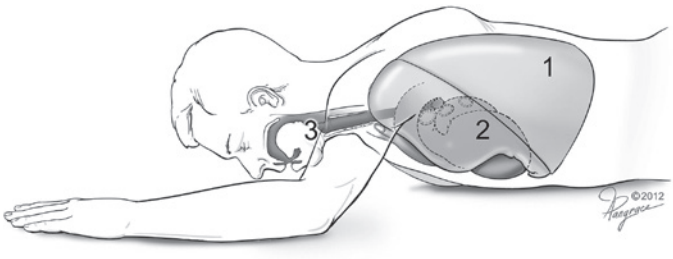

Fig. 29.10 Illustration outlining the three theoretical benefits of prone positioning: *1,* the posterior lung has a larger surface area for gas exchange which reduces V/Q mismatch; *2,* shifting the heart anterior offloads its weight from the surrounding lung tissue; and *3,* the large airways move to a gravitationally dependent position that better facilitates drainage of posterior and lower-lobe secretions. (From James MM, Beilman GJ: Mechanical ventilation, *Surg Clin North America* 92:1463–1474, 2012.)

Recent studies have demonstrated the advantages of prone ventilation (as compared with continued supine ventilation) beyond just improved oxygenation. The most successful and widely recognized of those trials, PROSEVA, was a multicenter European trial that used early introduction (<36 hours after intubation) of proning in patients with persistent, severe ARDS (P/F ratio < 150 for >12 hours).[59] Patients received a minimum of ventilation in the prone position for a minimum of 16 hours each day until oxygenation improved enough to discontinue. Most importantly, the outcome benefits to patients in the PROSEVA trial include improved survival. As a result, at many tertiary referral centers in the United States, prone positioning is currently considered to be the standard of care for patients with sustained severe ARDS after optimization of conventional strategies for mechanical ventilation with LPV and titration of PEEP.

Delivery of prone positioning to patients with ARDS requires experienced and committed bedside staff (nursing and RT) to facilitate turning and prevention of complications (e.g., inadvertent removal of indwelling catheters, skin breakdown), especially for obese patients. Some patients may not tolerate prone ventilation or may have a relative contraindication to proning, such as open surgical wounds or late-trimester pregnancy. However, as more centers gain experience and comfort with the logistics of rotating patients, acceptance and use of prone position has increased and become a first-line adjunctive therapy to assist in oxygenating the patient with severe ARDS.

Neuromuscular Blockade

Neuromuscular blocking paralytic agents have been used for decades to enhance compliance and synchrony with mechanical ventilation in patients with ARDS. With severe dyspnea and/or patient–ventilator dyssynchrony, a substantial portion of arterial O_2 content can be consumed by the increased work of the accessory respiratory muscles. Therefore, in patients who continue to remain hypoxemic despite optimizing ventilator settings and adequate sedation, a trial of NMB by bolus or continuous IV infusion is frequently performed.

Although the earliest studies of NMB consistently demonstrated improvements in oxygenation, they did not address whether NMB was associated with any survival advantage. A multicenter randomized trial, referred to as ACURASYS, considered 90-day in-hospital mortality as the outcome measure after treatment with a bolus followed by a 48-hour infusion of the paralytic drug cisatracurium.[60] The group receiving NMBs showed improved survival at 90 days after study onset, more days off the ventilator, and a lower incidence of barotrauma. Similar to prone positioning, the benefit of NMB was most evident in patients with severe ARDS (P/F ratio <120). In contrast to prone positioning, acceptance of NMB in severe ARDS among experts due to limitations in the ACURASYS trial. In particular, concerns for prolonged muscle weakness after use of NMB remain high particularly in the high percentage of critically ill patients who also receive corticosteroids for various indications during their ICU admission. Although no such effect was seen in ACURASYS, perhaps related to the short duration of paralysis, the study design did not include rigorous monitoring for

this important complication. As a follow-up to ACURASYS, a large multicenter trial of NMB is currently being completed by the PETAL Network (www.petalnet.org). It must be noted, that due to easier administration of NMB, as compared with prone positioning, many hospitals continue high use of NMB in severe ARDS. Use of NMB in patients with only mild to moderate ARDS who are stable on conventional ventilation should be avoided.

Inhaled Vasodilators

In ARDS, the potential benefits of pulmonary vasodilators delivered via the airway (as compared with intravenously) is based on delivery of the vasodilator will be distributed to well-ventilated portions of the lung, where the vasodilator leads to local vasodilation. In this way, well-ventilated areas of the lung receive a greater portion of the total pulmonary blood flow, which results in improved oxygenation by reducing shunt fraction and $\dot{V}/\dot{Q}$ mismatch (Fig. 29.11). For more comprehensive details regarding the administration of inhaled vasodilators, see Chapters 28, 36, and 42.

Nitric oxide (NO) and prostacyclin are naturally occurring potent vasodilators that play a critical role regulating blood flow within the normal lungs. NO is a highly soluble gas that diffuses readily through various tissues. Prostacylin is a naturally occurring prostaglandin, and several analogues have been pharmacologically developed (e.g., epoprostenol [Flolan]) and are standard of care in pulmonary arterial hypertension (see Chapter 28). Although not gaseous, epoprostenol and other prostacyclin analogues can be nebulized and provide effects similar to inhaled NO. The cost of NO and its patented delivery system (INOmax, Ikaria, Perryville, IL) is high, causing many institutions to limit its use. Nebulized epoprostenol serves as a less expensive alternative to NO at many centers.[61]

Despite initial enthusiasm for the potential benefits of inhaled NO in ARDS, an early large multicenter randomized trial demonstrated only short-term benefit in oxygenation but no change in survival or duration of ventilator support.[62] Subsequent systematic reviews and meta-analyses have also been completed and resulted in similar findings.[63] No large clinical trials of nebulized prostacyclin analogues have been completed in ARDS but are not expected to provide different results. The discrepancy in the effects of inhaled vasodilators—improvements on oxygenation without effect on longer-term patient outcomes—further emphasize that changes in oxygenation do not correspond closely to patient-centered outcomes in ARDS. We recommend that use of inhaled vasodilators be limited to patients with the most severe forms of ARDS (P/F < 80) and used only as a bridge to maintain oxygen while initiating more invasive adjunctive therapies (e.g., extracorporeal support).

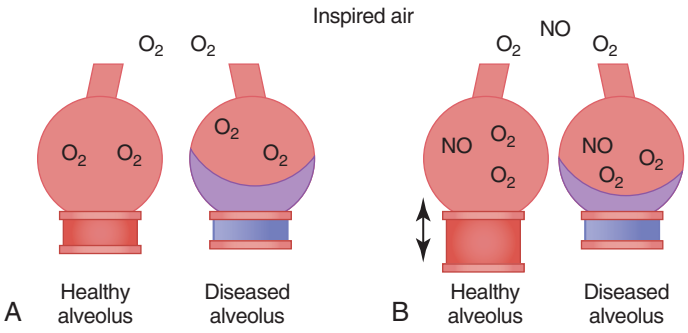

Fig. 29.11 The damage of acute lung injury and acute respiratory distress syndrome is heterogeneous. (A) Despite autoregulatory changes that favor vasodilation of well-oxygenated alveoli, perfusion goes to both the healthy, unaffected alveoli and the diseased alveoli that are unable to oxygenate blood. This results in $\dot{V}/\dot{Q}$ mismatch or a shunt-like state, resulting in deoxygenated blood returning from the lung and hypoxemia. (B) The addition of inhaled nitric oxide *(NO)* to the inspired gas results in vasodilating the capillaries adjacent to healthy alveoli, thereby promoting increased blood flow to the "good" alveoli and diminishing the percentage of blood going to diseased alveoli. This change results in improved $\dot{V}/\dot{Q}$ match and improved oxygenation.

Corticosteroids

As detailed earlier, a hallmark of ARDS is an intense, systemic inflammatory cascade that leads to a spectrum of injuries to the alveolus during the early acute phase in all cases and in the subacute fibroproliferative phase in the smaller subset of cases that require prolonged ventilatory support. The potential benefits of steroids in ARDS to reduce the burden of the inflammatory insult has long been debated, including mention in the original case series of adult patients with ARDS over 50 years ago.[1]

Use of steroids in the earliest stages of ARDS has been evaluated, but their impact on patient survival or duration of ventilation remains unclear and controversial. The earliest studies in ARDS often used high-dose steroids (>2 mg/kg/day), which were associated with increased risks for secondary nosocomial infections and should be avoided. In 2016 a combined analysis of eight small randomized trials that administered more commonly used doses of corticosteroids (methylpredisonolone or hydrocortisone) for a prolonged duration was published.[64] These compiled results suggest that ARDS resolution, liberation from mechanical ventilation, and mortality may be improved but are not sufficient to recommend use of steroids as a standard for care in early ARDS or a specific strategy for dosing. A separate randomized trial of hydrocortisone published in the same year demonstrated only improved oxygenation but survival was unchanged.[65] These studies with lower-dose steroid regimen have been associated with greater frequency of common steroid side effects (e.g., hyperglycemia) but not with increased risk of infections. Risks for prolonged weakness after critical illness have been associated with steroids and remain an unresolved question for their safety in ARDS.

Although most patients who survive ARDS have minimal residual pulmonary impairment, a small but significant number of patients require prolonged mechanical ventilatory support because of abundant fibroproliferation in the lung during recovery from ARDS. The high mortality rate among these patients seems to relate to the extent and severity of pulmonary fibrosis.[66] High-dose corticosteroids have been used to manage uncomplicated pulmonary fibrosis following ARDS, but results are mixed and controversial. In the largest multicenter trial, corticosteroids were used for patients with late fibroproliferative ARDS (>7 days' duration) and did not demonstrate a survival benefit.[67] Importantly, patients given steroids after 14 days from ARDS onset experienced a higher mortality rate than control patients, and

this has led most clinicians to conclude that steroids should be avoided after 14 days from ARDS onset.

Use of steroids in patients with ARDS for purposes other than their ARDS is common. As noted previously, the most common etiology for sepsis is sepsis, and use of steroids in septic shock has become increasingly common, despite conflicting data regarding their benefits and risks.[68] The impact on ARDS of a short course of steroids for septic shock is unknown. In addition, many patients who meet the syndrome definition of ARDS can have other pulmonary disease processes that mimic ARDS (e.g., alveolar hemorrhage, interstitial lung disease, organizing pneumonia), and many of these conditions respond to steroid therapy. In patients in whom one of these alternative diagnoses is a consideration, clinicians often will typically either perform an open lung biopsy or begin an empiric course of (high-dose) steroid therapy.

Beta-2 Agonists

In addition to their effects as bronchodilators, high doses of beta-2 agonists (e.g., albuterol, salbutamol) have been shown to accelerate clearance of alveolar edema by the epithelium of the alveolar wall in animal models.[69] However, neither of two clinical trials in humans using either aerosolized albuterol or IV salbutamol for ARDS were able to improve patient-centered outcomes.[70,71] In one of the trials, the beta-2 agonists did reduce lung water using a surrogate measurement and improved lung function (lower plateau pressures), but no change in oxygenation (i.e., P/F ratio) was observed. In the largest trial, completed by the ARDS Network, the trial was terminated early because of concern for increased mortality in the patients receiving beta-2 agonists, although the difference did not achieve statistical significance. At this time, beta-2 agonist therapy for improving alveolar fluid clearance in ARDS is not recommended.

Exogenous Surfactant Administration

Surfactant dysfunction and deficiency is a well-established component of RDS in premature infants, as well as in children and adults with ARDS. Surfactant abnormalities contribute to the development of ARDS by promoting instability of the alveolar units (airway shear trauma, atelectasis, and right-to-left shunt) and by allowing inflammatory injury to alveoli to continue unchecked. Delivery of exogenous surfactants via direct intratracheal administration has become a cornerstone of therapy in RDS since the early 1990s.[72] Multiple surfactant preparations are commercially available, including natural surfactants (harvested from lungs of animals used in the meat industry) and synthetic surfactants, which are created artificially.[73]

Unfortunately, the pathogenesis of surfactant deficiency in the ARDS of children and adults differs markedly from premature newborns. The depletion of surfactant in RDS of prematurity is secondary to the lack of lung maturation and surfactant production. In contrast, the surfactant depletion of ARDS is caused by inflammation of the alveolus and subsequent degradation of the endogenous surfactant. Numerous clinical trials have demonstrated improvement in oxygenation with intratracheal surfactant administration, including both natural and synthetic preparations.[74,75] However, the improvements in gas exchange have typically proven to be short lived (24 to 72 hours) and have not demonstrated significant impact on clinical outcomes such as mortality or duration of mechanical ventilation in survivors. These negative results in ARDS (in contrast to clear benefit in neonatal RDS) are most likely explained by degradation of the exogenously administered surfactant via the same inflammatory mechanisms that depleted the patient's native surfactant. Future studies of surfactant therapy are likely to include a combined approach that includes more prolonged courses of treatment and inhibitors of inflammation-mediated degradation.

Alternative and Rescue Ventilation Strategies

In the large majority of ARDS patients, the conventional LPV approach previously described proves to be sufficient and should be routinely used at the onset of ARDS in all patients. In patients with either severe ARDS alone or with ARDS in the setting of other chronic lung conditions, the severity of gas exchange abnormalities may progress and lead to an inability to maintain adequate oxygenation and/or ventilation to sustain the patient. In those uncommon scenarios, alternative ventilatory strategies are available and may prove beneficial in selected patients but are less well-studied or standardized. As such, these therapies are often referred to as "rescue" or "salvage" therapies. The thresholds for using alternative approaches differs across medical institutions but are typically defined by persistent markers of unsafe ventilation, such as excessive plateau pressures (e.g., >35 cm H_2O), FiO_2 (e.g., >80%), PEEP (e.g., 20 cm H_2O), or hemodynamic instability caused by positive pressure ventilation. Because the level of evidence regarding these approaches is lower, variation in practice is high and choices often depend on the local experience, expertise, and the availability of the necessary equipment.

Inverse-Ratio Ventilation

In conventional modes of mechanical ventilation, the respiratory cycle is typically characterized by I:E ratios of 1:≥2 with greater time spent during expiration than inspiration. During inverse ratio ventilation (IRV), the inspiratory time on the ventilator is prolonged so that the I:E ratio is reversed (i.e., inspiratory time now exceeds expiratory time). The mechanisms for benefit of IRV likely include some combination of increased percent of time during each respiratory cycle that alveoli remain patent to reduce V/Q mismatch and increasing mean airway pressure to recruit alveolar units. Increased mean airway pressure results from incomplete lung emptying, otherwise known as air trapping, auto-PEEP, or intrinsic PEEP. Although IRV can improve oxygenation, there are no clear advantages when compared with use of higher levels of extrinsic PEEP[76], and it can lead to increased patient discomfort and patient-ventilator dyssynchrony.

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a form of pressure control intermittent mandatory ventilation with IRV (I:E ratio of ≥4:1).[77] The aim of APRV is to increase the mean airway pressure for alveolar recruitment while allowing the patient to spontaneously breathe. This mode generally features two levels of PEEP: a high PEEP (approximately 25 to 30 cm H_2O for 5 to 6 seconds) and a low PEEP (approximately 0 to 5 cm H_2O for

0.5 to 1 second). Oxygenation can often improve when APRV is used, but there are risks for large tidal volumes, leading to VILI and high transpulmonary pressures.[78,79] As a rescue therapy, use of APRV is equally unproven, but was shown, in an uncontrolled manner, to improve a small case series of patients during the H1N1 influenza pandemic.[80] Taken together, although APRV remains an alternative strategy to consider, there are no specific cases or conditions in ARDS in which its use can be formally recommended.

High-Frequency Ventilation

HFV is different from any of the conventional modes of ventilation because it uses a rapidly moving piston to create movement of air through a circuit. The device allows setting a mean airway pressure over which oscillations happen. Tidal volumes generated by HFV are typically smaller than the patient's anatomic dead space and use higher mean airway pressures to maintain alveolar patency and theoretically prevent VILI and minimize hemodynamic compromise caused by larger inspiratory pressures of conventional modes.

High-frequency ventilation (HFV) was initially devised as a method to minimize the hemodynamic effects of conventional mechanical ventilation (i.e., the large inflating pressures and volumes). Delivery of HFV requires unique expensive equipment that can differ in ability to treat children and adults and requires experienced and specifically trained personnel (MD and RT) to deliver effectively. The RT must remember that patients on HFV will be exposed to high mean airway pressures and PEEP, which may reduce cardiac output and overall O_2 delivery despite elevated arterial oxygenation.

HFV has been successfully used in ventilating neonates with RDS including both as a routine and rescue therapy, but its use is controversial due to widely differing results.[81,82] In adults with ARDS, multiple randomized trials have assessed the potential benefit of HFV versus conventional ventilation in severe ARDS. Trials conducted prior to the proven benefit and routine implementation of LPV demonstrated feasibility of supporting gas exchange and hemodynamic tolerance.[83] During and shortly after the H1N1 influenza pandemic in 2009, interest in HFV as a therapy for severe ARDS renewed, leading to two large randomized trials. The OSCAR trial showed no difference between HFV and conventional mechanical ventilation, and the OSCILLATE trial was discontinued early due to increased mortality rate in the patients treated with HFV.[84,85] Based on these results, use of HFV in routine ARDS management is not recommended. Although HFV as a rescue strategy for patients with severe refractory ARDS (P/F < 80) remains an option at some highly experienced centers, there are no multicenter trials or large single-center results to support its benefit.[86]

Extracorporeal Support

Extracorporeal membrane oxygenation (ECMO) and **extracorporeal carbon dioxide removal** ($ECCO_2R$) involve establishing a circuit for diverting a large portion of the cardiac output through an artificial gas-exchange device, or "artificial lung," to facilitate the exchange of O_2 and CO_2. More complete details on the principles and application of extracorporeal support are provided in Chapter 51. For respiratory failure, extracorporeal support is typically performed using venovenous circuits (versus venoarterial), which are able to support gas exchange without need for invasive arterial cannulas and hemodynamic support and can currently be offered through a single venous cannula.

ECMO was first introduced with a flurry of interest as a potential rescue therapy for patients with severe refractory hypoxemic respiratory failure in the 1970s. Initial trials were unsuccessful, with high rates of complications that were attributed to limitations with equipment and clinical experience. With continued improvements in equipment and delivery methods and anecdotal cases with favorable results at a large number of centers, interest and enthusiasm for the potential benefits of ECMO in severe ARDS have persisted. During the 2009 H1N1 influenza pandemic in patients with ARDS deemed refractory to conventional ventilation, ECMO was often used as rescue therapy at many highly experienced centers.[87,88]

Two randomized trials of ECMO have been completed to date. In the CESAR trial, a complex method for randomization and referral to a single ECMO center in Great Britain was used and compared groups with or without the option to be placed on ECMO with conventional ARDS ventilator approaches targeted in all patients.[89] Results demonstrated reduction of a combined outcome including death and severe disability in the ECMO option group, but interpretation of the CESAR results remains controversial due to concern regarding lower adherence to conventional LPV approach in the control group managed without an ECMO option, often at hospitals outside the ECMO center. More recently, results of the multinational EOLIA trial revealed no significant difference in mortality at 60 days in the group randomized to early ECMO. However, interpretation of the study results is also complicated by a low study population sample size (lower mortality in the ECMO arm with *P* value = .09, but only 250 patients in both groups combined) and high rate of cross over to ECMO (~25% to 30%) in the control group.[90] Unfortunately, this debate may never be fully resolved because rigorous, large randomized trials for patients with severe disease are frequently not supported by many clinicians and families in the setting of extremely high potential for mortality.

MINI CLINI

In managing patients with severe, persistent acute respiratory distress syndrome (ARDS), oxygenation (PaO_2 or SpO_2) is a readily available measure that often attracts the attention of bedside providers. In attempts to improve levels of oxygenation, providers often start additional therapies such as pulmonary vasodilators (e.g., inhaled nitric oxide [NO]) or alternative approaches to mechanical ventilation (airway pressure release ventilation [APRV], high-frequency ventilation [HFV], etc.) that can often lead to improvements in oxygenation. However, improvements in hypoxemia from these therapies have not been linked with improvements in survival. Changes or additions in therapy that improve oxygenation only slightly beyond minimum thresholds (SpO_2 >88% to 92%) are unlikely to improve the patient's outcome. Furthermore, adding inhaled vasodilators or starting more complex and unfamiliar ventilation modes leads to increased cost and risks to delivery of care based on best available evidence. These maneuvers should be reserved for patients whose oxygenation status is insufficient to meet the needs of their total body oxygen demands and leads to nonrespiratory organ dysfunction, specifically neurologic or cardiac.

Not all patients are good candidates for extracorporeal support, especially those with multisystem organ failure or advanced chronic or comorbid health conditions (e.g., metastatic cancer, severe COPD). In considering ECMO for patients with refractory severe ARDS (P/F < 80), assessment and referral to ECMO center (if needed) should be made early after optimization of conventional approaches (with or without adjunctive therapies discussed previously) and time sufficient time is allowed to confirm lack of improvement or worsening.[91] Due to the lack of rigorous randomized trials, ECMO remains an unproven option to change outcomes in severe ARDS but is the most commonly available and used option for this small subset of patients.

Nonventilatory Supportive Care

Supportive care in the ICU, including patients with ARDS, focuses on maintaining function of key organs and minimizing the complications associated with critical illnesses and spending several days in an ICU. These points of management do not directly treat the primary risk factor that triggered ARDS but are nonetheless critically important to optimize patient outcomes, both during and after their time in the ICU. Many ICUs use checklists to ensure basic supportive care measures in critically ill patients are being done consistently, all of which can apply to and improve outcomes in patients with ARDS (Table 29.1). This section will briefly review a few key aspects of supportive care related to both the lungs and other key organs. Although RTs are not always the primary provider responsible for the delivery of these priorities, the RT should be familiar with their importance and serve to encourage and support their consistent application.

Conservative fluid management. Critically ill patients receive fluids both IV and oral for a wide variety of indications: to maintain perfusion, IV medications, nutrition, hydration, and correct electrolyte imbalance. The amount of fluids taken in by critically ill patients invariably exceeds the amount of fluids that the patient loses, and patients often gain approximately 1 L of fluid per day. Recent work suggests this positive fluid balance may be associated with increased mortality in the ICU.[92] Specific to ARDS, the ARDSNet Fluids and Catheters Treatment Trial (FACTT) compared a protocol-driven ***conservative fluid management*** strategy to a so-called *liberal strategy* that closely resembled typical fluid intake seen in prior ARDSNet studies.[93] The conservative strategy was achieved essentially by eliminating maintenance IV fluids and earlier institution of and increased attention toward diuresis. Although mortality did not differ between the groups, the group managed with the conservative fluid strategy had improved oxygenation, shorter duration of mechanical ventilation, shorter ICU length of stay, and no increased frequency of other organ failures, including renal failure. In practice and in subsequent clinical trials, a simplified version of the FACTT conservative protocol has been validated and should be initiated 12 hours after the end of shock (i.e., not needing fluid boluses or vasopressors).[94]

TABLE 29.1 Nonventilatory Supportive Care Checklist

Respiratory	Fluid conservative management
	Daily spontaneous breathing trial
Neurologic/Musculoskeletal	Minimize sedation and daily awakening
	Delirium prevention and treatment
	Early mobilization
Gastrointestinal	Gastric ulcer prophylaxis
	Enteral nutrition
	Avoid excess caloric intake
Infection Prevention	Remove indwelling catheters
	Antibiotic deescalation
	Oral chlorhexidine
	Head-of-bed elevation
	Hand hygiene

Sedation and Analgesia

Over the past two decades, approaches to managing sedation and analgesia in critically ill patients have changed dramatically. Protocolized sedation and scheduled daily interruptions of sedation (awakenings) lead to shorter times on mechanical ventilation and decreased length of ICU stay.[95] Furthermore, evidence from survivors of ARDS has demonstrated that many experience persistent problems with memory and cognition and that these changes relate to the types of sedation that patients receive during their care in the ICU. In particular, using benzodiazepines (e.g., lorazepam or midazolam) carries the greatest risk for these adverse neurocognitive effects. One of the earliest neurocognitive warning signs in the ICU is the development of ICU-associated *delirium*, which can be caused by several common environmental challenges in the ICU, including lack of sleep, noise, use of restraints, and immobility. The use of benzodiazepines also has been strongly linked to the development and progression of delirium in the ICU.

MINI CLINI

Managing Hydrostatic Pressure in Patients With Acute Respiratory Distress Syndrome

Problem

A patient presented to the intensive care unit (ICU) several days ago in septic shock, and although his shock and needs for pressors have improved, he remains hypoxic and having difficulty with weaning from mechanical ventilation. Severe bilateral infiltrates persist on the daily chest x-rays, and the patient is noted to have marked peripheral edema in his legs and dependent tissues (i.e., back/sacrum), despite having resolved a mild acute kidney injury that was present when he was admitted from the emergency room.

Discussion

Patients admitted with septic shock and other critical illnesses that cause hemodynamic compromise often receive large amounts of fluids during their initial resuscitation and then continue to receive large amounts of intake (intravenous and enteral) to maintain the many aspects of their care needs while in the ICU. The use of a protocol to guide conservative fluid management leads to faster liberation from mechanical ventilation in patients with ARDS. Once patients are no longer in shock (>12 h), the protocol should be started. All care providers, including RTs, should be aware of this important intervention and encourage its application in patients to accelerate the process of liberation from mechanical ventilation and avoid unnecessary complications associated with prolonged mechanical ventilation, sedation, and immobility.

Given these concerns related to the acute and long-term adverse effects of ICU sedation, current strategies for sedation aim to minimize the exposure to all sedatives, in particular benzodiazepines.[96] Initial efforts should focus on nonpharmacologic interventions, including adjustment of ventilator to minimize dyssynchrony (when appropriate), providing necessary vision and hearing aids, and use of distracting therapy such as music or noise-canceling headphones.[97] If patients need pharmacologic agents, a validated assessment should be performed and, if positive, patient treated with analgesia. Lastly, sedative agents can be used including propofol or dexmedetomidine. Antipsychotic drugs may be given for agitation, although their role in delirium prevention remains unproven.

Emphasis on reducing sedation for patients on mechanical ventilation poses a challenge for the RT, who, along with the nursing staff, must manage more awake, restless, and agitated patients who may attempt breathing out of synchrony with LPV goals. We cannot assume that heavy sedation to optimize ventilator synchrony is the best and safest approach. The best approach must balance the short-term ventilator risks with the longer-term risks of excessive sedation with daily reassessments of care goals among all care providers.

Nutrition

Malnutrition in the ICU leads to poor outcomes, but clinicians including RTs should be aware that excess nutritional supplementation can also lead to adverse consequences. The ARDSNet EDEN trial studied whether using trophic feeds (the minimum amount of enteral nutrition to maintain protection of the mucosal lining of the gastrointestinal [GI] tract and GI motility) was equally effective to full enteral nutrition during the first 6 days of care of patients with ARDS.[98] The results of the study showed no benefit for the full nutritional approach either during the ICU stay or 1 year later.[99] Currently, there is no specific recommendation regarding nutrition in patients with ARDS, but RTs should remain aware of the potential negative impact of overfeeding, which can lead to increased CO_2 production, increased minute ventilation, and potentially delayed liberation from mechanical ventilation.

Mobility

It has long been recognized that the prolonged period patients spend lying in bed on mechanical ventilation has an adverse effect on the mass and function of muscles for patients in the ICU, including those with ARDS. Profound and persistent weakness (≥12 months) is a commonly reported long-term outcome in ARDS survivors. This severe adverse consequence of ICU care is in part attributable to inflammatory injury to the muscles and peripheral nerves, pharmacologic agents (e.g., steroids and neuromuscular blockers), and most importantly immobilization, which is most severe in patients requiring mechanical ventilation, particularly when prolonged. Numerous clinical trials have established the safety of early mobilization in patients on mechanical ventilation with endotracheal tubes including ARDS patients with severe hypoxemia.[100,101] The precise intensity and duration of mobility needed to achieve positive outcomes remains to be determined.[102] Despite these assurances, early mobilization remains a struggle in many units due to fear of adverse events, difficulty coordinating with ongoing care, and perceptions of insufficient workforce. However, with interdisciplinary cooperation, education, and sustained leadership, mobilization protocols have been implemented across a variety of ICU settings and hospital sizes.[103]

ROLE OF THE RESPIRATORY THERAPIST IN ACUTE RESPIRATORY DISTRESS SYNDROME

The RT is an essential expert in mechanical ventilation and respiratory support for the ICU team. Patients with ARDS represent some of the most challenging patients to manage on mechanical ventilation and require the greatest experience and expertise. Current therapies that have been proven (or with demonstrated potential) to improve survival in ARDS (Box 29.5) should be built-in available bedside protocols and consistently prioritized. Using the original data from the clinical trials reviewed herein, the number of patients that need to be treated for one life to be saved (i.e., number needed to treat [NNT]) can be estimated, and the impact for each of these approaches is greater than many standard therapies in other more common acute and chronic conditions (e.g., cancer, heart attack, and stroke).

The pivotal roles that RTs play in caring for patients with ARDS include ventilator setup, recommending changes and adjustments in the provision of ventilator support, monitoring and frequent equipment checks, drawing ABGs, placing arterial lines or performing hemodynamic assessments, and monitoring pulse oximetry and/or exhaled CO_2 monitors.

In multiple randomized trials, RT-driven ventilator management protocols have outperformed usual care protocols in management of ARDS, including using the most advanced techniques (e.g., ECMO) and achieving liberation from the ventilator.[95,106] The input and assistance provided by RTs in ventilator management including ventilatory strategies, adherence to LPV, oxygen titration, and technical attention to equipment is invaluable.

More specific to the management of patients with ARDS, the RT must learn and consistently apply the following key general aspects of supportive care:

1. ARDS is a diffuse injury of the lungs but is not homogenous. Despite the presence of widespread pulmonary injury on radiographs and altered gas exchange in ARDS, there are areas of the lung with near-normal mechanical characteristics.
2. Better oxygenation (in terms of PaO_2 or SpO_2) is not always linked to better survival and should not take priority over

BOX 29.5 Therapies With Proven or Potential Survival Benefit in Acute Respiratory Distress Syndrome

1. Proven
   a. Lung-protective ventilation[104]
   b. Sedation interruption[95]
   c. Prone ventilation[59]
2. Potential
   a. Extracorporeal support (ECMO)[105]
   b. Neuromuscular blockade[60]

ECMO, Extracorporeal membrane oxygenation.

optimal conventional LPV strategies in the vast majority of cases.

3. Mechanical ventilation can lead to VILI, which, when not corrected, worsens ARDS and increases mortality secondary to MODS. The RT must always remember that current evidence indicates that either excessively high tidal volumes or driving pressures may lead to VILI.
4. Initiation and maintenance of LPV, including V_T = 6 mL/kg of predicted (not actual) body weight and sufficient PEEP to exceed the LIP, should become the priority and focus of daily care. The RT should take an active role in making sure that an accurate estimate of the patient's height has been obtained so an accurate PBW can be calculated.
5. Modes of mechanical ventilation that optimize V_T and driving pressure should be preferred. Many modes are capable of maintaining V_T, and no single mode has been proven to be superior, but RTs must be familiar with how to manage each mode so that these priorities are maintained. Unnecessary transitions between multiple modes of mechanical ventilation in patients with ARDS are typically not helpful and further complicate interpretation of the patient's response to therapy.
6. Inspiratory time can be prolonged in ARDS patients to target I:E ratios as low as 1 : 1.
7. Hypercapnia can and should be tolerated (permissive hypercapnia) as long as pH remains greater than 7.15 to 7.20.
8. Adjunctive therapies, in particular prone positioning and short-term NMB, may benefit respiratory function and be warranted in patients with severe ARDS.
9. Other nonrespiratory measures of supportive care, in particular conservative fluid management and avoidance of excess sedation, improve the outcomes of patients with ARDS. RTs should be familiar with these and encourage their consistent application in all ARDS patients.
10. Pharmacologic therapies (e.g., inhaled NO, surfactant) are available and can enhance oxygenation in patients with ARDS but are expensive and do not change patient outcomes. Their routine use in ARDS is not recommended and should be limited or discouraged.
11. A small percentage of patients with ARDS will develop refractory, severe hypoxemia in which the conventional approaches fail. Alternative or "rescue" therapies are as yet unproved but are available at large referral centers. Transfer of patients with refractory hypoxemia should be considered early in the course of disease within the initial 24 to 48 hours.

SUMMARY CHECKLIST

- Pulmonary edema from both hydrostatic (e.g., CHF) and nonhydrostatic (e.g., ARDS) causes leads to acute respiratory failure and can be difficult to differentiate on initial evaluation. Pulmonary edema leads to bilateral alveolar infiltrates on the chest radiograph, restriction in lung volumes, and significant decline in gas exchange, particularly oxygenation.
- The physical examination and chest x-ray do not distinguish CHF from ARDS, whereas the clinical history and noninvasive assessment of cardiac function (e.g., echocardiography) often provide key insights. Alternative diagnostic techniques such as bronchoscopy or pulmonary artery catheterization can be helpful but are typically not required or used.
- The pathologic findings of ARDS are characterized early by acute alveolar inflammation and injury with neutrophils and cytokines, which can rapidly reverse. In severe and/or persistent ARDS, a fibrotic phase can develop and can lead to a more prolonged course of recovery.
- The clinical definition and diagnosis of ARDS is based on the presence of a syndrome of characteristics that include abnormalities on the chest x-ray, hypoxemia, and a known risk factor or trigger that generates acute inflammation. There are well-established consensus definitions for ARDS that should be used by all caregivers.
- ARDS is a common critical illness with high associated mortality and morbidity, but close attention to care protocols for patients with ARDS, in particular lung-protective lung ventilation, has improved survival and reduced recovery time for survivors.
- Early management of ARDS focuses on identifying and treating the triggering risk factor and comprehensive supportive care of vital organs, particularly ventilation.
- Ventilatory strategies for patients with ARDS are designed to minimize VILI by emphasizing low tidal volumes and driving pressures and sufficient levels of PEEP.
- The size of tidal volume selected should be based on a patient's predicted (not actual) body weight, which requires an accurate measurement of the patient's height to determine.
- Multiple modes of mechanical ventilation can be used to achieve LPV, but providers must prioritize avoiding VILI and be willing to tolerate reduced gas exchange, including lower oxygenation and higher $PaCO_2$.
- Adjunctive strategies beyond mechanical ventilation, such as prone positioning and NMB, may be beneficial in patients with severe ARDS.
- A small subset of patients with very severe ARDS fail conventional LPV ventilation strategies, and multiple alternative management strategies often called "rescue" therapies can be considered but lack proof of efficacy. Using rescue strategies should be considered early (first few days), because their potential benefits likely decline over time.
- Of all rescue therapies, ECMO is the most promising and widely available option.
- Several nonventilatory supportive care measures (e.g., conservative fluid management and minimizing sedation) have been shown to improve outcomes in ARDS, and consistent adherence to those measures should be encouraged and supported by RTs.

Respiratory Management of Trauma, Obesity, Near Drowning, and Burns

Massimiliano Pirrone and Lorenzo Berra

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the clinical presentation and the differences in approach to the assessment of patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- Discuss the specific pathophysiology that would guide the application of respiratory care to the management of patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- List the factors affecting gas exchange in each of these patient types.
- Discuss indications for O_2 therapy, noninvasive ventilation, and invasive mechanical ventilation.
- Describe concerns associated with the application of mechanical ventilation to patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- Discuss the application of lung protective ventilation to patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- Discuss the use of positive end expiratory pressure, lung recruitment maneuvers, and prone positioning in patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.
- Discuss the process of ventilator discontinuation in patients with life-threatening trauma, pulmonary and body surface burns, obesity, and near drowning.

CHAPTER OUTLINE

KEY TERMS

% total body surface area
blunt trauma
carbon monoxide poisoning
cold shock cardiac-respiratory reflexes
cyanide toxicity
cyanocobalamin
cytochrome oxidase
decremental PEEP trial
dry drowning
escharotomy
exudates
fluvial or brackish water
Glasgow Coma Scale
glomerular filtration rate
hydrophilic drugs
lipophilic drugs
morbid obesity
myocardial contusion
obesity hypoventilation syndrome
obstructive sleep apnea
penetrating trauma
pulmonary contusion
recruitment maneuvers
severe obesity
super obesity
tension pneumothorax
thiosulfate
thoracic flap (flail chest)
transudates
wet drowning

LIFE-THREATENING TRAUMA

Epidemiology

Trauma is the third overall cause of death in the United States and the primary cause of death for Americans between 1 and 44 years of age.[1] Each year, trauma accounts for 26.9 million admissions to emergency departments (EDs) and 2.5 million hospital admissions. In 2016 alone, 161,374 Americans lost their lives to trauma. But what exactly is trauma? In the most basic sense, trauma is an injury to the body that threatens life and limb integrity. The injury is caused by a physical agent (a force, heat, radiations, etc.) acting on one or more regions of the human body. As a result, trauma patients can have vastly different presentations and clinical manifestations and can require different levels of care. Not every trauma that involves the thorax requires intensive care and respiratory support, just as some traumas that do not involve the chest might require intensive care and respiratory support (e.g., in the setting of transfusion-related acute lung injury or head trauma). In addition, patients who suffer from trauma and require invasive mechanical ventilation (for trauma that directly involves the thorax, because of the need for an artificial airway, or as a result of massive transfusion) are at higher risk for ventilator-associated pneumonia (VAP), thus complicating these patients' clinical courses. Among patients admitted to the intensive care unit (ICU) after trauma, it has been shown that the presence of traumatic brain injury (TBI) and a poor **Glasgow Coma Scale** score (GCS < 8; Table 30.1) on admission are the main determinants of patient outcome, measured as post-ICU disability and quality of life.[2] Neurologic damage appears to be pivotal in determining patient mortality and disability; therefore the respiratory therapist must pay special attention to maintaining adequate oxygenation without compromising perfusion and hemodynamics. Because of the heterogeneous presentation of trauma, there is no overarching rule of thumb regarding patient respiratory management, and the respiratory therapist plays a key role in identifying life-threatening problems and tailoring the support to respiratory function.

TABLE 30.1 Glasgow Coma Score

Response	Score
Best Eye Response (E)	
Spontaneously	4
To speech	3
To pain	2
No response	1
Best Verbal Response (V)	
Oriented to time, place, and person	5
Confused	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1
Best Motor Response (M)	
Obeys commands	6
Moves to localized pain	5
Flexion withdrawal from pain	4
Abnormal flexion (decorticate)	3
Abnormal extension (decerebrate)	2
No response	1
Total Score	*15*
Change in Mental Status	
Close monitoring is required.	14–9
Comatose. Securing the airway is required.	≤8
Totally unresponsive	3

Clinical Assessment and Specific Pathophysiologic Concerns

During the first evaluation of a trauma patient, the respiratory therapist, together with the medical team, should focus on the airway and breathing. If blunt injury is present, cervical spine injury always should be suspected, and immobilization of the cervical spine must be instituted immediately.[3]

Assessment of a victim of major trauma should start with a GCS evaluation. If a patient is fully awake, responsive (GCS = 15), and able to maintain a patent airway, close respiratory and neurologic monitoring should be instituted until the medical team completes surveillance. If a patient's GCS range is between 14 and 9, the respiratory therapist should pay extra attention to the status of the patient because the clinical condition might quickly deteriorate, requiring endotracheal intubation and invasive ventilation. A GCS lower than 8 always requires securing the airway by endotracheal intubation and further diagnostic evaluation, unless a decision has been made by an authorized party to provide only comfort care (see Chapter 58).

RULE OF THUMB Trauma victims with TBI and a GCS scores of less than 8 require endotracheal intubation and generally have poorer postinjury quality of life and greater disability (see Chapter 58).

Head, Neck, and Upper Airway Injuries

The presence of external injuries to the head should raise the suspicion of TBI. These patients are at risk for rapid neurologic deterioration as a result of an array of alterations in mental status, ranging from confusion to seizures to coma. The respiratory function of these patients can be compromised by upper airway obstruction because of loss of muscular tone or, as with seizures, to excessive muscular tone that requires immediate sedation, paralysis, and endotracheal intubation. Endotracheal intubation might be challenging because of the mandatory immobilization of the cervical spine (Fig. 30.1). Management of the upper airways is complicated by anatomic alterations of the rhino-oropharynx caused by the traumatic injury. Severe maxillofacial injuries or destructive trauma of the upper airway prompts tracheal access for definitive airway management.[4] The presence of blood, gastric contents, oral secretions, and foreign material complicates artificial airway placement and management.

Lower Respiratory Injuries

Chest trauma is usually classified either as **penetrating trauma** (i.e., high force applied to a small surface area of the body, such as with a gunshot) or **blunt trauma** (i.e., high force applied over

Fig. 30.1 (A) In trauma, cervical stabilization is generally obtained by a rigid collar that encircles the neck and supports the chin and the back of the head. The goal of cervical collars is to restrict flexion and extension while supporting the chin and the occiput. When rigid cervical collars are applied, venous outflow at the neck should always be maintained to avoid increased intracranial pressure. (B) During intubation, it may be necessary to undo the anterior part of the cervical collar while an assistant maintains in-line stabilization with the occiput held firmly in neutral position (hands are placed along the side of the head with fingertips on the mastoid holding the occiput down). When possible, another assistant applies cricoid pressure. This orientation might limit visualization of the vocal cords for the operator; however, reduction of atlantooccipital motion should be the priority. Awake or asleep fiberoptic intubation or newer airway management instrumentation should be planned before intubation of a patient with an unstable cervical spine.

a larger body surface, such as the case of a head-on-end motor vehicle accident).[5] However, most chest injuries do not fall into one of these two categories but instead represent a mix of the two. Depending on the depth of the penetrating lesions, patients can present different clinical features. An injury that penetrates the chest wall, entering the pleural space without injuring the lung, causes a decoupling of the chest wall/lung relationship. During spontaneous breathing, the chest wall tends to expand while the lung tends to collapse. This results in a physiologically negative pleural pressure. When the pleural space is exposed to atmospheric pressure, as in the case of a penetrating trauma injury, the negative pleural pressure causes air to enter the pleural space. At this point, the chest wall expands and the lung collapses, resulting in a pneumothorax. If the penetrating injury enters both the pleural space and the lung, air can enter the pleural cavity from both the chest wall and the lung. Patients with this particular injury are at high risk for developing a **tension pneumothorax**. A tension pneumothorax develops when the pleural lesion acts as a one-way valve, allowing the entrance of air into the pleural space and progressively trapping air in the expanding pleural cavity. With every breath, the volume of air increases in the pleural cavity. As volume increases, pressure increases, resulting in a force directed toward the opposite pleural cavity. The high unilateral pressure causes a shift of mediastinal structures, resulting in distortion and eventual collapse of the main vascular structures, specifically the vena cava. This phenomenon leads to rapid hemodynamic deterioration that, if unrecognized, results in cardiovascular collapse and death. Penetrating traumas may also involve one or more bronchial structures.

Bronchial injuries cause large volumes of air to rapidly enter the pleural cavity as well as the mediastinum, depending on the location of the injury.[6] The presence of bronchial injury should be suspected when, after the placement of a chest tube for pleural drainage, large amounts of air continue to exit the chest tube in a synchronized pattern with positive pressure ventilation. Tracheal lesions can be life-threatening and require prompt surgical evaluation and appropriate airway management. The chosen artificial airway should be capable of bypassing the tracheal lesion to provide adequate pressurization and mechanical ventilation to both lungs. Mechanical ventilation through a tracheal disruption leads to pneumomediastinum, hemodynamic instability, and mediastinal infection. Disruption of a large airway is one of the indications for the use of independent lung ventilation (see Chapter 49).

Esophageal rupture may result in a communicating lesion with the respiratory tract or with the mediastinum. In the first case, the main clinical features are gas leakage during mechanical ventilation and aspiration of gastric material, which can result in chemical pneumonia or full-blown acute respiratory distress syndrome (ARDS). It is vital to recognize and treat these lesions as soon as possible.[7]

Blunt trauma is the other main mechanism that can cause physical injury to the human body. The main sign that a significant blunt trauma has affected the thoracic region is the presence of rib fractures.[8] Rib fractures can be unifocal (one point of fracture per rib) or multifocal (two or more points of fracture in a single rib). This difference is fundamental in understanding the effects of rib fractures on respiratory function. Unifocal fractures can be either nondisplaced or displaced. Nondisplaced rib fractures do not usually require particular attention if the number of fractured ribs is low. However, multiple fractured ribs can be extremely painful and impair proper inspiration, leading to shallow breathing and fatigue. These patients benefit from pain medication and, eventually, pneumatic stabilization of the chest wall through continuous positive airway pressure (CPAP).[9]

RULE OF THUMB The finding of multiple and/or bilateral rib fractures, the fracture of the first rib or a flail chest is suggestive of severe, high-energy traumatic lesions. Such patients are at high risk of respiratory and/or circulatory failure.

Displaced rib fractures are even more painful, and sharp bone edges can cause pneumothorax through laceration of the visceral pleura. Pain control and pneumatic stabilization are encouraged. These patients should be routinely monitored because they can develop internal pleural bleeding, especially in the setting of anticoagulant therapy. The presence of blood in the pleural cavity (hemothorax) requires pleural drainage and close monitoring of the bleeding (total amount of blood lost and presence of active bleeding). Surgical evaluation is mandatory. Multifocal fractures of one or more ribs create a **thoracic flap (flail chest)** that is extremely painful and impairs normal respiratory mechanics. During inspiration, when pleural pressure becomes negative, the free flap will be pushed inward, whereas during exhalation, when pleural pressure is positive, it will be pushed outward. This causes extreme pain because the edges of the ribs will be subjected to continuous friction. Based on the extent of the lesion, flail chest can impair normal ventilation. The current therapeutic approach is based on pain management and CPAP. Needless to say, the presence of flail chest is associated with a high risk for pneumohemothorax, and some of these patients do require intubation and invasive ventilation.

RULE OF THUMB The presence of bronchial injury should be suspected when, after the placement of a chest tube for pleural drainage, large amounts of air continue to exit the chest tube in a synchronized pattern with positive pressure ventilation.

Blunt trauma also can cause **pulmonary and cardiac contusions**. Pulmonary contusion is characterized by acute inflammation and exudation of plasma and blood components into the alveolar space. Even though these lesions resolve spontaneously, they place the patient at high risk for bacterial or viral infection, leading to pneumonia.[10] These inflammatory processes are usually located in the regions of the lung that were subject to the traumatic force (Fig. 30.2). **Myocardial contusion** is a common finding in chest trauma, although difficult to diagnose. The severity of the condition ranges from simple bruising of the tissue to lethal damage to the valves. If a myocardial contusion is suspected or diagnosed, cardiogenic shock and arrhythmias should be anticipated, and the patient carefully monitored.

The application of a traumatic blunt force on the abdomen causes a rapid increase of intraabdominal pressure. This could

Fig. 30.2 Chest X-Ray of a 29-Year-Old Man, Victim of a Motorbike Accident. The chest x-ray was obtained at arrival in the emergency department. Extensive right lung contusion ("white" lung), pneumothorax, multiple multifocal rib fractures, and a right flail chest can be seen. (*Image courtesy Dr. Giovanni Babini.)*

lead to diaphragmatic rupture. A rupture of the diaphragm impairs normal respiratory function and represents a medical and surgical emergency. If positive pressure ventilation is not applied, the negative intrathoracic pressure during inspiration literally sucks visceral organs into the pleura, causing massive lung collapse, acute bowel obstruction, and possibly splanchnic ischemia.

RULE OF THUMB All patients with chest trauma, regardless of whether the injury is penetrating or blunt, require careful assessment for pneumothorax, airway injuries, disruption of thoracic vessels, and chest contusion leading to ARDS.

Special Considerations in Patients With Chest Trauma

All bedridden patients are at increased risk for atelectasis secondary to decreased tidal volume and residual volume. Mucus clearance is impaired by inadequate mobilization and excessive or inadequate pain control. Secretion retention might aggravate atelectasis by creating thick mucus plugs in the distal bronchial tree. This phenomenon exposes the bedridden patient to hospital-acquired pneumonia. Secretion retention is a major issue in patients with chest trauma. The pain associated with the trauma (i.e., rib fractures) further impairs the cough reflex. In addition, direct chest trauma might be complicated by lung contusion. The presence of edema and blood in the lung parenchyma represents a perfect growth medium for pathogenic bacteria. The role of the respiratory therapist is crucial in the prevention of potentially life-threatening respiratory complications. There are four interventions on which the respiratory therapist should focus (Box 30.1):

1. *Mobilization*. The patient should be assisted in changing positions periodically to help with mucus drainage and prevention of atelectasis. If tolerated, patient should be helped to move out of bed and to spend some time in a chair.[11]

BOX 30.1 Basic Respiratory Interventions in the Bedridden Trauma Patient

- Mobilization
- Humidification
- Pain control
- Incentive spirometry
- Noninvasive continuous positive airway pressure and bilevel positive airway pressure

2. *Humidification of the airways.* Regardless of mechanical ventilation, bedridden patients should receive optimal humidification of the airways to prevent the accumulation of dry secretions.
3. *Pain control.* Control of pain in the trauma patient is one of the most challenging tasks of the critical care team. Inadequate pain control generally results in minimal chest expansion as a reflex response to minimize pain associated with breathing. Excessive use of pain medications (i.e., opioids) also will decrease chest expansion and cough reflex because of sedative effects. Both scenarios exacerbate the pathophysiologic sequence of events described earlier, leading to pneumonia.[12]
4. *Incentive spirometry, positive expiratory pressure (PEP) therapy and noninvasive ventilation (NIV).* Patients should be encouraged as soon as possible to take advantage of incentive spirometry. Incentive spirometry consists of regular breathing exercises performed with the aid of a dedicated device. Regular exercise has been shown to prevent formation of atelectasis and reduces secretion retention. The use of such devices requires the full collaboration and dedication of the patient. Secretion clearance can be aided by gentle external chest percussion (i.e., chest physiotherapy), avoiding sites of injury, if tolerated. PEP therapy consists in breathing with active expiration against a positive pressure. It can be applied by a face mask or through a mouthpiece. PEP therapy promotes clearance of secretions from the lungs, improves lung ventilation, and reduces air trapping. Some devices also allow for the delivery of aerosolized drugs, such as bronchodilators. Should these interventions fail, the respiratory therapist should consider the use of NIV (CPAP or bilevel positive airway pressure) to reexpand the residual volume and assist tidal ventilation. Recruitment maneuvers should be carefully performed in patients with chest trauma. The presence of silent lesions could cause hypertensive pneumothorax under elevated airway pressures.[13]

Respiratory Management

Every trauma patient represents a case by itself, and the respiratory management of trauma patients should focus on the mechanism of chest injury. Supplemental O_2 is generally administered immediately after the trauma to prevent secondary hypoxic injury. However, any sign of pending respiratory failure should prompt endotracheal intubation and initiation of mechanical ventilation (Box 30.2). Upper airway disruption might require emergent tracheostomy. Advanced airway management such as a double-lumen endotracheal tube (ETT) may be required for injury of the trachea or for selective lung ventilation for bronchial injuries.

BOX 30.2 Mechanical Ventilation of the Trauma Patient

- Mode: Pressure or volume ventilation
- Tidal volume: 6–8 mL/kg predicted body weight
- Inspiratory time 0.6–1.0 s
- Plateau pressure: Less than 28 cm H_2O
- Driving pressure of 15 cm H_2O or less
- Rate only limited by the development of auto-PEEP
- Minute volume to maintain normal $PaCO_2$
- PEEP 5–10 cm H_2O
- FiO_2 set to maintain target PaO_2
- If ARDS, manage as any other ARDS patient

ARDS, Acute respiratory distress syndrome; *PEEP*, positive end expiratory pressure.

Injury to the lung parenchyma always should be suspected after major trauma. Extensive lung injury frequently evolves into traumatic ARDS, requiring protective lung ventilation strategies (see Chapters 29 and 49). In addition, trauma patients are at higher risk for developing lung injury resulting from the large volume of blood components that these patients may require (i.e., transfusion-related lung injury and/or transfusion-associated circulatory overload). Bronchoscopy plays a major role in the respiratory care of trauma patients. Bronchoscopy first allows removal of foreign bodies and drainage of blood clots and provides an excellent method for removal of tenacious mucus plugs. Moreover, it is the gold standard for diagnosing proximal and distal major airway lesions and is capable of providing first-line treatment. Trauma patients are at high risk for VAP, and preventive clinical bundles should be applied as soon as possible (see Chapter 24). Recent reports outlined beneficial effects of these bundles (i.e., decreased sedation, early mobilization, and improved secretion clearance) compared with early tracheostomy for patients requiring prolonged mechanical ventilation. However, it is still difficult to predict the time for liberation from mechanical ventilation.

OBESITY

Epidemiology

Obesity is defined by an excess of weight in relation to a person's height. It is mainly measured through the body mass index (BMI), which is the ratio of an individual's weight (kg) divided by the square of the individual's height (m):

$$BMI = (weight)/(height)^2 = kg/m^2$$

A normal BMI range for a healthy individual is between 20 and 25 kg/m^2, and a BMI over 30 kg/m^2 is defined as obesity. In the last decade, the prevalence of obesity progressively has increased in the U.S. population, reaching a plateau of over a third of the total population. There are differences in obesity prevalence among different ethnic groups, with non-Hispanic Asians having a lower prevalence compared to non-Hispanic whites, non-Hispanic African Americans, and Hispanic groups. Obesity is connected to a plethora of adverse health conditions and imposes considerable burdens on the U.S. healthcare system.

MINI CLINI

Trauma: Recognizing Common Life-Threatening Acute Respiratory Complications in Trauma Patients

Problem

A water-skier was sent by medical flight to the hospital after collision with a boat following a 30-foot acrobatic jump. The unknown young man was intubated with a 7.0-mm ETT at the scene for hypoxemia and GCS 6 with no lower limb movements. Vital signs at admission in the ED were heart rate 40 beats/min, blood pressure 80/40 mm Hg, O_2 saturation 99%, and body temperature 35°C. He weighs 160 lb and is 6 feet tall. The ventilator settings are as follows: volume-controlled ventilation mode, tidal volume (V_T) 500 mL, respiratory rate 14 breaths/min, and positive end expiratory pressure (PEEP) 5 cm H_2O. During central line placement, the RT notices that the peak airway pressure increased from 18 cm H_2O to 35 cm H_2O, activating the high pressure alarm, and SaO_2 declined rapidly from 99% to 90%. What are the next steps the RT should take?

Solutions

1. Immediately inform the medical team regarding the alarming acute increased peak pressure and decreased SaO_2.
2. Verify that the ETT did not migrate into the right main stem bronchus during neck positioning for central line placement by confirming tube positioning.
3. Pass a suctioning catheter to verify absence of ETT kinking or occlusion resulting from secretions or blood.
4. Visually inspect that the inspiratory and expiratory ventilator circuit is not kinked and that the water trap is not filled.
5. Auscultate breath sounds on all lung fields and inspect trachea for deviation or asymmetry in chest movements during ventilation. Tension pneumothorax should be suspected when breath sounds are absent on the affected part of the thorax and the trachea deviates away from the affected side. The thorax may also be hyperresonant with jugular venous distension. Increased intrathoracic pressure might cause hypotensive and hypoxemia. If not recognized, tension pneumothorax leads to cardiovascular collapse and death.
6. Immediate chest X-ray and arterial blood gas (ABG) analysis should be requested to confirm hypoxemia and rule out acute changes (i.e., pneumothorax, acute pleural effusion, hemothorax, bronchial mucus plug causing large lobar or entire lung collapse).
7. Until a pneumothorax is ruled out, V_T should be decreased and respiratory rate increased ideally by use of a manual ventilator. This is to ensure that limited pressure is applied to minimize the volume of gas extending the possible pneumothorax.
8. Regardless of the final diagnosis, the respiratory therapist has a key role in the care of the trauma patient in the acute setting. Common tasks of the RT are titrating the ventilator after acute changes in the patient's condition, travel to a computed tomography (CT) scan or other emergent hospital location (i.e., operating room or ICU), and assisting with procedures such as bronchoscopy, chest tube placements, or intracranial pressure monitoring.

RULE OF THUMB Among the different excesses of BMI, a BMI greater than 40 kg/m^2 is defined as **severe obesity**, a BMI greater than 45 kg/m^2 is defined as **morbid obesity**, and a BMI greater than 50 kg/m^2 is defined as **super obesity**.

Obesity is associated with increased morbidity and mortality in the context of both acute and chronic medical problems, including diabetes mellitus and related complications, hypertension, dyslipidemia, cardiovascular disease, gallstones, cholecystitis, and certain forms of cancer. Although there is now a considerable

amount of data available on the impact of obesity on ICU outcomes, there are still contradictory conclusions concerning the nature of this impact, possibly because obese ICU patients on average are younger and are affected with less severe diseases compared to nonobese ICU patients; however, obese ICU patients require the same level of intensive care.

Among people with a BMI within the range of severe obesity, the distribution of adipose tissue plays a major role in determining the risks for chronic diseases. Current guidelines concerned with the clinical care of the obese recommend measurement of waist circumference in people with a BMI greater than 25 kg/m^2 and propose that waist circumferences of 102 cm in men and 88 cm in women define abdominal adiposity. Most studies examining the association between fat distribution and mortality have shown that abdominal adiposity is an important predictor of mortality. In particular, waist circumference has been associated with mortality even in people with a normal BMI, indicating that BMI might be of limited use in assessing the severity of a person's obesity and that fat tissue distribution plays a major role in the pathophysiology of obesity.[14]

RULE OF THUMB Patients who are obese have a greater likelihood of mortality in the ICU if their waist circumference is greater 102 cm in men and 88 cm in women.

Specific Pathophysiologic Concerns

Adipose tissue is a potent source of proinflammatory molecules that induce a chronic inflammatory state mimicking critical illness and diminishing immune and metabolic reserves (Box 30.3). Moreover, an increased BMI requires additional cardiovascular, respiratory, and metabolic work, further diminishing an individual's physiologic reserves.[15]

Obesity is a risk factor for cardiovascular disease independent of diabetes mellitus and hypertension. The mechanism of obesity-related cardiovascular disease involves an increase in both preload and afterload. Adipose tissue is perfused on average by 3 mL of blood per each 100 g of tissue. The resulting expansion of blood volume increases venous return (preload), cardiac output, and cardiac work. Afterload is increased by secretion of steroids and catecholamines and through the renin-angiotensin endocrine axis. Myocardial hypertrophy and diastolic dysfunction are the results of these alterations, eventually leading to heart failure, arrhythmias, or sudden cardiac arrest. Myocardial hypertrophy and the resulting reduced heart-wall compliance, as well as reduced heart chamber volumes, are responsible for poor tolerance of intravenous fluids in these patients. In addition, the presence of diabetes mellitus and hypertension in this setting exponentially increases the risk for myocardial infarction. Moreover, the presence of diabetes mellitus increases the risk for a silent myocardial infarction being present at the time of admission or happening as a complication of critical illness. This risk is especially important at the extreme range of obese patients, whose physical activity is very limited and who may not manifest symptoms of myocardial ischemia or show signs of congestive heart failure before ICU admission.

BOX 30.3 Physiologic Concerns Associated With Obesity

- Cardiovascular disease
- Venous thrombosis and pulmonary embolism
- Chronic renal failure
- Obstructive sleep apnea
- Obesity hypoventilation syndrome
- Reduced lung volumes
- Expiratory flow resistance
- Air-trapping and auto-PEEP

PEEP, Positive end expiratory pressure.

The presence of a proinflammatory/procoagulatory state induced by adipose tissue and associated with a sedentary lifestyle and venous stasis puts these patients at high risk for venous thrombosis and pulmonary embolism. The increased cardiac output of obese patients is responsible for an increased glomerular filtration rate in patients whose obesity-related complications have not yet compromised kidney function. However, diabetes mellitus and hypertension can be responsible for chronic kidney failure. Thus, an evaluation of kidney function is mandatory in this patient population. Abnormal glomerular filtration and excess adipose tissue alter the clearance and the volume distribution of most drugs that are administered to obese paitents.

Dosing of **lipophilic drugs** should be based on the actual body weight of the patient, whereas dosing for **hydrophilic drugs** is best determined using the ideal body weight (IBW) or predicted body weight (PBW) of the patient and corrected for higher renal clearance if an abnormally high **glomerular filtration rate** is present. Because of altered clearance, distribution, and accumulation of drugs, obese patients are particularly prone to underdosage and overdosage of hypnotic medications. Because most of these drugs are lipophilic, allowing them to cross the blood–brain barrier, the accumulation of drugs in excess adipose tissue can occur and result in a slowed release into the bloodstream. Frequent spontaneous awakening trials are necessary to assess the accumulation of drugs in the adipose tissue and to determine the ability of the patient to promptly recover from sedation to avoid delaying liberation from mechanical ventilation.[16]

More than two-thirds of obese people have **obstructive sleep apnea** (OSA). OSA has been linked to daytime somnolence and higher risk of industrial and motor-vehicle accidents. However, the factors that lead to a higher incidence of OSA in obese patients are still poorly understood. It has been argued that obesity can act in different ways on the respiratory system, that it narrows the upper airway, causes upper airway collapsibility, and disrupts the normal physiologic respiratory drive. Full neuromuscular control of pharyngeal patency is of the utmost importance in these patients (see Chapter 34).

Lung volumes progressively decrease as BMI increases. Total lung capacity and residual volume decrease linearly as BMI increases, while functional residual capacity is exponentially reduced at higher BMI values, especially in patients with a central fat distribution (high waist circumference). Low functional residual capacity increases the risk for expiratory flow limitation and airway closure. This is thought to be due to an increase in pleural pressure caused by the transmission of the gravitational

weight of the abdomen. The weight of the abdomen displaces the diaphragm in a cephalad position, causing passive atelectasis in the most gravity-dependent regions of the lung. The collapsed lung tissue exerts less elastic recoil on adjacent structures, particularly on the smaller airways, reducing their diameter. The increase in pleural pressure further aggravates airway collapse. The ensuing expiratory flow limitation can lead to incomplete exhalation with air trapping, resulting in dynamic hyperinflation. Dynamic hyperinflation (auto-PEEP) is one of the most common sources of increased work of breathing and patient–ventilator asynchrony in mechanically ventilated patients.

Trapping of gas behind collapsed airways acts as a recoil pressure that needs to be released at the beginning of inspiration before the generation of a V_T, resulting in wasted work of breathing.[17,18] It has been observed that the sitting position can improve respiratory mechanics and gas exchange and lower the PEEP required to restore functional residual capacity to a normal physiologic level.[19] The presence of expiratory flow limitation and atelectasis in the dependent zones of the lung causes ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch and hypoxemia. To supplement the increased rates of O_2 consumption and carbon dioxide production, obese patients increase their minute ventilation, maintaining adequate alveolar ventilation at the expense of higher dead space ventilation. However, the most severely obese patients lose central chemosensitivity, impairing their ventilatory response to hypoxemia and hypercapnia (**obesity hypoventilation syndrome** [OHS]). These patients tend to slowly progress to hypoventilation with hypercapnic respiratory failure. Noninvasive nocturnal ventilation can be effective in restoring a more normal physiologic chemosensitivity and compensatory respiratory drive.[20]

RULE OF THUMB The majority of patients with severe obesity develop flow limitation, air trapping, and auto-PEEP, especially when ventilated in the supine position.

Clinical Assessment

Given an unstable respiratory/cardiovascular equilibrium, obese patients are particularly prone to acute respiratory failure in the setting of disease. Particular attention must be paid to gas exchange and signs of increased work of breathing (labored breathing, high respiratory rates, and use of accessory muscles), because any deterioration in their clinical status can quickly precipitate respiratory failure requiring mechanical ventilation.

BMI, body fat distribution, and history of snoring, sleepiness, and headaches should be determined or measured on admission. The degree of self-mobilization and physical daily activity should be investigated, and the risk for deep venous thrombosis or pulmonary embolism should be assessed. A plan for airway management and intubation should be discussed before the onset of respiratory failure, especially if the patient shows signs of a particularly difficult airway for intubation. The past use of and settings for home nocturnal CPAP or NIV should be investigated, and their continued use should be encouraged. In the presence of a history suggestive of OSA/OHS, intermittent/nocturnal noninvasive bilevel positive airway pressure/CPAP should be started regardless of the patient's respiratory status.

BOX 30.4 Respiratory Management of Obesity

- O_2 therapy for management of hypoxemia
- Inhalational bronchodilators for management of asthma symptoms
- Noninvasive CPAP for management of sleep apnea
- NIV for obesity hypoventilation syndrome and hypercarbic respiratory failure
- Invasive mechanical ventilation for management of hypoxemic and hypercarbic respiratory unresponsive to NIV

CPAP, Continuous positive expiratory pressure; *NIV,* noninvasive ventilation.

Respiratory Management

See Box 30.4.

Oxygen Therapy

Hypoxemia is the most common gas exchange abnormality in obese patients. It can be mild and easily corrected by O_2 supplementation, or it can be severe enough to require mechanical ventilation. However, a mild, progressive hypoxemia should prompt close monitoring of gas exchange, work of breathing, and mental status, because it might be a sign of impending respiratory failure. A sudden onset of hypoxemic respiratory failure should raise the suspicion for pulmonary embolism. If the patient's response to O_2 supplementation is inadequate but the patient's mental status is acceptable, NIV should be initiated.

Aerosolized Pharmacology

Obese patients have a higher incidence and severity of asthma, and they frequently require inhalation therapy. For a detailed discussion, see Chapter 39.

Noninvasive Ventilation

NIV should be attempted when the patient's neurologic status is relatively normal but O_2 therapy alone is ineffective at correcting hypoxemia or when hypercapnia complicates respiratory failure. By the time NIV is attempted, a plan for airway management and intubation already should have been made. NIV should be instituted immediately in the setting of hypercapnic respiratory failure. If qualified staff is available, noninvasive mechanical ventilation can be set up and begun in the ED or respiratory wards. An alert and cooperative mental status, proper mask-fitting, ability to clear secretions, and relative hemodynamic stability are essential factors that contribute to the success of NIV. Pressure-support ventilation with adequate PEEP is the preferred mode of ventilation. Vital signs, level of consciousness, respiratory pattern, oxygenation, delivered V_T, gas exchange, and circuit leaks should be frequently assessed to guarantee proper ventilatory therapy.[21] Refer to Chapter 50 on NIV for details on its application.

RULE OF THUMB If the first to second hour of NIV does not at least partially correct the patient's hypoxemia and hypercarbia, endotracheal intubation should be immediately considered.

Invasive Mechanical Ventilation

Intubation. Although airway management in obese patients can be challenging, there is no common agreement on which approach to intubation should be used in obese patients (see Chapter 22). A possible strategy is awake intubation using a flexible bronchoscope. Although this technique requires coordination, proper anesthesia of the upper airways, and complete collaboration of the patient, with this final factor being particularly important for success, even when all is ideal, intubation of the critically ill obese patient is difficult. The advent of video-laryngoscopy has significantly reduced the amount of difficulty that clinicians face in airway management, and the use of a video-laryngoscope should be strongly considered in any intubation plan for the critically ill obese patient. A kit for rapid airway access should be present at the bedside or within reach until the airway is secured. Regardless of the device or technique adopted, which should be based on patient evaluation and personal expertise, optimal positioning is mandatory to increase the chance of securing the airways. The "ramped position" consists of elevating the upper body and head of the patient to align the sternum and ear horizontally. This positioning technique results in a significantly improved laryngoscopic view. In addition, the elevated head-of-bed position improves respiratory mechanics and lung volumes during preoxygenation, increasing apnea time. The use of CPAP during preoxygenation can additionally increase the nonhypoxemic apnea time by 50%.

Tidal volume, minute volume, and respiratory rate. Pressure control ventilation or volume control ventilation are equally effective modes of mechanical ventilation in the obese patient (Box 30.5). However, regardless of mode of ventilation, ventilator settings *must not be calculated* based on actual body weight but on PBW or IBW, because an increased BMI does not reflect increased lung size. The most widely recommended formulas for determining PBW are listed as follows:

$$PBW_{MEN} = 50.0 + 0.905 * ([\text{Height in cm}] - 152.4)$$

$$PBW_{WOMEN} = 45.5 + 0.905 * ([\text{Height in cm}] - 152.4)$$

BOX 30.5 Mechanical Ventilation of the Obese Patient

- Mode: Pressure or volume ventilation
- Tidal volume: Average 6 mL/kg PBW, range 4–8 mL/kg PBW
- Inspiratory time 0.6–1.0 s
- Plateau pressure: Less than 28 cm H_2O, unless TPP measured then TPP less than 20 cm H_2O
- Driving pressure equal to or less than 15 cm H_2O
- Rate only limited by the development of auto-PEEP
- Minute volume generally 10 L/min or greater
- Lung recruitment maneuver with **decremental PEEP trial** to set PEEP
- PEEP frequently 15–25 cm H_2O dependent on the size of the patient
- FiO_2 set to maintain target PaO_2
- Position head of the bed to 30 degrees or greater elevation
- Noninvasive ventilation for 24–48 h after extubation

PBW, Predicted body weight; *PEEP,* positive end expiratory pressure; *TPP,* transpulmonary pressure.

Ventilator settings should be tailored for an adequate clearance of CO_2. In assisted partial ventilatory support, respiratory rate and volumes should be carefully monitored, especially in the setting of OHS, as central desensitization to CO_2 might result in depressed respiratory drive in the setting of normal oxygenation. It is reasonable in this context to have a lower oxygenation target (SpO_2 88% to 95%).

RULE OF THUMB V_T in obese patients always should be determined based on PBW, *not* actual body weight, because lung size is not based on weight; it is based on height and gender.

Lung recruitment and positive end expiratory pressure. It has been demonstrated in the ICU and in intraoperative settings that **recruitment maneuvers** in obese, mechanically ventilated patients are effective at improving respiratory system compliance and oxygenation without affecting hemodynamics.[22,23] This effect is due to the reversal of atelectasis that forms during induction and persists without adequate levels of PEEP during mechanical ventilation.[24] It is advisable to perform a recruitment maneuver whenever PEEP is increased or after temporary PEEP discontinuation (e.g., disconnection of the patient from the ventilator circuit in the setting of high PEEP).[25] Obese patients require higher PEEP levels to counter the pressure of abdominal weight on the lungs through the diaphragm. In obese patients with persistent hypoxemia, measurements of transpulmonary pressure and PEEP titration (whether based on best compliance or positive end-expiratory transpulmonary pressure) are highly suggested. See Chapter 49 for details on the performance of recruitment maneuvers.

Positioning. It has been shown that elevation of the head of the bed is effective at improving respiratory system compliance and oxygenation, reducing expiratory flow limitation, and reducing PEEP requirements for optimal ventilation in obese patients. This phenomenon is related to the gravitational effects of the abdomen on the diaphragm. When obese patients lie in the supine position, the abdominal content pushes against the diaphragm and displaces it in a cranial direction, resulting in increased pleural pressure and passive atelectasis in the dependent zones of the lung (see the section on pathophysiology). The adoption of a sitting position changes the vector of the gravitational forces of the abdomen, partially releasing the diaphragm from abdominal pressure. Changes in bed position in morbidly obese patients (e.g., from sitting to supine and back to sitting) should be followed by a recruitment maneuver in order to reexpand the regions of the lungs that collapsed during the transient increase in pleural pressure. In general, unless contraindicated, obese patients should be managed with the head of the bed elevated above 30 degrees.

RULE OF THUMB FiO_2 and pressure support level should always be weaned before PEEP level is decreased. When FiO_2 is approximately 0.40 and pressure support is 10 cm H_2O or less, PEEP can be decreased.

Ventilator discontinuation. One of the most challenging aspects of ventilatory management of obese patients is liberation from mechanical ventilation. Expiratory flow limitation, low

MINI CLINI

Obesity: The Role of Postoperative Noninvasive Ventilation

Problem

A 550-lb patient is recovering in the postoperative care unit after a laparoscopic cholecystectomy. The procedure was uneventful. The nurse called you because the SpO_2 decreased from 95% to 88% over the past hour despite a nonrebreather face mask at 12 L/min. You see the patient; she is calm, resting in no pain, and breathing regularly at 8 breaths/min. Other vital signs are heart rate 66 beats/min, blood pressure 128/70 mm Hg, and body temperature 36.5°C. After reviewing the nursing notes, you notice that patient required 4 mg of midazolam before surgery for anxiety, 4 mg of hydromorphone during surgery, and an additional 10 mg of morphine in the recovery room.

Solutions

Inform the medical/surgical team of the increased hypoxemia in this high-risk obese postsurgical patient. Suggest the medical/surgical team perform an ABG analysis to confirm hypoxemia and determine PCO_2 to rule out pharmacologic narcosis and request a chest X-ray to rule out postoperative atelectasis.

In this patient, NIV instead of CPAP is required because not only is there most likely marked atelectasis, but this patient's ventilatory drive has been depressed by sedatives and narcotics, requiring ventilatory support. NIV may be required for only 24 h, but considering the size of the patient and the likelihood that the patient has sleep apnea, the use of CPAP during sleep should be considered on an ongoing basis and the patient evaluated for sleep apnea once recovered from the acute episode.

respiratory system compliance, atelectasis, and impaired neurologic respiratory drive play an important role in determining increased work of breathing in morbidly obese patients. Post–critical illness muscular weakness aggravates the patient's respiratory condition. In addition, it has been shown that morbidly obese patients who undergo tracheostomy have a higher morbidity and mortality and are more prone to tracheostomy-related complications. In obese patients who required high levels of PEEP during their ICU stay, reducing PEEP in order to perform a spontaneous breathing trial can lead to dyspnea and desaturation due to a "pendelluft" effect, with air flowing within the lungs from dependent to nondependent regions of the lung, increasing work of breathing and progressing to a failed trial. In these patients, a spontaneous breathing trial can be attempted at their titrated PEEP level. If successful, they can be extubated with CPAP/NIV support.[26]

NEAR DROWNING

Epidemiology

Drowning is one of the major causes of accidental pediatric death and is more common in low-income and middle-income countries. In adults, drowning is generally associated with alcohol and drug abuse. From 2005 to 2014, there was an average of 3,536 fatal unintentional drownings annually in the United States, of which almost 700 were children younger than 14 years of age, not counting an additional 332 people who drown yearly in boating-related incidents. It has been calculated that for each drowning casualty, there are at least five times as many near-drowning–related admissions to EDs, of which half require hospitalization.

The essential feature of drowning and the primary cause of death is asphyxia leading to cardiopulmonary collapse. Permanent injuries include a spectrum of brain damage, starting with minor memory problems to severe learning disabilities, including a permanent vegetative state.[27–29]

Specific Pathophysiologic Concerns

The pathophysiologic mechanisms of drowning comprise the following two reflexes:

1. Inhalation of fluid causes irritation and cough response, resulting in fluid being either swallowed or inhaled. Laryngospasm with closure of the glottis prevents aspiration of large amounts of fluid in the lungs (**"dry drowning"**), diverting these fluids to the stomach. In general, the laryngospasm lessens with unconsciousness, leading to **"wet drowning"**—the aspiration of fluid, which is a more common occurrence.
2. **Cold shock cardiac-respiratory reflexes** occur with sudden immersion in water cooler than 25°C. The breathing pattern is characterized by gasping followed by hyperventilation and shallow breathing at almost total lung capacity. At lower water temperatures, sudden peripheral vasoconstriction can acutely increase systemic vascular resistance, leading to sudden cardiovascular collapse if the heart is unable to overcome the acute increase in preload and afterload.[30]

During "wet drowning," specific respiratory and blood chemistry dysfunction depend on whether fresh- or seawater has been inhaled.

1. Inhalation of freshwater.[31]
   a. *Inhalation of freshwater and its effects on the respiratory system*. Inhalation of freshwater rapidly depletes alveolar surfactant, leading to $\dot{V}/\dot{Q}$ mismatch. Inhaled water is quickly absorbed into the vascular system from the alveolar space by osmosis, causing alveolar collapse and worsening shunt and hypoxia. In addition, in the setting of inhaled freshwater, acute neurogenic pulmonary edema due to cerebral hypoxia has been shown to worsen alveolar flooding. However, if hypoxia is reversed, normal pulmonary function can be quickly restored.
   b. *The effects of inhalation of freshwater on other organs*. If a large volume of freshwater is inhaled, it is rapidly absorbed into the circulation, leading to electrolyte imbalance. Hyponatremia can lead to seizures, especially in pediatric patients. In addition, diluted plasma causes water to rapidly enter into erythrocytes by osmosis, causing hemolysis. The resulting hyperkalemia and hyponatremia can cause ventricular fibrillation, and the liberation of hemoglobin into the plasma can precipitate acute renal failure.
2. Inhalation of salt water.[32]
   a. *Inhalation of salt water and its effects on the respiratory system*. Seawater has a threefold higher osmolarity than blood. Hypertonic fluid inhalation therefore causes water to move from the circulation into the lungs. In experimental studies in animals, inhaled seawater accounted for less than 50% of the volume of water retrieved from the lungs at autopsy. In contrast with the inhalation of freshwater, this phenomenon explains the sustained edema and prolonged shunt after the inhalation of salt water. In addition,

BOX 30.6 Respiratory Management of Near Drowning

- Basic cardiopulmonary
- Airway clearance
  - Bronchoscopy
  - Lavage
  - Prone positioning
- Mechanical ventilation as in all ARDS patients

ARDS, Acute respiratory distress syndrome.

salt water causes direct damage to the alveolar-capillary membrane, enhancing lung injury.

b. *The effects of inhalation of salt water on other organs.* If a large volume of salt water is inhaled, the rapid loss of circulating volume into the alveolar space across the injured alveolar capillary membrane may cause hemoconcentration, hypernatremia, and hypoalbuminemia. This phenomenon, if not recognized and rapidly reversed, leads to vascular collapse and hypovolemic shock.

Despite the pathophysiologic differences and the obvious circumstantial differences between drowning in salt water versus freshwater, at autopsy, a definitive diagnosis cannot be made.[33–35]

Respiratory Management

Immediate management of patients who present with drowning or near-drowning events must follow the classic airway-breathing-circulation approach, and cardiopulmonary resuscitation should be started immediately, if needed (Box 30.6). If possible, prone positioning of the patient is preferable, because it allows optimal clearance of water from the tracheobronchial tree, especially in the case of salt water drowning. Temperature monitoring and active body temperature control should be started as soon as possible, because submersion and inhalation of water drastically reduces body temperature.

RULE OF THUMB Near-drowning victims almost always develop ARDS, and ventilator management should include all best practices regarding ARDS (see Chapter 29).

Airway Clearance Therapy

The aspiration of foreign matter occurs relatively commonly in drowning or near-drowning events, particularly events involving drowning in shallow water. The most common aspirated material is sand, mud, or dirt. This can be easily recognized if solid material is found in the upper airways or in the stomach. It has been reported that a CT scan can show distinct hyperdense "sand bronchograms" in cases of sand aspiration (Fig. 30.3). The inhalation of foreign material in the setting of drowning or near drowning is particularly harmful, because the material is usually solid, is nonsoluble, has a high density, and tends to consolidate and clog distal airways. This further worsens the onset of ARDS that follows drowning by enhancing the inflammatory response and by mechanically sealing the airways. Upper airway clearance should be performed as soon as possible. Foreign material in the distal airways can be washed after intubation through repeated bronchoscopy and bronchoalveolar lavages.[36,37]

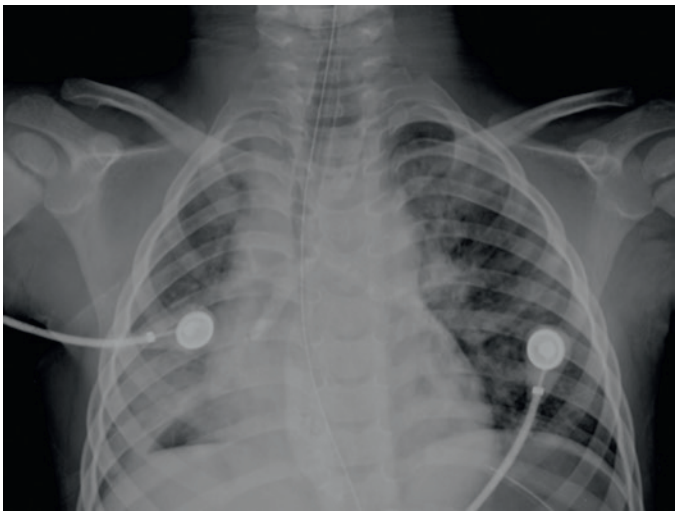

Fig. 30.3 Chest Imaging of a 4-Year-Old Child After Sand Aspiration. Radiopaque material can be seen inside the main bronchi and distal airways. Sand can cause direct mucosal injury, severe airway inflammation, and airway occlusion. (Image provided on MyPACS.net by Dr. Brenda Grabb.)

BOX 30.7 Mechanical Ventilation of the Near-Drowning Patient

- Mode: Pressure or volume ventilation
- Tidal volume: Average 6–8 mL/kg PBW
- Inspiratory time 0.6–1.0 s
- Plateau pressure: less than 28 cm H_2O
- Driving pressure equal to or less than 15 cm H_2O
- Rate only limited by the development of auto-PEEP
- Minute volume to maintain $PaCO_2$
- PEEP 5–10 cm H_2O
- FiO_2 set to maintain target PaO_2
- Prone position
- If ARDS, manage as normal for ARDS patients

ARDS, Acute respiratory distress syndrome; *PBW*, predicted body weight; *PEEP*, positive end expiratory pressure.

Mechanical Ventilation

Almost every patient who experiences drowning or near-drowning events will develop ARDS. Ventilatory management of these patients should follow ARDS ventilation guidelines as outlined in Chapters 29 and 49 (Box 30.7). Frequently, these patients develop bronchospasm as a result of the irritant effects of water in the airways. Laryngospasm and persistent upper airway closure are usually resolved by paralysis at intubation, but severe bronchospasm may persist, requiring bronchodilator therapy (see Chapter 40). Drowning in **fluvial or brackish water** or seawater is usually complicated by pneumonia caused by opportunistic pathogens inhaled at the moment of drowning. However, these bacteria usually do not show antibiotic resistance, and prompt antibiotic prophylaxis should be able to prevent pneumonia.

Positioning

Whenever feasible, prone positioning is preferable immediately after cardiovascular stabilization, especially in the case of brackish water or saltwater drowning, in which the osmotic activity of the inhaled salt causes continuous refilling of the lungs with water. The prone position allows clearance of salt-containing fluids from the lungs and might prove useful in the setting of severe ARDS.

RULE OF THUMB Once stabilized, salt-water near-drowning victims generally benefit from prone positioning, which allows better clearance of inhaled fluids from the lungs.

BURNS

Epidemiology

In the United States, each year, approximately 480,000 people receive medical treatment for burn injuries; of these patients, 40,000 are hospitalized. Over 60% of the estimated U.S. acute hospitalizations related to burn injury were admitted to 128 burn centers. Each year, 3200 patients die as a result of burn and/or smoke inhalation. In a selected case series, the reason for admission was 43% fire, 34% scald, 9% contact, 4% electrical, 3% chemical, and 7% other burn injuries.[38] The main feature characterizing the natural history of serious burns is burn shock. Burn shock can lead to death within the first hours after injury. The most important cause of mortality among those who survive burn shock is wound sepsis (Box 30.8). After recovery from the acute inflammatory phase, postburn deformities delay full functional recovery. Improved survival has been associated with early resuscitation, prevention of postburn sepsis, aggressive surgical treatment, improved perioperative care, and the development of multidisciplinary treatment teams. The first phase of the care of patients with serious burn injury is challenging in both respiratory care and hemodynamic management. Intensivists and RTs during the initial management period must work cooperatively in the management of these critically ill patients.[39]

BOX 30.8 Survival in Burn Patients

Survival in burn patients has been associated with:
- Early fluid resuscitation
- Prevention of postburn sepsis
- Aggressive surgical treatment
- Improved perioperative care
- Development of multidisciplinary teams

MINI CLINI

Near Drowning: Recognizing Life-Threatening Acute Respiratory Complications

Problem

An unresponsive 3-year-old boy is brought into the ED by his parents after he was rescued from their swimming pool. The parents were hosting a midsummer barbecue when they heard screaming kids and found their son face-down in the swimming pool. Vital signs at admission to the ED were heart rate 40 beats/min, blood pressure 50/20 mm Hg, $SatO_2$ 88%, and body temperature 33°C. What are the next steps, and how should the Respiratory Therapist (RT) respond?

Solutions

This is an emergency, and the team should be prepared for impending cardiac arrest because of near drowning. Advance Cardiac Life Support (ACLS) should be started right away without delay. While the medical team supports the circulation, the RT should be prepared for emergent and possibly difficult intubation because of aspiration, oral/pharyngeal/tracheobronchial fluids, and edema. A few pediatric ETT sizes, a pediatric intubation kit, and a difficult airway cart with an emergent tracheostomy kit should be at the bedside.

Wall suctioning should be readily available, and a pediatric flexible bronchoscope for deep suctioning and/or foreign body retrieval should be at the bedside.

In summary, a pediatric near drowning should be treated as an emergency with standard pediatric ACLS. However, immediately after recovery, the RT should focus on pulmonary toilette by body positioning, suctioning, and titration of the ventilator in anticipation of impending respiratory complications, refractory hypoxemia, and ARDS.

Clinical Assessment

During the clinical assessment of burn patients, the airway is the first priority. Burn patients always should be considered trauma patients; airway evaluation and management should follow what is described in the previous section on airway management of the trauma patient. Airways of burn patients should be monitored closely because exposure to hot gases, flames, and toxic gases causes airway obstruction as a result of acute edema. Early intubation in these patients is essential and early initiation of mechanical ventilation is required. Signs for early intubation include gradual but progressive compromise of respiratory mechanics and gas exchange and the presence of facial burns or any direct or indirect evidence of upper airway involvement.

Respiratory assessment of burn patients should focus on the following:[40]

1. Extent (**total body surface area** [TBSA]) and depth of external burns
2. Degree of involvement of lung tissue
3. Inhalation of toxic gases (carbon monoxide and cyanide)

The surface area of external burns can be easily quantified by the rule of nines, which estimates the total amount of the body surface area involved by the burns (%TBSA). The evaluation of external burns with the rule of nines is crucial to the medical team to guide fluid management during the first hours of treatment (Table 30.2). An adult patient of approximately 80 kg and with burns of 50% of TBSA would require 16 L of fluids in the first 24 hours, of which 8 L is given within the first 8 hours (1 L/h of fluid infusion). It is imperative for the RT to know the rate of fluid resuscitation and the hemodynamic response during the first critical hours after major burn. The severity of the burn depth is classified based on the anatomic planes progressively involved in the injury (Table 30.3). A first-degree burn is a superficial injury that involves only the epidermis. The second degree involves the dermis. Third-degree injury is characterized by the destruction of both the epidermis and dermis above the fascia. Fourth degree involves the muscles and the

TABLE 30.3 Severity of Burn Depth

Degree of Burn	Depth of Injury	Level of Pain
First degree	Superficial, only involving the epidermis	Tender and sore
Second degree	Involves the dermis	Very painful
Third degree	Destruction of the epidermis and dermis above the fascia	Very little to no pain
Fourth degree	Full-thickness burns involving the fascia, muscles, and bones	Painless

bones. Surgical intervention with debridement and grafting should be considered for all burns more severe than second degree.

Extensive chest wall burns commonly lead to worsening gas exchange and increased work of breathing. The formation of thick fibrous tissue (eschar) and the accumulation of edema in the chest wall and upper abdomen lowers chest wall compliance. The deterioration of respiratory mechanics can be so severe as to require emergent **escharotomy**, a circumferential or near-circumferential surgical incision through the eschar that relieves tissue pressure and reduces chest wall stiffness.

Lung injury frequently results from inhalation of hot gases and smoke. ARDS is the typical presentation of heat-related lung injury. Fluid overload and systemic inflammatory response usually complicates the respiratory status and respiratory management of burn patients. Direct visualization of the tracheobronchial tree by flexible bronchoscopy can be extremely helpful in revealing mucosal alterations and disruptions characterized by inflammation, erythema, carbonaceous debris, and ulcerations.

BOX 30.9 Early Clinical Features of Carbon Monoxide and Cyanide Poisoning

- Anxiety
- Tachycardia
- Arrhythmias
- Tachypnoea
- Hypertension followed by:
  - Headache
  - Confusion
- Dyspnea
- Hypotension
- Bradycardia followed by:
  - Neurologic system symptoms (seizures and reduced consciousness)
  - Respiratory failure with pulmonary edema
  - Coma
  - Death

Carbon monoxide poisoning and **cyanide toxicity** are common findings in patients who have fire-related burns. The RT should be aware that CO and cyanide poisoning do not cause cyanosis. SaO_2 in blood should be measured by ABG analyses, because most SpO_2 sensors are unable to distinguish oxyhemoglobin (O_2Hb) from methemoglobin (MetHb) and carboxyhemoglobin (COHb). This phenomenon results in falsely elevated pulse oximetry readings even when the patient is severely hypoxemic. In the absence of blood gas analyses, a cooximeter can measure concentration of MetHb and COHb. CO has an affinity for hemoglobin that is 100 times greater than that for O_2, and this can shift the oxyhemoglobin dissociation curve to the left. Patients become symptomatic when COHb levels are higher than 15%; levels greater than 50% are lethal. In these patients, 100% O_2 should be administered as soon as possible, because it reduces the half-life of COHb to 74 minutes (average).[41] When feasible, hyperbaric O_2 should be considered to prevent serious neurologic sequelae.[42,43] Inhalation of cyanide-containing gas during combustion of nitrogenous materials is characterized by the presence of an adequate O_2 delivery and metabolic acidosis with anion gap. Cyanide compounds work by interfering with mitochondrial O_2 usage, blocking the final step of the oxidative phosphorylation cascade. Impaired uptake of O_2 despite normal O_2 delivery is confirmed by a high mixed venous O_2 saturation. Concentration of cyanide higher than 20 parts per million (ppm) is considered dangerous, and 100 ppm is lethal. **Thiosulfate** and **cyanocobalamin** are administered as soon as possible to reduce the half-life of this toxic compound. For both CO and cyanide poisoning, early clinical features are anxiety, tachycardia and/or arrhythmia, tachypnea, and hypertension, followed by headache, confusion, dyspnea, hypotension, and bradycardia leading to neurologic symptoms, such as seizures and reduced consciousness, respiratory failure with pulmonary edema, coma, and death (Box 30.9).[44]

RULE OF THUMB CO and cyanide poisoning do not cause cyanosis. SaO_2 in blood should be measured by ABG analyses, because most SpO_2 sensors are unable to distinguish O_2Hb from MetHb and COHb. This phenomenon results in falsely normal SpO_2 readings (100%), even when the patient is severely hypoxemic.

MINI CLINI

Carbon Monoxide Intoxication: Early Recognition and Treatment

Problem

A 46-year-old was brought to the ED after being found unconscious in his bathroom, near an improvised heater. At arrival, the patient had closed eyes, is responsive to external stimuli, and is confused when questioned. Head CT scan showed nothing remarkable. After the CT scan, his neurologic status quickly deteriorated, and the patient became unresponsive, although breathing spontaneously at a rate of 34 breaths/min. Additional vital signs were heart rate 140 beats/min with ST-segment depression on monitor, blood pressure 135/80 mm Hg, $SatO_2$ 100% with bright red skin color, and body temperature 36.7°C. Blood gas analysis reported pH 7.17, PCO_2 21 mm Hg, lactate 10.5 mmol/L, and COHb 47%. What should the RT do?

Solutions

The patient is suffering from lethal CO poisoning. His neurologic status, electrocardiographic changes, and partially compensated lactate acidosis are signs of severe hypoxemia. The emergency team should be immediately called, and the RT should be prepared for emergent rapid-sequence intubation and be prepared for possible difficult intubation. Throughout the procedure and after securing the airway, FiO_2 should be kept at 100%. Deep sedation and paralysis are helpful in reducing O_2 consumption to a minimum. Respiratory rate should be titrated to keep pH slightly acidic in order to improve O_2 delivery. Emergency hyperbaric O_2 therapy is required. After being treated with 100% O_2 at 2.8 atmospheric pressures for 90 min, COHb decreased to 1.5%, and the patient was successfully extubated 10 h after the accident.

Pathophysiology of Burn Patients

Burn injury can cause extensive tissue destruction, leading to an extensive inflammatory process, which starts with the release of inflammatory cytokines. To simplify, there is a local burn effect at the site of the burn and a systemic effect mediated by inflammatory mediators that are released. However, these two effects are interlinked and difficult to separate from each other.

It is generally better to divide burn patients according to the systemic response over time: a severe systemic response that lasts up to the first 48 hours followed by a late response starting at 48 hours, and ending at approximately 72 hours after the burn accident.[40]

1. Commonly, if TBSA exceeds 25%, a systemic inflammatory process becomes evident, and fluids from the intravascular space enter the extravascular space and develop generalized edema. Edema expands quickly within the first hours after the injury. If patients are not sufficiently hydrated, this fluid shift rapidly leads into an impairment of local and systemic perfusion with tissue and organ damage, causing ischemia, metabolic acidosis, and mixed venous desaturation, as a result of hypovolemic and distributive shock. The hematocrit gradually increases due to hemoconcentration. At the same time, the massive systemic inflammation commonly leads to cardiovascular instability followed by myocardial depression if not treated.
2. The first few hours after injury are characterized by a hyperdynamic state with high metabolic requirements with elevated CO_2 production and O_2 consumption. Massive vasodilation increases pulmonary shunt fraction, worsening hypoxemia that can develop into full pulmonary edema. However, this phase is short-lived and progresses to a catabolic state. At this stage, patients are at high risk for developing infections, with pneumonia being the most common.
3. The effects of the inhalation injury on the tracheobronchial tree and the lungs lead to edema, bronchospasm, and buildup of secretions. Different degrees of ARDS usually follow lung burn injury. When the burn circumferentially surrounds the chest, a mechanical constriction can develop, worsening chest and respiratory system compliance.

Specific Concerns

Burn-injured patients with an inhalation injury are at significantly increased risk for morbidity and mortality. Inhalation injury can complicate 20% of burn patients, and these patients often present with facial burns. Patients presenting with facial burns, burnt nasal hairs, soot in the oral and nasal pharynx, and any signs of upper airway burns should be immediately intubated, because serious airway obstruction developing over time is almost inevitable. On admission, it is difficult to identify characteristic radiographic features of inhalation injury. The effects become evident over time only when secondary complications such as inflammation, infection, or atelectasis develop. For this reason, the respiratory status and the airway patency of burn victims should be continuously monitored; they are at high risk for developing airway obstruction if an artificial airway is not already in place. Securing the airways as soon as possible should be the priority before catastrophic, irreversible airway obstruction occurs. One of the challenges in the respiratory care of severely injured burn patients is the clearance of copious and tenacious secretions. Secretions are accumulating throughout the tracheobronchial tree as a result of increased mucus secretion, buildup of toxic debris and necrotic cells, and peribronchial inflammatory **exudates** and **transudates**. In addition, mucociliary transport is severely impaired by disrupted tracheal-bronchial epithelium causing small airway plugs, worsening alveolar collapse, and predisposing to pulmonary infections. Optimization of airway humidification, careful ETT suctioning, and bronchoscope toilette are milestones of daily respiratory care for these particularly vulnerable patients.[45–47]

RULE OF THUMB Burn-injured patients with an inhalation injury have a significantly increased risk for morbidity and mortality.

Respiratory Management

Respiratory care of burn patients is complex. Hemodynamics, fluid resuscitation, %TBSA involvement and related injuries, time from the injury, and upper and lower respiratory conditions

are some of the key elements that the RT needs to know while caring for these patients.

Oxygen Therapy

The SaO_2 of burn patients has to be monitored continuously. Until proven otherwise, all victims rescued from a fire should be treated with O_2 for suspected cyanide and CO poisoning. Cyanide poisoning is treated pharmacologically. The RT should monitor continuously the level of MetHb in the blood, especially if cyanide is treated with nitrite donors. Methylene blue should be administered if levels of MetHb become symptomatic. CO poisoning treatment is focused on dislodging CO from the hemoglobin. Administering a high concentration of inspired O_2 through a nonrebreathing mask is mandatory in these patients because O_2 shortens the half-life of CO. When available, a hyperbaric chamber is used in the treatment of the most severely CO poisoned burn patients; CO is quickly dissociated from hemoglobin and **cytochrome oxidase**. Hyperbaric O_2 at three times atmospheric pressure reduces the half-life of CO to approximately 3 minutes, compared with 74 minutes for regular 100% O_2 through a nonrebreather mask. It also may reduce cerebral (and other organ) tissue ischemia by increasing O_2 transport in plasma to the brain.[48,49]

RULE OF THUMB Patients presenting with facial burns, burnt nasal hairs, soot in the oral and nasal pharynx, and any signs of upper airway burns should be immediately intubated, because the development of serious airway obstruction developing over time is almost inevitable.

Early Endotracheal Intubation

In these patients, early endotracheal intubation is generally recommended for four reasons: (1) protection of the airways from the risk for occlusion secondary to mucosal and interstitial edema, (2) the need for extensive pulmonary toilette by multiple bronchoscopies, (3) delivery of high fraction of inspired O_2 during CO poisoning, and (4) initiation of early lung-protective ventilation in patients at high risk for developing ARDS.

Flexible Bronchoscopy

Flexible bronchoscopy is often used in these patients for diagnostic and treatment purposes. Bronchoscopy is used in acute settings for clearance of foreign bodies from the airways, disrupted mucosa, and mucous debris that might cause hypoxemia by alveolar obstruction, collapse, and atelectasis (see Chapter 22). The copious and tenacious secretions and necrotic tissue often require multiple bronchoscopies over time. Clearance of the tracheobronchial tree has three purposes: (1) improving ventilation while avoiding $\dot{V}/\dot{Q}$ mismatch, (2) preventing bacterial overgrowth within the bloody-necrotic secretions and pneumonia, and (3) enhancing nebulized drug delivery that is commonly used in these patients (e.g., bronchodilators, antioxidants, and pulmonary vasodilators). Other uses of bronchoscopy in these patients includes inspection of injury and monitoring over time of major lesions and bronchoalveolar lavage for a microbiologic sample if pneumonia is clinically suspected.[50]

RULE OF THUMB Hyperbaric O_2 at three times atmospheric pressure reduces the half-life of CO to approximately 3 min, compared with 74 min for regular 100% O_2 delivered through a nonrebreather mask.

Active Humidification

Active humidification with heated humidifiers supplied by heated wire circuit should be used when possible. The aim of using continuous heated well-humidified ventilation is avoidance of mucus plugs in the distal airways and ETT while preventing body temperature loss.

Mechanical Ventilation

Mechanical ventilation should be titrated according to the underlying major respiratory condition of the patient (i.e., upper airway edema, lower airway injury, intoxication, ARDS, or pulmonary edema). In addition, the RT should be prepared to change ventilation management according to the rapid cardiovascular and respiratory changes of the patient's clinical course during hospitalization. A typical early pulmonary scenario is a combination of pulmonary edema resulting from the high rate of fluid infusion and distal atelectasis due to secretions and mucus accumulation. Often ARDS develops, complicating the multifactorial respiratory failure and worsening lung compliance and hypoxemia. An early protective lung ventilation approach with low V_T and high PEEP is especially advantageous in these patients. Neuromuscular blocking drugs are often beneficial to optimize low V_T ventilation (Box 30.10). In refractory hypoxemia, prone positioning and the use of inhaled pulmonary vasodilators might be considered an adjunct to respiratory treatment when feasible. The use of venovenous extracorporeal membrane oxygenation remains highly controversial in patients with extensive burns because of the risk for exsanguination. Early tracheostomy is often advocated because it improves secretion management by cough and suctioning, patient recovery by weaning from anesthetic medications, and wound care by patient collaboration.[51,52]

BOX 30.10 Mechanical Ventilation of Patients With Smoke Inhalation and Pulmonary Burns

- Mode: Pressure or volume ventilation
- Tidal volume: 4–8 mL/kg PBW
- Inspiratory time 0.6–1.0 s
- Plateau pressure: Less than 28 cm H_2O unless chest wall compliance decreased
- If compliance decreased, plateau pressure should exceed 28 cm H_2O
- Measure end inspiratory transpulmonary pressure to determine acceptable plateau pressure
- Driving pressure equal to or less than 15 cm H_2O
- Rate only limited by the development of auto-PEEP
- Minute volume to maintain normal $PaCO_2$
- PEEP 5–10 cm H_2O, unless ARDS
- FiO_2 1.0 initially because of concern for CO poisoning
- If ARDS, manage as any other ARDS patient

ARDS, Acute respiratory distress syndrome; *PBW*, predicted body weight; *PEEP*, positive end expiratory pressure.

MINI CLINI

Burn: Recognizing Hypoxemia in Patients After a Fire and Titrating Ventilation

Problem

A 55-year-old firefighter presents at the hospital with second- and third-degree burns on the front and back of the torso, on both arms and first-degree burns on the face after the successful rescue of an entire family from their burning house. The patient is 6 feet, 2 inches, and 240 lb. During transport to the hospital, he was intubated with an 8.0-mm ETT for increased shortness of breath and changes in mental status. Breath sounds are audible bilaterally. Ventilator settings are pressure support ventilation 15, PEEP 5 cm H_2O, and FiO_2 0.5. The patient's vital signs are heart rate 110 beats/min, blood pressure 90/50 mm Hg, respiratory rate 30 breaths/min, and SpO_2 98%. Endotracheal suctioning shows moderate dark/black secretions. The medical team started fluid resuscitation at a rate of 1 L/h of normal saline. An arterial line was placed in his right radial artery, and the medical team has been struggling for the past half hour in the emergency room to place a central line. His SpO_2 has declined to 92%, but the other vital signs are unchanged. What should the RT do?

Solutions

Immediately confirm ETT positioning by auscultation of bilateral breath sounds and suggest a chest X-ray to the medical team if it was not requested already. Confirm by ETT suctioning the dark/black secretions in the airways, which imply a severe inhalation burn and cyanide poisoning.

Obtain a blood gas sample as soon as possible to rule out CO poisoning and evaluate metabolic acidosis. It is imperative to perform a blood gas analysis as soon as possible in any burn patient with a TBSA greater than 25% admitted to the ED even when SaO_2 is 99% to 100%. It might be a falsely high reading because of MetHb and COHb. The blood gas analysis should include PaO_2, MetHb, COHb, $PaCO_2$, pH, anion gap, lactate, and base excess. If available, noninvasive continuous monitoring for MetHb and COHb should be applied to trend MetHb and COHb values and evaluate response to treatment.

This is a critically ill patient with extensive and severe burns with TBSA 58.5% (front and back torso, both arms, face), second- and third-degree burn, and inhalation injury with an ongoing massive fluid resuscitation requirement. Ventilator settings should be titrated according to the clinical scenario; however, the following should be recommended: (1) increase FiO_2 up to 100% until the presence of CO and cyanide poisoning has been ruled out; (2) increase minute volume ventilation, avoiding increased V_T and mean airway pressure to minimize effects of metabolic acidosis; (3) titrate PEEP by performing a best PEEP trial. This patient most likely will develop pulmonary edema due to inflammation and fluid resuscitation and ARDS due to inhalation injury.

SUMMARY CHECKLIST

- In trauma patients, careful assessment for injuries of the head, neck, upper airway, and chest should occur immediately on presentation.
- Obese patients are at significant risk for cardiovascular disease. In addition, lung volumes are generally decreased, with atelectasis and airflow limitation that can result in air trapping and auto-PEEP. High levels of PEEP are frequently required.
- Near-drowning victims frequently have aspirated foreign material and present with significant pulmonary edema and electrolyte imbalances.
- Patients with smoke inhalation and pulmonary burns require careful assessment of their airways. Any clinical signs of upper airway injury generally require immediate intubation and mechanical ventilation.
- Chest trauma frequently results in injuries that cause disruption of major vessels and the development of tension hemothorax or pneumothorax.
- All obese patients should be assessed for sleep apnea and OHS.
- Freshwater drowning frequently results in hyponatremia, hemolysis, hyperkalemia, and ventricular fibrillation. Salt water drowning frequently results in marked pulmonary edema, hemoconcentration, hypernatremia, and hypoalbuminemia.
- Respiratory assessment of burn patients should focus on percent of TBSA, degree of tissue involvement, and inhalation of toxic gases.
- In general, gas exchange abnormalities in trauma victims are a result of disruption of the chest wall and pulmonary contusion.
- In general, gas exchange abnormalities in obesity are a result of low lung volumes and the development of atelectasis.
- In general, gas exchange abnormalities in near drowning are a result of fluid shifts and the activation of inflammatory mediators.
- In general, gas exchange abnormalities in burns are a result of burns to the lung parenchyma and inhalation of foreign materials and toxic gases, specifically CO and cyanide.
- O_2 therapy is immediately indicated in the management of near drowning and pulmonary burns. Obese patients and trauma victims require O_2 therapy based on the severity of the patient's clinical presentation.
- Noninvasive ventilation is primarily indicated in the management of patients with sleep apnea, patients with OHS, and trauma patients with unstable chest walls.
- Invasive mechanical ventilation can be indicated in all four settings based on the severity of the injury.
- The primary concern during mechanical ventilation to trauma patients is the presence of a tension pneumothorax and hemodynamic instability.
- The primary concern with the application of mechanical ventilation to obese patients is the appropriate selection of V_T (based on PBW) and the appropriate application of PEEP.
- Near-drowning victims and pulmonary burn patients frequently and rapidly develop ARDS.
- In all four categories of patients, lung-protective mechanical ventilation should be used from the onset of mechanical ventilation.
- PEEP and lung recruitment maneuvers should be applied to the markedly obese patient and any patient who develops ARDS unless contraindicated. Prone positioning should be considered early in near-drowning patients and any patient

with refractory hypoxemia unresponsive to the lung recruitment maneuvers and the setting of PEEP by a decremental trial.
- Spontaneous breathing trials are the primary approach to liberation from ventilatory support for all of these patients.

Acute Heart Failure

Jacopo Fumagalli and Lorenzo Berra

CHAPTER OBJECTIVES

- To identify the epidemiology, causes, symptoms, and major therapies for acute heart failure (AHF);
- To appreciate lifesaving treatment for the most severe cases of heart failure and the role of intensive care in the treatment of these patients
- To learn to assess heart–lung interaction and realize the potential beneficial effects of ventilator therapy on the diseased cardiovascular system
- To appreciate the role of continuous positive airway pressure (CPAP) or noninvasive mechanical ventilation (NIV) as the most effective respiratory rescue therapies to treat respiratory failure during AHF
- To assess readiness and criteria for initiating CPAP and NIV, to list risk factors for failure of the latter, and to consider alternatives including invasive ventilation strategies when these rescue therapies fail
- To understand the monitoring of CPAP and NIV in patients with respiratory distress and appreciate that time at the bedside and knowledge of ventilator parameter adjustment is essential for the optimal delivery of these treatments
- To appreciate that sedation represents a therapeutic option but that it requires close monitoring.

CHAPTER OUTLINE

KEY TERMS

acute coronary syndrome (ACS)
cardiorenal syndrome
diuretic
heart failure
hypoperfusion
inotropic support
left ventricular heart failure
mechanical support
preload
pulmonary edema
right ventricular heart failure
systemic vasodilation

DEFINITION, EPIDEMIOLOGY, AND BURDEN OF CARE

Acute **heart failure** (AHF) is defined as a new onset or rapid worsening of cardiac output, leading to inadequate perfusion to meet the metabolic needs of body organs. The onset and severity of symptoms of AHF vary and depend on the nature of the underlying cardiac disease and the rate at which the syndrome develops.[1] In more economically developed countries, the most frequent cause of decompensated heart failure is myocardial infarction (MI). Between 20% and 40% of hospitalized patients with a diagnosis of MI develop AHF. The most common causes of new-onset AHF are summarized in Box 31.1.

AHF is one of the most frequent causes of unscheduled hospital admissions and high postdischarge readmission rates[2]; it is also associated with significant early and late morbidity and mortality.[3,4] A great proportion of patients admitted for AHF are diagnosed for the first time with underlying chronic HF. The 30-day mortality rate ranges from 8% to 16%, depending on patient age.

RULE OF THUMB Although primarily a cardiac disease due to inadequate blood circulation, AHF leads to a systemic disorder affecting all vital organs: the two predominant mechanisms of organ dysfunction are congestion and hypoperfusion.

PATHOPHYSIOLOGY OF ACUTE HEART FAILURE

Different classifications of AHF have been proposed based on both etiology and clinical presentation.[5] This chapter describes AHF according to the pathophysiologic characteristics that are common with any clinical cause of AHF.[6-8] AHF is responsible for a variety of symptoms that arise whenever the cardiac muscle loses its contractile force to a point where it is no longer able to maintain adequate cardiac output and blood pressure. The reduction in blood pressure triggers a catecholaminergic response aimed at improving cardiac function by increasing both the heart rate and the contractility of the remaining functional muscle tissue. Over time, both compensatory mechanisms further aggravate heart failure. Generally both the right and left ventricles are involved in the sequelae. Due to ventricular interdependence, the declining function of one ventricle may worsen the function of the other. Of note, although left ventricular dysfunction is more common, right ventricular dysfunction is predominant in patients affected by chronic lung diseases such as chronic obstructive pulmonary disease, interstitial lung disease, or pulmonary hypertension. Although AHF is primarily a cardiac disease due to inadequate blood circulation, it eventually becomes a systemic disorder affecting all vital organs. The two predominant mechanisms of organ dysfunction are congestion and **hypoperfusion**.

Congestion is the consequence of a reduced ventricular ejection fraction, which leads to increases in volume and pressure within the cardiac chambers, ventricles, atrium, and beyond.[9] Blood stasis in the venous system upstream from the failing ventricle causes increases in capillary pressure and the extravasation of plasma from the vascular space into the tissues. **Pulmonary edema** is one of the main clinical manifestations of **left ventricular AHF** (LV-AHF) and affects up to 15% of patients as the first manifestation of AHF. Increased interstitial and pleural fluid retention causes a decrease in pulmonary functional residual capacity, thus both decreasing lung compliance and increasing shunt fraction. Patients classically experience a sudden sensation of suffocation and air hunger, accompanied by extreme anxiety, cough, and the expectoration of a pink foamy liquid. As a consequence, patients place themselves in the upright sitting position and become unable to speak a full sentence. Their respiratory rate is increased, and signs of increased work of breathing are present: inspiratory retraction of the intercostal spaces and supraclavicular fossae are common. Usually inspiratory and expiratory rhonchi, wheezes, and fine crepitant rales are audible bilaterally, increasing in a craniocaudal direction. There is also hypoxemia, which may lead to an alteration of consciousness as well as signs of increased adrenergic tone (sweating, cold skin, etc.). When valvular abnormalities and/or mechanical complications after MI result in AHF, the murmurs of mitral and aortic regurgitation and ischemic ventricular septal defect are often audible. The chest x-ray may show cardiomegaly and signs of interstitial/alveolar edema.

Right ventricular AHF (RV-AHF) involves similar pathophysiologic mechanisms: venous congestion represents the main pathologic dysfunction, causing edema of the liver, splanchnic organs, and lower limbs. The size of the liver and ascites can serve as parameters for evaluating the severity and progression of RV-AHF. The presence of systemic hypoperfusion depends on the ability of the left heart to compensate for the decreased left-sided venous return. Pulmonary congestion and dyspnea are usually absent. However, due to ventricular interdependence, progressive RV failure leads to remodeling and displacement of the interventricular septum, with consequent LV diastolic and subsequent systolic dysfunction. End-stage RV-AHF causes

BOX 31.1 Causes of New-Onset Acute Heart Failure

Coronary Artery Disease
Acute coronary syndrome
Myocarditis

Acute Valve Syndromes
Acute mitral or aortic regurgitation
Thrombosed mechanical aortic or mitral valve

Progressive Valve Disease
Severe aortic or mitral valve stenosis
Severe aortic or mitral regurgitation

Cardiomyopathic States
Hypertrophic cardiomyopathy
Recent-onset dilated cardiomyopathy
Tachycardia mediated cardiomyopathy
Stress cardiomyopathy
Poorly controlled hypertension

LV-AHF, leading to biventricular failure with pulmonary edema (LV-AHF) and hypoperfusion of the distal organs (RH-AHF).

RULE OF THUMB Dyspnea secondary to *pulmonary* congestion is the main symptom in patients with LV-AHF. In patients with RV-AHF, however, *venous* congestion leads to the main symptoms of ascites, an enlarged liver, engorgement of the splanchnic organs, and edema of the lower limbs.

A rare and different clinical presentation can result from AHF due to high-output heart failure; it is commonly characterized by pulmonary congestion, tachycardia, wide pulse pressure, and warm extremities. Common causes of high-output AHF are anemia, thyrotoxicosis, advanced liver failure, and skeletal conditions such as Paget disease.

Hypoperfusion is the consequence of reduced cardiac output and of compensatory mechanisms to maintain vital organ perfusion. To cope with the reduced blood pressure due to the decline in cardiac output, the cardiovascular system increases adrenergic tone by increasing heart rate and vasoconstriction. This mounting stress on the ischemic heart causes a further increase in myocardial oxygen consumption and decreased myocardial perfusion by decreasing diastolic time and increasing myocardial wall stress (Fig. 31.1). When the heart fails to maintain adequate organ perfusion, cardiogenic shock commences, which is the most severe form of AHF. Cardiogenic shock is defined as prolonged hypotension, with systolic blood pressure (sBP) usually less than 90 mm Hg and/or a requirement for vasopressor agents to maintain sBP above 90 mm Hg in the absence of hypovolemia and signs of hypoperfusion (e.g., cold periphery or clammy skin, confusion, oliguria, elevated serum lactate).

MEDICAL MANAGEMENT OF ACUTE HEART FAILURE

In the first hours after emergency department (ED) admission, patients with AHF are at high risk for complications, including death. Indeed, patients with AHF may die in the ED before advanced treatment can be instituted in the intensive care unit (ICU).[10] Early diagnosis, triage, and the initiation of specific treatment for AHF are associated with reduced mortality as well as a shorter length of hospital stay. Rapid identification of the precipitating factor for AHF, especially if reversible (e.g., **acute coronary syndrome** [ACS]), is essential for the early initiation of specific treatments. The following stepwise approach to the management of AHF patients has been shown to be useful.[11]

RULE OF THUMB Once a diagnosis of AHF has been obtained, supportive therapies should be instituted and treatment initiated without delay.

Identifying Respiratory Distress and Hemodynamic Instability

Immediate identification of patients at higher risk of complications is associated with improved survival. Altered vital signs (heart rate, arterial pressure, respiratory rate, and peripheral oxygen saturation) together with symptoms of AHF on physical examination (respiratory distress, cool extremities, increased capillary refill time, and altered mental status) should promptly identify patients who are in need of higher-intensity care and transfer to a cardiac ICU.

Confirming the Diagnosis of Acute Heart Failure

Table 31.1 lists parameters for assessing and monitoring of heart function and hemodynamics during AHF. AHF is a clinical diagnosis based on the presence of a constellation of symptoms and signs. Respiratory fatigue is the most common cause of ED presentation in patients with AHF. Fatigue, dizziness, palpitations, and increased body weight with peripheral edema, together with decreased diuresis, are also common manifestations. Clinical examination should investigate the presence of signs of both pulmonary (increased respiratory efforts and abnormal lung sounds) and systemic congestion (increased jugular venous pressure, hepatomegaly, and peripheral edema). Signs of hypoperfusion should be sought as well (cold extremities, slow capillary refill time oliguria/anuria). A detailed history should be obtained

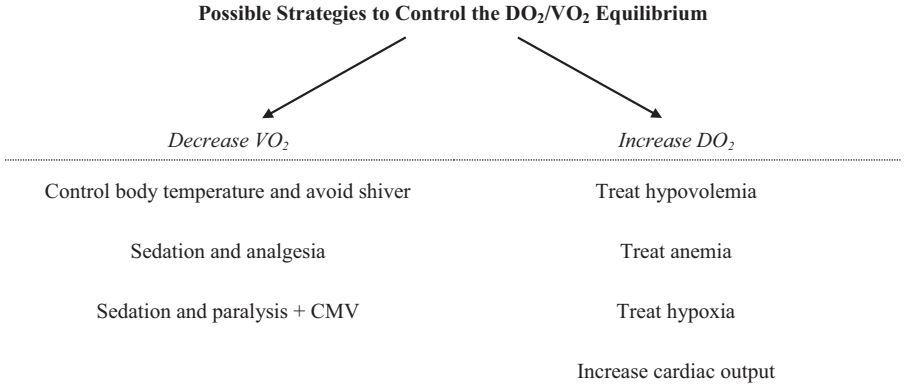

Fig. 31.1 During acute heart failure, the ultimate therapeutic goal is to maintain an energetic balance in favor of oxygen delivery *(DO_2)* versus oxygen consumption *(VO_2)*. This figure illustrates the potential therapeutic strategies aimed at improving the DO_2/VO_2 equilibrium. *CMV,* Controlled mechanical ventilation.

TABLE 31.1 Assessment and Monitoring of Heart Function and Hemodynamics During Acute Heart Failure

	Parameter	Monitoring	Explanation
Contractility	Ejection fraction	Echocardiography	Ventricular systolic emptying
	TAPSE/MAPSE		Valvular plane systolic motion
Fluid responsiveness	PPV/SVV	Arterial line	Pulse pressure/stroke volume Inspiratory excursion
Organ perfusion	Serum lactate	Blood test	Tissue anaerobic metabolism
	Urine output	Diuresis	Renal perfusion
	$SmvO_2/ScvO_2$	Central line/PAC	Tissue oxygen extraction fraction
Heart performance	Cardiac output	PAC or Calibrated pulse contour analyzers	Thermodilution
Preload	PCWP	PAC	Volumetric or pressure evaluation of cardiac preload
	GEDV	PiCCO system	
	Atrial/ventricular size	Echocardiography	
	IVC collapsibility	Echocardiography	
Afterload	SVR	CVP and mAP	Systemic and pulmonary cardiac afterload
Left ventricular	PVR	CVP and mPAP	
Right ventricular			

CVP, Central venous pressure; *GEDV,* global end-diastolic volume; *IVC,* inferior vena cava; *mAP,* mean arterial pressure; *MAPSE,* mitral annular plane systolic excursion; *mPAP,* mean pulmonary artery pressure; *PAC,* pulmonary artery catheter; *PCWP,* pulmonary capillary wedge pressure; *PiCCO,* pulse contour cardiac output; *PPV,* pulse pressure variation; *PVR,* pulmonary vascular resistance; *$ScvO_2$,* oxyhemoglobin central venous saturation; *$SmvO_2$,* oxyhemoglobin mixed venous saturation; *SVR,* systemic vascular resistance; *SVV,* stroke volume variation; *TAPSE,* tricuspid annular plane systolic excursion.

to guide the differential diagnosis: previous diagnoses of HF or prior history of coronary artery disease increase the probability of an AHF diagnosis. Plasma natriuretic peptides can be used both as adjunctive confirmation of AHF and to assess its severity. Low levels of either BNP or NT-proBNP should exclude the diagnosis of AHF; high plasma natriuretic peptides levels should identify the most severe cases.[12,13] Plasma lactate levels help to identify early cases with worsening AHF moving toward cardiogenic shock.[14]

Identifying the Causes of Acute Heart Failure

It is imperative to rapidly identify the cardiac causes of shock. A 12-lead electrocardiogram (ECG) should be obtained as early as possible. In the presence of ST-segment elevation myocardial infarction (STEMI), or non-STEMI with hemodynamic instability or persistent chest pain, transfer to the cardiac catheterization laboratory for primary revascularization is mandatory.[15]

After an ACS has been excluded, echocardiography should be done as soon as possible to exclude either cardiac tamponade or other mechanical cause of AHF and to further characterize left and right ventricular function. Pulmonary embolism should always be considered in the differential diagnosis of patients with signs of RV-AHF.

Assessing Organ Injuries

Serum troponin (T or I) levels should be obtained in any patient with possible ACS.[16] Increased levels of serum creatinine and blood urea nitrogen from before the acute event of AHF are the main criteria for the diagnosis of **cardiorenal syndrome**. In general, decreased renal function is commonly found in patients with advanced HF. Either chest x-ray or lung ultrasound can be helpful in characterizing the degree of bilateral alveolar edema. The presence of unilateral pulmonary changes should challenge the AHF diagnosis. Pleural effusion might be present but is infrequent in patients with a primary diagnosis of AHF. Liver dysfunction might be present, leading to high suspicion of right-sided heart failure. A complete blood count may help to identify the presence of infection or anemia, which may have precipitated the event.

The goal of AHF treatment is to restore adequate oxygen delivery, which is often achieved by improving perfusion pressure. Together with cardiac function and hemodynamics, distal organ function is also closely monitored. Treatment and monitoring varies according to the level of acuity and the patient's cardiac reserve. The next section of the chapter provides a detailed discussion of cardiovascular monitoring and treatment, as well as respiratory implications and treatment during AHF.

MONITORING AND ASSESSMENT OF CARDIAC FUNCTION

Monitoring of a patient with AHF is generally initiated at admission in the ED, but the level of monitoring can vary widely depending on the severity of cardiac decompensation.[17]

Hemodynamics

In the acute phase of AHF, adequate titration of vasoactive and antihypertensive drugs is commonly used to obtain adequate blood pressure and ensure coronary and distal organ perfusion while avoiding an excessive workload for the failing heart. In patients with cardiogenic shock, invasive measurement of arterial pressure is preferred. The arterial line allows obtaining serial blood gases and lactate levels to assess the effect of the

interventions performed on distal organ perfusion and oxygenation. Measurement of serum lactate levels in response to therapeutic intervention is suggested to determine improvement or worsening of tissue hypoperfusion.[18]

RULE OF THUMB The level of cardiac and hemodynamic monitoring increases according to the severity of impaired cardiac function.

Normovolemia and adequate perfusion pressure are regularly assessed. In mechanically ventilated patients, a wide variation of pulse pressure throughout a breathing cycle is considered an index of fluid responsiveness, or the heart's ability to increase cardiac output in response to a fluid load.

Unstable patients are given higher-intensity monitoring, measuring cardiac output either through a pulmonary artery catheter or other calibrated system (pulse contour cardiac output [PiCCO]). Uncalibrated systems measuring cardiac output may provide incorrect information in this setting. The measurement of cardiac output allows (1) direct measurement of the effect on cardiac performance of the therapies undertaken; (2) measurement of systemic vascular resistance, calculated as mean arterial pressure–central venous pressure divided by the cardiac output; and (3) for obtaining an estimate of cardiac **preload** either via a variation in wedge pressure or the global end-diastolic volume.[19] Fig. 31.2 exemplifies how information from advanced hemodynamic monitoring can be integrated. The use of a pulmonary artery catheter (PAC) may be indicated in patients with right heart failure to target interventions on pulmonary arterial pressure,[20,21] and the venous mixed hemoglobin oxygen saturation can be used as an index of the severity of organ hypoperfusion.[22,23] However, recent trials caution regarding the use of a PAC to determine a hemodynamic endpoint in patients with shock.[24] Whenever infusion of a vasopressor is indicated, a central venous line should be established in order to have a dedicated line for the infusion of vasoactive drugs.

Blood Tests

Serial blood tests are indicated to assess organ function—specifically hepatic and renal function. Adequate blood oncotic pressure should be maintained (serum albumin level), as should hemoglobin levels to ensure tissue perfusion and oxygen delivery.

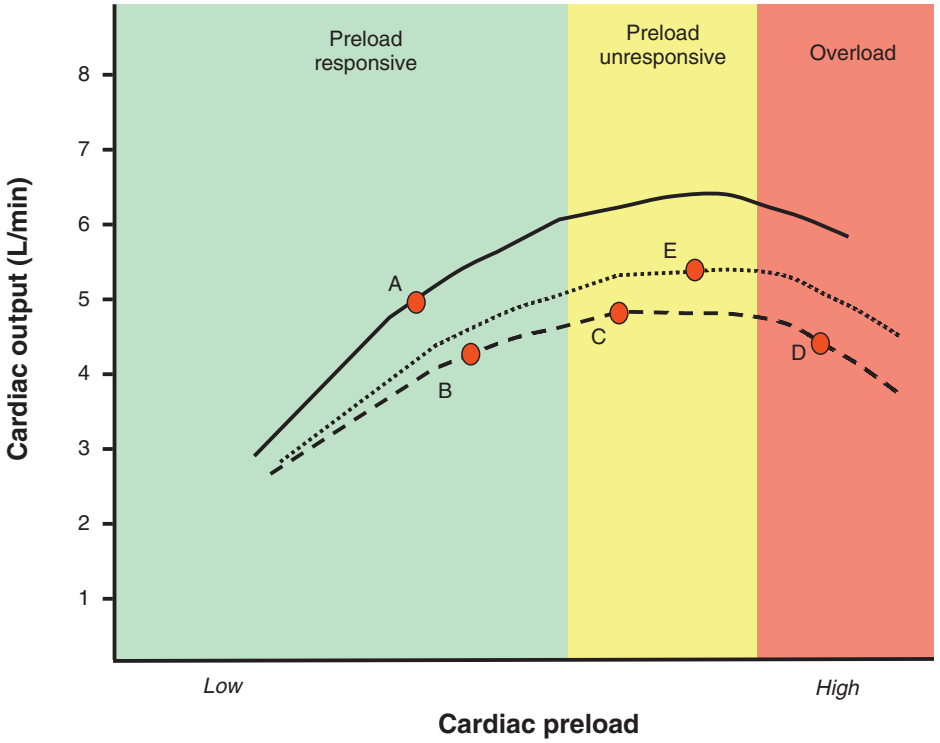

Fig. 31.2 A clinical case of acute heart failure illustrating the Frank-Starling relationship of preload to cardiac output. This figure illustrates the relationship between cardiac preload (right atrial pressure, pulmonary capillary wedge pressure, global end-diastolic volume, left ventricular end-diastolic volume) and cardiac output. The solid line represents a normally functioning myocardium *(A)*, when, despite the cause, heart function exacerbates decreases in cardiac output congestion and leads to an increase in cardiac preload *(B)*. preload increases, cardiac output may also increase *(C)* until further worsening is observed *(D)*. Various strategies *(E)* can improve heart function and decrease cardiac afterload (i.e., systemic vasodilators, intra-aortic balloon pump), decrease congestion (i.e., diuretic therapy), and improve myocardial performance (either through inotropic support or by addressing the primary heart disease). (From Guyton AC, Jones CE, Coleman TG: *Circulatory physiology: cardiac output and its regulation*, Philadelphia, 1973, W.B. Saunders.)

Whenever along the course of treatment further worsening of cardiac function occurs, an ischemic event should be suspected. In this setting, serial troponin measurements are indicated.

Monitoring of plasma electrolytes is indicated in patients receiving large-volume fluids and **diuretic** therapy: hypophosphatemia may be responsible for decreased cardiac inotropism, hypokalemia is associated with arrhythmias, diuretic therapy (particularly furosemide) may cause metabolic alkalosis, hyponatremia can occur in patients with the syndrome of inappropriate antidiuretic hormone (SIADH) due to stress, and hypernatremia is frequently seen in cases of fluid overload and secondary hyperaldosteronism.

Concurrent infections are not rare. Thus blood tests for total white blood count, C-reactive protein, and procalcitonin may be used as a guide either to trigger an infectious disease consult or the withdrawal of antibiotic therapy.

Fluid Balance and Weight Change

Because the kidneys are highly sensitive to hypoperfusion, close monitoring of a patient's diuresis is a simple but effective parameter for assessing peripheral perfusion. Diuretic therapies may represent a confounder; thus volume loss over time should be compared in similar conditions.[25]

Although the early phases of AHF are usually characterized by a positive fluid balance and increases in weight, as soon as cardiac function has improved as a consequence of therapeutic interventions, a negative fluid balance should be targeted with a progressive decrease in body weight.

Daily planning of fluid and salt input and monitoring of 24-hour urinary electrolytes and urine output should guide diuretic therapy. Transition from intravenous fluids to enteral water intake is suggested to avoid large infusions of intravenous saline solution, which favors water retention.

Electrocardiography

Daily performance of a 12-lead ECG and following any significant modification of the patient's clinical status is suggested to identify myocardial ischemia. Continuous monitoring of heart rate is required to identify cardiac arrhythmias in hemodynamically unstable patients.

Echocardiography

Noninvasive cardiac imaging obtained through both transthoracic and transesophageal ultrasound is now widely recognized as an essential exam both for monitoring cardiac function at the bedside and for the diagnosis of acute changes in cardiac performance. Due to its user-friendly characteristics, echocardiography has become a point-of-care exam available at any time at bedside in most modern hospitals.[26]

Specifically, in the case of AHF due to myocardial ischemia, echocardiography can often identify areas of reduced and/or absent wall motion and contractility in the left and right chambers of the heart. Ventricular interdependence can be investigated by analyzing the shape of the interventricular septum and its movement during the cardiac cycle.

Several parameters are usually adopted to describe heart function: first an accurate description of cardiac morphology (e.g., wall thickness, chamber size) should be reported and valvular defects or intracardiac shunt, if present, should be explored;[27] ventricular ejection fraction, defined by the ratio between the volume ejected during systole and the ventricular volume at the end of the diastole, is the parameter that is commonly used to describe cardiac systolic performance. To investigate the function of the right and the left ventricles, the tricuspid and mitral annular plane systolic excursions (TAPSEs and MAPSEs, respectively) are measured. Diastolic function is expressed as the ratio between the blood flow velocity during early passive diastole and during active atrial contraction. Whenever ventricular filling relies on the presence of atrial contraction, diastolic dysfunction is present.[28] The patient's volumetric status can also be assessed by echocardiography and analysis of variations in the inferior vena cava's diameter during the respiratory cycle. Last, during an emergency, echocardiography has a role in ruling out cardiac tamponade and pulmonary embolism.

Coronary Angiography

The direct imaging of coronary arteries represents an invasive diagnostic exam that should be reserved for cases with suspected active cardiac ischemia.[29] Some lesions identified by coronary angiography may be treated directly (reperfused) by coronary angioplasty and stent positioning. Many modern tertiary care centers have ad hoc 24/7 cardiac catheterization laboratories to guarantee the timely treatment of myocardial ischemia. Whenever intravascular treatment is not an option, the patient should be quickly referred to cardiac surgery.

Cardiac Computed Tomography and Heart Magnetic Resonance Imaging

Most modern cardiac imaging techniques, such as synchronized computed tomography or magnetic resonance imaging, have been found to have a diagnostic role in unveiling rare cardiac diseases underlying HF (i.e., myocardial amyloidosis, neoplasm) as well as in monitoring the evolution of disease (i.e., myocardial fibrosis and remodeling). However, as yet, advanced cardiac imaging has not been found advantageous in the emergent management of AHF.

Lung Imaging

Since lung function is highly sensitive to cardiac performance, congestion due to left heart failure directly determines lung interstitial edema and eventually alveolar edema. The chest x-ray (CXR) provides highly sensitive but not specific information regarding lung edema. During AHF, pulmonary edema appears as a bilateral, bibasilar (gravity dependent) infiltrate (Fig. 31.3). Although a single lung CXR might be poorly informative, a series of such x-ray images over the course of treatment is likely to be more informative.[30]

Although in the past the lung has been commonly considered "inscrutable" to ultrasound, it is now common clinical practice to take advantage of ultrasound artifacts derived from ultrasound beam interaction with lung parenchyma to measure pulmonary features. Pulmonary edema is seen on lung echography as multiple (comet tail) B-lines whose number per field of observation is proportional to the degree of lung edema.[31] Pleural effusions

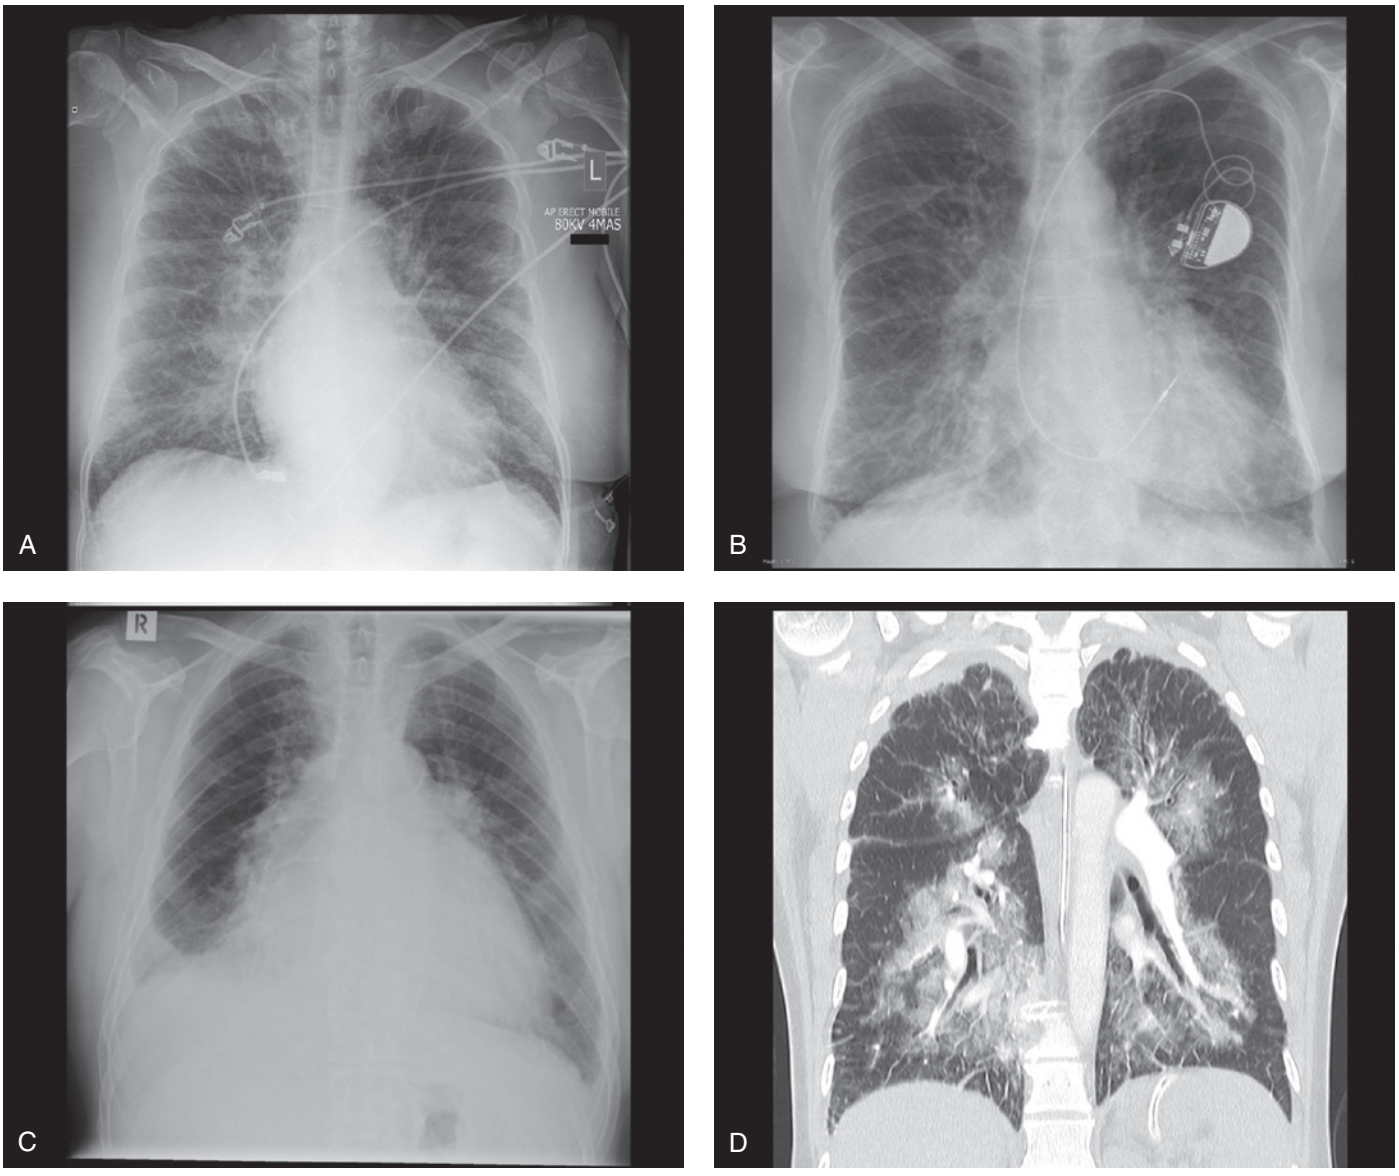

Fig. 31.3 Radiologic Images of Acute Pulmonary Edema During Acute Heart Failure. Radiography of the chest is the imaging technique most frequently used in patients admitted to the emergency department with an acute onset of dyspnea. It provides useful information to either confirm or exclude acute pulmonary edema and quantify the severity of the clinical presentation. Panel A *(upper left)* shows a mild degree of pulmonary edema characterized by increased interstitial markings throughout the lungs, vascular redistribution in the upper zone, and bilateral perihilar alveolar opacification. Panel B (upper right) is a representative case showing evidence of both interstitial (peripheral septal lines—Kerley B lines) and alveolar edema (confluent nodular opacities). Peripheral septal lines are due to thickening of the interlobular septa. It is also evident that the craniocaudal gradient in the distribution of edema is due to gravity. Panel C (lower left) is representative of bilateral pleural effusion (more pronounced in the right pleural cavity). Panels B and C are both characterized by increased size of the cardiac silhouette. Panel D (lower right) is a midthoracic chest computed tomographic image of acute pulmonary edema, which clearly illustrates the peribronchial cuffing effect. ([A] Case courtesy A. Prof Frank Gaillard," https://radiopaedia.org/cases/shenton-line-diagram. [B] Case courtesy Dr. Henry Knipe, https://radiopaedia.org/cases/acute-pulmonary-oedema-5. [C] Case courtesy A. Prof Frank Gaillard, https://radiopaedia.org/cases/acute-pulmonary-oedema-1. [D] Case courtesy Dr. Andrew Dixon, https://radiopaedia.org/cases/acute-pulmonary-oedema-on-ct.)

can be identified and easily quantified by lung ultrasound.[32] As for CXR, the degree of interstitial water retention is expected to follow a gravitational gradient; this feature helps in differentiating congestive heart failure from other causes of bilateral pulmonary infiltrates, e.g., as in acute respiratory distress syndrome (ARDS).

TREATMENT

Effective and comprehensive therapy in HF, targeting improving survival, should aim to both optimize cardiac mechanical status (decreasing preload and afterload) and prevent the excessive neurohumoral activation that can lead to myocyte dysfunction and cardiac remodeling.

In the acute setting, AHF therapy relies on the treatment of the cause of heart failure decompensation. Different pharmacologic and nonpharmacologic interventions may be adopted in order to relieve symptoms until definitive treatment can be established. Major advances in pharmacology over the past decade have decreased the mortality attributable to AHF by preventing cardiac remodeling. Most of the drugs involved are antihypertensive medications, including angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs), as well as agents used to control heart rate (i.e., β-blockers).

MINI CLINI

Acute Heart Failure: Establishing Initial Treatment in the Emergency Department

Problem

A 65-year-old man with a history of ischemic health disease is admitted to the ED for shortness of breath and chest pain. The 12-lead ECG performed during transport to the hospital showed an anterior lateral wall infarct (STEMI). On arrival at the ED the patient is in respiratory distress with preserved mental status, a respiratory rate 33 bpm, SpO_2 88%, blood pressure 135/97 mm Hg, and body temperature 36.8°C. Echocardiography confirms the presence of a hypokinetic anterolateral myocardial wall and absence of mechanical defects. An intravenous line is established to administer medical therapy (aspirin and nitrates) and to draw blood samples for lab analysis.

The ED medical team immediately transports the patient to the cardiac catheterization laboratory to perform primary angioplasty and arrange subsequent admission to the cardiac ICU for cardiac/respiratory monitoring and support. The respiratory therapist (RT) in charge is asked to set up the respiratory support necessary for the transport.

Management

On the patient's arrival at the cardiac ICU, the RT checks hiss vital signs: now SpO_2 is 93% with oxygen mask with reservoir at 10 L/min, respiratory rate is still 33 bpm, and blood pressure is 125/82 mm Hg. The RT asks for an arterial ABG, which shows respiratory acidosis (pH = 7.28 and $PaCO_2$ = 57 mm Hg). Mental status is preserved (Glasgow Coma Scale score = 15), but the patient complains of air hunger.

Noninvasive mechanical ventilation represents the first option to be tested, because oxygen therapy alone failed to relieve patient's respiratory distress and signs of respiratory failure remain present. The RT must explain to the patient that she is going to place a mask either on the patient's nose, mouth, or entire face and that communication would then be impaired but that this is necessary to improve ventilator function. An ICU ventilator is used, showing airway pressure and flow waveforms. The best-fitting interface is selected and bilevel positive airway pressure (BIPAP, or pressure support with positive end-expiratory pressure [PEEP]) is started with the following initial settings: FiO_2 60%, PEEP 5 cm H_2O, appropriate trigger level, pressure support 10 cm H_2O, and cycling-off criteria 40% of peak inspiratory flow. The rise time should be set as rapid as possible but avoiding airway pressure overshoot at the onset of inspiration. Expiratory flow should be checked to detect the presence of auto-PEEP. Air leakage should be addressed by adjusting mask fit, and/or inspiratory pressure or inspiratory ramp may decrease leak. After a few minutes of adaptation to the new ventilatory settings, vital signs should be checked and patient comfort and relief of air hunger assessed. Tidal volume and asynchrony should be monitored. It is essential to have the RT's assistance throughout transport and catheterization lab procedures to ensure the detection of problems and proper adjustment of ventilator settings. Continuous SpO_2 monitoring is mandatory.

PHARMACOTHERAPY

Vasodilators

The rationale for using **systemic vasodilation** during AHF is to decrease cardiac afterload by lowering systemic vascular resistance and reducing ventricular filling pressure by decreasing cardiac preload. In patients with mitral regurgitation (possibly due to left atrial dilation), lowering left ventricular afterload further favors effective stroke volume.

Hydralazine acts as a vasodilator by causing direct arteriolar smooth muscle relaxation; it demonstrates a benefit particularly in African-American patients.[33]

Nitrates, by releasing nitric oxide, act as both venodilators (at low doses) and arteriodilators (at higher doses), thus reducing cardiac preload and afterload.[34] Nitrate therapy represents an option particularly in the ED setting, given its rapid onset of action and effective improvement symptoms.[35] However, nitrates are contraindicated in cases of shock (sBP <90 mm Hg) and in patients with a history of clinically relevant mitral or aortic valvular stenosis. Caution should also be used in patients with suspected right ventricular failure due to the risk of reducing coronary perfusion pressure.[36]

Sodium nitropusside is a potent vasodilator with an extremely short half-life; this is useful in modulating of systemic vascular resistance in the critical care setting. A relevant side effect of sodium nitroprusside infusion is the generation of methemoglobinemia, the oxidized form of hemoglobin, which cannot transport oxygen and cyanide compounds. Use of sodium nitropusside should be limited to 24 to 48 hours to avoid methemoglobinemia.

Selective pulmonary vasodilators (i.e., inhaled nitric oxide) are indicated in selected cases of severe acute right ventricular failure due to pulmonary hypertension.[37,38]

The classes of drugs associated with the greater survival benefit in patients with cardiac failure are the ACEIs and ARBs.[39,40] Both these classes of antihypertensive drugs act by blocking the action of angiotensin II, a potent endogenous vasoconstrictor, either by lowering the production of angiotensin II or preventing its binding at the receptor site. An oral ACEI/ARB should be started once the patient is hemodynamically stable and without signs of acute kidney injury. Because initiation of these therapies is known to improve outcomes, it is recommended to start them prior to hospital discharge.

Similar to ACE inhibitors, β-blockers lower the action of catecholamines on myocardial tissue; they have been proven to reduce HF mortality regardless of the stage of disease.[41-43] By decreasing heart rate, β-blockers allow a slower relaxation, thus reducing diastolic dysfunction and increasing the time during which coronary perfusion occurs. However, they should be used cautiously, particularly in the acute phase of HF, where they have been documented to increase the risk of worsening the patient's clinical status. In patients on β-blocker therapy prior to hospitalization, withdrawal of therapy is indicated only if hemodynamic instability is present. Starting β-blocker therapy is suggested at low dosages and once euvolemia has been achieved.

Diuretics

Cardiorenal syndrome is present in 10% to 30% of patients with AHF,[44] and the severity of organ dysfunction indicates which

therapeutic approach would be most beneficial. Diuretics are frequently needed in the acute phase of AHF, and renal replacement therapy represents the ultimate therapeutic option, which may be needed in most severe cases.[45,46]

In patients with signs of congestion, administration of a challenge dose of diuretics should be attempted. Furosemide is the first-choice drug because of its venodilator and diuretic effects. Immediate symptom relief might be achieved by decreasing respiratory fatigue. The onset of diuresis typically occurs within 30 minutes, with peak diuresis achieved usually by 1 to 2 hours after intravenous administration. Repeated doses of furosemide should be carefully monitored to avoid rapid fluid and electrolyte shifts; in particular, levels of K^+ and Mg^+ should be monitored.[47] Continuous infusion of furosemide can be attempted to obtain a progressive fluid loss with a maximal dose of 800 mg over 24 hours.[48,49]

Vasopressin receptor antagonists have been proposed as adjunctive therapeutic options in patients with fluid overload and hyponatremia (serum Na^+ <120 mmol/L) despite water restriction and diuretic therapy.[50] The use of vasopressin receptor antagonists should be restricted to hospitalized patients, the duration should be time-limited, and, the drug should be avoided in patients with concomitant liver disease.

Randomized trials have demonstrated that spironolactone, an aldosterone antagonist with natriuretic properties, reduces mortality when included in the long-term management of selected patients with systolic HF while carefully monitoring serum potassium and renal function.[51-53]

Vasopressors and Inotropes

Inotropic and vasopressor support is indicated in patients with cardiogenic shock in order to support myocardial function and improve tissue perfusion. Intravenous inotropic agents such as dobutamine and/or milrinone may be required as temporizing measures in patients with severe left ventricular systolic dysfunction and low-output syndrome with diminished peripheral perfusion and end-organ dysfunction.[54] Duration of inotropic/vasopressor therapy should be limited to the shortest time required and its effects should be closely monitored until definitive therapy (e.g., coronary revascularization, mechanical circulatory support, or heart transplantation) is instituted or the acute precipitating problem has been resolved.

RULE OF THUMB Inotropic and vasopressor therapy should be guided by accurate assessment of cardiac preload and afterload together with the monitoring of cardiac function.

Among the available drugs, the two most commonly used are milrinone and dobutamine.

Milrinone is a phosphodiesterase inhibitor that increases cardiac contractility by increasing the concentration of cytosolic cyclic adenine monophosphate and decreases both afterload and preload by acting on the cyclic-guanosine monophosphate–nitric oxide pathway.[55] Because it does not act directly on β-receptors, milrinone is also efficacious in patients receiving β-blockers. The use of milrinone during AHF has been associated with an increased incidence of prolonged hypotension and atrial arrhythmias.[56]

Dobutamine is a sympathomimetic drug that increases cardiac inotropism by acting on the cardiac β1 receptors; it also causes modest vasodilation via β2 agonism.[57]

Other Drugs and Common Combinations of Drugs[58]

Levosimendan is a calcium-sensitizing agent with a duration of action of 24 hours after the drug is administered.[59] A patient-tailored approach aimed at maximizing organ perfusion may combine the inotropic effect of dobutamine/levosimendan and perfusion pressure optimized by concurrent norepinephrine infusion, to increase peripheral tone mediated by norepinephrine α1 agonism. Although dopamine has been proposed as a potential therapeutic agent combining both inotropism and vasoconstriction, it has become less popular due to its arrhythmogenic effect and the variability of patient response.[60]

Digoxin therapy represents a further therapeutic option that has been shown to decrease HF symptoms and hospitalization, thus improving quality of life but without a benefit in mortality.[61] Digoxin acts by inhibiting the Na-K-ATPase pump, thus reducing the intracellular concentration of sodium and increasing the gradient for intracellular calcium influx. The rise in intracellular calcium concentration increases myocyte contractility and contributes to digoxin's hemodynamic, neurohumoral, and electrophysiologic effects. Digoxin is not indicated for the primary stabilization of patients with an acute exacerbation of HF or whenever ejection fraction is preserved. Due to its narrow therapeutic range, careful titration is mandatory.

As discussed previously, continuous monitoring of the hemodynamically unstable patient is a cornerstone of the care of these patients. At the same time, continuous monitoring allows appropriate initiation, titration, and weaning of medications. For example, a worsening of cardiac output during inotropic therapy might be due to occlusion of the left ventricular outflow tract during systole; echocardiographic visualization of the left ventricular outflow tract enables the clinician to exclude the presence of dynamic obstruction.

Antiarrhythmic Treatment

Cardiac remodeling occurring in AHF, regardless of the baseline disease, can cause alterations in both the generation of cardiac pacing and in the conduction of electrical impulses through the myocardium. This pathophysiologic mechanism represents the substrate explaining the high incidence of malignant arrhythmias in AHF patients. Unfortunately, most of the pharmacologic agents available to either treat or prevent arrhythmic events have a negative inotropic effect, which limits their utility.[62]

In patients affected by diastolic dysfunction, the loss of an atrial contribution to ventricular preload severely decreases stroke volume. Atrioventricular resynchronization should be pursued either by pharmacologic or electrical cardioversion or catheter ablation.[63,64] Whenever the atrioventricular conduction system is irreversibly damaged, the positioning of a totally implantable pacemaker should be considered to guarantee an adequate heart rate and obtain atrioventricular synchronization.[65]

Anticoagulation

Venous thromboembolism prophylaxis—either mechanical (intermittent compression devices) or pharmacologic—is indicated in critically ill hospitalized patients due to the high risk for pulmonary embolism.[20] Specific indications for systemic anticoagulation, such as atrial fibrillation or previous thromboembolism, should be considered.

RULE OF THUMB Mechanical cardiovascular support devices represent either a bridge to transplantation or a destination therapy.

ALTERNATIVE INTERVENTIONS (OTHER THAN PHARMACOTHERAPY)

Mechanical Treatment

When medical therapy fails, **mechanical support** options such as the intra-aortic balloon pump, extracorporeal membrane oxygenation (ECMO), and ventricular assist devices (VADs; Fig. 31.4) should be considered.

The intra-aortic balloon pump is a long (approximately 15 cm) intravascular balloon introduced percutaneously and positioned in the midthoracic descendent aorta. The device is synchronized with the cardiac cycle and inflates during diastole, favoring coronary perfusion and further enhancing perfusion pressure and blood supply to distal organs. Deflation during late diastole causes a "vacuum effect," which decreases left ventricular afterload. Despite the pathophysiologic rationale, the application of an intra-aortic balloon pump during AHF shows a varying degree of success and is not currently recommended.[66,67]

Venoarterial extracorporeal membrane oxygenation (VA-ECMO) and VADs represent two possible alternatives designed to bridge patients either to recovery or to definitive treatments such as transplantation.[68-72] VA-ECMO (see Chapter 51 for details) is particularly indicated in cases of combined left and right ventricular heart failure. VADs are implantable mechanical pumps that help to pump blood from the ventricular to either the systemic or pulmonary circulation. VADs can be specifically left ventricular devices, right ventricular devices, or both. However, the most common type are the left ventricular VADs. Implantation of VADs and VA-ECMO should be done only in highly specialized centers due to the high level of care these procedures and these patients require.[73]

Surgical Treatment

A cardiac surgical consult should be obtained in all AHF patients with any of the following:

Presence of AHF secondary to coronary artery disease.

Presence of mechanical defects either due to valvular disease or wall/papillary muscle rupture requiring valvular repairs.

Requirement for miocardiectomy (i.e., the removal of part of the myocardium in hypertrophic disease)[74] and cardiomyoplasty (i.e., the transposition of an electrified skeletal muscle to surround the heart). Both treatments are potential interventions that are still being studied.

Candidates for heart transplant. The major limiting factors for the performance of cardiac transplantation are as follows: the shortage of suitable organs; management of the preoperative evaluation of the candidate for transplantation; the surgical procedure; and the postoperative follow-up, involving a multidisciplinary highly trained staff. Heart transplantation dramatically improves the quality of life of these patients, with a 5-year survival of about 70%. A survival longer than 20 years after heart transplantation has frequently been reported.[75]

MINI CLINI

Postcardiac Surgery Respiratory Failure

Problem

A 55-year-old obese (45 kg/m body mass index)[47] patient with history of unstable angina undergoes coronary bypass surgery for three-vessel disease. The procedure is performed on cardiopulmonary bypass in the absence of mechanical ventilation. When the cardiopulmonary bypass is removed at the end of surgery, the patient requires high doses of epinephrine (0.1 μg/kg per minute) to ensure adequate arterial blood pressure. Due to her hemodynamic instability, the patient remains sedated and intubated and is transported to the cardiac ICU.

Management

At arrival in the ICU, mechanical ventilation was set in volume-controlled ventilation 8 mL/kg ideal body weight, PEEP of 5 cm H_2O, respiratory rate of 12 breaths per minute, and FiO_2 100%. With this setting, the arterial blood gas analysis revealed profound hypoxemia (PaO_2 of 65 mm Hg) with modest mixed respiratory and metabolic acidosis (pH 7.32, pCO_2 of 48 mm Hg, and base excess of –6). The CXRs showed bilateral lung opacities. Due to worsening hemodynamic function (increasing adrenaline dosage with unstable arterial pressure levels), emergency transthoracic echocardiography was performed, showing a normally functioning left ventricle and dilated and hypocontractile right ventricle. A pulmonary artery catheter was placed in order to obtain a continuous measurement of right heart function. Cardiac output was 3.2 L/min, right atrial pressure was 15 mm Hg, pulmonary artery pressure was 42/24, and the pulmonary capillary wedge pressure was 10 mm Hg. Calculated pulmonary vascular resistance was about 500 dyne•s/cm^5. Recent surgery discourages the start of a VA-ECMO support due to the anticoagulation levels required, and medical management is preferred. Inhaled nitric oxide is started at 20 ppm while monitoring the levels of methemoglobinemia. Immediate improvement of hemodynamics is observed, with a drop in pulmonary artery pressure levels to 33/18 mm Hg, and cardiac output improved at 4.3 L/min with a slight increase in pulmonary capillary wedge pressure (PCWP) of 12 mm Hg. Derived peripheral vascular resistance (PVR) is now about 205 dyne•s/cm^{-5}. However, profound hypoxemia did not resolve with a modest increase in PaO_2 83 mm Hg at a FiO_2 70% (PaO_2/FiO_2 = 118 mm Hg). High levels of driving pressures (22 cm H_2O) were measured despite a reduction of tidal volume to 6 mL/kg ideal body weight to ensure protective mechanical ventilation: plateau inspiratory pressure was 27 cm H_2O and respiratory system compliance was 25 mL/cm H_2O. Lung ultrasound evidenced bilateral dependent lung consolidations with modest edema (according to the number of B-lines per field of observation). A lung recruitment maneuver was performed while carefully monitoring hemodynamic parameters, and a decremental PEEP trial identified PEEP at 15 cm H_2O associated with best respiratory system compliance (44 mL/cm H_2O). Oxygenation dramatically improved (PaO_2/FiO_2 = 277 mm Hg), allowing progressive weaning of FiO_2. Despite higher levels of intrathoracic pressure pulmonary vascular resistance did not increase, and hemodynamic stability improved, allowing the weaning of epinephrine.

Device	Mechanism	Schema	Duration
IABP A	Counterpulsation		Days
VA-ECMO B	CBP		Days-Weeks
VAD (LVAD and BiVAD) C			Days-Weeks
Short Term

RESPIRATORY SUPPORT AND MONITORING DURING ACUTE HEART FAILURE

Respiratory Pathophysiology of Acute Heart Failure

The failing heart tries to compensate for reduced cardiac output by increasing end-diastolic ventricular volume in order to increase myocardial contractility; when the compensatory mechanisms are exhausted, ventricular end-diastolic pressure rises, causing venous congestion in the pulmonary capillary system.[76] The main mechanism demonstrated to produce respiratory failure during AHF is a rapid increase in pulmonary capillary hydrostatic pressure and transvascular fluid filtration that exceeds the lymphatic interstitial drainage capacity, producing lung interstitial edema and alveolar flooding.[77] Two different mechanisms might be postulated to cause the increase in pulmonary artery occlusion pressure: (1) reduction in left ventricular compliance as a consequence of either left ventricular wall stiffening or ventricular compression (enlargement of the right ventricle, which compresses the left ventricle) and (2) left ventricular engorgement.[78] Pulmonary congestion results in a reduced functional residual capacity, increased intrapulmonary shunt, reduced lung compliance, and reduced distal airway diameters, resulting in increased airway resistance. Hypoxemia enhances the respiratory drive, which—together with the reduced lung compliance and the increased airway resistance—increases the energy demand of the respiratory muscles and increases oxygen consumption. Furthermore, the increased negative intrathoracic pressure negatively impacts left ventricular function by increasing left ventricular transmural pressures and thus left ventricular afterload.[79]

Ventilatory Support as Part of the Treatment of Right and Left Acute Heart Failure

The main goal of respiratory support in a patient with AHF is to increase oxygen availability and decrease work of breathing while the underlying cause of heart failure is treated. In patients with AHF admitted to the ED, oxygen therapy is the most common treatment to increase arterial oxygen content. Noninvasive ventilation (NIV), however, has further benefits for both the cardiovascular and respiratory systems.[80,81] Continuous positive airway pressure (CPAP) decreases left and right ventricular preload by increasing the gradient between peripheral venous pressure and intrathoracic venous pressure.[82] Furthermore, increased intrathoracic pressures decrease left ventricular afterload by reducing systolic wall stress.[83]

RULE OF THUMB The main goal of respiratory support in a patient with AHF is to increase oxygen availability and decrease work of breathing while the underlying cause of heart failure is treated.

Special attention should be paid to cases of predominant right ventricular failure where the application of a PEEP might worsen right heart performance due to an increase in pulmonary vascular resistance. A drop in systemic blood pressure after the initiation of NIV should prompt immediate intervention to adjust the CPAP level. The benefit for the respiratory system from the application of CPAP is attributable to the recruitment of collapsed alveoli, the dam-like effect of the positive intra-alveolar pressure against further alveolar edema, and avoidance of the development of negative intra-alveolar pressure during pronounced respiratory efforts. When an inspiratory pressure support is added during NIV (BIPAP), a further reduction of patient work of breathing may be obtained.[84] For this reason, BIPAP should be considered as first-line therapy in patients with exhausted respiratory reserve and hypercarbia.[85] On the other hand, CPAP is indicated in patients with pulmonary edema and hypoxemia but without hypercarbic respiratory failure. It is always necessary to test different NIV modalities and adjust ventilator settings to avoid the risk of patient–ventilator asynchronies.[86] The early application of both CPAP and BIPAP during acute respiratory failure due to cardiogenic pulmonary edema accelerates the improvement of PaO_2/FiO_2, resolution of hypercarbia and dyspnea; it also reduces respiratory rate and decreases the risk for endotracheal intubation.[87] The effects of NIV on outcome are not definitive.[88,89] Medical management is the key to sustained reversal of the acute respiratory failure. High-flow nasal cannula (HFNC) has recently gained popularity due to a demonstrated reduction of respiratory distress in patients with acute respiratory failure.[90] HFNC provides high-flow humidified air (with adjustable FiO_2) with a low-discomfort interface for the patient. The hypothesized benefit of HFNC is attributable to the generation of a minimal PEEP level (2 to 4 cm H_2O, when the mouth is closed) and to the reduced anatomic dead space by washout of the CO_2 in the upper airways. However, in the setting of AHF, **HFNC is *not indicated*** because higher levels of PEEP are needed to obtain its beneficial cardiovascular and respiratory effects.[91] Risk factors for NIV failure are listed in Box 31.2.

RULE OF THUMB Hemodynamic effects of respiratory support should always be considered if the patient's hemodynamic status worsens after the institution of respiratory support; potential mechanisms such as reduced cardiac preload, increased patient distress due to patient–ventilator asynchrony, or right as opposed to left heart failure should be considered.

BOX 31.2 Risk Factors for Noninvasive Ventilation Failure

Prior to initiation of NIV
- Diagnosis of lung infection
- Altered mental status
- Hypotension
- Copious and thick secretions
- Respiratory rate >40 bpm
- Severe impairment of PaO_2/FiO_2

At initiation of NIV
- Inappropriate ventilator settings
- Poorly fitting or poorly accepted patient-ventilator interface
- Patient-ventilator asynchrony

During NIV treatment
- No reduction in respiratory rate
- No improvement in pH, carbon dioxide, or oxygenation levels
- Signs of excessive respiratory effort or persistent fatigue
- Neurologic impairment
- Worsening of underlying disease

NIV, Noninvasive ventilation; *bpm,* breath per minute; *PaO_2/FiO_2,* arterial partial pressure of oxygen to inspiratory oxygen fraction ratio.

BOX 31.3 Criteria for Endotracheal Intubation During Acute Heart Failure

- Cardiac or respiratory arrest
- Altered mental status and need to protect the airway
- Progressive worsening of pH, $PaCO_2$, or PaO_2 during NIV
- Signs of fatigue despite optimization of NIV settings
- Persistent hemodynamic instability
- Agitation or intolerance to NIV with progressive respiratory failure

NIV, Noninvasive ventilation; *$PaCO_2$,* arterial carbon dioxide partial pressure; *PaO_2,* arterial partial pressure of oxygen.

Invasive mechanical ventilation should be reserved for the most acutely ill patients (Box 31.3).[92] Despite the risks associated with invasive mechanical ventilation (pulmonary infections, sedation, and the need for a critical care environment), the two main clinical reasons for initiating controlled mechanical ventilation are (1) to reduce oxygen consumption by abolishing spontaneous ventilation and (2) to take control of the patient's respiratory effort by preventing self-inflicted lung injury and excessive left ventricular afterload.

Titration of Ventilatory Support During Acute Heart Failure

The patient–ventilator interface is of critical importance when noninvasive respiratory support is initiated; different devices should be available and tested if necessary (see Chapter 50 for details). Skin protection and active heated humidification are mandatory to enhance patient compliance with respiratory therapy. When either CPAP or BIPAP is being delivered, the ventilator should allow the patient to generate up to 80 to 100 L/min of inspiratory flow to avoid drops in airway pressure throughout the respiratory cycle. Initiation of respiratory support is a critical moment: time and careful detailed communication are essential to explain to the patient the treatment and the actions that will be undertaken. Air leakage should be minimal, less than 0.4 L/s. It is advisable to start with low-level PEEP (3 to 5 cm H_2O or less, depending on the patient's initial tolerance) and inspiratory pressure support for NIV (3 to 5 cm H_2O or less, depending on the patient's initial tolerance). PEEP should then be slowly increased to 8 to 12 cm H_2O during CPAP based on patient tolerance or to lower levels of 6 to 8 cm H_2O during BIPAP. With BIPAP, the pressure support level should be titrated to obtain a tidal volume of 6 to 7 mL/kg ideal body weight. FiO_2 should be adjusted to obtain and maintain SpO_2 more than 92%[10] while avoiding hyperoxia.[93] Trigger sensitivity, inspiratory ramp, and cycling-off criteria should be titrated according to patient comfort and to avoid patient–ventilator asynchrony. Due to their respiratory distress, AHF patients usually seem to prefer high inspiratory peak flow and short inspiratory times. Intubation and pharmacologic sedation should be considered as a therapeutic option once ventilator settings have been optimized and the patient is still unable to adapt to ventilatory support. In most severe cases of pulmonary edema requiring ECMO, treatment for both cardiac and lung support, esophageal manometry can provide information on both chest wall compliance (possibly decreased due to tissue edema) and the level of PEEP required to overcome the increased lung weight.[94,95]

Close monitoring of patients undergoing NIV is necessary to ensure success of the therapy.[96] Reduction of respiratory rate and distress (dyspnea, accessory muscle use, abdominal paradoxical breathing) are the hallmarks of a successful treatment. Instead, worsening of patient's mental status and persistent respiratory distress should be immediately considered as a treatment failure and endotracheal intubation promptly performed. Monitoring the patient's respiratory drive ($P^{0.1}$ = negative inspiratory pressure developed within the first 100 ms against an occluded airway) and the patient's inspiratory effort (pressure muscle index [PMI], or inspiratory pressure developed by the patient during assisted breathing[97]), help in the early identification of patients requiring higher levels of sedation and assistance through controlled mechanical ventilation. Continuous monitoring of SpO_2 and the repeated measurement of arterial blood gases can help to tailor respiratory support. Respiratory parameters should be recorded over time, and alarms should be set carefully (apnea or high respiratory rate, low/high minute ventilation, high/low airways pressure) in order to rapidly identify a change in patient status. Visual inspection of the flow and pressure waveforms on the ventilator is recommended to detect asynchronies.

RULE OF THUMB[8] At 60–90 minutes after NIV initiation, increases in respiratory rate, $PaCO_2$, patient discomfort, and serum lactate help to identify NIV failure.

Similar to the initiation of respiratory support in AHF patients, withdrawal of respiratory support should occur as the AHF comes under control. In patients requiring either noninvasive or invasive mechanical ventilation for a period longer than 24 hours, the weaning process should be carefully monitored. Progressive lowering of inspiratory support first followed by FiO_2 and then PEEP is recommended. Once a minimal support level has been reached (FiO_2 40% and PEEP of 5 cm H_2O), a spontaneous breathing trial should be attempted. Most critical patients might deserve a transition to HFNC once FiO_2 is ≤40% and flow is ≤10 L/min using standard oxygen masks/cannulas.[98,99] Care should always be exercised during the removal of ventilatory support, as abrupt or too rapid an interruption of ventilatory support can lead to a sudden increased left-ventricular workload and a new onset of AHF.[78]

SUMMARY CHECKLIST

- AHF is defined as a new onset or increasingly rapid reduction of cardiac output leading to inadequate perfusion of the body's organs, thus failing to meet their metabolic demands.
- Between 20% and 40% of hospitalized patients with a diagnosis of MI develop AHF.
- The two predominant mechanisms of organ dysfunction are congestion and hypoperfusion.
- The goal of AHF treatment is to restore adequate oxygen delivery, which is often achieved by improving perfusion pressure.

- Critical to the management of the AHF patient is the monitoring of cardiovascular and respiratory function. The level of monitoring increases with the severity of cardiac impairment.
- In the acute setting, AHF therapy relies on treatment of the cause of the decompensated cardiac function.
- Primary pharmacotherapy for AHF includes oxygen, vasodilators, diuretics, vasopressors, inotropes, antiarrhythmics, and anticoagulants.
- Patients with severe acute right heart failure may require mechanical support with intra-aortic balloon pumps, VAD, and extracorporeal membrane oxygenation.
- Surgical treatment may be necessary if the AHF is due to coronary artery disease, valvular disease, or papillary muscle rupture.
- Patients with severe left-sided heart failure develop acute pulmonary edema.
- The primary goal of ventilatory support in AHF is to increase oxygen availability and decrease work of breathing while the underlying cause of heart failure is treated.
- Noninvasive ventilation in the form of CPAP is first-line treatment for acute pulmonary edema; however, in patients who also have severe right-sided heart failure, the increased intrathoracic pressure may worsen right heart performance due to an increase in pulmonary vascular resistance.
- CPAP should be set at 8 to 12 cm H_2O with the FiO_2 adjusted to prevent hyperoxia (SpO_2 >92% but <97%).
- Invasively ventilated patients should be managed with a lung-protective ventilatory approach ensuring the careful titration of PEEP.

Lung Cancer

Peter J. Mazzone and Hilary Petersen

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the epidemiology of lung cancer in the United States, particularly current trends.
- Identify risk factors for lung cancer.
- State the classification of lung cancer types and the cellular features of the four common types of lung cancer.
- Describe our current understanding of the pathophysiology of lung cancer.
- Identify the clinical features of the common types of lung cancer.
- Describe the diagnostic approach to lung cancer.
- State the importance of proper staging for lung cancer.
- Describe the treatment and outcomes for the common types of lung cancer by stage.
- State the role of the respiratory therapist in managing patients with lung cancer.

CHAPTER OUTLINE

KEY TERMS

adenocarcinoma
chemotherapy
computed tomography
flexible bronchoscopy
large cell carcinoma
magnetic resonance imaging
mass
nodule
non–small cell carcinoma
Pancoast syndrome
paraneoplastic syndrome
positron emission tomography (PET)
radiotherapy
screening
small cell carcinoma
squamous cell carcinoma
staging system
surgical resection
tumor, node, metastasis (TNM) staging
transbronchial needle aspiration
transthoracic needle biopsy

Lung cancer is a major public health problem. In the United States, approximately 25% of cancer deaths are caused by lung cancer.[1] Most of these deaths could be avoided if people did not smoke tobacco-related products; however, worldwide, tobacco consumption has not been declining, suggesting lung cancer will remain an epidemic for years to come. Advances in early detection and treatment have been slow but steady. The overall prognosis remains poor, with just over one in six lung cancer patients still living 5 years after diagnosis. This chapter provides an overview of lung cancer for the respiratory therapist (RT).

EPIDEMIOLOGY

New Cases

In 2018, an estimated 234,030 new cases of lung cancer were diagnosed in the United States.[1] Lung cancer is the second most frequently diagnosed cancer in men and women. The incidence of lung cancer peaked in men in 1984 and has since been declining; however, in women, the incidence increased during the 1990s, with a leveling off toward the end of the decade. These trends parallel the smoking patterns of men and women.[1] The World

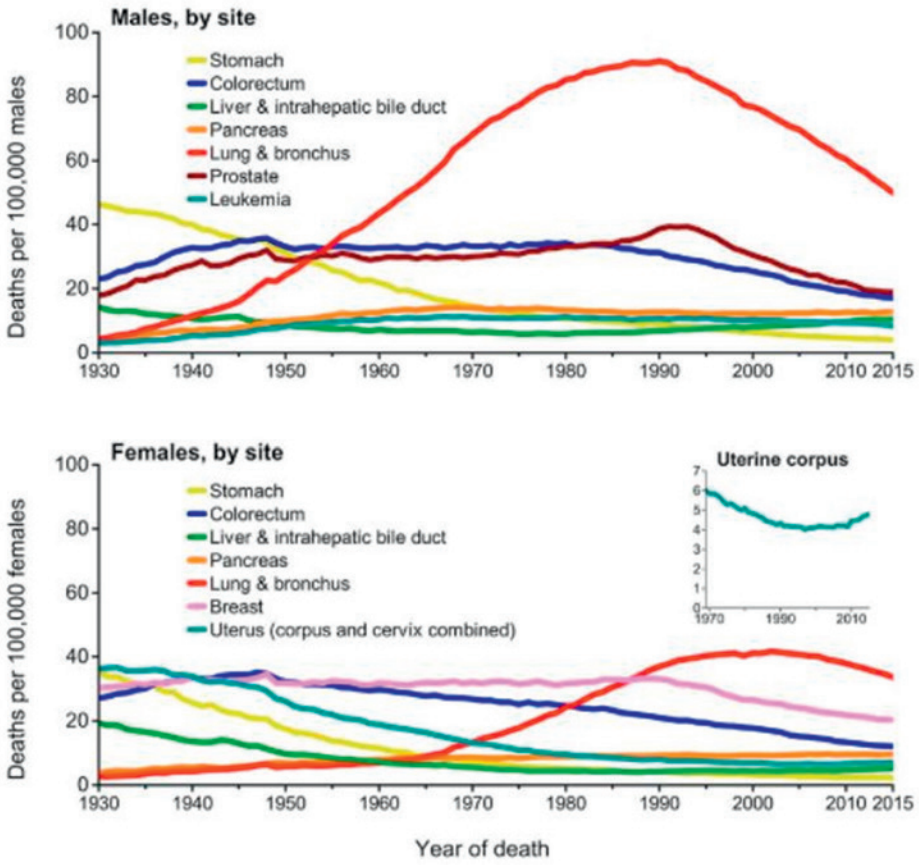

Fig. 32.1 Death Rate From Lung Cancer by Gender From 1930 to 2015. (Modified from Siegel R, Miller K, Jemal A. Cancer statistics, 2018. *CA Cancer J Clin.* 2018;68(1):7–30.)

Health Organization estimates that there are 2 million cases of lung cancer worldwide each year.

Deaths

Lung cancer is the number one cause of cancer-related death in men and women (Fig. 32.1), surpassing colon cancer in the early 1950s in men and breast cancer in the late 1980s in women. There are more deaths from lung cancer than breast, colon, and prostate cancer combined. Mortality rates in men declined significantly in the 1990s, whereas a slow increase occurred in women; these rates parallel the smoking patterns of men and women. In 2018, in the United States, an estimated 154,050 deaths were caused by lung cancer. In men, lung cancer is the leading cause of cancer-related deaths from age 40 years to the end of life, and in women, lung cancer surpasses breast cancer in the age group 60 and older.[1]

Tobacco-Related Products

Direct exposure to tobacco has occurred in 85% to 90% of individuals with lung cancer, and many tobacco-related carcinogens have been identified. The age at which smoking began, the number of cigarettes smoked per day, and the duration of smoking all influence the likelihood of developing lung cancer. Furthermore, the intensity of smoking, the depth of inhalation, and the composition of the cigarette influence the risk. All types (see later) of lung cancer are associated with smoking, with the strongest associations being with two of the cell types: *small cell* and *squamous cell carcinoma*. The risk for developing lung cancer decreases over time after smoking cessation, although it never reaches that of a lifelong nonsmoker.

There is evidence that *nicotine,* a chemical in tobacco, is highly addictive.[2] Approximately one-fifth of all adults in the United States smoke cigarettes. Progress had been made in the fight against cigarette use; in the decades from 1970 to 1990, the percentage of women who smoked declined from 33% to 25%, and the rate of smoking among men decreased from 43% to 28%. The annual decline that had occurred since the early 1970s began to slow through the 1990s despite mounting evidence associating smoking with disease and death.[3] In addition, smoking prevalence remains high in vulnerable populations (e.g., lower socioeconomic status, lower education attainment) and among sexual minorities. Cigarette smoking and other tobacco use among young people is also a major public health concern. Of young adults (18 to 24 years), 19.6% have been reported as current users of tobacco products, and 8.9% of youths (12 to 17 years) reported use within the past 30 days. In the context that a person who has not started smoking as a teenager is unlikely ever to become a smoker, the tobacco industry has focused on young people and developing countries as the primary sources of new customers.[4]

Other forms of exposure to tobacco-related products also pose risk for promoting lung cancer. Cigar smoking, which has

increased considerably over the past several years, is known to be an independent risk factor for developing lung cancer.[5] Furthermore, other non-cigarette forms of tobacco products and nicotine delivery systems (e.g., electronic cigarettes, smokeless tobacco, hookah) are more widely available and commonly used by young adults and youths. In 2013 and 2014, approximately 40% of tobacco users used multiple tobacco products, with cigarettes and e-cigarettes being the most common combination. The impact of non-cigarette nicotine delivery systems (such as e-cigarettes; "vaping") on population health is currently unknown. The small liquid pod included in most e-cigarettes contains a nicotine dose equivalent to a pack of cigarettes, and many e-cigarettes are flavored with chemicals. Exposure to the products of combustion of these chemicals may have adverse health consequences. E-cigarettes marketed to youths is a new way to get children and young adults addicted to nicotine.[4]

Exposure to *sidestream smoke,* or *passive smoking,* may also lead to an increased risk of lung cancer. The risk is generally much lower than active smoking but varies with the intensity of exposure.[6] It has been estimated that 3000 to 5000 deaths in the United States and 21,400 deaths worldwide from lung cancer occur each year because of secondhand smoke exposure.[7]

Occupational Agents and Other Risks

Many other risk factors have been identified (Box 32.1). Occupational agents are known to act as lung cancer carcinogens, with arsenic, asbestos, and chromium posing the highest risk. This risk increases when there is also exposure to tobacco products. Indoor radon exposure is also a risk factor for developing lung cancer. Radon is a naturally occurring gas produced by the breakdown of uranium ore or other rocks such as shale and granite, and indoor radon exposure generally comes from the soil underneath homes and buildings.[8] Particulates in the atmosphere (i.e., pollution) can also increase the risk for lung diseases including lung cancer.

Family members of people who develop lung cancer have an increased risk.[9-11] Women seem to have a higher baseline risk for developing lung cancer and a greater susceptibility to the effects of smoking. Differences in the metabolism of tobacco-related carcinogens and their metabolites, an effect of hormone differences, or both are thought to account for the increased susceptibility,[11] but dietary factors can also modify risks. Higher consumption of fruits and vegetables is associated with a reduced lung cancer risk, and increased dietary fat intake may lead to a higher risk.[13,14] Supplementation with vitamin A, vitamin E, or β-carotene appears not to reduce cancer risk.[14] The presence of chronic obstructive pulmonary disease (COPD) does place a person at higher risk.[15,16]

CLASSIFICATION

Lung cancers are divided into two major groups—**small cell carcinoma** and **non–small cell carcinoma**—based on pathologic features that are visible under light microscopy. The evaluation and management of a patient are guided by the type and stage (see later) of lung cancer. The non–small cell cancer category consists of **adenocarcinoma**, **squamous cell carcinoma**, **large cell carcinoma** (which has come under recent revision), and variants (Fig. 32.2). Table 32.1 presents the pathologic and epidemiologic features of the four common types of lung cancer.[17]

PATHOPHYSIOLOGY

The pathophysiology of lung cancer development is complex and incompletely understood. Damage to genetic material in lung cells is the result of exposure to chemical carcinogens such as the carcinogens contained in tobacco smoke.[16] People who develop lung cancer may have a genetic predisposition to the

BOX 32.1 Lung Cancer Risk Factors

Tobacco smoke exposure
- Active (mainstream)—cigarette, cigar
- Passive (sidestream)

Occupational and environmental exposures
- Arsenic
- Asbestos
- Chromium
- Beryllium
- Bis(chloromethyl)ether
- Cadmium
- Nickel
- Polycyclic aromatic hydrocarbons
- Radon
- Vinyl chloride

TABLE 32.1 Classification of Most Common Types of Lung Cancer

Category	Cell Type	Pathologic Features (Light Microscopy)	Epidemiology
Non–small cell carcinoma	Adenocarcinoma	Formation of glandular structures; heterogeneous differentiation	Accounts for >40% of lung cancers in North America; increasing frequency in women
	Squamous cell carcinoma	Cytokeratin and intercellular bridges	Second most frequent type of lung cancer in United States
	Large cell carcinoma	Sheets and nests of cells, necrosis, lack of squamous cell or glandular features	Less common than adenocarcinoma or squamous cell carcinoma. Only labeled in surgically resected specimens.
Small cell carcinoma	Small cell carcinoma	Round to fusiform nuclei; faint to absent nucleoli; scant cytoplasm	Accounts for 13% of lung cancers

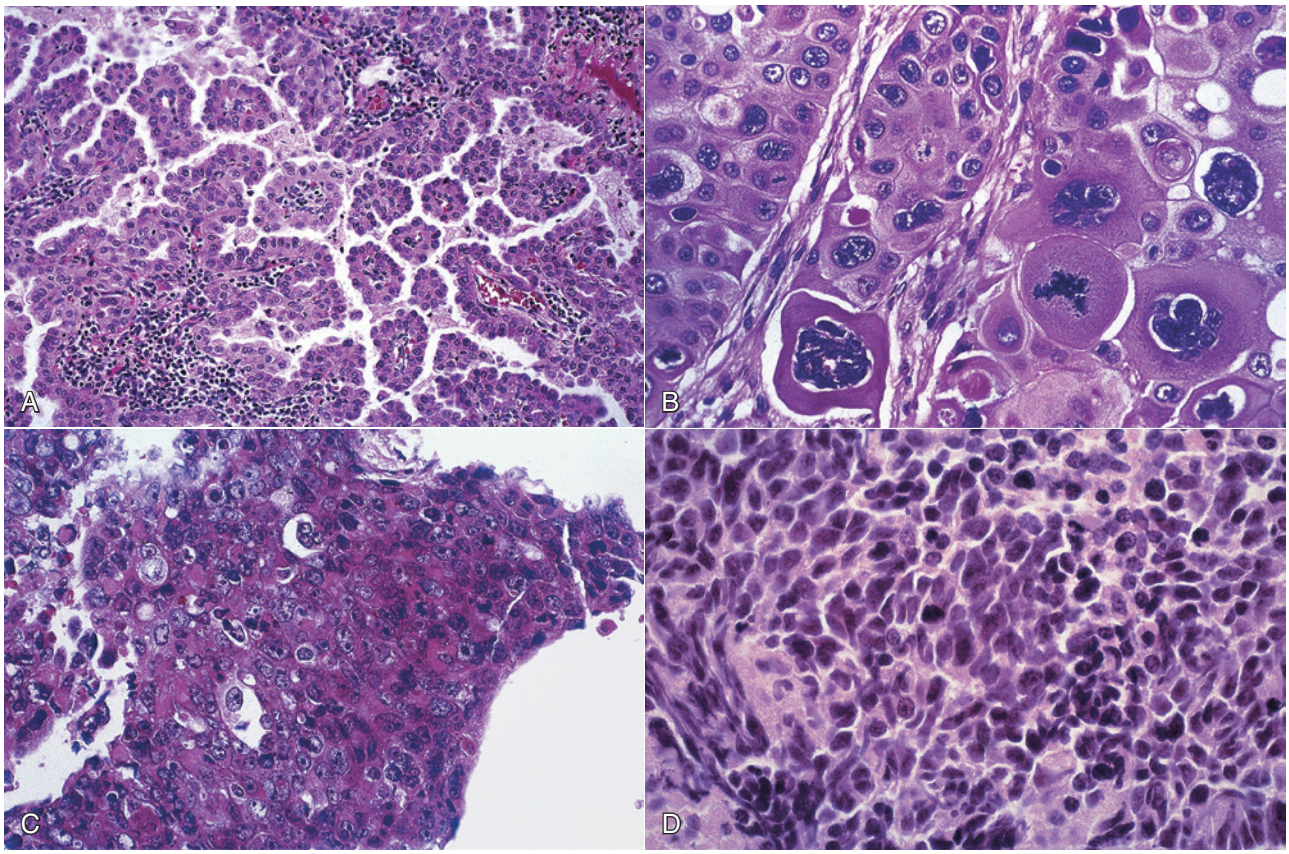

Fig. 32.2 Lung Cancer Histology. (A) Adenocarcinoma, characterized by heterogeneous differentiation in the same tumor. (B) Squamous cell carcinoma, characterized by the presence of cytokeratin differentiation with keratinization and intercellular bridges. (C) Large cell carcinoma, characterized by sheets and nest with extensive necrosis, large nuclei with prominent nucleoli, and lack of definitive evidence of squamous or glandular differentiation. (D) Small cell carcinoma, characterized by round to fusiform nuclei, nuclear molding, faint or absent nucleoli, and scant cytoplasm. (Courtesy Cleveland Clinic, Cleveland, Ohio.)

effects of these carcinogens. The genes influenced in the pathogenesis of lung cancer produce proteins involved in cell growth and differentiation, cell cycle processes, *apoptosis* (programmed cell death), *angiogenesis* (production of new blood vessels), tumor progression, and immune regulation. If enough of these pathways have been affected, the uncontrolled growth of cells that defines cancer occurs. By understanding the mechanisms that lead to genetic damage and the impact of that damage, novel means of risk stratification, prevention, early detection, and therapy could be developed.

CLINICAL FEATURES

The clinical features of lung cancer result from the effects of local growth of the tumor, regional spread through the lymphatic system, hematogenous (blood-borne) distant metastatic spread, and remote effects from tumor products or immune cross reaction with tumor antigens (Box 32.2). Some manifestations occur more commonly with a particular cell type. Only 15% of patients with a diagnosis of lung cancer do *not* have symptoms at the time of presentation.

Local growth in a central location (e.g., in a main stem bronchus) can cause a cough, hemoptysis, or features of large airway obstruction. Squamous cell carcinoma and small cell carcinoma are more likely to grow in a central location than other cell types. Adenocarcinoma occurs more commonly in the periphery of the lung. Peripheral growths may also cause cough and dyspnea; smaller tumors may not cause any symptoms. If the pleura or chest wall is involved, pain may occur.

Regional spread may lead to esophageal compression *(dysphagia),* recurrent laryngeal nerve paralysis (hoarseness), phrenic nerve paralysis with an elevated hemidiaphragm (dyspnea), and sympathetic nerve paralysis leading to Horner syndrome (ptosis [droopy eyelid], miosis [small pupils], anhidrosis [lack of facial sweating], and enophthalmos [sunken eye]). Growth at the very top of the lung may lead to a **Pancoast syndrome,** with shoulder pain radiating in an ulnar distribution as a result of involvement of the brachial plexus. The superior vena cava can become obstructed, resulting in swelling of the face, neck, and upper chest, plethora (swollen facial veins causing a ruddy complexion), and dilation of superficial veins over these areas. This is called the *superior vena cava syndrome*. Lung cancer can grow to involve the heart and pericardium. Lymphatic obstruction and spread can lead to dyspnea, hypoxemia, and pleural effusions.

Distant metastatic disease can affect most organs, with the brain, bones, liver, and adrenal glands most commonly involved.

BOX 32.2 Lung Cancer Manifestations

Local growth
- Cough
- Dyspnea
- Hemoptysis
- Pain

Regional growth
- Dysphagia
- Dyspnea
- Hoarseness
- Horner syndrome
- Hypoxemia
- Pancoast syndrome

Pericardial and pleural effusions
- Superior vena cava syndrome

Metastatic disease
- Headache
- Hepatomegaly
- Mental status change
- Pain
- Papilledema
- Seizures
- Skin or soft tissue mass
- Syncope
- Weakness

Paraneoplastic
- Cutaneous or skeletal
  - Acanthosis nigricans
  - Clubbing
  - Dermatomyositis
  - Hypertrophic osteoarthropathy
- Endocrine
  - Cushing syndrome
  - Humoral hypercalcemia
  - Syndrome of inappropriate antidiuretic hormone
  - Tumor necrosis factor (cachexia)
- Hematologic
  - Anemia or polycythemia
  - Disseminated intravascular coagulation
  - Eosinophilia
  - Granulocytosis
  - Thrombophlebitis
- Neurologic
  - Cancer-associated retinopathy
  - Encephalomyelitis
  - Lambert-Eaton syndrome
  - Neuropathies
  - Cerebellar degeneration
- Renal
  - Glomerulonephritis
  - Nephrotic syndrome

Courtesy Cleveland Clinic, Cleveland, OH.

Neurologic symptoms such as headaches, vision changes, and seizures may suggest brain metastases. Back pain and changes in strength or sensation in an extremity may indicate spinal cord compression and bone pain could indicate bone metastases. Laboratory abnormalities may point to bone marrow or liver involvement. Imaging may detect adrenal involvement.

MINI CLINI

Pancoast Tumor

Problem

A 65-year-old man who has smoked two packs of cigarettes per day for the past 40 years has had drooping of the left eyelid for the past 3 weeks. A chest x-ray reveals a mass in the apex of the left lung. Is there a link between the drooping of the eyelid and the lung mass?

Discussion

Lung tumors involving the apex of the lung (superior sulcus tumors) are also known as *Pancoast tumors*. If they involve the cervical sympathetic nerves in the neck, these tumors result in Horner syndrome, which is characterized by ptosis (drooping of the eyelid), anhidrosis (absence of sweating), and miosis (constricted pupil) on the same side as the tumor. Other manifestations of Pancoast tumor include pain and weakness in the upper extremity (caused by involvement of the brachial plexus), rib destruction, and destruction of vertebral bodies. Treatment depends on the extent of local and distant spread of the tumor.

MINI CLINI

Mediastinal Adenopathy

Problem

A 60-year-old man has been found to have small cell lung cancer on the basis of results of bronchoscopic biopsy findings, and a computed tomography scan of the chest shows extensive mediastinal adenopathy. The patient has been admitted to the oncology floor for **chemotherapy.** You are called to assess him because he cannot lie down owing to shortness of breath (orthopnea). When you arrive, the patient is sitting on the edge of the bed. You notice that his face and neck are swollen and he has dilated veins over the face, neck, chest, and arms. How do you explain these findings?

Discussion

This patient has superior vena cava obstruction caused by compression by the mediastinal adenopathy. The swelling of the face, neck, and arms is caused by impairment of the venous drainage from the upper body (the superior vena cava distribution). The dilated chest and arm veins are collateral vessels (or alternative pathway vessels) that compensate for the superior vena cava obstruction, which can be caused by various benign or malignant conditions that involve the mediastinum or the right upper lung. Treatment is usually therapy for the underlying problem.

When symptoms develop that are the result of the presence of cancer but are not related to the growth or spread of the cancer, these symptoms constitute a **paraneoplastic syndrome.** Paraneoplastic syndromes can result from the effects of proteins produced by the tumor that circulate through the body to have their effects on distant organs or result from the immune response of the body to a tumor antigen that is similar to antigens in other parts of the body, causing immune injury to the distant organ. Paraneoplastic syndromes may occur before the primary tumor can be detected or can be an indication of tumor recurrence. Examples of tumor secretion include the production of excess adrenocorticotropic hormone or its precursors (ectopic Cushing syndrome), parathyroid hormone (hypercalcemia of malignancy), and antidiuretic hormone (syndrome of inappropriate antidiuretic hormone). Immune cross-reactivity leads to

MINI CLINI

Paraneoplastic Syndrome

Problem

A 55-year-old man is brought to the emergency department by family members because of confusion and progressive generalized weakness. Examination in the emergency department shows the patient is dehydrated, lethargic, and confused. Chest x-ray reveals a cavitary lesion in the right upper lobe. Results of arterial blood gas analysis are normal. Results of chemical analysis urgently performed with the blood gas analysis reveal a sodium level of 150 mEq/L (normal 135 to 145 mEq/L) and a calcium level of 17 mg/dL (normal 9 to 10.5 mg/dL). How is the lung mass related to this patient's presentation and biochemical abnormalities?

Discussion

This patient's confusion and weakness are caused by hypercalcemia, which is a paraneoplastic presentation of lung cancer, especially squamous cell carcinoma (the cavitating mass on the chest x-ray). Paraneoplastic syndromes are systemic manifestations of lung cancer that are not caused by metastasis. Most paraneoplastic syndromes are associated with small cell lung cancer. However, hypercalcemia is more common with squamous cell carcinoma and is caused by secretion by the tumor of parathyroid hormone–related peptide. Treatment consists of hydration, diuresis, and use of medications that can reduce the levels of calcium.

paraneoplastic neurologic syndromes that can affect all parts of the neurologic system, resulting in emotional lability (limbic encephalitis), loss of balance (cerebellar degeneration), or proximal muscle weakness of the arms and legs with autonomic dysfunction (Lambert-Eaton myasthenic syndrome). Other paraneoplastic syndromes include skeletal and connective tissue syndromes (digital clubbing, hypertrophic pulmonary osteoarthropathy), coagulation and hematologic disorders, cutaneous and renal manifestations, and systemic symptoms (anorexia, cachexia, and weight loss).[18]

DIAGNOSIS

Approximately 85% of patients with lung cancer present with one or more of the previously described symptoms and in the remainder, lung cancer is detected by radiographic evaluation performed for an unrelated problem. This proportion may change in the future as **computed tomography** (CT) screening programs become widespread. Most patients have a chest x-ray and CT scan of the chest performed in their initial evaluation. These studies show a small spot (<3 cm in diameter) termed a **nodule** in the lungs or a larger spot (>3 cm in diameter) termed a **mass**. Other findings on imaging may include enlarged lymph nodes in the hila (where the bronchi and central blood vessels emerge from the mediastinum into the lung) or mediastinum, or a pleural effusion. An individual patient's clinical and radiographic presentation determines further evaluation.

The symptoms of lung cancer are nonspecific. There are many reasons that someone could have a cough or be short of breath. Similarly, an abnormality such as a lung nodule can be present on chest imaging for various reasons. Certain clinical and radiographic features make it more likely that the presentation represents lung cancer. The older the patient is and the more he or she has smoked over time, the more likely the chest finding is lung cancer. Furthermore, individuals with prior cancers are more likely to have lung cancer. Hemoptysis increases concern about cancer.

MINI CLINI

No Response to Antibiotics

Problem

A 55-year-old woman who does not smoke has a 3-month history of dyspnea on exertion, weight loss, and cough productive of copious amounts of clear, frothy sputum. She has no fever or chills. She has been treated for 2 weeks for "double pneumonia" without relief of the symptoms. Examination reveals finger clubbing and decreased air entry in both lung bases with dullness to percussion. A chest x-ray shows bilateral alveolar infiltrates. What should be done next?

Discussion

The patient has a variant of adenocarcinoma of the lung. Cough productive of copious amounts of clear, frothy sputum is characteristic of this type of lung cancer. The radiographic appearance may be indistinguishable from that of pneumonia, especially when there is sputum production. The absence of fever, the chronic presence of infiltrates, and the lack of response to antibiotic therapy should raise suspicion for this type of lung cancer. Bronchoscopy with transbronchial biopsy would be a reasonable next step to confirm the diagnosis.

Radiographic features are also used to determine the probability of cancer. The larger the lung abnormality, the more likely it is to be cancer. When the abnormality has reached the size of a mass (3 cm), it needs to be considered a cancer until proven otherwise. The rate of growth of the lesion is also helpful. If a nodule grows rapidly (doubles in size in <1 month) or grows very slowly or not at all over a couple of years, it is unlikely to be caused by cancer. If the nodule appears to be heavily calcified on imaging, it has likely been present for quite some time and is unlikely to represent cancer. If the abnormality has an irregular border, is lobulated, or is spiculated (with sharp, pointy edges), it is more likely to be a cancer than if the border is smooth and rounded. Finally, if the lesion is cavitary, the thickness of the wall of the cavity can suggest cancer. A wall thickness of 14 mm or greater is likely to represent a cancer.[19]

RULE OF THUMB A solid solitary pulmonary nodule that has not grown in 24 months is unlikely to be malignant.

After the clinical and standard imaging features are reviewed, a probability of malignancy can be determined. If the probability is very high, the potential cancer does not seem to have spread, and the individual is fit, proceeding directly to surgery would be reasonable. If the previously mentioned features suggest a very low probability of malignancy, the clinician and patient might choose to follow along with serial chest imaging over time to assess for growth. When the probability falls between these extremes, adjunctive imaging and invasive procedures can be used to help characterize the finding. The most commonly used additional imaging technique is **positron emission tomography** with fluorodeoxyglucose (FDG-PET [Chapter 21]). Owing to the fact that malignant cells are metabolically very active, they take up the glucose analogue called FDG more avidly than

non-malignant cells. The attached radioactive tracer becomes trapped in the cells, allowing it to be imaged. When this test is used to help predict the presence of lung cancer, it has a sensitivity of 89% and a specificity of 78%. PET imaging can produce false-positive results in other metabolically active conditions such as infections. It can be falsely negative if the lesion is too small (<10 mm) or if the tumor is slow growing and not very metabolically active (e.g., some adenocarcinomas, carcinoid tumor).[20]

Ultimately, tissue is obtained to confirm the diagnosis of lung cancer. **Flexible bronchoscopy** and **transthoracic needle biopsy** are invasive, nonsurgical approaches used to obtain tissue. If these procedures fail or are deemed unnecessary, a surgical approach is used.

Flexible bronchoscopy is a procedure in which a long, thin, flexible camera is passed through a patient's nostril or mouth into the lungs (see Chapter 22). The camera can be extended into the branches of the lung as far as the branches are large enough to admit it. The camera has a small channel through which very thin biopsy instruments can be passed out deeper into the lung to take samples from concerning areas. Flexible bronchoscopy has a high diagnostic yield for lesions that are endoscopically visible within the larger airways. Samples are collected by washing saline over the lesion, sending a small brush through the camera to collect cells on its bristles, and taking biopsy samples with forceps or a needle. The diagnostic yield from lesions in the periphery of the lung, beyond where the camera is able to see, is lower. Conventional sampling techniques and peripheral **transbronchial needle aspiration** complement each other. Factors that influence the diagnostic yield of flexible bronchoscopy for peripheral lesions include the size of the lesion, its location, and the presence of a 'bronchus sign' on CT (an airway leading directly into the lesion). Smaller, more peripheral lesions, without a visible bronchus within or leading directly to them, are less likely to be diagnosed by flexible bronchoscopy.[21] More recent technologic advances, such as multiplanar imaging, electromagnetic navigation of the bronchoscopy instruments, and peripheral endobronchial ultrasound, have been able to improve the yield of flexible bronchoscopy for these small peripheral lesions.[22] Not infrequently, the hilar or mediastinal lymph nodes are enlarged as a result of spread of the tumor. Diagnosis and staging can be accomplished during bronchoscopy, with endobronchial ultrasound used to guide biopsies of these lymph nodes.[23,24]

Transthoracic needle biopsy, using fluoroscopic or CT guidance, can also be used to obtain a tissue sample. With this procedure, an aspirating needle is passed through the skin into the lung lesion under the guidance of chest imaging. The yield of transthoracic biopsy is a little higher than bronchoscopy, but lymph nodes cannot be sampled during this procedure, smaller nodules in central locations have lower diagnostic rates, and there is a higher rate of pneumothorax.[23] The choice of which procedure to use is guided by the size and location of the lesion and the local expertise with each technique.

STAGING

A major factor that determines the prognosis of lung cancer and guides the selection of appropriate treatment is the extent to which the cancer has spread in the lungs and throughout the body. The extent of cancer spread is termed the *stage* of the cancer. Non–small cell lung cancer is staged using the **TNM staging** system (*T* for extent of primary tumor, *N* for regional lymph node involvement, and *M* for metastases). The eighth edition of the TNM system for non–small cell lung cancer has recently been adopted.[24]

The T component of the **staging system** is divided into T1 through T4 lesions, as follows:

- A *T1 tumor* is a small tumor confined to the lung. It must be less than 3 cm in diameter and be surrounded by lung or visceral pleura and cannot extend into a main bronchus. T1a tumors are less than or equal to 1 cm in diameter, T1b tumors are greater than 1 and up to 2 cm, and T1c is greater than 2 cm and up to 3 cm.
- A *T2 tumor* has a cut-off size of 5 cm. Any size tumor involving the mainstem bronchus or leading to partial or total atelectasis of the lung is also a T2 tumor.
- A *T3 tumor* is greater than 5 cm and up to 7 cm in size. Multiple tumor nodules in the same lobe, those involving the chest wall, phrenic nerve, and parietal pericardium regardless of size, are also considered T3 tumors.
- A *T4 tumor* is greater than 7 cm in size. Separate tumor nodules in a different ipsilateral lobe of the lung, and tumors invading the diaphragm, mediastinum, or great vessels, are also considered T4 tumors.

The N component of the staging system is determined by which lymph nodes, if any, are involved with the tumor, as follows:

- *N0 spread* indicates that the cancer has not spread to the lymph nodes.
- *N1 spread* indicates the presence of cancer in lymph nodes within the ipsilateral lung (the same side as the tumor) in hilar or peribronchial regions.
- *N2 spread* signifies cancer in lymph nodes in the mediastinum ipsilateral to the primary tumor.
- *N3 spread* signifies cancer in *contralateral* ('opposite side') mediastinal or hilar lymph nodes, *ipsilateral* or *contralateral* scalene, or supraclavicular nodes.

The M part of the staging system represents the absence *(M0)* or presence *(M1)* of metastases outside of the chest. *M1a* refers to metastasis of separate tumor nodules in the contralateral lung or the presence of a malignant pleural or pericardial effusion. *M1b* refers to a single distant site of metastatic spread, such as liver, bone, or brain lesions. *M1c* refers to multiple distant sites of metastases.

The most recent revision to this staging system occurred in 2017 (Table 32.2 and Fig. 32.3). The stages are labeled from stage IA to stage IVB based on the combination of T, N, and M features.[24,25]

For patients with small cell lung cancer, the TNM staging system was previously thought to be less useful. Instead, small cell lung cancer has been staged as limited or extensive disease. *Limited-stage* disease is present when the tumor is confined to a hemithorax (including ipsilateral mediastinal and supraclavicular lymph nodes) and can be contained within a radiotherapy port. *Extensive-stage* disease is present when the tumor extends beyond these boundaries. The recent lung cancer staging revision

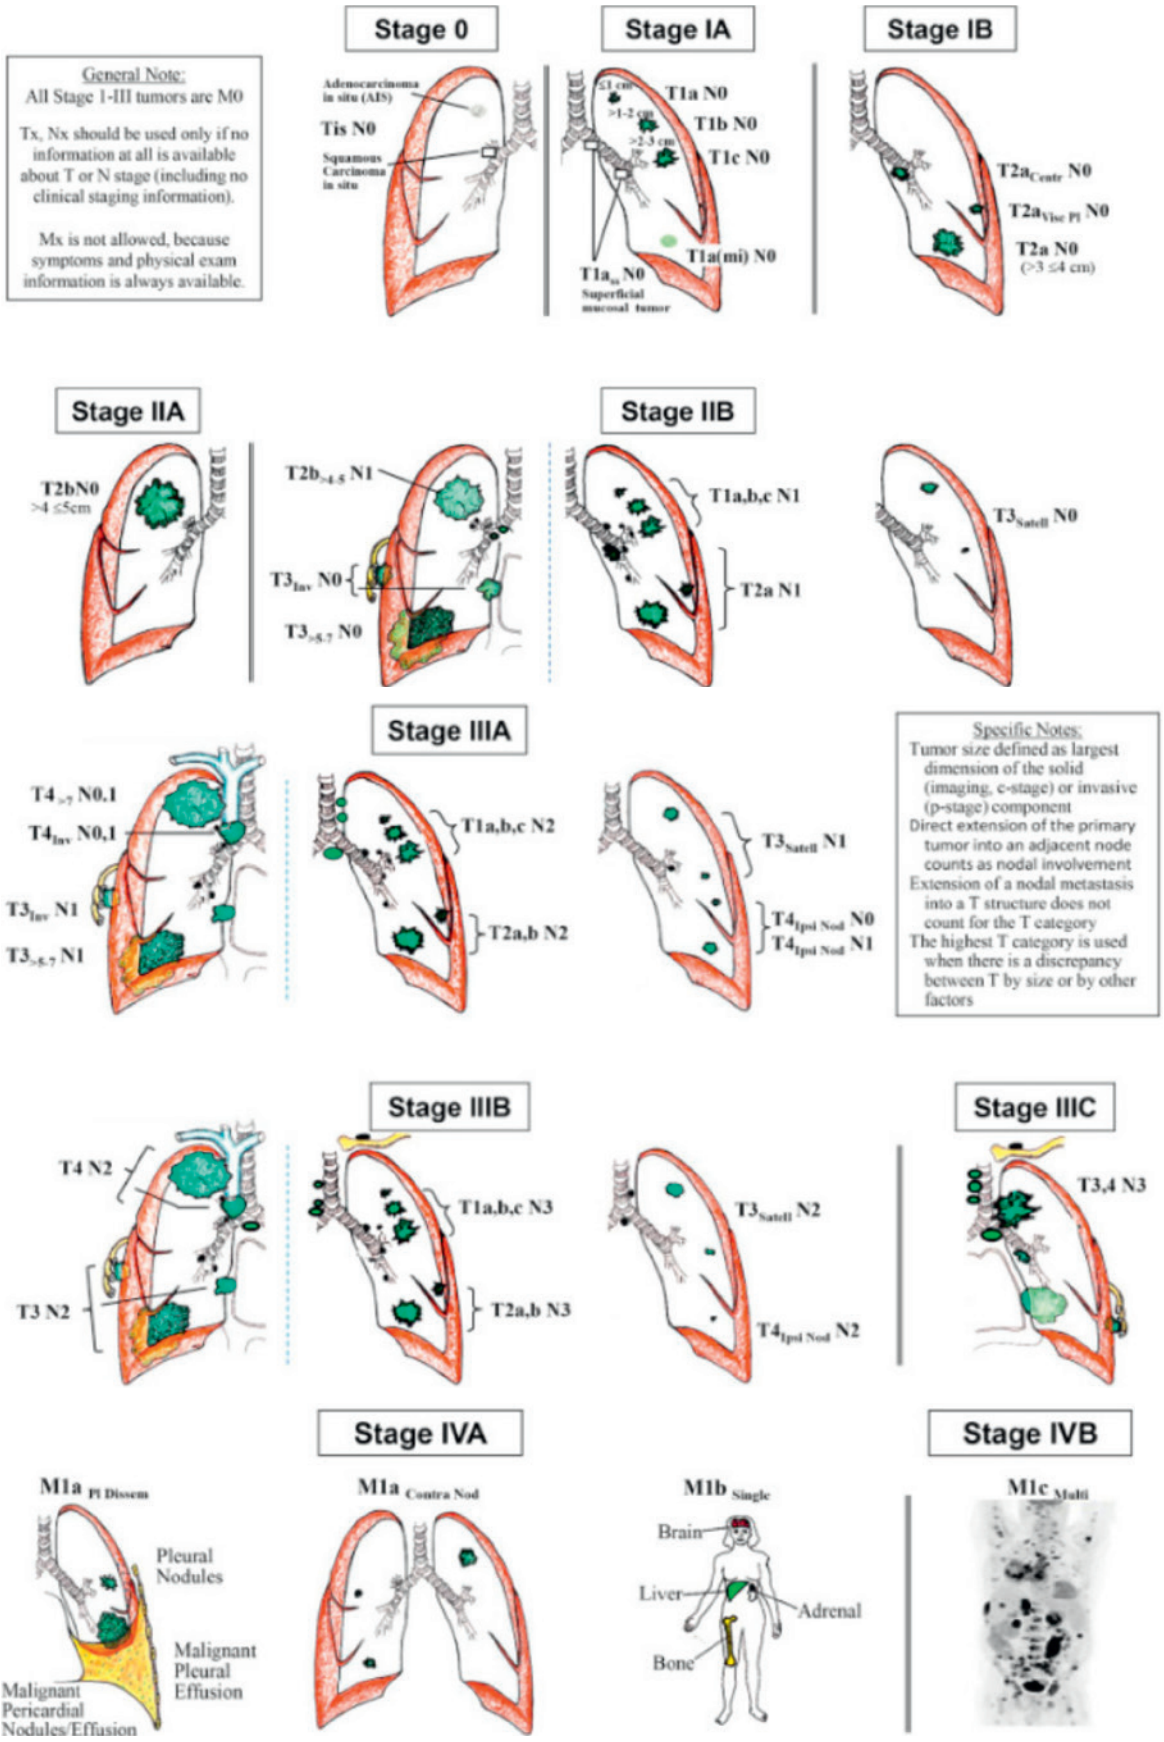

Fig. 32.3 Graphic Illustrations for Tumor, Node, Metastasis Staging of Lung Cancer. (Detterbeck FC, Boffa DJ, Kim AW, et al. The 8th edition lung cancer stage classification. *Chest*. 2017;151(1):193–203.

recognized a benefit to applying the TNM staging system used for non–small cell cancer to small cell cancer as well.[24-26]

The proper use of testing to stage a patient with lung cancer was addressed in recent guidelines.[26] The history and physical examination are important in guiding testing. The extent of spread is best evaluated using CT of the chest extending to the upper abdomen to include the liver and adrenal glands; this should be ordered in all patients. **Magnetic resonance imaging** (MRI) has not proved to be more accurate except in the setting of a Pancoast tumor. Evidence shows that integrated PET/CT scanning has better test characteristics for staging lymph node and distant disease involvement than other types of imaging (Fig. 32.4).[27-29]

Because noninvasive tests can have false-positive results, tissue confirmation is necessary. Bronchoscopy with transbronchial needle aspiration is useful to stage the mediastinum. The addition of endobronchial and endoscopic ultrasound has increased the yield of non-surgical mediastinal staging.[23,28] Surgical staging (e.g., mediastinoscopy, mediastinotomy, or thoracoscopy) is offered when lymph nodes are concerning on imaging but were negative on bronchoscopy. Despite the advances in imaging technology and sampling techniques, definitive staging with **surgical resection** and mediastinal dissection remains the gold standard in a patient with resectable disease. The assigned clinical stage (determined by the previously listed testing, including mediastinoscopy) can be lower than the pathologic staging (assigned after surgery).

The evaluation of metastatic disease also takes into consideration the history, physical examination, laboratory results (electrolytes, calcium, alkaline phosphatase, liver profile, and creatinine), and pathologic examination results.

Per guidelines, a head CT or MRI scan should be performed if symptoms or signs of metastatic disease are present or when evaluating what appears to be stage IIIA through IV disease. Although there is no proved survival benefit from CT versus MRI, many clinicians prefer to use MRI of the brain because it has greater sensitivity to detect metastatic disease.[26,29] The rest of the body is assessed by PET imaging, as is the mediastinum. PET imaging is recommended for all patients.

Along with evaluating the anatomic extent of disease, a patient's performance status is important in determining his or her prognosis and ability to tolerate any proposed treatment. The two most commonly used scales of performance status are the *Zubrod scale* and the *Karnofsky scale*. Although their definitions differ, the general principles of the two scales are the same, with ratings based on activity level, independence in daily activities, and severity of symptoms.

RULE OF THUMB Staging for lung cancer is complex and should involve a multidisciplinary team. Stage I cancers are small tumors and stage II cancers involve nearby hilar lymph nodes or are larger tumors. When mediastinal nodes are positive, the patient is at least stage III and when a malignant pleural effusion or distant sites such as the brain or bones are involved, the patient is stage IV.

PREOPERATIVE EVALUATION FOR LUNG RESECTION SURGERY

To determine if a patient would tolerate lung resection surgery, patients go through testing of their pulmonary, cardiovascular, and overall health. Reports of activity tolerance, pulmonary function testing, and exercise testing are used to assess the risk. The amount of risk is weighed against the benefit of having a traditional lung resection surgery (a lobectomy—one lobe removed, or pneumonectomy—a lung removed) versus a sublobar resection or non-surgical treatment. Traditional resection is the best chance for cure and reduces local recurrence. As would be expected, a pneumonectomy requires better preoperative lung function than a lobectomy. When a lobe is removed, patients generally have a 10% to 15% drop in lung function. With a pneumonectomy, 30% to 35% is lost.

Cardiac conditions requiring medications, or an inability to climb two flights of stairs, should prompt a cardiac evaluation.

BOX 32.3 To Calculate Percent Predicted Postoperative Values

The segment method

PPOFEV1 = pre-operative FEV1 × (1 − number of resected segments/19)

19 representing the total number of segments in both lungs:
Right upper lung: 3
Right middle lung: 2
Right lower lung: 5
Left upper lung: 5
Left lower lung: 4

The **thoracic revised cardiac risk index** can be used to identify patients at risk for cardiac complications. Those with any combination of the following conditions (i.e., score ≥ 2) should have noninvasive cardiac stress testing or a cardiology consultation: previous ischemic heart disease, stroke or transient ischemic attack, creatinine >2 mg/dL or planned pneumonectomy. Similarly, those with a cardiac condition requiring medication, or with a newly suspected cardiac condition, and those unable to climb two flights of stairs should be considered for noninvasive cardiac stress testing or a cardiology consultation.

The evidence shows that the volume exhaled during the first second of a forced expiratory maneuver (FEV_1) (see Chapter 20) and diffusing capacity for carbon monoxide (DLCO) are the most frequently used pulmonary function tests and the best predictors for postoperative complications, including death. Traditional preoperative cutoff values have been replaced by percent predicted postoperative (PPO) values as starting points. PPO values of FEV_1 and DLCO can be calculated by multiplying the percent predicted *pre*operative value by the fraction of the total number of lung segments that will remain postoperatively. This is the segment method (Box 32.3). Alternatively, quantitative perfusion imaging can be used to guide the calculation. If the PPO FEV_1 and DLCO are greater than 60%, the patient is considered at low risk for lung resection. If PPO values fall between 30% and 60%, an exercise test should be performed. The stair climb test, shuttle walk, and 6-minute walk tests can be used. For patients with PPO values below 30%, inadequate low-technology exercise testing results, or when measured values and predictions seem discordant with an individual's reported activity tolerance, a formal cardiopulmonary exercise test should be performed (Fig. 32.5). If the peak oxygen uptake is greater than 20 mL/kg/min (or 75% predicted), the patient is considered at low risk for any resection. If the peak O_2 uptake is less than 10 mL/kg/min (or 35% predicted), the patient is considered at high risk and conventional surgery should not be performed. Patients with a peak O_2 consumption value between these two limits are at moderate risk, and should be considered on a case-by-case basis.[31,32]

RULE OF THUMB Patients with a PPO FEV_1 and DLCO greater than 60% predicted can safely undergo surgical resection for lung cancer, even if pneumonectomy is needed.

MINI CLINI

Lung Cancer Screening

Problem

A 68-year-old man presents to the clinic with the concern of developing lung cancer in the future. He currently smokes one pack of cigarettes per day and has smoked for 45 years. He does not cough or feel shortness of breath. He has a history of high blood pressure and high cholesterol. He is otherwise in his regular state of health. Should this man have lung cancer screening?

Discussion

Based on the evidence, he meets criteria to have a low-dose CT chest to screen for lung cancer. He does not have any symptoms that also make screening appropriate. A vitally important part of the conversation with this patient should be tobacco cessation. Quitting smoking at any age reduces the risk for lung cancer and other health problems.

SCREENING

Given the poor prognosis for advanced-stage lung cancer and the high proportion of patients who present in an advanced stage, there has been great interest in **screening** for lung cancer. The earliest efforts at radiographic screening involved the analysis of mass chest x-ray screenings from the population of an individual city. Subsequently in the 1970s, there were large efforts to use chest x-ray, sputum, or a combination of the two as screening tools. Finally, a large randomized trial of chest x-ray as a screening test did not show any benefit; thus screening with chest x-ray is not recommended.[33-35]

Given the disappointing overall results from studies of chest x-ray as a screening technique, efforts have centered on the use of low-dose CT imaging as a screening tool.[36,37]

One trial, the National Lung Screening Trial, reported a 20% reduction in lung cancer-specific mortality in patients with very high risk for developing lung cancer. This finding has changed the clinical discussion regarding lung cancer screening. The U.S. Preventive Services Task Force gave low-dose CT chest screening a grade B recommendation for high-risk individuals (age 55 to 80 and at least 30 pack-years of current smoking [pack years = the number of packs per day × years smoked], or at least 30 pack-years of former smoking and quit within 15 years). The evidence shows that CT lung screening is most effective when performed in a setting where expertise in lung cancer and lung nodules is available.[38-40]

TREATMENT AND OUTCOMES

Although the respiratory therapist (RT) would not be administering the treatments for lung cancer, and the therapies change with advances over time, a brief discussion to familiarize the RT with the approach to treatment and the types of available therapy is important.

Non–Small Cell Lung Cancer (Table 32.3)

Three types of treatment are used to treat non–small cell lung cancer: surgical resection, **radiotherapy**, and **systemic therapy** (including traditional chemotherapy, targeted, and

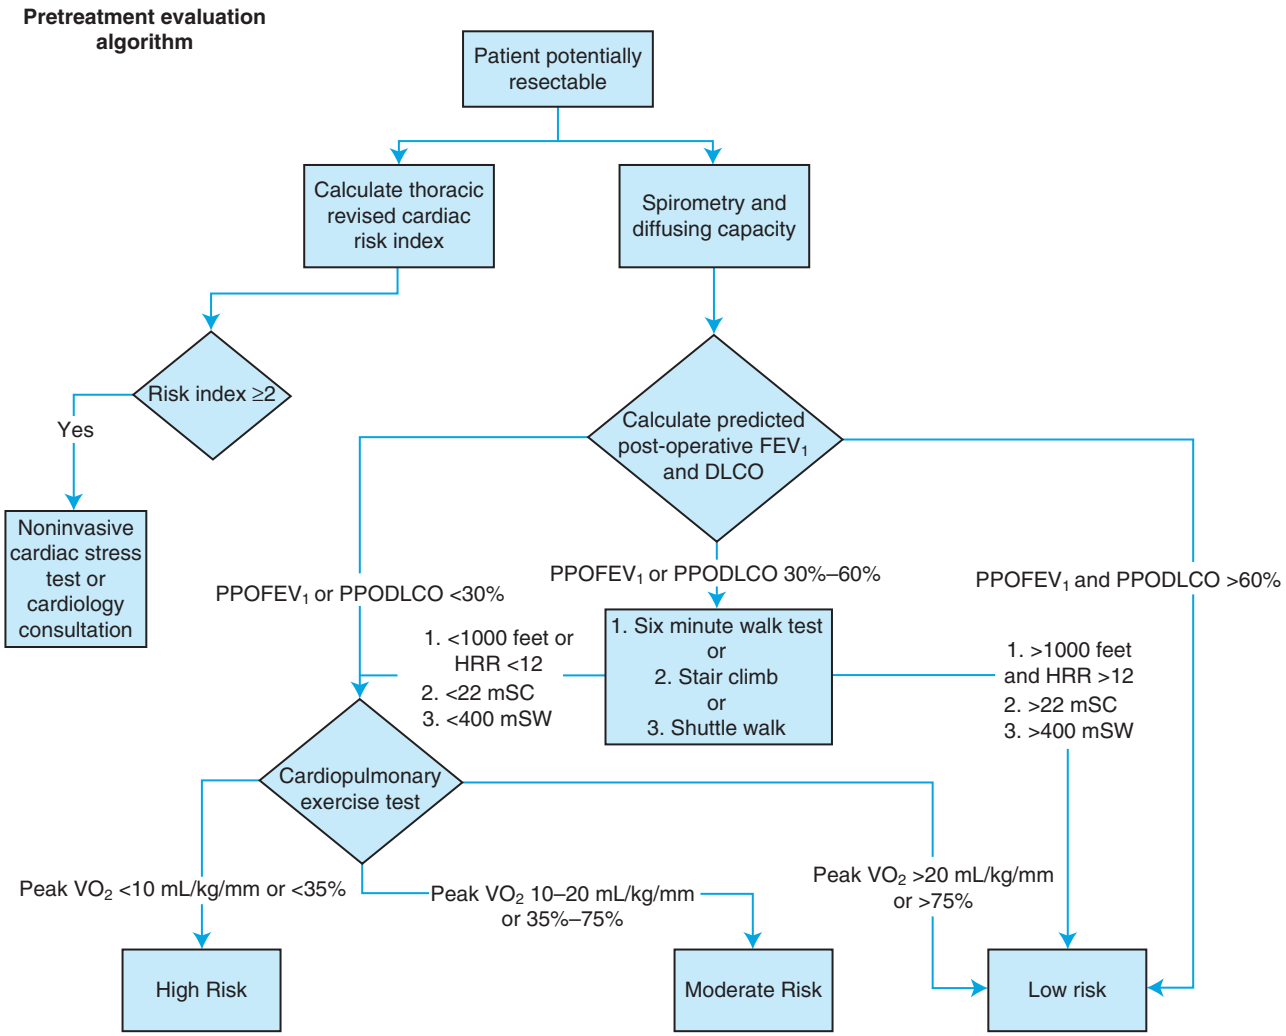

Fig. 32.5 Algorithm for Patients Considered for Lung Resection Surgery. Note 1: The algorithm represents an assessment of risk for traditional resection (lobectomy, pneumonectomy). One must consider the benefits of traditional resection over alternative therapies (sublobar resection, ablative therapies), the relative risks of the therapeutic choices and the patient's values when selecting treatment. Note 2: The 6-min walk is included in this algorithm but is not part of other guidelines owing to relatively small literature support. It is a more practical and available low-technology exercise study than the recommended tests, and we have substantial experience with this test, leading us to include it in our algorithm. Note 3: Potential modifiers of risk include smoking cessation, adequate treatment of comorbid pulmonary conditions, preresection or postresection pulmonary rehabilitation, and the surgical approach (VATS versus thoracotomy). Each of these should be considered when assessing risk. Note 4: For lobectomy, the segment method or quantitative perfusion scan can be used to calculate predicted post-operative values. For pneumonectomy, the quantitative perfusion scan should be used. Note 5: Management of cardiac disease per American College of Cardiology/American Heart Association guidelines. *DLCO*, Diffusion capacity for carbon monoxide; *FEV1*, forced expiratory volume in 1 second; *HRR*, heart rate recovery; *PPO*, predicted post-operative; *PPO*, Predicted post-operative values; *SC*, stair climb; *SW*, shuttle walk; *VO_2*, oxygen consumption; mL/kg/min, milliliters per kilogram per minute.

immune checkpoint inhibitor therapies) (Box 32.4). The first two treatments provide local control of the cancer, and the last is used to treat systemic disease. Which therapy or combination of therapies is recommended depends on the stage of the cancer, the patient's ability to tolerate treatment, and the type of cancer (or its histology). Molecular changes within the tumor now drive treatment choices for patients with advanced-stage disease.

Early Stage Non–Small Cell Carcinoma

Surgical resection offers the best chance of cure for early-stage non–small cell lung cancer (stages I and II). The surgery of choice is a *lobectomy*, in which the entire lobe of the lung containing the cancer is removed. If the tumor is very central, a pneumonectomy may be required. Sublobar resections, such as *segmentectomy*, or *wedge resection*, can be performed in patients with modest lung function to spare as much lung tissue as

Modified from Goldstraw P, Chansky K, et al. International Association for the Study of Lung Cancer International Staging Committee; IASLC Lung Cancer Staging Project: Proposals for the revision of the TNM stage groupings in the forthcoming (eighth) edition of the TNM classification of malignant tumors. *J Thorac Oncol* 2015;11:39–51.

possible. In most patients, sublobar resection leads to a slightly lower survival rate and a higher rate of local recurrence of cancer.[41,42] In the smallest cancers and in patients who are older than 70 years, a sublobar resection may be as effective as a lobectomy.[43] Recurrence usually involves distant metastases.

Radiotherapy has been used with curative intent in early-stage non–small cell lung cancer in patients who cannot tolerate surgery or in patients who elect not to undergo surgery. Stereotactic body radiotherapy is a novel radiation therapy technique in which multiple convergent beams of radiation are precisely targeted on the tumor. This targeting allows very high doses of radiation to be delivered to the tumor while sparing the normal lung tissue. Rates of local control and survival are impressive in selected groups, approaching the rates of lung resection.[44]

Adjuvant platinum-based chemotherapy leads to a significant survival benefit in selected patients with completely resected stage II lung cancers.[45] The potential benefit of adjuvant chemotherapy in patients with stage IB disease is debated.

Locally and Regionally Advanced Non–Small Cell Carcinoma

Tumors that involve the chest wall or large airways but have not spread elsewhere can frequently be treated with surgical resection. When a Pancoast tumor is present, chemoradiotherapy followed by surgical resection (lobectomy ± chest wall resection) is performed if possible. The invasion of local structures (rib, vertebral body, subclavian artery, or sympathetic chain) is a poor prognostic sign.

The approach to stage III disease caused by N2 lymph node involvement varies among institutions. Generally, the more advanced the lymph node involvement (number, extension, or location), the poorer the prognosis. Patients who have bulky lymph nodes or who require a pneumonectomy are less likely to benefit from including resection in the treatment plan. Concurrent chemoradiotherapy is the standard of care, with resection included in specialized centers. An immune checkpoint inhibitor may now be added to chemoradiotherapy.[46,47]

T4 disease without advanced nodal status (stage IIIB) may be considered for surgical treatment in only a few settings. T4 disease involving the main carina may be considered for resection at centers with expertise. The role of induction therapy in this setting has not yet been defined. Disease at the N3 level (stage IIIB) is generally considered non-surgical.[47]

Metastatic Non–Small Cell Carcinoma

In stage IV lung cancer, platinum-based chemotherapy regimens have been shown to improve survival and enhance quality of life. They are also cost-effective. This treatment is most appropriate for individuals with a good performance status. Resection

BOX 32.4 Options for Treatment of Lung Cancer

Non–Small Cell

Stages IA, IB, IIA, IIB

- Surgical resection standard of care if patient deemed able to tolerate resection
- Sublobar resection if patient is unable to tolerate larger resection
- Radiotherapy, particularly stereotactic body radiotherapy in NO disease, if patient is unable to tolerate or chooses not to undergo resection
- Adjuvant radiotherapy possibly of use if incomplete resection has occurred
- Adjuvant chemotherapy in patient with stage II disease who can tolerate it; consider in stage IB

Stage IIIA

- Concurrent chemoradiotherapy using platinum-based regimen and a PDL-1 inhibitor if performance status is reasonable
- Induction chemoradiotherapy followed by resection and adjuvant chemotherapy in selected patients

Stage IIIB

- Concurrent chemoradiotherapy using platinum-based regimen and a PDL-1 inhibitor if performance status is reasonable
- Induction chemoradiotherapy followed by resection in highly selected patients, only as part of a study protocol

Stage IV

- Platinum-based chemotherapy regimen plus a PDL-1 inhibitor in patients with adequate performance status; consider PDL-1 inhibitor alone if PDL-1 staining in > 50% of cancer cells
- Targeted therapies (e.g., EGFR and ALK inhibitors) in appropriate subgroups (where molecular testing suggests efficacy)

Small Cell

Limited Stage

- Combination chemotherapy with concurrent hyperfractionated radiotherapy if performance status is adequate
- Prophylactic cranial radiation for patients with complete response to chemoradiotherapy

Extensive Stage

- Combination chemotherapy if performance status is adequate

ALK, Anaplastic lymphoma kinase; *EGFR,* epithelial growth factor receptor; *VEGF,* vascular endothelial growth factor.

of an isolated brain metastasis in patients with a good performance status can improve survival. Standard chemotherapy typically involves two agents administered in cycles, each approximately 3 weeks apart, for a total of four to six cycles. More recently, agents with improved tolerance have been shown to benefit patients who have shown a good response to treatment when administered as maintenance treatment, until progression is noted.[48]

Standard chemotherapy targets all growing cells, not just cancer cells (hence the common side effects seen). Chemotherapy for advanced non–small cell lung cancer (NSCLC) has progressed over the past several years to sequentially include traditional cytotoxic chemotherapies (platinum-based doublet therapy), agents that target cancer-driver mutations, and agents that improve the body's immune response to the tumor. The tumor biopsy is used to characterize the tumor, including determining the histology, identification of cancer-driver mutations, and status of the immune response to the tumor. These guide treatment choices.

Targeted therapies have been developed where the mechanism of action is more specific to the cancer cell when *driver mutations* are present. In lung cancer, inhibitors of epidermal growth factor receptors (EGFRs), vascular endothelial growth factor (VEGF), and anaplastic lymphoma kinase (ALK) translocations have been studied. EGFR and ALK inhibitors have been most successful in patients with EGFR-activating mutations and ALK translocations in their cancer tissue. Several other mutations have been identified.

Lung cancer can trick the body's immune system so that it does not attack the tumor. Immune checkpoint inhibitors have led to improved survival when combined with traditional chemotherapy in patients with advanced disease, when used alone in patients with advanced disease and high levels of programmed death-ligand 1 (PDL-1) expression, and when combined with chemoradiation in patients with N2 disease.[48-51]

Small Cell Lung Cancer

Treatment of small cell lung cancer is based on its staging (see Box 32.4). In limited-stage disease, combination chemotherapy with concurrent hyperfractionated radiotherapy is recommended. The drug etoposide and a platinum agent are standard. Prophylactic brain radiation is generally recommended for patients who have a complete response to chemoradiotherapy. Surgery is limited to cases in which the diagnosis is in doubt or in rare cases that manifest as a single lung nodule. In patients with extensive-stage disease, combination chemotherapy improves the quality of life and median survival. A poor performance status and an elevated lactate dehydrogenase level suggest a poor prognosis.[52]

RULE OF THUMB Surgery is the treatment of choice for early-stage non–small cell lung cancer. Systemic therapy (chemotherapy, target therapy, and/or immune checkpoint inhibitors) is the modality of choice for advanced non–small cell lung cancer. Chemotherapy with or without radiation therapy is used to treat small cell lung cancer.

Palliation of symptoms related to lung cancer is an important aspect of overall management. The use of analgesic agents for pain, antiemetics for nausea, and antidepressants can improve quality of life. Radiotherapy can be used to palliate bone pain related to metastatic disease, hemoptysis, or symptoms of airway obstruction. Invasive bronchoscopic procedures (e.g., laser ablation, electrocautery, stent placement) may be palliative in patients with airway obstruction. Evidence shows that in patients with end-stage non–small cell lung cancer, early integration of palliative care (see Chapter 58) can increase median survival and quality of life.[53]

FUTURE SCENARIO

The prospect of major advances in the prevention, detection, and treatment of lung cancer is strong. An attainable vision for 2038 could be as follows: Primary prevention campaigns have successfully lowered the number of individuals who are smoking to 5% of the adult population; legislation has been passed to broadly prevent exposure to tobacco smoke in public places; progress has been made in occupational exposure avoidance; and successful measures have been enacted to clean the air. Individuals who have changes in lung cells that suggest lung cancer could develop are now identified and are being treated with medication to prevent it from developing. Individuals at risk for developing lung cancer are part of a screening program that detects early-stage lung cancer with an accurate test that is inexpensive and acceptable to all. Technology has improved diagnostic abilities by making imaging more specific and biopsies more accurate. Noninvasive diagnostics have expanded, with advances in blood and breath testing, while artificial intelligence is being used to help characterize lung nodules, and population management tools are assisting clinicians and patients to be compliant with guideline and value-based recommendations. In addition to tumor appearance, researchers are identifying characteristics of tumor biology that allow more selection in choosing treatments. The best form of local control for a given tumor in a given patient (resection, radiation) is known, and means have been developed to minimize the effect of these interventions on the quality of life. Novel agents have been developed that can reach and kill tumor cells while avoiding injury to healthy tissue and stimulate our immune system to attack cancer cells without impacting healthy tissues. As evidence of successes, lung cancer is no longer the leading cause of cancer-related mortality in the United States.

ROLE OF THE RESPIRATORY THERAPIST IN MANAGING PATIENTS WITH LUNG CANCER

RTs perform many important roles in the evaluation and management of patients with lung cancer. Being among the first clinicians with which patients have contact after they are admitted, RTs are often on the front lines to help identify patients who are at risk for lung cancer. Risk factors such as smoking history or occupational exposure may be revealed to the RT as part of a formal history or in more casual conversation during an initial assessment. In the case of patients who are actively smoking, the RT has the opportunity to educate these individuals on the dangers of smoking and on the means available to help

MINI CLINI

Evaluating Surgical Risk

Problem

A 62-year-old man with a long history of smoking has a chronic, productive cough. A chest CT obtained because of a recent episode of hemoptysis reveals a lung mass in the right upper lobe. Results of transbronchial biopsy suggest the presence of adenocarcinoma. There is no evidence of metastasis. As part of the patient's evaluation for surgery, he has the following spirometry and diffusing capacity results:

Forced vital capacity (FVC) 4.2 L (80% of predicted value)
FEV_1 1.6 L (60% of predicted value)
FEV_1/FVC 0.4
DLCO 15.5 (60% of predicted)

Can he undergo surgery?

Discussion

Assessment of lung reserve is an important step in the preoperative evaluation of patients with lung cancer being considered for surgical resection. After calculating his PPO values with the segment method ($60 \times [1 - 3/19]$), he is found to have a PPO FEV_1 and PPO DLCO of 50%. This patient, similar to most patients with lung cancer, has PPO values between 30% and 60% because of underlying COPD. He needs further evaluation with exercise testing such as a stair climb or shuttle walk test to better assess his risk. Furthermore, he needs treatment optimization for his COPD. If the patient's lung function remains at moderate risk after these steps, a cardiopulmonary exercise test may help to clarify his risk.

them quit. Patients who are surgical candidates may see the RT when performing pulmonary function testing and other prescreening assessments. RTs can offer guidance on the proper use of inhaled medications, the use of supplemental O_2, and the role of pulmonary rehabilitation before and after treatment. RTs are frequently key participants in pulmonary rehabilitation programs and may also be part of the home care teams that care for patients using supplemental oxygen. Also, many RTs assist with diagnostic tests such as bronchoscopy and staff pulmonary function laboratories. Finally, in the context that the RT may spend substantial time with the patient with lung cancer, the RT may be an important source of psychologic support and help. Taken together, these various diagnostic and treatment roles establish that the RT plays a crucial role in helping to manage patients with lung cancer.

SUMMARY CHECKLIST

- Approximately 234,030 cases of bronchogenic carcinoma were newly diagnosed in the United States in 2018, making bronchogenic carcinoma a major health hazard. It is the leading cause of cancer-related mortality in the United States.
- Approximately 85% of all cases of bronchogenic carcinoma are linked to smoking.
- The major histopathologic types of bronchogenic carcinoma include adenocarcinoma, squamous cell carcinoma, and small cell carcinoma. Adenocarcinoma is the most common type, representing more than 40% of all cases.
- The clinical manifestations of bronchogenic carcinoma result from local growth of the tumor, regional spread, metastases to extrathoracic and intrathoracic organs, and paraneoplastic syndromes.
- The staging system most commonly used for non–small cell bronchogenic carcinoma is based on status of the primary tumor (T), local and regional lymph node involvement (N), and the presence of metastasis (M). The TNM classification groups patients in stages or categories that correlate with survival. Small cell lung cancer is classified in two stages, limited and extensive, although the TNM system can be used as well.
- The most commonly used treatments for patients with non–small cell lung cancer are surgical resection, radiation therapy, and systemic therapy (chemotherapy, targeted, and immunetherapies). Treatment of most patients with small cell carcinoma includes chemotherapy, with radiation therapy added when this cancer is limited stage.
- The most effective way to prevent lung cancer is to prevent smoking.

Neuromuscular and Other Diseases of the Chest Wall

Adam Alter, Eduardo Mireles-Cabodevila, and Rendell W. Ashton

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Identify pulmonary function test results typically seen in patients with neuromuscular disease.
- List the potential respiratory complications associated with neuromuscular disease.
- Identify the clinical signs and symptoms associated with respiratory muscle weakness.
- Describe techniques for monitoring patients with respiratory muscle weakness.
- Describe general respiratory care management of patients with respiratory muscle weakness.
- Describe the clinical findings and treatment for each of the following neuromuscular disorders: Duchenne muscular dystrophy, myotonic dystrophy, polymyositis, myasthenia gravis, Lambert-Eaton syndrome, Guillain-Barré syndrome, diaphragmatic paralysis, amyotrophic lateral sclerosis, ventilator-induced diaphragm dysfunction, spinal cord injury, stroke, traumatic brain injury, and kyphoscoliosis.
- Understand the role of the RT in caring for patients with neuromuscular and chest wall diseases.

CHAPTER OUTLINE

KEY TERMS

amyotrophic lateral sclerosis
ankylosing spondylitis
bilateral diaphragm paralysis
bulbar palsy
Duchenne muscular dystrophy
dermatomyositis
Guillain-Barré syndrome
kyphoscoliosis
Lambert-Eaton syndrome
myotonic dystrophy
myasthenia gravis
neuropathy
obstructive sleep apnea
paradoxical motions
polymyositis
sleep-related hypoventilation
stroke
traumatic brain injury
unilateral diaphragm paralysis
ventilator-induced diaphragm dysfunction

Neuromuscular diseases are the group of conditions that affect the function of muscles and/or nerves. The impact of neuromuscular function on the respiratory system can be understood by splitting the respiratory system into separate components, including the lungs, the ventilatory pump, the airway, and the neural respiratory centers. In this scheme, even if the lungs are normal, diseases that affect the brain, nerves, muscles, or thoracic cage can lead to respiratory failure or hypoxemia. (See Table 33.1 for a list of respiratory system components and their functions.)

Understanding the interactions between these components is essential to understanding how their dysfunction leads to disease. The neuromuscular components of the respiratory system are shown in Fig. 33.1. Maintenance of normal respiratory function depends on intact, functional components of the neuromuscular system. The neuromuscular system contributes to

TABLE 33.1 Respiratory System Components

Lungs	Provide air-blood gas exchange.
Ventilatory pump	Composed of the rib cage, diaphragm, and other respiratory muscles. Functions to bring atmospheric air in and out of the lungs.
Upper airway	The mouth and throat are responsible for speech, swallow, cough, airway protection, prevention of aspiration, and avoidance of airway closure during sleep.
Neural respiratory centers	Control of ventilation is provided by integrated systems in the brain and the peripheral nervous system

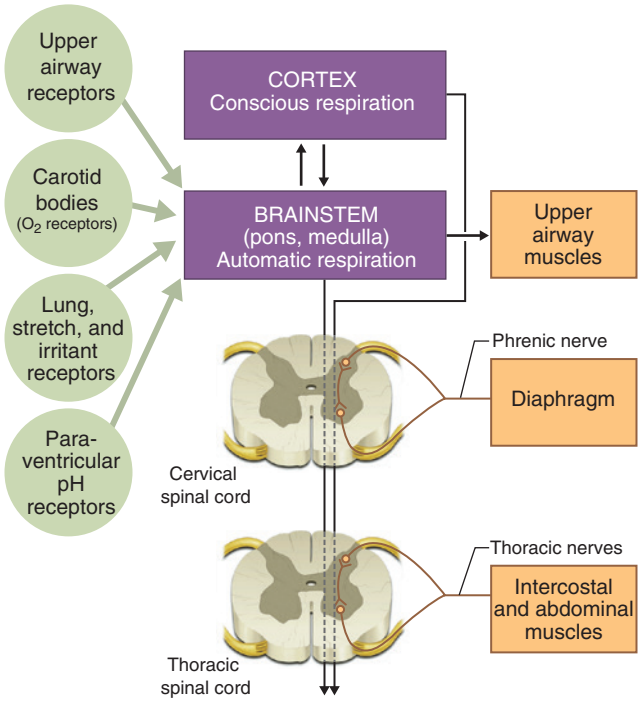

Fig. 33.1 The neuromuscular components of the respiratory system include elements of the cortex (which allow conscious alteration of breathing) and motor centers (which maintain upper airway tone). Brainstem structures receive input from peripheral O_2, pH, and stretch receptors and generate automatic respiration. Efferent nerves carry central nervous impulses to the muscles of respiration through the phrenic and spinal nerves, which drive the muscles of respiration.

respiratory function in three main ways: (1) regulation of respiratory drive, (2) ventilation, and (3) airway protection (e.g., cough). The respiratory consequences of neuromuscular disease typically develop in the following sequence:

- Atelectasis
- Impaired cough
- Airway plugging from retained secretions
- Sleep-disordered breathing
  - Obstructive sleep apnea
  - **Sleep-related hypoventilation**
- Hypoventilation while awake
- Ankylosis (stiffening) of the ribcage
- Aspiration

TABLE 33.2 Locations at Which Several Neuromuscular Diseases Affect the Respiratory System

Location	Disease
Cerebral cortex and brainstem (including the respiratory center)	Stroke and traumatic brain injury
Spinal cord	Trauma, transverse myelitis, multiple sclerosis
Motor neurons (upper and lower)	ALS, spinal muscular atrophy, progressive muscular atrophy, poliomyelitis, and postpoliomyelitis
Peripheral nerves	Guillain-Barré syndrome, neuralgic amyotrophy, Lyme disease, Diphtheria polyneuropathy
Neuromuscular junction	Myasthenia gravis, Lambert-Eaton syndrome, botulism
Muscle	Duchenne muscular dystrophy, polymyositis, acid maltase deficiency, polymyositis, and dermatomyositis
Thoracic cage	Kyphoscoliosis and ankylosing spondylitis

ALS, Amyotrophic lateral sclerosis.

- Pneumonia
- Respiratory failure
- Death

A basic understanding of the physiology of ventilation and chest wall mechanics (see Chapters 11 and 19) is needed to understand how abnormalities of the upper airway, chest wall, diaphragm, and abdominal muscles cause disease. This chapter reviews major disorders of the neuromuscular and skeletal systems that affect breathing. Disorders are grouped according to which functional unit of the neuromuscular system is affected, focusing on pulmonary manifestations of these disease processes (Table 33.2).

PATHOPHYSIOLOGY AND PULMONARY FUNCTION TESTING

Pulmonary function testing in patients with neuromuscular weakness typically reveals a restrictive ventilatory defect even if the lungs are normal (Chapter 20). Vital capacity (VC), forced expiratory volume in 1 second (FEV_1), and total lung capacity (TLC) are decreased. Functional residual capacity is normal or decreased. Residual volume (RV) may be increased, especially as weakness becomes more severe. Diffusing capacity is usually normal or near normal, representing normal lungs with preserved gas exchange function.[1] Clinically significant weakness of the diaphragm presents with orthopnea and can be identified by a decrease in VC going from the upright to the supine position. The normal decrease is 7% to 10%. A 10% to 20% decrease suggests diaphragm weakness or unilateral paralysis but can also be seen in obesity and or abdominal wall disorders. A 25% decrease has a 79% sensitivity and 90% specificity for diaphragm weakness (Table 33.3 and Fig. 33.2).[2] Whereas a decreased maximal inspiratory pressure (PImax) is generally specific for diaphragm weakness, a decreased maximal expiratory pressure (PEmax) is not specific to any single muscle group.[3]

TABLE 33.3 Pulmonary Function Testing Results From a Patient With Profound Diaphragm Weakness

	Predicted Value	Lower Limit of Normal	Sitting Position	% of Predicted	Supine Position	% Change From Sitting
FVC	4.42	3.55	1.85	42	0.89	–52
FEV_1	3.36	2.62	1.51	45	0.68	–55
FEV_1/FVC	75.88	66.20	81.75	108	75.76	–7
TLC	6.53	4.92	4.21	64		
RV	2.10	1.34	2.39	114		
DLCO	24.93	16.67	17.16	69		
Plmax	110.58	75.02	18.46	17		
PEmax	207.29	140.04	26.52	13		

DLCO, Diffusing capacity for carbon dioxide; *FEV_1,* forced expiratory volume in 1 second; *FVC,* forced vital capacity; *PEmax,* decreased maximum expiratory pressure; *Plmax,* decreased maximal inspiratory pressure; *RV,* residual volume; *TLC,* total lung capacity.

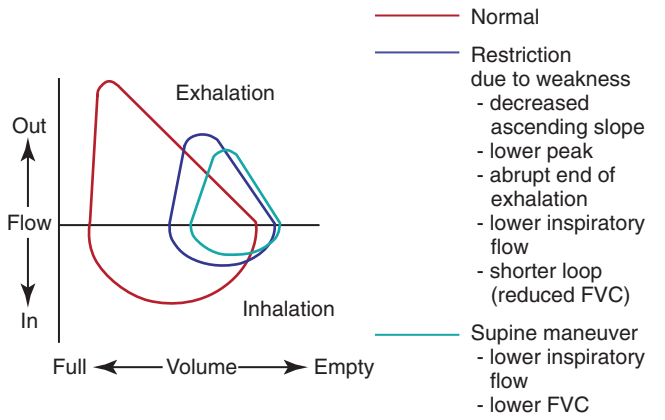

Fig. 33.2 Normal flow-volume loop compared with loops from a patient with neuromuscular weakness, showing characteristic ventilatory restriction, which worsens when the patient is placed in the supine position. *FVC,* Forced vital capacity.

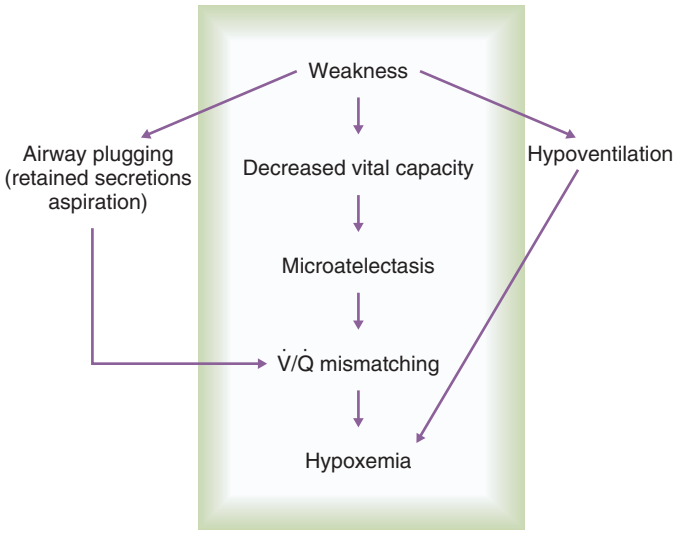

Fig. 33.3 Atelectasis as a mechanism of hypoxemia in patients with respiratory muscle weakness. V̇/Q̇, Ventilation/perfusion.

Gas exchange, which can be evaluated by arterial blood gas (ABG) analysis, is often normal in early neuromuscular pulmonary dysfunction. As the dysfunction progresses, ABGs will show hypercapnia, and, in later stages of disease, hypoxemia. Hypoxemia develops for several reasons, including hypoventilation, atelectasis, and airway plugging, each of which leads to ventilation/perfusion (V̇/Q̇) mismatching within the lung (Fig. 33.3). Supplemental oxygen (O_2) can be dangerous for patients with neuromuscular dysfunction and preexisting hypercapnia, as it can result in acute worsening of hypercapnia.[4] When starting O_2 in such patients, close monitoring with ABGs is needed to ensure safety.

Effective cough has three phases: inflation, compression, and expulsion. Inflation requires adequate inspiratory muscle strength to pull in enough volume in the lungs to generate appropriate cough pressure. The glottis must then close to allow compression, where the expiratory muscles start to pressurize the air in the lungs and narrow the central airway lumen. During expulsion, the glottis opens and air moves down the pressure gradient through the narrowed tracheobronchial tree at high velocities, thus clearing the airways. Dysfunction in any component (inspiratory muscles, glottis dysfunction, and expiratory muscles) leads to diminished peak cough flow. Although not objective, simple observation of the strength of a patient's cough can provide insight. Measuring peak cough flow is more objective; values less than 270 L/min are inadequate and should prompt consideration of cough-assist techniques (Table 33.4). A peak cough flow between 160 and 270 L/min may be adequate during periods of health but may worsen during respiratory tract infection, and so cough-assist techniques should be considered during times of illness.

RULE OF THUMB Neuromuscular weakness of the respiratory muscles may be present before any substantial decrease in VC or FEV_1 is measured. Values of PEmax may be decreased by 50% or more before any decrease in VC or FEV_1 is noticed.

CLINICAL SIGNS AND SYMPTOMS

In the early stages of neuromuscular disease, patients with respiratory muscle weakness initially report exertional dyspnea, fatigue, and poor sleep quality. The first symptoms usually start by affecting sleep. Patients with neuromuscular weakness are especially vulnerable during the night. Sleep is affected due to the effects of normal sleep stages on respiratory muscle function. This leads to nocturnal hypoventilation and interrupted sleep. The patients will often recognize a change in the quality of sleep, frequent

TABLE 33.4 Respiratory Modalities Commonly Used in Neuromuscular Weakness

Step 1: Lung Hyperinflation, Reexpansion of Atelectasis

Initiation: These therapies are generally the first respiratory support offered to patients with neuromuscular weakness and should be started when the risk of atelectasis becomes problematic, corresponding to FVC <40% predicted. Periodic hyperinflation helps manage atelectasis, increases peak cough flow aiding airway clearance, and reduces long-term risk of thoracic cage kyphosis (stiffening).

Self-inflating manual ventilation devices (e.g., Ambubag)	A simple form of hyperinflation can be achieved by delivering a single breath during inhalation. A more complex technique involves breath-stacking multiple inhalations, which requires coordination of glottis opening/closing and breath delivery.
Breath-stacking with mouthpiece ventilation	Volume-targeted ventilators with "kiss-trigger" can achieve the same breath-stacking and hyperinflation as manual breaths with a self-inflating bag.
Incentive spirometry	This device guides patients through a slow, deep inhalation. Although helpful in other conditions (postoperative, etc.) there is limited application in neuromuscular weakness.

Step 2: Cough-Assist and Secretion Clearance Modalities

Initiation: These therapies should be added when unassisted cough is not adequate to clear secretions. Indicated for regular use when peak cough flow <160 L/min or during respiratory tract infections when peak cough flow <270 L/min.

Mechanical insufflation-exsufflation	Device is applied to the airway, often with face mask, and provides brief positive pressure, followed by negative pressure to expel secretions. The insufflation component can also be used to achieve hyperinflation. When introducing the device, low pressures should be used (+10/–10 cm H_2O); if tolerable, the pressure should be titrated up (e.g., +40/–40 cm H_2O or higher). A single session should include multiple consecutive insufflation/exsufflations, and there should be multiple sessions daily. Suction may be needed to clear the mobilized phlegm.
Manually assisted cough	Somewhat similar to the Heimlich maneuver, this technique requires a second person to place their hands on the anterior chest and upper abdomen and deliver inward thrusts after the patient takes a deep inspiration.
Suction device	Helpful in patients with **bulbar** (mouth and throat) **palsy** (weakness) who have difficulty managing oral secretions.
Nebulized treatments	Albuterol or saline may help thin deep airway secretions, aiding clearance
High-frequency chest wall therapy	Manual or device-based therapy with a vest can be used to mobilize secretions in peripheral airways. Although helpful in cystic fibrosis and bronchiectasis, these therapies have limited application in neuromuscular conditions, as the airways are generally healthy, with normal mucus-clearing function.
Airway vibration device	Multiple devices apply vibration waves to the airway, intended to loosen secretions deep in the tracheobronchial tree; as with chest wall therapies above, there is limited application in neuromuscular conditions.

Step 3: Ventilatory Support Devices

Initiation: Sleep-disordered breathing (sleep hypoventilation and obstructive sleep apnea) always develops before wakeful hypoventilation; thus nighttime support is generally started prior to daytime ventilation. Hypoventilation and obstructive sleep apnea share many of the same features, including poor sleep quality, daytime drowsiness, and mood changes. Differentiating these conditions may require overnight oximetry and capnography, polysomnography, and daytime ABG or end-tidal exhaled CO_2.

Noninvasive ventilation (NIV)	Modern ventilators are more portable and functional, allowing different modes of vent support and different interfaces for daytime vs. nighttime (e.g., intermittent mouthpiece ventilation during daytime and continuous BiPAP via nasal pillows at night). In chronic stable neuromuscular disease, NIV is indicated for treatment of sleep-disordered breathing and daytime hypoventilation. In neuromuscular disease with acute worsening, NIV can be helpful for postextubation support as well as to prevent intubation (e.g., myasthenic crisis)
Interfaces for noninvasive ventilators	Nasal pillows and nasal mask are generally preferred for nighttime use, but the right interface depends mostly on patient factors, especially comfort. A mouthpiece interface for daytime ventilation has many advantages (unrestricted speech and swallow, freedom from tight-fitting masks, control over when to receive breathing assistance) but requires adequate strength to engage and disengage the mouthpiece and to achieve lip-seal.
Invasive ventilation via tracheostomy	Invasive ventilation allows higher airway pressures, while tracheostomy allows reliable clearance of airway secretions, but these advantages come at the expense of compromised speech and swallowing and increased risk of pneumonia.
Body ventilators	The "iron lung", pneumatic belt, and rocking bed ventilators are of historic interest, but there is ongoing interest in cuirass-style ventilation.
Diaphragm pacing	Stimulation of electrodes surgically implanted into the branches of the phrenic nerve within the diaphragm can provide ventilatory support. Limited but positive clinical experience with weaning spinal cord–injured patients from ventilation.
Glossopharyngeal breathing, "frog-breathing"	This technique trains patients with intact bulbar (mouth and throat) function but ventilatory pump dysfunction how to take a mouthful of air and "gulp" it into their lungs. This can be used as a rescue technique if ventilation is unexpectedly stopped (e.g., power outage) or to augment lung hyper-inflation and assist cough assist.
Supplemental O_2	Although neuromuscular patients may be hypoxic, supplemental O_2 is generally *contraindicated*, as hypoventilation can actually be worsened with administration of O_2. Occasionally, patients with both lung disease and neuromuscular weakness may benefit from cautious use of O_2.

ABG, Arterial blood gas; *BiPAP*, bilevel positive airway pressure; *FVC*, forced vital capacity.

MINI CLINI

Problem

What physical findings may suggest developing respiratory failure in a patient with neuromuscular weakness?

Discussion

Patients whose respiratory muscle strength is inadequate to meet their ventilatory needs have a *rapid, shallow breathing* pattern and use *accessory muscles* of inspiration, especially the neck strap muscles (e.g., sternocleidomastoid). The use of accessory muscles in the setting of a weak or paralyzed diaphragm pulls the diaphragm upward (cephalad) during inspiration, resulting in paradoxical inward movement of the abdomen, called ***paradoxical breathing***. Inability to complete a sentence in one breath is called *staccato speech*. Nonrespiratory signs include sweating, tachycardia, and restlessness. Any of these findings may signal the need for respiratory support.

awakenings, morning headaches, daytime sleepiness, and fatigue. As the disease process progresses, patients may complain of orthopnea and show signs of cor pulmonale (remodeling of the right ventricle, usually in response to pulmonary hypertension, which causes symptoms including dyspnea, fatigue, anorexia, chest pain, edema, and syncope). These changes occur because the muscles involved with respiration can no longer generate or maintain normal ventilation, initially during sleep and ultimately during wakefulness. The response to hypoxemia of increased respiratory drive is preserved in most patients with neuromuscular weakness.[5] Because these patients often do not have the strength to take deep breaths, they maintain minute ventilation by increasing respiratory rate and adopting a rapid, shallow breathing pattern, which requires less respiratory muscle strength but provides less efficient ventilation. Patients with poor inspiratory muscle function (especially diaphragm weakness) may have marked orthopnea and prefer to sleep in a seated position. They also may experience a decline in voice volume or quality. Muscle weakness can progress to the point that adequate ventilation is no longer maintained and hypercapnia occurs.

RULE OF THUMB When a patient complains of immediate shortness of breath on lying down, especially if one side is worse than the other, the problem is diaphragm weakness until proven otherwise.

MONITORING AND ASSESSING PATIENTS WITH NEUROMUSCULAR RESPIRATORY WEAKNESS

There are multiple important physiologic processes to monitor in patients with neuromuscular respiratory weakness, including oxygenation, ventilation, lung expansion, cough adequacy, aspiration risk, and nutrition and sleep quality.

Routine measurement of O_2 saturation (e.g., pulse oximetry) is indicated. A decrease in O_2 saturation can represent hypoventilation or development of atelectasis/pneumonia. Early on or in mild neuromuscular impairment, it often represents atelectasis and airway plugging (see Fig. 33.3), but as the disease progresses, hypoventilation and pneumonia are common causes. Hypoxemia due to atelectasis should prompt lung hyper-inflation therapy (see Table 33.4).

Cough adequacy was discussed above in the section "Pathophysiology and Pulmonary Function Testing" and is assessed with clinical observation and measurement of peak cough flows. Often, asking the patient if they feel capable of coughing effectively will yield important information.

The risk of aspiration is especially high in patients with bulbar weakness (weakness of the mouth and throat), a situation that is often worsened by ineffective cough. In these patients, the inability to clear the airway can increase the work of breathing, resulting in muscle fatigue, hypoventilation, and respiratory failure. Aspiration pneumonia is another major risk. Risk of aspiration can be assessed in several ways. A history of frequent coughing while eating or drinking should raise suspicion for aspiration. Formal evaluation with a video fluoroscopic swallow study can assess the specific risk of aspiration with different kinds of foods and drinks. A simple but informative bedside test is to watch the patient drink a small amount of water: aspiration is suspected if they cough after swallowing.

Malnutrition is a major risk in patients with neuromuscular weakness, especially with bulbar dysfunction. Weight loss is a reliable sign of malnutrition and can result in a vicious cycle, where malnutrition leads to weakness, which further exacerbates malnutrition. Once identified, malnutrition should prompt consideration of dietary supplements, or—if consistent with the patient's goals of care—a feeding tube.

Patients with neuromuscular weakness are especially vulnerable to sleep-disordered breathing, including sleep hypoventilation and **obstructive sleep apnea** (OSA). Although polysomnography is the gold standard for diagnosis and treatment of sleep-disordered breathing, home-based sleep studies (oximetry ± capnography) or nocturnal pulse oxymetry are more convenient and can be used in any patient with neuromuscular weakness who endorses symptoms of sleep-disordered breathing (e.g., poor sleep quality, daytime drowsiness).[6] In addition, modern home ventilators (both invasive and noninvasive) have sophisticated technology that records many ventilatory and physiologic parameters and allow remote access to these data through "device download" functions. These devices are both therapeutic and diagnostic, allowing care providers to review information such as the apnea-hypopnea index, inspiratory and expiratory pressures, respiratory rate, tidal volume, and minute ventilation.

Routine ventilatory function testing includes measurement of sitting and supine VC, inspiratory and expiratory pressure, and CO_2 levels (using end-tidal CO_2 or ABG). However, patients with bulbar weakness may have difficulty achieving a lip-seal on the mouthpiece of the spirometer; in this case, the sniff inspiratory pressure is sometimes more practical, as it can be done with a face mask.

MANAGEMENT OF RESPIRATORY MUSCLE WEAKNESS

Ventilatory support, initially used only during sleep, then extending into intermittent use while awake and eventually to 24-hour continuous use, is a well-recognized treatment for respiratory

MINI CLINI

Assessment of a Patient With Neuromuscular Weakness

Problem

A 50-year-old man with amyotrophic lateral sclerosis (ALS) is admitted to the hospital because of right lower lobe pneumonia. His PO_2 is 68 mm Hg on room air. ALS was diagnosed 3 years previously, and he has had progressive worsening of dyspnea since then. These symptoms first occurred with mild exertion and then with supine position, which the patient has noticed in the last 1 or 2 months. A recent measurement of VC at the physician's office was 2.1 L (50% predicted value). The patient has recently noticed difficulty with swallowing and frequent coughing at meals. What features in the patient's history may be relevant with regard to management?

Discussion

This patient has a disease that progresses slowly in most cases, now with acute deterioration probably due to aspiration pneumonia. The earliest symptom of neuromuscular weakness in the respiratory muscles is exertional dyspnea, which this patient has had for some time. A more significant finding is orthopnea, which is highly suggestive of diaphragmatic weakness. Patients with significant diaphragmatic weakness prefer an upright position, which allows the abdominal contents to shift toward the feet, thus reducing the paradoxical breathing that compromises ventilation. Although the patient may not have had a critically low VC recently, his value is low. Additional loading of already compromised ventilatory machinery can lead to fatigue and frank respiratory failure. It is important to recognize that acute diseases like pneumonia or viral illness exacerbate the weakness and will predispose a patient with stable neuromuscular weakness to respiratory fatigue and subsequent respiratory failure. The history of feeding difficulty suggests that the pneumonia is related to aspiration. The location of pneumonia in the lower lobe also favors the diagnosis if the aspiration occurred when the patient was seated upright. Noninvasive ventilation (NIV) could be considered for long-term treatment at this time.

failure from progressive neuromuscular weakness, but other respiratory support measures should be started earlier in the disease process (see Table 33.4). Lung hyperinflation (breath stacking) can be beneficial in the early stages of weakness when the risk of atelectasis becomes problematic. Breath stacking also allows patients to maintain clear airways. When breath stacking is not feasible due to bulbar disease, cough assist should be added to the therapy. Used together, these interventions can decrease hospitalizations for respiratory complications in patients with neuromuscular disease.[7] In addition to these interventions, general rehabilitation focusing on aerobic conditioning, muscle strengthening, and respiratory muscle training often can delay the need for ventilatory support and improve the overall quality of life for patients with muscle weakness.[8]

NIV is used for long-term support of patients with neuromuscular disease, as well as temporarily during episodes of acutely worsened respiratory status (see Table 33.4). Long-term NIV for stable neuromuscular weakness is started as nighttime support to treat sleep hypoventilation. If the disease progresses, NIV can be extended into daytime hours and can even be used continuously 24 h/day, but special care is needed to prevent skin breakdown at the site of mask contact. NIV can also be used as a rescue therapy for acute decompensation, such as caused by pneumonia, aspiration, or surgery. In this case, NIV should be started when the patient begins to feel fatigued by work of breathing, when there is still opportunity to recover. If NIV is delayed until frank hypercarbia has developed, it may fail simply because the patient is too severely fatigued.[9] NIV can also be used to reduce the risk of reintubation as patients are recovering from an acute illness requiring temporary invasive ventilation. Postextubation NIV is most likely to be successful when the patients tolerate NIV because of previous experience and the burden of secretions is manageable.

NIV should be considered in patients with chronic or acute neuromuscular weakness, exacerbations of myasthenia gravis (MG), postextubation support for patients intubated for transient respiratory failure, and neuromuscular patients who also have COPD or congestive heart failure. Clinical situations where NIV is not usually indicated or performs poorly include Guillain-Barré syndrome, acute spinal cord injury, severe hypercapnia, acute brain injury with coma, severe agitation requiring sedation, a large amount of respiratory secretions, hemodynamic instability (e.g., shock), and procedures requiring sedation or anesthesia.[9]

Starting NIV on a patient with chronic neuromuscular weakness is a key moment in their life: first impressions affect long-term adherence. Thus achieving comfortable settings on a device that fits in with the patient's lifestyle is crucial. Modern ventilators are small and lightweight, with a battery that allows portability. These advanced devices can also switch between separate nighttime and daytime ventilator modes, which is generally indicated as the interface and settings needed for good sleep are usually different than what is needed for daytime support. A full face mask, nasal mask, or nasal pillows are often the most comfortable for nighttime NIV. The best daytime interface is more variable; some patients may have multiple interfaces to use throughout the course of one day. A mouthpiece interface for daytime ventilation has many advantages (improved speech and swallow, freedom from tight-fitting masks, control of timing, and volume of ventilatory support) but requires adequate strength to engage and disengage the mouthpiece and to achieve lip-seal. Mouthpiece interface with a "kiss-triggered" volume-cycled ventilator can be used to breath-stack, achieving lung-hyperinflation, cough augmentation, and louder voice (even shouting!). During acute decompensation, a face mask that fits over the mouth and nose may be preferable, as it provides the most reliable positive airway pressure (PAP).

The airway pressures and mode of ventilation should be set to achieve the following: comfort/tolerance, adequate ventilatory support, avoidance of rapid shallow breathing, and elimination of OSA. The expiratory positive airway pressure (EPAP, also known as PEEP or continuous positive airway pressure [CPAP]) should be set as low as possible (<4 cm H_2O) to reduce air leaks and patient–ventilator dyssynchrony. The exception to this rule occurs in patients with sleep apnea, when EPAP needs to be set high enough to eliminate obstructive events. Inhalations can be delivered either via volume or pressure control. In volume control, the tidal volume is preset, and the machine will deliver regardless unless pressure limits or alarms are met. In pressure control, the IPAP is preset, and the delivered tidal volume varies based on patient effort and respiratory system characteristics. There are other modes of NIV, none with more evidence than simple bilevel. These modes use adaptive targeting and adjustment algorithms (e.g., volume-assured pressure support [VAPS or

MINI CLINI

Care of a Patient With Myotonic Dystrophy

Problem

A 45-year-old man has myotonic dystrophy. He has progressive dyspnea that has increased, particularly in the last year. PCO_2 determined from ABG analysis is 55 mm Hg. VC is 2.3 L (40% predicted). He has been using a mechanical insufflation-exsufflation device with good clearance of secretions and no episodes of pneumonia. The patient reports daytime drowsiness and is sleeping in a semi-recumbent position at night because of orthopnea. What interventions are indicated for this patient?

Discussion

The patient has a disease that can result in respiratory insufficiency. VC is decreased, and arterial carbon dioxide levels are increased. These factors are consistent with hypoventilation secondary to neuromuscular weakness. The patient has dyspnea on exertion and orthopnea. All these factors suggest that mechanical ventilation should be considered.

AVAPS]) to adjust the IPAP according to tidal volume or minute ventilation targets. Although studies are underway, issues with synchrony, adjustment of IPAP and how to set targets are still not standardized.[10] This highlights the importance of setting up and appropriately titrating the NIV device. Care should also be taken to choose the appropriate trigger to initiate inhalation: a threshold that is not sensitive enough could result in missed triggers (a patient breathing effort without assistance from the ventilator), whereas a threshold that is too sensitive will increase risk of auto-triggering (inappropriate delivery of a ventilator breath). A backup rate can be set to reduce the risk of hypoventilation from missed triggers.

Diaphragm pacing in patients with spinal cord injury (SCI) has been described using direct stimulation of an intact phrenic nerve to contract the diaphragm and produce negative intrathoracic pressure and inspiration, with favorable clinical experience.[11,12] A proof-of-concept study demonstrated that pacing may prevent diaphragm atrophy due to mechanical ventilation.[13] Unfortunately, despite early nonrandomized studies showing benefit of diaphragm pacing in ALS,[14] more recent randomized controlled trials demonstrated higher mortality.[15,16]

NIV may be a reasonable first choice for this patient. The patient's mental status and bulbar function are intact. He has no significant problems with secretions. (Important factors for successful application of NIV are discussed in Chapter 50.) Use of a biphasic PAP unit may be instituted and titrated to patient tolerance. NIV use overnight should be especially helpful, but it may be helpful for adjustment to start by using the device during the day. A time-triggered backup rate can be set on some ventilators to facilitate ventilation of patients who may inadequately trigger the ventilator. As long as bulbar function and secretion management are maintained, NIV is a reasonable choice for ventilatory support.

RULE OF THUMB Patient with neuromuscular weakness should generally receive the low EPAP and a relatively high inspiratory airway pressure (IPAP). The difference between IPAP and EPAP represents the pressure support that is augmenting ventilation.

SPECIFIC NEUROMUSCULAR DISEASES

Disorders of the Muscle (Myopathic Disease)

Primary muscle disease can decrease the ability of a normal neural impulse to generate effective muscle contraction. Some commonly recognized myopathies include Duchenne muscular dystrophy (DMD), myotonic dystrophy, and polymyositis. Box 33.1 presents a more complete list of myopathic diseases associated with ventilatory dysfunction.

Duchenne Muscular Dystrophy and Becker Muscular Dystrophy

Duchenne muscular dystrophy is a genetic muscle-wasting disorder caused by mutations in the dystrophin gene.[17] Because it is an X-linked recessive disorder with shortened survival, it affects essentially only males. The diagnosis is made when a dystrophin mutation is found in DNA from circulating white blood cells or when dystrophin is found to be absent or abnormal in biopsied muscle tissue.

DMD manifests early in life with proximal muscle weakness that leads to a waddling gait, exaggerated lumbar curvature (lordosis), and frequent falls. Most affected children need a wheelchair by 12 years of age. Death used to occur by 20 years of age as a result of declining respiratory muscle strength and subsequent infection. However, over the last decade, the improvement and widespread use of NIV has improved survival.

Other systemic effects of DMD include scarring of the left ventricle and decreased bowel motility (ileus). The progressive

- Dermatomyositis
- Hypothyroid-related and hyperthyroid-related myopathies
- Endocrine myopathies
- Steroid-induced myopathies (including critical illness myopathy)
- Miscellaneous myopathies
- Electrolyte disorders (e.g., hypophosphatemia and hypokalemia)
- Rhabdomyolysis
- Periodic paralysis
- Postneuromuscular blockade myopathy

decline in respiratory function in patients with DMD is due to global loss of muscle strength and typically manifests at the time of wheelchair dependence.

Progressive scoliosis is associated with DMD and can contribute further to respiratory insufficiency. Many patients undergo spine fusion surgery, and often the procedure allows greater comfort and ease in maintaining an upright posture. Although no randomized trials have proved any benefit of surgery on pulmonary function,[18] it appears that the rate of respiratory decline is slower after fusion surgery.[19]

OSA is present in a significant proportion of patients with DMD, but diagnosis with formal polysomnography is burdensome, and progression of the disease would require frequent retitrations of PAP support. New home-based PAP devices have advanced technologies that allow automatic adjustment of PAP to eliminate OSA events, as well as transmission of physiology and device data to care providers to aid decision making around therapy customization.

Whether to start positive pressure ventilation (PPV) is a decision that most patients will face at some point in the disease. Nocturnal PPV is indicated with signs of hypoventilation, often corresponding to forced vital capacity (FVC) less than 40% predicted.[20,21] It can be started in response to home-based oximetry showing O_2 desaturation during sleep with or without capnography showing elevations of CO_2.

Nocturnal ventilation usually improves daytime ventilatory function in patients with DMD,[22] presumably through prevention of respiratory muscle fatigue. Despite this improvement, studies of early "prophylactic" PPV for patients with DMD have shown that early PPV failed to delay the need for invasive ventilatory support.[23]

Myotonic Dystrophy

Myotonic dystrophy is the most common form of muscular dystrophy in adults, with an estimated frequency of 1 in 8000 persons.[24] *Myotonia,* or delayed muscle relaxation, is the key feature of this neuromuscular disorder. This autosomal dominant disorder causes progressive muscle weakness, abnormalities of the cardiac conduction system, endocrine dysfunction, and cataracts.

Respiratory dysfunction in myotonic dystrophy is common, usually occurring late in the course of disease, and can include respiratory muscle weakness, OSA, and bulbar muscle dysfunction leading to aspiration. Sleep-disordered breathing is common, even at an early age.[25]

Patients with myotonic dystrophy can be very sensitive to anesthesia and respiratory depressants. Both respiratory failure and prolonged neuromuscular blockade have been reported in patients with myotonic dystrophy given usual doses of these agents. NIV can be used postoperatively, especially if the patient has had the opportunity to adjust to NIV preoperatively. Prolonged monitoring after surgery is prudent.[26,27]

Nocturnal NIV is effective for these patients and should be considered if the patient has declining SaO_2 or hypercapnia despite optimal use of lung hyper-inflation and cough-assist techniques. Tracheostomy can often be avoided but may become necessary if NIV fails, often because of inability to clear secretions.

Polymyositis and Dermatomyositis

Polymyositis and **dermatomyositis** are inflammatory myopathies that occasionally involve the respiratory muscles and may also cause interstitial lung disease (e.g., scarring or other changes in the lung tissue). Respiratory muscle weakness generally parallels limb weakness, and can progress rapidly. Respiratory failure can develop within weeks to months, especially if interstitial lung disease is also present. The diagnosis of these diseases is based on clinical findings of myalgia, elevated muscle enzyme levels (creatine phosphokinase or aldolase), and compatible electromyographic or muscle biopsy results.[28,29]

Corticosteroids are important in the initial management of polymyositis and dermatomyositis, especially if interstitial lung disease is present. Other immunosuppressive and cytotoxic agents are used for aggressive disease control and to limit long-term steroid exposure. Various antisynthetase antibodies (e.g., the Jo-1 antibody) have been identified that are associated with polymyositis and dermatomyositis; when these antibodies are present, the risk of interstitial lung disease is increased.[30–32] Pulmonary vasculitis can occur with polymyositis and dermatomyositis and can lead to O_2 exchange abnormalities and pulmonary hypertension.

Ventilator-induced diaphragm dysfunction. **Ventilator-induced diaphragm dysfunction** (VIDD) is very common among critically ill patients and results in weaning failure and long-term respiratory impairment.[33] Sepsis and mechanical ventilation are definite risk factors for VIDD, while steroids and paralytics are less consistently implicated.[34] The mechanism of development is multifactorial, but disuse atrophy plays a major role, while other contributors include neuropathy, myopathy, malnutrition, and systemic inflammation. VIDD can start developing within 24 hours of ventilation.[35] Studies have demonstrated that respiratory effort by the patient impacts the development of VIDD: atrophy develops with "over-assistance" by the ventilator and minimal patient effort. Conversely, with "under-assistance" from the ventilator and excessive patient breathing efforts, the diaphragm thickens, potentially representing muscle injury, and these patients have similarly bad outcomes. Optimal assistance with mechanical ventilation that preserves a normal diaphragmatic effort has been recently proposed as a "muscle-protective ventilation" strategy, but further studies are needed.[36–39]

Disorders of the Neuromuscular Junction

Disorders of the neuromuscular junction decrease conduction of nervous system impulses to the peripheral muscles, resulting in muscle weakness. Different clinical syndromes are caused by defects in different molecules or components of the neuromuscular junction, which is represented schematically in Fig. 33.4, which compares a normal neuromuscular junction with an abnormal junction in MG. Disorders of the neuromuscular junction include MG, Lambert-Eaton syndrome (LES), and certain poisonings (organophosphate, tetanus, botulism).

Myasthenia Gravis

Myasthenia gravis is characterized by intermittent muscular weakness, which worsens on repetitive stimulation and improves with administration of anticholinesterase medications, such as edrophonium or neostigmine.[40] Muscle involvement commonly

MINI CLINI

Care of an Intensive Care Unit Patient to Minimize the Risk for Ventilator-Induced Diaphragm Dysfunction

Problem

A 60-year-old man is in the ICU with respiratory failure secondary to severe influenza pneumonia. He has developed acute respiratory distress syndrome (ARDS), and gas exchange is severely impaired, with a PaO_2/FiO_2 ratio of 90. He is requiring relatively high positive end expiratory pressure (PEEP) and FiO_2 to maintain adequate SaO_2. He has septic shock, requiring pressors immediately after intubation for the initiation of mechanical ventilation. Along with the immediate needs for stabilization, resuscitation, and supportive care, the ICU team needs to consider what impact their therapeutic choices now will have on his risk for developing ventilator-induced diaphragm dysfunction.

Discussion

This scenario is seen in high-acuity ICUs, in which patients with severe ARDS and sepsis are frequently found. This patient is at risk of poor respiratory outcome, from ARDS and VIDD, as well as long-term global outcomes from ICU-acquired weakness and neurocognitive impairment. Lung-protective ventilation using low-tidal volumes is important early in ARDS, but the deep sedation and continuous infusions of paralytics used to achieve this goal run counter to "muscle-protective ventilation" and may be detrimental for the diaphragm. The benefit of lung-protective ventilation in ARDS is time dependent; as the disease resolves, the risk-to-benefit ratio of deep sedation and paralytics will no longer be favorable. At that point, allowing the patient to resume a "normal" breathing effort, without overloading or under loading the diaphragm, may help work toward weaning from mechanical ventilation.

affects the muscles of the mouth, neck, and especially the eyes, with a presenting complaint of diplopia (double vision) or ptosis (a drooping eyelid) in more than 65% of patients (Fig. 33.5).[41] Weakness worsens with repetitive use and improves with rest, thus varying throughout the day, often worst in the evening and best in the early morning. MG is "a disease of young women and old men," as reflected by hospital admission demographics.[42]

Auto-antibodies target different elements in the neuromuscular junction in MG, often the acetylcholine receptor (ACh-R). The antibodies inactivate the ACh-R and block transmission of electrical impulses from the nerve to the muscle.[43] Antibody negative disease is confirmed with nerve studies and appropriate response to therapy.[40] Thymus abnormalities are common in MG, including hyperplasia and thymoma, and are involved in the pathogenesis of MG, as thymectomy improves the disease course.[44]

Myasthenic crisis is defined as respiratory failure or delayed postoperative extubation resulting from myasthenic weakness.[45] Triggers of myasthenia crisis include respiratory infection, aspiration, surgery, pregnancy, or new medications. Patients at risk of needing respiratory support should be monitored in an ICU. Measuring VC has limited value in predicting an impending myasthenic crisis, as muscle strength can deteriorate quickly and unexpectedly due to fatigue.[40] However, muscle strength can also recover very quickly in MG. For this reason, NIV can be very effective in providing support for an impending myasthenic crisis, provided that it is initiated before irreversible respiratory muscle fatigue has developed.[46] Multiple retrospective studies have concluded that if NIV is initiated early on during ventilatory decompensation, intubation can be avoided. NIV is likely to fail if

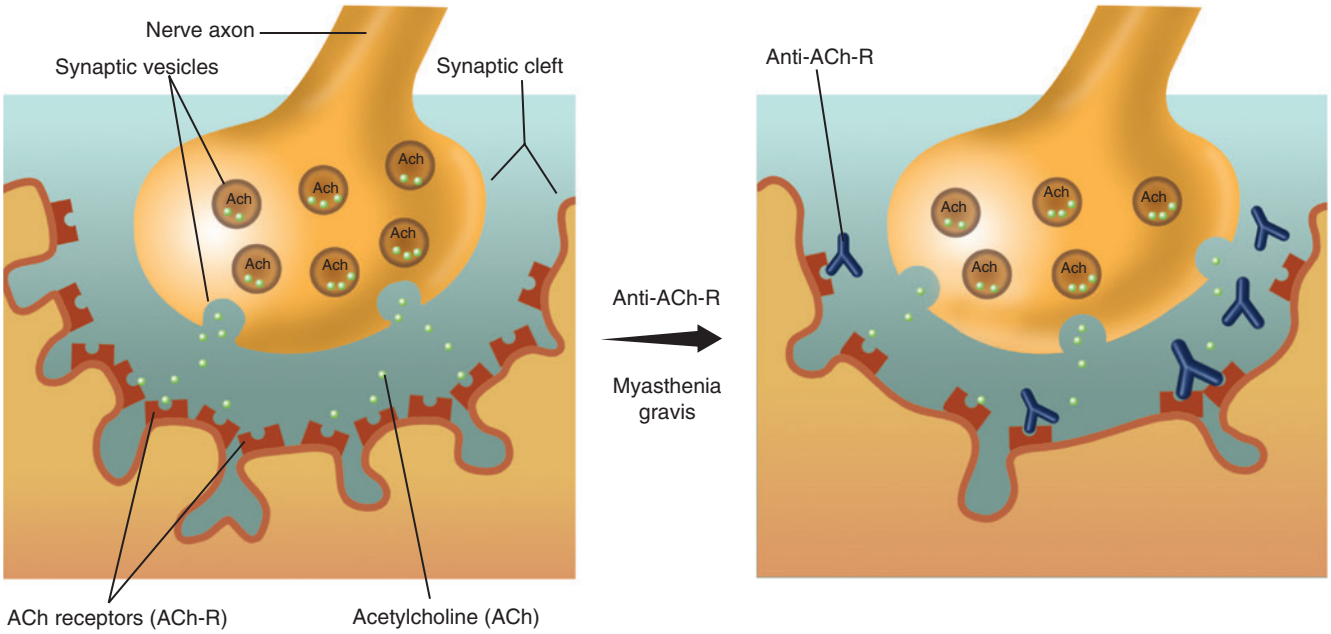

Fig. 33.4 The neuromuscular junction with acetylcholine *(ACh)* stored in presynaptic vesicles. ACh is released by exocytosis into the synaptic cleft in response to a presynaptic nerve impulse. ACh binds to its cognate *ACh-R* on the postsynaptic membrane. This process depolarizes the nerve, propagates the impulse, and causes muscle contraction. Binding of anti-ACh-R antibodies to ACh-R mediates autoimmune destruction of the receptors. This process leads to abnormal muscle activation and the weakness that occurs in patients with myasthenia gravis.

Fig. 33.5 Features of Ocular and Facial Weakness in a Patient With Myasthenia Gravis. At rest *(left),* there is slight bilateral lid ptosis, which is partially compensated by asymmetric contraction of the frontalis muscle, raising the right eyebrow. During attempted smile *(right),* there is contraction of the medial portion of the upper lip and horizontal contraction of the corners of the mouth without the natural upward curling, producing a "sneer." (From Sanders DB, Howard JF: Disorders of neuromuscular transmission. In Bradley, editor: *Neurology in Clinical Practice,* ed 5, Philadelphia, 2008, Butterworth Heinemann.)

initiation is delayed until after the onset of hypercarbia, a late sign of ventilatory failure.[9]

Lambert-Eaton Syndrome

Another syndrome of neuromuscular weakness arising from a disorder at the neuromuscular junction is **LES**. More than 50% of cases of LES are associated with cancer, especially small cell carcinoma of the lung, which accounts for 80% of malignancies causing the syndrome.[47] Autoantibodies against voltage-gated calcium channels at the nerve terminals impair the release of acetylcholine and can lead to both muscular weakness and autonomic insufficiency.[48] Increasing muscle strength with repetitive stimuli is a characteristic feature of LES, which differentiates it from MG; MG is characterized by progressive fatigue of muscular contraction with repetitive stimulation.

In comparison to MG, respiratory muscle involvement is uncommon in LES and—when it does occur—tends to be mild. Respiratory failure is rare, but can be triggered by medications (e.g., paralytics). Patients with LES usually present with weakness of the proximal muscles. The clinical course of LES tends to be one of relative stability with less fluctuation than MG. Management is aimed at treating the underlying cancer. If no malignancy is found, surveillance for lung cancer is recommended every 6 months, and LES is managed symptomatically with immunosuppressive medication or acetylcholinesterase inhibitors.[47,49]

Disorders of the Nerves

The peripheral nerves may be affected by toxic agents, inflammatory processes, vascular disorders, malignant diseases, and metabolic or nutritional imbalances. Hundreds of conditions have been associated with neuropathies leading to respiratory muscle dysfunction. Representative conditions are listed in Box 33.2.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is acute inflammatory immune-mediated polyradiculoneuropathy and is the most common peripheral **neuropathy** causing respiratory insufficiency. GBS is characterized by paralysis and diminished reflexes, often with sensory symptoms and pain. The disease can be triggered by gastrointestinal or respiratory infection, which is thought to generate autoantibodies that target the myelin of the nerve sheath.[50] The diagnosis of GBS is based on a combination of clinical, laboratory, and electrophysiologic data (Table 33.5). Treatment for GBS may be beneficial when started within 2 weeks of symptom onset. Intravenous immunoglobulin or plasma exchange can be used (but not both). Corticosteroids offer little if any benefit in GBS.[51,52]

About 30% of patients with GBS will develop respiratory muscle weakness significant enough to require intubation and mechanical ventilation.[53] Median duration of mechanical ventilation is 28 days and is occasionally much longer. Tracheostomy should be considered in all patients who continue to require ventilatory support at 1 week and who are unable to lift their arms and have very abnormal nerve conduction tests.[54,55] NIV can be helpful during the recovery phase to achieve liberation from invasive ventilation, but given the prolonged course of patients who develop respiratory muscle weakness, NIV is unlikely to prevent intubation, and the delay could be dangerous.[9] Weaning trials during invasive ventilation should begin in the recovery phase, when VC is greater than 15 mL/kg and PImax greater than 30 cm H_2O.

BOX 33.2 Causes of Phrenic Nerve Dysfunction Leading to Respiratory Dysfunction

- Cardiac surgery (cold cardioplegia to arrest the heart can cause "frostbitten" phrenic nerves; ischemic injury to nerves also can complicate cardiac surgery)
- Neuralgic amyotrophy
- Diabetes
- Trauma
- Thoracic aneurysm

TABLE 33.5 Comparison of Myasthenia Gravis and Guillain-Barré Syndrome

	MG	GBS
Pattern of muscle involvement	Eye muscles are almost always involved. Weakness can be widespread or localized, usually proximal rather than distal.	Leg and arm weakness develop initially, which moves proximally with widespread muscle involvement, ("ascending paralysis"). Initial bulbar weakness is less common but can mimic MG.
Triggers	Pneumonia, aspiration, medications, surgeries, and pregnancy	Infection of gastrointestinal or respiratory tract 2–3 weeks prior to symptoms
Timeline of weakness	Weakness waxes and wanes throughout a single day. Disease responds to medical management but may require treatment for years.	A single episode of weakness steadily progressing over days to weeks, followed by recovery. (i.e., monophasic illness)
Diagnosis	Clinical impression + supportive findings: • Positive antibodies (e.g., acetylcholine receptor antibodies) • Nerve conduction studies show weakness developing with repetitive stimulation • Weakness improves with edrophonium (acetylcholinesterase inhibitor)	Clinical impression: • Bilateral weakness, especially legs • Absent reflexes • Monophasic (see "timeline" above) • Absence of alternative diagnosis Supportive findings: • Cerebrospinal fluid with high protein and low cells • Nerve conduction studies show conduction block or decreased velocities
Respiratory support	Noninvasive ventilation (NIV) is helpful when initiated early on as respiratory muscle fatigue is developing. Aggressive bronchopulmonary hygiene (lung hyperinflation, suctioning, cough assist) can be helpful.	Although ~70% of GBS patients will NOT require ventilatory support, those who do will not quickly recover and often require prolonged intubation. During the recovery phase, NIV can be helpful to prevent reintubation.
Medical treatment	Long-term treatment: cholinesterase inhibitors, steroids, and/or other immunotherapy Myasthenic crisis: plasma exchange and intravenous immunoglobulin, with high-dose steroids and rituximab for intractable disease	Intravenous immunoglobulin and plasma exchange may be helpful if given early in the disease. No long-term therapy is helpful.
Long-term outcome	Response to medical therapy is usually good. Prolonged intubation is largely avoidable.	Tracheostomy and prolonged recovery are common in patients requiring intubation. Even so, the large majority of patients will eventually regain the ability to walk.

GBS, Guillain-Barré syndrome; *MG*, myasthenia gravis.

RULE OF THUMB Patients with GBS whose vital capacity becomes less than 20 mL/kg or whose PImax is less than 30 cm H_2O and PEmax is less than 40 cm H_2O are at risk for respiratory failure and may need ventilatory support. Patients who meet the criteria of this "20-30-40 rule" are at high risk of decompensating, and intubation should be considered, especially if weakness is still progressing or if there is difficulty managing oral secretions.[56,57]

If he continues to require invasive ventilation after one week of intubation, without progress during ventilator weaning trials, then tracheostomy should be considered. Upper airway function (speech, swallow, and cough) is impaired by an oral endotracheal tube (ETT), and early tracheostomy would relieve this impairment, although full restoration of speech, swallow, and cough will be determined by neuromuscular recovery. Tracheostomy is a comfortable and secure airway compared to an oral ETT, permitting patient mobility and active rehabilitation. As his respiratory status recovers, NIV can be introduced (while deflating the cuff completely and capping the tracheostomy), especially at night, when the risk of hypoventilation for diaphragmatic weakness is greatest. If nocturnal NIV is successful, the tracheostomy can be down-sized or decannulated, as determined by his need for airway suctioning.

Phrenic Nerve Dysfunction and Diaphragm Paralysis

Each hemidiaphragm is supplied by its own phrenic nerve. The phrenic nerves emerge from the spinal cord at level C3 to C5

MINI CLINI

Respiratory Care of a Patient With Guillain- Barré Syndrome

Problem

A previously healthy 52-year-old man is admitted to the hospital with complaint of difficulty walking for the past 3 days. He reports having a diarrheal illness 2 weeks ago, which has now resolved. During the first several days of hospitalization, he experiences low-grade fever and intense pain in his legs, and his leg weakness spreads upward to involve his trunk and hands. A lumbar puncture shows elevated albumin but no inflammatory cells. Nerve conduction studies show evidence of a demyelinating process. The diagnosis of GBS is made, and he is started on intravenous immunoglobulin. Because his weakness continues to worsen, he is transferred to the ICU for closer monitoring. The next morning, he reports dyspnea with increased arm weakness.

Discussion

This patient has the typical clinical picture for GBS, with worrisome features of progression involving the respiratory muscles. Monitoring in the ICU should include serial assessment of VC, PImax, and PEmax. If he meets any of the "20-30-40" criteria, then elective intubation should be considered. Other factors that influence the decision to intubate include the tempo of his illness, ability to manage airway secretions, and autonomic lability, which can be problematic in GBS. Ideally, intubation should be performed electively, while he still has physiologic reserve. Waiting for emergency intubation can be lethal.

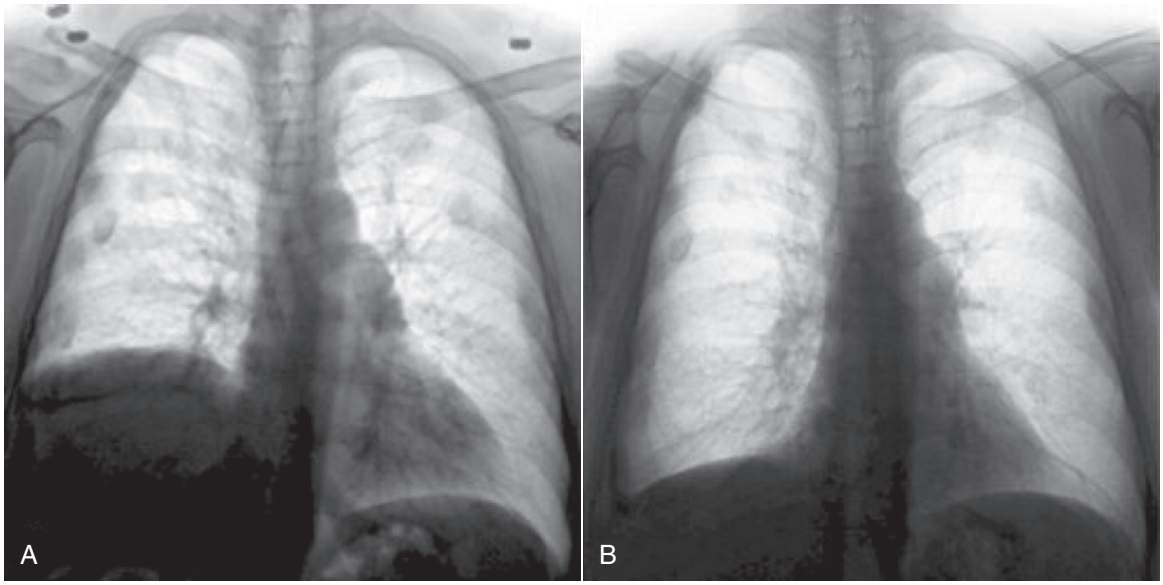

Fig. 33.6 (A) Chest X-ray showing elevation of a right hemidiaphragm. (B) Chest X-ray in the same patient 1 year after laparoscopic diaphragm plication. (From Groth SS, Andrade RS: Diaphragm plication for eventration or paralysis: a review of the literature, *Ann Thorac Surg* 89:S2146–S2150, 2010.)

and descend through the mediastinum along the great vessels of the chest and pericardium. Damage to or interruption of either phrenic nerve leads to paralysis of the ipsilateral hemidiaphragm. Bilateral involvement is seen in high SCI and causes complete diaphragmatic paralysis. Many of the other neuromuscular disorders discussed in this chapter cause respiratory impairment because of bilateral diaphragm involvement. Unilateral diaphragmatic paralysis has many causes, including trauma, brachial plexus injury, or inflammation and cardiac surgery, but in many cases, a cause cannot be determined (i.e., idiopathic).

Bilateral diaphragm paralysis generally causes significant dyspnea, especially when lying flat, bending over, or when immersed in water. Pulmonary function tests show decreased VC while upright, with values often dropping 30% to 50% further in the supine position. Sleep-disordered breathing is common, as normal ventilation is highly dependent on diaphragm function, especially during REM-sleep. For this reason, nocturnal NIV is generally helpful. Diaphragm pacing (discussed as follows in the section *Spinal Cord Injury*) is an appealing option, but clinical experience is quite limited. Because paradoxical movement of the diaphragm is not a major culprit in bilateral paralysis, diaphragm plication is not helpful.[58]

Unilateral diaphragm paralysis is usually minimally symptomatic but can contribute to respiratory impairment, especially in the presence of other comorbidities. Patients with unilateral diaphragmatic paralysis often have near-normal pulmonary function test, but VC may drop 10% to 30% in supine position. An elevated hemidiaphragm on chest X-ray is often the presenting finding (Fig. 33.6A). At fluoroscopy, the paralyzed hemidiaphragm paradoxically rises into the thorax during a sudden forceful inspiration (sniff test). Surgical plication moves the weak hemi-diaphragm downward to a more normal position (see Fig. 33.6B), minimizes paradoxical motion, and improves overall lung function.[59–62] Unilateral diaphragm weakness may slowly improve, sometimes over years, so plication should be delayed until serial testing shows that no further improvement is occurring, usually 2 years from the onset of weakness.[58]

RULE OF THUMB Unilateral diaphragm paralysis is often minimally symptomatic, but surgical plication can be offered to selected patients with significant dyspnea and respiratory impairment who are unlikely to recover (e.g., surgical transection of the nerve, or symptoms persisting >2 years from onset).

Disorders of the Spinal Cord

Upper motor neurons arise from cell bodies in the motor areas of the brain and terminate on the anterior horn cells in the spinal cord, which constitute the lower motor neurons that extend out to the skeletal muscles. Motor neuron diseases such as ALS specifically affect the neurons in the spinal cord that control movement, whereas trauma of the spinal cord can potentially damage all of the neurons (motor, sensory, autonomics, etc.) at the site of injury. Other examples of spinal cord pathology include transverse myelitis, syringomyelia, poliomyelitis, and spinal cord tumors.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis is the prototypical motor neuron disease, with progressive paralysis due to degeneration of motor neurons in the brain and spinal cord (i.e., upper and lower motor neurons). Weakness from ALS usually begins in a localized muscle group, often the arms, and spreads out progressively to involve most muscles, including the diaphragm.[63] In one quarter of cases, weakness begins in the bulbar muscles. Rarely, ALS starts as isolated diaphragm dysfunction in an otherwise intact patient. Respiratory paralysis eventually occurs in all patients with ALS and is the most frequent cause of death. There is no cure for ALS, and medications—such as riluzole and edaravone—provide limited improvement in survival.[63] NIV is the only therapy that has increased survival and quality of life in patients with ALS.[64]

The profile of respiratory impairment in ALS depends on the pattern of muscle involvement and stage of the disease. Gradual decline in respiratory muscle strength may be punctuated by acute respiratory infection or aspiration, resulting in abrupt respiratory failure. Diaphragm weakness will result in impaired cough, orthopnea, and sleep hypoventilation, deteriorating to wakeful hypoventilation. Bulbar weakness will result in malnutrition, impaired cough, aspiration, and pneumonia. Speech is also impaired, which can be socially and psychologically troubling. Limb weakness will result in functional decline and impaired mobility with eventual wheelchair dependence.

Respiratory support can be added in a stepwise fashion, as outlined in Table 33.4, tailored to each patient's specific needs. NIV is a reasonable option for many patients and has been shown to slow the rate of pulmonary decline, improve symptoms, and prolong survival.[64–66] Severe bulbar dysfunction, with poorly managed secretions and aspiration, limits the benefit of NIV. Because the disease invariably advances, patients and care providers should plan ahead and discuss invasive ventilation and tracheostomy. Many patients with ALS choose not to receive invasive mechanical ventilation and opt for palliative management. However, many patients do desire invasive ventilatory support; up to 90% of such patients report satisfaction with their decision and would choose tracheostomy and ventilation again in the same situation.[67] Conversely, caregivers of patients with ALS who receive home ventilation often report frustration and unhappiness.[68]

RULE OF THUMB The timing and type of ventilatory intervention (noninvasive or invasive) in the care of patients with ALS are the subject of much discussion. General guidelines for considering ventilatory assistance include VC less than 50% predicted, orthopnea, maximal sniff nasal inspiratory force less than 60 cm H_2O, daytime hypercapnia, and abnormal nocturnal oximetry.[69]

RULE OF THUMB ALS is a complex and devastating disease and often requires a multidisciplinary approach, with input and active participation from many clinical specialties, including pulmonology, neurology, gastroenterology, palliative medicine, respiratory care, physical therapy, occupational therapy, social work, home nursing, psychiatry, and spiritual care.

Traumatic Spinal Cord Injury

Approximately 17,500 SCIs occur in the United States each year,[71] with the majority of disability due to the cervical SCI. While young men continue to be far more likely than females to sustain a SCI, there is a recent trend towards older men being injured, often due to a fall. Complete cord injury is associated with absent motor and sensory function below the level of injury, and the patient's condition rarely improves. Patients with incomplete injury have residual function and tend to improve to varying degrees. Pneumonia and sepsis are the leading causes of death in SCI.[71]

The respiratory manifestations of SCI depend on the level of injury and extent of damage. Cervical cord injuries can be functionally divided into two classes: high cervical cord lesions (C1 to C2) and middle to low cervical cord lesions (C3 to C8). The diaphragm receives innervation from nerve roots exiting the spinal cord at levels C3 to C5. Complete injury above this level results in total respiratory muscle paralysis and death unless urgent intubation and ventilation are performed. Injury to the cord at C3 to C5 can severely reduce respiratory strength, as manifested by reductions in PEmax, PImax, FVC, and FEV_1, consistent with a restrictive ventilatory defect. Patients adopt a rapid, shallow breathing pattern and inhale with the aid of the neck strap muscles (e.g., sternocleidomastoid and scalenes), whose innervation is spared except with high cervical cord injury. Despite the serious nature of injury between C3 and C5, 80% of intubated patients with this lesion can ultimately be liberated from invasive ventilation. The muscles of expiration (muscles of the chest and

MINI CLINI

Respiratory Care of a Patient With Amyotrophic Lateral Sclerosis

Problem

A 57-year-old man was diagnosed with ALS 1 year ago, after he developed weakness in his left arm. He is now wheelchair bound because of severe weakness in all four extremities. Nocturnal NIV was started 4 months ago and has improved his orthopnea, poor sleep, and nightmares; his FVC at that time was 50% predicted, with a 30% drop while supine. He is now using NIV increasingly into waking hours, with a nasal pillow interface. He is having more difficulty speaking, especially when wearing NIV. He has lost 40 pounds in the last 6 months due to decreased appetite. He denies coughing while eating. O_2 saturation is 92% on ambient air. Cough peak flow is 160 L/min. What measures can be offered to help him maintain his respiratory function, avoid exacerbations that could lead to acute respiratory failure, and plan for the future?

Discussion

This patient is experiencing the progressive weakness involving most muscle groups, which is typical of ALS. Diaphragm and generalized muscle weakness is objectively measured by a low FVC that drops further in the supine position. His self-initiated use of daytime NIV indicates progressive ventilatory muscle weakness and a clinical opportunity to provide better daytime support. Daytime mouthpiece ventilation may be very helpful, provided he has enough bulbar function to create a good lip seal. A volume controlled mode delivering 700 to 1500 mL (adjusted to comfort) can be used for breath stacking, which cannot be done with a pressure-cycled mode. Using a "sip trigger" or "kiss trigger," multiple back-to-back inhalations will be delivered by the ventilator, which helps reexpand atelectasis (which is suggested by his mild hypoxemia), augment peak flows during cough, and possibly reduce the risk of thoracic cage kyphosis. If his "breath-stacked" cough peak flow remains less than 270 L/min, then thoraco-abdominal compressions ("quad cough") done after breath stacking will improve cough efficiency. If these do not facilitate effective cough, or if glottic closure is not effective, then a mechanical insufflator-exsufflator should be introduced for cough-assistance. The initial pressures should be low to achieve tolerance, and then titrated upward to achieve effect. Importantly, patients with ALS and bulbar (mouth and throat) weakness may not tolerate high pressures with this technique because of airway closure.[70] His 40-pound weight loss may be due to respiratory insufficiency impairing his ability to eat and might improve with daytime mouthpiece ventilation, which—compared with other ventilator interfaces—supports better swallow and speech function (even shouting). Unfortunately, even if there is a response, it will likely be short-lived, and a feeding tube should eventually be considered. Importantly, a discussion with him and his loved ones on goals of care is urgently needed, as there is high risk of acute respiratory deterioration.

abdominal wall) receive neural input from spinal levels T1 to L1 and are predominantly affected by middle to low cervical cord lesions. This condition manifests as a marked reduction in PEmax compared with PImax and a weak or ineffective cough.

There is a curious type of inverted paradoxical breathing when a low cervical SCI causes paralysis and atrophy of the chest and abdominal wall but preserves diaphragm strength. During inhalation when lying flat, the diaphragm contracts downward—which moves the abdomen outward—and generates negative intrathoracic pressure, which pulls the paralyzed and atrophied rib cage inward. Lying flat assists exhalation, because the weight of the abdomen acts as a restoring force and pushes the diaphragm upwards. Respiratory mechanics are impaired in the upright position; because the abdominal wall muscles are atrophied and highly compliant, there is no restoring force to assist exhalation, compromising ventilation and gas exchange. This leads to a rare type of positional respiratory impairment termed "platypnea-orthodeoxia syndrome": dyspnea and hypoxemia in the upright position. Abdominal binding in athletes with low cervical SCI was shown to improve respiratory mechanics.[72]

Bulbar strength is preserved in SCI, but many airway-protective behaviors (e.g., cough, sneezes, sighs) are impaired, due to disruption in the neural circuitry responsible for these reflexes.[73] There is significant functional recovery of airway-protective behaviors within 1 year of injury due to plasticity and regeneration in the nervous system.

Sleep-disordered breathing is highly prevalent in SCI, approaching 60% in complete tetraplegia.[74] A case series of adults with SCI using home-based sleep studies combined with transcutaneous capnography demonstrated OSA in 81%, nocturnal hypercapnia in 28%, and central sleep apnea in 24%.[75] The same group reported positive clinical experience in treatment of sleep-disordered breathing in SCI, using autotitrating CPAP to treat OSA and NIV with VAPS to treat nocturnal hypercapnia.[76]

Acute Brain Injury

Traumatic brain injury, **stroke**, and intracranial hemorrhage are all types of brain injury that can lead to respiratory failure through several mechanisms, most commonly failure to protect the airway often associated with decreased level of consciousness (LOC). While intubation for acute ischemic stroke is rare,[77] patients with acute severe trauma often need urgent airway management because of risk of aspiration and impaired ventilatory drive and function.[78] For more information on the initial airway and ventilation management of trauma patients, please see Chapter 30 on trauma.

The prognosis of brain-injured patients who are intubated varies significantly, with some patients quickly recovering normal function, while others will be permanently neurologically devastated. As these patients stabilize, multiple factors determine when the patient can be safely extubated, especially mental status, ability to protect the airway, resiliency, and frailty, as reflected by age and comorbidities.[79] Airway management in brain injury highlights an important concept: the ability to ventilate is separate from the ability to protect the airway. Successful ability to ventilate, as assessed by "conventional" weaning parameters such as rapid shallow breathing index and a spontaneous breathing trial, does not predict successful extubation in patients with acute brain injury. Although there is much debate around which brain-injured patients should have a trial of extubation versus proceeding straight to tracheostomy, there are a few guiding principles. First, extubation is more likely to fail when airway-protective behaviors are absent (cough, gag, and swallow).[80,81] Second, a decreased LOC, as reflected by a low Glasgow coma score, in the absence of other concerning factors, should not prevent a trial of extubation.[82,83] On the other hand, decreased LOC is a risk factor for failure of extubation and is a major factor in the decision to pursue tracheostomy.

Tracheostomy provides reliable long-term artificial airway protection and allows rescue ventilation when needed. Multiple studies have compared early versus late tracheostomy in severely brain-injured patients, with some evidence of a few modest benefits from early tracheostomy, including shorter duration of ventilation and ICU length-of-stay in brain-injured patients.[84,85] Families or decision-makers of brain-injured patient should know that 25% of patients who underwent tracheostomy after a severe stroke were alive and decannulated 12 months later, often with some functional neurologic improvement.[86]

MINI CLINI

Respiratory Dysfunction in Spinal Cord Injury

Problem

A young man who is otherwise healthy falls from a ladder and transects the spinal cord at the level of C6. Which muscles of the respiratory system will be affected, and what will be the effect?

Discussion

Transection of the spinal cord at the level of the sixth cervical vertebra paralyzes any muscle group that receives its innervation from nerve roots that exit the spinal vertebral canal below C6. A review of the innervation of the major muscles of inspiration and expiration is important:

Upper airway, tongue, palate (bulbar muscles): Cranial nerves IX, X, XI, and XII
C3 to C5: Diaphragm
C3 to C8: Neck strap and shoulder girdle muscles
T1 to T12: Intercostal muscles
T7 to L1: Abdominal muscles

The upper airway, tongue, shoulder girdle muscles, and diaphragm should be intact in this patient's injury, but the airway defense behaviors (cough, sigh, and sneeze) will be impaired because of disrupted neural networks involving the thorax. Maintenance of intrathoracic volume depends partly on continuous activation of intercostal muscles, which stabilize and expand the thoracic cage. With these muscles paralyzed, there will be inverted paradoxical breathing, with inward movement of the ribcage during inhalation while the abdomen moves outward in a normal fashion. Cough will be impaired because it depends on activation of abdominal and intercostal muscle groups, both of which are paralyzed in this injury. Although he has an intact diaphragm, this patient has a poor cough mechanics and impaired airway defense behaviors, which increases the risk of atelectasis, airway plugging, and pneumonia.

DISORDERS OF THE THORACIC CAGE

The thoracic cage contains the lungs and is composed of the ribcage and spine, which provide the framework on which the

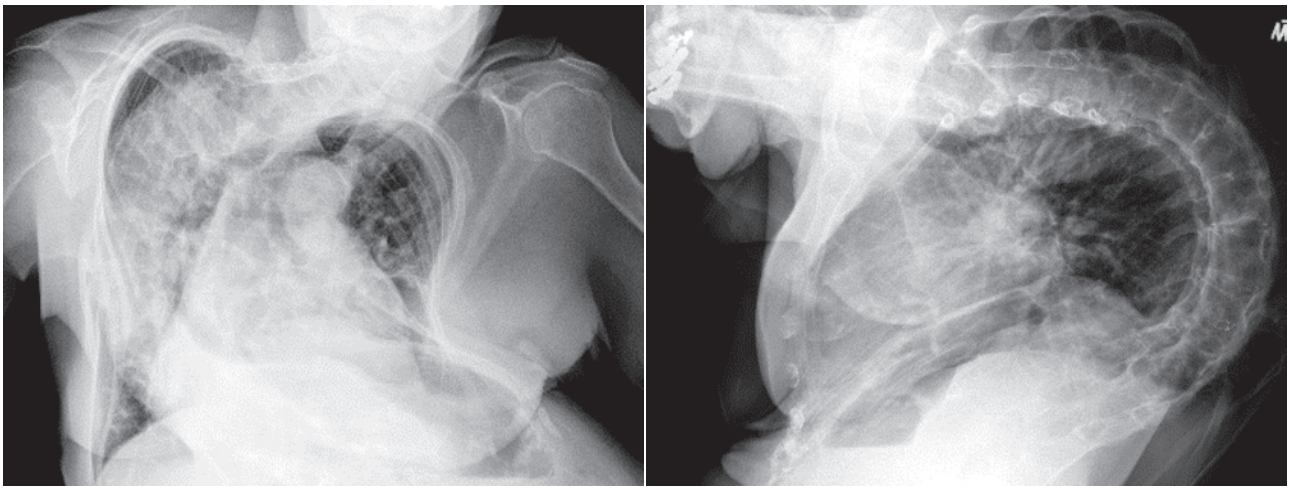

Fig. 33.7 Frontal and Lateral Chest X-Ray Views of the Same Patient, Showing Severe Scoliosis and Kyphosis.

respiratory muscles act. Normal ventilatory mechanics depend on a compliant thoracic cage with normal geometry, allowing unrestricted movement throughout the respiratory cycle. Restriction of the ribcage is usually secondary to spinal deformity and rigidity. Respiratory impairment is due to a combination of factors. First, the elastic work of breathing is increased due to the stiff thoracic cage. Second, the diaphragm and other muscles of ventilation are placed at a mechanical disadvantage from abnormal geometry. Finally, lung volumes are reduced and, in the case of children, lung growth can be limited. As with many other neuromuscular conditions, respiratory impairment first manifests with sleep-disordered breathing, particularly sleep hypoventilation, and, if untreated, progresses to daytime hypercapnia and complications of pulmonary hypertension.

Kyphoscoliosis

Kyphosis is anterior angulation of the thoracic cage. *Scoliosis* is lateral curvature of the spine (Fig. 33.7). These two deformities often occur together (called **kyphoscoliosis**) as a result of the compensatory effects of the spine in response to the primary lateral curve in scoliosis.

Idiopathic scoliosis is typically noticed during childhood and progresses during adolescence. Less commonly, scoliosis develops secondary to neuromuscular disease, such as DMD. The degree of scoliosis is measured by the *Cobb angle,* which is determined by the intersection of lines drawn between the upper and lower limbs of the primary curve in scoliosis (Fig. 33.8). Severe kyphoscoliosis (Cobb angle >90 to 100 degrees) can lead to respiratory impairment, especially sleep-disordered breathing. However, the degree of pulmonary dysfunction cannot be predicted from the Cobb angle alone.[87,88]

Surgical spine fixation can stabilize kyphoscoliosis and restore the thoracic curvature to close to normal. Fixation prevents complications resulting from progressive curvature, loss of compliance, and subsequent ventilatory dysfunction. Few options are available to restore pulmonary function to older patients with established kyphoscoliosis. Surgery to correct the deformity can be undertaken, but this treatment generally does not improve pulmonary function.[89] Better long-term results are seen when surgery or brace therapy to correct the angulation is undertaken in adolescence.[90]

Both noninvasive and invasive ventilation are used in some patients with severe kyphoscoliosis, with improvement in gas exchange, respiratory muscle strength, symptoms of dyspnea,[91] and exercise capacity.[92]

Ankylosing Spondylitis

Ankylosing spondylitis is a rheumatologic disease that affects the spine and chest wall. Chronic joint inflammation ultimately leads to fusion of the joints of the vertebrae and ribs, typically leading to a dramatic decrease in thoracic cage compliance due to kyphosis and ankylosis (stiffness due to bone and joint fusion). The most severe respiratory consequence is parenchymal lung disease, which occurs in approximately 10% of patients with ankylosing spondylitis in the form of apical fibrocystic changes that can decrease gas exchange and provide a location for chronic infection, especially fungal infection.[93]

THE ROLE OF THE RESPIRATORY THERAPIST IN CARING FOR PATIENTS WITH NEUROMUSCULAR WEAKNESS AND OTHER DISEASES OF THE CHEST WALL

Many of the diseases discussed in this chapter are chronic, progressive conditions that evolve into respiratory failure over time. Optimal management depends on the degree, rate, and specific manifestations of the disease process, and there is considerable variability. Physicians, nurses, and respiratory therapists (RTs) caring for these patients must be familiar with the course and symptoms of this progression so they can provide appropriate diagnostic testing and therapy at the right time (see Table 33.4).

RTs with expertise in caring for these patients are essential. Many patients require close monitoring of their respiratory symptoms and function, and these results must be reliable and consistent, because decisions such as when to begin a new

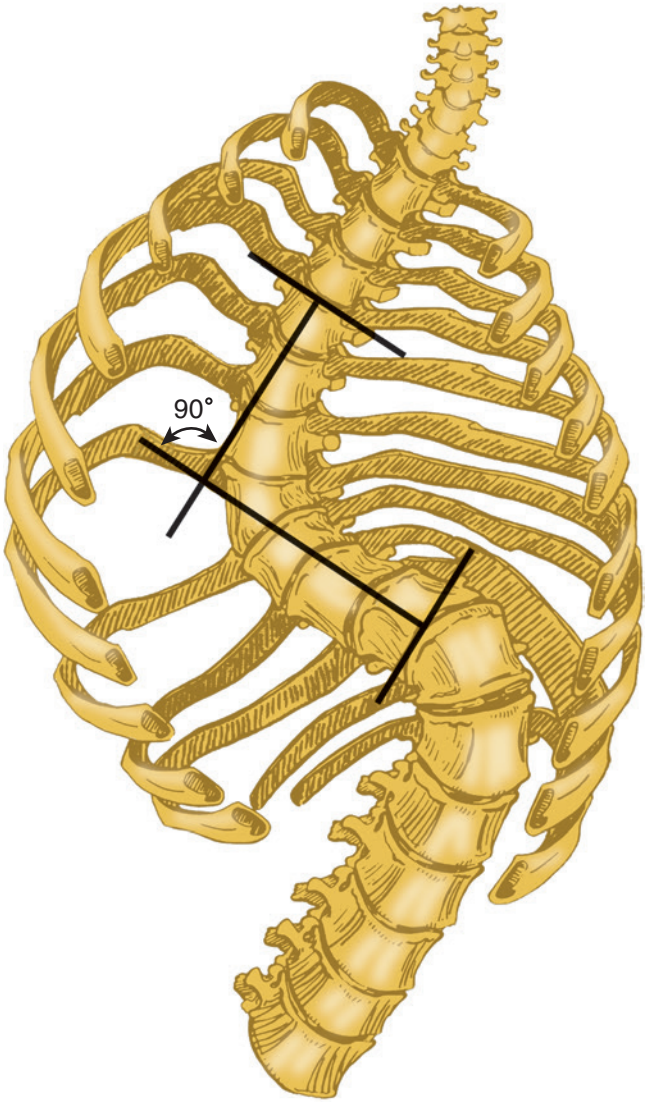

Fig. 33.8 Scoliosis Is Lateral Curvature of the Spine. The degree of scoliosis is measured by the Cobb angle, which is determined by the intersection of lines drawn between the upper and lower limbs of the primary curve in scoliosis. Respiratory insufficiency rarely occurs until the Cobb angle exceeds 90 to 100 degrees. (Modified from Fishman AP: Acute respiratory failure. In: Fishman AP, editor: *Pulmonary Disease*, New York, 1992, McGraw-Hill, p 2300.)

supportive therapy may rely heavily on them. Maneuvers such as spirometry and maximal respiratory pressures, as well as the use of respiratory devices such as NIV and cough-assist technology require explanation, education, reinforcement, and troubleshooting. Without this kind of supervision and support, many patients will use their devices improperly or not at all, which will render them of no benefit and may lead to the inaccurate conclusion that the therapies have failed.

Neuromuscular diseases also carry with them the burdens common to many chronic and progressive diseases, including depression and other psychological burdens. RTs involved in the care of these patients can provide longitudinal support, including encouragement not to give up on therapies that may be effective, and perspective when there are still additional measures that can be added to improve quality of life. The more familiar RT's are with specific disease entities as well as the diagnostic and therapeutic options, the better they can help patients understand and cope with their chronic conditions.

SUMMARY CHECKLIST

- The components of the neuromuscular system that affect respiration include the brain, spinal cord, nerves, neuromuscular junction, respiratory muscles, thoracic cage, and the upper airway.
- Respiratory failure is often the most important clinical dysfunction for many patients with neuromuscular diseases.
- Other effects of neuromuscular disease on the respiratory system include sleep hypoventilation, obstructive sleep apnea, aspiration, pneumonia, atelectasis, pulmonary hypertension, and cor pulmonale.
- Signs and symptoms that may indicate weakness of the respiratory muscles include poor sleep quality, morning headaches, daytime sleepiness, exertional dyspnea, orthopnea, weak or ineffective cough, accessory muscle use, and paradoxical breathing movements.
- Pulmonary function abnormalities in patients with inspiratory muscle weakness typically include decreases in PImax, TLC, VC, and FEV_1. Residual volume can be increased. There often is an abnormally large decrease in FVC and FEV_1 (30% to 50%) when patients repeat testing in the supine position, compared to the seated position. Diffusing capacity typically is normal.
- Common neuromuscular disorders that cause respiratory compromise include ALS, myotonic dystrophy, spinal cord injury, Guillain–Barré syndrome, Duchenne muscular dystrophy, and myasthenia gravis.
- Cervical spine injury above the C3 level results in complete paralysis of the respiratory muscles and necessitates emergency mechanical ventilation. Cervical spine injury below C5 leads to weakness of the expiratory muscles with decreased ability to cough and clear secretions.
- Unilateral diaphragmatic paralysis resulting from phrenic nerve damage usually is asymptomatic and is associated with minor reductions in respiratory function in an otherwise healthy patient, whereas bilateral diaphragmatic paralysis can have significant respiratory symptoms.
- Kyphoscoliosis is abnormal curvature of the spine. Respiratory insufficiency can occur if the curve is severe.

Disorders of Sleep

Robert C. Stansbury and Patrick J. Strollo, Jr.

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define obstructive sleep apnea (OSA).
- Identify why airway closure occurs only during sleep.
- State the long-term consequences of uncontrolled OSA.
- State how a diagnosis of OSA is made.
- Identify what groups of patients are at particular risk for OSA.
- State the treatments available for patients with OSA.
- Describe how continuous positive airway pressure (CPAP) works.
- Identify problems associated with CPAP.
- Determine when bilevel pressure is useful in the treatment of OSA.
- Define "autotitrating" CPAP.
- Identify the surgical alternatives for patients with severe OSA.

CHAPTER OUTLINE

KEY TERMS

bilevel positive airway pressure
central sleep apnea
continuous positive airway pressure
excessive daytime sleepiness
obesity hypoventilation
obstructive sleep apnea
sleep-disordered breathing
STOP-BANG Assessment Tool
uvulopalatopharyngoplasty
upper airway stimulation

Obstructive sleep apnea (OSA) syndrome is a common clinical problem that is underdiagnosed.[1] Previous prevalence estimates reported 2% to 4% of adults have OSA.[2] Recent data, in part due to the obesity epidemic, suggest that up to 14% of men and 5% of women have OSA.[3] The spectrum of disease ranges from sleep disruption related to increased airway resistance to profound daytime sleepiness in conjunction with a multitude of health consequences (Box 34.1).[4]

Sleep apnea is defined as repeated episodes of complete cessation of airflow for 10 seconds or longer. The events can be obstructive (caused by upper airway closure) or central (caused by lack of ventilatory effort). Primary central nervous system lesions, stroke, congestive heart failure, and high-altitude hypoxemia can impact respiratory control and cause central apnea events.[5] **Central sleep apnea** (CSA) is not as common as OSA. Only 10% to 15% of patients with sleep-disordered breathing are classified as having CSA.[6] Mixed sleep apnea has an initial central component followed by an obstructive component (Fig. 34.1).[7]

Hypopnea is defined as a 30% to 90% decrease in airflow in conjunction with 3% oxygen (O_2) desaturation.[7] Most investigators agree that physiologically significant hypopnea is associated with a decrease in O_2 saturation (SaO_2) and/or arousal from sleep.[8]

Respiratory therapists (RTs) are likely to encounter both OSA and CSA when treating patients. OSA is the most commonly encountered type of sleep apnea and is underdiagnosed by health professionals. The focus of this chapter is on the pathophysiology and management of OSA.

PATHOPHYSIOLOGY

Obstructive Sleep Apnea

The primary cause of OSA is a small or unstable upper (pharyngeal) airway. This condition can be caused by soft tissue factors, such as upper body obesity or tonsillar hypertrophy (rare in adults), and skeletal factors, such as a small or recessed chin.[9] During the waking state, pharyngeal patency is maintained by increased neural activity of the upper airway dilator muscles. Sleep onset is associated with a decrease in neural activity to these muscles.[10] The result is narrowing or closure of airways that are at risk due to obesity or craniofacial deficiency (e.g., a small jaw). In an unstable upper airway, narrowing and closure during sleep frequently involves multiple sites.[11]

BOX 34.1 Adverse Consequences of Obstructive Sleep Apnea

Cardiopulmonary
- Nocturnal arrhythmia
- Diurnal hypertension
- Pulmonary hypertension
- Right or left ventricular failure
- Myocardial infarction
- Stroke

Neurobehavioral
- Excessive daytime sleepiness
- Diminished quality of life
- Adverse personality change
- Motor vehicle accidents

Metabolic
- Insulin resistance
- Altered lipid metabolism

Partial or complete closure of the upper airway during sleep is associated with several serious neurobehavioral, metabolic, and cardiopulmonary consequences (see Box 34.1).[12] Compared with the general population, studies suggest patients with untreated OSA have an increased risk for mild pulmonary hypertension, stroke, nocturnal arrhythmias, heart failure, systemic hypertension, myocardial infarction, and overall mortality.[13-18] The repetitive cycle of upper airway closure and opening during sleep has deleterious effects, including recurrent arousals from sleep, profound increases in intrathoracic pressure, hypoxemia, and hypercapnia. These effects lead to an increase in inflammation, sympathetic tone, and oxidative stress that have systemic consequences, particularly to the cardiovascular system.[19]

Obesity, especially of the upper body, has been shown to correlate positively with the presence of OSA. In most instances, patients with OSA are obese with a large amount of peripharyngeal adipose tissue in addition to adipose tissue in the neck.[20] A body mass index (BMI) greater than 28 (>120% of ideal body weight normalized for height) should alert the practitioner to the possibility of OSA and the need for further assessment and referral, particularly if the patient reports excessive daytime sleepiness (EDS).[2]

Patients who are of normal body weight can be predisposed to OSA if they have an abnormal craniofacial configuration. Men may grow a beard to disguise such a craniofacial abnormality. If the chin is recessed (retrognathic) or small (micrognathic), the upper airway space may be narrow, and the risk for airway closure during sleep increases.[9,21] Patients with a deviated nasal septum or trauma to the nasal passages increase resistive load to the upper airway and contribute to the risk of upper airway closure during sleep. However, an isolated nasal abnormality is an unusual cause of OSA.

OSA also can have a genetic predisposition.[22,23] There have been reports of families in which obesity alone does not explain the increased prevalence of OSA.[24] It has been suggested that

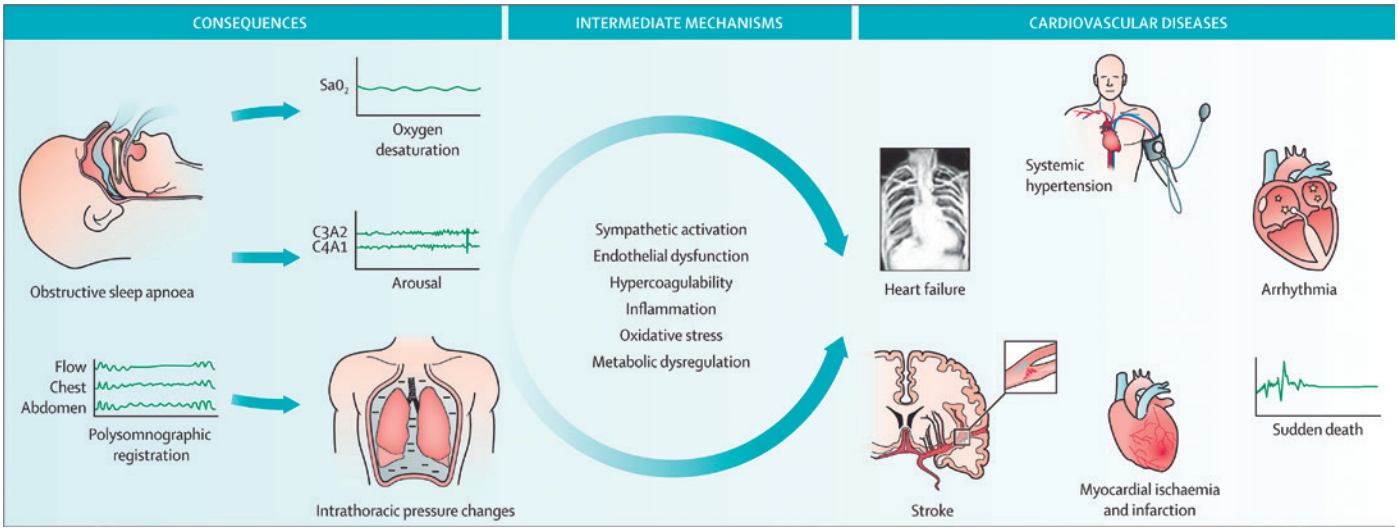

Fig. 34.1 Obstructive sleep apnea consequences and intermediate mechanisms that potentially contribute to risk of cardiovascular disease. The events associated with collapse of the upper airway lead to brain arousal, intrathoracic pressure changes, and hypoxemia and reoxygenation. Several intermediate mechanisms link obstructive sleep apnea with the initiation and progression of cardiovascular diseases. *C3A2* and *C4A1*, Electroencephalographic channels; *SaO_2*, oxygen saturation. (From Sánchez-de-la-Torre M, Campos-Rodriguez F, Barbé F: Obstructive sleep apnoea and cardiovascular disease. *The Lancet Respiratory Medicine* 1(1):61–72 2013.)

craniofacial abnormalities and/or abnormal ventilatory control may explain the increased frequency of OSA in these families.

Central Sleep Apnea

Although a detailed discussion of the pathophysiology of CSA is beyond the scope of this chapter, several concepts are important to RTs. In contrast to OSA, which represents a spectrum of the same disease related to upper airway instability, CSA is a heterogeneous group of disorders driven in part by loss of neurologic output from the respiratory centers in the brainstem that control breathing.[25] Patients have a ventilatory pattern known as periodic breathing, in which there is a waxing and waning of respiratory drive, which is reflected clinically as an increase and then a decrease in respiratory rate and tidal volume (V_T). Secondary causes of CSA typically affect the central nervous system and/or the respiratory muscles. Examples include cerebrovascular diseases such as stroke, neuromuscular diseases such as muscular dystrophy, Guillain-Barré or amyotrophic lateral sclerosis (ALS), cardiovascular disease such as congestive heart failure, chronic opiate use, and congenital abnormalities such as Chiari malformation or congenital central hypoventilation syndrome.[26] Cheyne-Stokes respiration, which often occurs in patients with congestive heart failure or stroke, is a type of periodic breathing characterized by a crescendo-decrescendo pattern of hyperpnea alternating with apnea.[27] After apnea occurs, there may be an increase in central ventilatory drive and an increase in V_T.

Overlap Syndrome

Chronic obstructive pulmonary disease (COPD) and OSA are both common respiratory disorders and coexist in many individuals. This combination is referred to as *overlap syndrome* and is associated with particularly poor outcomes including a high mortality rate.[28,29] Patients are usually obese and have a history of smoking. Patients with overlap syndrome tend to have moderate to severe nocturnal oxyhemoglobin desaturation (especially during rapid eye movement [REM] sleep) and more severe blood gas abnormalities than patients with the same degree of OSA but without COPD.[30] Undiagnosed OSA complicates the course at night with arousals, awakenings with dyspnea, and O_2 desaturation values resistant to supplemental O_2.[31]

Hypoventilation Syndromes

In addition to OSA and CSA, chronic hypoventilation syndromes are increasingly being recognized.[32,33] Patients with neuromuscular disorders such as ALS, muscular dystrophy, or spinal cord injury with diaphragm dysfunction may have underlying restrictive lung physiology. These patients may benefit from early detection of sleep-related hypoventilation. Treatment with noninvasive ventilation may result in improved breathing during sleep, quality of life, gas exchange, and mortality.[34] Alternative therapies such as placement of a diaphragmatic pacemaker also may benefit selected patients with spinal cord injuries.[35]

CLINICAL FEATURES

Classic signs and symptoms of OSA are described in Table 34.1.[20] No sign or symptom alone strongly predicts the presence of OSA. However, a combination of these signs and symptoms is predictive and useful for risk stratifying individuals for the presence of OSA.[20,36] Questionnaires and prediction rules utilizing these findings lack sufficient accuracy to detect the presence of OSA, but they are helpful in identifying patients who require screening and aid in determining appropriate diagnostic testing.[37]

TABLE 34.1 Common Signs and Symptoms in Obstructive Sleep Apnea

Signs	Symptoms
Male (gender 3× risk)	Snoring, gasping, or choking during sleep
Age greater than 40 years	Excessive sleepiness
Large neck (>42 cm in men and 40 cm in women)	Morning headaches
Obesity (body mass index >35)	Fatigue
Facial abnormalities (retrognathia)	Nocturnal GERD
Small upper airway (Mallampati ≥3, large tonsils, high arched palate)	Apneas reported by bed partner
Hypertension	Sleep fragmentation
Arrhythmias (atrial fibrillation)	Nocturia
Pulmonary hypertension	Decreased concentration and/memory loss
Stroke	Erectile dysfunction

GERD, Gastroesophageal reflux disease.

Of note, the presence of **excessive daytime sleepiness** is not found in all patients with OSA, and there is no association between apnea severity and degree of sleepiness.[38] Recent work evaluating presentations of OSA has identified three clinical phenotypes[39]: (1) asymptomatic, (2) EDS, and (3) insomnia. As a result, patients with OSA may report minimal symptoms related to OSA yet have severe disease that may require intervention.

A thorough history and physical examination are essential in identifying individuals at risk for sleep-disordered breathing. A significant proportion of occult OSA in the general population would be missed if screening or case finding were based on BMI or male gender, and breathing pauses may be particularly insensitive for identifying OSA in older adults.[40] Providers should keep a high index of suspicion for OSA, particularly in certain disease cohorts in whom treatment may impact their disease course. These disease states include pulmonary hypertension, nocturnal arrhythmias, congestive heart failure, diabetes, stroke, polycythemia, and refractory hypertension.[41-48] Providers should have a high index of suspicion for individuals undergoing preoperative assessment for bariatric surgery and high-risk driving populations.[35]

RULE OF THUMB Untreated OSA can cause daytime hypoxemia. The diagnosis of OSA should be considered when the degree of hypoxemia is out of proportion to the defect on spirometry. When the arterial partial pressure of O_2 is less than 60 mm Hg but the forced expiratory volume in 1 s (FEV_1) is greater than 30% of predicted, COPD alone is inadequate to explain the hypoxemia, and coexisting OSA should be considered. OSA in this setting is frequently associated with pulmonary hypertension and evidence of right heart failure on physical examination. Hypoxemia, pulmonary hypertension, and right heart failure can be substantially improved with management of OSA. If the patient adheres to therapy, the need for supplemental O_2 may be reduced or eliminated.

In the acute care setting, patients who present with previously undiagnosed OSA can pose a particular challenge for diagnosis and management.[49-51] Unfortunately, many patients with OSA, particularly when associated with obesity hypoventilation syndrome (OHS), come to attention during hospitalization for acute on chronic respiratory failure.[52] A high clinical suspicion for OSA in hospitalized patients is necessary because untreated or unrecognized OSA can complicate recovery from acute illness such as COPD, heart failure, stroke, and recent surgery.[53-56] Despite the potential benefit of treatment, many patients with sleep-disordered breathing are unrecognized while in the hospital.[57] Increasingly, portable testing is used to identify hospitalized patients with OSA.[58] Outpatient follow-up and evaluation are important to insure adequate adherence to therapy for effective long-term treatment. RTs should ask patients if they are treated for OSA at home, and in most instances, this therapy should be continued while hospitalized. Occasionally, patients may bring their machine from home for use during their hospital stay.

SCREENING QUESTIONNAIRES

An initial history and physical examination may be inadequate for identifying OSA. Several screening questionnaires have been developed to aid in rapidly identifying individuals with OSA. In general, screening questionnaires have good sensitivity but limited specificity for the diagnosis of OSA. The Berlin Questionnaire, the American Society for Anesthesiology (ASA) screening questionnaire, and the Sleep Apnea Clinical Score (SACS) have been validated for use as screening for OSA.[59,60] The STOP-BANG questionnaire has been used commonly because of simplicity and ease of use, particularly in patients undergoing elective surgery (Box 34.2).[61] This questionnaire has demonstrated high sensitivity using a cutoff score of ≥3 detecting sleep apnea but has a modest specificity, yielding a high false-positive rate.[61] In general, the STOP-BANG is a useful and efficient screening tool that has been validated in multiple populations but may be less useful in identifying sleep apnea in specific groups such as the veteran population and individuals with chronic renal disease.[62,63] Regardless of the questionnaire used, a diagnostic sleep study is required for diagnosing OSA.

BOX 34.2 STOP-BANG Questionnaire to Screen for Obstructive Sleep Apnea

Snore:	Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?
Tired:	Do you often feel tired, fatigued, or sleepy during the daytime?
Observed:	Has anyone observed you stop breathing during sleep?
Pressure:	Do you have or are you being treated for high blood pressure?
BMI:	Greater than 35 kg/m^2?
Age:	Age older than 50 years?
Neck:	Neck circumference greater than 40 cm?
Gender:	Gender male?

One point assigned for each positive question.
Total score <3 = low probability for OSA.
Total score >3 = high probability for OSA.
Total score >5 = high probability of moderate to severe OSA.
From Chung F, Subramanyam R, Liao P, et al: High STOP-BANG score indicates a high probability of obstructive sleep apnoea, *Br J Anaesth* 108:768–775, 2012.

LABORATORY TESTING

When sleep apnea is suspected, an overnight polysomnogram (PSG) or home sleep apnea test (HSAT) should be obtained to confirm the clinical diagnosis.[37,64] Since the approval of home sleep testing by Centers for Medicare and Medicaid Services (CMS) in 2008, an increasing number of individuals are being diagnosed with OSA outside the laboratory. A full-night PSG in the sleep laboratory monitored by a sleep technologist is considered the "gold standard" method for diagnosing OSA.

In a laboratory-based sleep study, several physiologic signals are recorded to determine whether airway closure occurs during sleep and to what extent the events disturb sleep continuity and cardiopulmonary function. An electroencephalogram (EEG), electrooculogram (EOG), and chin electromyogram (EMG) are obtained for assessment of sleep stage and documentation of sleep disruption due to sleep-related breathing disturbance. Airflow (measured at the nose and mouth), ventilatory effort (using inductive plethysmography or piezoelectric belts), cardiac rhythm (with a modified lead II electrocardiogram [ECG]), tibial EMG leads, and SaO_2 (measured with pulse oximetry) are included for standard testing.

Various devices are available for HSAT. Most portable devices measure two respiratory parameters (airflow and respiratory effort), oxygen saturation, and heart rate or ECG. Newer technology for HSAT including peripheral artery tonometry has also been validated.[65] In general, HSAT has demonstrated adequate diagnostic performance compared to in-lab polysomnography in adult patients with a high pretest probability of moderate to severe sleep apnea who do not have significant cardiopulmonary comorbidities.[66]

In obstructive apnea or hypopnea, airflow is absent or decreased for at least 10 seconds in the presence of continued ventilatory effort. Asynchronous (paradoxical) movement of the abdomen and rib cage can be observed. O_2 desaturation may or may not occur (required for hypopnea). The degree of the O_2 desaturation depends on the length of the apneic event or the patient's baseline saturation (see Fig. 34.1). Respiratory effort–related arousals are characterized by increased ventilatory effort, leading to arousal from sleep that does not meet the criterion of an apneic or a hypopneic event (see Fig. 34.1).[27]

Scoring an apnea (absence of airflow for ≥10 seconds) either by laboratory or HSAT is straightforward. The diagnosis of hypopnea may be affected by the measurement technique used. In 1999, an American Academy of Sleep Medicine (AASM) task force conducted an evidence-based review of measurement techniques for detecting hypopnea.[67] The scoring system was as follows: *A,* good to excellent agreement with a reference standard (face mask pneumotachograph); *B,* limited data but good theoretical framework and clinical experience suggest the method is valid; *C,* no data, weak theoretical framework or clinical experience; and *D,* research or clinical experience suggests the method is invalid.

The measuring techniques were scored as follows: nasal pressure, B; respiratory inductance plethysmography (RIP) with sum of chest and abdominal signals, B; dual-channel RIP, C; single-channel RIP, C; piezoelectricity sensors, strain gauges, and thoracic impedance, D; breathing measurement signal with a desaturation or arousal, B; expired carbon dioxide (CO_2), D; and thermal sensors, D. A face mask pneumotachograph allows the greatest precision in measuring airflow, but it is poorly tolerated. Nasal pressure is a reliable way to detect hypopnea and is well tolerated by patients undergoing a diagnostic PSG.[67]

After the in-lab polysomnography study is completed, the sleep technologist scores it. The number of apneas and hypopneas per hour of sleep is reported as an apnea-hypopnea index (AHI) or respiratory disturbance index (RDI). The AASM has operationally defined the severity of OSA as follows: mild, AHI 5 to 15; moderate, AHI 15 to 30; and severe, AHI greater than 30. AHI less than 5 is considered within the normal range for adults. The number of arousals per hour (arousal index), percentage of each sleep stage, frequency of SaO_2, mean SaO_2, and nadir of SaO_2 also are reported (Box 34.3).

Measurement error is inevitable with HSAT compared with standard polysomnography. For instance, the AHI is calculated in HSAT by adding the total number of apneas or hypopneas divided by the total recording time rather than sleep time. Thus the index derived from the HSAT is usually lower than the index derived on polysomnography. Most of the HSAT devices do not include EEG, making identification of arousals and distinguishing from REM and non-REM sleep challenging. Sensor dislodgement and poor signal quality are additional factors that made lead to measurement error during a HSAT. If a single HSAT recording is determined to be negative (significant apnea not identified) or technically inadequate, and high suspicion remains for OSA, in-laboratory polysomnography should be performed.[37]

Since 2007, HSAT use for the diagnosis of OSA has increased dramatically. Although data interpretation at times can be troublesome, editing the data manually seems to improve the accuracy of interpretation.[68] For HSAT devices, the AHI is determined by adding up the total number of respiratory events and dividing by the total hours of valid recording time (not sleep time as done in PSG). These devices are being utilized more frequently in hospitalized patients to diagnose OSA and qualify patients for positive pressure on discharge. Challenges exist when performing these studies in the hospital, particularly when supplemental oxygen is used, which can impair the device's ability to identify respiratory events. The poor sleep patients tend to get in the hospital setting can also impact diagnostic accuracy. Despite these challenges, there is evidence that identifying OSA in the hospital and discharging patients on therapy leads to improved outcomes, including a decrease in hospital readmission rates.[53,69,70]

BOX 34.3 Key Features of Sleep Studies to Be Analyzed and Reported for Obstructive Sleep Apnea

- Apnea-hypopnea index
- Arousal index
- Sleep stage distribution
- Frequency of oxyhemoglobin desaturations
- Mean oxyhemoglobin saturation
- Nadir of oxyhemoglobin saturation

RULE OF THUMB Intermittent checks of O_2 saturation cannot reliably exclude sleep-related desaturation secondary to OSA. Placing the oximetry probe on the patient frequently awakens the patient. In addition, isolated readings may not allow sampling of all sleep stages, especially REM sleep, during which sleep-disordered breathing and nocturnal desaturation tend to be most prominent. Continuous overnight oximetry is a better assessment of the degree of oxyhemoglobin desaturation with sleep.

TREATMENT

As we enter the era of personalized medicine, management of OSA should be individualized based on disease phenotype, severity, and patient preference. Behavioral therapy should be pursued in the care of all patients. Medical and surgical therapy must be tailored to the individual patient. The likelihood of acceptance and adherence to the prescribed therapeutic intervention must be considered. The goals of treatment are to normalize SaO_2 and ventilation; eliminate apnea, hypopnea, and snoring; and improve sleep architecture and continuity, as well as improve symptoms of OSA if present (Box 34.4).

Behavioral Interventions and Risk Counseling

Patients must be informed of the risks of uncontrolled sleep apnea, particularly in severe cases. Several behavioral interventions can be beneficial, including weight loss in obese patients; avoiding alcohol, sedatives, and hypnotics; and avoiding sleep deprivation. Although weight loss clearly improves the severity of sleep apnea, it is frequently difficult to accomplish and does not lead to complete resolution of OSA in all individuals.[71,72] Involving the patient with a dietitian or nutritionist can be helpful. Alcohol should be avoided by patients believed to have sleep apnea. Alcohol decreases arousal threshold and upper airway muscle tone, making the upper airway more prone to complete or partial closure and longer periods of apnea.[73] Sedatives and hypnotics can decrease the stability of the upper airway and suppress certain stages of sleep.[74] Research suggests that the impact of these medications on indices of OSA severity are minimal.[75]

Positional Therapy

When a sleep study indicates that apnea and snoring occur only in the supine position, instruction on sleeping in the lateral position or head of bed elevation can be beneficial; however, adherence is typically poor.[76] Use of the "tennis ball" technique, in which a ball is sewn onto the back of the patient's sleeping garment, or other positional devices that discourage the patient

BOX 34.4 Goals of Treating Obstructive Sleep Apnea

- Eliminate apnea, hypopnea, and snoring
- Normalize O_2 saturation and ventilation
- Improve sleep architecture and continuity

from rolling into the supine position can be effective in treating positional OSA.[77,78]

Medical Interventions

Positive Pressure Therapy

Continuous positive airway pressure therapy. **Continuous positive airway pressure** (CPAP) therapy was introduced for management of OSA in 1981 and reduces sleep-disordered breathing by pressurizing the upper airway preventing collapse during sleep.[79] CPAP is typically delivered through a nasal or full face mask at a fixed pressure that remains constant throughout inhalation and exhalation. Positive pressure therapy to treat OSA is most often delivered using a CPAP device because it is the simplest and most extensively studied mode of therapy. The most current AASM practice parameters recommend a full montage in lab polysomnographic study (as outlined previously) to determine the optimal CPAP setting to address an individual's sleep-disordered breathing.[80] A "split-night" sleep study, in which first part of the study is dedicated to establishing a diagnosis of sleep-disordered breathing and the remainder of the study is used to titrate CPAP to effectiveness, may be used in certain scenarios.[80,81] Attempts to use an algorithms or a prediction equations as replacements for in-laboratory titrations have not been uniformly successful.[82,83] Recently, autotitrating devices (discussed later) are being used in the home setting for initiation of treatment of OSA without the need for an in-lab titration study.

CPAP therapy has been shown in numerous studies to improve daytime sleepiness, sleep-related quality of life, vigilance, and cognition and has demonstrated a modest beneficial effect on cardiovascular, psychiatric, and metabolic disease.[84-91] CPAP is the best studied treatment modality for OSA. Other positive pressure therapies have demonstrated effectiveness in controlling OSA. These modalities have less-robust outcome data compared with CPAP. Most experts agree that the positive pressure treatment modality is not the critical factor for improving outcomes in OSA. What is important, regardless of the treatment modality used, is normalization of SaO_2 and ventilation; elimination of apnea, hypopnea, and snoring; and the improvement of sleep architecture and continuity.

Bilevel positive airway pressure therapy. **Bilevel positive airway pressure** therapy was first introduced as a potential treatment for OSA in the early 1990s.[92] Bilevel differs from the continuous fixed pressure delivered by CPAP in that it allows independent adjustment of the expiratory positive airway pressure (EPAP) and inspiratory positive airway pressure (IPAP). The difference between the IPAP and EPAP is the pressure support and can provide support to the respiratory muscles and augment tidal volume. Like CPAP, bilevel PAP is typically titrated in the laboratory setting, and specific guidelines for bilevel titration are available.[81] The IPAP and EPAP are titrated together to eliminate apnea. The IPAP is increased independently to eliminate hypopneas, snoring, and arousals. Given the reduction in expiratory pressure-related discomfort with the use of bilevel therapy, one would expect improvement in adherence and other outcomes with the use of these devices. Yet, no studies to date have proven advantage to the use bilevel compared to CPAP therapy in CPAP-naive patients.[93]

MINI CLINI

Nocturnal Angina in an Obese Middle-Aged Man

History

A 45-year-old, morbidly obese nonsmoker is admitted to the coronary care unit after awakening at 4 a.m. with chest pain typical of angina pectoris. The pain has resolved by the time he reached the emergency department. The patient is unsure of the duration of the pain before he called for his wife, who sleeps in a separate bedroom because of his very loud habitual snoring. The patient reports exertional shortness of breath but no chest pain before this event. He states that he frequently gets "indigestion" that sometimes is worse at night, but that this pain was different.

Medications

- Captopril, 25 mg by mouth twice per day
- Furosemide (Lasix), 20 mg by mouth every day
- Omeprazole (Prilosec), 20 mg by mouth daily

Medical History

- Hypertension and gastroesophageal reflux
- No significant cardiac disease
- Cardiac catheterization 1 year ago showed normal left ventricular function and minimal coronary artery occlusion

Physical Examination

- *Vital signs:* Blood pressure 160/98 mm Hg, heart rate 100 beats/min, temperature 98.6°F (37°C), respiration 18 breaths/min
- *General:* Mildly diaphoretic obese white man
- *Neck:* 52 cm (20.5 inches) in circumference
- *Lungs:* Clear breath sounds bilaterally
- *Heart:* Regular rate and rhythm
- *Abdomen:* Obese; soft, normal bowel sounds
- *Extremities:* 4-mm pretibial pitting edema

Laboratory Data

- *Room air arterial blood gases (ABGs):* pH 7.36, PCO_2 37 mm Hg, PO_2 62 mm Hg, SaO_2 92%
- *Chest x-ray:* Pulmonary congestion, otherwise normal
- *ECG:* Sinus tachycardia without acute changes

Problem

Why did this patient experience angina during sleep?

Discussion

Serial cardiac enzyme values revealed no evidence of myocardial infarction. A stress test result was negative, but a submaximal effort was obtained. The patient's weight precludes an adenosine thallium stress test. A repeat cardiac catheterization demonstrated no change in the minimal coronary artery occlusion reported previously. The pulmonary consultant called to evaluate the patient's shortness of breath recommended a nocturnal PSG to rule out sleep apnea. The sleep study result is positive for severe sleep apnea (AHI 110; lowest SaO_2 70% on the oximeter during REM sleep). A CPAP titration test was performed. The patient was discharged home on CPAP 17.5 cm H_2O using a nasal mask. He returns to the pulmonary clinic 1 month after discharge. He reported no further episodes of nocturnal angina. Reflux and shortness of breath have been relieved. The patient has lost 10 lb (4.5 kg) without dieting. Lower extremity edema is markedly decreased. A download of data from his CPAP machine shows excellent CPAP adherence with use on 85% of nights, as well as good response to therapy with an average estimated AHI 3.5.

A trial of bilevel therapy is reasonable in persons intolerant of CPAP therapy. As mentioned previously, bilevel therapy can provide ventilatory support and OSA patients with concurrent respiratory disease or obesity hypoventilation syndrome may derive benefit from bilevel therapy compared with CPAP.[94,95] More advanced modes of bilevel therapy exist and are beyond the scope of this discussion. These include bilevel ST, adaptive support ventilation (ASV), and volume-assured pressure support ventilation (VAPS). These modalities are typically reserved for more complex sleep-disordered breathing or other disease processes. Due to its simplicity and lower cost, CPAP remains the initial PAP modality of choice for the treatment of uncomplicated OSA.

RULE OF THUMB Retrognathia can be the cause of OSA in young patients who are at or close to ideal body weight. CPAP therapy is highly effective for these patients, but upper airway reconstruction (phases I and II surgery) can be curative.

Autotitrating devices. A new generation of autotitrating CPAP (APAP) devices has been developed and are frequently used to address sleep apnea without the need for a formal titration study to identify a fixed CPAP pressure in the laboratory. These devices use a computer algorithm for adjusting the level of CPAP in response to dynamic changes in airflow or vibration caused by airway collapse, snoring, or both. When upper airway flow is decreased or impedance is changed, the proprietary algorithm will increase the pressure until flow is restored and/or upper airway resistance is normalized. These devices will then reduce pressure until a limitation in airflow or an increase in airway resistance is identified. Autotitrating devices have the potential to better address apnea as it adjusts when the individual's apnea becomes worse such as during REM sleep or moving into the supine position.

The initial development of APAP was prompted by a need to address issues of patient access to care, patient compliance, patient comfort, and variability of the CPAP requirement throughout the night.[96-100] Studies to date have shown little to no difference in use of fixed CPAP versus APAP in terms of improvement in AHI, subjective sleepiness, adherence, and quality of life.[101-103] Many patients are currently managed with a completely ambulatory pathway for the diagnosis and treatment of OSA. They will begin the evaluation with HSAT, and, if significant sleep apnea is identified, APAP therapy will be initiated in the home setting. Patients either remain on APAP or the APAP will be used to determine a fixed CPAP setting. This ambulatory approach to straightforward OSA in high-risk individuals has been demonstrated to be feasible and potentially an effective means of addressing OSA.[104-106] Although ambulatory treatment of OSA with APAP can be effective, it is important to note that the treatment studies have excluded several patient populations. These populations include those with congestive heart failure, COPD, central sleep apnea, neuromuscular disease, and hypoventilation syndromes. Due to lack of data in these specific populations, the most recent practice parameters do not recommend the use of APAP in individuals with these significant comorbidities.[93]

MINI CLINI

Young Man Hospitalized for Observation After a Single-Vehicle Accident in the Midafternoon

History

A 27-year-old nonsmoker is admitted to the coronary care unit for monitoring so that the diagnosis of cardiac contusion can be ruled out. The patient has been involved in a single-vehicle automobile accident. The accident occurred at 3:30 p.m. on a clear day. The patient felt drowsy immediately before the event. He became conscious after hitting the guardrail. The patient's chest hit the steering wheel. The patient reports anterior chest wall pain and denies having angina or feeling faint.

Medications

- None

Medical History

- Negative

Physical Examination

- *Vital signs:* Blood pressure 140/88 mm Hg, heart rate 100 beats/min, temperature 98.6°F (37°C), respirations 16 breaths/min
- *General:* Well-developed, well-nourished white man
- *Head, eyes, ears, nose throat:* Elongated soft palate, mild crowding of tonsillar pillars, retrognathic chin (i.e., small chin due to a posterior displaced mandible that narrows the airway)
- *Neck:* 40 cm (16 inches) in circumference
- *Chest:* Contusion on anterior portion of the chest
- *Lungs:* Clear breath sounds bilaterally
- *Heart:* Regular rate and rhythm
- *Abdomen:* Soft with normal bowel sounds
- *Extremities:* No clubbing, cyanosis, or edema
- *Skin:* Multiple small lacerations

Laboratory Data

- *Chest x-ray:* No cardiomegaly, mass, infiltrate, or effusion
- *ECG:* Sinus tachycardia
- *Troponin:* 0.4 ng/mL (normal)

Problem

What caused the patient to fall asleep at the wheel?

Discussion

The patient is found to have bradycardia during sleep on the night of admission. These episodes appeared to be associated with snoring and oxyhemoglobin desaturation on O_2 at 2 L/min through a nasal cannula. The cardiology consultant recommended a diagnostic nocturnal PSG to rule out sleep apnea. The study shows severe sleep apnea (AHI 85 with a low SaO_2 of 60%). A CPAP titration study determined that the patient requires 10 cm H_2O of CPAP delivered via nasal pillows. At follow-up 1 month later, the patient states he no longer experiences the fatigue he had previously reported. In retrospect, the patient believes that before treatment with CPAP, he was quite sleepy during the day. Despite this improvement, he wants to explore other treatment options. A surgical consultation is obtained.

Autobilevel devices use proprietary algorithms to automatically adjust the EPAP and IPAP in response to respiratory events. Research data for these devices thus far are limited, and no clear recommendations regarding their use in the treatment of OSA can be made at this time. However, these devices are commonly used in clinical practice, particularly in patients who struggle with other positive pressure modalities.

MINI CLINI

Middle-Aged Woman With Pulmonary Hypertension

History

A 59-year-old former smoker is admitted to the hospital for right and left heart catheterization. A previous ECG was compatible with pulmonary hypertension. The patient denies having angina or exertional chest discomfort. She admits to dyspnea on exertion that has been increasing over the past few months and to a chronic non-productive cough. She denies taking "diet pills."

Medications

- Nifedipine, 10 mg by mouth 3 times per day
- Furosemide (Lasix), 20 mg by mouth daily
- Potassium chloride, 20 mEq by mouth twice per day

Medical History

- Hypertension and allergic rhinitis
- No cardiac disease

Physical Examination

- *Vital signs:* Blood pressure 145/88 mm Hg, heart rate 90 beats/min, temperature 98.6°F (37°C), respirations 12 breaths/min
- *General:* Obese white woman in no acute distress
- *Neck:* 40 cm (16 inches) in circumference
- *Lungs:* Clear breath sounds bilaterally
- *Heart:* Regular rate and rhythm, increased second heart sound (P_2)
- *Abdomen:* Obese; soft, normal bowel sounds
- *Extremities:* 2-mm pretibial pitting edema

Laboratory Data

- *Chest x-ray:* Mildly enlarged heart, no mass, infiltrate, or effusion
- *ECG:* Normal sinus rhythm with P pulmonale
- *Left heart catheterization:* No significant coronary artery disease, normal left ventricular function
- *Right heart catheterization:* Pulmonary hypertension (75/25 mm Hg), pulmonary artery wedge pressure 23 mm Hg
- *Room air ABGs:* pH 7.45, PCO_2 41 mm Hg, PO_2 54 mm Hg, SaO_2 84%
- *Spirometry:* Forced vital capacity (FVC) 1.69 L (55% of predicted value), FEV_1 1.27 L (55% of predicted value), FEV_1/FVC 75, forced expiratory flow midexpiratory phase ($FEF_{25\%–75\%}$) 0.96 L/s (37% of predicted value); no significant improvement with single-dose bronchodilator

Problem

What is the cause of the pulmonary hypertension?

Discussion

The pulmonary service is consulted for evaluation for pulmonary hypertension in association with abnormal spirometry results. Results of bilateral lower extremity Doppler examinations and a ventilation/perfusion scan are normal. Because of a history of snoring, an overnight portable cardiopulmonary sleep study is performed. The study revealed evidence of snoring, nonpositional apnea and hypopnea, and desaturation to less than 60% on the oximeter for most of the monitoring period. Results of a PSG performed in the sleep laboratory confirmed the presence of moderate to severe OSA with AHI 28. The patient responded well to the application of CPAP titrated to 12 cm H_2O. Dyspnea was relieved at the time of follow-up. Repeat ABG values improved. The patient no longer required portable liquid O_2 to maintain SaO_2 greater than 90% at rest or with exercise.

It is likely this patient has pulmonary hypertension that is due to OSA, as opposed to idiopathic pulmonary artery hypertension, which generally affects younger women. Chronic thromboembolic disease should be excluded, as it was in this case. Chronic right heart failure secondary to sleep apnea can be improved with proper treatment.

Side effects and troubleshooting strategies for positive airway pressure therapy. Side effects of positive pressure therapy are frequently related to the interface and to the pressure prescribed. Feelings of claustrophobia, nasal congestion, rhinorrhea, skin irritation, and nasal dryness may be reported (Fig. 34.2). Claustrophobia and skin irritation can be managed by changing the interface to one that is more easily tolerated by the patient. Nasal congestion, rhinorrhea, skin irritation, and nasal dryness can be managed by using combinations of topical nasal steroids, antihistamines, nasal saline sprays, and lotions. An inline humidifier is standard on current machines, and the amount of humidity provided can be modified by the patient. Heated humidification has been shown to improve adherence.[100] If the patient reports a sensation of too much pressure, particularly at sleep initiation, prescribing a ramp in pressure (standard in most devices) can be beneficial. The ramp allows a gradual increase in pressure over 5 to 45 minutes. The ramp time is empirically determined by the prescribing physician. Another intervention that may be beneficial in some patients who have difficulty exhaling against pressure is the pressure release feature. This feature briefly decreases the PAP pressure by 1 to 3 cm H_2O during exhalation and then quickly returns pressure to the set CPAP pressure before the start of inspiration. There is no objective evidence that a ramp feature or pressure relief setting improves patient acceptance or compliance.[107,108]

Pressure leaks are another problem that the RT may encounter. Most interfaces involve the nose (nasal mask or nasal pillows) or the nose and mouth (oronasal mask). Some patients tend to breathe partially or mainly through the mouth. The addition of a chin strap may not resolve the problem. Changing the interface to an oronasal mask may be required for effective "pressurization" of the upper airway in these patients.[109] Leaks are important to address in patients prescribed APAP and autobilevel, because these devices can have difficulty distinguishing from leak and respiratory events, leading to excessive delivered pressure and worsening leak. Patient accommodation and long-term adherence to therapy can be impacted by available masks and devices from the home care company or medical facility. Initial optimization and acceptance of PAP therapy is of the upmost importance, as research has demonstrated long-term usage and success with PAP treatment is predicted by the usage pattern in the first few weeks of therapy.[110]

Oral Appliance Therapy

Oral appliances are devices that enlarge the airway by moving the mandible forward or by keeping the tongue in an anterior

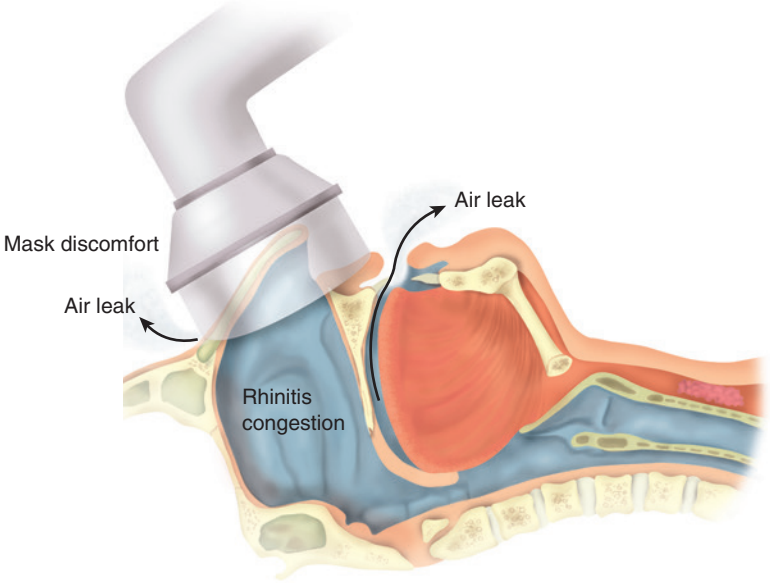

Fig. 34.2 Positive Airway Pressure Problems. Various problems can be encountered with continuous positive airway pressure.

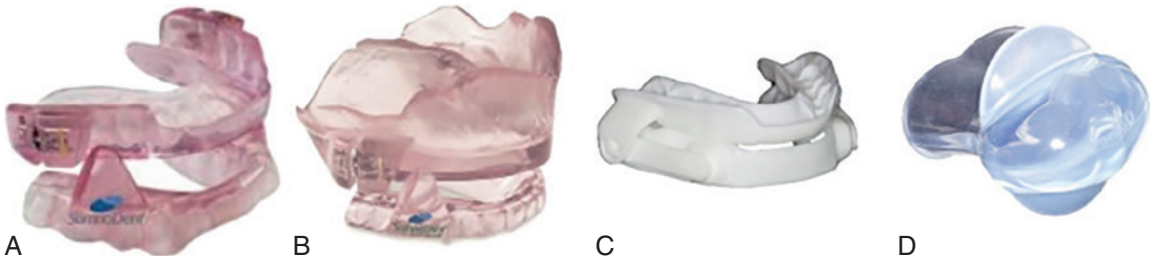

Fig. 34.3 Examples of Commercially Available Oral Appliances. (A) SomnoDent Flex, a custom-made oral appliance that moves the mandible forward (OA_m) for the dentate patient. (B) SomnoDent Edentulous, a custom-made OA_m for patients with an edentulous maxilla. (C) Narval, a custom-made OA_ms for the dentate patient. (D) AveoTSD, a prefabricated Tongue Stabilizing Device. (Modified from Hamoda MM, Kohzuka Y, Almeida FR: Oral appliances for the management of OSA. An updated review of the literature. *Chest* 153(2): 544–553, 2018.)

position (Fig. 34.3). Patients who have mild-to-moderate sleep apnea may be offered this therapeutic option up front or may be treated with an oral appliance if they are unable to tolerate PAP therapy. Oral appliances are worn only during sleep and come in various forms. The appliances are custom-fitted by dentists and are generally well-tolerated by patients. They are overall less effective in decreasing the AHI but may be of equal efficacy given higher adherence rates with oral appliance therapy compared with PAP treatment.[111,112] A few studies suggest oral appliances and PAP therapy have similar outcomes in terms of improvements in sleepiness and quality of life and at least short-term effects on blood pressure.[113-115] The role of oral appliance therapy in the acute care setting, such as patients hospitalized for acute heart failure or after elective surgery, is unclear.

Medications

Medications have proven at best minimally effective for most patients with OSA. Given the efficacy of other current treatment options, medications are currently not recommended for the treatment of OSA. The antidepressants protriptyline and fluoxetine have been used by some providers to manage mild OSA. These drugs are minimally effective in most patients.[116-118] Newer research has focused on cholinergic agents such as donepezil and cannabinoids such as dronabinol to treat OSA. Although this early work is promising, further research is necessary to evaluate the efficacy of these medications.[119-121]

O_2 therapy may be useful for patients with oxyhemoglobin desaturation who refuse positive pressure therapy. O_2 therapy can improve nocturnal desaturation but has no significant effect on ventilatory arousals and daytime sleepiness.[122] Previous work suggested O_2 therapy could lengthen apneic spells and thus potentially worsen apnea severity.[123,124] However, more recent work suggests that the effect supplemental O_2 has on apnea depends on the specific physiology underlying an individual's sleep-disordered breathing (i.e., high loop gain versus those with a more stable ventilatory control system).[125] Supplemental oxygen can be entrained into PAP devices for individuals who have persistent hypoxemia despite correction of obstructive therapy with positive airway pressure therapy. Supplemental oxygen should be used with caution in patients with significant respiratory impairment who may retain CO_2.

MINI CLINI

Worsening Right-Sided Heart Failure in a Patient With Chronic Obstructive Pulmonary Disease Who Is Using Oxygen

History

A 50-year-old former smoker previously found to have severe COPD (FEV_1 of 0.9 L [30% of predicted value]) is admitted to the hospital for evaluation and management of worsening shortness of breath and persistent bilateral leg swelling. He has been using O_2 at 2 L/min 24 h per day for the past 3 months. A chronic productive cough of clear sputum has been unchanged. He denies having chest pain.

Medications

- Ipratropium bromide by metered dose inhaler, 2 puffs 4 times per day
- O_2, 2 L/min 24 h per day
- Hydrochlorothiazide, 50 mg by mouth daily
- Roflumilast 500 mcg by mouth daily

Medical History

- Hypertension and chronic bronchitis
- No cardiac disease

Physical Examination

- *Vital signs:* Blood pressure 150/90 mm Hg, heart rate 100 beats/min, temperature 98.6°F (37°C), respirations 18 breaths/min
- *General:* Obese white man who appears short of breath
- *Neck:* 46 cm (18 inches) in circumference
- *Lungs:* Decreased breath sounds bilaterally
- *Heart:* Faint sounds but regular rate and rhythm
- *Abdomen:* Obese; soft, normal bowel sounds
- *Extremities:* "Dusky" lower extremities with 4-mm pitting edema to the knees

Laboratory Data

- *ABGs:* pH 7.36, PCO_2 44 mm Hg, PO_2 56 mm Hg, SaO_2 89% (on 2 L/min O_2)
- *Chest x-ray:* "Pulmonary congestion"; otherwise normal
- *ECG:* Sinus tachycardia without acute changes
- *Echocardiogram:* "Technically limited" but reported to be without segmental wall abnormalities or to show normal left ventricular function
- *Bilateral lower extremity Doppler examination:* Negative for deep venous thrombosis

Problem

What could be the cause of this patient's continued signs of right heart failure?

Discussion

The patient has overlap syndrome (COPD and OSA). He has been appropriately treated for COPD (bronchodilators and O_2) but has not been treated for OSA. His physician never asked and the patient never volunteered a history of nightly loud snoring with observed apnea and daytime fatigue. Subsequent evaluation with a nocturnal PSG reveals severe nocturnal desaturation to 40% on the oximeter despite treatment with O_2 at 2 L/min. A CPAP titration study is performed. The patient is discharged with CPAP set at 15 cm H_2O via a nasal mask. He returns to the outpatient clinic 3 months later and reports "feeling great." He reports that the shortness of breath has decreased and that he has much more energy during the day. Physical examination shows trace pedal edema. ABG studies on 2 L/min of O_2 reveal pH 7.40, PCO_2 40 mm Hg, PO_2 75 mm Hg, and SaO_2 93%.

BOX 34.5 Surgical Alternatives for Obstructive Sleep Apnea

- Bypass of the upper airway
- Tracheostomy
- Reconstruction of the upper airway
- Nasal surgery
- Palatal surgery
- Maxillofacial surgery

Surgical Interventions

Surgical treatments for OSA can be divided into two broad categories: procedures that bypass the upper airway and procedures that reconstruct the upper airway (Box 34.5). Before CPAP therapy became available, tracheostomy was the primary therapy for severe OSA. Because of the psychosocial and medical morbidity associated with the procedure, use of tracheostomy is currently limited to managing severe OSA when all other therapies have been exhausted.[126,127] In most instances, if a surgical approach to OSA is considered, the surgeon will perform an airway exam to identify the site(s) of airway obstruction and determine which approach will best address an individual's pattern of airway collapse. A new procedure termed drug-induced sleep endoscopy (DISE) may allow surgeons to better identify the site and mechanisms of upper airway collapse preoperatively, thus allowing the most appropriate surgical intervention for the patient.[128]

Palatal Surgery

Uvulopalatopharyngoplasty (UPPP) is palatal surgery performed with a standard "cold knife" technique or a laser. Portions of the soft palate, the uvula, and additional redundant tissue are removed in these procedures. The success rate of UPPP in 1996 was reported to be less than 50% overall.[129] Improvements in technique and the tissue-sparing modified UPPP may be more effective with less complications in the treatment of appropriately selected patients with OSA.[130]

Most patients with OSA have airway collapse at multiple levels. Thus surgical approaches such as UPPP targeting one level of obstruction typically lead to only modest improvement in OSA in most individuals. UPPP is much more commonly used nowadays as part of a multilevel approach to OSA and may be performed in conjunction with other airway procedures such as genioglossus advancement or hyoid suspension. This multilevel approach may have a greater success rate compared with standalone procedures targeting one site of obstruction.[131]

Maxillofacial Surgery

Maxillomandibular advancement surgically projects the jaw and the attached soft tissues forward, increasing the caliber of the airway and putting tension across the pharyngeal wall. This approach decreases the likelihood of airway collapse (Fig. 34.4). Maxillomandibular advancement has been shown to be effective in improving apnea severity, sleepiness, and quality of life.[132-134] These surgical procedures are a major undertaking and are performed at only a few specialized centers. A coordinated effort by a dedicated team of otolaryngologists, oral surgeons, and

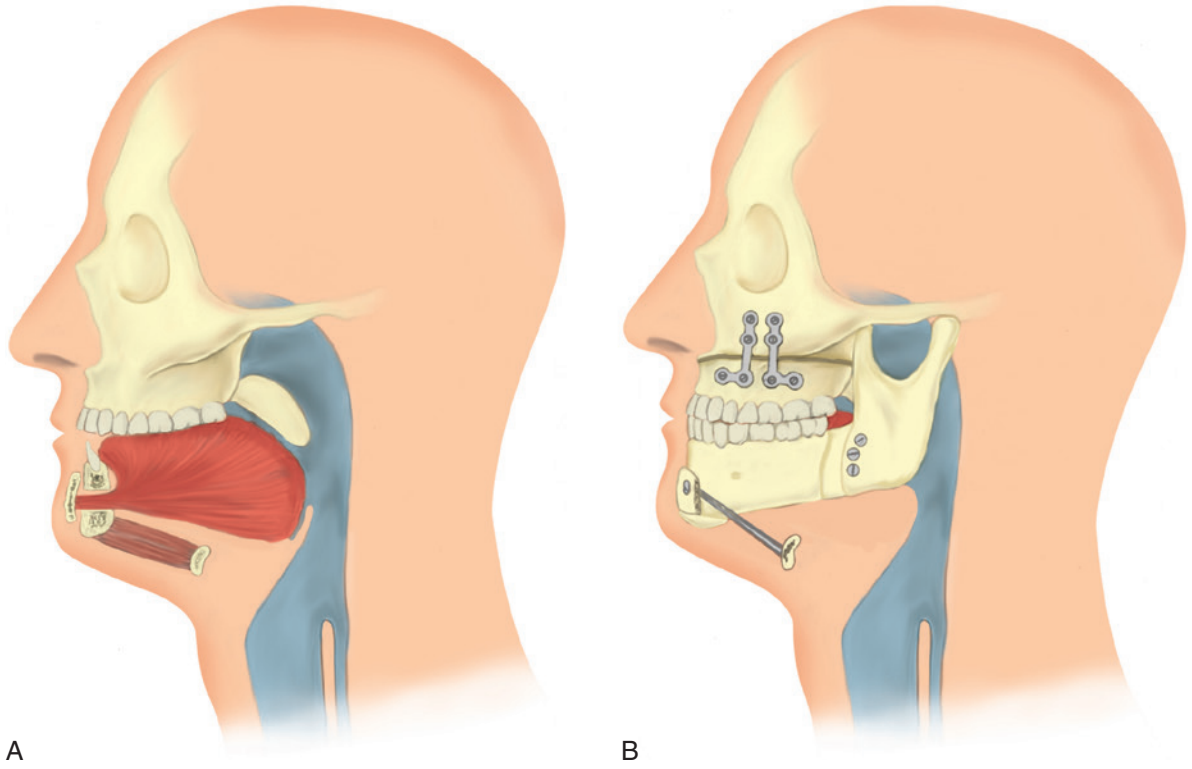

Fig. 34.4 Phase I and Phase II Upper Airway Reconstruction. (A) Phase I surgery. Lateral cutaway view of the skull shows tongue (genioglossal) and hyoid bone advancement in conjunction with uvulopalatopharyngoplasty. (B) Phase II surgery. Lateral cutaway view of the skull shows advancement of the maxilla (upper jaw) and mandible (lower jaw) in a patient who has undergone a phase I procedure.

sleep specialists is essential. Regardless of the surgical option chosen, a postoperative sleep study should be obtained to document improvement objectively.[135]

Upper Airway Stimulation

A new therapy for OSA uses a surgically implanted neurostimulator. This device stimulates the hypoglossal nerve, leading to protrusion of the tongue and bulk movement of upper airway soft tissues with the goal of maintaining airway patency. The only commercially available device was approved in 2014 based on a pivotal trial demonstrating effectiveness of this intervention in a highly selected group of 126 patients with OSA.[136] Three-year follow-up in this group has demonstrated persistent improvements in OSA and quality-of-life measures.[137] Currently, this device has very specific eligibility criteria, and its role in the management of OSA continues to evolve.

Additional Therapies

Alternative treatment options for OSA include nasal resistance devices, negative pressure oral appliances, and negative external pressure devices. These therapies can improve snoring, but their efficacy in patients with OSA, particularly moderate to severe disease, requires further evaluation.[138-140]

In addition, of interest currently is the use of combination therapy for OSA. Occasionally, patients may not have their apnea controlled optimally with PAP alone or may require a pressure that is too high for them to tolerate. The use of PAP in combination with an oral appliance may be of benefit in these situations.[141] Surgery in combination with PAP therapy may also lead to improved outcomes. Nasal procedures including turbinate reduction, septoplasty, and/or nasal valve surgeries have been minimally effective as stand-alone therapy for OSA but may lead to significant improvement in PAP adherence in those initially intolerant to PAP therapy.[142]

RULE OF THUMB Sleep symptoms may present early in patients with neuromuscular disease. Treatment with noninvasive ventilation during sleep may improve daytime symptoms.

ROLE OF THE RESPIRATORY THERAPIST IN DISORDERS OF SLEEP

RTs play a vital role in identifying high-risk patients through history and physical and either themselves doing further assessment with a STOP-BANG questionnaire or recommending referral for further assessment. As part of the multidisciplinary team, RTs prepare patients for the overnight PSG and obtain key information relating to their sleep history. During the study, RTs assess for **sleep-disordered breathing** and apply and titrate positive pressure. They are also involved with education that is important in assisting with the patient's understanding and compliance with positive pressure therapy. Some RTs pursue special certification in sleep technology.

RTs may see patients with sleep disorder–related symptoms during their clinical practice and can encourage diagnostic testing

MINI CLINI

Young Woman With Mental Status Changes After Orthopedic Surgery

History

A 37-year-old obese smoker is admitted to the hospital after elective surgical repair of a biceps tendon and ulnar collateral ligament. She initially sustained the injury after a fall when riding a bicycle. After outpatient orthopedic evaluation and preoperative cardiac clearance, an elective repair of the tendon and ligament was scheduled. She was intubated electively for the procedure, and her operative course was unremarkable. Postoperatively, she was extubated and noted to be slightly lethargic but easily arousable and in pain while in postoperative recovery. On transfer to the floor, she became increasingly lethargic and hypoxemic despite the addition of up to 6 L/min of supplemental O_2 via nasal cannula. An emergency code is called. She is transferred to a step-down bed and further testing is performed.

Medications at Home

- None

Medical History

- Hypertension, not on medications

Physical Examination

- *Vital signs:* Blood pressure 158/74 mm Hg, heart rate 68 beats/min, temperature 98.6°F (38.6°C), respirations 12 breaths/min
- *General:* Obese woman, lethargic and arousable
- *Neck:* 46 cm (18 inches) in circumference
- *Lungs:* Diminished breath sounds bilaterally
- *Heart:* Faint sounds but regular rate and rhythm
- *Abdomen:* Obese; soft, normal bowel sounds
- *Extremities:* Right arm wound intact with bandages in place, pulses equal

Laboratory Data

- *ABGs on 6 L/min O_2 via nasal cannula:* pH 7.11, PCO_2 109 mm Hg, PO_2 110 mm Hg, SaO_2 87%
- *Chest x-ray:* No mass, infiltrate, or effusion
- *ECG:* Normal sinus rhythm
- *CT scan of the head without contrast agent:* No mass, hemorrhage, or midline shift
- *CT scan of the chest with contrast agent:* No evidence of pulmonary embolism or parenchymal abnormality
- *EEG:* No seizure activity

Problem

How should this patient be managed?

Discussion

The patient requires bilevel noninvasive ventilator support intermittently for the next several days. After her work-up reveals nothing remarkable, a pulmonary and sleep consultation is obtained. Review of the medical records reveals the patient has been receiving hydromorphone (Dilaudid) frequently for pain control. After stopping opioid medication, the patient's mental status gradually returns to baseline. Repeat ABGs on room air show pH 7.39, PCO_2 62 mm Hg, PO_2 110 mm Hg, and SaO_2 93%. A diagnostic nocturnal PSG is performed, which reveals severe OSA with AHI of 55 and low SaO_2 of 72% and evidence of chronic **obesity hypoventilation**. Positive pressure titration is performed successfully with volume-assured pressure support with the goal V_T of 8 mL/kg. The patient is discharged home with a follow-up appointment in the sleep clinic.

MINI CLINI

Fatigue in a Patient With Neuromuscular Disease

History

A 54-year-old man with a recent diagnosis of ALS presents to the outpatient clinic with fatigue. He states he has been more tired and sleepy for the last few months. He had been diagnosed with ALS approximately 6 months ago but has been doing fairly well at home. He does notice that he has some difficulty sleeping at night, sometimes sleeping in a reclining chair. He denies snoring or weight gain, and in fact has lost 15 lb in the last few months. On further questioning, he reports feeling short of breath with exertion or when lying flat.

Medications

- None

Medical History

- Hypertension and gastroesophageal reflux
- No significant cardiac disease

Physical Examination

- *Vital signs:* Blood pressure 135/70 mm Hg, heart rate 80 beats/min, temperature 98.6°F (37°C), respiration 16 breaths/min
- *General:* Thin, no distress, pleasant man
- *Neck:* 52 cm (20.5 inches) in circumference
- *Lungs:* Clear breath sounds bilaterally
- *Heart:* Regular rate and rhythm
- *Abdomen:* Thin; soft, normal bowel sounds
- *Extremities:* no edema

Laboratory Data

- *Room air ABGs:* pH 7.38, PCO_2 52 mm Hg, PO_2 88 mm Hg, SaO_2 94%
- *Chest x-ray:* Normal
- *Pulmonary function tests:* FVC 1.52 L (42% predicted), FEV_1 1.41 L (53% predicted), FEV_1/FVC ratio 0.73

Problem

Why does this patient have fatigue?

Discussion

The patient's symptoms are concerning for respiratory compromise because of his neuromuscular disease. His pulmonary function tests reveal restrictive lung physiology, with decreased FVC and FEV_1 on spirometry. He also has evidence for chronic hypoventilation with elevated PCO_2 on ABG analysis. He may benefit from starting noninvasive ventilation. The patient was started on positive pressure therapy with pressure support, and his sleep quality and daytime energy improved.

by discussion with the patient or the managing physician or both. In the acute care setting, RTs and nursing staff are in a unique position to observe directly evidence of abnormal breathing during sleep or other clinical clues that may prompt further clinical action.

RTs who work for durable medical equipment companies may see patients in their home and help to manage the CPAP or bilevel PAP machines, interfaces, and supplemental O_2. In the context of rehabilitation or bariatric surgery, RTs may help to care for patients recovering from surgery or participating in rehabilitation programs for weight loss or improvement in cardiopulmonary function. The role of the RT can be key in serving

as the bridge between physician and patient to enable education, identify obstacles to therapy, and improve overall compliance. In all these ways, RTs play an invaluable role as members of the sleep medicine team.

SUMMARY CHECKLIST

- There are three types of sleep apnea: OSA, CSA, and mixed sleep apnea; OSA is the most common.
- OSA is common, underdiagnosed, and controllable.
- The major risk factor for airway narrowing or closure during sleep is a small or unstable upper airway.
- The shift in the physiologic state from wakefulness to sleep and the consequent decrease in muscle tone result in partial or complete airway closure of the upper airway in patients with OSA.
- The long-term harmful effects of OSA include poor daytime functioning, impaired metabolic function, and increased risk for cardiovascular morbidity and mortality.
- Risk factors for OSA include male sex, age greater than 40 years, upper body obesity (neck size >16.5 inches), habitual snoring, and diurnal hypertension.
- PSG is the most accurate way to make the diagnosis of OSA; however, home sleep testing is becoming increasingly common. The PSG measures several physiologic variables and allows for the staging of sleep and measurement of airflow, ventilatory effort, ECG, and SaO_2.
- First-line medical therapy for OSA is CPAP. This modality is almost always effective in the laboratory, although long-term adherence with CPAP therapy may be suboptimal.
- Bilevel PAP therapy may be useful in salvaging selected patients who have difficulty accepting or complying with CPAP.
- Autotitrating positive airway pressure devices (auto-CPAP or autobilevel PAP) are being used in managing OSA without an in-laboratory titration study.
- Oral appliances can be effective in patients with mild to moderate OSA.
- Surgical therapy including upper airway stimulation may be an option for a select group of patients who have undergone an extensive preoperative analysis of the upper airway and do not accept or comply poorly with medical therapy.
- Optimal management of OSA, regardless of the modality, requires patient education, continued monitoring, and reassessment.

Neonatal and Pediatric Respiratory Disorders

Robert M. DiBlasi and Edwin L. Coombs, Jr.

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the clinical findings, radiographic abnormalities, and treatment of patients with respiratory distress syndrome.
- Describe the clinical manifestations and treatment of patients with transient tachypnea of the newborn.
- Describe the pathophysiology, presentation, and treatment of meconium aspiration syndrome.
- Identify the clinical signs and symptoms associated with bronchopulmonary dysplasia and the approaches used to manage these infants.
- State the cause and treatment of apnea of prematurity.
- Describe the pathophysiology, diagnosis, and treatment of persistent pulmonary hypertension of the newborn.
- Discuss the pathophysiology, diagnosis, and treatment of congenital diaphragmatic hernia.
- Identify the anatomic defects associated with tetralogy of Fallot.
- Describe the clinical presentation of a ventricular septal defect.
- Describe types and associated conditions for abdominal wall defects.
- Define the epidemiologic factors associated with increased risk for sudden infant death syndrome.
- Identify the respiratory problems associated with gastroesophageal reflux disease.
- State the clinical findings commonly observed in patients with bronchiolitis.
- Describe the clinical features and treatment of children with epiglottitis.
- Describe the clinical manifestations and treatment of cystic fibrosis.

CHAPTER OUTLINE

KEY TERMS

apnea of prematurity
bronchiolitis
bronchopulmonary dysplasia
croup
cystic fibrosis
ductus arteriosus
epiglottitis
gastroesophageal reflux disease
meconium aspiration syndrome
nasal flaring
persistent pulmonary hypertension of the newborn
respiratory distress syndrome
sudden infant death syndrome
tetralogy of Fallot
transient tachypnea of the newborn
transposition of the great arteries

Many perinatal disorders can affect the respiratory system. Some disorders are developmental abnormalities of the heart, lungs, or airways; some are caused by prematurity; some are caused by problems during labor and delivery; and some are caused by complications from treating the underlying disorders. Common disorders in the neonatal period with which respiratory therapists (RTs) should be familiar are respiratory distress syndrome (RDS), transient tachypnea of the newborn (TTN), meconium aspiration syndrome (MAS), apnea of prematurity, bronchopulmonary dysplasia (BPD), persistent pulmonary hypertension of the newborn (PPHN), and congenital cardiopulmonary abnormalities.

NEONATAL RESPIRATORY DISORDERS

Lung Parenchymal Disease

Respiratory Distress Syndrome

Background. Neonatal **respiratory distress syndrome** (RDS) affects approximately 40,000 infants each year in the United States.[1] Although the mortality rate has decreased dramatically over the past four decades, many infants still perish or have chronic conditions that are associated with the treatment of the syndrome (i.e., oxygen and positive pressure). RDS, previously known as *hyaline membrane disease*, is a disease of prematurity. The incidence increases with decreasing gestational age, occurring in more than 80% in neonates less than 28 weeks.[2] The major factors in the pathophysiology of RDS include surfactant deficiency, underdeveloped alveolar units and capillaries and decreased alveolar surface area, reduced lung compliance, poor gas exchange, and the presence of a **ductus arteriosus**.

RULE OF THUMB The incidence and severity of RDS, as well as incidence of chronic complications, both increase with decreasing gestational age and weight. Many of these complications can be avoided with judicious use of oxygen and positive pressure.

Surfactant production depends on both the maturity of the lung and the adequacy of fetal perfusion. Maternal factors that impair fetal blood flow, such as abruptio placentae and maternal diabetes, also may lead to RDS.

Pathophysiology. In preterm infants, adequate amounts of surfactant are present in the lung; however, the surfactant is trapped inside type II alveolar cells. In infants with RDS, type II alveolar cells do not release adequate amounts of surfactant. The surfactant that is released is incompletely formed and does not decrease alveolar surface tension. Because the surfactant molecule in the alveolus is structurally abnormal, the type II cells and alveolar macrophages have more rapid uptake for recycling. Thus there is a qualitative deficiency of alveolar surfactant.

Fig. 35.1 outlines the pathophysiologic events associated with RDS. A qualitative decrease in surfactant increases alveolar surface tension forces, which causes alveoli to become unstable and collapse and leads to atelectasis and increased work of breathing (WOB). At the same time, the increased surface tension draws fluid from the pulmonary capillaries into the alveoli. In combination, these factors impair oxygen (O_2) exchange and cause severe hypoxemia. The severe hypoxemia and acidosis increase *pulmonary vascular resistance (PVR)*. As pulmonary arterial pressure increases, extrapulmonary right-to-left shunting increases, and hypoxemia worsens. Hypoxemia and acidosis also impair further surfactant production. Steroids given to the pregnant mother before birth (antenatally) have been shown to accelerate lung maturation and surfactant function in the fetus, decrease the severity of RDS, and improve outcomes.[3,4]

Clinical manifestations. The first signs of respiratory distress in infants with RDS normally appear soon after birth. Tachypnea usually occurs first. After tachypnea, worsening retractions, paradoxical breathing, and audible grunting are observed. **Nasal flaring** also may be seen. Chest auscultation often reveals fine inspiratory crackles. Cyanosis may or may not be present. If central cyanosis is observed, it is likely that the infant has severe hypoxemia. Certain other conditions, such as systemic

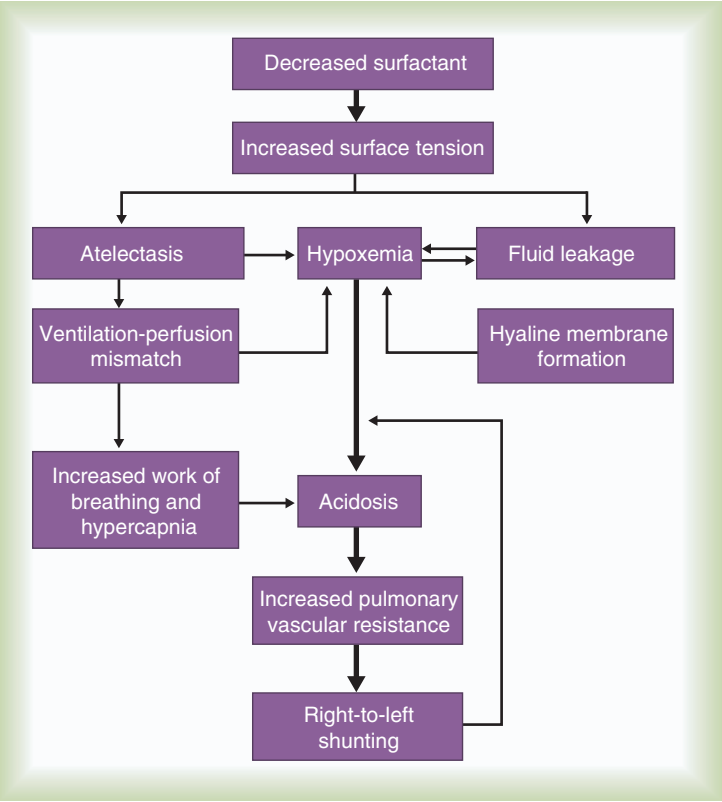

Fig. 35.1 Pathophysiology of Respiratory Distress Syndrome.

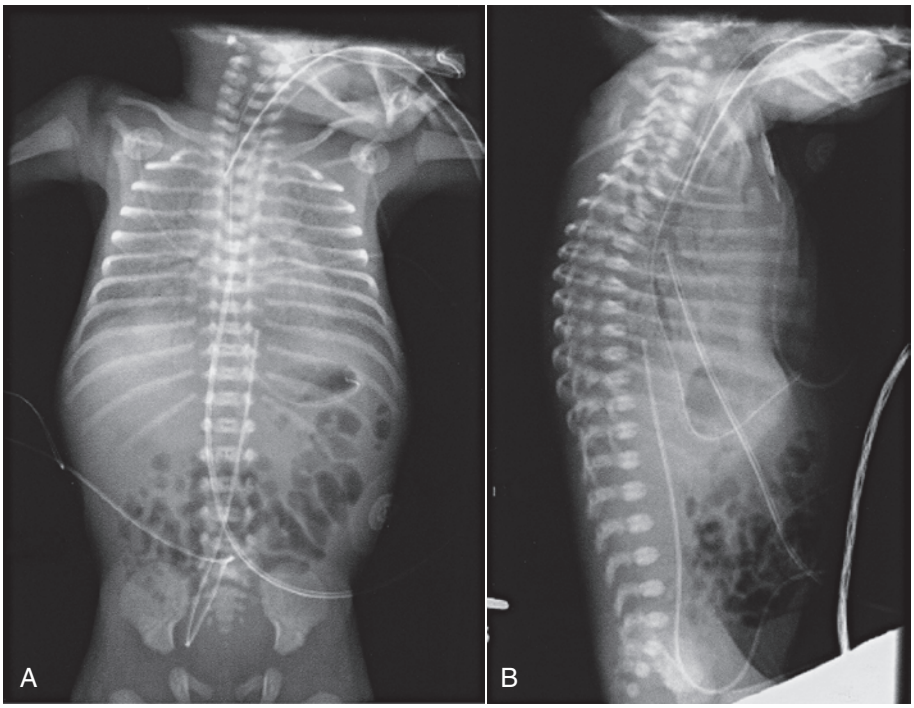

Fig. 35.2 Radiopaque Appearance of Severe Respiratory Distress Syndrome. Anteroposterior (A) and lateral (B) chest x-rays show diffuse hazy appearance with low lung volumes and air bronchograms that extend into the periphery.

hypotension, hypothermia, and poor perfusion, can mimic this aspect of RDS.

A definitive diagnosis of RDS usually is made with chest x-ray (Fig. 35.2). Diffuse, hazy, ground-glass appearance or reticulogranular densities with the presence of air bronchograms with low lung volumes are typical of RDS. The reticulogranular pattern is caused by aeration of respiratory bronchioles and widespread alveolar collapse. Air bronchograms appear as aerated, dark, major bronchi surrounded by the collapsed or consolidated lung tissue.

Treatment. *Continuous positive airway pressure (CPAP)*, surfactant replacement therapy, and mechanical ventilation with conventional or *high frequency ventilation (HFV)*, are common interventions used to manage RDS. High-flow nasal cannula (HFNC),[5] Nasal Intermittent Mandatory Ventilation (NIMV),[6] and unless the infant's condition is severe (high WOB, FiO_2 >0.4, and/or severe apnea), a trial of nasal CPAP is indicated (4 to 6 cm H_2O).[4-8] Because of the hazards of endotracheal tubes (ETTs), nasal prongs or mask are preferred. If the infant's clinical condition deteriorates rapidly, a more aggressive approach is required. Endotracheal intubation should be performed under controlled conditions as an elective procedure. Mechanical ventilation with positive end-expiratory pressure (PEEP) should be initiated if gas exchange does not improve with CPAP or if the patient's frequent apnea does not respond to stimulation.

Historically, premature infants have been intubated and placed on a ventilator in order to improve gas exchange, reduce WOB, or give surfactant to prevent RDS. However, even short-term invasive ventilation in premature infants is associated with severe complications,[9] and CPAP is gentler on premature infants' lungs.[10] If it is likely that respiratory support with a ventilator will be needed, early administration of surfactant via ETT and ventilator, followed by rapid extubation—known as INtubate, SURfactant, and Extubation to CPAP (INSURE)—is preferable to prolonged ventilation.[11,12] Early CPAP after birth and subsequent selective surfactant administration in preterm infants that develop severe RDS (high WOB, apnea, and/or FiO_2 >0.4 on CPAP) has been shown to result in lower incidence of death, development of chronic lung disease, and other complications[13] than INSURE and is now the preferred practice in preterm infants.[14]

Other forms of noninvasive support for premature RDS may include HFNC and NIMV. HFNC provides positive pressure similar to CPAP but with the added benefit of purging CO_2 from the anatomic deadspace.[15] It is unclear whether HFNC should be used as an initial form of support, like CPAP, but it appears to be as effective as and with less nasal airway pressure injuries than CPAP following extubation of premature infants.[16] NIMV is essentially "CPAP with a rate" and has been shown to provide greater support than CPAP by reducing apnea and the need for intubation in premature infants.[17,18]

RULE OF THUMB HFNC has been shown to be as clinically effective as nasal CPAP, but with fewer nasal injuries following extubation from mechanical ventilation in premature infants.

RULE OF THUMB Nasal intermittent mandatory ventilation or "CPAP with a rate" may be an effective option for avoiding intubation in infants with severe RDS that are not responding to HFNC or CPAP.

MINI CLINI

Respiratory Distress Syndrome

Problem

A woman is about to deliver at 26 weeks of gestational age. What should the RT have available for resuscitation of the infant?

Discussion

An infant at 26 weeks of gestational age is most likely going to have RDS—ranging from mild to severe disease. The RT should have equipment, supplies, and drugs necessary to support the infant. Many infants require mask-bag ventilation. It is crucial that the RT be acutely attuned to using the lowest pressures necessary to move the chest. It is very easy to injure the lung with high V_T. Most authorities recommend the use of a T-piece resuscitator that delivers manual breaths at fixed pressures, decreasing the risk for traumatic injury from high V_T. The aim of mechanical ventilation for RDS is to prevent lung collapse and maintain alveolar inflation. In severe RDS, collapse of alveoli with every breath necessitates very high reinflation pressures. To prevent the need for this high reinflation pressure, use of PEEP is necessary.

The time constant of the lungs in RDS is short, so the lung empties very quickly with each ventilator cycle. If alveolar ventilation is inadequate, either peak inspiratory pressure, tidal volume, PEEP, or rate should be increased. Modes classified as pressure control with adaptive targeting (e.g., A/C volume guarantee) have been shown to cause fewer complications than traditional pressure control breath types (with set-point targeting) in this population.[19] Such modes allow the operator to set an average tidal volume target, and the ventilator automatically adjusts inspiratory pressure to achieve the target as respiratory system mechanics change (see Chapter 47). These modes are often referred to in the pediatric literature as "volume-targeted" modes, although this term is also used to refer to volume control modes (i.e., preset tidal volume and inspiratory flow). Preset tidal volume targets of 4 to 6 mL/kg should be used, and peak inspiratory pressure limit should be kept less than 30 cm H_2O for larger premature infants, and even lower pressure is indicated for more immature infants.[20] Higher limits may be needed if the infant has an ETT leak, high airway resistance, or reduced pulmonary compliance.

RULE OF THUMB Infants receiving conventional ventilation have traditionally been supported with pressure control ventilation with set-point targeting (e.g., pressure controlled-synchronized intermittent mandatory ventilation [PC-SIMV]). Volume-targeted breath types (e.g., pressure regulated volume control) may result in fewer complications and better outcomes than pressure control, especially in preterm babies with RDS. The current standard of care is to deliver replacement surfactant to infants that have severe RDS and are not tolerating CPAP.

Surfactant replacement therapy also is used as both a rescue treatment (in infants who already have RDS) and a prophylactic therapy (in the care of infants delivered prematurely). Some centers use prophylactic surfactant replacement therapy in the care of all very small infants (<1500 g). Therapies aimed at decreasing pulmonary edema, improving cardiac output, and weaning from O_2 and high ventilator volumes are essential in successfully treating infants receiving surfactant. Recent evidence supports the use of noninvasive ventilatory support (e.g., bubble CPAP) to support even the smallest of infants.[21,22]

Surfactant proteins are important for decreasing alveolar surface tension. All of these preparations are liquid suspensions that are instilled directly into the trachea. Four surfactant preparations are currently available in the United States for managing neonatal RDS: beractant (Survanta; Abbott Laboratories, North Chicago, IL), calfactant (Infasurf; ONY, Amherst, NY), poractant alfa (Curosurf; Chiesi, Cheadle, UK), and lucinactant (Surfaxin, Discovery Labs, Warrington, PA).[23]

Animal-derived surfactants may have several advantages over synthetic surfactants and are the most commonly used.[23] Beractant and calfactant are natural bovine surfactant extracts. Poractant alfa is a natural porcine surfactant extract. When compared with Beractant, high-dose Poractant has been shown to result in better outcomes in preterm infants.[23] Lucinactant is a completely synthetic surfactant that is under investigation for use in aerosolization during CPAP. The synthetic surfactant uses an amino acid sequence that acts like surfactant protein.[24]

RULE OF THUMB Maintenance of functional residual capacity (FRC) is best supported by targeting appropriate tidal volumes and positive end-expiratory pressure (CPAP or PEEP).

All surfactants appear to be equally effective. More than a single dose has been shown to be beneficial. Each specific surfactant has different dosing volumes and intervals (Table 35.1). Multiple doses of surfactant appear to result in better clinical outcomes than a single dose.[25] Traditionally, infants are administered surfactant through the ETT and require a mechanical ventilator. If infants are intubated, it is preferable to give the surfactant early in the ventilation course rather than later.[13] The surfactant product insert describes the positioning of the infant for surfactant delivery. General practice is to position the infant with different sections of the lung dependent so that the surfactant enters that section of the lung with gravity flow. If the infant is very sick and cannot be repositioned, surfactant can be administered with the infant in the supine position.

There are many complications associated with surfactant administration, which are related to airway obstruction from the liquid in the airways.[26] Several studies are underway to evaluate aerosolized surfactant or surfactant delivered through a thin tracheal catheter delivery during CPAP, so that babies can avoid intubation, mechanical ventilation, and lung injury.[27,28]

Transient Tachypnea of the Newborn

Background. **Transient tachypnea of the newborn** (TTN), often called *type II RDS*, is probably the most common respiratory disorder of newborns.[29,30] The cause of TTN is unclear, but it is most likely related to delayed clearance of fetal lung liquid.[31] During most births, approximately two-thirds of this fluid is expelled by thoracic squeeze in the birth canal; the rest is reabsorbed through the lymphatic vessels during initial breathing. These mechanisms are impaired in infants born by cesarean section or infants with incomplete development of the lymphatic vessels (preterm or small-for-gestational-age infants). The residual lung fluid causes an increase in airway resistance and an overall decrease in lung compliance. Because compliance is low, the infant must generate more negative pleural pressure to breathe. This process can result in hyperinflation of some areas and air trapping in others. Most infants with TTN are born at term without any specific predisposing factors in common. Mothers of neonates who have TTN tend to have longer labor intervals and a higher incidence of failure to progress in labor, which leads to cesarean delivery. In many cases, however, maternal history and labor and delivery are normal.

Clinical manifestations. During the first few hours of life, infants with TTN breathe rapidly. Alveolar ventilation, as

TABLE 35.1 Surfactant Dosing

Dosing Information	Beractant (Survanta)	Calfactant (Infasurf)	Poractant Alfa (Curosurf)	Lucinactant (Surfaxin)
Dose mg/kg of birth weight	100	100	100–200	20
Dose: mL/kg birth weight	4	3	1.25–2.5	5.8
Administration	¼ dose quickly in each of four positions	½ dose slowly supine then rotated	Whole or ½ dose supine	Dose in each of four positions
Dosing interval	Every 6 h or more often	Every 12 h or more often	Every 12 h or more often	Up to 4 doses in 48 h, minimum of 6-h interval

measured by arterial pH and $PaCO_2$, usually is normal. The chest x-ray findings, which may initially be indistinguishable from pneumonia, are hyperinflation, which is due to air trapping, and perihilar streaking. The perihilar streaking probably represents lymphatic engorgement. Pleural effusions may be evident in the costophrenic angles and interlobar fissures.

Treatment. Infants with TTN usually respond readily to a low FiO_2 by nasal cannula or high-flow nasal cannula (see Chapter 42). Infants requiring a higher FiO_2 may benefit from CPAP. Because the retention of lung fluid may be gravity-dependent, frequent changes in the infant's position may help speed lung fluid clearance. Also, diuretics, bronchodilators, and fluid restriction are common therapies.[31] Because TTN and neonatal pneumonia have similar clinical signs, intravenous administration of antibiotics should be considered for at least 3 days after appropriate culture samples are obtained. Mechanical ventilation is rarely needed, and when it is, this probably indicates a complication. Clearing of the lungs evident on a chest x-ray and with clinical improvement usually occurs within 24 to 48 hours. A few infants with TTN eventually have persistent pulmonary hypertension.

RULE OF THUMB A high-flow nasal cannula is preferred to prevent nasal injury and skin breakdown versus nasal continuous positive airway pressure [NCPAP] interfaces in TTNB (see Chapter 42). If a high-flow nasal cannula is not tolerated, infants require positive pressure to support spontaneous breathing and lung clearance.

Meconium Aspiration Syndrome

Background. **Meconium aspiration syndrome** is a disease of term and near-term infants. It involves aspiration of meconium into the central airways of the lung. MAS is usually associated with perinatal depression and asphyxia.

Pathophysiology. Amniotic fluid consists mainly of fetal lung fluid, fetal urine, and transudate from the uterine wall. *Meconium,* the contents of the fetal intestine, occasionally is expelled from the fetus into the surrounding amniotic fluid. Meconium consists of mucopolysaccharides, cholesterol, bile acids and salts, intestinal enzymes, and other substances. Meconium normally is not passed until after delivery.[32] Infants who have perinatal asphyxia may pass meconium in utero. The pathophysiologic control mechanisms for the passage of meconium in utero are not completely understood. It is widely accepted that infants can have meconium aspiration in utero. Amniotic fluid stained with meconium is found in approximately 12% of all births.[32] About 5% of neonates born with meconium-stained amniotic fluid develop MAS.[33] MAS has been reported to have mortality as high as 26%.[34,35]

Meconium-stained amniotic fluid is rare among infants younger than 37 weeks of gestational age. The clinical syndrome develops in 2 of every 1000 infants. Of infants with inhaled meconium, 95% clear their lungs spontaneously.[36] Amniotic fluid infusion into the uterus before the delivery of infants with meconium-stained fluid has been shown to improve neonatal outcomes.[37]

For many years, the aspirated meconium itself was considered the primary cause of MAS. More recent evidence suggests that the real causative agent is fetal asphyxia that precedes aspiration. Fetal asphyxia causes pulmonary vasospasm and hyperreactivity of the vasculature, which lead to persistent pulmonary hypertension.[38,39]

MAS involves three primary problems: pulmonary obstruction, lung tissue damage, and pulmonary hypertension.[38] Obstruction occurs because of plugging of the airways with particulate meconium. This obstruction often is of the ball-valve type, which allows gas entry but prevents gas exit. Ball-valve obstruction causes air trapping and can lead to volutrauma (Fig. 35.3). The lung tissue injury caused by MAS is chemical pneumonitis. Persistent pulmonary hypertension with intracardiac and extracardiac right-to-left shunting frequently complicates MAS.[38]

Clinical manifestations. Before birth, thick meconium, fetal tachycardia, and absent fetal cardiac accelerations during labor are evidence that the fetus is at high risk for MAS. After delivery, if the infant has a low umbilical artery pH, an Apgar score less than 5, and meconium aspirated from the trachea, intensive care and close observation for MAS are warranted. Infants with MAS typically have gasping respirations, tachypnea, grunting, and retractions. The chest x-ray usually shows irregular pulmonary densities, which represent areas of atelectasis, and hyperlucent areas, which represent hyperinflation due to air trapping (Fig. 35.4). Arterial blood gases (ABGs) typically show hypoxemia with mixed respiratory and metabolic acidosis. In the most severe cases, there is right-to-left shunting and persistent pulmonary hypertension.[32]

Treatment. It is no longer recommended that vigorous infants with meconium-stained fluid be intubated and suctioned.[40] Traditionally, an ETT has been inserted immediately in severely respiratory-compromised (nonvigorous) infants with thick meconium, and suction applied directly to the ETT.[41] The ETT is removed and inspected for meconium. If meconium is present, the procedure is repeated with a new ETT until no further

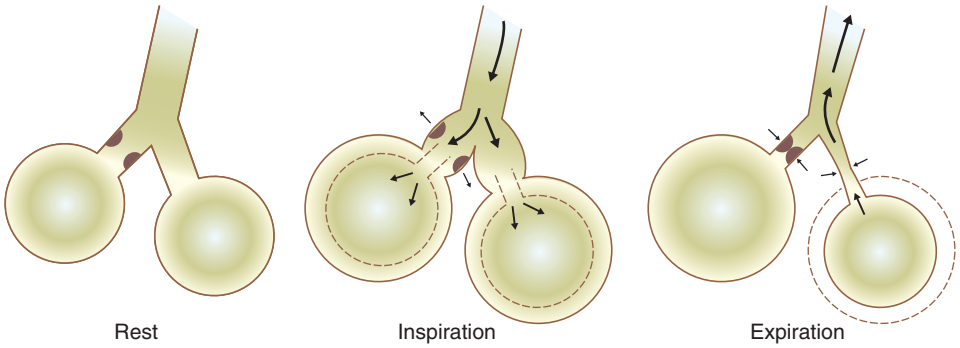

Fig. 35.3 Ball-Valve Effect. At rest, the airway lumen is partially obstructed. With inspiration, negative intrathoracic pressure opens the airway and relieves obstruction. Gas enters and expands the alveoli. With expiration, intrathoracic pressure changes to positive force, which narrows the airway and causes total occlusion. Gas cannot be expelled and is trapped within the alveoli. (Modified from Koff PB, Eitzman DV, Neu J: *Neonatal and pediatric care*, ed 2, St Louis, 1993, Mosby.)

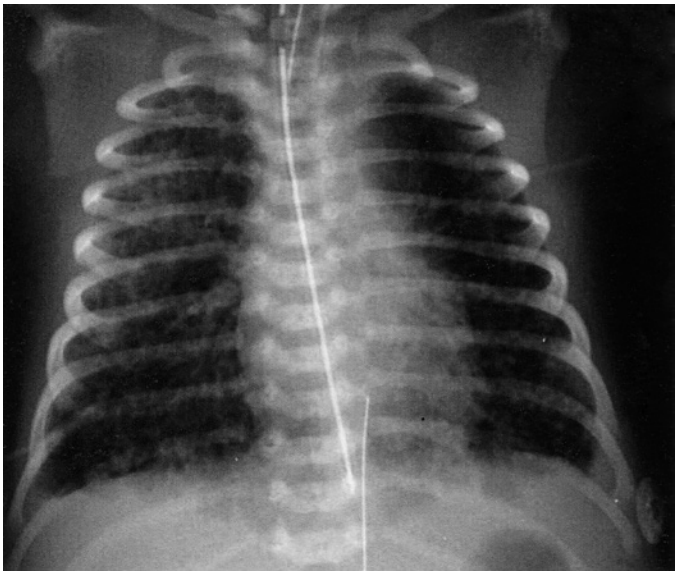

Fig. 35.4 Chest X-Ray of a Patient With Meconium Aspiration Syndrome. Anteroposterior radiograph shows diffuse patchy areas of atelectasis and emphysema.

meconium is aspirated or until two to four aspirations have been performed. The ETT should be left in place, and mechanical ventilation should be started. In 2011, that practice remained unchanged. However, it was suggested that if attempted intubation is prolonged and unsuccessful, bag-mask ventilation should be considered, particularly if there is persistent bradycardia.[41] Most recently the practice of routine endotracheal suctioning for infants with meconium aspiration has changed. Rather, the use of positive pressure ventilation is preferred to minimize any delay in initiating ventilation.[42] However, one recent study showed that this practice change has been associated with unfavorable clinical outcomes compared with the prior practice of electively intubating and suctioning depressed infants.[43] There is evidence that tracheal lavage with dilute surfactant improves the clinical course and outcome of infants with MAS.[44]

If the infant's condition worsens as evidenced by nasal flaring, substernal retractions, increased respiratory rate, and/or cyanosis, the use of NCPAP, HFNC, or mechanical ventilation may be indicated.[45] CPAP is indicated if the primary problem is hypoxemia. By distending the small airways, CPAP can sometimes overcome the ball-valve obstruction and improve both oxygenation and ventilation. If respiratory acidosis is severe or clinical assessment indicates excessive work in breathing, mechanical ventilation should be started. Inhaled nitric oxide (NO) is an extremely effective option in infants with MAS and persistent fetal circulation both with noninvasive and invasive ventilation.[46,47] Fig. 35.3 shows the ball-valve effect.[47] At rest, the airway lumen is partially obstructed. With inspiration, negative intrathoracic pressure opens the airway and relieves the obstruction. Gas enters and expands the alveoli. With expiration, intrathoracic pressure changes to a positive force, which narrows the airway and causes total occlusion. Gas cannot be expelled and is trapped within the alveoli. It is difficult to provide ventilation to infants with severe MAS. These infants often retain CO_2 and need increased ventilatory support. Because of high airway resistance, the lungs have a long time constant. High ventilator rates and pressures increase the risk for air trapping and volutrauma.

Evidence suggests that both HFV and synchronous intermittent mechanical ventilation decrease the risk for air leak.[48] Various[49] studies have shown improvement in MAS with the use of HFV and surfactant.[50] NO has become a major adjunct in managing persistent pulmonary hypertension.[51] Corticosteroids have not yet been shown to improve outcomes for infants with MAS.[52,53] High mean airway pressures may worsen pulmonary hypertension and aggravate right-to-left cardiac shunting.

Bronchopulmonary Dysplasia

Background. Preterm infants (i.e., 1000 g or less and/or 10 weeks premature) may develop a common chronic pulmonary condition called **bronchopulmonary dysplasia** (BPD). BPD is a complex disease that is characterized by lung injury/inflammation from oxygen and/or positive pressure. BPD may cause altered lung development, pulmonary emphysema, and pulmonary hypertension.[54,55] Historically, BPD has been commonly defined by the requirement for supplemental oxygen at 28 days in infants born at below 32 weeks gestation.[56] Furthermore, BPD is divided into three severity grades (mild, moderate, or severe), based on respiratory support needs at 36 weeks of postmenstrual age.

MINI CLINI

Meconium Aspiration Syndrome

Problem

The RT is called to the delivery room to attend the delivery of a term infant with meconium-stained amniotic fluid. What should the RT have available for the resuscitation of this infant?

Discussion

The RT should have the standard resuscitation equipment available. Current recommendations for resuscitating a newborn with meconium staining do not include immediate intubation and tracheal suctioning for a vigorous infant. If the infant is depressed and not breathing, the infant should be resuscitated similar to any other depressed and apneic infant, which includes intubation. However, there is no consensus on whether the depressed infant would benefit from intubation and tracheal suctioning or not.

Most babies who have BPD get better in time, but they may need chronic respiratory support for months or even years. They may continue to have lung problems throughout childhood and even into adulthood.

Pathophysiology. The development of BPD is complex and involves many pathways. The initiating factors are related to ventilator-induced ling injury: *atelectrauma* (due to lung collapse) and *volutrauma* (due to large tidal volume, V_T). Factors such as hyperoxia and hypoxia, mechanical forces, pulmonary growth arrest, inflammation, nutrition, and genetics contribute to the abnormal development of the lung and lead to BPD.

Atelectrauma[54] is a term coined to describe the lung injury caused by repetitive opening and closure of unstable or collapsed lung units. Atelectrauma results from using inadequate PEEP and/or tidal volumes, which leads to ongoing derecruitment (e.g., areas of alveolar collapse) and inflammation in the lung. *Volutrauma* is the term used to describe local overinflation (and stretch) of airways and alveoli from excessive tidal volumes and/or PEEP. Similar to atelectrauma, volutrauma leads to damage to airways, pulmonary capillary endothelium, alveolar and airway epithelium, and basement membranes. The combination of atelectrauma and volutrauma synergistically increases lung injury and places infants at risk for developing BPD.[57,58]

Both atelectrauma and volutrauma cause a need for increased supplemental O_2 concentrations. This use of supplemental O_2 leads to overproduction of superoxide, hydrogen peroxide, and perhydroxyl radicals. Preterm infants are particularly susceptible to O_2 radicals because the antioxidant systems develop in the last trimester of pregnancy. Prolonged hyperoxia begins a sequence of lung injury that leads to inflammation, diffuse alveolar damage, pulmonary dysfunction, and death.

Chronic injury and inflammation from ventilator and oxygen-induced lung injury has been shown to delay or "arrest" pulmonary growth and development.[59,60] A "new" BPD is being described that shows decreased alveolarization rather than the prominent airway damage of the "old" BPD.[61] This change in the pathologic characteristics of BPD is thought to be related to improvements in ventilator management, the use of surfactant, judicious use of oxygen, and processes that interrupt alveolar development (e.g., postnatal steroid therapy).[62]

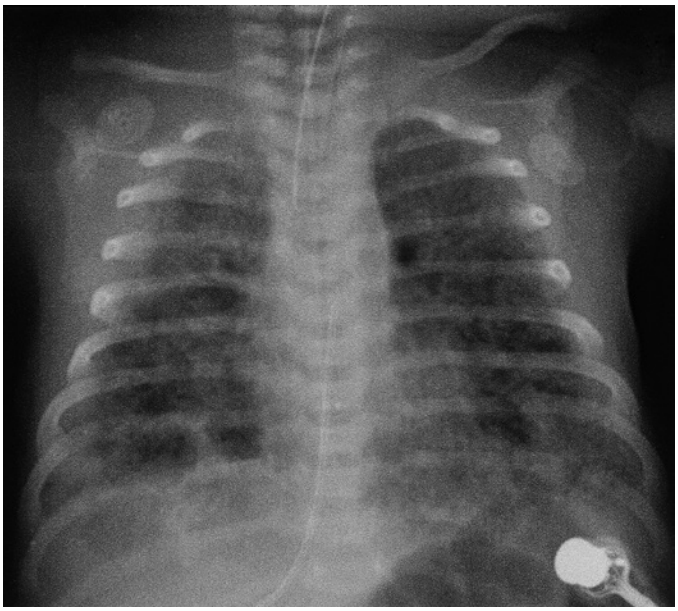

Fig. 35.5 Chest X-Ray of a Patient With Bronchopulmonary Disease. The anteroposterior chest x-ray shows areas of scarring, atelectasis, emphysema, and cysts. This film is consistent with severe bronchopulmonary disease.

Clinical manifestations. BPD has various clinical manifestations. Some infants may start with little or no O_2 requirement and little or no mechanical ventilation requirement. Progressive respiratory distress develops at approximately 2 to 3 weeks of life, and then the infant may need O_2 and/or mechanical ventilation. Other immature infants may begin with pneumonia or sepsis and need very high levels of O_2 and mechanical ventilation. In either of these scenarios, progressive vascular leakage and areas of atelectasis and emphysema develop in the lungs, and progressive pulmonary damage occurs. The chest x-ray in severe disease shows areas of atelectasis, emphysema, and fibrosis diffusely intermixed throughout the lung (Fig. 35.5). ABG measurements reveal varying degrees of hypoxemia and hypercapnia due to airway obstruction, air trapping, pulmonary fibrosis, and atelectasis. There is a marked increase in airway resistance with an overall decrease in lung compliance. Many infants with BPD may develop floppy upper airways (tracheobronchomalacia) due to prolonged ventilation of stiff lungs through relatively compliant airways.[63] This is also a major reason why infants with BPD may require chronic tracheostomy, mechanical ventilation, and longer hospital stays.[64] Infants with BPD who exhibit distress may benefit from high CPAP or PEEP levels (8 to 12 cm H_2O) to prevent airway collapse at end-exhalation.[65] Bronchodilator therapy should be used with caution, as it may relax smooth muscle and cause the airway to become floppier.[66] Approximately 10% to 20% of infants with severe BPD will have pulmonary hypertension from vascular anomalies, chronic ventilation, and poor gas exchange.[67] These infants are at greater risk than other BPD infants for tracheostomy, chronic ventilation, and mortality.

Treatment. The best management of BPD is prevention. Prevention of atelectrauma and volutrauma begins in the delivery room. Establishment of an optimal FRC without overstretching the lung requires careful attention to detail in providing manual ventilation with optimizing PEEP and avoiding large V_T.

TABLE 35.2 Evaluation of an Infant With Apnea

Possible Cause	Associated Signs	Investigation
Infection	Lethargy, respiratory distress, temperature instability	Complete blood count, sepsis evaluation
Metabolic disorder	Poor feeding, lethargy, jitteriness	Glucose, calcium, electrolyte levels
Impaired oxygenation	Respiratory distress, tachypnea, cyanosis	O_2 monitoring, arterial blood gases, chest x-ray
Maternal drugs	Maternal history, hypotonia, central nervous system depression	Magnesium level, urine drug screen
Intracranial lesion	Abnormal neurologic findings, seizures	Cranial ultrasonography
Environmental	Lethargy	Monitor temperature (infant and environment)
Gastroesophageal reflux	Feeding difficulty	Specific observation, barium swallow x-ray examination

From Stark AR: Disorders of respiratory control in infants, *Respir Care* 36:673, 1991.

Treatment of infants with BPD involves steps for rapidly weaning from mechanical ventilation to minimize additional lung damage or using CPAP over invasive ventilation whenever possible. Infants with severe disease may be dependent on supplemental O_2 or mechanical ventilation for months or years, and have symptoms of airway obstruction. Therapy usually is supportive throughout the course of the disease. Supplemental O_2 can help decrease pulmonary hypertension. Mechanical ventilation strategies to reduce hyperinflation may require larger tidal volumes (8 to 10 mL/kg), higher PIP, slower rates (20 to 25 breaths/min), and longer inspiratory times and PEEP than what is used in infants without BPD.[62]

Multiple treatments have been suggested for infants with BPD.[62] Diuretics are given as needed to decrease pulmonary edema; antibiotics are given to manage existing pulmonary infection. Bronchodilator therapy may help decrease airway resistance but should be used cautiously in patients with floppy airways. Steroid therapy with dexamethasone can produce substantial short-term improvement in lung function, often allowing rapid weaning from ventilatory support. However, steroid therapy has little effect on long-term outcome such as mortality and duration of O_2 therapy.[68-70] Steroid therapy also has been implicated in decreased alveolarization and increased developmental delay. Although steroids are still given in clinical practice, they should be used cautiously. In BPD patients with severe pulmonary hypertension, inhaled NO (INO) may be useful, but this still remains controversial.[46]

TABLE 35.3 Treatment Strategies for Infants With Apnea

Treatment	Rationale
Manage underlying cause if identified	Removes precipitating factor
Tactile stimulation	Increases respiratory drive by sensory stimulation
CPAP	Reduces mixed and obstructive apnea by splinting the upper airway
Theophylline or caffeine	Increases respiratory center output and CO_2 response, enhances diaphragm strength, adenosine antagonist
Doxapram	Stimulates respiratory center and peripheral chemoreceptors
Transfusion	Decreases hypoxic depression by increasing O_2-carrying capacity
Mechanical ventilation	Provides support when respiratory effort is inadequate

CPAP, Continuous positive airway pressure.
From Stark AR: Disorders of respiratory control in infants, *Respir Care* 36:673, 1991.

Control of Breathing

Apnea of Prematurity

Background. **Apnea of prematurity** is a common, controllable disorder among premature infants, which usually resolves over time.[71] Premature infants frequently have periodic respiration, which comprises sequential short apneic episodes of 5 to 10 seconds, followed by 10 to 15 seconds of rapid respiration. Apneic spells are abnormal if (1) they last longer than 15 seconds, or (2) they are associated with cyanosis, pallor, hypotonia, or bradycardia.

If no effort to breathe occurs during a spell, the apnea is called *central* apnea. If breathing efforts occur, but obstruction prevents airflow, the apnea is termed *obstructive.* Mixed apnea is a combination of the central and obstructive types that starts as obstructive apnea and then develops into central apnea.[72-74]

Cause. Premature infants have immature control of respiratory drive in response to O_2 and carbon dioxide (CO_2).[75] In mature animals, an increase in alveolar $PaCO_2$ elicits an increase in V_T and respiratory rate. A decrease in FiO_2 below room air also triggers an increase in V_T. Conversely, in premature animals, an increase in $PaCO_2$ temporarily increases V_T but does not increase respiratory rate. A decrease in FiO_2 below room air decreases V_T and respiratory rate. This effect can lead to apnea in a premature infant. In addition to prematurity, several other factors can cause apnea in infants. Table 35.2 summarizes the potential causes, associated signs, and diagnostic indicators.

Treatment. Infants with apnea need continuous monitoring of heart and respiratory rates. Continuous noninvasive monitoring of oxygenation by transcutaneous electrode or pulse oximetry is recommended. Most apneic episodes can be quickly ended with gentle mechanical stimulation, such as picking the infant up, flicking the sole of the foot, or rubbing the skin.[74,76] If the cause of apnea is not prematurity, treatment must be directed at resolving the underlying condition. Table 35.3 outlines current treatment strategies for infants with apnea.[77] Apnea due to prematurity responds well to methylxanthines, especially theophylline and[78] caffeine.[79,80] These agents stimulate the central nervous system and increase the infant's responsiveness to CO_2. For infants with apnea that does not respond to treatment with theophylline, doxapram may be used, but its use remains controversial, and doxapram may cause multiple toxicities.[81]

The "Back to Sleep" program initiated by the American Academy of Pediatrics has significantly decreased the incidence of sudden infant death syndrome (SIDS) from apnea.[82] It is thought that when a newborn, which has a relatively heavy head and weak neck muscles, manages to position its face into a soft surface (e.g., mattress, pillow, bunting, etc.), it will develop increased CO_2 retention and become apneic. Unlike older infants, newborns will not have a response to awaken and move; they then become apneic, then bradycardic, and then have cardiopulmonary arrest.

CPAP also can be used to manage infant apnea.[83] Although the mechanism of action is not known, CPAP probably reduces airway obstruction, increases FRC, and improves PaO_2 and $PaCO_2$. CPAP may stimulate vagal receptors in the lung, increasing the output of the brainstem respiratory centers. Severe or recurrent apnea that is unresponsive to these interventions may necessitate mechanical ventilatory support.

As the respiratory control mechanisms mature, apnea of prematurity normally resolves without intervention. Apneic spells begin to disappear by weeks 37 to 44 of postmenstrual age with no apparent long-term effects. Infants who have apnea of prematurity are not at higher risk for **sudden infant death syndrome** (SIDS) than other infants.

Sudden Infant Death Syndrome

Historically, SIDS has been a leading cause of death (40%) among infants younger than 1 year in the United States. Approximately 2500 infants die of SIDS each year in the United States.[84,85] The incidence of SIDS has decreased more than 50% in the past 20 years, largely as a result of new guidelines that place babies supine and not in a prone position to sleep.[86]

A presumptive diagnosis is based on the conditions of death in which a previously healthy infant dies unexpectedly, usually during sleep. Autopsy shows that many infants who die of SIDS have evidence of repeated episodes of hypoxemia, ischemia, and airway obstruction. Factors associated with increased frequency of SIDS are presented in Box 35.1.

Cause

The cause of SIDS is unknown. Apnea of prematurity is not a predisposing factor, and there is no evidence that immaturity of the respiratory centers is a cause. Although infants in families in which two or more SIDS deaths have occurred are at slightly higher risk, there is no evidence of a genetic link. The best knowledge of SIDS comes from population or epidemiologic studies and is summarized in Box 35.2. Risk factors for SIDS include preterm delivery, African American race, maternal age <20, and receipt of poor prenatal care. Infants 1 to 3 months old are most susceptible, and death is most likely to occur at night during the winter. The risk for SIDS also is high among infants who previously experienced an apparent life-threatening event. Such an event occurs when an infant becomes apneic, cyanotic, or limp enough to frighten the parent or caregiver. The strongest evidence supports a direct relationship between nonsupine sleeping and SIDS.[87] It is difficult to differentiate death from SIDS and death from intentional suffocation. The possibility of intentional suffocation must be investigated but with great sensitivity, especially in infants who sleep with their parent(s).

BOX 35.1 Factors Associated With Increased Frequency of Sudden Infant Death Syndrome

Maternal Characteristics
- Age <20 years
- Lower socioeconomic status
- African American, Native American, or Alaskan Native
- Previous fetal loss
- Cigarette smoking
- Narcotic abuse
- Illness during pregnancy
- Inadequate prenatal care

Infant Characteristics at Birth
- Male gender
- Premature birth
- Small for gestational age
- Low Apgar score
- Resuscitation with O_2 and ventilation at birth
- Second or third in birth order or of a multiple birth
- Sibling death from SIDS

SIDS, Sudden infant death syndrome.
From Koff PB, Eitzman DV, Neu J: *Neonatal and pediatric respiratory care*, ed 2, St Louis, 1993, Mosby.

BOX 35.2 Infant Characteristics Near the Time of Death From Sudden Infant Death Syndrome
- Age younger than 6 months (peak between 1 month and 3 months)
- Winter season
- Asleep at night
- Mild illness in week before death
- History of apparent life-threatening event
- Prone sleep position
- Mother smokes cigarettes

Prevention

Prevention of SIDS is key. Successful prevention requires that infants at high risk be identified through reviewing risk factors and monitoring or event recording. After identifying an infant at risk, the family is trained in apnea monitoring and cardiopulmonary resuscitation. The American Academy of Pediatrics (AAP) recommends placing infants in either the supine or the side-lying position for the first 6 months of life and reducing soft objects in the infant's sleeping environment.[88,89] To define the need and appropriate approach for home monitoring of infants, the AAP has developed a policy statement on infantile apnea and home monitoring (Box 35.3).

Apnea monitoring devices can allow infants who are otherwise ready for discharge but still having occasional episodes of apnea to go home (see Chapter 57).[90] However, socioeconomic factors, the home environment, and parental/family support issues must be addressed prior to discharge. A home apnea

BOX 35.3 American Academy of Pediatrics Recommendations on Home Apnea Monitoring

1. Home cardiorespiratory monitoring should not be prescribed to prevent SIDS.
2. Home cardiorespiratory monitoring may be warranted for premature infants who are at high risk for recurrent episodes of apnea, bradycardia, and hypoxemia after hospital discharge. The use of home cardiorespiratory monitoring in these infants should be limited to approximately 43 weeks postmenstrual age or after the cessation of extreme episodes, whichever comes last.
3. Home cardiorespiratory monitoring may be warranted for infants who are technology-dependent (tracheostomy, CPAP), have unstable airways, have rare medical conditions affecting regulation of breathing, or have symptomatic chronic lung disease.
4. If home cardiorespiratory monitoring is prescribed, the monitor should be equipped with an event recorder.
5. Parents should be advised that home cardiorespiratory monitoring has not been proved to prevent sudden unexpected deaths in infants.
6. Pediatricians should continue to promote proved practices that decrease the risk for SIDS, including supine sleep position, safe sleeping environments, and elimination of prenatal and postnatal exposure to tobacco smoke.

CPAP, Continuous positive airway pressure; *SIDS,* sudden infant death syndrome.
From Committee on Fetus and Newborn: American Academy of Pediatrics: Apnea, sudden infant death syndrome, and home monitoring, *Pediatrics* 111(4 Pt 1):914–917, 2003.

monitoring program must include proper training for caregivers, emergency procedures, and care of the equipment. Home monitors lack the sophistication of ICU monitors and may very frequently false alarm.[90] While there is regrettably no evidence that apnea monitoring prevents SIDS, such monitoring may well serve as an effective precaution for those babies prone to apnea of prematurity.

Pulmonary Vascular Disease

Persistent Pulmonary Hypertension of the Newborn

Background. **Persistent pulmonary hypertension of the newborn** (PPHN) is a complex syndrome with many causes.[91] The common denominator in PPHN is a return to fetal circulatory pathways, usually because of elevated PVR. This condition results in further right-to-left shunting, severe hypoxemia, and metabolic and respiratory acidosis.

Pathophysiology. In the uterus, the fetus does not use the lungs as a gas-exchange organ. PVR is high, and systemic vascular resistance (SVR) is low. This condition produces a PVR/SVR ratio greater than 1. A fetus has two anatomic shunts that are not present in older infants, children, or adults: the foramen ovale and ductus arteriosus. With a PVR/SVR ratio greater than 1 and the anatomic shunts, blood flow bypasses the lung either at the atrial level (foramen ovale) or at the pulmonary artery level (ductus arteriosus). Intrauterine total pulmonary blood flow and systemic arterial O_2 saturation (SaO_2) are low.

In the transition to extrauterine life, PVR decreases owing to gas filling the lungs and increasing PaO_2 in the pulmonary venous circulation. SVR increases with the removal of the placenta from the circulation, and this makes the PVR/SVR ratio less than 1. If PVR does not decrease to allow the PVR/SVR ratio to become less than 1, the infant has PPHN. The major cause of this condition is parenchymal lung disease (MAS, RDS) or lung hypoplasia (CDH), but PPHN may also be idiopathic.[92]

The three fundamental types of PPHN relate to vascular spasm, increased muscle wall thickness, and decreased cross-sectional area of pulmonary vessels.[93] Vascular spasm is an acute event that can be triggered by many different conditions, including hypoxemia, hypoglycemia, hypotension, and pain. Increased muscle wall thickness is a chronic condition that develops in utero in response to several different causative factors, including chronic fetal hypoxemia, increased pulmonary blood flow (e.g., intrauterine closure of the ductus arteriosus), and pulmonary venous obstruction (e.g., total anomalous pulmonary venous return with obstructed below-diaphragm return). Decreased cross-sectional area is related to hypoplasia of the lungs and occurs with congenital diaphragmatic hernia, Potter sequence (absent kidneys), and oligohydramnios syndromes (decreased amniotic fluid).

Clinical manifestations. PPHN should be suspected when an infant has rapidly changing O_2 saturation (SaO_2) without changes in FiO_2 or has hypoxemia out of proportion to the lung disease detected with chest radiography or $PaCO_2$ measurement. In infants with a significant shunt through the ductus arteriosus, there usually is a substantial gradient (>5%) between preductal and postductal O_2 saturation. Continuous pulse oximetry screening is valuable in the ongoing treatment of the newborn with PPHN, allowing the caregiver to assess the patient's oxygen saturation over time and the adequacy of oxygen delivery at the tissue level.

Oximeter probes can be placed on preductal (right hand) and postductal (feet) sites to assess for right-to-left shunting at the level of the foramen ovale and ductus arteriosus. A difference greater than 10% between preductal and postductal oxygen saturations indicates right-to-left ductal shunting. Sites on the left hand should be avoided, because it may be preductal or postductal. Significant right-to-left shunting at the level of the foramen ovale may result in lower-than-expected preductal oxygen saturations (right hand), although a significant differential should still be evident when compared with postductal oxygen saturations.

Treatment. Initial therapy for PPHN is removal of the underlying cause, such as administration of O_2 for hypoxemia, surfactant for RDS, glucose for hypoglycemia, and inotropic agents for low cardiac output and systemic hypotension. If correction of the underlying problem does not correct hypoxemia, the infant needs intubation and mechanical ventilation. Because pain and anxiety may contribute to PPHN, the infant may need sedation and, frequently, paralysis. If these measures do not improve oxygenation, the next step is HFV. This mode of ventilation allows a higher FRC without a large V_T. INO, which is a potent pulmonary vasodilator, is considered the next intervention (see Chapter 42). In fact, PPHN is the only indication for which the FDA has formally approved the use of INO therapy. INO has been shown to reduce the combined outcome of death and need for ECMO in infants with PPHN.[51] An early INO strategy (at lower oxygenation indices) is preferred over late/rescue therapy.[94] In addition, several experimental forms of aerosolized inhaled pulmonary vasodilators are being used as an alternative to INO therapy. If

MINI CLINI

Problem

The RT is called to the bedside of a term infant who has mild respiratory distress, is receiving nasal cannula O_2 of 1 L/min, has an FIO_2 of 1.0, and has a SpO_2 of 75%. Shortly after birth, the infant's chest x-ray showed a normal-size heart and clear, slightly hyperlucent lung fields with no infiltrates. The bedside nurse describes that she has just finished taking the infant's vital signs and changing its diaper. Before her touching the infant, the infant's saturation was 96%. What is this infant's problem? What should the RT do?

Discussion

This infant is exhibiting signs of persistent pulmonary hypertension. Placing a preductal (right hand) and postductal (left hand) oxygen saturation probe and evaluating the differences in SpO2 can help determine whether ductal shunts exist. The immediate interventions potentially could include increasing the O_2 flow, lowering the lights in the room, decreasing the activity and ambient noise in the room, swaddling the infant, and minimizing physical contact with the infant. All of these interventions are aimed at getting the infant into a quiet, calm environment, allowing the infant to relax, and reducing shunting.

In addition, the RT and nurse should contact the physician who is caring for this infant and alert him or her to the possibility of persistent pulmonary hypertension. Potential additional therapies could include sedation, intubation, mechanical ventilation, and INO.

all of these modalities fail to improve oxygenation, the infant may be a candidate for extracorporeal membrane oxygenation (ECMO).[95] The use of IV sildenafil is increasingly being promoted in infants with PPHN.[96] In addition, several other experimental forms of aerosolized pulmonary vasodilators are being used as an alternative to INO therapy.[97-99] Even with all of these treatments, PPHN remains a complex disease with high morbidity and mortality.

Congenital Abnormalities Affecting Respiration

Congenital abnormalities that affect respiration can be divided into several groups: airway diseases, lung malformations, chest wall abnormalities, abdominal wall abnormalities, and diseases of neuromuscular control.

Airway Diseases

Airway abnormalities have three fundamental mechanisms: internal obstruction, external obstruction, and disruption. Internal obstruction includes common problems, such as laryngomalacia, that cause obstructive apnea. Less common problems caused by internal obstruction are tracheomalacia, laryngeal webs, tracheal stenosis, and hemangiomas. All of these diseases usually manifest as a combination of inspiratory stridor, gas trapping, expiratory wheezing, and accessory respiratory muscle activity.

External compression can be caused by hemangiomas, neck or thoracic masses, and vascular rings. These lesions are far less common than diseases caused by internal obstruction, but they are not rare. The symptoms are similar to those of internal obstruction. Neck masses usually are obvious at visual inspection. Intrathoracic masses and vascular rings must be suspected on the basis of the clinical manifestations: noise during the respiratory cycle that worsens with exertion. The infant may have difficulty with swallowing.

Airway disruptions usually are related to tracheoesophageal fistula (TEF) in a newborn. This malformation usually is associated with esophageal atresia. There are five types of TEF: esophageal atresia with a proximal fistula, esophageal atresia with a distal fistula, esophageal atresia with both a proximal and a distal fistula, esophageal atresia without either fistula, and an intact esophagus with a so-called *H fistula*.[100] The most common of these malformations is esophageal atresia with a distal fistula, which accounts for 85% to 90% of all TEFs. The least common is the H fistula. All of these malformations manifest as difficulty swallowing, bubbling and frothing at the mouth, and choking, particularly during attempts at feeding. These anomalies can occur in isolation or as part of an association of defects. The most common is the VATER or VACTERL association of vertebral anomalies, imperforate anus, TEF, and renal or radial anomalies. In VACTERL, cardiac anomalies are added, and renal and limb anomalies replace renal or radial anomalies in the acronym. These associated anomalies must be sought in any infant with TEF. TEF is managed with surgical ligation of the fistula (tying it closed) and reconnection of the interrupted esophagus.[101] Most infants with TEF have a good outcome; however, some infants have severe malformations that can cause chronic problems. Infants with TEF usually need only supportive respiratory care. They usually do not have lung disease. However, some infants need HFV because the air leak through the fistula can become larger than the airflow to the alveoli.

Lung Malformations

There is a broad spectrum of rare lung malformations that occur in the newborn period. These lesions are thought to be part of a continual spectrum of diseases that originate as defects in lung segmentation. The most common is congenital pulmonary adenomatoid malformation (CPAM); this was previously known as *cystic adenomatoid malformation of the lung*. CPAM is classified into five types on the basis of the type and size of the cyst.[102,103] The disease may affect entire lobes of the lung. The affected parts of the lung do not participate in exchange gas and can become infected. The usual treatment is surgical removal of the affected lobe. There is also the potential for malignant transformation.

Some affected fetuses can develop "hydrops." Hydrops fetalis is a serious fetal condition that is characterized by an abnormal accumulation of fluid in two or more fetal compartments. This can include ascites, pleural effusions, pericardial effusions, or skin edema while in utero. Most infants with CPAM have symptoms of lung volume loss.[104] As the mass expands, the normal surrounding lung is compressed. Some CPAMs resolve spontaneously. A few infants have severe cardiorespiratory compromise and need respiratory support and emergency surgery. However, better results are seen when surgery can be performed electively.

Other, less common lung malformations include pulmonary sequestration and lobar emphysema. Both of these diseases involve maldevelopment of lobes of the lung. Sequestration is a primitive, frequently cystic lung lobe that is not in communication with the tracheobronchial tree and frequently receives no pulmonary vascular blood flow.

Lobar emphysema is an airway malformation that causes gas trapping in a lobe of the lung. These malformations manifest

as space-occupying masses within the thorax. They usually are treated by surgical removal.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia is a severe disease that usually manifests in newborns as severe respiratory distress.[105] The pathophysiologic mechanism is a complex combination of lung hypoplasia, including decreased alveolar count and decreased pulmonary vasculature, pulmonary hypertension, and unusual anatomy of the inferior vena cava.[106,107] This disorder varies between asymptomatic (rare) and severe life-threatening disease (frequent). There are two types of hernia: Bochdalek hernia (lateral and posterior defect, usually on the left) and Morgagni hernia (medial and anterior, which may be on either side). Hernias that occur in the right hemidiaphragm may be less severe because the liver can block the defect and decrease the volume of abdominal contents that can enter the thorax.[107]

Some authors speculate that the diaphragmatic hernia complex is a developmental field defect and not just a simple cascade of events related to a hole in the diaphragm. This theory is partly based on long-term outcomes of survivors with diaphragmatic hernias. These survivors frequently have severe scoliosis in the direction of the diaphragm defect. They also frequently have severe esophageal reflux disease.

Most cases of congenital diaphragmatic hernia can be diagnosed in utero with ultrasonography. Physical examination may yield the following findings: scaphoid abdomen (because the abdominal contents are in the thorax), decreased breath sounds, displaced heart sounds (because the heart is pushed away from the hernia), and severe cyanosis (from lung hypoplasia and pulmonary hypertension). The diagnosis is established with chest radiography.

Initial treatment of congenital diaphragmatic hernia is insertion of an ETT, paralysis, and mechanical ventilation. A large sump tube is placed in the stomach and connected to continuous suction. These therapies allow adequate ventilation and oxygenation and prevent gas insufflation of the intestine. Most centers delay surgical repair for several days to allow the natural decrease in PVR. On day 7 to 10 of life, a surgeon closes the defect. This scenario occurs only for infants with easily correctable pulmonary hypertension. Infants with severe pulmonary hypertension may need HFV and ECMO. At some centers, the diaphragm is repaired while patients are on ECMO,[108] though most centers try to wean the infant from ECMO before performing the surgery.[109] While there is no clear consensus on whether the surgical repair should be done on ECMO or not, newer evidence supports weaning from ECMO before attempting surgical[110] repair of CDH. Despite all these advanced therapies, the mortality risk with this disease is high.[111] Survival[112] depends on many complex variables (e.g., liver herniation into the thorax, fetal head-to-lung ratio, initial PaO_2, and $PaCO_2$).[106,111]

Abdominal Wall Abnormalities

Because all newborns are primarily abdominal breathers, the abdominal wall is an intrinsic part of the respiratory system. Large defects in the abdominal wall can cause severe respiratory compromise. One of the most common of these defects is omphalocele.[113,114] An omphalocele is an abdominal wall defect that involves the insertion of the umbilical cord. The umbilical cord goes into the omphalocele. The bowel of an infant with an omphalocele is usually covered by a membrane that looks like the surface of the umbilical cord. Occasionally, the omphalocele membrane ruptures and exposes the bowel of the infant. Omphaloceles must be distinguished from gastroschisis. Gastroschisis is an abdominal wall defect that is completely separate from the insertion of the umbilical cord. The bowel of an infant with a gastroschisis is not covered by a membrane and is outside of the abdomen. Because the bowel has been out of the abdomen, the abdominal cavity is small. There are two methods of repairing gastroschisis. If the abdominal cavity is of sufficient size and the amount of bowel outside is small, a primary closure is done in which all of the bowel is returned to the abdominal cavity and the small defect is closed. However, if the abdominal cavity is too small or the amount of bowel is too large, the surgeon will place the bowel into a Silastic chimney (or silo). The open end is inserted into the defect and the closed end is suspended from the bed. Over the next several days, gravity and the gradual stretching of the abdominal wall will allow the bowel to come back into the abdomen.

Usually only large omphaloceles cause respiratory distress. When they are greater than 10 cm in diameter, these defects can cause severe respiratory distress and frequently require prolonged mechanical ventilation. Infants with gastroschisis usually have normal lungs. However, if they need to have a silo placed, this is like a water column (the height of bowel in the silo) applying pressure against the diaphragm. These infants will need PEEP to support FRC.

MINI CLINI

Delivery of an Infant With an Abdominal Wall Defect

Problem

The RT is called to the delivery room to assist in the delivery of a term infant with an abdominal wall defect. What should the RT consider for assisting this infant?

Discussion

There are many types of abdominal wall defects. The two most common are gastroschisis and omphalocele. These anomalies can be differentiated by whether the insertion of the umbilical cord into the abdomen is involved in the defect. In a gastroschisis, the umbilical cord inserts directly into the abdomen and is separate from the defect. In an omphalocele, the umbilical cord inserts directly into the defect. Although there is usually a membrane covering the bowel in an omphalocele, if the membrane has ruptured, the only means of distinguishing an omphalocele is by the umbilical cord insertion.

Most infants with these abdominal wall defects are term. Most do not have significant lung disease. An abdominal wall defect increases the intraabdominal pressure. It pushes the diaphragm up into the thorax, decreasing FRC. The RT should be aware that these patients will need support of their FRC. Typically, if the FRC can be supported with CPAP or PEEP, the infant will not need high rates or a high V_T to achieve adequate gas exchange.

Neuromuscular Control

Many diseases of poor neuromuscular control affect newborns,[115,116] including spinal muscular atrophy, congenital

myasthenia gravis, and myotonic dystrophy. These diseases frequently require respiratory support in the newborn and pediatric periods. The morbidity and mortality of these diseases are extremely variable. New technologies may allow noninvasive respiratory support of some patients.[117,118] Some diseases can be quite severe in the newborn period and improve with age. It is important to make an accurate diagnosis to be able to estimate prognosis and provide genetic counseling. Many of these diseases are inherited with known inheritance patterns.

Congenital Heart Disease

A full discussion of congenital heart disease is beyond the scope of this chapter. However, basic knowledge of the common defects is essential to good practice in pediatric and neonatal respiratory care. Congenital heart diseases usually are divided into two large categories: cyanotic and acyanotic heart disease.[119,120] Cyanotic heart diseases are diseases in which blood shunts from right to left, bypassing the lungs, and is deoxygenated. Acyanotic heart diseases are diseases in which blood shunts from left to right, causing congestive heart failure. Fig. 35.6 compares normal cardiac anatomy with the features of the five most common congenital defects.

Cyanotic Heart Diseases

The two most common cyanotic heart diseases are tetralogy of Fallot and transposition of the great arteries.

Tetralogy of Fallot. **Tetralogy of Fallot** is a defect that includes (1) obstruction of right ventricular outflow (pulmonary stenosis), (2) ventricular septal defect (VSD; a hole between the right and left ventricles), (3) dextroposition of the aorta, and (4) right ventricular hypertrophy. The severity of tetralogy of Fallot varies from mild disease, which is initially diagnosed in early childhood, to severe disease, which is diagnosed in the newborn period.[120,121] The mild form of the disease manifests as a heart murmur, intermittent severe cyanotic spells, a history of the infant squatting or entering a knee-chest position, or a combination of these features. The severe form of the disease manifests as a heart murmur and severe continuous cyanosis. Chest x-ray may reveal a "boot-shaped" cardiac silhouette. Most types of tetralogy of Fallot can be managed surgically. The type and timing of the surgical repair depend on the anatomy of the defects. Children with this defect are at increased risk for sudden death from arrhythmia later in life.

Transposition of the great arteries. **Transposition of the great arteries** is the heart disease that most frequently causes severe cyanosis.[119,122,123] It usually manifests as moderate to severe cyanosis immediately after birth. Partially oxygenated blood flow is dependent upon the infant's patent ductus arteriosus at birth until surgical correction can be made. A murmur may be present. Infants with this abnormality frequently need emergency atrial septostomy (cutting a hole in the wall between the two atria). This procedure historically has been performed in cardiac catheterization laboratories, but many pediatric cardiologists who perform invasive procedures have begun performing this procedure with ultrasound guidance in the neonatal intensive care unit. The condition of infants who need atrial septostomy usually stabilizes. The goal is to allow the PVR to decrease and then to perform the arterial switch operation in week 2 or 3 of life.

MINI CLINI

Newborn With Transposition of the Great Arteries

Problem

The RT is called to the delivery room to assist in the delivery of an infant to be born by repeat cesarean section without rupture of membranes. Fetal heart rate monitoring has been unremarkable. There is no evidence of meconium in the amniotic fluid. After delivery, the infant is breathing comfortably but fails to "pink up" (i.e., the infant is cyanotic). The transcutaneous O_2 saturation stabilizes in the low 70s, despite mask-bag ventilation with an FiO_2 of 1. What should the RT consider as the source of this problem?

Discussion

The most common reasons for a significantly cyanotic term infant immediately after delivery include pneumothorax, persistent pulmonary hypertension, and cyanotic heart disease. Spontaneous pneumothorax occurs occasionally. The infant should have decreased breath sounds in the affected hemithorax. These infants usually have a significant increase in WOB.

Excluding pneumothorax leaves persistent pulmonary hypertension and cyanotic congenital heart disease as the main differential diagnoses. The two most likely cyanotic congenital heart diseases to manifest with significant cyanosis immediately after birth are transposition of the great arteries (particularly with an intact ventricular septum) and tetralogy of Fallot (particularly with pulmonary atresia instead of pulmonary stenosis). An echocardiogram must be done as soon as possible to distinguish between these possibilities.

Infants with cyanotic heart diseases are cyanotic. Some of these infants have saturations in the low 80s. Some of them have saturations in the 40s to 50s. Because there is an anatomic right-to-left shunt, attempts to improve oxygenation with increased delivery of O_2 would be unsuccessful. Increased O_2 delivery would lead to problems with O_2 toxicity. Improvement in systemic oxygenation occurs only by developing a left-to-right shunt in the central circulation. Acutely, this shunt can be managed with administration of prostaglandin to reopen the ductus arteriosus. Long-term management requires intervention by cardiac catheterization or surgery.

RULE OF THUMB An infant with profound cyanosis at birth most likely has cyanotic heart disease or PPHN.

Hypertension of the Newborn

Acyanotic Heart Diseases

Some of the most common and most severe congenital heart diseases are acyanotic. VSD is probably the most common congenital heart disease. Hypoplastic left heart syndrome (HLHS) is one of the most severe congenital heart diseases.

Ventricular septal defect. Defects along the septum separating the right and left ventricles are quite common. VSD can occur alone or in combination with other anomalies. A simple VSD usually causes left-to-right shunting and congestive heart failure. This defect usually does not appear immediately after birth. It appears at 6 to 8 weeks of age, when the PVR has decreased enough that the shunt becomes large.

Historically, closure of VSDs has required surgery. In the last few years, many VSDs have been able to be closed during heart catheterization.[124-126]

Atrial septal defect. The most common type of atrial septal defect is a small, slit-like opening that persists after closure of

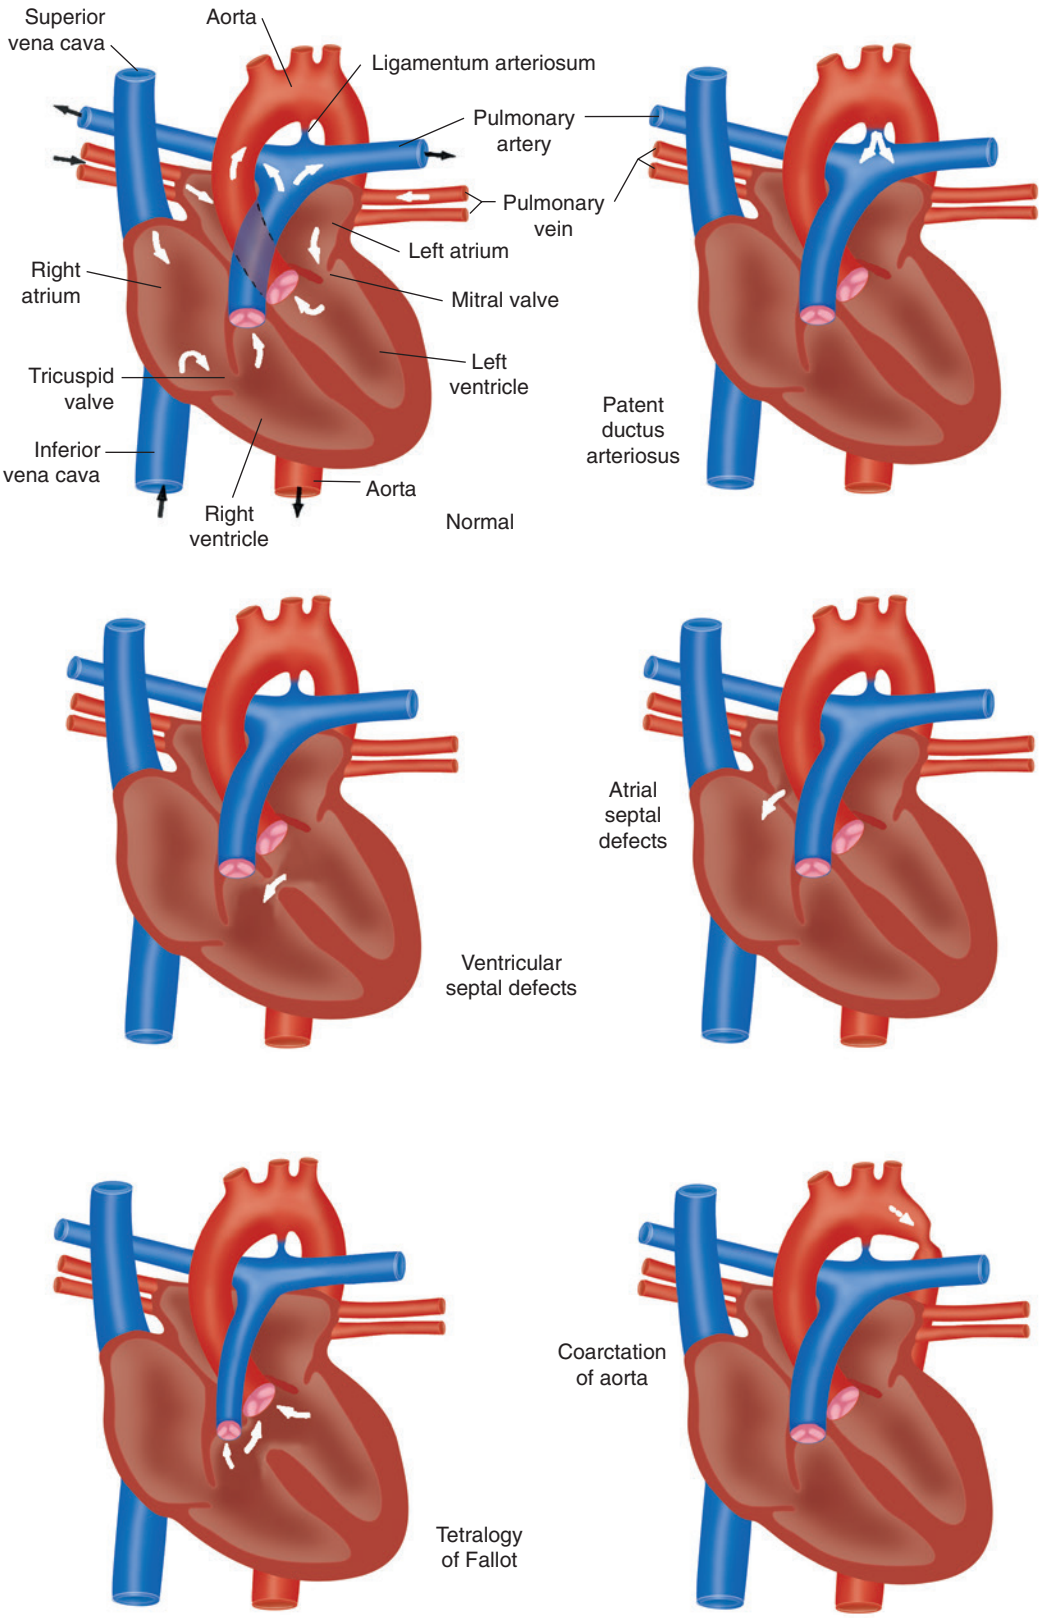

Fig. 35.6 Normal flow of blood through the heart and some congenital defects that cause abnormal flow. (Modified from Jacob S, Francone C, Lossow WJ: *Structure and function in man*, ed 5, Philadelphia, 1982, Saunders.)

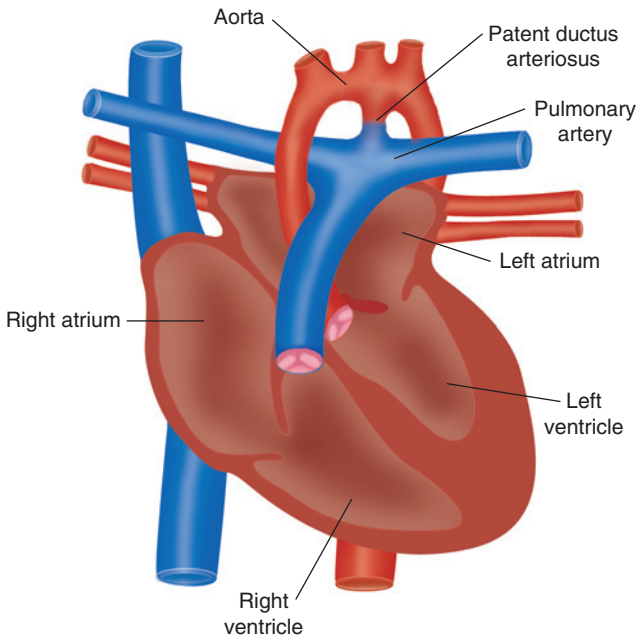

Fig. 35.7 Hypoplastic Left Heart Syndrome.

the foramen ovale.[127] An isolated atrial septal defect is of little clinical importance. As with VSDs, some ASDs can be closed during heart catheterization.[128]

Patent ductus arteriosus. In a fetus, most of the pulmonary blood flow is shunted through the ductus arteriosus to the aorta. Closure of the ductus normally occurs 5 to 7 days after birth of a term infant. Patent ductus arteriosus usually is a disease of immature, preterm infants. Factors altering pressure gradients or affecting smooth muscle contraction can cause the ductus not to close or to reopen after it has closed. Depending on the pressure gradients established, shunting through an open ductus may be either right to left (pulmonary pressure greater than aortic) or left to right (aortic pressure greater than pulmonary artery pressure). Treatment is either pharmacologic (indomethacin) or surgical (ligation). In recent years, the best timing of treatment and the treatment mechanism for PDA closure have become quite controversial, especially in premature infants (<1000 g).[129]

Left ventricular outflow obstructions. HLHS (Fig. 35.7), interrupted aortic arch, and coarctation of the aorta have in common obstruction of left ventricular outflow.[130] These conditions all manifest in the newborn period with symptoms of acute heart failure. Systemic blood flow depends on patency of the ductus arteriosus. When the ductus spontaneously closes (usually at 5 to 7 days of age), severe congestive heart failure develops. The symptoms range from moderate respiratory distress to complete cardiovascular collapse. Initial treatment is intravenous administration of prostaglandin E_1. Most infants with these defects need support with mechanical ventilation. These infants typically do not have lung disease. The pressures and rates used should be set appropriately.

There are standard surgical repairs for both interrupted aortic arch and coarctation of the aorta. Interrupted aortic arch has been classified into three types (A, B, and C) based on the site of aortic interruption. In type A interrupted left aortic arch, the arch interruption occurs distal to the origin of the left subclavian artery. In type B interrupted left aortic arch, the interruption occurs distal to the origin of the left common carotid artery. In type C interrupted left aortic arch, the interruption occurs proximal to the origin of the left common carotid artery.

Coarctation of the aorta is a narrowing of the aorta. When this occurs, the heart must pump harder to force blood through the narrowed part of the aorta.

HLHS is a birth defect that affects normal blood flow through the heart. As the baby develops during pregnancy, the left side of the heart does not form correctly. Patients with HLHS require corrective surgery or other procedures soon after birth. HLHS affects a number of structures on the left side of the heart that do not fully develop. Examples may include the *left ventricle* is underdeveloped and too small, the *mitral valve* is not formed or is very small. The *aortic valve* is not formed or is very small and the ascending portion of the *aorta* is underdeveloped or is too small.

HLHS has several accepted treatments, including a palliative surgical procedure (Norwood procedure) and heart transplantation.[131,132] The Norwood procedure usually is done within the first 2 weeks of a baby's life.[133] A "new" aorta is crafted by surgery and connects it to the right ventricle, making a tube from either the aorta or the right ventricle to the vessels supplying the lungs (pulmonary arteries). Thus the right ventricle can pump blood to both the lungs and the rest of the body.

NEONATAL RESUSCITATION

Resuscitation of the newborn is a subset of resuscitation techniques. Most infant resuscitations occur in the delivery room. Although these resuscitations can range from minimal intervention to full resuscitation, more than 90% of them can be successfully dealt with by stimulation, ensuring the presence of an airway, and providing breathing support.[40] RTs[41] are very important members of any resuscitation team. Their expertise in establishing and supporting an airway and initiating respiratory support is essential. While it is beyond the scope of this chapter to delineate the guidelines of neonatal resuscitation, the reader is referred to the neonatal resuscitation guidelines published by the American Academy of Pediatrics.

PEDIATRIC RESPIRATORY DISORDERS

Compared with the common cardiopulmonary diseases in the neonatal period, the pulmonary conditions that occur among older infants and children commonly result from airway obstruction caused by bacterial or viral infections. Other entities discussed in this section include asthma, gastroesophageal reflux disease, and cystic fibrosis.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is the regurgitation of stomach contents into the esophagus and is common in childhood. Some causes of GERD are not pathologic. There is general agreement that there are important interactions between GERD and various disorders of the respiratory system.[134,135] Respiratory

problems caused by gastroesophageal reflux include reactive airways disease, wheezing, aspiration pneumonia, laryngospasm, stridor, chronic cough, choking spells, and apnea.[136] GERD should be considered when an infant has faced a sudden life-threatening event and when an older child has unexplained chronic head and neck problems. GERD can be diagnosed with esophageal pH testing, upper gastrointestinal contrast studies, and gastric scintiscan. When GERD has been diagnosed, medical therapy can begin.[137,138] Occasional[139] cases that do not respond to medical management may require surgical intervention.

Bronchiolitis

Bronchiolitis is an acute infection of the lower respiratory tract, usually caused by respiratory syncytial virus (RSV). Nearly 1 in 10 infants younger than 2 years of age acquires a bronchiolitis infection. The outcome is generally good, although approximately 1% of infants hospitalized for bronchiolitis die of respiratory failure. Infants most prone to respiratory failure as a consequence of bronchiolitis are very young and immunodeficient and have a comorbidity, such as congenital heart disease, BPD, CF, or childhood asthma.[140,141]

Clinical Manifestations

The clinical manifestations of bronchiolitis are inflammation and obstruction of the small bronchi and bronchioles. Bronchiolitis commonly occurs soon after a viral upper respiratory tract infection. The infant may have a slight fever with an intermittent cough. After a few days, signs of respiratory distress develop, particularly dyspnea and tachypnea. Progressive inflammation and narrowing of the airways cause inspiratory and expiratory wheezing and increase airway resistance. A chest x-ray shows signs of hyperinflation with areas of consolidation. The diagnosis of RSV infection can be established by immunofluorescent assay the same day and assists in the implementation of a treatment plan.

Prophylaxis. In recent years, passive immunization for RSV has become available.[142,143] Initially, passive immunization was recommended only for preterm infants with BPD. However, passive immunization is now recommended for high-risk infants younger than 2 years of age who require medical therapy for chronic lung disease, infants born at less than 32 weeks of gestational age, and infants with congenital heart disease who have cardiovascular compromise (Box 35.4).[143]

Treatment. Treatment of a patient with bronchiolitis varies with the severity of the infection and the clinical signs and symptoms. Many patients can be treated at home with humidification and oral decongestants. Patients with more severe symptoms (apnea) and comorbidity usually are hospitalized, and treatment is directed at relieving the airway obstruction and associated hypoxemia. Hospitalized children frequently are treated with systemic hydration and O_2 via nasal cannula, high-flow nasal cannula, or nasal cannula, and assisted with airway clearance primarily by nasal and/or nasopharyngeal suction.[144,145] Antibiotics may be administered to control secondary bacterial infections. If bronchiolitis progresses to acute respiratory failure, noninvasive support or mechanical ventilation is required. Because of the obstructive nature of this disorder, high PEEP, low respiratory rates, and long expiratory times may be needed to prevent air trapping. Heliox has been used for severe airways disease requiring mechanical ventilation.[146,147] Bronchodilators and chest physiotherapy[148] have not been found to be effective in routine management in patients with bronchiolitis (Box 35.5).

BOX 35.4 American Academy of Pediatrics Recommendations for Respiratory Syncytial Virus Prophylaxis

Indications for RSV Prophylaxis

- Preterm infants without CLD or congenital heart disease
  - Preterm infants born before 29 weeks, 0 days gestation who are younger than 12 months at the start of the RSV season
  - Not recommended for the second year of life
- Preterm infants with CLD
  - Infants with CLD of prematurity defined as gestational age <32 weeks, 0 days, and requiring FiO_2 >21% oxygen for at least the first 28 days after birth
  - Second year of life recommendation only for those infants who continue requiring medical support during the 6-month period before the start of the second RSV season
- Infants with hemodynamically significant CHD
  - Acyanotic heart disease requiring medications to control congestive heart failure and will require cardiac surgical procedures in infants with moderate to severe pulmonary hypertension
  - Cyanotic heart defects in the first year of life
  - Infants after surgical procedures that involve cardiopulmonary bypass
    - These infants may need a postoperative dose.
  - Infants younger than 2 years of age undergoing cardiac transplantation
- Children with anatomic pulmonary abnormalities or neuromuscular disorder
- Immunocompromised children
  - Children younger than 24 months of age who are severely immunocompromised
- Children with Down syndrome
  - Routine use is not recommended unless they have qualifying heart disease, CLD, airway clearance issues, or prematurity
- Children with cystic fibrosis
  - Routine use not recommended unless other indications are present
  - Infants with CF and CLD or nutritional compromise in the first year of life
  - Infants with CF and severe lung disease requiring hospitalization, or abnormalities on chest radiograph/computed tomography, or weight for length less than 10%
- Alaska Native and American Indian infants

CF, Cystic fibrosis; *CHD,* congenital heart disease; *CLD,* chronic lung disease; *RSV,* respiratory syncytial virus.

Croup

Croup is a viral disorder of the upper airway that normally results in subglottic swelling and obstruction. Termed *laryngotracheobronchitis*, viral croup is usually caused by the parainfluenza virus and is the most common form of airway obstruction in children 6 months to 6 years old. RSV and influenza virus are less common causes. Bacterial superinfection with *Staphylococcus aureus,* group A *Streptococcus pyogenes,* or *Haemophilus influenzae* may worsen croup.

Clinical Manifestations

Symptoms become evident after 2 or 3 days of nasal congestion, fever, and coughing. A child typically has slow, progressive

BOX 35.5 American Academy of Pediatrics Recommendations for Diagnosis and Management of Bronchiolitis

Diagnosis

1a. Diagnosis and severity should be made on the basis of history and physical examination. Routine laboratory and radiologic studies are not needed.

1b. Assess for history of risk factors in patients younger than 12 weeks of age.
Prematurity
Underlying cardiopulmonary disease
Immunodeficiency

Treatment

2a. Bronchodilators should not be routinely used.

2b. A carefully monitored trial of α-adrenergic or β-adrenergic is an option. Inhaled bronchodilators should be continued only if there is a documented positive clinical response.

3. Corticosteroids should not be used routinely.

4. Ribavirin should not be used routinely.

5. Antibacterial medications should be used only with specific indications of the coexistence of a bacterial infection.

6a. Assess hydration and the ability to take oral fluids.

6b. Chest physiotherapy should not be used routinely.
Supplemental oxygen is indicated if oxyhemoglobin saturation (SpO_2) falls persistently below 90%.

7a. Supplemental O2 should be discontinued if SpO2 is ≥90% and the infant is feeding well and has minimal respiratory distress.

7b. As the child's clinical course improves, continuous measurement of SpO2 is not routinely needed.

7c. Infants with a known history of hemodynamically significant heart or lung disease and premature infants require close O2 monitoring as the O2 is being weaned.

Prophylaxis

8a. Palivizumab prophylaxis should be done according to the new AAP Guidelines (Box 35.4).

9a. Hand decontamination is the most important step in preventing nosocomial spread of RSV.
Hands should be decontaminated before and after direct contact with the patient, and after contact with inanimate objects in the direct vicinity of the patient.

9b. Alcohol-based rubs are preferred for hand decontamination.

9c. Educate personnel and family members on hand sanitation.

10a. Infants should not be exposed to passive smoking.

10b. Breastfeeding is recommended to decrease a child's risk for developing a lower respiratory tract disease.

11. Inquire about the use of complementary and alternative medicines.

- Infants with chronic lung disease
  - Infants born at younger than 32 weeks of gestational age
  - Infants born at 32–35 weeks to gestational age who are at high risk for severe infection and younger than 90 days of age
- If two or more of following risks are present
  - Childcare attendance
  - School-age siblings
  - Exposure to environmental air pollutants
  - Congenital abnormalities of the airways
  - Severe neuromuscular disease
- Infants with hemodynamically significant congenital heart disease (cyanotic and acyanotic)
- Following cardiopulmonary bypass

From American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis: Diagnosis and management of bronchiolitis, *Pediatrics* 118:1774–1193, 2006.

inspiratory and expiratory stridor and a barking cough. As the disease progresses, dyspnea, cyanosis, exhaustion, and agitation occur. An x-ray of the upper airway is helpful in confirming the diagnosis and ruling out epiglottitis, but is usually not needed in most cases of croup. Classic croup is seen on an anteroposterior x-ray as characteristic subglottic narrowing of the trachea, called the *steeple sign* (Fig. 35.8).

Treatment

The evaluation and treatment of a child with croup must focus on the degree of respiratory distress and associated clinical findings. If stridor is mild or occurs only on exertion and cyanosis is not present, hospitalization is generally not required and the child is treated at home. If there is stridor at rest (accompanied by harsh breath sounds, suprasternal retractions, and cyanosis with breathing of room air), hospitalization is indicated. The traditional treatment of a child with mild to moderate croup has involved cool mist therapy with or without supplemental O_2. However, there is no evidence that this practice is beneficial.[149] Corticosteroids and aerosolized racemic epinephrine have been shown to have the greatest benefit for decreasing the length and severity of respiratory symptoms associated with viral croup.[150,151] The addition of budesonide has been shown to reduce the severity of symptoms in mild to moderate cases of croup.[152] Progressive

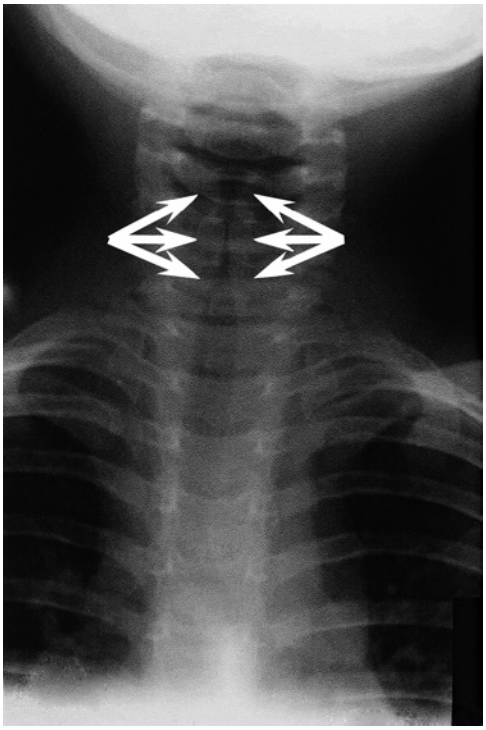

Fig. 35.8 Anteroposterior Chest X-Ray of a Patient With Croup. Subglottic narrowing typical of croup is evident *(arrows)*.

worsening of the clinical signs despite treatment indicates the need for intubation and mechanical ventilation. Heliox has been used for infants and children with severe disease (see Chapter 42). There is some evidence to show short-term benefit; however, long-term benefit has not yet been shown.[153,154]

Epiglottitis

Epiglottitis is an acute and often life-threatening infection of the upper airway that causes severe obstruction secondary to supraglottic swelling. Evidence suggests that the incidence of epiglottitis is decreasing among children and increasing in adults,[155] probably because of the use of vaccines. The most common cause is *H. influenzae* type B infection. Other organisms that are increasingly found to be causes of acute epiglottitis include group *S. pneumoniae*, *S. aureus*, *Klebsiella pneumoniae*, *Haemophilus parainfluenzae*, and β-hemolytic streptococci (groups A, B, C, and F).[156]

Clinical Manifestations

A child with epiglottitis usually has a high fever, sore throat, stridor, and labored breathing.[151,156] The presence of high-grade fever, drooling, muffled voice, and absence of a croupy bark are key features that distinguish epiglottitis from croup. Children with epiglottitis have a sickly appearance and may assume a tripod position for breathing or only tolerate certain positions that result in optimal airway patency. Older children may report a sore throat and difficulty swallowing. Difficulty swallowing may cause drooling. Lateral x-rays of the neck (Fig. 35.9) show that the epiglottis is markedly thickened and flattened (thumb sign) and the aryepiglottic folds are swollen; the vallecula may not be visualized. Visual examination of the upper airway is dangerous in these children and always should be performed in a controlled setting by personnel expert in emergency intubation. Inadvertent traction of the tongue can cause further and immediate swelling of the epiglottis and abrupt and total upper airway obstruction. Children with suspected epiglottitis should be accompanied by personnel expert in emergency intubation during any transport for diagnostic procedures.

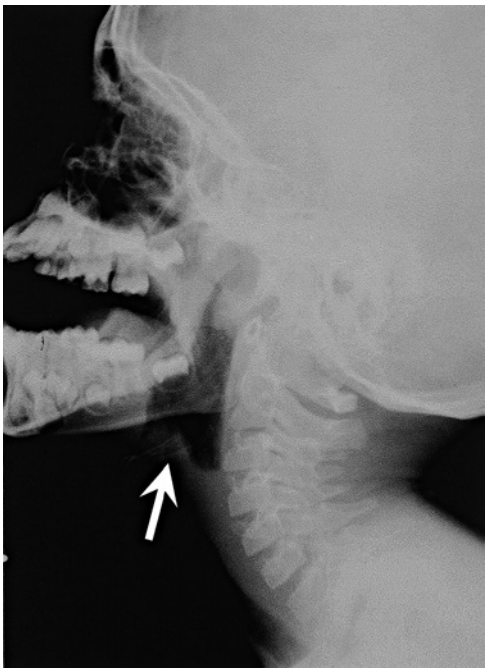

Fig. 35.9 Lateral Radiograph of the Neck of a Patient With Epiglottitis. The thumb sign is prominent *(arrow)*.

Treatment

Children with epiglottitis need elective intubation under general anesthesia in the operating room. Tracheostomy may be needed if the patient's condition warrants; however, this procedure is rarely used. There should be no attempt to lay the child down or attempts to intubate until the child is sedated. Premature attempts at intubation can precipitate acute airway obstruction and respiratory arrest. After an airway is secured, a sample for bacterial culture should be obtained and antibiotic therapy should be started. Corticosteroids may decrease the swelling.[157,158] Children with an ETT should be sedated and restrained to prevent inadvertent extubation. An upper airway leak following ET tube cuff deflation may indicate less edema but does not predict whether the extubation will be successful or not.

Cystic Fibrosis

Cystic fibrosis (CF) is one of the most common life-limiting autosomal recessive diseases, occurring in approximately 1 in every 3500 newborns in the United States.[159] There are approximately 1000 new cases of CF per year in the United States.[160] CF affects approximately 30,000 persons in the United States and 70,000 persons worldwide.[159] The prevalence varies by race and ethnicity, affecting approximately 1:3200 whites, 1:9500 Hispanics, 1:15,000 African Americans, and 1:31,000 in Asian Americans.[161] CF is caused by mutations in the gene that encodes a multifunctional protein called the *CF transmembrane conductance regulator (CFTR)*.[162] One of the main functions of this protein

MINI CLINI

Extubation

Problem

A 3-year-old child underwent emergency intubation 5 days earlier for epiglottitis. The physician asks the RT to evaluate the patient for extubation. What would the RT evaluate before making the decision to extubate? What equipment would the RT want to have at the bedside during extubation?

Discussion

Clinical examination of vital signs (e.g., body temperature), breath sounds, sensorium, and degree of airway leak should be considered. Equipment for rapid reintubation must be at the bedside, including racemic epinephrine for aerosolization.

Extubation of any patient should take into consideration the pathophysiologic condition that led to intubation. In this case, the RT should look for evidence that the infection is resolving and that the upper airway is no longer inflamed. A lack of fever for at least 12 hours and visual inspection of the throat that reveals minimal inflammation would be most helpful. After extubation, close monitoring must be performed for evidence of airway compromise. Cool mist and aerosolized racemic epinephrine may be helpful to minimize inflammation after extubation.

is to serve as an apical chloride channel in airway, intestinal, and exocrine cells.[163] The movement of chloride ions and regulation of sodium ions is important to the proper regulation of the water content of secretions.[164] The dehydrated viscous secretions that result from the *CFTR* abnormality lead to organ dysfunction, causing the clinical manifestations of the disease.[164] There are more than 1900 known *CFTR* mutations,[165] which are grouped into 6 classes that result in varying levels of *CFTR* production and dysfunction.[165] The variety of *CFTR* mutations explains some of the variability in the severity of the clinical manifestations of the disease.

RULE OF THUMB Both parents must be carriers of the mutated CF gene *(CFTR)* for a child to be born with CF. If both parents have a *CFTR* mutation associated with disease, the chance that CF will develop in their offspring is 1 in 4.

Clinical Manifestations

Patients with CF primarily experience abnormalities in the respiratory, digestive, and reproductive tracts.[166] Complications of lung disease are the leading cause of death in patients with CF.[167] The decreased airway surface liquid secondary to *CFTR* dysfunction leads to impaired mucus clearance, resulting in inflammation and infection of the airways that[168] cause a patient to have a chronic productive cough. Chronic airway infections can occur early in life, most frequently with *S. aureus*, *H. influenzae*, or *Pseudomonas aeruginosa*.[159] Certain organisms, including *P. aeruginosa*, methicillin resistant *S. aureus*, and *Burkholderia cepacia,* have been associated with more rapid rates of lung function decline.[169,170,171] Infection control guidelines aim to reduce the risk of acquiring pathogens that can be worsen the health of patients with CF.[172] As the disease progresses, the cycle of inflammation, infection, and lung damage results in lung hyperinflation and bronchiectasis.[163] Patients with end-stage CF lung disease have severe debility from respiratory failure and may develop pulmonary hypertension and cor pulmonale.[167]

Approximately 85% of patients with CF have exocrine pancreatic insufficiency.[159] *CFTR* dysfunction in the pancreas dramatically reduces the amount of digestive enzymes, leading to malabsorption of fats and proteins and less so for carbohydrates.[173] Malabsorption results in bulky, greasy, foul-smelling stools, fat-soluble vitamin deficiencies, and poor weight gain with failure to thrive. Some newborns present with a condition called *meconium ileus* due to bowel obstruction of thick and hardened meconium that sometimes causes intestinal perforation.[174] Rectal prolapse also can occur as a result of malabsorption and elimination of bulky stools.[175] Patients with pancreatic sufficiency can have recurrent bouts of pancreatitis.[176] Liver disease can result in prolonged obstructive jaundice in the newborn period.[177] Some children and adults have progressive liver disease leading to cirrhosis and portal hypertension.[178]

Males with CF have obstructive azoospermia as a result of congenital absence of the vas deferens.[179] Males and females with CF often have pubertal delays.[180] Females also have reduced fertility.[181]

As children with CF age, the risk for diabetes increases, and by adulthood, the majority of patients have abnormal glucose tolerance testing.[159]

The electrolyte composition of sweat in CF patients is abnormal because of the higher content of salt.[182] Increased salt losses in the sweat may lead to the initial presentation of some CF patients with hyponatremic hypochloremic metabolic alkalosis.[183] The sweat chloride test used for the diagnosis of CF is based on the abnormal concentration of chloride in the sweat of patients with the disease.[184]

Diagnosis

Since 2010, screening for CF in newborns indicating persistent hypertrypsinogenemia is performed in all 50 states and the District of Columbia.[159] The clinical gold standard for diagnosis is confirmed by a sweat chloride test, ideally performed at an accredited CF center. The skin is stimulated to produce sweat (pilocarpine iontophoresis), and a sweat chloride level greater than or equal to 60 mEq/L confirms the diagnosis of CF.[185] The diagnosis in some infants is challenging because they have a normal sweat chloride (<30 mEq/L in infants younger than 6 months) but two abnormal CFTR mutations.[185]

The diagnosis of CF in patients not identified by newborn screening can be made by performing a sweat test in children or adults with signs or symptoms suggestive of CF. Signs and symptoms include recurrent sinus or lung infections, bronchiectasis, nasal polyps, digital clubbing, malabsorption, failure to gain weight as expected, recurrent pancreatitis, salt-losing syndromes, and male infertility resulting from obstructive azoospermia. Testing is often conducted when there is a sibling with CF. Having two sweat chloride test results greater than 60 mEq/L confirms the diagnosis.

Monitoring

CF patients should be managed at an accredited CF center.[159] The CF Foundation recommends that newborns with CF are seen soon after a positive newborn screen result and then at least on a monthly basis until 6 months of age, then every 2 months until age 1 year, and every 2 to 3 months thereafter.[186] It is recommended that older children and adults should be seen quarterly at a minimum. Because CF lung disease is progressive, patients are closely monitored by symptom assessment, physical examination, sputum cultures to monitor airway flora, and objective measurements with spirometry and chest radiography. The nutritional status of each patient is also monitored very closely, including their growth, body mass index, protein stores, and fat-soluble vitamin levels.

Treatment

Multiple therapies are used to maintain a patient's lung health. Airway clearance has been a mainstay of therapy in CF.[187,188] There are many options for airway clearance, including percussion and postural drainage, positive expiratory pressure, autogenic drainage, autocycle of breathing technique, oscillatory positive expiratory pressure, and high-frequency chest compression. Airway clearance therapies have been shown to increase sputum production, improve exercise tolerance, and decrease the rate of lung function decline. In general, no specific airway clearance

technique is superior to another; therefore, airway clearance must be tailored to the individual patient.

As a result of the cellular debris from chronic infection and inflammation, there is free DNA in the airways that contributes to the viscosity of secretions. To treat this, inhaled recombinant deoxyribonuclease (DNase) is used to degrade the viscous DNA.[189] The routine daily use of inhaled DNase has been shown to improve pulmonary function and reduce exacerbations in patients with CF.[190] Inhaled DNase is recommended for daily use in patients 6 years of age and older.[191] Nebulized 7% hypertonic saline is thought to improve mucociliary clearance and has been shown to improve lung function and reduce exacerbations.[192,193] Nebulized 7% hypertonic saline is currently recommended for twice-daily use in patients 6 years and older.[191] High doses of the anti-inflammatory drug ibuprofen, when used at doses resulting in appropriate levels, reduce the progression of CF lung disease and are recommended for use in children 6 to 17 years of age with an FEV1 greater than 60% predicted.[191] The regular use of azithromycin helps preserve lung function and decreases the frequency of pulmonary exacerbations, possibly related to the anti-inflammatory and antimicrobial properties of azithromycin. On this basis, azithromycin is recommended in patients 6 years and older.[191] Patients taking azithromycin should be monitored for the acquisition of nontuberculous mycobacteria, at which time their azithromycin monotherapy should be discontinued.[191]

The lungs of CF patients are chronically colonized with bacteria. One of the most common organisms is *P. aeruginosa*,[159] which has been associated with more rapid decline in lung function and decreased survival.[169] Inhaled antibiotics directed against this organism are recommended for eradiation and chronic suppression. Currently two inhaled antibiotics—inhaled tobramycin and inhaled aztreonam—are available for use.[191,194,195]

More recently, developed therapies are aimed at correcting the underlying *CFTR* defect or potentiating its function. In 2012 ivacaftor, a potentiator that activates defective *CFTR*, was approved for use in the United States in patients with a specific variant of CF—the G551D *CFTR* mutation. In 2014, approval for use of ivacaftor was expanded to some other gating *CFTR* mutations. Ivacaftor has been shown to improve lung function and significantly reduce pulmonary exacerbations. Ivacaftor also was observed to significantly decrease the sweat chloride concentration and enhance antimicrobial action against *P. aeruginosa*.[196] Treatment with two CFTR modulator drugs (e.g., teazacaftor, lumacaftor) is recommended for some CF variants, and triple therapy with novel corrector molecules is being studied. In addition to treatment with corrector molecules like ivacaftor, gene therapy has been explored as a treatment for CF.[197]

Lung transplantation is an option for patients with advanced severe CF lung disease.

The malabsorption due to deficiency of pancreatic enzymes is managed with pancreatic enzyme supplementation and vitamin supplementation.[166] Some patients also require oral calorie supplements to assist with their nutritional needs.

Prognosis

The prognosis for patients with CF has steadily improved with treatment advances over the last several decades. When CF was first described in 1938, children lived approximately 6 months.[198] Survival has since significantly improved. In 2002 the median age of survival was 31.3 years, and 10 years later in 2012, the median survival of patients with CF rose to 41.1 years.[159] In the near future, the number of adults will outnumber the children with CF.[159] It has been projected based on 2016 data that the life expectancy for a baby born with CF in 2016 is 47 years of age.[199] This means that half of all babies born in 2016 are expected to live to be at least 47 years old.

ROLE OF THE RESPIRATORY THERAPIST IN NEONATAL AND PEDIATRIC RESPIRATORY DISORDERS

As in all clinical situations, the role of the RT in the special environment of neonatal and pediatric care is to use his or her expertise and knowledge to improve patient outcomes. Because there are significant differences in the diseases, pathophysiologies, and function of respiratory support equipment between adult and pediatric patients, the RT must be thoroughly familiar with all aspects of pediatric care. The old adage "children are not little adults" is true. Equally, newborns are not little children. Each of these age groups has unique characteristics that require specialized knowledge and experience. The RT is an important part of a team that is dedicated to the health and well-being of these fragile patients.

Also, the RT has an important role in providing education and emotional support, not only to the pediatric patient but also to the families and caregivers. Frequently, the RT is at the bedside of patients when the parents or caregivers are present. The RT is invaluable in helping patients and parents understand the respiratory goals of each individual patient.

SUMMARY CHECKLIST

- The incidence of RDS increases with decreasing gestational age.
- A qualitative decrease in surfactant increases alveolar surface tension forces in RDS patients. This process causes alveoli to become unstable and collapse and leads to atelectasis and increased WOB.
- The definitive diagnosis of RDS usually is made by chest x-ray. Diffuse, hazy, reticulogranular densities with the presence of air bronchograms and low lung volumes are typical of RDS.
- TTN, often referred to as type II RDS, is probably the most common respiratory disorder of the newborn. The cause of TTN is unclear but is most likely related to delayed clearance of fetal lung liquid. Infants with TTN usually respond readily to low FiO_2 by O_2 hood or nasal cannula. Infants who need higher FiO_2 levels may benefit from CPAP.
- Meconium aspiration syndrome (MAS) is a disease of term and near-term infants. It involves aspiration of meconium into the central airways of the lung. This disorder usually is associated with perinatal depression and asphyxia.
- The best management of BPD is prevention. Prevention of atelectrauma and volutrauma begins in the delivery room.

- PPHN should be suspected when an infant has rapidly changing SaO_2 without changes in FiO_2 or has hypoxemia out of proportion to the lung disease detected on the chest x-ray or on the basis of $PaCO_2$.
- Congenital diaphragmatic hernia is a severe disease that usually manifests as severe respiratory distress in the newborn period. The pathophysiologic mechanism is a complex combination of lung hypoplasia, including decreased alveolar count and decreased pulmonary vasculature, pulmonary hypertension, and unusual anatomy of the inferior vena cava.
- The cause of SIDS is unknown, but there is evidence to recommend placing infants in a supine position to sleep. Apnea of prematurity is not a predisposing factor, and there is no evidence that immaturity of the respiratory center is a cause.
- Bronchiolitis is an acute infection of the lower respiratory tract usually caused by RSV.
- Croup is a viral disorder of the upper airway that normally results in subglottic swelling and obstruction. Termed *laryngotracheobronchitis*, viral croup is caused by the parainfluenza virus and is the most common form of airway obstruction in children 6 months to 6 years old.
- Epiglottitis is an acute, often life-threatening infection of the upper airway that causes severe obstruction secondary to supraglottic swelling. Evidence suggests that the incidence of epiglottitis is decreasing among children, probably because of the use of vaccines. A child with epiglottitis usually has a high fever, sore throat, stridor, and labored breathing.
- Cystic fibrosis is the most common lethal genetic disorder among whites. It is inherited as an autosomal recessive trait that affects approximately 30,000 people in the United States. Treatment of CF lung disease requires aggressive efforts to control pulmonary infections and clear pulmonary secretions. RTs often play a key role in treating patients with CF.

Airway Pharmacology

Douglas S. Gardenhire

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Analyze the three phases that constitute the course of drug action from dose to effect.
- Describe the classes of drugs that are delivered via the aerosol route.
- Compare the mechanisms of action, indications, and adverse effects that characterize each major class of aerosolized drug.
- Compare the available aerosol formulations, brand names, and dosages for each specific drug class.
- Select the appropriate drug class for a specific patient or clinical situation.
- Assess the outcomes for each class of aerosol drug therapy.

CHAPTER OUTLINE

KEY TERMS

adrenergic
agonists
antagonists
antiadrenergic
anticholinergic
catecholamine
cholinergic
drug signaling
leukotriene
L/T ratio
muscarinic
neutropenia
pharmacodynamic phase
pharmacokinetic phase
prodrug
tachyphylaxis
vasopressor

The primary focus of respiratory care pharmacology is the delivery of inhaled aerosols to the respiratory tract for the diagnosis and treatment of pulmonary diseases. Although other drug classes are used in respiratory care, the discussion in this chapter is limited to bronchoactive inhaled aerosols. Other drug classes are discussed in standard pharmacology texts.[1,2]

PRINCIPLES OF PHARMACOLOGY

The course of drug action from dose to effect comprises three phases: *drug administration, pharmacokinetics,* and *pharmacodynamics*. These three phases of drug action can be applied to drug treatment of the respiratory tract with inhaled agents.

Drug Administration Phase

The drug administration phase describes the method by which a drug dose is made available to the body. Administering drugs directly to the respiratory tract uses the inhalation route, and the dose form is an aerosol of liquid solutions, suspensions, or dry powders. The most commonly used devices to administer orally or nasally inhaled aerosols are the metered-dose inhaler (MDI), soft-mist inhaler (Respimat), small-volume nebulizer (SVN), and dry-powder inhaler (DPI). Reservoir devices—including holding chambers with one-way inspiratory valves and simple, nonvalved spacer devices—are often added to MDIs to reduce the need for complex hand-breathing coordination and to reduce oropharyngeal impaction of the aerosol drug (see Chapter 40).

The advantages of treatment of the respiratory tract with inhaled aerosols are as follows:

- Aerosol doses are usually smaller than doses for systemic administration.
- Onset of drug action is rapid.
- Delivery is targeted to the organ requiring treatment.
- Systemic side effects are often fewer and less severe.

Disadvantages of the delivery of inhaled aerosols in treating respiratory disease include the number of variables affecting the delivered dose and lack of adequate knowledge of device performance and use among patients and caregivers.[3]

RULE OF THUMB: Increasing the L/T Ratio The higher the ratio of lung availability to total systemic availability (the L/T ratio), the greater the clinical or therapeutic effect of the bronchoactive aerosol deposited in the airway. The use of more efficient aerosol devices can increase L/T ratios. For example, the use of a spacer or valved holding chamber with a MDI can increase deposition in the lung and reduce oral impaction, leading to a higher L/T ratio.

Pharmacokinetic Phase

The **pharmacokinetic phase** of drug action describes the time course and disposition of a drug in the body based on its absorption, distribution, metabolism, and elimination. Inhaled aerosols are intended for local effects in the airway. Undesired systemic effects result from absorption and distribution throughout the body.

An inhaled aerosol distributes to the lung by inhalation and the stomach through swallowing of drug that deposits in the oropharynx. The therapeutic effect of the aerosol drug is caused by the portion in the airway, whereas systemic effects are due to absorption of the drug from the airway and gastrointestinal (GI) tract. The ideal aerosol would distribute only to the airway, with none reaching the stomach. The ratio of lung availability to total systemic availability (**L/T ratio**) quantifies the efficiency of aerosol delivery to the lung:

$$\text{L/T ratio} = \text{Lung availability}/(\text{Lung} + \text{GI availability})$$

This concept, proposed by Borgström[4] and elaborated by Thorsson,[5] is illustrated in Fig. 36.1, showing delivery of albuterol by inhalation using a MDI and a DPI.

Pharmacodynamic Phase

The **pharmacodynamic phase** describes the mechanisms of drug action by which a drug molecule causes its effects in the body. Drug effects are caused by the combination of a drug with a matching receptor. **Drug signaling** mechanisms include the following:

Signaling Mechanism	Example
Mediation by G protein (guanine nucleotide)–linked receptors	β-adrenergic agonists, antimuscarinic agents
Attachment to intracellular receptors by lipid-soluble drugs	Corticosteroids

The mechanisms of drug action are briefly described here for each class of bronchoactive drug.

Airway Receptors and Neural Control of the Lung

Pharmacologic control of the airway is mediated by receptors found on airway smooth muscle, secretory cells, bronchial epithelium, and pulmonary and bronchial blood vessels. There are *sympathetic (adrenergic)* and *parasympathetic (cholinergic)* receptors in the lung. The terminology for drugs acting on these receptors is based on the usual neurotransmitter that acts on the receptor. The usual neurotransmitter in the sympathetic system is norepinephrine, which is similar to epinephrine. The usual neurotransmitter in the parasympathetic system is acetylcholine. The receptors responding to these neurotransmitters are termed *adrenergic* and *cholinergic*. **Agonists** (stimulating agents) and **antagonists** (blocking agents) that act on these receptors are given the following classifications:

- **Adrenergic** (adrenomimetic): Drug that stimulates a receptor responding to norepinephrine or epinephrine
- **Antiadrenergic**: Drug that blocks a receptor for norepinephrine or epinephrine
- **Cholinergic** (cholinomimetic): Drug that stimulates a receptor for acetylcholine
- **Anticholinergic**: Drug that blocks a receptor for acetylcholine
- **Muscarinic**: Drug that stimulates acetylcholine receptors specifically at one of the two types of acetycholine receptors called the muscarinic receptors

TABLE 36.1 Airway Receptors and Their Effects in the Cardiopulmonary System

Location	Receptor	Effect
Heart	β1-adrenergic	Increased rate, force
	M_2-cholinergic	Decreased rate
Bronchiolar smooth muscle	β2-adrenergic	Bronchodilation
	M_3-cholinergic	Bronchoconstriction
Pulmonary blood vessels	α1-adrenergic	Vasoconstriction
	β2-adrenergic	Vasodilation
	M_3-cholinergic	Vasodilation
Bronchial blood vessels	α1-adrenergic	Vasoconstriction
	β2-adrenergic	Vasodilation
Submucosal glands	α1-adrenergic	Increased fluid, mucin
	β2-adrenergic	Increased fluid, mucin
	M_3-cholinergic	Exocytosis, secretion

Adrenergic and muscarinic cholinergic receptor subtypes are indicated.
M_2, M_3, Subtypes of muscarinic *(M)* cholinergic receptors.

Because cholinergic receptors exist at autonomic ganglia and at the myoneural junction in skeletal muscle, the terms *muscarinic* and *antimuscarinic* distinguish cholinergic agents whose action is limited to parasympathetic sites. Neostigmine is a cholinergic (indirect-acting) drug that increases receptor stimulation at both the myoneural junction and the parasympathetic sites. By contrast, atropine is an antimuscarinic agent that blocks the action of acetylcholine only at the parasympathetic sites. Table 36.1 summarizes receptors and their effects on the cardiopulmonary system. A more detailed description of the autonomic nervous system and receptor subtypes is provided by Katzung and colleagues.[2]

ADRENERGIC BRONCHODILATORS

Adrenergic bronchodilators represent the largest group of drugs among the aerosolized agents used for oral inhalation. Table 36.2 lists bronchodilators in this group, with their aerosol formulations, selected brand names, and dosages.

Indications for Use

The general indication for use of an adrenergic bronchodilator is the presence of reversible airflow obstruction. The most common use of these agents clinically is to improve flow rates in asthma (including exercise-induced asthma), acute and chronic bronchitis, emphysema, bronchiectasis, cystic fibrosis (CF), and other obstructive airway states.

Indication for Short-Acting Agents

Short-acting β2 agonists (SABAs), such as albuterol and levalbuterol, are indicated for relief of acute reversible airflow obstruction in asthma or other obstructive airway diseases. Short-acting agents are termed *rescue agents* in the 2007 National Asthma Education and Prevention Program Expert Panel III (NAEPP EPR III) guidelines.[6]

TABLE 36.2 Adrenergic Bronchodilator Agents Available in the United States

Drug	Brand Name	Receptor Preference	Adult Dosage	Time Course (Onset, Peak, Duration)
Ultrashort-Acting Adrenergic Bronchodilator Agents				
Racemic epinephrine	Asthmanefrin[a]	α, β	SVN: 2.25% solution, 0.25–0.5 mL (5.63–11.25 mg) qid	*Onset:* 3–5 min *Peak:* 5–20 min *Duration:* 0.5–2 h
Short-Acting Adrenergic Bronchodilator Agents				
Albuterol	Proventil HFA, Ventolin HFA, ProAir HFA, ProAir Respiclick AccuNeb, VoSpire ER	βa-2	SVN: 0.5% solution, 0.5 mL (2.5 mg), 0.63 mg, 1.25-mg, and 2.5-mg unit dose, tid, qid MDI: 90 mcg/puff, 2 puffs tid, qid Tab: 2 mg, 4 mg, and 8 mg, bid, tid, qid DPI: 108 mcg/puff, 2 puffs tid, qid Syrup: 2 mg/5 mL, 1–2 tsp tid, qid	*Onset:* 15 min *Peak:* 30–60 min *Duration:* 5–12 h
Levalbuterol	Xopenex, Xopenex HFA	β-2	SVN: 0.31 mg/3 mL tid, 0.63 mg/3 mL tid or 1.25 mg/3 mL tid, concentrate 1.25 mg/0.5 mL, tid MDI: 45 mcg/puff, 2 puffs q4–6h	*Onset:* 15 min *Peak:* 30–60 min *Duration:* 5–8 h
Long-Acting Adrenergic Bronchodilator Agents				
Salmeterol	Serevent Diskus	β-2	DPI: 50 mcg/blister bid	*Onset:* 20 min *Peak:* 3–5 h *Duration:* 12 h
Formoterol	Perforomist	β-2	SVN: 20 mcg/2 mL unit dose bid	*Onset:* 15 min *Peak:* 30–60 min *Duration:* 12 h
Arformoterol	Brovana	β-2	SVN: 15 mcg/2 mL unit dose, bid	*Onset:* 15 min *Peak:* 30–60 min *Duration:* 12 h
Indacaterol	Arcapta Neohaler	β-2	DPI: 75 mcg/inhalation, qd	*Onset:* 5 min *Peak:* 30 min *Duration:* 24 h
Olodaterol	Stiverdi Respimat	β-2	SMI: 2.5 mcg/actuation, 2 actuations qd	*Onset:* 15 min *Peak:* 30–60 min *Duration:* 12 h

[a]Available over the counter.
DPI, Dry-powder inhaler; *MDI,* metered dose inhaler; *SMI,* soft-mist inhaler; *SVN,* small-volume nebulizer

Indication for Long-Acting Agents

Long-acting β agonists (LABAs)—salmeterol, formoterol, arformoterol, indacaterol, olodaterol, and vilanterol—are indicated for maintenance bronchodilation, control of bronchospasm, and the treatment of nocturnal symptoms in asthma or other obstructive diseases, such as chronic obstructive pulmonary disease (COPD). NAEPP EPR III guidelines consider LABAs *controllers;* their slower time to peak effect makes them poor rescue drugs. In asthma, a long-acting bronchodilator is usually combined with an antiinflammatory medication for the control of airway inflammation and bronchospasm. Although some LABAs have a rapid onset and peak effect similar to or better than that of albuterol, their prolonged activity makes them better maintenance drugs compared with an acute reliever or rescue agent.

Indication for Racemic Epinephrine

Racemic epinephrine is often used by inhaled aerosol or direct lung instillation for its strong vasoconstricting effect in order to reduce airway swelling after extubation or during epiglottitis or croup or to control airway bleeding during endoscopy.

RULE OF THUMB: Differentiating β1 From β2 β1 stimulation increase heart rate and contractility, whereas β2 stimulation results in smooth muscle relaxation. To assist in differentiating these, remember that you have one (1) heart (β1) and two (2) lungs (β2).

Mechanism of Action and Effects

Adrenergic bronchodilators can stimulate one or more of the following receptors, with the effects described:

- *α-receptor stimulation:* Causes vasoconstriction and a **vasopressor** effect (increased blood pressure)
- *β1-receptor stimulation:* Causes increased heart rate and myocardial contractility
- *β2-receptor stimulation:* Relaxes bronchial smooth muscle, stimulates mucociliary activity, and has some inhibitory action on inflammatory mediator release

Bronchodilation, through the stimulation of β2 receptors, is the desired therapeutic effect. Both α- and β-adrenergic receptors are linked with G-protein receptors. Fig. 36.2 illustrates the mechanism of action for the relaxation of airway smooth muscle

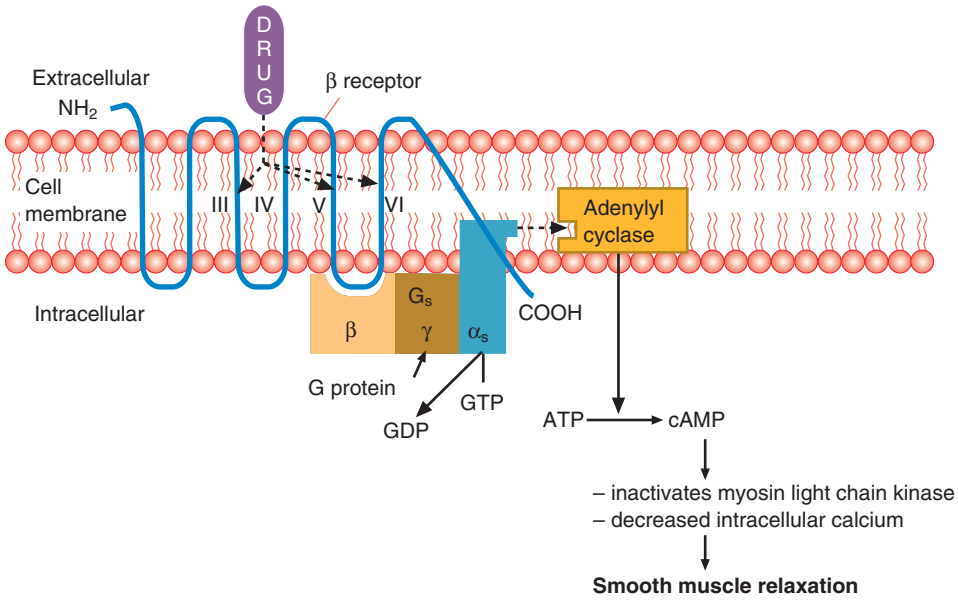

Fig. 36.2 Mechanism of action by which a β-agonist stimulates the G protein–linked β receptor to cause smooth muscle relaxation. Adrenergic agonists, such as albuterol or epinephrine, attach to β receptors, which are polypeptide chains traversing the cell membrane seven times. This causes activation of the stimulatory G protein, designated G_S, linked to the receptor. When stimulated, the receptor undergoes a conformational change, and the α subunit of the G protein attaches to adenyl cyclase. Activation of adenyl cyclase by the G_S protein causes an increased synthesis of the second messenger, cyclic adenosine monophosphate *(cAMP)*. This ultimately causes smooth muscle relaxation and bronchodilation. *ATP,* Adenosine triphosphate; *COOH,* carboxy terminus; *GDP,* guanosine diphosphate; *GTP,* guanosine triphosphate. (From Gardenhire DS: *Rau's Respiratory Care Pharmacology*, ed 10, St. Louis, 2020, Elsevier.)

when a β2 receptor is stimulated. The nature of the β receptor and its activity is presented in more detail by Chung and colleagues.[7]

Adrenergic Bronchodilator Agents

Adrenergic bronchodilator agents represent the evolution of a drug class. Although all of these agents are adrenergic agonists, the differences among individual agents are due to their receptor preference (α-adrenergic, β1-adrenergic, β2-adrenergic) and their different pharmacokinetics, as listed in Table 36.2. These differences determine the clinical application of individual agents. The adrenergic bronchodilators form three subgroups.

Ultrashort-Acting Catecholamines

Racemic epinephrine, the older agent, is a **catecholamine.** This agent lacks β2 specificity. As a result, cardiac effects, especially tachycardia and increased blood pressure, are common. Catecholamines are metabolized by the enzyme catechol *O*-methyltransferase, which causes a short duration of action. Because of a strong α1 activity and vasoconstricting effect, racemic epinephrine is used to reduce swelling in the nose (nasal decongestant) and larynx (croup, epiglottitis) and to control bleeding during bronchoscopic biopsy.

Short-Acting Noncatecholamine Agents

Because of their short duration of action and lack of β2 specificity, catecholamines were replaced by longer-acting, β2-specific agents such as albuterol and levalbuterol. Because their duration of action averages 4 to 6 hours, these drugs are better bronchodilating agents than catecholamines and can be taken on a four-times-daily schedule. However, their modest duration of action results in loss of an overnight bronchodilating effect.

Single-isomer β agonists. Levalbuterol is approved as a single-isomer β2-selective agonist. Previous inhaled formulations of adrenergic bronchodilators all were synthetic racemic mixtures, containing both the *(R)* isomer and the *(S)* isomer in equal amounts. Levalbuterol is the pure *(R)* isomer of racemic albuterol. Both stereoisomers of albuterol are shown in Fig. 36.3 with the single-isomer (*[R]* isomer) form of levalbuterol. Although the *(S)* isomer is physiologically inactive on adrenergic receptors, there is evidence that it is not completely inactive. Box 36.1 lists some of the physiologic effects of *(S)* albuterol noted in the

BOX 36.1 Effects and Characteristics of *(S)*-Isomer of Albuterol

- Increases intracellular calcium concentration in vitro[8]
- Activity is blocked by the anticholinergic atropine[8]
- Does not produce pulmonary or extrapulmonary β2–mediated effects[9]
- Enhances experimental airway responsiveness in vitro[10]
- Increases contractile response of bronchial tissue to histamine or leukotriene C_4 in vitro[11]
- Enhances eosinophil superoxide production with interleukin-5 stimulation[12]
- Slower metabolism than *(R)*-albuterol in vivo[13]
- Preferential retention in the lung when inhaled by metered dose inhaler (in vivo)[14]

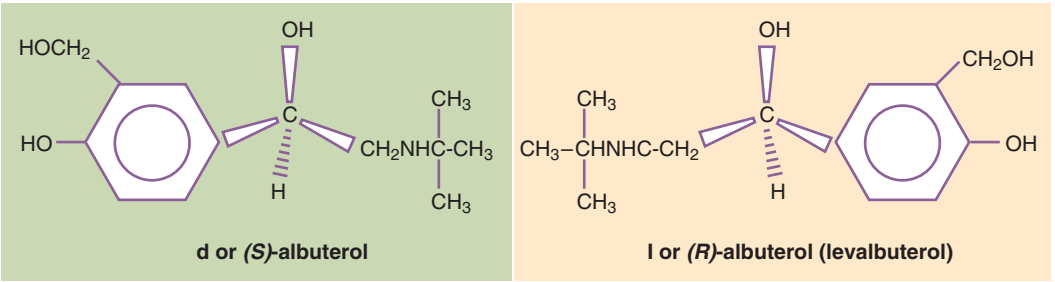

Fig. 36.3 *(R)*- and *(S)*-isomers of racemic albuterol. Levalbuterol is the single, *(R)*-isomer form of racemic albuterol and contains no *(S)*-isomer.

literature.[8–14] The effects antagonize the bronchodilating effects of the *(R)* isomer and promote bronchoconstriction. In addition, the *(S)* isomer is more slowly metabolized than the *(R)* isomer.

Levalbuterol is available in many strengths and formulas, as shown in Table 36.2. Side effects of tremor and changes in heart rate are less with the single-isomer formulation.[15] The 1.25-mg dose shows a higher peak effect on forced expiratory volume in 1 second (FEV_1) with an 8-hour duration compared with racemic albuterol. Side effects with this dose are equivalent to the side effects seen with racemic albuterol. An equivalent clinical response is seen with one-fourth of the racemic dose (0.63 mg) using the pure isomer, although the racemic mixture contains 1.25 mg of the *(R)* isomer (half of the total 2.5-mg dose).

Long-Acting Adrenergic Bronchodilators

Upon its release, salmeterol became the first LABA available in the United States. In contrast to previous agents, the duration of action of salmeterol is approximately 12 hours. The pharmacokinetics of salmeterol makes it suitable for maintenance therapy—in particular, in dealing with nocturnal asthma (although LABAs are not to be used alone in treating asthma and are best used in combination with inhaled corticosteroids). However, salmeterol should not be used for relief of acute airflow obstruction or bronchospasm because its onset is longer than 20 minutes, with a peak effect occurring by 3 to 5 hours. Although this agent is a β2 agonist, its exact mechanism of action differs from those of previous β2 agonists, allowing persistent receptor stimulation over a prolonged period (hours).

RULE OF THUMB: Onset of Action: Long-Acting β Agonists Many LABAs have a quicker onset of action and peak effect than SABAs (i.e., albuterol and levalbuterol). It is important to remember that LABAs should not be used in place of SABAs for acute exacerbations. LABAs should be used for maintenance in chronic lung conditions.

Formoterol has a duration of effect of approximately 12 hours, but in contrast to salmeterol, the onset of action and peak effect of formoterol are rapid and similar to those of albuterol.[16] Formoterol should not be used as a rescue inhaler. As with salmeterol, the extensive side chain or tail makes formoterol more lipophilic than shorter-acting bronchodilators and is the basis for its longer duration of effect.

Arformoterol, the single *(R)* isomer of formoterol, is available as a 2-mL unit-dose vial for an inhalation solution delivering 15 mcg/dose. The recommended dosage is 1 unit dose twice daily. Arformoterol is indicated for the maintenance of bronchospasm in COPD, including chronic bronchitis and emphysema.

Indacaterol (Arcapta Neohaler) a novel once-daily therapy. It has been used mainly to treat asthma; in the United States, however, it is indicated only in the treatment of COPD. Indacaterol is similar to formoterol, with a quick onset; however, it is even faster—with onset at approximately 5 minutes and a duration of 24 hours.[17]

Olodaterol is an ultra-LABA for the once-daily treatment of COPD. It has a quick onset similar to that of formoterol and indacaterol, with a change in FEV_1 at approximately 5 minutes.[18] Currently, olodaterol is not approved for the treatment of asthma; however, it has been shown to be effective as monotherapy and in combination with tiotropium.[19]

Vilanterol is an ultra-LABA that is available in fixed combinations with fluticasone (Breo Ellipta), umeclidinium (Anoro Ellipta), and fluticasone plus umeclidinium (Trelegy Ellipta). Vilanterol in not available as monotherapy but has been studied with good results in COPD.[20]

RULE OF THUMB: Metabolic Disturbances The use of SABAs and LABAs, which are often prescribed together, can produce high levels of β-agonist activity. Additionally, continuous nebulizer therapy may contribute to higher-than-normal levels of β-agonist activity. These increased levels can increase glucose and decrease serum potassium levels. With the use of β agonists, attention to lab results is needed. Moreover, it is possible that the use of high doses of an inhaled β agonist can temporarily treat hyperkalemia.

Adverse Effects

Older adrenergic agents, such as isoproterenol, commonly caused tachycardia, palpitations, and an "adrenaline effect" of shakiness and nervousness. Newer, more β2-selective agents are safer and typically cause tremor as the main side effect. Other common side effects with the inhaled agents include headache, insomnia, and nervousness. Patients should be reassured that some tolerance to these effects does occur. Potential adverse effects with the use of adrenergic bronchodilators include the following:

- Dizziness
- Hypokalemia
- Loss of bronchoprotection
- Nausea
- Tolerance (**tachyphylaxis**)

- Worsening ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio (decrease in PaO_2/SpO_2)

Inhalation results in fewer and less severe side effects than oral administration. Although tolerance develops to the bronchodilating effect, this is not a contraindication to use of the drugs, and relaxation of airway smooth muscle still occurs. Desaturation resulting from a $\dot{V}/\dot{Q}$ mismatch with inhalation of the aerosol is not clinically significant and reverses quickly. The implication of β2-adrenergic agonists in deaths from asthma—termed the *asthma paradox* or the *β-agonist controversy*—remains debated.[21] There is evidence of loss of a bronchoprotective effect with use of β agonists, and patients should be cautioned to avoid asthma triggers. The increased prevalence of asthma in general remains a troublesome and unresolved issue.

Assessment of Bronchodilator Therapy

Assessment of therapy with adrenergic bronchodilators should be based on the indication for the aerosol agent (presence of reversible airflow obstruction owing to primary bronchospasm or other obstruction secondary to an inflammatory response or secretions, either acute or chronic). Basic vital signs (respiratory rate and pattern, pulse, breath sounds) should be assessed before and after treatment, especially for initial drug use, and the patient's subjective reaction (complaints of breathing difficulty). Patients should be instructed in the correct use of the aerosol device, backed up with a demonstration of correct use. Finally, the patient's subjective reaction to the treatment should be monitored for any change in breathing effort. This assessment applies to all subsequent drug groups by aerosol and is not repeated for each class. The following specific actions are suggested to evaluate patient response to this class of drugs:

- Monitor flow rates using bedside peak flowmeters, portable spirometry, or laboratory reports of pulmonary function before and after bronchodilator studies to assess reversibility of airflow obstruction.
- Assess arterial blood gases (ABGs) or pulse oximetry saturation as needed for acute states with asthma or COPD to monitor changes in gas exchange.
- β agonists increase blood glucose and decrease K^+ when high doses are used, with continuous nebulization or emergency department treatments.
- In the long term, monitor pulmonary function studies of lung volumes, capacities, and flows.
- Instruct asthmatic patients in the use and interpretation of disposable peak flowmeters to assess the severity of asthmatic episodes and provide an action plan for treatment modification.
- Emphasize in patient education that β agonists do not treat underlying inflammation and do not prevent the progression of asthma; also that additional antiinflammatory treatment or more aggressive medical therapy may be needed if there is a poor response to the rescue β agonist.
- Instruct and then verify correct use of the aerosol delivery device (i.e., SVN, MDI, reservoir, Respimat, or DPI).
- Instruct patients in the use, assembly, and cleaning of aerosol inhalation devices.

The following actions are suggested to evaluate patient response to LABA:

- Assess ongoing lung function, including predose FEV_1 over time and variability in peak expiratory flows.
- Assess the amount of rescue β-agonist use and nocturnal symptoms.
- Assess the number of exacerbations, unscheduled clinic visits, and hospitalizations.
- Assess days of absence from school or work because of symptoms.
- Assess the patient's ability to reduce the dose of concomitant inhaled corticosteroids.

Note: Death has been associated with excessive use of inhaled adrenergic agents in severe acute asthma crises. Individuals using such drugs should be instructed to contact a physician or an emergency department if there is no response to the usual dose of the inhaled agent.

Because of the ongoing safety concerns with long-acting β2 agonists, the US Food and Drug Administration (FDA) is requiring changes on how these drugs are used in the treatment of asthma. The FDA suggests that if a LABA is used, it should be done in conjunction with a corticosteroid. Once the asthma episode has improved, the LABA should be discontinued. If a child needs a LABA, it is preferred that a combination product (with a corticosteroid) be used to improve adherence.

MINI CLINI

Assessing β-Agonist Side Effects

Problem

The respiratory therapist (RT) has administered an aerosol treatment of albuterol using an MDI with a holding chamber; the patient is a 67-year-old man with newly diagnosed COPD who was admitted for an acute exacerbation and shortness of breath. When the RT returns for the second treatment that day, the patient informs the RT that he began to feel very shaky and nervous beginning about 30 minutes after the previous treatment. He also noticed a tremor when he held his water cup and took a drink. His pulse during the earlier treatment was 84 beats/min. Clinical assessment shows that he is coherent, has good color, is not diaphoretic, and is in no respiratory distress. His respiratory rate is 16 breaths/min and regular, and his pulse is 82 beats/min and regular. Auscultation reveals mild wheezing and scattered rhonchi, with little change from earlier breath sounds. A mild tremor is apparent when he holds his hand out. On questioning, he states that he is now feeling better and that the "shakiness" has subsided a bit.

Discussion

This patient's situation exemplifies a common reaction to inhaled adrenergic bronchodilators. Although albuterol is β2 preferential, it is still an epinephrine-like drug and can produce side effects secondary to sympathetic stimulation. The description of the symptoms is suggestive of common adrenergic side effects (tremor, shakiness). The timing of the symptoms coincides with the pharmacokinetics of albuterol (peak effect in 30–60 minutes). As presented in the case description, it is important to rule out other complications. The physical examination shows no changes from the earlier treatment in the patient's vital signs.

It is important to caution patients about "normal" expected side effects and to reassure them that the side effects decrease with tolerance to the medication. In addition, the RT must be alert to the possibility that a patient may have deteriorated or experienced an adverse change in his or her respiratory status.

RULE OF THUMB: Choosing an Aerosol Agent An aerosol agent to treat the respiratory tract is chosen based on the indication for the agent or class of drugs and a corresponding presence of the indication in the patient.

- *Example:* Adrenergic bronchodilator. The indication is presence of reversible airflow obstruction. The patient shows a 20% improvement in FEV_1 on spirometry with use of inhaled albuterol. Choose an adrenergic bronchodilator. (Note, the American Thoracic Society definition of reversible airflow obstruction is a 12% *and* 200 mL rise in the FEV_1 postbronchodilator. The percent alone does not define a response; if FEV_1 is very low, a small change in FEV_1 that is clinically insignificant could exceed a 20% increase.)
- *Example:* Inhaled corticosteroid. The indication is mild, moderate, or persistent asthma. The patient with asthma reports a need to use a β-agonist rescue inhaler more than a few days each week and complains of waking up at night with shortness of breath. Choose to add an inhaled corticosteroid. Additionally, a LABA may have to be added as well, depending on symptoms. Each patient should always have a rescue inhaler on hand.

ANTICHOLINERGIC BRONCHODILATORS

A second method of producing airway relaxation is through blockade of cholinergic-induced bronchoconstriction. An important difference between β agonists and anticholinergic bronchodilators is the active stimulatory action of the former versus the passive blockade of the latter. A cholinergic blocking agent is effective only if bronchoconstriction exists due to cholinergic activity.

Indications for Use

Table 36.3 lists the dosage, forms, and pharmacokinetics of anticholinergic bronchodilators available in the United States. Generally, anticholinergic agents have been found to be as effective as β agonists in airflow improvement in COPD but less so in asthma. A nasal formulation of ipratropium is also available for relief of allergic and nonallergic perennial rhinitis, including the common cold.

TABLE 36.3 Inhaled Anticholinergic Bronchodilator Agents

Drug	Brand Name	Adult Dosage	Time Course (Onset, Peak, Duration)
Ipratropium bromide	Atrovent HFA	HFA MDI: 17 mcg/puff; 2 puffs qid[a] SVN: 0.02% solution (0.2 mg/mL), 500 mcg tid, qid Nasal spray: 21 mcg; 42 mcg; 2 sprays per nostril 2–4 times qd (dosage varies)	*Onset:* 15–30 min *Peak:* 1–2 h *Duration:* 6 h
Ipratropium bromide and albuterol	Combivent Respimat	SMI: ipratropium 20 mcg and albuterol 100 mcg/puff, 1 inhalation qid SVN: ipratropium 0.5 mg and albuterol 2.5 mg	*Onset:* 15 min *Peak:* 1–2 h *Duration:* 6 h
Aclidinium bromide	Tudorza Pressair	DPI: 400 mcg/inhalation, 1 inhalation bid	*Onset:* 10 min *Peak:* 2 h *Duration:* 12
Glycopyrrolate bromide	Lonhala Magnair Seebri Neohaler	VMN: 25 mcg/1 mL bid DPI: 15.6 mcg/inhalation bid	*Onset: 15–30 min* *Peak: 1–2 h* *Duration: 12 h*
Glycopyrrolate bromide and formoterol	Bevespi Aerosphere	MDI: 9 mcg/inhalation and 4.8 mcg/inhalation bid	*Onset: 5–15 min* *Peak: 30 min–1 h* *Duration: 12 h*
Glycopyrrolate bromide and indacaterol	Ubitron Neohaler	DPI: 15.6 mcg/inhalation and 27.5 mcg/inhalation bid	*Onset: 5–15 min* *Peak: 30 min-1 h* *Duration: 12 h*
Tiotropium bromide	Spiriva; Spiriva Respimat	DPI: 18 mcg/inhalation, 1 inhalation from 1 capsule qd SMI: 2.5 mcg/inhalation, 2 inhalations qd (COPD) SMI: 1.25 mcg/inhalation, 2 inhalations qd (asthma)	*Onset:* 30 min *Peak:* 1–3 h *Duration:* 24 h
Tiotropium bromide and olodaterol	Stiolto Respimat	SMI: tiotropium 2.5 mcg/inhalation and olodaterol 2.5 mcg/inhalation, 2 inhalations qd	*Onset:* 15 min *Peak:* 1–2 h *Duration:* 24 h
Umeclidinium bromide	Incruse Ellipta	DPI: 62.5 mcg/inhalation, 1 inhalation qd	*Onset:* 5–15 min *Peak:* 1–3 h *Duration:* 24 h
Umeclidinium bromide and vilanterol	Anoro Ellipta	DPI: umeclidinium 62.5 mcg/inhalation and vilanterol 25 mcg/inhalation, 1 inhalation qd	*Onset:* 5–15 min *Peak:* 1–3 h *Duration:* 24 h

[a]A holding chamber is recommended with MDI administration to prevent accidental eye exposure.
COPD, Chronic obstructive pulmonary disease; *DPI,* Dry-powder inhaler; *HFA,* hydrofluoroalkane; *MDI,* metered-dose inhaler; *SMI,* soft-mist inhaler; *SVN,* small-volume nebulizer

Indication for Anticholinergic Bronchodilators

Anticholinergic agents are indicated as bronchodilators for maintenance treatment in COPD, including chronic bronchitis and emphysema. Additionally, tiotropium is now used as an add-on treatment for asthma when first-line agents (e.g., LABA and inhaled corticosteroids) have been less effective.

Indication for Combined Anticholinergic and β-Agonist Bronchodilators

A combination anticholinergic and β agonist, such as ipratropium bromide and albuterol (Combivent Respimat, DuoNeb), is indicated for use in patients with COPD receiving regular treatment who require additional bronchodilation for relief of airflow obstruction. Ipratropium bromide is also commonly used in severe asthma in addition to β agonists, especially in acute bronchoconstriction that does not respond well to β-agonist therapy.

Mechanism of Action

Anticholinergic or antimuscarinic agents act as competitive antagonists for acetylcholine at muscarinic receptors on airway smooth muscle. Part of the airflow obstruction in COPD may be due to vagally mediated reflex cholinergic stimulation. Airway irritation and inflammation stimulate afferent sensory C fibers in the airway, which synapse with efferent vagal (cholinergic) fibers to the airway and mucous glands. The muscarinic receptor subtype on smooth muscle and submucosal mucous glands is the M_3 receptor, which is a G protein–linked receptor. The effect of acetylcholine, the usual neurotransmitter, on the muscarinic (M_3) receptors on airway smooth muscle is bronchoconstriction.

All anticholinergic agents have affinity for M_1, M_2, and M_3 receptors; however, the main difference is how slowly they dissociate from the receptor. Ipratropium dissociates much faster; therefore it does not have as long a duration. Aclidinium, glycopyrrolate, tiotropium, and umeclidinium dissociate from the M_3 receptor much more slowly, allowing for a much longer duration of action.[22] The site of action of anticholinergic agents in reversing cholinergic-induced airflow obstruction is shown in Fig. 36.4.

Adverse Effects

Side effects of inhaled anticholinergics usually include the local topical effect of dry mouth, pupillary dilation, lens paralysis, increased intraocular pressure, increased heart rate, urinary retention, and altered mental state. Box 36.2 details the common side effects of anticholinergics.

BOX 36.2 Side Effects Seen With Anticholinergic Aerosol Agents

SVN, MDI, and DPI (Common)
- Cough, dry mouth

MDI (Occasional)
- Nervousness, irritation, dizziness, headache, palpitation, rash

SVN and DPI
- Pharyngitis, dyspnea, flu-like symptoms, bronchitis, upper respiratory tract infections, nausea, occasional bronchoconstriction, eye pain, urinary retention

PRECAUTIONS: Use with caution in patients with narrow-angle glaucoma, prostatic hypertrophy, bladder neck obstruction, constipation, bowel obstruction, or tachycardia.
Side effects were reported in a small percentage (1%–5%) of patients.
DPI, Dry-powder inhaler; *MDI,* metered dose inhaler; *SVN,* small-volume nebulizer.

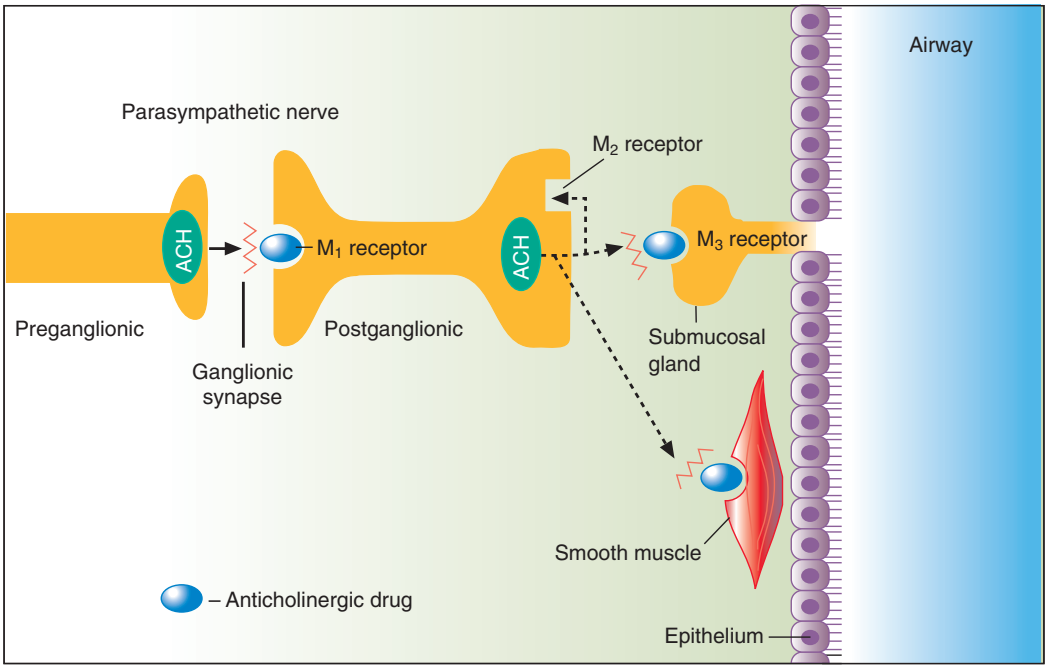

Fig. 36.4 Mechanism of action of anticholinergic agents in blocking muscarinic receptors in the airway to inhibit cholinergic-induced bronchoconstriction. *ACH,* Acetylcholine. (From Gardenhire DS: *Rau's Respiratory Care Pharmacology*, ed 10, St. Louis, 2020, Elsevier.)

The actual amount of drug delivered should be considered; for example, the nebulizer dose of ipratropium is more than 10 times greater than the MDI dose (500 vs 34 mcg). If a patient receives approximately 10% of the SVN volume in the lung, a much larger dose is given with an SVN than with an MDI. Although ipratropium is not contraindicated in patients with prostatic hypertrophy, urinary retention, or glaucoma, the drug should be used with caution and adequate evaluation for possible systemic side effects in these patients. Specifically, it is recommended that patients with certain forms of glaucoma use a mouthpiece and not a mask when they are taking ipratropium bromide via SVN. The eyes must be protected from drug exposure with aerosol use due to accidental spraying from an MDI. There is less chance for eye exposure with the MDI formulation than the SVN solution; a holding chamber is recommended with MDI use.

Assessment

Assessment of bronchodilator therapy with an anticholinergic agent is the same as assessment for adrenergic agents. In addition, preexisting conditions of narrow-angle glaucoma, prostatic hypertrophy, or urinary retention warrant caution with continued evaluation.

MUCUS-CONTROLLING AGENTS

The two agents approved in the United States for oral inhalation with an effect on mucus are *N*-acetyl cysteine (NAC) and dornase alfa. Both agents are mucolytic, although their mechanisms of action differ. Table 36.4 lists these agents along with their formulations, dosages, and bland aqueous aerosols. A review by Balsamo[23] provides additional detail.

N-Acetyl Cysteine

NAC is the *N*-acetyl derivative of the amino acid L-cysteine and is given by either nebulization or direct tracheal instillation.

Indications for Use

NAC is indicated to reduce the accumulation of airway secretions with concomitant improvement in pulmonary function and gas exchange and the prevention of recurrent respiratory infection and airway damage. Diseases of excessive viscous mucous secretions and poor airway clearance include COPD, acute tracheobronchitis, and bronchiectasis. NAC is also used to treat or prevent liver damage that can occur when a patient takes an overdose of acetaminophen.[24] Despite excellent in vitro mucolytic activity and a long history of use, no data clearly demonstrate that oral or aerosolized NAC is effective therapy for treating lung disease.[25] However, in a meta-analysis, Cazzola and colleagues suggest that patients with chronic bronchitis and COPD who were treated with oral NAC had fewer exacerbations.[26]

Mechanism of Action

NAC acts as a classic mucolytic to reduce the viscosity of mucus by substituting its own sulfhydryl group for the disulfide group in mucus, breaking a portion of the bond forming the gel structure. When NAC comes into physical contact with mucus, it begins to reduce viscosity, and mucolytic activity increases with a higher pH of 7.0 to 9.0.

MINI CLINI

Calculating Drug Doses

Problem

The dose of ipratropium bromide (Atrovent) released from the valve of the MDI is 17 mcg. With a usual dose of two actuations, this would release 34 mcg total. The SVN solution is a vial of 2.5 mL of 0.02% strength (concentration), all of which is placed in the nebulizer. Does the nebulizer dose contain the same amount of drug as the two actuations from the MDI?

Discussion

The amount of drug in milligrams or micrograms can be calculated for the nebulizer solution by using the following formula for percentage strength:

$$\%\,(\text{as decimal}) = \frac{\text{Drug solute (in g)}}{\text{Total solution (in mL)}}$$

$$0.0002 = \frac{x\ \text{g}}{2.5\ \text{mL}}$$

$$x\ \text{g} = 0.0002 \times 2.5\ \text{mL} = 0.0005\ \text{g}$$

Converting 0.0005 g to milligrams gives 0.5 mg, or 500 mcg. Two actuations of the MDI release 34 mcg, whereas the dose contained in the SVN is 500 mcg (or >10 times more). The lower-dose MDI is the reason that additional actuations of four or six are needed if a patient does not obtain relief. The SVN solution may also provide relief by giving a higher dose of the drug.

TABLE 36.4 Mucoactive Agents Available for Aerosol Administration

Drug	Brand Name	Adult Dosage	Use
N-acetylcysteine 10% N-acetylcysteine 20%	Mucomyst	SVN: 3–5 mL	Efficacy has not been demonstrated for any lung disease
Dornase alfa	Pulmozyme	SVN: 2.5 mg/ampule, 1 ampule qd[a]	CF
Aqueous water, saline		SVN: 3–5 mL, as ordered	Sputum induction
Hyperosmolar 3-7% saline	Hypersal Pulmosal	SVN: 4 mL	Airway clearance
Mannitol	Bronchitol[b]	DPI: 400 mg, bid	Airway clearance in CF

[a]Nebulizer system recommended (see package insert).
[b]Orphan designation only.
CF, Cystic fibrosis; *DPI,* dry power inhaler; *SVN,* small-volume nebulizer.

Side Effects

Because of its several side effects, NAC has come to be less used in patients with hypersecretory states. The drug is irritating to the airway and can produce bronchospasm, especially in individuals with asthma and hyperreactive airways. The general effect of airway irritation works against the goal of lessening the hypersecretion of mucus. To reduce the occurrence of bronchospasm, use of the 10% solution, which is less hypertonic than the 20% solution, is recommended. Pretreatment with an adrenergic bronchodilator, allowing adequate time for a bronchodilator effect, can prevent or reduce airflow obstruction caused by NAC.

Other side effects that can occur include the following:

- Airway obstruction secondary to rapid liquefaction of secretions
- Disagreeable odor secondary to hydrogen sulfide
- Incompatibility with certain antibiotics (sodium ampicillin, amphotericin B, erythromycin, tetracyclines, and aminoglycosides) if mixed in solution
- Increased concentration and toxicity of nebulizer solution toward end of treatment (It is recommended to dilute with equal volume of sterile water to reduce a concentration that might lead to airway irritation.)
- Nausea and rhinorrhea

MINI CLINI

Calculating Drug Doses of Differing Percent Strengths

Problem

A health care practitioner orders 4 mL of 10% Mucomyst (NAC) for her patient. The RT finds that the supplier carries only 20% Mucomyst. How would she determine the correct amount of 20% Mucomyst solution to use in order to provide 4 mL of 10% Mucomyst solution?

Discussion

When the active ingredient or solute is already diluted less than 100%, the following equation, solving for *x*, can be used:

$$\%\,(\text{as decimal}) = \frac{\text{Drug solute} \times \text{Percent strength of solute (as decimal)}}{\text{Total solution}}$$

$$0.10 = \frac{x\,(0.20)}{4\text{ mL}}$$

$$x = \frac{4(0.10)}{0.20}$$

$$x = 2\text{ mL of 20\% Mucomyst}$$

No matter the percent strength, multiplying the percent strength (in decimal form) with the amount of ordered solute and dividing by the original percent strength that is utilized will determine the amount needed. Alternatively, it can be viewed in terms of milligrams (mg) ordered. In the previous example, the ordered amount was 4 mL of 10% Mucomyst. If you know that 1% solution equals 10 mg/mL of drug, you can easily calculate that 10% = 100 mg/mL. The order is for 4 mL, so 4 × 100 = 400 mg. The order is asking to give 400 mg; therefore if you have 20% Mucomyst (200 mg/mL), you would have to provide 2 mL of 20% Mucomyst.

- Stomatitis
- Reactivity of acetylcysteine with rubber, copper, iron, and cork

Dornase Alfa

Dornase alfa (Pulmozyme) is a genetically engineered clone of the natural human pancreatic DNase enzyme, which can digest extracellular DNA material. It is a peptide mucolytic and can reduce extracellular DNA and F-actin polymers. It is occasionally referred to as *rhDNase* (recombinant human DNase). It is designated as an orphan drug. Administration and dosage are given in Table 36.4.

Indication for Use

Dornase alfa is indicated in the management of CF to reduce the frequency of respiratory infections requiring parenteral antibiotics and to improve these patients' pulmonary function.[27]

Mechanism of Action

Dornase alfa is a proteolytic enzyme that can break down the DNA material from neutrophils found in purulent secretions (Fig. 36.5). This agent is more effective than acetylcysteine in reducing the viscosity of infected sputum in CF.[28]

Side Effects

In contrast to its predecessor, pancreatic dornase (Dornavac), a natural enzyme obtained from animal preparations, dornase alfa has not been shown to produce antibodies that might cause allergic reactions, including bronchospasm. Common side effects associated with the drug include pharyngitis and voice alteration, laryngitis, rash, chest pain, and conjunctivitis. Other effects are less common but are reported as various respiratory symptoms (cough, dyspnea, pneumothorax, hemoptysis, rhinitis, sinusitis), flu syndrome, GI obstruction, hypoxemia, malaise, and weight loss. Contraindications to the drug include hypersensitivity to dornase, Chinese hamster ovary (CHO) cell products, or other components of the drug preparation.

Other Mucoactive Agents

Bland aerosols of water—including distilled water and normotonic, hypertonic, and hypotonic saline—have traditionally been nebulized to improve the mobilization of secretions in respiratory disease states. The mucous gel layer is relatively resistant to the addition or removal of water after it is formed. Bland aerosols have been found to increase the clearance of secretions, to improve sputum production, and to enable productive coughing. The effect is probably a vagally mediated reflex production of cough and secretion of mucus. Bland aerosols are more properly considered expectorants rather than mucolytic agents. Clinicians must be alert to the possibility of bronchospasm with nonisotonic solutions, in particular in patients with hyperreactive airways. Studies have confirmed that long-term use of inhaled hypertonic saline improves pulmonary function in patients with CF.[29] Additionally, hypertonic saline has been found favorable in treating bronchiectasis. Inhaled hypertonic saline is inexpensive and is recommended as part of the treatment regimen for CF.

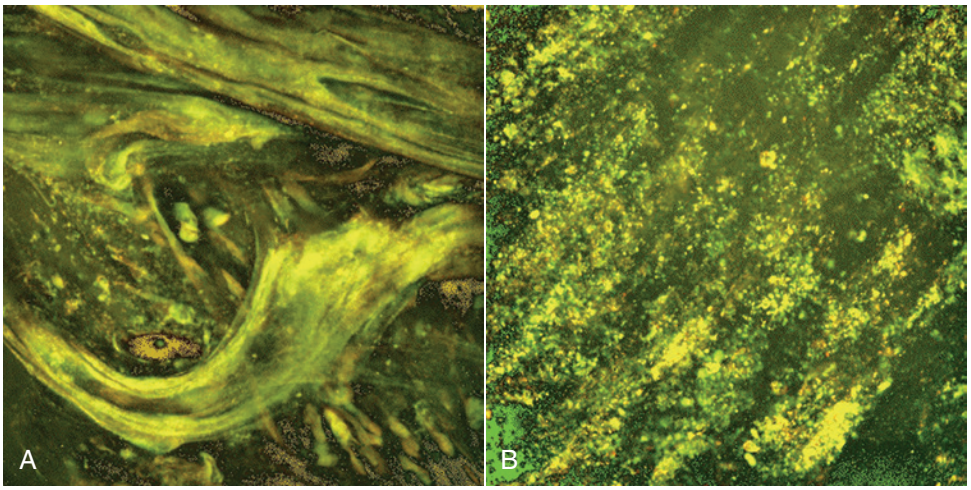

Fig. 36.5 Illustration of the mechanism of action of dornase alfa in reducing DNA polymers in cystic fibrosis (CF) sputum. Confocal micrograph showing CF sputum stained (with YOYO-1) for DNA before (A) and after (B) treatment with dornase alfa in vitro. The long DNA polymers are degraded after dornase treatment. (From Gardenhire DS: *Rau's Respiratory Care Pharmacology*, ed 10, St. Louis, 2020, Elsevier.)

Inhaled mannitol administered by DPI (Bronchitol) has been approved outside the United States. Studies have shown inhaled mannitol to be safe and well tolerated in treating patients with CF or bronchiectasis. However, because some children with CF experience bronchial hyperreactivity with inhaled mannitol,[30] it is important to pretreat with a short-acting bronchodilator before use.

Sodium bicarbonate has been aerosolized and directly instilled into the airway in intubated patients to reduce the viscosity of airway secretions. This agent is not approved for such use. The reduction in secretion viscosity is thought to be caused by the increase in topical airway pH, with degradation of bonding in the mucin polysaccharide.

Expectorants are mucoactive but stimulate the production and clearance of airway secretions rather than causing mucolysis. Examples of such agents include guaifenesin (also known as glyceryl guaiacolate), iodinated glycerol, and saturated solution of potassium iodide (SSKI). Guaifenesin is found in many over-the-counter cough and cold products.

Assessment of Mucoactive Drug Therapy

Assessment of drug therapy for respiratory secretions is difficult. FEV_1 is relatively insensitive to changes in mucociliary clearance. The rate of change in lung function over time is a better marker. In addition, during maintenance therapy, the volume of sputum expectorated varies from day to day and does not reflect effective therapy. The following assessments should be performed.

Before Treatment

- Assess the patient's adequacy of cough and level of consciousness to determine need for treatment with mechanical suctioning or adjunct bronchial hygiene (postural drainage or percussion, positive expiratory pressure therapy) to clear the airway or if treatment is contraindicated.

During Treatment and in the Short Term

- Teach and then verify correct use of aerosol nebulization system, including cleaning.
- Assess therapy based on indication for drug.
- Monitor changes in FEV_1.
- Assess the patient's breathing pattern and rate.
- Assess the patient's breathing effort or pattern.
- Discontinue therapy if the patient experiences adverse reactions.

In the Long Term

- Discontinue therapy if the patient experiences adverse reactions.
- Monitor number and severity of respiratory tract infections and need for antibiotic therapy, emergency visits, and hospitalizations.
- Monitor pulmonary function for improvement or slowing in the rate of deterioration.

General Contraindications

Mucoactive therapy should be used with caution in patients with severely compromised vital capacity and expiratory flow, as in the presence of end-stage pulmonary disease or neuromuscular disorders. Generally, if FEV_1 is less than 25% of predicted, it becomes difficult to mobilize and expectorate secretions. Theoretically, with profound airflow compromise, clearance of secretions could decline.

Gastroesophageal reflux and inability of the patient to protect the airway are risk factors for postural drainage that should be considered if postural drainage is necessary with mucoactive therapy. Mucoactive agents should be discontinued if there is evidence of clinical deterioration. Patients with acute bronchitis or exacerbation of chronic disease (CF, COPD) may be less responsive to mucoactive therapy, possibly secondary to infection and muscular weakness, which can reduce airflow-dependent mechanisms further.

BOX 36.3 Potential Hazards and Side Effects of Aerosolized Corticosteroids

Systemic

- Adrenal insufficiency[a,b]
- Extrapulmonary allergy[a]
- Acute asthma[a]
- HPA suppression (minimal, dose dependent)
- Growth retardation[b]
- Osteoporosis[b]

Local (Topical)

- Oropharyngeal fungal infections
- Dysphonia
- Cough, bronchoconstriction
- Incorrect use of MDI

[a]Following substitution for systemic corticosteroid therapy.
[b]Effect with inhaled corticosteroids alone is unclear.
HPA, Hypothalamo-pituitary-adrenocortical; *MDI,* metered dose inhaler.

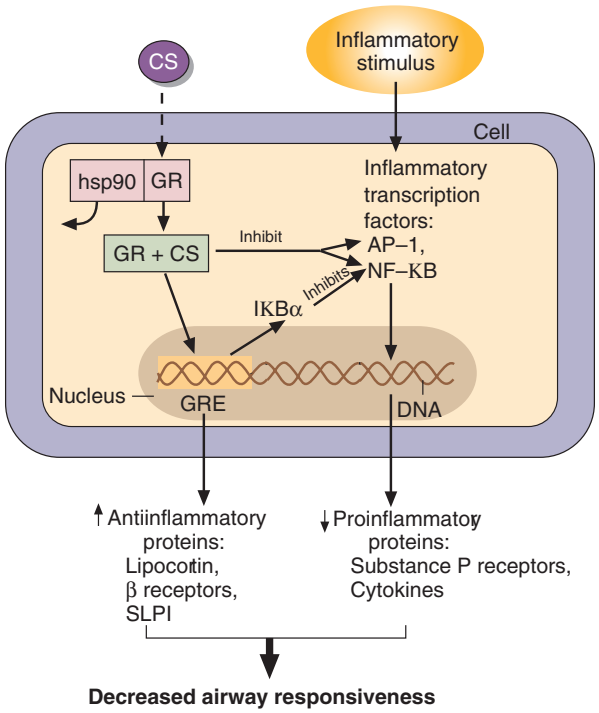

Fig. 36.6 Mechanism of action by which corticosteroids modify cell response to inhibit inflammatory response in the airway. Corticosteroids *(CS)* diffuse into the cell and bind to a glucocorticoid receptor *(GR).* When the steroid binds to the GR, a protein, heatshock protein 90 (hsp 90), dissociates from the GR, and the steroid-GR complex moves into the cell nucleus. The drug-receptor complex binds to glucocorticoid response elements *(GREs)* of the nuclear DNA to upregulate transcription of antiinflammatory substances such as lipocortin, a protein that inhibits the generation of the arachidonic acid cascade by phospholipase A_2. There is evidence that steroids also upregulate inhibitors of factors in the cell, such as nuclear factor-κB (NF-κB), which can cause transcription of inflammatory substances. There may be direct inhibition of factors such as NF-κB to limit the inflammatory process further. *AP-1,* activator protein-1; *iκBα,* inhibitor of nuclear factor-κBα; *SLPI,* secretory leukocyte protease inhibitor. (From Gardenhire DS: *Rau's Respiratory Care Pharmacology*, ed 10, St. Louis, 2020, Elsevier.)

INHALED CORTICOSTEROIDS

Corticosteroids are endogenous hormones produced in the adrenal cortex that regulate basic metabolic functions in the body and exert an antiinflammatory effect. The use of aerosolized corticosteroids is reviewed in this section. All corticosteroids used to treat asthma and COPD are glucocorticoids.

Indications and Purposes

The two general formulations of aerosolized glucocorticoids are orally inhaled and intranasal aerosol preparations. Orally inhaled preparations are listed in Table 36.5. The primary use of orally inhaled corticosteroids is for antiinflammatory maintenance therapy of persistent asthma[6] and severe COPD.[31] The use of intranasal steroids is for control of seasonal allergic or nonallergic rhinitis. With the exception of the combination drugs, most agents in Table 36.5 are available as intranasal preparations.

Mechanism of Action

Glucocorticoids are lipid-soluble drugs that act on intracellular receptors. The complex action of steroids is illustrated in Fig. 36.6.[32–33] It is important for patients to understand that inhalation of an aerosolized steroid does not provide immediate relief, as with an adrenergic bronchodilator. However, daily compliance with the inhaled medication is essential to controlling the inflammation of asthma. Oral corticosteroids may be needed initially to clear the airway or as "burst" therapy to control asthma or COPD exacerbations.

Adverse Effects

As with other classes of aerosolized drugs, the types and severity of side effects seen with inhaled aerosolized corticosteroids are much less than with systemic use of these drugs. Box 36.3 lists systemic and local effects that can occur with inhaled steroids. The systemic effect of adrenal suppression is not usually seen with inhaled doses less than 800 mcg/day in adults or less than 400 mcg/day in children. Use of a reservoir device should be routine with inhaled steroids so as to prevent the swallowed portion from adding to the systemic effect and to prevent the local effects of oral candidiasis and dysphonia.

RULE OF THUMB: Mouth Rinsing With Inhaled Corticosteroids
Instruction should be given to patients receiving inhaled corticosteroids to reduce common local effects of oral candidiasis (thrush) and dysphonia. The use of a reservoir (preferably a holding chamber) with MDI reduces impaction of corticosteroids in the oral cavity. No matter the aerosol device, a patient should *always* rinse his or her mouth with water and spit at the conclusion of therapy.

Special Considerations

The mechanisms of action of all inhaled glucocorticoids are the same with one exception: ciclesonide, a **prodrug,** is given as an inactive compound and is converted to an active metabolite, desisobutyryl ciclesonide, by intracellular enzymes. Ciclesonide is available as an intranasal formulation (Omnaris, Zetonna) and a pressurized MDI (Alvesco).

TABLE 36.5 Corticosteroids and Combination Products Available by Aerosol for Oral Inhalation

Drug	Brand Name	Formulation and Dosage
Beclomethasone dipropionate	QVAR Redihaler	MDI: 40 and 80 mcg/puff
		Adults and children ≥12 years: 40–80 mcg bid[a] or 40–160 mcg bid[b]
		Children ≥4 years: 40–80 mcg bid
Ciclesonide	Alvesco	MDI: 80 mcg/puff and 160 mcg/puff
		Adults and children ≥12 years: 80–160 mcg bid[a] or 80–320 mcg bid[b]
Flunisolide hemihydrate	AeroSpan	MDI: 80 mcg/puff
		Adults and children ≥12 years: 2 puffs bid, adults no more than 4 puffs qd[c]
		Children 6–11 years: 1 puff qd, no more than 2 puffs qd
Fluticasone propionate	Flovent HFA	MDI: 44, 110, and 220 mcg/puff
		Adults and children ≥12 years: 88 mcg bid,[a] 88–220 mcg bid,[b] or 880 mcg bid[c]
		Children 4–11 years: 88 mcg bid[d]
	Flovent Diskus	DPI: 50, 100, and 250 mcg
		Adults and children ≥12 years: 100 mcg bid,[a] 100–250 mcg bid,[b] 1000 mcg bid[c]
		Children 4–11 years: 50 mcg bid
	Armonair Respiclick	DPI: 55, 113, 232 mcg/puff
		Adults and children ≥12 years: 55–232 mcg bid
Fluticasone furoate	Arnuity Ellipta	DPI: 50 mcg/actuation, 100 mcg/actuation and 200 mcg/actuation
		Adults ≥12 years: 100 mcg or 200 mcg, qd
		Children≥5 years: 50 mcg qd
Budesonide	Pulmicort Flexhaler	DPI: 90 mcg/actuation and 180 mcg/actuation
		Adults and children ≥12 years: 180–360 mcg bid,[a] 180–360 mcg bid,[b] 360–720 mcg bid[c]
		Children ≥6 years: 180–360 mcg bid
	Pulmicort Respules	SVN: 0.25 mg/2 mL, 0.5 mg/2 mL, 1 mg/2 mL
		Children 1–8 years: 0.5-mg total dose given qd or bid in divided doses[a,b] 1 mg given as 0.5 mg bid or qd[c]
Mometasone furoate	Asmanex Twisthaler	DPI: 110 mcg/actuation; or 220 mcg actuation
		Adults and children ≥12 years: 220–440 mcg qd,[a] 220–440 mcg qd,[b] 440–880 mcg qd[c]; children 4–11 years: 110–220 mcg qd
	Asmanex HFA	MDI: 100 mcg/actuation; or 200 mcg actuation
		Adults and children ≥12 years: 100–200 mcg bid
Fluticasone propionate/ salmeterol	Advair Diskus	DPI: 100 mcg fluticasone/50 mcg salmeterol, 250 mcg fluticasone/50 mcg salmeterol, or 500 mcg fluticasone/50 mcg salmeterol
		Adults and children ≥12 years: 100 mcg fluticasone/50 mcg salmeterol, 1 inhalation bid, ~12 h apart (starting dose if not currently taking inhaled corticosteroids)
		Maximal recommended dose 500 mcg fluticasone/50 mcg salmeterol bid
		Children ≥4 years: 100 mcg fluticasone/50 mcg salmeterol, 1 inhalation bid, ~12 h apart (for patients who are symptomatic while taking an inhaled corticosteroid)[c]
	Advair HFA	MDI: 45 mcg fluticasone/21 mcg salmeterol, 115 mcg fluticasone/21 mcg salmeterol, or 230 mcg fluticasone/21 mcg salmeterol[c]
		Adults and children ≥12 years: 2 inhalations bid, ~12 h apart
	AirDuo Respiclick	DPI: 55 fluticasone/14 salmeterol, 113 fluticasone/14 salmeterol, or 232 mcg fluticasone/14 mcg salmeterol
		Adults and children ≥12 years: Respiclick, Any dose combination, 1 inhalation bid
Budesonide/formoterol fumarate HFA	Symbicort	MDI: 80 mcg budesonide/4.5 mcg formoterol and 160 mcg budesonide/4.5 mcg formoterol bid
		Adults and children ≥12 years: 320 mcg budesonide/9 mcg formoterol; or 160 mcg budesonide/9 mcg formoterol bid
Mometasone furoate/ formoterol fumarate HFA	Dulera	MDI: 100 mcg mometasone/5 mcg formoterol and 200 mcg mometasone/5 mcg formoterol
		Adults and children ≥12 years: If previously on medium dose of corticosteroids, ≤400 mcg mometasone/20 mcg formoterol qd; if previously on high dose of corticosteroid, ≤800 mcg mometasone/20 mcg formoterol qd
Fluticasone furoate/vilanterol	Breo Ellipta	DPI: 100 mcg fluticasone/25 mcg vilanterol and 200 μg fluticasone/25 mcg vilanterol
		Adults: 100 mcg fluticasone/25 mcg vilanterol qd and 200 mcg fluticasone/25 mcg vilanterol qd
Fluticasone furoate/ umeclidinium/vilanterol	Trelegy Ellipta	DPI: Adults, 100 mcg fluticasone furoate/62.5 mcg umeclidinium/25 mcg vilanterol, qd

[a]Recommended starting dose if taking only bronchodilators.
[b]Recommended starting dose if previously taking inhaled corticosteroids.
[c]Recommended starting dose if previously taking oral corticosteroids.
[d]This dose should be used regardless of previous therapy.
Individual agents are discussed in the text. Detailed information about each agent should be obtained from the manufacturer's drug insert.
HFA, Hydrofluoroalkane.

Assessment of Drug Therapy

The basic actions to evaluate an aerosol drug treatment should be followed (see Assessment of Bronchodilator Therapy, earlier). As with other drug therapy, the indications for this class of drug should be present. The NAEPP and Global Initiative on Obstructive Lung Disease (GOLD) COPD guidelines are recommended for guidance.[6,31] In addition, with inhaled corticosteroids, the following actions are suggested:

- Verify that the patient understands that a corticosteroid is a controller agent and is different from a rescue bronchodilator; assess the patient's understanding of the need for consistent use of an inhaled corticosteroid (compliance).
- Instruct the patient in the use of a peak flow meter to monitor baseline peak expiratory flow (PEF) and changes. Verify that there is a specific action plan based on symptoms and PEF results. The patient should understand when to contact a physician with deterioration in PEF or exacerbation of symptoms.

In the Long Term

- Assess severity of symptoms (coughing, wheezing, nocturnal awakenings, symptoms during exertion; use of rescue bronchodilator; number of exacerbations; missed work or school days; and pulmonary function) and modify level or dosage as recommended by NAEPP and GOLD guidelines.[6,31]
- Assess for the presence of side effects with inhaled steroid therapy (oral thrush, hoarseness or voice changes, cough or wheezing with MDI use); use a reservoir (preferably a holding chamber) with MDI use, and verify correct technique.
- Ophthalmologic assessment may be needed for long-term use of inhaled corticosteroids (ICSs), it can be associated with cataracts and glaucoma.

MINI CLINI

Patient Education

Problem

A 24-year-old patient with asthma has complained of waking up at night and being short of breath. She also reports feeling tightness in her chest and needs to use her albuterol inhaler 5–6 days/week to get relief. She is not currently on other inhaled medications. Her allergist prescribes an inhaled MDI corticosteroid and salmeterol to be taken on a daily basis. What instructions should she be given in using these agents by inhalation?

Discussion

The key points with corticosteroid inhalation should be reviewed. These are small doses and safe to take. However, it is important to take the prescribed corticosteroid dose regularly every day if the drug is to have an antiinflammatory effect in the lung. The patient should also use a reservoir device with the MDI. Rinsing her mouth with water after a treatment can reduce further the chance of oral candidiasis or dysphonia. With salmeterol, she should be instructed to follow her prescribed dose, which is usually two inhalations twice daily. Because of its pharmacokinetics, salmeterol is considered a long-term controller and not a quick reliever. It is not helpful in relieving bronchospasm if the patient experiences acute difficulty in breathing. For acute respiratory problems, she should have a quick-acting adrenergic agent such as albuterol or levalbuterol. If she experiences wheezing or chest tightness, one or two actuations of one of these agents would help. Salmeterol should be taken at the regularly prescribed time, usually every 12 h.

NONSTEROIDAL ANTIASTHMA DRUGS

Nonsteroidal antiinflammatory drugs constitute a growing class of drugs in the treatment of asthma. These include antileukotrienes, also termed **leukotriene** modifiers (zafirlukast, zileuton, montelukast) and monoclonal antibodies (benralizumab, mepolizumab, omalizumab, and relizumab). Antileukotrienes are administered orally and monoclonal antibody agents are given parenterally, but these are included as bronchoactive drugs. Table 36.6 lists the pharmaceutical details for each agent.

Indication for Use

The general indication for the clinical use of nonsteroidal antiasthma agents is prophylactic management (control) of persistent asthma (step 2 or greater asthma, using the classification in the NAEPP guidelines[6]). *Step 2 asthma* is defined as more than 2 days/week with (but not daily) symptoms and more than 2 nights/month with awakenings and FEV_1 of 80% or greater. *Step 3 asthma* is defined as daily symptoms and 3–4 nights/month with awakening and FEV_1 greater than 60% but less than 80%. *Step 4 and above asthma* is defined as symptoms throughout the day as well as night awakenings more than once per week and FEV_1 less than 60%.

The following are qualifications to the general indications for use of these agents:

- Antileukotrienes are typically recommended as alternatives to introducing inhaled corticosteroids in step 2 and 3 asthma.
- Antileukotrienes, montelukast in particular, are often used in infants and young children as alternatives to inhaled corticosteroids in step 2 asthma because of their safety profiles.
- Antileukotrienes can be useful in combination with inhaled steroids to reduce the dose of the steroid and are listed as alternatives in step 2 through 4 asthma.
- The monoclonal antibodies benralizumab, mepolizumab, omalizumab and relizumab are available for consideration in the appropriate population.[34–37]

All of the nonsteroidal antiasthma drugs described in this chapter are controllers, not relievers, and are used in asthma requiring antiinflammatory drug therapy (Box 36.4).

Mechanism of Action

Zafirlukast and montelukast act as leukotriene receptor antagonists and are selective competitive antagonists of leukotriene receptors LTD_4 and LTE_4. Leukotrienes such as LTC_4, LTD_4, and LTE_4 (previously known as *SRS-A*) stimulate leukotriene receptors termed $CysLT_1$ to cause bronchoconstriction, secretion of mucus, vascular permeability, and plasma exudation into the airway. The mechansim of action is shown in Fig. 36.7. The drug inhibits asthma reactions induced by exercise, cold air, allergens, and aspirin.

Zileuton inhibits the 5-lipoxygenase enzyme that catalyzes the formation of leukotrienes from arachidonic acid (see Fig. 36.7). Omalizumab is a recombinant DNA–derived humanized antibody that binds to immunoglobulin E (IgE). The agent inhibits the attachment of IgE to mast cells and basophils, reducing the release of chemical mediators of the allergic response.

TABLE 36.6 Nonsteroidal Antiasthma Medications

Generic Drug	Brand Name	Formulation and Dosage
Antileukotrienes		
Zafirlukast	Accolate	Tablets: 10 and 20 mg Adults and children ≥12 years: 20 mg bid, without food Children 5–11 years: 10 mg bid
Montelukast	Singulair	Tablets: 10 mg and 4-mg and 5-mg cherry-flavored chewable; 4-mg packet of granules Adults and children ≥15 years: One 10-mg tablet qd Children 6–14 years: One 5-mg chewable tablet qd Children 2–5 years: One 4-mg chewable tablet or one 4-mg packet of granules qd 6–23 months: One 4-mg packet of granules qd
Zileuton	Zyflo; Zyflo CR	Tablets: 600 mg Adults and children ≥12 years: One 600-mg tablet 4 qid; CR, 2 tablets bid, within 1 h of morning and evening meals
Monoclonal Antibody		
Omalizumab	Xolair	Adults and children ≥12 years: subcutaneous injection q 4 wk; dose dependent on weight and serum immunoglobulin E level
Benralizumab	Faserna	Adults and children ≥12 years: SQ: 30 mg, q4wk
Mepolizumab	Nucala	Adults and children ≥12 years: SQ: 100 mg, q4wk
Relizumab	Cinqair	Adults and children ≥1 years: IV: 3 mg/kg, q4wk

Detailed prescribing information should be obtained from the manufacturer's package insert.

BOX 36.4 Bronchoactive Agents Distinguished as Controllers or Relievers in Treating Asthma

Long-Term Control

- Inhaled corticosteroids
- Long-acting β2 agonists
  - Inhaled: salmeterol, formoterol
  - Oral: sustained-release albuterol
- Leukotriene modifiers
- Systemic corticosteroids
- Methylxanthines (theophylline)

Quick Relief

- Short-acting inhaled β2 agonists: albuterol, levalbuterol
- Anticholinergic (antimuscarinic): Ipratropium
- Systemic corticosteroids (oral burst therapy, intravenous therapy)

From National Asthma Education and Prevention Program, National Heart, Lung and Blood Institute, National Institutes of Health: *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma*. NIH Publication No. 08-4051. Bethesda, MD; 2007, National Institutes of Health.

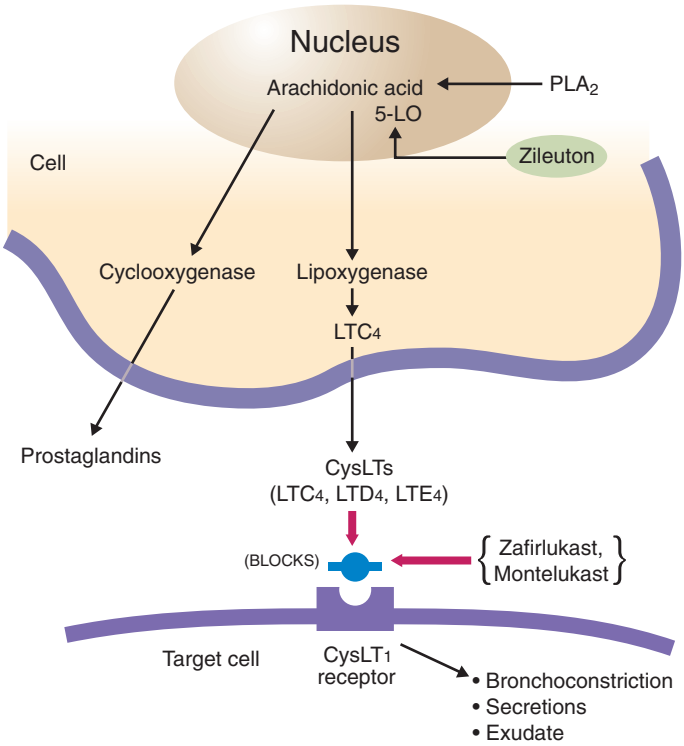

Fig. 36.7 Mechanisms and sites of action for leukotriene modifiers zileuton, zafirlukast, and montelukast. Zileuton inhibits the 5-LO enzyme, whereas zafirlukast and montelukast block the leukotriene receptor ($CysLT_1$). *LT,* Leukotriene; *PLA,* phospholipase A.

TABLE 36.7 Summary of Comparative Features of Three Available Antileukotriene Agents

Features	Zileuton	Zafirlukast	Montelukast
Brand name	Zyflo; Zyflo CR	Accolate	Singulair
Action	5-LO inhibitor	$CysLT_1$ receptor block	$CysLT_1$ receptor block
Age range	≥12 years	≥5 years	≥6 months
Dosage	600-mg tab, qid; CR: two 600-mg tab bid; 1 h within morning and evening meal	Adult: 20-mg tab bid Children 5–11 years: 10-mg tab bid	Adult: 10-mg tab hs 6–14 years: 5-mg tab hs 2–5 years: 4-mg tab hs 6–23 months: 4-mg oral granules hs
Administration	Can be taken with food	1 h before or 2 h after meal	Taken with or without food
Drug interaction	Yes (theophylline, warfarin, propranolol)	Yes (warfarin, theophylline, aspirin)	No
Side effects (common)	Headache, dyspepsia, unspecified pain, liver enzyme elevations	Headache, infection, nausea, possible liver enzyme changes	Headache, influenza, abdominal pain
Contraindications	Active liver disease or elevated liver enzyme levels, hypersensitivity to components	Hypersensitivity to components	Hypersensitivity to components

Enralizumab, mepolizumab and reslizumab block interleukin-5 (IL-5), changing the signaling of IL-5 reducing eosinophils.

Adverse Effects

A potential adverse effect with any nonsteroidal antiasthma drug is inappropriate use. These agents are not bronchodilators and offer no benefit for acute airway obstruction in asthma.

Table 36.7 summarizes information and comparative features of the three antileukotriene agents, including drug interactions, common side effects, and contraindications. The most common adverse reactions seen with monoclonal anitbodies include injection site reaction, viral infections, respiratory tract infections, headache, sinusitis, and pharyngitis.

Assessment of Drug Therapy

As with other drug therapy, the indication for this class of drug should be present.

- Verify that the patient understands that nonsteroidal antiasthma agents are controller drugs and that they differ from rescue bronchodilators; assess the patient's understanding of the need for consistent use of these agents (compliance).
- Instruct the patient in the use of a peak flow meter to monitor baseline PEF and changes. Verify that there is a specific action plan based on symptoms and PEF results. The patient should be clear on when to contact his or her physician with a deterioration in PEF or exacerbation of symptoms.

In the Long Term

- Assess the severity of symptoms—coughing, wheezing, nocturnal awakenings, symptoms during exertion, use of rescue medication, number of exacerbations, missed work or school days, pulmonary function—and modify the level of asthma therapy (up or down, as described in the NAEPP EPR III guidelines for step therapy).
- Assess for the presence of side effects with nonsteroidal antiasthma agents; refer to the particular agent and its side effects (listed previously).

AEROSOLIZED ANTIINFECTIVE AGENTS

Multiple aerosolized antiinfective agents are available. Some may be used less often than others in respiratory therapy. The antiinfective agents pentamidine, ribavirin, inhaled tobramycin, inhaled aztreonam, and zanamivir are briefly outlined here. Drug formulations and dosages are given in Table 36.8.

Pentamidine Isethionate

Pentamidine isethionate (NebuPent) is an antiprotozoal agent that has been used in the treatment of opportunistic pneumonia caused by *Pneumocystis jirovecii,* which is the causative agent of *Pneumocystis* pneumonia, or PJP (previously called PCP for *Pneumocystis carinii*). PJP is usually seen in immunocompromised patients, especially patients with AIDS with impaired immune status.

Indication for Use

General recommendations for the prophylaxis of PJP were published by the US Centers for Disease Control and Prevention (CDC) for HIV-positive children[38] and adults.[39] In the 2018 CDC recommendations, oral trimethoprim/sulfamethoxazole (TMP/SMX) is preferred for treatment and prophylaxis of PJP as long as adverse side effects from TMP/SMX were absent or acceptable.[40] Aerosolized pentamidine is recommended as an alternative therapy for primary and secondary prophylaxis of PJP; it is not recommended as a treatment.[38,39]

Adverse Effects

Possible side effects with aerosolized pentamidine include cough, bronchial irritation, bronchospasm, wheezing, shortness of breath, fatigue, bad or metallic taste, pharyngitis, conjunctivitis, rash, and chest pain. Systemic effects also have been noted with inhaled pentamidine, including decreased appetite, dizziness, rash, nausea, night sweats, chills, spontaneous pneumothoraces, **neutropenia,** pancreatitis, renal insufficiency, and hypoglycemia. Extrapulmonary infection with *P. jiroveci* can occur with prophylactic inhaled pentamidine.

TABLE 36.8 Inhaled Antiinfective Agents

Drug	Brand Name	Formulation and Dosage	Clinical Use
Pentamidine isethionate	NebuPent	300 mg powder in 6 mL sterile water; 300 mg q4wk	PJP prophylaxis
Ribavirin	Virazole	6 g powder in 300 mL sterile water (20 mg/mL solution); given q 12–18 h/day for 3–7 days by SPAG nebulizer	RSV
Tobramycin	TOBI	300-mg/5-mL ampule; adults and children ≥6 years: 300 mg bid, 28 days on/28 days off drug	*Pseudomonas aeruginosa* infection in CF
Tobramycin	Bethkis	300-mg/4-mL ampule; adults and children ≥6 years: 300 mg bid, 28 days on/28 days off drug	*P. aeruginosa* infection in CF
Aztreonam	Cayston	75 mg/1 mL; adults and children ≥7 years: 75 mg tid, 28 days on/28 days off drug	*P. aeruginosa* infection in CF
Zanamivir	Relenza	DPI: 5 mg/inhalation; adults ≥5 years: 2 inhalations (one 5-mg blister per inhalation) bid, 12 h apart for 5 days	Influenza

Details on use and administration should be obtained from manufacturer's drug insert material before use.
CF, Cystic fibrosis; *DPI,* dry-powder inhaler; *PJP, Pneumocystis jirovecii* pneumonia; *RSV,* respiratory syncytial virus; *SPAG,* small-particle aerosol generator

Assessment

When aerosolized pentamidine is being administered, an environmental containment isolation system (e.g., a booth or negative pressure room) and personnel barrier protection should be provided. Patients should be screened for tuberculosis. The drug is given using a nebulizer system with one-way valves and scavenging expiratory filters (e.g., Respirgard); this reduces environmental contamination. Nebulizer systems capable of producing a mass median diameter of 1 to 2 μm for peripheral lung deposition may reduce coughing. The patient should be monitored for onset of any of the previously described adverse reactions. In addition, the following actions are recommended:

- If coughing and bronchospasm are present, provide a short-acting β agonist or an anticholinergic bronchodilator such as ipratropium with inhaled pentamidine.
- Monitor for occurrence rate of *P. jiroveci* and rate of long-term hospitalizations.
- Monitor for presence of side effects (shortness of breath, possible pneumothorax, conjunctivitis, rash, neutropenia, dysglycemia) or appearance of extrapulmonary *P. jiroveci* infection.
- Evaluate need for prior use of a bronchodilator if symptoms of bronchospasm or coughing occur after inhalation of pentamidine.

In the Long Term

Monitor the efficacy of pentamidine prophylaxis in preventing episodes of *P. jiroveci* infection.

Ribavirin

Ribavirin (Virazole) is classified as an antiviral drug; it is active against respiratory syncytial virus (RSV), influenza viruses, and the herpes simplex virus. Recommendations for use of the drug were published in a statement by the American Academy of Pediatrics.[40] Generally, the drug is not recommended for routine RSV infection, but it may be considered for life-threatening infections. Administration of the aerosol requires use of a special large-reservoir nebulizer called a small-particle aerosol generator (SPAG). For more information on the SPAG, see Chapter 40.

Adverse Effects

Skin rash, eyelid erythema, and conjunctivitis have been noted with aerosol administration. Important equipment-related effects during mechanical ventilation include endotracheal tube occlusion and occlusion of ventilator expiratory valves or sensors. Deterioration of pulmonary function can occur. Patients or practitioners who are pregnant should not have exposure to ribavirin.

Assessment

- Monitor signs of improvement in RSV infection severity, including vital signs, respiratory pattern and work of breathing, level of FiO_2 needed, level of ventilatory support, ABGs, body temperature, and other indicators of pulmonary gas exchange.
- Monitor the patient for evidence of side effects, such as deterioration in lung function, bronchospasm, occlusion of endotracheal tube, cardiovascular instability, skin irritation from the aerosol drug, and equipment malfunction related to drug residue.

Inhaled Tobramycin

Patients with CF have chronic respiratory infection with *Pseudomonas aeruginosa* and other microorganisms. Such chronic infection causes recurrent acute respiratory infections and deterioration of lung function. With the exception of the quinoline derivatives such as ciprofloxacin, antibiotics such as the aminoglycosides (e.g., tobramycin), which are effective against *Pseudomonas* organisms, have poor lung bioavailability when taken orally. Consequently these antibiotics must be given either intravenously or by inhalation. The aminoglycoside tobramycin has been approved for inhaled administration and is intended to manage chronic infection with *P. aeruginosa* in patients with CF. Goals of therapy are to treat or prevent early colonization with *P. aeruginosa* and maintain present lung function or reduce the rate of deterioration.[41]

Adverse Effects

Side effects with parenteral aminoglycosides include possible auditory and vestibular damage with potential for deafness and

BOX 36.5 Side Effects With Aminoglycosides and Tobramycin

Parenteral Administration
- Ototoxicity (auditory and vestibular)
- Nephrotoxicity
- Neuromuscular blockade
- Hypomagnesemia
- Cross-allergenicity
- Fetal harm (deafness)

Inhaled Nebulized Tobramycin
- Voice alteration
- Tinnitus
- Nonsignificant increase in bacterial resistance

nephrotoxicity. Other possible effects are listed in Box 36.5. Risk for more serious side effects with tobramycin, whether by inhaled or parenteral routes, increases with the use of other aminoglycosides, in the presence of poor renal function and dehydration, with preexisting neuromuscular impairment, or with use of other ototoxic drugs.

The following precautions are suggested with the use of inhaled tobramycin:
- Inhaled tobramycin should be used with caution in patients with preexisting renal, auditory, vestibular, or neuromuscular dysfunction.
- Tobramycin solution should not be mixed with β-lactam antibiotics (penicillins, cephalosporins) because of admixture incompatibility, and mixing with other drugs in general is discouraged.
- Nebulization of antibiotics during hospitalization should be performed under conditions of containment, as previously described for pentamidine and ribavirin, to prevent environmental saturation and development of resistant organisms in the hospital.
- Aminoglycosides can cause fetal harm if administered to pregnant women; exposure to ambient aerosol drug should be avoided by women who are pregnant or trying to become pregnant.
- Local airway irritation resulting in cough and bronchospasm with decreased ventilatory flow rates is possible with inhaled antibiotics and seems to be related to the osmolality of the solution. Peak flow rates and chest auscultation should be used before and after treatments to evaluate airway changes. Pretreatment with a β-agonist may be needed.
- Allergic reactions in the patient, staff, or family should be considered if exposure to the aerosolized drug is not controlled. The use of a nebulizing system with a scavenging filter, one-way valves, and thumb control could reduce ambient contamination with the drug, as previously described.

In clinical trials, inhaled tobramycin was administered using the PARI LC Plus nebulizer with a DeVilbiss Pulmo-Aide compressor. Studies have reported that not all nebulizer-compressor systems perform adequately with antibiotic solutions, and higher flow rates of 10 to 12 L/min may be needed with nebulizers.[42]

Assessment
- Verify that the patient understands that nebulized tobramycin should be given after other CF therapies, including other inhaled drugs.
- Check whether the patient has renal, auditory, vestibular, or neuromuscular problems or is taking other aminoglycosides or ototoxic drugs. Consider whether tobramycin should be used for the patient based on severity of preexisting or concomitant risk factors.
- Monitor lung function to note improvement in FEV_1.
- Assess rate of hospitalization before and after institution of inhaled tobramycin.
- Assess need for intravenous antipseudomonal therapy.
- Assess improvement in weight.
- Monitor for occurrence of side effects, such as tinnitus or voice alteration; have the patient rinse and expectorate after aerosol treatments.
- Evaluate for changes in hearing or renal function during use of inhaled tobramycin.

Inhaled Aztreonam

Aztreonam was approved in December 1986 by the FDA as a monobactam, a synthetic bactericidal antibiotic; it is given as an intravenous solution. Inhaled aztreonam (Cayston) treats pulmonary symptoms in patients with CF colonized with *P. aeruginosa.*[43] Inhaled aztreonam is not indicated for patients younger than 7 years of age or patients with *Burkholderia cepacia* infection. This agent has been studied only in patients with FEV_1 greater than 25% or less than 75% of predicted. The agent is delivered by itself using the Altera Nebulizer System.

Adverse Effects

Inhaled aztreonam can cause bronchospasm and decrease FEV_1. All patients should be screened for baseline pulmonary function results and treated with a bronchodilator before inhaled aztreonam is administered.

Patients have been reported to experience severe allergic reactions with injectable aztreonam. Careful observation is warranted when first using inhaled aztreonam because it could cause an allergic reaction.

The use of antibiotics in the absence of infection may lead to the development of drug-resistant bacteria. Inhaled aztreonam should not be used in patients with CF who are not infected with *P. aeruginosa.*

Colistimethate Sodium

Colistimethate sodium (colistin) is an antibiotic used to treat sensitive strains of gram-negative bacilli, particularly *P. aeruginosa.* Colistimethate sodium is available as an inhaled formulation in Europe as Promixin; this agent is not approved by the FDA for inhalation. However, nebulization of the parenteral formulation is commonly used in patients with CF.[44]

Adverse Effects

Side effects seen with parenteral administration include neurotoxic events and nephrotoxicity. Because colistimethate sodium

is mainly eliminated by the renal system, renal insufficiency should be considered. Neurotoxic events associated with colistimethate sodium include dizziness, confusion, muscle weakness, and possible neuromuscular blockade leading to respiratory arrest. When aerosolized colistimethate sodium is used, the most common complication seen is bronchospasm. Pretreatment with a β-agonist can decrease the potential for this complication.

Inhaled Zanamivir

Zanamivir is an inhaled powder aerosol (DPI). Despite the availability of zanamivir and the oral antiinfluenza agent oseltamivir (Tamiflu), prophylactic vaccination against influenza is still recommended, especially in high-risk individuals with cardiovascular or pulmonary disease. Zanamivir and oseltamivir represent a new class of antiviral agents termed *neuraminidase inhibitors.*

Indication for Use

Inhaled zanamivir is indicated for the treatment of uncomplicated acute illness caused by influenza virus in adults and children 5 years of age or older who have been symptomatic for no longer than 2 days. The agents have an off-label use for treatment and prophylaxis of H1N1 influenza A.

Mechanism of Action

The influenza virus attaches to respiratory tract cells by binding of viral surface hemagglutinin to the cell's surface molecule of sialic acid (Fig. 36.8). The viral particle also has an enzyme, neuraminidase, on its surface. When replicated viral particles are released from the host cell after infection, the viral neuraminidase cleaves the sialic acid on both the host cell surface and other viral particle surfaces so that mature virus can be released and spread. Without neuraminidase, influenza virus would clump together and to the host cell, preventing spread. Zanamivir and oseltamivir (which is taken by pill) combine with the surface neuraminidase, preventing its action and the spread of viral particles.

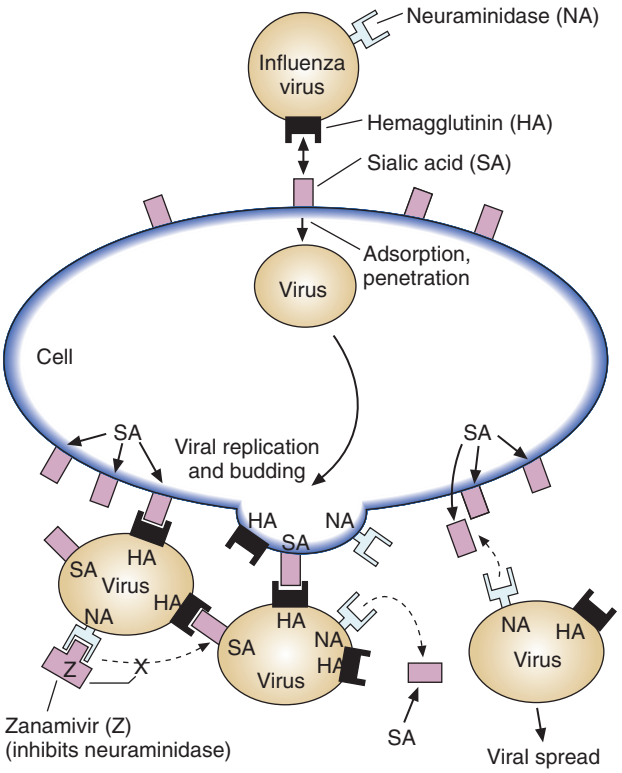

Fig. 36.8 Mechansim of action by which inhaled zanamivir exerts an antiviral effect on influenza virus. Zanamivir is a sialic acid analogue and binds to neuraminidase, the enzyme responsible for cleaving sialic acid and preventing viral binding to sialic acid. This causes viral aggregation, with binding of viral particles to each other and to the host cell, thus preventing viral spread. (From Gardenhire DS: *Rau's Respiratory Care Pharmacology*, ed 10, St. Louis, 2020, Elsevier.)

Adverse Effects

Several adverse effects can occur with inhaled zanamivir:

- Bronchospasm and deterioration in lung function, especially in patients with COPD or asthma
- Possible undertreatment of bacterial infection masquerading as a viral infection or a secondary bacterial infection in the presence of influenza
- Allergic reactions, as may occur with any drug
- Adverse reactions, such as diarrhea, nausea, vomiting, bronchitis, cough, sinusitis, dizziness, and headaches

Because of the effect on lung function in patients with respiratory disease and reports of adverse reactions, revised labeling for the drug carries a warning that zanamivir is not generally recommended for patients with underlying airways disease.[45,46]

Clinical Efficacy

In studies of clinical efficacy, the use of zanamivir resulted in shortening of the median time to alleviation of symptoms by 1 day. In subjects who began treatment within 30 hours of illness, the median time to alleviation of symptoms was reduced by approximately 3 days.[46] Zanamivir is not approved for prophylaxis of influenza, although some data suggest a preventive effect in patients exposed to influenza virus.[46] Cost-versus-efficacy issues revolve around the modest reduction in symptoms and inability to confirm the presence of influenza quickly, easily, and inexpensively as the basis for the drug treatment.

Assessment

- Assess improvement in influenza symptoms, including fever reduction, less myalgia and headache, reduced coughing and sore throat, and less systemic fatigue.
- Patients should be monitored for airway irritation and symptoms of bronchospasm, especially during initial use of the dry-powder aerosol. Provide a short-acting β agonist if needed or if the patient is at risk for airway reactivity (COPD, asthma).

INHALED PULMONARY VASODILATORS

The use of nitric oxide gas to treat neonates with persistent pulmonary hypertension is approved by the FDA and is discussed in detail in Chapters 42 and 54. In addition to this medical gas, inhaled medications are being tested and used to treat pulmonary hypertension. Several such agents are being studied, including epoprostenol (Flolan, Veletri)[47] and alprostadil (Prostin VR

Pediatric); however, only two, iloprost and treprostinil, are approved by the FDA for widespread use.

Nitric Oxide

Indications for Use

INOmax (nitric oxide) is indicated in the treatment of neonates greater than 34 weeks of gestational age with hypoxic respiratory failure.[48] INOmax should be delivered utilizing the company's delivery system with infrared technology (DS_{ir}). Nitric oxide is described in more detail in Chapters 42 and 54.

Iloprost

Indications for Use

Iloprost (Ventavis) inhalation is indicated for the treatment of pulmonary hypertension.[49] Iloprost inhalation is administered with the I-neb nebulizer.

Mechanism of Action

Iloprost is a synthetic analogue of prostacyclin (PGI_2). This agent dilates pulmonary arterial vascular beds and affects platelet aggregation. It is unknown whether platelet aggregation plays a role in the treatment of pulmonary hypertension.

Adverse Effects

Syncope and pulmonary edema may occur secondary to the vasodilatory properties of iloprost. During the 12-week clinical trial, headache and increased cough were the most noted adverse reactions.

Treprostinil

Indication for Use

Treprostinil (Tyvaso) is indicated for the treatment of pulmonary arterial hypertension to increase walking distance in patients with New York Heart Association class III symptoms.[50] It is administered using the Tyvaso Inhalation System, which is an ultrasonic pulsed-delivery device.

Mechanism of Action

Treprostinil is a prostacyclin analogue that causes vasodilation of the pulmonary and systemic arterial vascular beds and inhibits platelet aggregation. Treprostinil is available in a 2.9-mL ampule, which contains 1.74 mg of treprostinil (0.6 mg/mL). It is provided as an aerosol in the Tyvaso Inhalation System.

Adverse Effects

Treprostinil has not been studied in patients with underlying lung disease (e.g., asthma, COPD). Treprostinil may cause bronchospasm. This agent should not be mixed with any other agents.

SUMMARY CHECKLIST

- Orally inhaled aerosol drug classes include β-agonist bronchodilators, anticholinergic (antimuscarinic) bronchodilators, mucolytics, corticosteroids, nonsteroidal antiasthma drugs, antiinfective agents, and anti–pulmonary hypertension agents.
- β-agonist and anticholinergic bronchodilators are used to reverse or improve airflow obstruction; mucolytics are used to reduce mucus viscosity and improve mucociliary clearance; corticosteroids and nonsteroidal antiasthma agents are used to reduce or prevent airway inflammation in asthma; the antiinfective agent pentamidine is used to treat PJP, especially in patients with acquired immunodeficiency syndrome; ribavirin is used to treat RSV infection in at-risk infants and children; inhaled tobramycin and aztreonam are used in patients with CF to prevent or manage gram-negative *Pseudomonas* infections; and inhaled zanamivir is used to treat acute influenza.
- All aerosol treatments are assessed immediately by monitoring respiratory vital signs, which include respiratory rate and pattern, pulse, breath sounds on auscultation, general patient appearance (e.g., color, diaphoresis), and patient report of subjective reaction (e.g., chest tightness). Additional assessment should be related to the indication for the drug (e.g., monitoring of peak flow rates or bedside spirometry with bronchodilator use; frequency of exacerbation or β-agonist use with inhaled corticosteroids in asthma).
- Each class of aerosol drug has its own mechanism of action. Practitioners should be familiar with how agents they administer work. Common side effects with each class of drug include tremor and shakiness with β-agonists, dry mouth with anticholinergic agents, bronchial irritation with acetylcysteine, dysphonia and voice changes with dornase alfa, and oral fungal infections with corticosteroids.
- Agents used in asthma that provide quick relief include short-acting β agonists (albuterol, levalbuterol) and anticholinergic bronchodilators. Agents that provide long-term control include LABAs (salmeterol, formoterol, arformoterol, indacaterol, olodaterol, vilanterol), inhaled corticosteroids, and nonsteroidal antiasthma drugs (cromolyn, montelukast, and other leukotriene antagonists). Systemic corticosteroids are used for both quick relief (intravenously) and long-term control (orally).
- Newer inhaled medications within a class known as *aerosolized prostacyclins* are being introduced to help treat pulmonary hypertension. Several agents are being studied, including epoprostenol (Flolan, Veletri) and alprostadil (Prostin VR Pediatric); however, only treprostinil (Tyvaso) and iloprost (Ventavis) are approved by the FDA for use in aerosols

Airway Management

Carolyn J. La Vita

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how to perform endotracheal and nasotracheal suctioning safely.
- Describe how to obtain sputum samples properly.
- Assess the need for and select an artificial airway.
- Identify the complications and hazards associated with insertion of artificial airways.
- Describe how to perform orotracheal and nasotracheal intubation of an adult.
- Assess and confirm proper endotracheal tube placement.
- Describe how to use alternative airway appliances.
- Describe the rationale and the methods for performing a tracheotomy.
- Identify the types of damage that artificial airways can cause.
- Describe how to maintain and troubleshoot artificial airways properly.
- Describe techniques for measuring and adjusting tracheal tube cuff pressures.
- Identify when and how to extubate or decannulate a patient.

CHAPTER OUTLINE

KEY TERMS

decannulation
endotracheal tubes
extubation
fenestrated
intubation
laryngectomy
obturator
pharyngeal airways
radiopaque
stenosis
suctioning
tracheoesophageal fistula
tracheoinnominate artery fistula
tracheomalacia
tracheostomy
tracheostomy tubes
tracheotomy

Respiratory therapists (RTs) are an important part of the health-care team whose aim is to optimize patient ventilation and gas exchange. Because adequate ventilation and gas exchange are impossible without a patent airway, RTs often assume responsibility for airway management of patients in both the acute care and the post–acute care settings. RTs must develop skills in three broad areas of airway care. First, the RT must be proficient in airway clearance techniques, including methods designed to ensure the patency of the patient's natural or artificial airway. Second, the RT must be able to insert and maintain artificial airways designed to support patients whose own natural airways are inadequate. Third, the RT must be able to assist physicians in performing special procedures related to airway management. This chapter explores each of these areas.

SUCTIONING

Airway obstruction can be caused by retained secretions, foreign bodies, and structural changes such as edema, tumors, or trauma. Retained secretions increase airway resistance and the work of breathing and can cause hypoxemia, hypercapnia, atelectasis, and infection. Difficulty in clearing secretions may be due to the thickness or amount of the secretions or to the patient's inability to generate an effective cough.

RTs can remove retained secretions or other semiliquid fluids from the airways by suctioning. **Suctioning** is the application of negative pressure (vacuum) to the airways through a collecting tube (flexible catheter or suction tip). Removal of foreign bodies, secretions, or tissue masses beyond the mainstem bronchi requires bronchoscopy, which is generally performed by a physician; however, an increasing number of centers have trained RTs to perform therapeutic bronchoscopy. RTs often assist physicians in performing bronchoscopy (refer to Chapter 22). Other suctioning adjuncts include mechanical in-exsufflation, chest physiotherapy, and positive expiratory pressure (PEP) therapy are discussed in Chapter 44. These techniques raise secretions from lung periphery and small airways to large airways, allowing for removal via suctioning.

Suctioning can be performed by way of either the upper airway (oropharynx) or the lower airway (trachea and bronchi). Secretions or fluids also can be removed from the oropharynx by using a rigid tonsillar or Yankauer suction tip (Fig. 37.1). Access to the lower airway is by introduction of a flexible suction catheter (Fig. 37.2) through the nose (nasotracheal suctioning) or artificial airway (endotracheal suctioning). Tracheal suctioning through the mouth should be avoided because it causes gagging.

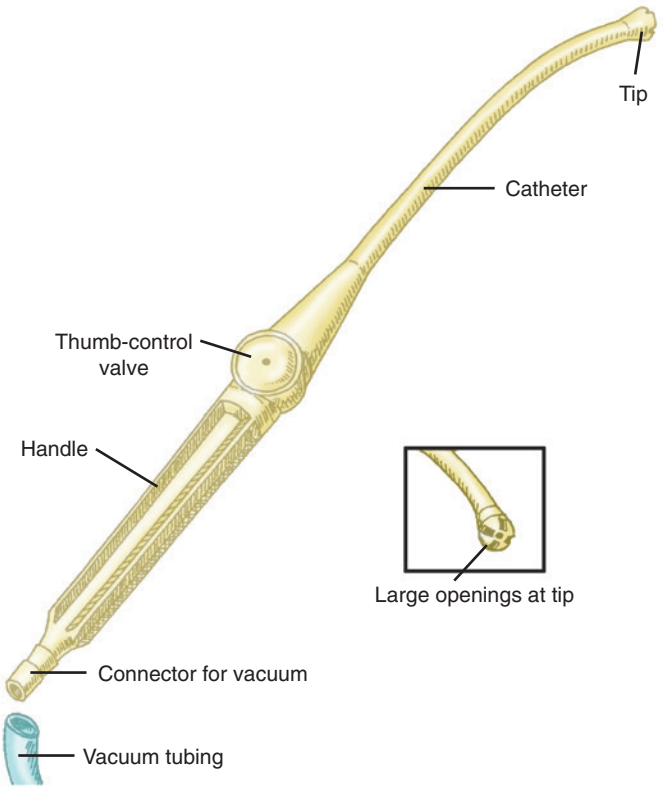

Fig. 37.1 Rigid tonsillar, or yankauer, suction tip. (Modified from Sills JR: *The comprehensive respiratory therapist exam review, entry and advanced levels*, ed 5, St. Louis, 2010, Mosby.)

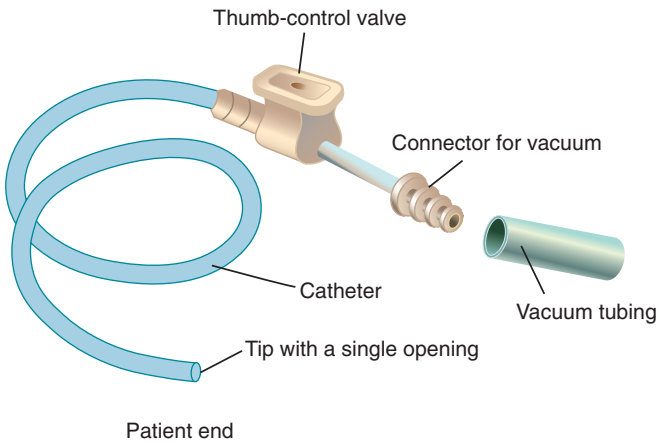

Fig. 37.2 Flexible suction catheter for lower airway suctioning.

Endotracheal Suctioning

Equipment and Procedure

There are two techniques for endotracheal suctioning: open and closed. The open, sterile technique requires disconnecting the patient from the ventilator. This technique is often used when the patient with a tracheostomy is receiving humidified gas via tracheostomy collar and not receiving mechanical ventilation support. The closed technique uses a sterile, closed, in-line suction catheter that is attached to the ventilator circuit so that the suction catheter can be advanced into the patient's endotracheal airway without disconnecting the patient from the ventilator.

There are also two methods of suctioning based on how deep the suction catheter is inserted in the artificial airway: deep suctioning and shallow suctioning. Deep suctioning is when the catheter is inserted until resistance is met and then withdrawn approximately 1 cm before applying suction. Shallow suctioning is when the catheter is advanced to a predetermined depth, which is usually the length of the airway plus the adapter.[1] Using shallow suctioning rather than deep suctioning is recommended in infants and children,[2] and in adults the use of deep tracheal suctioning is being questioned because of its effects on lung volume and oxyhemoglobin saturation.

Step 1: Assess Patient for Indications.

In general, a patient should never be suctioned according to a preset schedule. Although very thick secretions may not move with airflow and may not create any adventitious sounds, the patient should be assessed for clinical indicators, such as rhonchi heard on auscultation, which suggest the need for suctioning. Suctioning done with lack of clinical indication can lead to unnecessary complications including hypoxemia, bronchospasm, mucosal irritation, and patient discomfort.

Step 2: Assemble and Check Equipment.

The equipment needed for endotracheal suctioning is listed in Box 37.1. The suction catheter, gloves, and cup are often prepackaged together in disposable sterile kits for use during

BOX 37.1 Equipment Needed for Suctioning

- Vacuum source
- Calibrated, adjustable regulator
- Collection bottle and connecting tubing
- Disposable gloves: sterile (open suction) or clean (closed suction)
- Sterile suction catheter
- Sterile water and cup (open suction), if needed to clear catheter
- Goggles, mask, and other appropriate equipment for standard precautions
- Oxygen (O_2) source with a calibrated flowmeter (open suction) or ventilator (closed suction)
- Pulse oximeter
- Manual resuscitation bag equipped with O_2-enrichment device for emergency backup use
- Stethoscope

Optional Equipment

- Electrocardiograph
- Sterile sputum trap for culture specimen

MINI CLINI

Indication for Endotracheal Suctioning

Problem

The respiratory therapist is called to the bedside to assess an adult patient exhibiting moderate respiratory distress, with respiratory rate of 32 breaths per minute, heart rate of 115 beats per minute, and O_2 saturation (SpO_2) of 91%. The patient has amyotrophic lateral sclerosis (ALS) and underwent tracheostomy tube placement to aid in secretion clearance. Upon assessing bilateral breath sounds, the RT notes the patient has rhonchorous breath sounds throughout the left lung and absent breath sounds in the right lung. The most recent chest x-ray demonstrates complete opacification of the right hemithorax. The care team asks for the RTs clinical assessment.

Discussion

Coarse rhonchi indicate airflow through retained secretions. Absent breath sounds with complete opacification on chest x-ray in a patient with an impaired cough could indicate a mucus plug in the mainstem bronchus and is likely the reason for the increased work of breathing. The RT should increase the FiO_2, suction the patient, and suggest a trial of cough assist for prevention of additional problems. If no clinical improvement is seen, the RT could suggest a flexible bronchoscopy to remove the secretions.

the open suctioning technique. Suction pressure should always be checked by occluding the end of the suction tubing before attaching the suction catheter. The suction pressure should be set at the lowest effective level. Negative pressures of 80 to 100 mm Hg in neonates and less than 150 mm Hg in adults are generally recommended.[3]

Suction catheters are available in various designs, most with side ports to minimize mucosal damage. Most suction catheters for adult are 22 inches long (sufficient to reach the main stem bronchi) and sized in French units (external circumference). A curved-tip catheter, or catheter coudé, is available to help direct access to the left mainstem bronchus. The size of the catheter may be more important than its design. A catheter that is too large can obstruct part or all of the airway by occupying too much of its opening. Too large a suction catheter combined with negative pressure quickly evacuates lung volume and can cause atelectasis and hypoxemia. To avoid this problem, the diameter of the catheter should be less than 50% of the internal diameter of the artificial airway in adults.[4,5] In infants and small children, the diameter of the suction catheter should be less than 70% of the internal diameter of the artificial airway.[6]

RULE OF THUMB To estimate quickly the proper size of suction catheter to use with a given tracheal tube, first multiply the tube's inner diameter by 2. Then use the next smallest size catheter.

Example: 6-mm endotracheal tube: 2×6 = 12;
next smallest catheter is 10 F

Example: 8-mm endotracheal tube: 2×8 = 16;
next smallest catheter is 14 F

An in-line suction catheter can be used for patients receiving ventilatory support (Fig. 37.3) and is recommended over open suction because ventilation is continued during suctioning regardless of the level of ventilatory support provided.[7-10] These systems are incorporated directly into the ventilator circuit and used repeatedly. In addition, cross contamination is less likely with in-line catheter systems. The use of in-line suction catheters is cost-effective because they need to be changed only if soiled or malfunctioning and not on a daily basis.[11] However, in-line suction catheters have no effect on risk for ventilator-associated pneumonia (VAP).[12] The extra weight an in-line catheter adds to a ventilator circuit may increase tension on the endotracheal tube (ETT), so care should be taken to support the ventilator tubing appropriately.

Basic indications for the use of closed suction catheters are listed in Box 37.2.[13] Routine instillation of sterile normal saline to aid secretion removal before suctioning is not recommended because there is no evidence that this practice is beneficial, and it may increase infection risk and destabilize the patient. If the secretions are extremely tenacious, instillation of acetylcysteine or sodium bicarbonate (2%) may be more effective than normal saline; this generally requires a physician's order. The use of these medications is discussed in more detail in Chapter 36.

After connecting the catheter to the suction source, the level of suction pressure should be checked by closing the catheter thumb port and aspirating some sterile water or saline from the basin. If no vacuum is generated, it is necessary to check for leaks in the tubing, at the collection container, or at the suction regulator. In addition, if the collecting bottle is full, the float-valve closes and prevents vacuum transmission.

RULE OF THUMB Set suction pressure 120–150 mm Hg for adults, 100–120 mm Hg for children, and 80–100 mm Hg for infants.

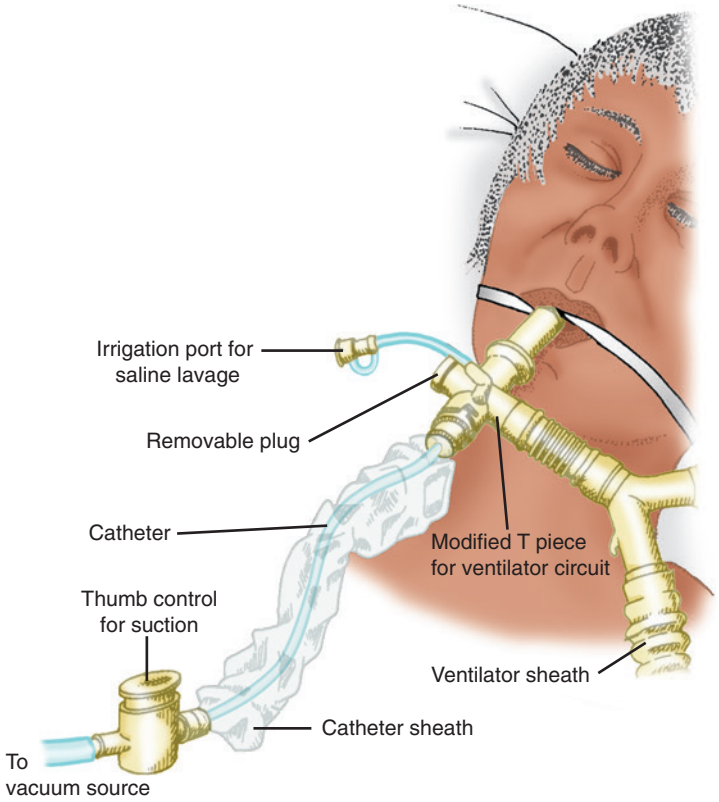

Fig. 37.3 In-line, closed-system multiuse suction catheter. (Modified from Sills JR: *The comprehensive respiratory therapist exam review, entry and advanced levels*, ed 5, St. Louis, 2010, Mosby.)

BOX 37.2 Indications for Use of Closed Suctioning Technique

Mechanically ventilated patients, especially neonates and patients with:

- Positive end expiratory pressure ≥10 cm H_2O
- Mean airway pressure ≥20 cm H_2O
- Inspiratory time ≥1.5 s
- FiO_2 ≥0.60
- Frequent suctioning (≥6 times/day)
- Hemodynamic instability associated with ventilator disconnection
- Respiratory infections requiring airborne or droplet precautions (see Chapter 4)
- Inhaled agents that cannot be interrupted by ventilator disconnection (e.g., nitric oxide, helium/oxygen mixture)

Step 3: Assess Patient for Hyperoxygenation.
Before suctioning, delivery of 100% oxygen (O_2) for 30 to 60 seconds to pediatric and adult patients is suggested, especially to patients who are at risk for hypoxemia.[14] In addition, the O_2 concentration should be increased by 10% in neonates before suctioning[15]; this may be done by increasing the set FiO_2 or activating the temporary 100% setting on microprocessor ventilators. Manual ventilation before suctioning is not recommended since derecruitment occurs whenever the ventilator is disconnected from the patient and high pressure is normally applied to the airway potentially causing lung injury.[16] However, if there is no other alternative to hyperoxygenating the patient, positive end-expiratory pressure (PEEP) should be maintained by adding a PEEP valve to the manual resuscitator during manual ventilation with 100% O_2.

Step 4: Insert Catheter.
To prevent tracheal mucosal trauma, especially in infants, the shallow suction method should be used, advancing the catheter just to the end of the artificial airway.

Step 5: Apply Suction and Clear Catheter.
Suction is applied while withdrawing the catheter. Total suction time should be kept to less than 15 seconds.[17,18] After removing the catheter, it should be cleared using sterile water or saline. The closed suction catheter has an adapter for saline vials to be placed in line with the device. The catheter is cleared by squeezing the saline vial and applying suction at the same time. Caution must be used to ensure that saline is being drawn into the catheter and not entering the airway. If any untoward response occurs during suctioning, the catheter should be immediately removed and the patient should be oxygenated.

Step 6: Reoxygenate Patient.
The patient should be hyperoxygenated by the same method used in Step 3 for at least 1 minute. Routine hyperventilation is not recommended. If there are indications of derecruitment, lung recruitment maneuvers may be used.

Step 7: Monitor Patient and Assess Outcomes.
Steps 3 through 7 are repeated as needed until improvement is seen or an adverse response is observed. Any necessary corrective steps should be taken.

Minimizing Complications and Adverse Responses

Careful adherence to procedure is the best way to avoid or minimize complications of endotracheal suctioning. Potential complications are as follows:

- Hypoxemia
  - Minimized by preoxygenating the patient, preferably without disconnecting patient from the ventilator.[19]
  - Minimized by using closed suction technique, especially in neonates and adults requiring high FiO_2 or PEEP, or both or at risk for lung derecruitment.
- Cardiac dysrhythmias
  - Bradycardia may occur secondary to vagal nerve stimulation.
  - Tachycardia may occur as a result of agitation and/or hypoxemia.
  - If either occurs, stop suctioning, administer O_2 and ventilation.
- Hypotension or hypertension
  - May occur as a result of cardiac dysrhythmia, hypoxemia, anxiety, stress, pain, or coughing.
  - If either occurs, stop suctioning, administer O_2 and ventilation.
- Atelectasis (collapse of alveoli)/lung derecruitment
  - Limit amount of negative suction pressure used (see Rule of Thumb).
  - Keep duration of suctioning less than 15 seconds.
  - Use appropriate-size catheter (see Rule of Thumb).
  - Avoid disconnection from ventilator by using closed suction technique, especially in neonates and adults who require high FiO_2 or PEEP.
- Mucosal trauma
  - Limit amount of negative suction pressure used (see Rule of Thumb).
  - Use shallow suctioning method.
- Increased intracranial pressure (ICP)
  - Usually transient and returns to baseline within 1 minute.
  - For patients who already have increased ICP, administer aerosolized topical anesthetic (lidocaine) 15 minutes before suction to minimize cough, discomfort, and increased ICP.[20]
- Bacterial colonization of lower airway
  - Use sterile technique during open suctioning.
  - Do not routinely instill normal saline; only instill normal saline to help mobilize very thick secretions.
  - Use closed suction technique to avoid disconnection from ventilator.

RULE OF THUMB To minimize hypoxemia and lung derecruitment when suctioning a mechanically ventilated patient, preoxygenate and suction the artificial airway with a closed-system in-line catheter to avoid disconnecting the patient from the ventilator.

Nasotracheal Suctioning

Nasotracheal suctioning is indicated for patients who have retained secretions but do not have an artificial airway. The nasal passages are highly vascularized. Mucosal trauma and bleeding can occur with repeated suctioning, adding to difficulty managing secretions. The use of soft suction catheters and/or a nasopharyngeal airway/trumpet is recommended to prevent these complications.

MINI CLINI

Suctioning Complications

Problem

A patient in the intensive care unit is intubated following a cardiac arrest. The RT notices the patient coughing and attempts to suction the ETT using a closed suction catheter system and the deep method. When the RT meets resistance, the patient's heart rate precipitously drops, oxygen saturation decreases, and blood tinged secretions are noted in the catheter.

Discussion

This patient's cardiac status is tenuous, and the bradycardia is likely a result of stimulation of the vagus nerve. The hypoxemia is most likely due to alveolar derecruitment and/or decreased perfusion. Blood-tinged secretions can be a result of mucosal trauma. To minimize these complications, the RT should consider using the shallow suction method, limiting the suction duration and suction pressure used, and preoxygenating the patient before the procedure.

Equipment and Procedure

The equipment and procedure for nasotracheal suctioning are similar to the equipment and procedure for endotracheal suctioning. Only the key differences are highlighted here. In addition to the equipment and supplies used for endotracheal suctioning (see Box 37.1), sterile water-soluble lubricating jelly is needed to aid catheter passage through the nose. Use of a nasopharyngeal airway should be considered to help reduce mucosal trauma in the nose of patients who require repeated, long-term nasotracheal suctioning.

The key aspect of the nasotracheal suctioning procedure is catheter insertion. After lubricating the catheter, the RT inserts it gently through the nostril, directing it toward the septum and floor of the nasal cavity without applying negative pressure. The catheter is gently twisted if any resistance in the nose is felt. If twisting does not help, the catheter is withdrawn and inserted through the other nostril.

As the catheter enters the lower pharynx, the patient should assume a "sniffing" position (Fig. 37.4). This position helps to align the opening of the larynx with the lower pharynx, making catheter passage through the larynx more likely. The catheter is continually advanced until the patient coughs or a resistance is felt.

Minimizing Complications and Adverse Responses

Complications of nasotracheal suctioning are as follows:

- Gagging and/or regurgitation
  - To minimize this risk, avoid suctioning soon after a meal or tube feeding; coordinate with nurse.
  - If this occurs, reposition patient and suction oropharynx if necessary.
- Airway trauma (bleeding)
  - To avoid, before suctioning, assess patient for any bleeding disorder (check platelet count and/or bleeding studies and anticoagulation medications).

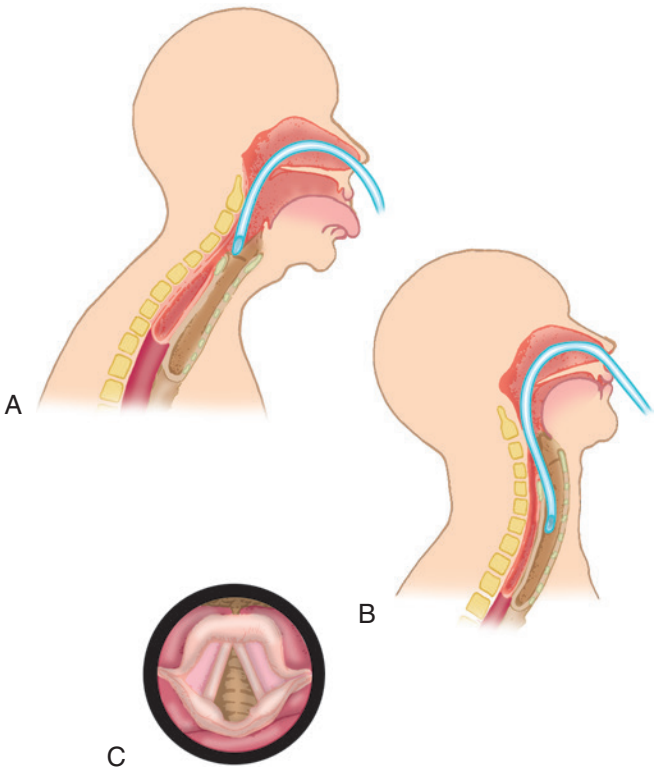

Fig. 37.4 Nasotracheal Suctioning Technique. (A) Optimal position of the head to insert catheter into the trachea. The neck is flexed, and the head is extended. The tongue is protruded (and held by a 4 × 4 gauze pad). (B) After catheter has advanced into the trachea, the tongue is released, and the patient's head is allowed to assume a comfortable position. (C) View of vocal cords from above. The cords are most widely separated during inspiration. (Modified from Sanderson RG: *The cardiac patient: a comprehensive approach*, Philadelphia, 1972, Saunders.)

  - To minimize, do not use excessive force when advancing catheter.
  - To minimize, lubricate catheter.
  - To minimize, use nasopharyngeal airway or soft suction catheters to protect nasal mucosa.
- Contamination of the lungs
  - Immunosuppressed patients are especially at risk.
  - To avoid, use sterile technique and gentle insertion of catheter.
- Bronchospasm or laryngospasm
  - These incidents may be stimulated by the catheter in the lower airway.
  - Patients with hyperactive airway disease are especially at risk.
  - If these occur, stop suctioning and administer aerosolized bronchodilator if needed.

RULE OF THUMB A nasopharyngeal airway may be left in the patient's nares to prevent mucosal trauma from repeated suctioning.

Sputum Sampling

Sputum samples are often collected to identify organisms infecting the airway. To obtain the sample, the suctioning procedures described previously should be followed. In addition to the usual equipment, a sterile specimen container is needed. This device consists of a plastic tube or cup with flexible tubing on one end to attach to the suction catheter. The other outlet is a stiff plastic nozzle that connects to the suction tubing from the wall vacuum unit (Fig. 37.5).

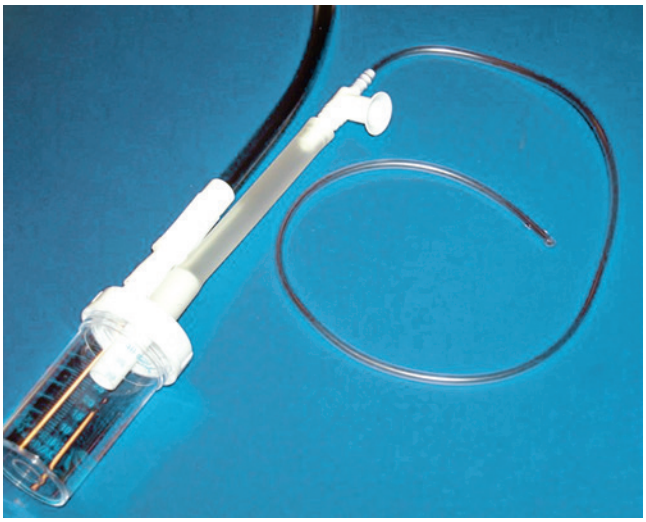

Fig. 37.5 Specimen container placement between the suction catheter and wall suction source.

It is important to maintain sterile technique when touching the connection points on the trap. If a closed suction system is being used, a new catheter should be placed just before suctioning the patient for the sample. When an adequate sample is obtained, the container is removed from the suction catheter and suction tubing. The flexible tubing on the container is attached to the open nozzle; this creates a closed container. The container should be labeled according to hospital or facility policy. The suctioning procedure is completed as previously described.

ESTABLISHING AN ARTIFICIAL AIRWAY

Routes

Artificial airways are inserted for various reasons and involve varying degrees of invasion into the upper airway. **Pharyngeal airways** extend only into the pharynx. Artificial airways that are placed through the mouth or nose into the trachea are called **endotracheal tubes (ETTs)**. The process of placing an artificial airway into the trachea is referred to as **intubation.** When the ETT is passed through the nose first, the procedure is referred to as *nasotracheal intubation*. When the tube is passed through the mouth on its way into the trachea, the procedure is called *orotracheal intubation*.

Pharyngeal Airways

Pharyngeal airways prevent airway obstruction by keeping the tongue pulled forward and away from the posterior pharynx. This type of obstruction is common in an unconscious patient as a result of a loss of muscle tone.

A *nasopharyngeal airway* (Fig. 37.6) is most often placed in a patient who requires frequent nasotracheal suctioning. Although

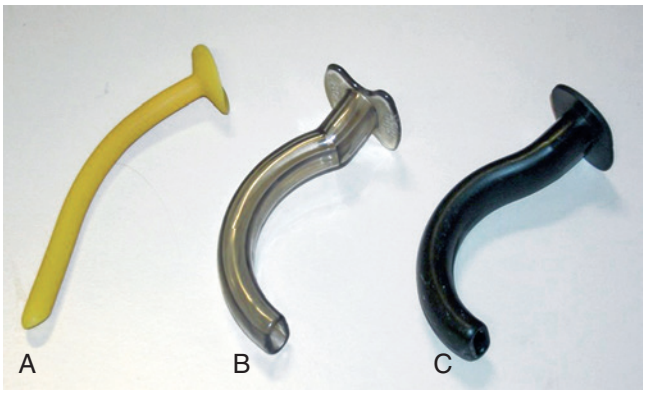

Fig. 37.6 Pharyngeal Airways. (A) Nasopharyngeal airway. (B and C) Oropharyngeal airways.

it does not ensure entry into the trachea, it minimizes damage to the nasal mucosa that can be caused by the suction catheter. A nasopharyngeal airway also may be placed in a patient who was recently extubated after facial surgery. The nasopharyngeal airway helps to maintain the patency of the upper airway despite swelling.

Oropharyngeal airways (see Fig. 37.6) are inserted into the mouth over the tongue. Use of oropharyngeal airways should be restricted to unconscious patients to avoid gagging and regurgitation. These airways maintain a patent airway when the tongue would otherwise obstruct the oropharynx. The airway also can be used as a bite block for patients with oral tubes.

Pharyngeal airways are used mainly in emergency life support. Further details on their use, insertion techniques, and size selection are provided in Chapter 38.

Tracheal Airways

Tracheal airways extend beyond the pharynx into the trachea. The two basic types of tracheal airways are *endotracheal (translaryngeal) tubes* and *tracheostomy tubes (TTs)*. ETTs are inserted through either the mouth or the nose (orotracheal or nasotracheal), through the larynx, and into the trachea. **Tracheostomy tubes** are inserted through a surgically created opening in the neck directly into the trachea. Table 37.1 summarizes the advantages and disadvantages of each of these three approaches.

Artificial Airways

Endotracheal Tubes

ETTs are semirigid tubes most often composed of polyvinyl chloride or related plastic polymers.[21] Fig. 37.7 shows a typical ETT, its key components, and a stylet used for insertion. The proximal end of the tube is attached to a standard adapter with a 15-mm external diameter. The curved body of the tube usually has length markings, indicating the distance (in centimeters) from the beveled tube tip. In addition to the beveled opening at the tip, there is a side port, or "Murphy eye," that ensures gas flow if the main port should become obstructed. The angle of the bevel minimizes mucosal trauma during insertion. The tube cuff is permanently bonded to the tube body. Inflation of the cuff seals off the lower airway, either for protection from gross aspiration or to provide positive pressure ventilation. A small

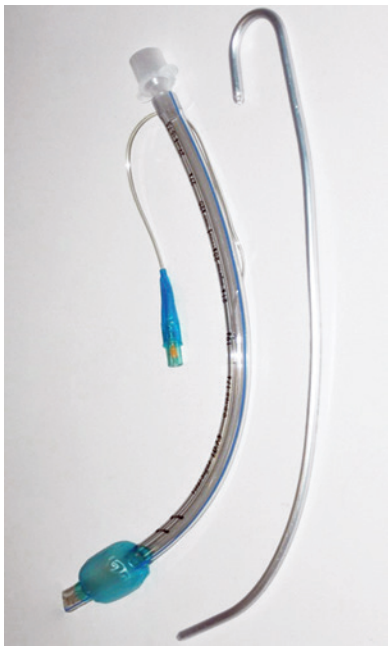

Fig. 37.7 Typical endotracheal tube and stylet.

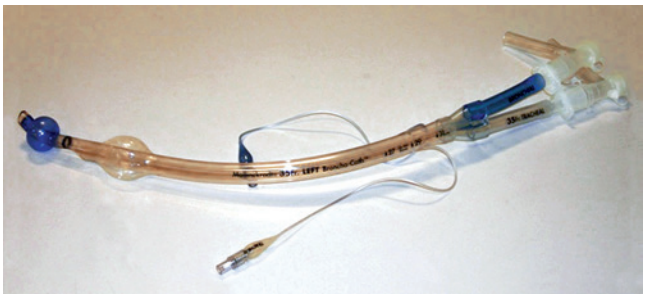

Fig. 37.8 Double-lumen endotracheal tube for independent lung ventilation.

filling tube leads from the cuff to a pilot balloon, used to monitor cuff status and pressure when the tube is in place. Finally, a valve with a standard connector for a syringe allows inflation and deflation of the cuff. Although not shown in Fig. 37.7, included with most modern ETTs is a **radiopaque** indicator that is embedded in the distal end of the tube body. This indicator allows for easy identification of tube position on chest x-ray.

Specialized endotracheal tubes. Some standard ETTs have been modified for specific uses, including special ventilation methods, lung pathologic conditions, and surgical procedures. Some more common tubes, including double-lumen tubes, tubes with special adapters for jet ventilation, tubes with subglottic suction ports, and laryngeal mask airways (LMAs), are discussed.[22] Advantages and disadvantages of the double-lumen tube and LMA are summarized in Table 37.2.

Special mechanical ventilation techniques may require unique types of ETTs. When unilateral lung disease occurs, independent lung ventilation may be needed. This ventilation requires the use of a double-lumen ETT (Fig. 37.8). This tube has two proximal ventilator connectors (15-mm adapter), two inner lumens for gas flow, two cuffs, and two distal openings. The larger cuff

TABLE 37.1 Advantages and Disadvantages of Tracheal Airway Routes

Route	Advantages	Disadvantages
Oral intubation	Insertion is faster, easier, less traumatic, and more comfortable	Esthetically displeasing, especially long term
	Larger tube is tolerated	Greater risk for self-extubation or inadvertent extubation
	Easier suctioning	Greater risk for main stem intubation
	Less airflow resistance	Risk of tube occlusion by biting or trismus
	Decreased work of breathing	Risk of injury to lips, teeth, tongue, palate, and oral soft tissues
	Easier passage of bronchoscope	
	Reduced risk for tube kinking	May require additional use of oral airway
	Avoidance of nasal and paranasal complications, including epistaxis and sinusitis	Great risk for retching, vomiting, and aspiration
		Pain and discomfort, especially with inadequate preparation
Nasal intubation	Less retching and gagging	Nasal and paranasal complications, including epistaxis, sinusitis, otitis
	Greater comfort in long-term use	
	Less salivation	More difficult to perform
	Improved ability to swallow oral secretions	Spontaneous breathing required for blind nasal intubation
	Improved communication	Smaller tube is necessary
	Improved mouth care and oral hygiene	Greater suctioning difficulty
	Avoidance of occlusion by biting or trismus	Increased airflow resistance
	Easier nursing care	Increased work of breathing
	Avoidance of oral route complications	Difficulty passing bronchoscope
	Less posterior laryngeal ulceration	Smaller risk for transient bacteremia
	Better tube anchoring, less chance of inadvertent extubation	
	Reduced risk for main stem intubation	
	Some patients can swallow liquids, providing a means of nutritional support	
	Blind nasal intubation does not require muscle relaxants or sedatives	
	May avert "crash" oral intubation	
Tracheotomy	Avoidance of laryngeal and upper airway complications of translaryngeal intubation	Greater expense
		Requirement for use of operating room in most cases
	Greater comfort	Need for general anesthesia in most cases
	Aids feeding, oral care, suctioning, speech	Permanent scar
	Psychologic benefit (improved motivation)	More severe complications
	Easier passage of flexible bronchoscope	Greater mortality rate
	Easier reinsertion	Delayed decannulation
	Esthetically less objectionable	Increased frequency of aspiration
	Facilitation of weaning from ventilator	Greater bacterial colonization rate
	Elimination of risk for main stem intubation	Persistent open stoma after decannulation, reducing cough efficiency
	Reduced work of breathing	
	Better anchoring (reduced risk for decannulation)	
	Improved ability to place curve-tipped suction catheter in left bronchus	
	Improved mobility (transfer out of intensive care unit to ward or extended-care facility)	

From Stauffer JL, Silvestri RC: Complications and consequences of endotracheal intubation and tracheostomy, *Respir Care* 27:417, 1982.

seals the tracheal lumen and allows gas to flow into one bronchus. The smaller cuff seals the opposite bronchial lumen (Fig. 37.9).

There are important points to consider when using double-lumen ETTs. These tubes are stiffer and bulkier to insert than standard tubes and must be rotated during insertion to align with the proper bronchus. Flexible bronchoscopy should be performed to ensure proper placement. The resistance to flow through each tube is increased because each lumen is smaller than the same-size single-lumen tubes. Tube position must also be regularly assessed.

The double-lumen airway (Combitube) is designed to be inserted blindly through the oropharynx and into the trachea or the esophagus (Fig. 37.10).[23] Its external design is similar to that of a double-lumen ETT with two external openings, two 15-mm adapters, two lumens, and two cuffs. One cuff seals the oropharynx. The second seals the trachea or the esophagus.

If the tube is placed into the esophagus and the cuffs are inflated, ventilation is accomplished by air passing through a series of holes in the area of the hypopharynx and into the trachea. The pharyngeal cuff prevents air from leaving through the mouth. The distal cuff in the esophagus helps to decrease regurgitation. If the tube is placed in the trachea, it functions like an ETT. To assess placement, the RT can manually ventilate through the external adapters and determine which gives the best breath sounds.

High-frequency jet ventilation uses a special ETT adapter (Fig. 37.11). This adapter replaces the standard ETT adapter. There is a jet port for the injection of high-flow pulses from the

TABLE 37.2 Advantages and Disadvantages of Alternatives to Endotracheal Intubation for Maintaining Upper Airway Patency

Device	Advantages	Disadvantages
Oral and nasal airways	Little training required	Does not guarantee airway patency
	No special equipment necessary	May worsen obstruction
	Inexpensive	Poorly tolerated by awake patient
	Can be quickly placed	Does not prevent aspiration
		Short-term use
		Does not facilitate positive pressure ventilation
Double-lumen airway (Combitube) placement	Less skill than bag-valve-mask or intubation	Difficulty distinguishing tracheal vs. esophageal insertion
	No special equipment necessary	Short-term use
	Protection against aspiration	Aspiration during removal
	Facilitates positive pressure ventilation	Cannot suction in esophageal position
		Only one size (adult)
		Potential for esophageal injury
Laryngeal mask airway (LMA)	Easy to insert	Short-term use
	No special equipment necessary	Aspiration not avoided
	Can intubate without removing LMA	Cannot provide high ventilation pressures if needed
	Avoids laryngeal and tracheal trauma	

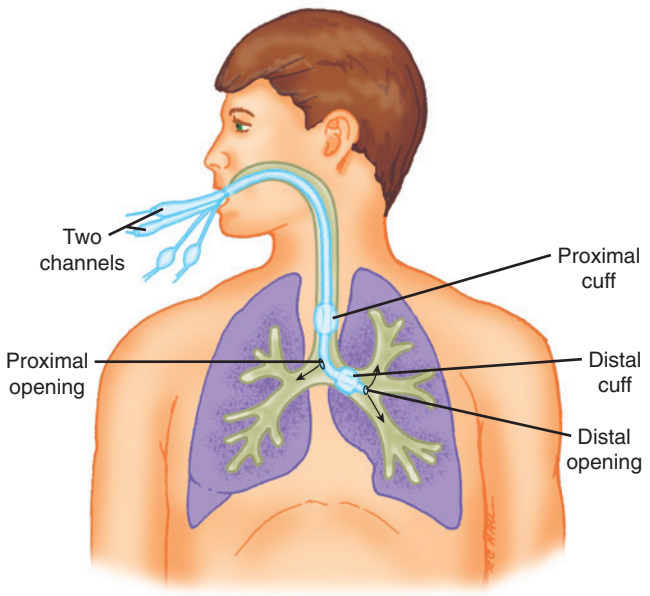

Fig. 37.9 Correct positioning of double-lumen endotracheal tube.

jet ventilator and a 15-mm connection for conventional ventilation. A pressure monitoring tube also is available for monitoring airway pressures.

A specialized ETT with a subglottic suction port has been designed to allow for removal of secretions that often accumulate above the cuff (Fig. 37.12). A separate channel in the wall of the tube attaches to a wall suction source. The suction source is run continuously at negative pressures of 20 to 30 cm H_2O or aspiration is preformed intermittently. Every 4 hours, a small amount of air should be injected into the suction port to ensure the port and tubing are not clogged. Due to the removal of subglottic secretions, use of this tube has been reported to decrease the incidence of VAP, in conjunction with head of bed elevation greater than 30 degrees, use of medications for stress ulcer prophylaxis, and timely removal of the artificial airway.[24,25]

The algorithm created by the American Society of Anesthesiologists for management of a difficult airway has been modified to show the various uses of the LMA.[26] The LMA consists of a short tube and a small mask that is inserted deep into the oropharynx (Fig. 37.13).[23,26] The open surface of the mask faces the laryngeal opening, and the tip of the mask is just above the esophageal sphincter. The short tube has a 15-mm adapter that can be connected to a manual resuscitator bag. A small tube is used to inflate a cuff when the device is in place. LMAs range in size from size 5 for adults to size 1 for infants.

Compared with bag and mask ventilation, a greater amount of ventilation is directed to the lungs by the LMA. The ease and speed of insertion offer an advantage over intubation when the intubator is inexperienced, the patient cannot be positioned for intubation, or the intubation is difficult.

The insertion of the LMA does not require any equipment (Fig. 37.14).[23] Before insertion, the posterior surface of the mask must be lubricated, and the cuff must be fully deflated. The index finger is used to guide insertion of the mask along the palate and down into the oropharynx. When the cuff is in place, it is inflated to a maximum of 60 cm H_2O. Inflation causes the mask to rise slightly out of the mouth.

Use of the LMA has two major limitations.[23] First, it cannot be used in a conscious or semicomatose patient because of stimulation of the gag reflex. Second, if ventilating pressures greater than 20 cm H_2O are needed, gastric distension may occur. This device does not protect against aspiration should regurgitation occur.

The classic LMA can be used to facilitate intubation because the opening faces the glottis. However, because of the small size of the ventilating tube on the mask, a small ETT is needed. A specially designed LMA with a small handle facilitates intubation (Fig. 37.15).

RULE OF THUMB The cuff on an LMA tube requires a large volume of air to inflate to 60 cm H_2O to seal the airway. The RT should be prepared with a large syringe when using this type of alternative airway.

Tracheostomy Tubes

TTs are generally made from polyvinyl chloride or silicone, although some are still made from metal.

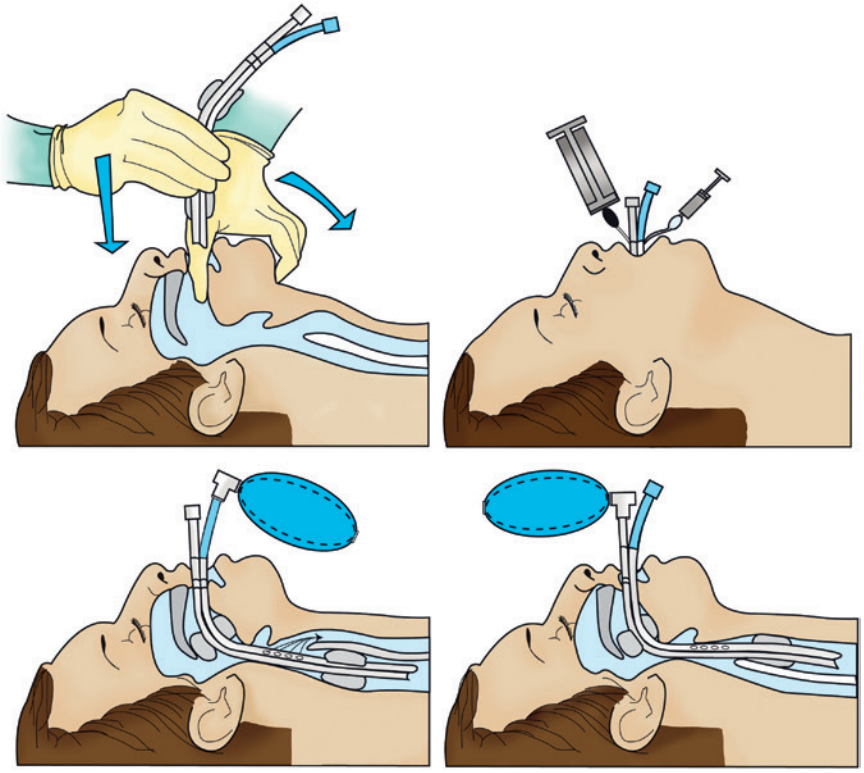

Fig. 37.10 Insertion of a double-lumen airway (combitube). (Modified from Cairo JM, Pilbeam SP: *Mosby's respiratory care equipment*, ed 8, St. Louis, 2010, Mosby.)

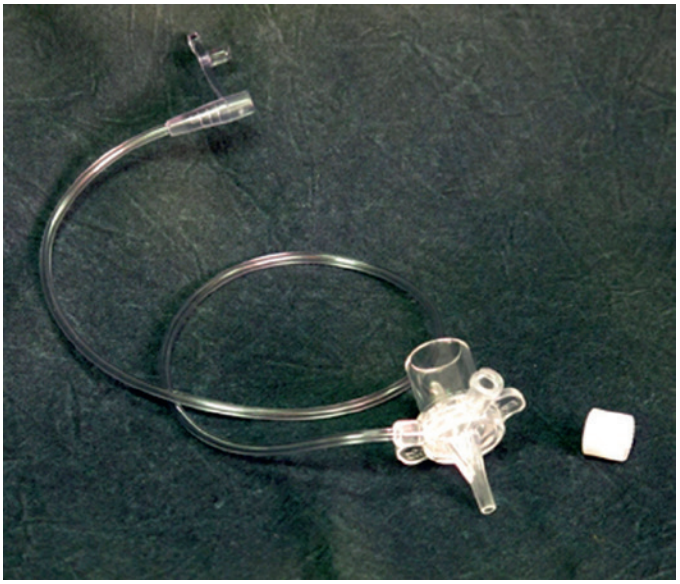

Fig. 37.11 Endotracheal tube adapter for jet ventilation. LifePort adapter. (Courtesy Bunnell Incorporated, Salt Lake City, Utah.)

Fig. 37.12 Endotracheal and tracheostomy tubes with subglottic suction ports.

Fig. 37.16 shows a typical TT and its key components. The outer cannula forms the primary structural unit of the tube, to which the cuff and a flange are attached. The flange prevents tube slippage into the trachea and provides the means to secure the tube to the neck. There are single-cannula and double-cannula TTs. The double-cannula tube has a removable inner cannula with a standard 15-mm adapter. It is normally kept in place within the outer cannula. To prevent accidental removal, the inner cannula can be locked in place at the proximal end of the outer cannula. The inner cannula may be disposable or nondisposable. If the tube becomes occluded with very thick secretions or blood clots, the inner cannula can be easily removed and cleaned or replaced to establish a patent airway. This prevents emergently changing of the entire TT when obstructed. Double-cannula tubes are

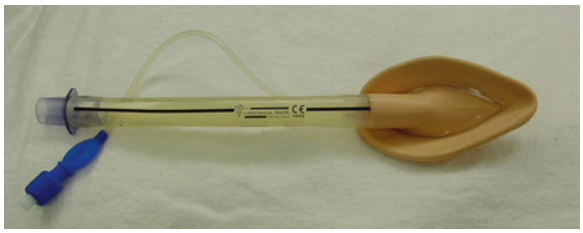

Fig. 37.13 Laryngeal mask airway. (From Gartsman G: *Shoulder arthroscopy*, ed 2, Philadelphia, 2009, Saunders.)

especially recommended for patients who are going home with a TT or in situations in which the humidity delivered to the airway is less than optimal. However, the inner cannula in some TTs can decrease the inner diameter of the tube, causing some patients to have difficulty breathing through the tube because of the increased airway resistance. In other double-cannula tubes the outer diameter is larger than the outer diameter of the same-size single-cannula tube. This can decrease the room around the tube with the cuff deflated so that a patient may not be able to

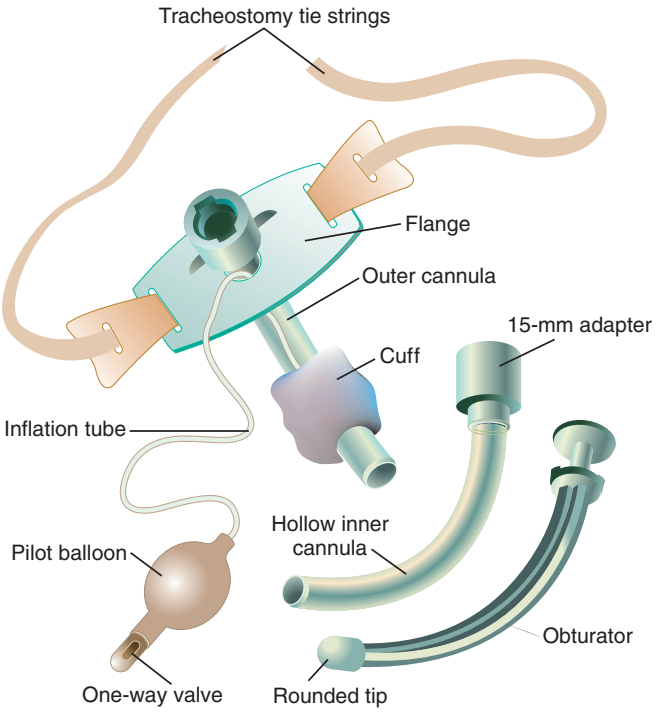

Fig. 37.16 Parts of a tracheostomy tube.

breathe around it with a speaking valve or cap on the tube. In this case the tube would need to be changed to a one with a smaller outer diameter.[27]

As with an ETT, an inflation tube leads from the cuff to a pilot balloon and valve. The tube is stabilized at the stoma site with cotton tape, which attaches to the flange and is tied around the neck or, more frequently, a soft TT holder with Velcro fasteners. An **obturator** with a rounded tip is used for tube insertion. Before insertion, the obturator is placed within the outer cannula, with its tip extending just beyond the far end of the tube; this minimizes mucosal trauma during insertion. Finally, as with ETTs, a radiopaque indicator in the distal end of the tube helps to confirm tube position on a chest x-ray.

As with ETTs, various modified TTs are available. Extra-long TTs may be used in patients who require extra proximal or distal length because of anatomic considerations, such as a thick neck. Some extra-long tubes have an adjustable flange so that the tube,

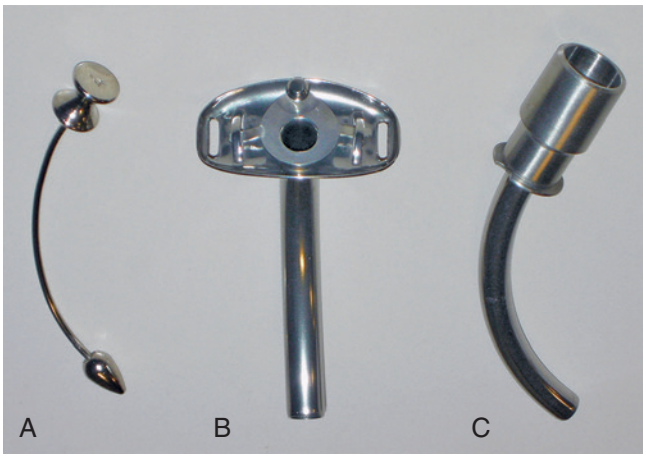

Fig. 37.17 Jackson Tracheostomy Tube Made From Stainless Steel. It has no cuff and no 15-mm adapter. (A) Obturator. (B) Outer cannula. (C) Inner cannula.

Fig. 37.18 Laryngectomy tubes.

under direct vision with a bronchoscope, can be placed past an abnormality in the trachea, such as a tumor or tracheal stenosis. Other modifications address cuff design. Cuffless TTs are used in patients without high risk of aspiration or need for mechanical support. These promote airflow over the vocal cords and increase speech. Tight-to-shaft (TTS) cuffs conform to the outer cannula of the TT when deflated. These are also used to aid in speech. The cuff material is more porous than a standard cuff, so must be filled with sterile water instead of air.

The metal Jackson TT is made of stainless steel with an inner and outer cannula (Fig. 37.17). There is no cuff at the distal end or 15-mm adapter at the proximal end. This TT is generally used in patients with a long-term need for an airway but who do not require a seal to protect the airway from aspiration or to facilitate positive pressure ventilation. If the patient requires manual ventilation, a 15-mm adapter should be inserted into the proximal opening. If the patient requires a sealed airway, the tube needs to be changed to the standard cuffed tube described earlier. A laryngectomy tube is a shorter tube without a cuff inserted into the stoma after a laryngectomy. The tube keeps the stoma open until it heals. There are several different types, some with a flange that can be secured with a fastener around the patient's neck and some without a flange (low profile). The tube may be easily removed to be cleaned and then reinserted (Fig. 37.18).

Fig. 37.19 Commercially available cricothyroidotomy kit. (Courtesy Smith's Medical International, Kent, United Kingdom.)

Surgical Emergency Airways

Despite various alternatives to establish ventilation, occasionally the problem of "cannot intubate/cannot ventilate" occurs.[28] In these situations, a surgical transtracheal airway must be established. Cricothyroidotomy and percutaneous transtracheal ventilation are options. Commercial kits are available, or a series of available supplies can be used (Fig. 37.19).[29]

Complications include bleeding, subcutaneous emphysema due to inspiratory airway resistance through a small lumen, and air trapping secondary to expiratory flow resistance. Nevertheless, cricothyroidotomy and percutaneous transtracheal ventilation are the preferred routes over emergent tracheotomy until a more definitive airway can be placed after the emergency has passed. Surgical placement of a TT should be accomplished in 48 to 72 hours.[29,30]

MINI CLINI

Alternative Airway Devices

Problem

A female patient is admitted to the emergency room after suffering an intracranial hemorrhage. She is unconscious and not breathing. Intubation attempts are unsuccessful and a clinician skilled at intubation is not present. What alternative airway device could be used?

Discussion

A laryngeal mask airway (LMA). The LMA offers ease and speed during insertion for the inexperienced intubator. The airway can be secured quickly and mechanical ventilation commenced. This patient was unconscious, so the LMA is appropriate. The patient was admitted with a neurologic injury and likely has normal respiratory system resistance and compliance. Ventilating pressures greater than 20 cm H_2O will likely not be needed. The patient should be stabilized, and once appropriate personnel are present, the LMA should be exchanged for an ETT.

Procedures

Orotracheal Intubation

Orotracheal intubation is the preferred route for establishing an emergency tracheal airway because the oral passage is the quickest and easiest route in most cases. Orotracheal intubation can be safely performed by an appropriately trained physician, RT, nurse, or paramedic.[28] Typically, this training involves manikin practice and application on anesthetized patients under the guidance of an anesthesiologist or other appropriately skilled individual. The basic steps in orotracheal intubation are described here.[31] Proficiency in this technique can be developed only with extensive training and experience.

BOX 37.3 Equipment Needed for Endotracheal Intubation

- Oxygen flowmeter and tubing
- Suction apparatus
- Flexible sterile suction catheters
- Sterile gloves for endotracheal suctioning
- Yankauer (tonsillar) tip suction
- Manual resuscitation bag and mask
- Colorimetric carbon dioxide detector
- Oropharyngeal airways
- Laryngoscope (two) with assorted blades (size 2 or 3 for adults, size 1 or 2 for children, size 0 or 1 for infants)
- Endotracheal tubes (three appropriate sizes)
- Tongue depressor
- Stylet
- Stethoscope
- Tape or endotracheal tube holder
- 10- or 12-mL syringe
- Water-soluble lubricating gel
- Magill forceps
- Local anesthetic (spray)
- Towels (for positioning)
- CDC barrier precautions (gloves, gowns, masks, goggles, or face shields)

CDC, U.S. Centers for Disease Control and Prevention.

Step 1: Assemble and Check Equipment.

Box 37.3 lists the equipment necessary for intubation. All suction equipment is assembled, and the vacuum pressure is checked before intubation because vomitus or secretions may obscure the pharynx or glottis. The appropriate-size laryngoscope blade (see Box 37.3) is attached to its handle, and the light source is checked for secure attachment and brightness. If the light does not function, the bulb first should be checked to see if it is tight. If the scope still does not light, the batteries should be checked or the bulb should be replaced.

An appropriate-size tube should be selected, and other tubes should be available that are at least one size larger and one size smaller. Table 37.3 lists recommended orotracheal tube sizes according to patient weight or age. ETTs are sized by their internal diameter (in millimeters). Tube lengths given in Table 37.3 are averages after insertion, confirmed placement, and fixation (incisor teeth to tube tip).

RULE OF THUMB In general, a woman is intubated with a No. 7 or No. 7.5 orotracheal tube and a man is intubated with a No. 8.0 or No. 8.5 orotracheal tube.

After selecting the correct size of tube, the RT inflates the tube cuff and checks for leaks. The RT must be sure to deflate the cuff before insertion. To ease insertion, the outer surface

TABLE 37.3 Guideline for Infant, Pediatric, and Adult Oral Endotracheal Tube Sizes

Age	Tube Size (mm internal diameter)	Distance (in cm) From Incisors (lip in infants) to Tip of Tube
Infant, <1 kg	2.5	6.5–8
Infant, 1–2 kg	3.0	7–8
Infant, 2–3 kg	3.5	8–9
Infant, 4 kg	3.5–4.0	9–10
6 months	3.5–4.0	10–11
18 months	3.5–4.5	11–13
3 years	4.5–5.0	12–14
5 years	4.5–5.0	13–15
6 years	5.5–6.0	14–16
8 years	6.0–6.5	15–17
12 years	6.0–7.0	17–19
16 years/small women	6.5–7.0	18–20
Women (average)	7.5–8.0	19–21
Men	8.0–9.0	21–23

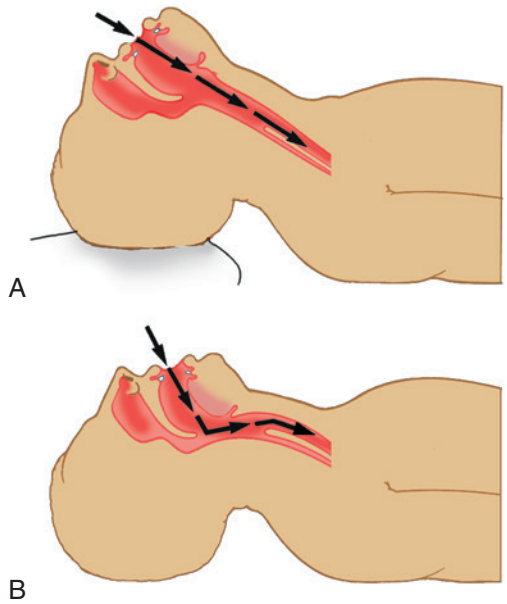

Fig. 37.20 (A) Correct head position before intubation. (B) Incorrect head position before intubation.

of the tube should be lubricated with a water-soluble gel. Finally, many clinicians insert a stylet into the tube to add rigidity and maintain shape during insertion. The tip of the stylet must never extend beyond the ETT tip.

Step 2: Position Patient.

To visualize the glottis and insert the tube, the RT aligns the patient's mouth, pharynx, and larynx. This alignment is achieved by combining moderate cervical flexion with extension of the atlantooccipital joint. Placement of one or more rolled towels under the patient's shoulders helps. Next the RT flexes the patient's neck and tilts the head backward with his or her hand, placing the patient into the sniff position (Fig. 37.20).

MINI CLINI

Indications for Endotracheal Intubation

Problem

A woman is admitted to the emergency department after sustaining chest trauma during a motor vehicle accident. The patient is unconscious, cyanotic, and tachypneic and has blood in the mouth and pharynx. Breath sounds are diminished on both sides. The physician requests that the RT immediately perform orotracheal intubation. Why?

Discussion

This patient exhibits several indications for insertion of an artificial airway. First, being unconscious, the patient is probably unable to protect her lower airway adequately. With blood in the mouth and pharynx, there should be increased concern for protecting her lungs from aspiration. The blood also may indicate partial airway obstruction; the breath sounds, cyanosis, and respiratory distress contribute to that conclusion. Finally, the cyanosis and chest trauma indicate potential hypoxemic respiratory failure, which may require positive pressure ventilatory support through, a cuffed ETT.

Step 3: Preoxygenate and Ventilate Patient.

A patient in need of intubation is often apneic or in respiratory distress. Providing ventilation and oxygenation by manual resuscitator bag and mask with 100% O_2 before intubation helps to ensure the patient tolerates the intubation procedure. In many, continuous positive airway pressure (CPAP) or high-flow nasal cannula are also being used during preoxygenation. No more than 30 seconds should be devoted to any intubation attempt. If intubation fails, immediate ventilation and oxygenation of the patient for 3 to 5 minutes before the next attempt should occur.

Step 4: Insert Laryngoscope.

The RT should use the left hand to hold the laryngoscope and the right hand to open the mouth (Fig. 37.21). The laryngoscope is inserted into the right side of the mouth and moved toward the center, displacing the tongue to the left. The tip of the blade is advanced along the curve of the tongue until the epiglottis is visualized.

RULE OF THUMB A No. 3 curved Macintosh or straight Miller laryngoscope blade is commonly used to intubate adults.

Step 5: Visualize Glottis.

As the laryngoscope blade reaches the base of the tongue, the RT looks for the arytenoid cartilage and epiglottis (Fig. 37.22). If these structures are not visible, the blade is probably advanced too far and may be in the esophagus. If this is the case, the RT should maintain upward force on the laryngoscope and slowly withdraw the blade until the larynx is seen.

Step 6: Displace Epiglottis.

The technique used to displace the epiglottis depends on the type of blade chosen (Fig. 37.23). With the curved or MacIntosh blade, the epiglottis is displaced indirectly by advancing the tip of the blade into the vallecula (at the base of the tongue), and the laryngoscope is lifted up and forward (see

Fig. 37.23A). With the straight or Miller blade, the epiglottis is displaced directly by advancing the tip of the blade over its posterior surface and the laryngoscope is lifted up and forward (see Fig. 37.23B).

One should avoid levering the laryngoscope against the teeth while lifting the tip of the blade because this can damage the teeth and gums. This problem can be avoided by keeping the wrist fixed and moving the handle of the laryngoscope in the direction it is pointing when visualizing the epiglottis.

Step 7: Insert Tube.

When the epiglottis is displaced and the glottis is visualized, the tube is inserted from the right side of the mouth and advanced without obscuring the glottic opening (Fig. 37.24). When the tube tip is seen passing through the glottis, it is advanced until the cuff has passed the vocal cords. When the tube is in place, the RT stabilizes it with the right hand and uses the left hand to remove the laryngoscope and stylet. The cuff is inflated to seal the airway, and ventilation and oxygenation are immediately provided.

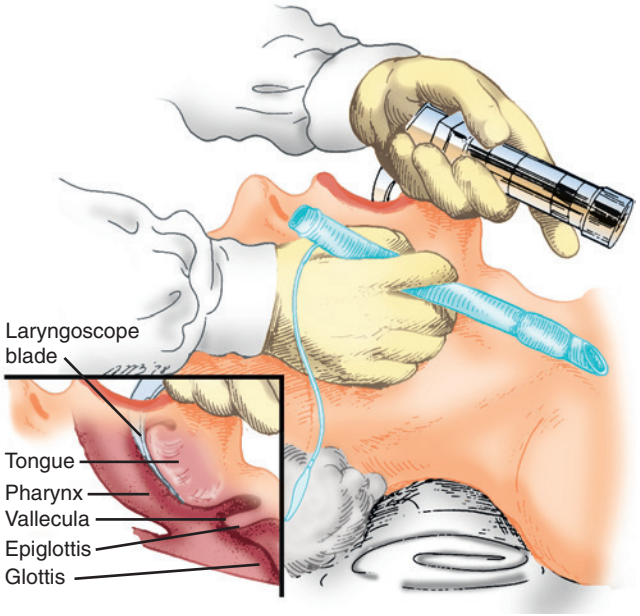

Fig. 37.21 To achieve orotracheal intubation, the respiratory therapist holds the laryngoscope in the left hand, introduces the blade into the right side of mouth, and displaces the tongue to the left. BOX 37.4 Bedside Methods to Assess Endotracheal Tube Position

- Auscultation of chest and abdomen
- Observation of chest movement
- Tube length (centimeters to teeth)
- Light wand
- Capnometry
- Colorimetry
- Flexible laryngoscopy or bronchoscopy
- Videolaryngoscopy
- Ultrasound

Step 8: Assess Tube Position.

Ideally, the tip of an ETT should be positioned in the trachea approximately 3 to 5 cm above the carina.[32] One or more of several bedside methods can be used to assess positioning of the ETT before stabilization (Box 37.4). With the exception of direct laryngoscopy and bronchoscopy, none of these methods can absolutely confirm proper tube placement. Use of bedside ultrasound technology for evaluation of ETT placement is increasing. Ultrasound machines are more readily available and provides clinicians with immediate assessment.

After tube passage and cuff inflation, the RT listens for equal and bilateral breath sounds as the patient is being ventilated. Air movement or gurgling sounds over the epigastrium indicate possible esophageal intubation. In addition, the chest wall is observed for adequate and equal chest expansion. These movements, combined with good breath sounds, are reinforcing. The combination of decreased breath sounds and decreased chest wall movement on the left side may indicate right main stem intubation. Right mainstem intubation is corrected by slowly withdrawing the tube while listening for the return of left-side breath sounds. Other conditions may cause decreased breath sounds in the left lung (e.g., atelectasis, pleural effusion).

The depth of tube insertion (length from incisor teeth to tip) is useful to help determine tube position. As indicated in Table 37.3, the average length from the teeth (incisors) to the tip of a properly positioned oral ETT in men is 21 to 23 cm. For women, this distance is approximately 2 cm less. Tube length alone cannot confirm proper placement; a tube with the 23-cm mark positioned at the teeth could just as well be in the esophagus as in the trachea. A light wand is a flexible stylet with a lighted bulb at the tip. If a light wand is used during intubation, as the stylet and ETT pass into the larynx, a characteristic glow is seen under the skin, just above the thyroid cartilage.[33] This glow is not as bright or focused if the tube is in the esophagus.

Esophageal intubation is best assessed using exhaled carbon dioxide (CO_2) analysis (capnometry) and should be performed after every intubation. Because inspired air contains only approximately 0.04% CO_2 and end-tidal gas contains approximately 5% CO_2, placement of an ETT in the respiratory tract causes CO_2 levels to increase abruptly during expiration. This increase is evident on a capnographic display (Fig. 37.25). If the tube is in the esophagus, CO_2 levels remain near zero.[34] However, of concern is patients who may have recently consumed carbonated fluids, because CO_2 may be released via the esophagus.

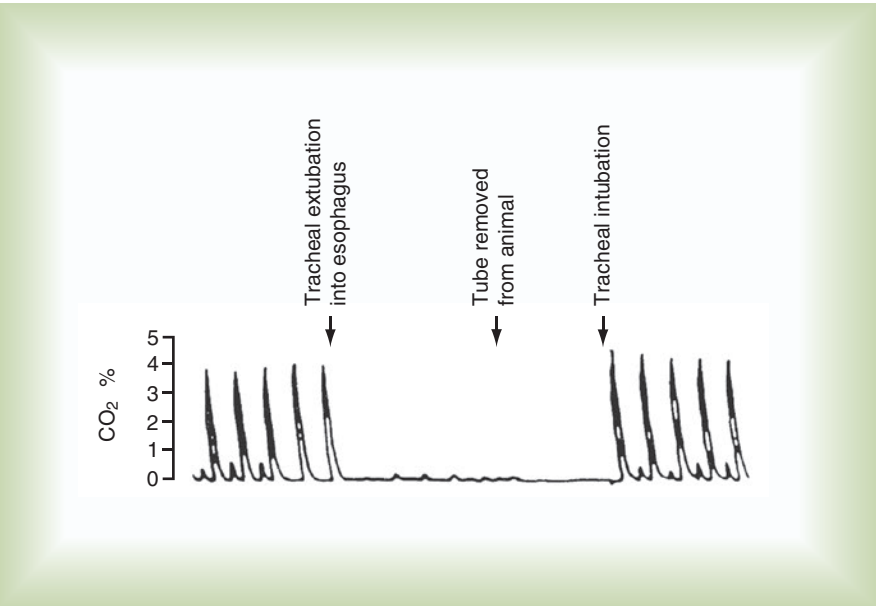

Fig. 37.25 Capnogram tracing showing changes in expired percent carbon dioxide with proper and improper placement of endotracheal tube in test animals.

Fig. 37.26 Disposable colorimetric carbon dioxide detector for confirming tracheal intubation. (Used by permission from Nellcor Puritan Bennett LLC, Boulder, Colorado, doing business as Covidien.)

Colorimetric CO_2 analysis is an inexpensive alternative to capnometry. Functioning similar to pH paper, a colorimetric system has an indicator that changes color when exposed to different CO_2 levels.[35] Fig. 37.26 shows a disposable colorimetric system designed specifically to confirm tube placement during intubation. Colorimetric devices are portable and disposable and are commonly used in hospitals.

Both devices are effective in detecting most esophageal intubations. However, in patients with cardiac arrest, expired CO_2 levels may be near zero because of poor pulmonary blood flow, yielding a false-negative result.[33-35] Waveform capnography can also be used to assess the effectiveness of chest compressions during cardiopulmonary resuscitation. If the exhaled CO_2 begins to fall, chest compressions are inadequate and compressors should be rotated. In general, expired CO_2 levels increase with the return of spontaneous circulation due to the significant increase in amount of CO_2 returned to the lungs. CO_2 analysis, colorimetric or waveform, is an unreliable indicator of mainstem bronchial intubation.

RULE OF THUMB In general, an orotracheal tube initially should be inserted to the 21- to 23-cm mark at the teeth in men and to the 19- to 21-cm mark at the teeth in women and adjusted based on the results of the patient assessment (bilateral breath sounds) and chest x-ray findings after intubation.

Proper tube placement in the trachea can be confirmed without a chest x-ray by using a flexible laryngoscope or bronchoscope (Fig. 37.27).[36] After ensuring patient reoxygenation, a flexible bronchoscope can be inserted directly into the ETT. Visualization of the carina distal to the tip of the ETT ensures proper placement in the trachea. More precise placement is possible by moving the bronchoscope from the tube tip to the carina, while measuring this distance.

A videolaryngoscope can also be used to ensure proper placement of the ETT, especially in anticipated difficult intubations. It provides a better view of the airway, especially when there is limited mobility of the patient's neck or mouth. A camera is incorporated into the distal tip of the laryngoscope. The image is projected onto a mobile screen, allowing other clinicians to see the airway and help if needed.[37]

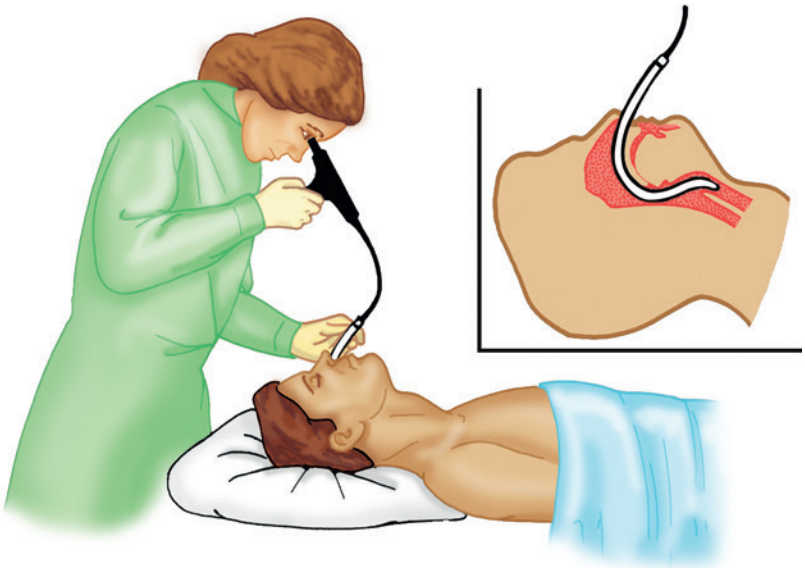

Fig. 37.27 Flexible laryngoscopy used to confirm endotracheal tube placement.

MINI CLINI

Capnometry and Endotracheal Tube Placement

Problem

At a code blue in the emergency department, a patient is intubated by the RT. A capnometer is attached to the ETT to confirm placement in the trachea. The end-expired CO_2 reads 0% as the patient is ventilated with a manual resuscitator. At this time, no one is performing cardiac compressions. Should the RT conclude that the ETT is not in the trachea?

Discussion

No. If the patient is in cardiac arrest, no blood is perfusing the alveoli and no CO_2 is entering the alveoli. The result is an end-tidal CO_2 of 0%. When cardiac compressions begin (and they should begin immediately in confirmed cardiac arrest) and if compressions are effective, one should see an increase in end-tidal CO_2 as blood begins to perfuse the alveoli and CO_2 diffuses from the blood.

There are other simple ways to assess ETT placement in the trachea, such as bilateral breath sounds on auscultation and chest excursions.[38] However, an increase in end-tidal CO_2 is a sure indication that the ETT is in the lungs because the only source of CO_2 is in the alveoli.

Step 9: Stabilize Tube and Confirm Placement.

The tube should not be secured until correct placement has been assessed by using one or more of the previously mentioned methods. After assessing placement and while holding the tube in position, the RT secures the tube to the skin above the lip and on the cheeks using tape or an ETT holder. A bite block, oropharyngeal airway, or similar device may be needed to prevent the patient from biting down on the tube (Fig. 37.28). After the tube is stabilized, a chest x-ray should be taken to confirm its position.

The most common complication of emergency airway management is tissue trauma. The most serious complications are acute hypoxemia, hypercapnia, bradycardia, and cardiac arrest.[39,40] These problems can be minimized by using proper technique, providing the patient with adequate ventilation and oxygenation (before, during, and after), and strictly adhering to intubation time limits. In addition, sedation and anesthesia can reduce complications and facilitate intubation in a semicomatose or combative patient.[28] Muscle-relaxing or muscle-paralyzing agents can be used in a combative patient who cannot be controlled by sedation. A paralyzed patient has no ability to compensate for hypoxemia or hypercapnia. It is imperative that the patient can be adequately ventilated by bag and mask. Rapid-sequence induction is used with the administration of a sedative-hypnotic medication and a muscle-relaxing or -paralyzing agent. Difficult intubations occur because of inability to open the patient's mouth, inability to position the patient, or unusual airway anatomy. Special intubation equipment (e.g., laryngoscope blades, videolaryngoscopy, or specialized stylets) or alternative techniques can be used.[28,38] A thin soft guide, referred to as a bougie, can be used if a clinician encounters difficulties passing an ETT through the glottic opening. Under direct laryngoscopy, a bougie can be passed first, with an ETT fed over the proximal end. Placement of a bougie ensures access to the trachea. Additional details of these techniques are beyond the scope of this chapter.

Nasotracheal Intubation

Nasotracheal intubation is not the preferred route of intubation, but it is the route of choice in certain clinical situations. Examples include intubation of patients when the oral route is unavailable, such as patients with maxillofacial injuries or undergoing oral surgery.

Nasotracheal intubation is performed either blindly or by direct visualization.[39] The direct visualization approach requires either a standard or a flexible laryngoscope. For the blind technique to

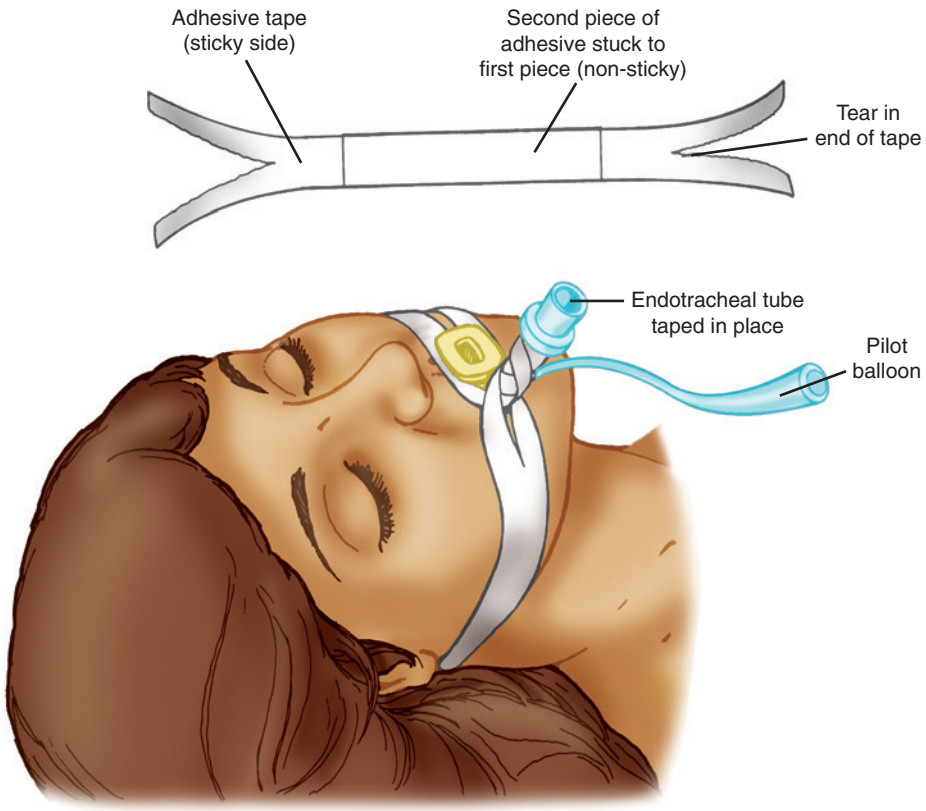

Fig. 37.28 Securing the endotracheal tube.

work, the patient must be breathing spontaneously. Equipment assembly, patient positioning, and preoxygenation are essentially the same as with oral intubation. A mixture of 0.25% phenylephrine and 3% lidocaine may be applied to the nasal mucosa with a long cotton-tipped swab to provide local anesthesia and vasoconstriction of the nasal passage.

Direct visualization. The equipment needed for nasal intubation by direct visualization is the same as for oral intubation, with the addition of Magill forceps. A smaller ETT also may be needed. The tube should be prelubricated with water-soluble gel to aid passage. To insert the tube, the bevel is positioned toward the septum and advanced along the floor of the nasal cavity (inferiorly). When the tip of the tube is in the patient's oropharynx, the RT opens the patient's mouth, inserts the laryngoscope (with the left hand), and visualizes the glottis. The RT uses the Magill forceps with the right hand to grasp the tube just above the cuff and direct it between the vocal cords (Fig. 37.29). To help advance the tube past the vocal cords, the neck may need to be flexed. Confirmation of position and stabilization follows, as with the oral route.

Alternatively, a flexible bronchoscope or laryngoscope can be used to guide tube passage.[36] With the bronchoscopic method, the distal end of the scope is passed through the ETT and directly into the trachea. When placement is ensured, the RT slides the ETT down over the scope into proper position. The procedure is similar with a flexible laryngoscope. However, because directional control of the scope is limited, the RT may have to reposition the patient's head and neck to help guide the tube.

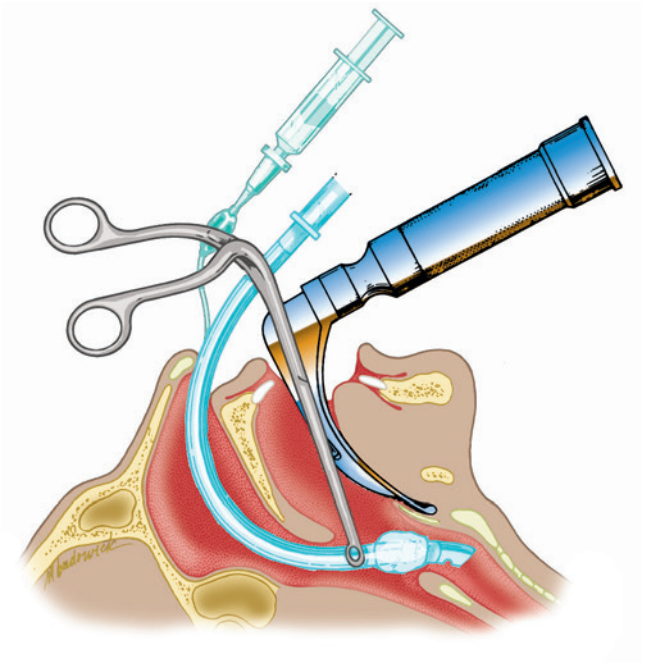

Fig. 37.29 Nasal intubation using Magill forceps. (Modified from Finucane BT, Santora AH: *Principles of airway management*, Philadelphia, 1988, FA Davis.)

RULE OF THUMB Nasotracheal intubations are beneficial for patient with maxillofacial trauma or undergoing oral surgery.

Blind passage. For blind nasal intubation, the patient is placed in either the supine or the sitting position. As with direct visualization, the tube is inserted through the nose. As the tube approaches the larynx, one can listen through the tube for air movement. The breath sounds become louder and more tubular when the tube passes through the larynx. Successful passage of the tube through the larynx usually is indicated by a harsh cough, followed by vocal silence. If the sounds disappear, the tube is moving toward the esophagus. A malpositioned tube can be corrected by manipulating the tube and repositioning the patient's head and neck. Confirmation of tube placement and stabilization should follow. As previously indicated, a light wand can help to ensure proper tracheal placement during blind nasotracheal intubation.

Tracheotomy

Tracheotomy is the procedure of establishing access to the trachea via a neck incision. The opening created by this procedure is called a **tracheostomy.** Tracheotomy may be performed as a regular surgical procedure or by a percutaneous dilation procedure.

Tracheotomy is the preferred, primary route for overcoming upper airway obstruction or trauma and for patients with poor airway protective reflexes. Another indication for tracheotomy is the continuing need for an artificial airway after a prolonged period of oral or nasal intubation. If the patient still needs an artificial airway after approximately 7 to 14 days, a tracheostomy is commonly considered. The benefits of a tracheostomy versus oral or nasal intubation are elimination of vocal cord injury, increased patient comfort, less need for deep sedation, easier removal of secretions, decreased work of breathing, and potentially shorter weaning time.[40] The decision when to switch from an ETT to a TT should be individualized. Pertinent factors that should be considered in making this decision are summarized in Box 37.5. Fig. 37.30 is a decision-making algorithm useful for timing tracheotomy in critically ill patients.

BOX 37.5 Factors to Consider in Switching From Endotracheal Tube to Tracheostomy

- Projected time the patient will need an artificial airway
- Patient's tolerance of endotracheal tube
- Patient's overall condition (including nutritional, cardiovascular, and infection status)
- Patient's ability to tolerate a surgical procedure
- Relative risks of continued endotracheal intubation vs. tracheostomy

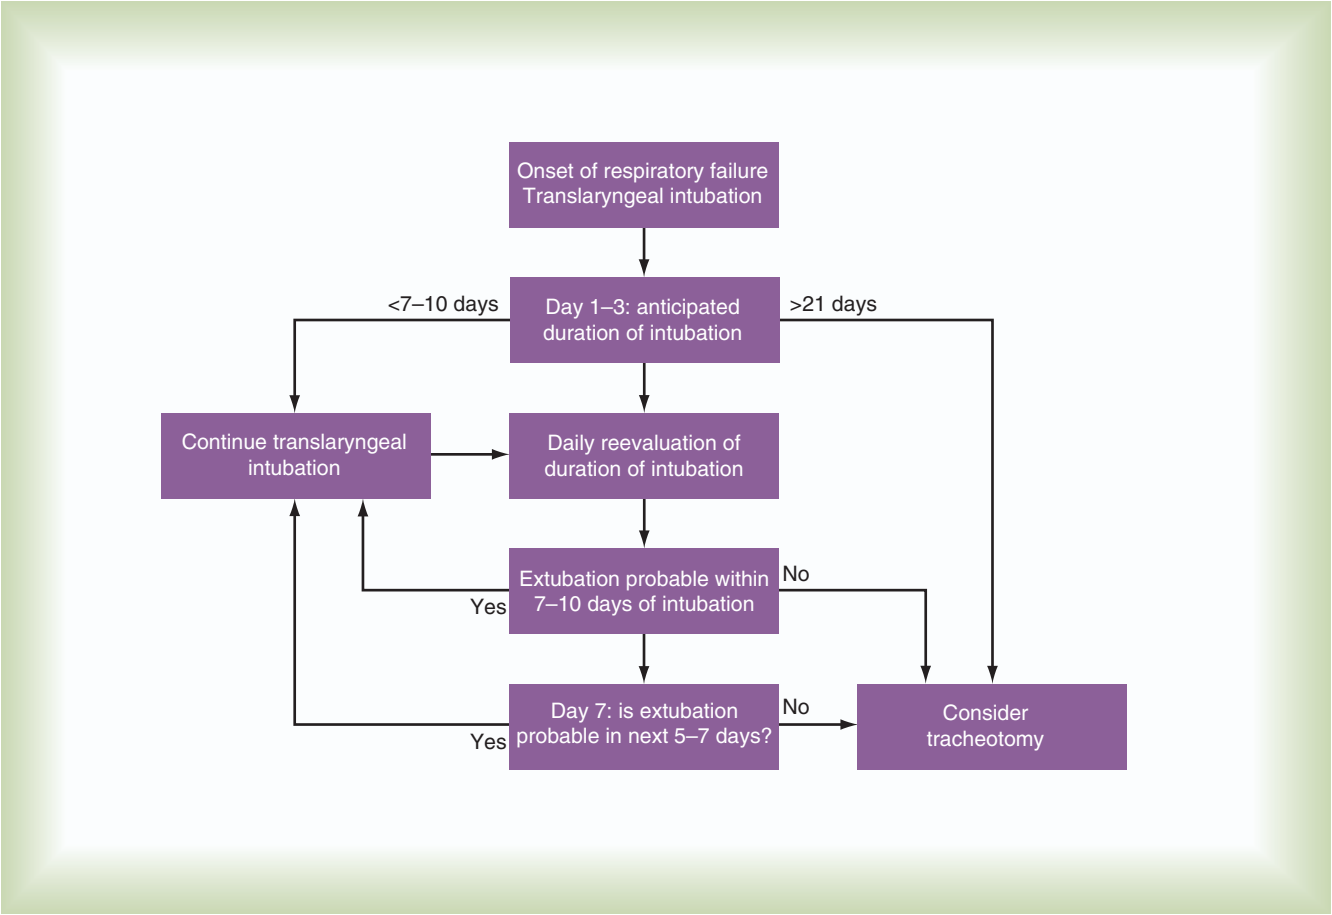

Fig. 37.30 Approach to timing tracheotomy in patients intubated and mechanically ventilated for respiratory failure. (From Heffner JE: Timing of tracheostomy in ventilator-dependent patients, *Clin Chest Med* 12:611–625, 1991.)

Procedure. Tracheotomy should be performed as an elective procedure by a skilled physician or surgeon after the patient's airway is stabilized. Mortality and morbidity are greater when the procedure is performed on an emergency basis. The RT may be asked to assist in tracheotomy, especially if performed at the bedside. For this reason, we briefly describe both the traditional surgical procedure and the percutaneous dilation method.[40]

A local anesthetic is used, and the patient is mildly sedated if conditions permit. If an ETT is in place, it should not be removed until just before the insertion of the TT. Keeping the ETT in place this way ensures a patent airway and provides additional stability to the trachea during the procedure.

In traditional surgical tracheotomy, the surgeon makes an incision in the neck over the second or third tracheal ring. After the skin and subcutaneous tissue have been incised, the surgeon divides the superficial muscles and locates the underlying thyroid gland. The surgeon divides and ligates the thyroid isthmus, which overlies the second and third tracheal rings. The surgeon then enters the trachea through either a horizontal incision between rings or a vertical incision through the second and third rings. As little cartilage as possible should be removed to promote better closure after decannulation.

In percutaneous dilation tracheotomy, the initial steps to prepare the patient are similar to the steps in the traditional tracheotomy procedure. After dissection to the anterior tracheal wall, the ETT is retracted to keep the tip of the tube inside the larynx. A bronchoscope can be used to reassess placement for the ETT for the duration of the procedure. A large leak around the ETT may develop, requiring adjustment of mechanical ventilation. If the patient is unable to tolerate the large leak, and adjustments to ventilatory support cannot compensate for the leak, a surgical procedure may be indicated for that patient.

The physician inserts a needle and sheath into the trachea between the cricoid and first tracheal ring or between the first and second rings. The physician then inserts a guidewire through the sheath, the sheath is removed, and a dilator is passed over the guidewire. Increasingly larger dilators are introduced until the stoma is large enough for a standard TT. The physician slips the TT over the last dilator used. An alternative to the use of multiple dilators is to use a single dilator with increasing diameter from the proximal to the distal end.

The procedure may be performed under direct vision with a bronchoscope passed through the ETT or an LMA. Compared with the traditional surgical procedure, a percutaneous dilation tracheotomy is rapid, with fewer complications from the surgical site, and has a better cosmetic appearance after decannulation. Contraindications for percutaneous tracheotomy are listed in Box 37.6.

Insertion of the tube, inflation of the cuff, and securing the tube follow both methods. TT ties should be secure enough to prevent movement of the tube but not so tight as to cause skin ulceration. The role of the RT in the procedure may include managing the ETT, making ventilator changes as needed, assisting with the bronchoscope, and monitoring the patient. Advantages and disadvantages of percutaneous and open surgical tracheotomy are listed in Table 37.4.

In general, the tube size is correct if it occupies two-thirds to three-quarters of the internal tracheal diameter. TTs come in various sizes, lengths, and shapes depending on the manufacturer. The size marked on the flange usually indicates the internal diameter, but some TTs with inner cannulas use Jackson sizing. Table 37.5 lists the sizes, internal diameter, external diameter, and length of commonly used brands and styles of adult TTs. Table 37.6 provides guidelines for selecting a TT according to a patient's age. Within an age category, the exact size of tube chosen depends on the patient's height, weight, and airway anatomy. To choose a TT that fits a patient properly, it is important to consider not only the internal and external diameter of the tube but also the length and shape of the tube.

BOX 37.6 Contraindications for Percutaneous Dilation Tracheostomy

Absolute
- Need for emergent surgical airway

Relative
- Children younger than 12 years of age
- Poor landmarks secondary to body habitus, abnormal anatomy, or occluding thyroid mass
- Positive end expiratory pressure less than 15 cm H_2O
- Coagulopathy
- Pulsating blood vessel over tracheotomy site
- Limited ability to extend cervical spine
- History of difficult intubation
- Infection, burn, or malignancy at tracheotomy site

From Park S, Goldenberg D: Percutaneous tracheotomy: Griggs technique, *Op Tech Otolaryngol* 18:95, 2007.

TABLE 37.4 Comparison of Percutaneous and Open Surgical Tracheotomy

Procedure	Advantages	Disadvantages
Percutaneous tracheotomy	May be done in intensive care unit	Not done in children younger than 12 years
	Sedation and local anesthetic given	
	Stoma usually stabilizes in 5 days	May be difficult to insert because of calcified cartilaginous rings
Open surgical tracheotomy	Done in patients with poor landmarks because of abnormal anatomy or body habitus	Usually done in operating room
	May be done emergently	General anesthesia given
	Done in children younger than 12 years	Stoma usually takes longer to stabilize (7–10 days)

Laryngectomy

Total **laryngectomy,** removal of the larynx (voice box), is usually done to treat laryngeal cancer. It also may be done to treat severe trauma, such as from a gunshot wound to the neck or damage to the larynx from radiation (radiation necrosis). Besides removing the larynx, the surgeon creates a hole in the neck (stoma) and attaches the trachea to the stoma. The patient will now

TABLE 37.6 Guideline for Infant, Pediatric, and Adult Tracheostomy Tube Sizes

Age/Weight[a]	ID (mm)
Premature <2 kg	2.5 cuffless neonatal
Infant	3.0–3.5 cuffless neonatal
6–18 months	3.5–4.0 neonatal or pediatric
18 months to 4–5 years	4.0–4.5 pediatric
4–5 years to 10 years	4.5–6.0 pediatric
10–14 years	5.0–6.5 pediatric or adult
14 years to adult	6.0–9.0 adult

[a]Typical pediatric size = (16 + age) / 4 or (age / 4) + 4.
NOTE: The difference between the same size (ID) neonatal and pediatric tube or pediatric and adult tube is the length; that is, the adult tube is longer than the pediatric tube, and the pediatric tube is longer than the neonatal tube.
ID, Inner diameter.

breathe through this permanent stoma. A laryngectomy tube may be inserted into the stoma to keep it open while it heals.

The surgeon may also do a tracheoesophageal puncture (TEP), which is a small opening between the posterior wall of the trachea and esophagus. The surgeon will insert a small device (prosthesis) that has a one-way valve. This prosthesis allows the patient to speak when the patient occludes the stoma during exhalation once the patient has been trained by a speech and language pathologist (Fig. 37.31). Some patients with TEP use their thumb, and others use an attached tracheostoma adjustable valve to occlude the stoma during exhalation to be able to speak. Another way a laryngectomy patient can speak is by holding an electrolarynx against the throat. This is a battery-operated device that creates vibrations that are transmitted through the pharynx and mouth to produce a voice.[41]

The risks associated with this surgery are hematoma, wound infection, fistulas, stomal stenosis (narrowing), leaking around tracheoesophageal prosthesis, difficulty swallowing and eating, and problems speaking.

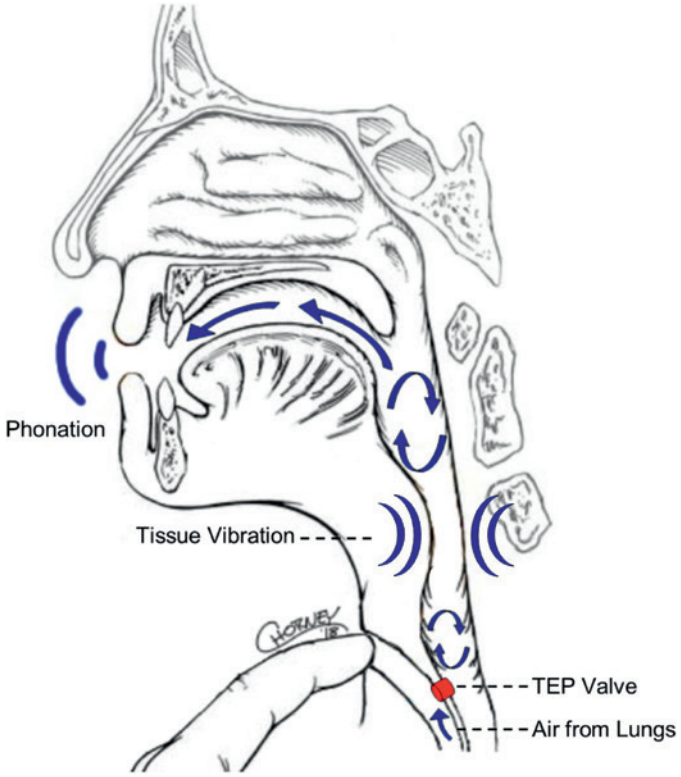

Fig. 37.31 Laryngectomy with tracheoesophageal voice prosthesis. (From Chorney MA, Dubin RM, Levine MS: Tracheobronchial foreign body aspiration in laryngectomized patient with tracheoesophageal voice prosthesis. Clinical Imaging 49:181–183, 2018.)

Sometimes the surgeon will perform only a partial laryngectomy. A tracheotomy is also done and a TT is inserted while the surgical site is allowed to heal. There is still communication between the pharynx and trachea, so the patient should eventually be able to breathe using the normal upper airway and may even be able to speak once the TT is removed.[42]

It is important to know whether a patient has had a total or partial laryngectomy, in case the patient accidentally loses the artificial airway and requires manual ventilation. In the case of a total laryngectomy the RT would apply bag-mask ventilation over the stoma, ideally using a small pediatric mask that would fit more closely over the stoma than an adult mask. In a partial laryngectomy the RT would cover the stoma with a gauze pad and apply bag-mask ventilation over the nose and mouth with the standard adult mask because there is still communication between the trachea and upper airway.

AIRWAY TRAUMA ASSOCIATED WITH TRACHEAL TUBES

Artificial airways do not conform exactly to patient anatomy, which may result in pressure on soft tissues that can result in ischemia and ulceration.[43] In addition, artificial airways tend to shift position as the patient's head and neck move or as the tube is manipulated. This shifting can result in friction-like injuries. Occasional reaction to the materials composing the tube also may cause problems.

Depending on the type of tube, damage to the patient's airway can occur anywhere from the nose down into the lower trachea. Because TTs do not pass through the larynx, structural injury resulting from these airways is limited to tracheal sites. Laryngeal dysfunction may occur secondary to a lack of stimulation from airflow or restricted movement due to equipment.[15]

Because injury often cannot be assessed while an artificial airway is in place, the patient's airway should always be evaluated carefully after extubation. Techniques commonly used to diagnose airway damage include physical examination, air tomography, fluoroscopy, laryngoscopy, bronchoscopy, magnetic resonance imaging, and pulmonary function studies.[44]

Laryngeal Lesions

The most common laryngeal injuries associated with endotracheal intubation are glottic edema, vocal cord inflammation, laryngeal or vocal cord ulcerations, and vocal cord polyps or granulomas. Less common and more serious injuries are vocal cord paralysis and laryngeal stenosis.[32,43]

Glottic edema and vocal cord inflammation are transient changes that occur as a result of pressure from the ETT or trauma during intubation.[43] The primary concern with glottic edema and vocal cord inflammation occurs after extubation. Because swelling can worsen over 24 hours after extubation, patients should be evaluated periodically for delayed development of glottic edema.

The primary symptoms of glottic edema and vocal cord inflammation are hoarseness and stridor. Hoarseness occurs in most extubated patients and usually resolves quickly. Stridor is a more serious symptom than hoarseness, indicating a significant decrease in diameter of the airway. Stridor is often treated with epinephrine (2.25% racemic solution or levoepinephrine 1:1000) via aerosol.[43] The treatment goal is to reduce glottic or airway edema by mucosal vasoconstriction. A steroid also may be added to the aerosol to reduce inflammation further. Both of these techniques are more commonly used in children than in adults.

To reduce laryngeal edema in patients who have had prolonged intubation or patients who have failed prior extubation because of glottic edema, intravenous steroids, and/or diuretics may be given 24 hours before extubation.[43] If stridor continues and is unresponsive to treatment, structural changes that narrow the airway should be suspected.

Laryngeal and vocal cord ulcerations may cause hoarseness soon after extubation. Symptoms usually resolve spontaneously, and no treatment is indicated. Vocal cord polyps and granulomas develop more slowly, taking weeks or months to form. Symptoms include difficulty in swallowing, hoarseness, and stridor. If symptoms are severe or persistent, the polyps or granulomas may have to be removed surgically.

Vocal cord paralysis is likely in extubated patients with hoarseness and stridor that does not resolve with treatment or time. In some patients, symptoms may resolve within 24 hours, and

full movement of the vocal cords can return over several days. If the obstructive symptoms continue, tracheotomy may be indicated.

Laryngeal **stenosis** occurs when the normal tissue of the larynx is replaced by scar tissue, which causes stricture and decreased mobility. The symptoms of laryngeal stenosis are similar to symptoms of vocal cord paralysis—stridor and hoarseness. Because laryngeal stenosis does not resolve spontaneously, surgical correction is usually required. Some patients require a permanent tracheostomy.

Tracheal Lesions

Although laryngeal lesions occur only with oral or nasal ETTs, tracheal lesions can occur with any tracheal airway. These tracheal lesions include granulomas, **tracheomalacia,** and tracheal stenosis.[45] Less common but more serious complications are tracheoesophageal and tracheoinnominate artery fistulas.

Tracheomalacia and tracheal stenosis can occur either separately or together. *Tracheomalacia* is the softening of the cartilaginous rings, which causes collapse of the trachea during inspiration and expiration. *Tracheal stenosis* is a narrowing of the lumen of the trachea, which can occur as fibrotic scarring, causing the airway to narrow. In patients with ETTs, this type of damage most often occurs at the cuff site. In patients with TTs, stenosis may occur at the cuff, tube tip, or stoma sites; the stoma site is the most common. Stenosis at the stoma site is associated with too large a stoma, infection of the stoma, movement of the tube, frequent tube changes, and advanced age.[46]

Signs of possible tracheal damage before extubation include difficulty in sealing the trachea with the cuff and evidence of tracheal dilation on chest x-ray.[43] Signs and symptoms of postextubation problems include difficulty with expectoration, dyspnea, and stridor. Although these findings may appear acutely, they may develop over several months and may not be present until the radius is reduced by 50% to 75%. Dyspnea at rest may not be seen until the diameter of the trachea is less than 5 mm. Symptoms are often incorrectly attributed to the development of asthma or chronic lung disease.

Tomography, fluoroscopy, and pulmonary function studies (especially flow-volume loops) may be helpful in quantifying the severity of the damage. Flow-volume loops are also helpful in distinguishing between tracheomalacia and tracheal stenosis. Tracheomalacia appears as a variable obstruction with different inspiratory and expiratory patterns. As an example, with variable extrathoracic obstruction (e.g., when the extrathoracic trachea is floppy or malacic), the flow-volume loop shows flattening of the inspiratory limb and the expiratory limb is normal. Tracheal stenosis appears as a fixed obstructive pattern, with flattening of both the inspiratory and the expiratory limbs of the flow-volume loop (Fig. 37.32).

Treatment depends on the severity of the lesion, especially the length and circumference of the damage.[44] Laser therapy may be useful if the lesion is small. Resection and end-to-end anastomosis may be indicated when the damage involves fewer than three tracheal rings. More involved damage may require staged repair. Stents may be placed to maintain the patency of the airway.

A **tracheoesophageal fistula** is a direct communication between the trachea and the esophagus. Tracheoesophageal fistula is a rare complication of both tracheotomy and endotracheal intubation. If it occurs soon after a tracheotomy, incorrect surgical technique may be the cause. Later development is related to sepsis, malnutrition, tracheal erosion from the cuff and tube, and esophageal erosion from nasogastric tubes.[43] The diagnosis can be made based on a history of recurrent aspiration and abdominal distension as air is forced into the esophagus during positive pressure ventilation. The diagnosis is also made by direct endoscopic examination of the trachea and esophagus. Treatment involves surgical closure of the defect.

A **tracheoinnominate artery fistula** can occur when a TT causes tissue erosion through the innominate artery. The result

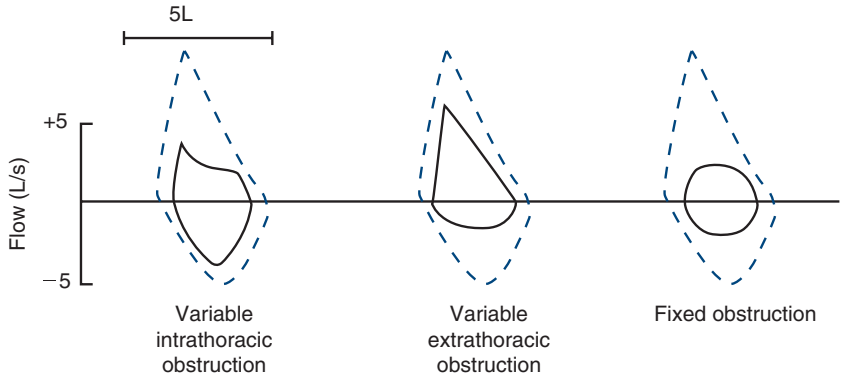

Fig. 37.32 Patterns of Pulmonary Dysfunction Revealed by Flow-Volume Loops. *Dashed lines* are normal values for comparison. Tracheomalacia is typically seen as a variable obstruction, whereas stenosis most often manifests with a fixed obstruction pattern. (From Mottram C: *Ruppel's manual of pulmonary function testing,* ed 10, Mosby, 2013, St. Louis.)

is massive hemorrhage and, in most cases, death. Tracheoinnominate artery fistula is a rare complication, probably caused by improper low positioning of the stoma or excessive movement of the tube.[44] Pulsation of the TT may be the only clue before actual hemorrhage. When hemorrhage begins, hyperinflation of the cuff may slow the bleeding, but the patient still needs surgical intervention.[44] Even with proper corrective action, only 25% of patients who develop this serious complication survive.

Prevention

Several actions can minimize the trauma caused by tracheal airways. Many studies suggest that tube movement is a primary cause of injury.[43,44] Several methods can be used to limit tube movement. Sedation can help keep patients comfortable and decrease the likelihood of self-extubation. Nasotracheal tubes are easier to stabilize and may move less than orotracheal tubes. Swivel adapters can be used to minimize tube traction whenever respiratory therapy equipment is attached to patients with tracheostomies. If a patient with a tracheostomy requires O_2 therapy, tracheostomy collars are preferred to T-tubes or Briggs adapters.

Selection of the correct airway size is also important. Once in place, endotracheal and TTs should not be changed unless necessary. To minimize vocal cord closure around ETTs, patients should be discouraged from unnecessary coughing or efforts to talk. Tracheal wall injury from the endotracheal or TT cuff can be reduced by maintaining pressures of 20 to 30 cm H_2O.[13,45] If the airway is in place solely for suctioning or to bypass an obstruction, a cuff may not be needed.

Infected secretions have been implicated in the development of tracheitis and mucosal destruction, and infection of the tracheotomy stoma has been linked to tracheal stenosis.[44] Sterile techniques should be used when cleaning or suctioning TTs. Good tracheostomy care, including aseptic cleaning of the stoma with sterile normal saline, should be carried out routinely, and soiled tracheostomy dressings should be changed as needed. If there is significant drainage from the stoma, it is better to use a foam dressing, which will absorb the drainage away from the skin, rather than a standard gauze dressing, which when wet will keep the skin moist. (See discussion of tracheostomy care procedure later in the chapter.) When sutures are used to secure the TT flange to the patient's neck, it can be very difficult to properly clean around the stoma. So, if sutures are present, it is recommended to remove them as soon as possible, ideally by day 5 to 7 after the tracheostomy was performed. If there are any signs of pressure injury from the trach flange, place a hydrocolloid dressing under the flange. Sometimes because of a patient's neck anatomy, changing the TT to another type with a different style of flange as soon as it is safe to do so may also prevent further skin injury.

RULE OF THUMB In adults, tracheal tube cuff pressure should be maintained at 20–30 cm H_2O to minimize tracheal mucosal injury and aspiration of oral secretions.

AIRWAY MAINTENANCE

The RT must attend to several aspects of airway maintenance when a tracheal airway is in place. Critical responsibilities in this area include: (1) securing the tube and maintaining its proper placement, (2) providing for patient communication, (3) ensuring adequate humidification, (4) minimizing the possibility of infection, (5) aiding in secretion clearance, (6) providing appropriate cuff care, and (7) troubleshooting airway-related problems.

Securing the Airway and Confirming Placement

The most common way to secure ETTs is with tape. The tape is secured to one side of the face and then wound around the tube and airway once or twice before the end is secured to the skin again (see Fig. 37.28). Silk tape is adequate if the period of intubation is short, such as during surgery; however, silk tape is easily loosened by oral secretions. Cloth tape seems to be better for longer use and may adhere better if the skin is prepared with a nonirritating medical liquid adhesive. Instead of using tape to secure the tube, practitioners can choose among several commercial ETT stabilizers. Case reports indicate that use of these stabilizers can result in less skin damage, tube movement, and self-extubations than with traditional taping. However, these stabilizing devices cannot prevent airway or skin trauma, so the skin around the mouth or nose should be checked regularly. If there is evidence of skin irritation, the tube should be moved to the other side of the mouth or the other nares and then resecured. Alternation of securing sites for ETTs should be done on a routine basis to prevent skin breakdown. However, consensus does not exist on the exact interval.

A TT can be secured by threading cloth ties through the tube flange and tying them together on the side of the patient's neck. Alternatively, a commercial TT holder made of soft foam with Velcro attachments threaded through the tube flange can be used. This soft TT holder is easier to change and does not cause skin ulceration as often as cloth ties. Whichever tube holder is used, skin damage can be minimized by keeping the ties loose enough to slip one finger underneath easily.

Proper placement of an ETT or TT normally is confirmed by chest x-ray. The tube tip should be approximately 3 to 5 cm above the carina in adults, or between the second and fourth tracheal rings.[32,46] Keeping the tube position in this range minimizes the chance of the tube moving down into the main stem bronchi or up into the larynx. Even so, the ETT position changes with movement of the head and neck (Fig. 37.33).[47] Flexion of the neck moves the tube toward the carina, whereas extension pulls the tube toward the larynx.[48,49] When reviewing a chest x-ray for tube placement, the clinician should also check the position of the head and neck. If the tube is malpositioned, the old tape should be removed and the tube repositioned, using the centimeter markings as a guide. This maneuver usually requires two people to prevent extubation.

As an alternative to using chest films to confirm tube placement, a practitioner trained in flexible laryngoscopy or bronchoscopy may confirm the position of the tube visually.[50] With

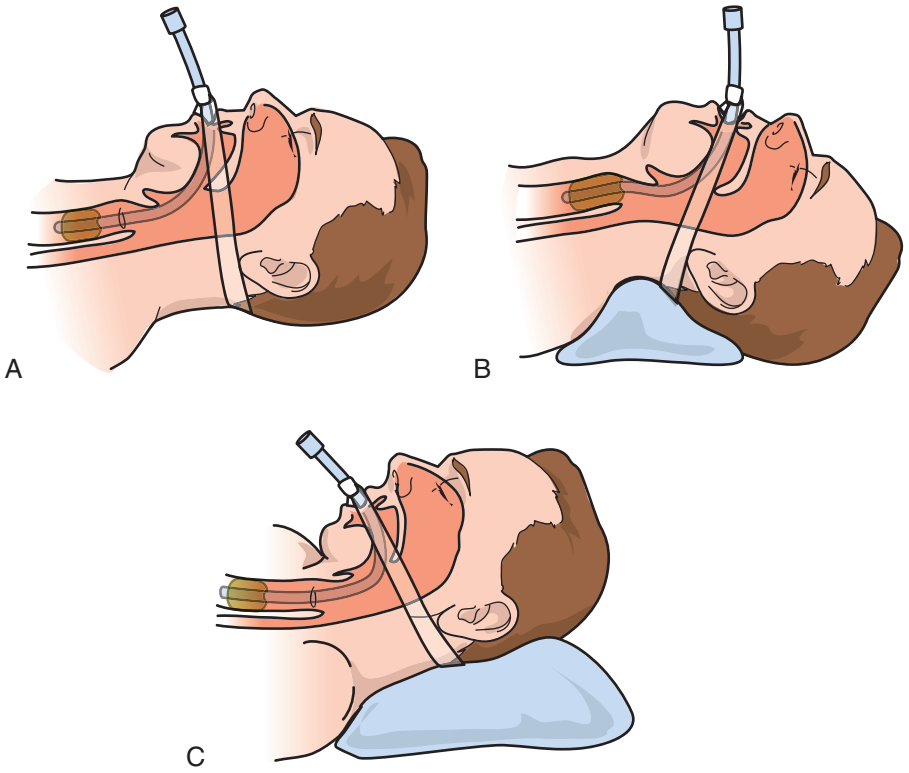

Fig. 37.33 (A) Properly positioned and secured endotracheal tube, with the head and neck in the neutral position. The tip of the tube is in the middle third of the trachea. Extension of the head and neck (B) causes the tip of the tube to rest in the upper third of the trachea, while flexion (C) of the head and neck moves the tip of the tube to the lower third of the trachea.

this method, the flexible scope is inserted into the tube and the carina is directly visualized. By moving the scope from the tube tip to the carina and measuring the distance of bronchoscopy displacement, the exact distance of insertion can be determined.

MINI CLINI

Securing the Artificial Airway and Confirming Location

Problem

A male patient in the intensive care unit was recently intubated following drug overdose and ventilated in the AC/PC mode. The ventilator is alarming for low exhaled minute ventilation, and a cuff leak is audible. Attempts to seal the airway with addition of air to the cuff are unsuccessful. Upon further inspection, the RT notes the silk tape used to secure the ETT has become loose and the tube is resting at 19 cm mark at the teeth. The most recent chest x-ray report does not comment on the ETT.

Discussion

The ETT in this patient has partially migrated out and is at risk of dislodging. The silk tape that was used to secure the ETT was not sufficient. The cuff leak could not be rectified by adding air as the cuff is likely in the hypopharynx. It is difficult to see this ETT on x-ray, because the distal tip is likely just at the thoracic inlet. The RT should call the nurse and doctor immediately and advance the ETT. An alternative securing method, such as commercial tube holder, should be used. A follow-up chest x-ray is important to document proper location.

Providing for Patient Communication

One of the most frustrating aspects of caring for a patient with a tracheal tube is his or her inability to talk. Phonation requires moving vocal cords, resulting in airflow between them. ETTs prevent vocal cord movement and airflow through the cords. Standard TTs allow vocal cord movement but prevent airflow. Without the ability to speak, the patient cannot easily inform the healthcare providers of changes in symptoms or make basic requests. This situation may lead to agitation and stress in the patient. If that agitation is treated with sedatives, a patient on a ventilator may wean more slowly.[51]

An experienced practitioner may use lip reading, but this technique is very difficult in patients with orotracheal tubes. Alternatively, an alert patient may write messages on paper or some other writing surface. However, for many patients, restricted hand movement because of restraints or vascular catheters makes writing impossible. Some critically ill patients simply cannot hold up their heads. A better solution is a letter, phrase, or picture board.[51] These devices allow patients to communicate by simple pointing. Large and simple drawings are particularly important for patients who cannot see print clearly. Some patients may choose to use special electronic devices to communicate, especially patients who have a TT because of the need for chronic mechanical ventilation. Speech-language pathologists often work with these patients to figure out which device will work best so an individual patient can communicate.

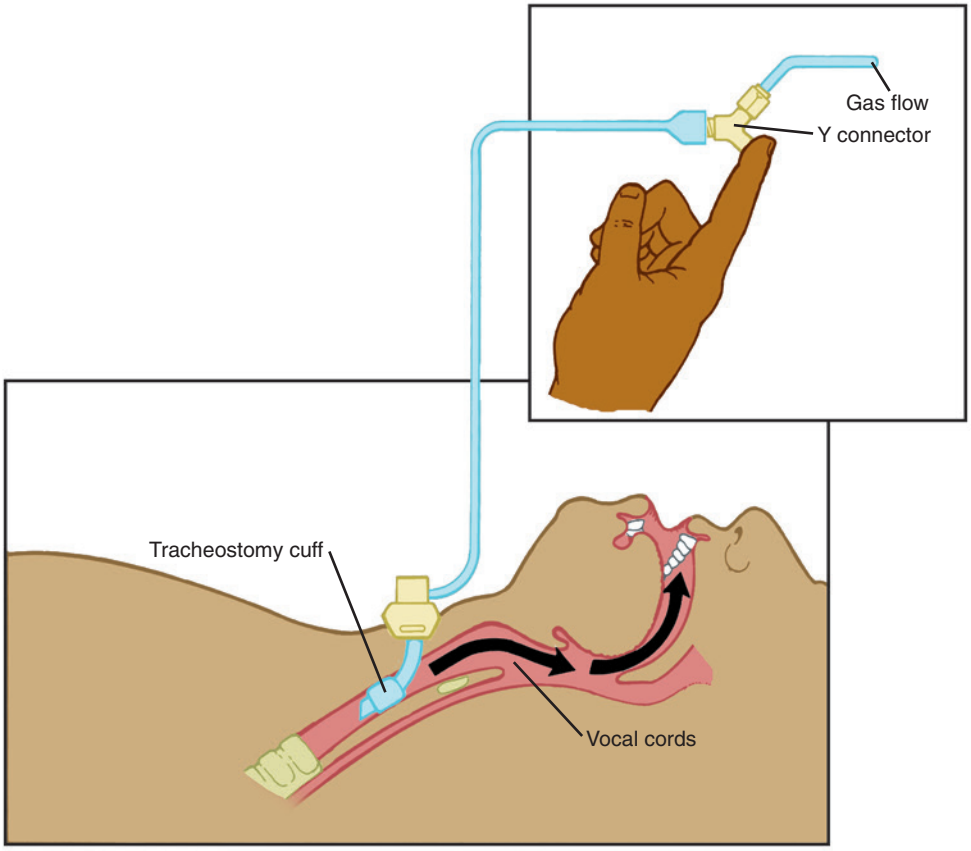

Fig. 37.34 "Talking" tracheostomy tube.

For conscious patients with a long-term tracheostomy who are ventilator-dependent, communication can be enhanced with a "talking" TT (Fig. 37.34).[31] These special airways provide a separate inlet for compressed gas, which escapes above the tube, allowing phonation. However, there are some problems associated with these tubes. The continuous gas flow through a new tracheostomy may cause air leaks. High flow rates may cause mucosal drying and irritation. Finally, secretions may occlude the speaking gas outlets. Although not life threatening, these problems can be frustrating for both the patient and the practitioner.

Another TT, the Blom fenestrated TT, has a special speech cannula that allows ventilator-dependent patients to speak with the cuff fully inflated. With the speech cannula inserted during inhalation, the flap valve opens and the flexible bubble valve expands, blocking the fenestrations. During exhalation the flap valve closes and the bubble valve collapses, which allows air to pass through the fenestrations, so the patient can speak (Fig. 37.35).[31]

Fig. 37.35 Blom fenestrated trach tube with speech cannula.

An alternative to a speaking TT is to place a one-way valve (speaking valve) on the external opening of the TT.[31] With this device in place and the TT cuff deflated, the patient inhales around and through the tube and exhales only around the tube through the larynx. Speech is coordinated with exhalation through the larynx. A patient who is a good candidate for a speaking valve is one who is medically stable, is able to communicate, and has a low risk for aspiration. Several types of speaking valves are available, as shown in Fig. 37.36. They can be used with spontaneously breathing or ventilator-dependent patients. When using the speaking valve, the cuff on the tube must be completely deflated to allow airflow around the tube. This deflation of the cuff causes a leak on inspiration and a decrease in tidal volume (V_T) delivery during mechanical ventilation. However, an increase in the set V_T on the ventilator during initial trials of the valve should compensate for this.

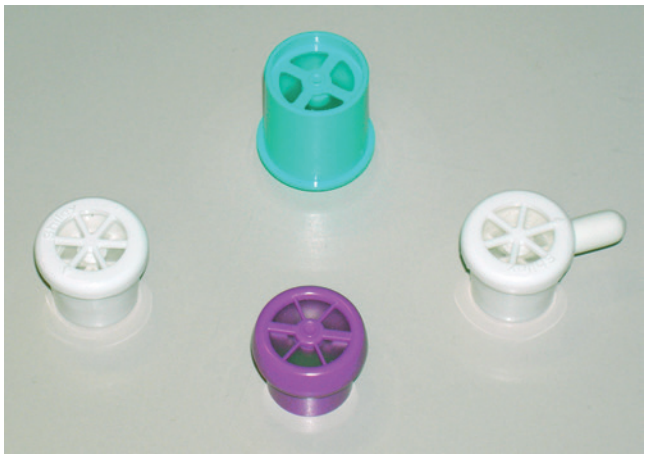

Fig. 37.36 Speaking valves.

Fig. 37.37 Setup to measure transtracheal pressures with speaking valve on tracheostomy tube.

During the initial placement of the speaking valve, the patient's ability to exhale around the TT should be assessed by measuring the tracheal pressure during exhalation with the valve in place as shown in Fig. 37.37. If the tracheal pressure is greater than 5 cm H_2O, it may indicate that there is increased resistance during exhalation. The most common causes of this problem are the size of the TT relative to the size of the trachea, tube position, inadequate cuff deflation, or an upper airway abnormality.[31] The tube may need to be changed to a smaller size, to a cuffless tube, or to a tube with a TTS cuff. The speaking valve then can be placed and the tracheal pressure measured again. If an upper airway abnormality is suspected, an otolaryngologist should be consulted. A speech-language pathologist may be consulted to assist in the assessment of the patient's risk for aspiration and tolerance of the speaking valve.

RULE OF THUMB A speaking valve can aid in communication and can safely be used if transtracheal pressures are less than 5 cm H_2O.

BOX 37.7 Why Tracheal Airways Increase the Incidence of Pulmonary Infection

- Bypassed upper airway filtration
- Increased aspiration of pharyngeal secretions
- Contaminated equipment or solutions
- Impaired mucociliary clearance in trachea
- Increased mucosal damage owing to tube or suctioning
- Ineffective clearance via cough

Assessment of heart rate, respiratory rate, and saturation should follow initial placement of the valve for all patients. In addition to facilitating communication, other benefits of airflow over the upper airway include better function of the vocal cords, better sense of smell, and fewer secretion problems. Improved swallowing function and less aspiration have been reported with the speaking valve.[50,52]

RULE OF THUMB The tracheostomy tube cuff must be completely deflated before a speaking valve is placed on the tracheostomy tube.

Ensuring Adequate Humidification

Although tracheal tubes provide an artificial airway to conduct gas to and from the lungs, they do not function as well as natural airways. Specifically, artificial tracheal airways bypass the normal humidification, filtration, and heating functions of the upper airway. The decreased humidity in the inspired air can cause secretions to thicken. Cool air also can decrease ciliary function. These conditions may impair mucociliary clearance and cause retention of secretions. Several devices that provide artificial heat and humidification are available.

The selection of a humidification device ultimately should be based on patient needs and assessment of the airway and include the volume and thickness of secretions and the history of mucous plugging or tube occlusions. More details on humidification are provided in Chapter 39.

Minimizing Nosocomial Infections

Patients with tracheal airways are very susceptible to bacterial colonization and infection of the lower respiratory tract. The presence of infection is suggested by changes in the patient's sputum (color, consistency, or amount), breath sounds (wheezes, crackles, or rhonchi), or chest radiograph (infiltrates or atelectasis).[53] Additional changes associated with bacterial infection include fever, increased heart rate, and leukocytosis.

There are several reasons why tracheal tubes increase the incidence of pulmonary infection (Box 37.7).[53,54] To guard against infection, the clinician first should avoid introducing organisms into the airway. The clinician does this by (1) adhering to sterile technique during suctioning, (2) ensuring that only aseptically clean or sterile respiratory equipment is used for each patient, and (3) consistently performing hand hygiene between patient contacts (see Chapter 4).[55]

In addition, efforts should be made to prevent retention of secretions. Suctioning, chest physiotherapy, and adequate

humidification are useful to this end. Closed suction systems may be preferred to open suction systems in preventing infection.[55] Routinely cleaning or changing the inner cannula on TTs also may help to minimize bacterial contamination and infection. Techniques to decrease the consequences of pharyngeal aspiration include: (1) use of medications for stress ulcer prophylaxis, such as sucralfate, that maintain normal gastric pH; (2) positioning of patients with the head of the bed elevated 30 degrees or more to decrease reflux; and (3) continuous aspiration of subglottic secretions.[56]

Facilitating Secretion Clearance

The most common cause of airway obstruction in critically ill patients is retained secretions. To remove retained secretions, blood, or other semiliquid fluids from the large airways, the patient is suctioned as described previously in this chapter. Suctioning involves application of negative pressure to the large airways through a catheter. This method may be used alone or in combination with noninvasive techniques described in Chapter 44. One noninvasive technique is the mechanical insufflator-exsufflator (Cough Assist, J. H. Emerson, Cambridge, MA). The mechanical in-exsufflator (MIE) is primarily used to facilitate secretion clearance in patients with impaired cough, especially due to neuromuscular disease, such as ALS, spinal muscular atrophy (SMA), and muscular dystrophy (MD).[57]

Providing Cuff Care

Tracheal tube cuffs are used to seal the airway for mechanical ventilation or to prevent or minimize aspiration. As previously mentioned, tracheal stenosis and tracheomalacia are associated with cuff use. The pathogenesis of these problems is related to the amount of cuff pressure transmitted to the tracheal wall, impeding the flow of blood and lymphatic fluid. If cuff pressure exceeds the mucosal perfusion pressure, ischemia, ulceration, necrosis, and exposure of the cartilage may result (Fig. 37.38).

Importance of Cuff Pressure

In the past, high-pressure tracheal tube cuffs were a major cause of airway damage. Since the 1970s, high-residual-volume, low-pressure cuffs have become the norm (Fig. 37.39). The fully inflated diameter of these cuffs is greater than the diameter of the trachea. This means that the cuff does not have to be fully inflated to seal the airway, and less internal cuff pressure is needed. When properly used, these cuffs transmit less pressure to the tracheal wall than the older high-pressure designs. Although low-pressure cuffs have reduced the incidence of tracheal damage, they have not eliminated the problem entirely.

Cuff Inflation and Measuring and Adjusting Cuff Pressure

Key aspects of airway care are cuff inflation and cuff pressure measurement and adjustment. The goal is to keep cuff pressures less than the tracheal mucosal capillary perfusion pressure, estimated to range from 20 to 30 mm Hg.[45] Higher pressure cuts off mucosal blood flow and causes tissue damage. However, if the cuff pressure is too low, it does not prevent silent aspiration of pharyngeal secretions, which can contribute to the development of VAP. It is recommended to inflate the cuff to 20 to 30 cm H_2O, which should prevent tracheal mucosal injury. Minimal occluding volume and minimal leak inflation techniques are no longer recommended because they increase the risk for silent aspiration.[45]

Cuff pressure can be measured with various devices designed for this purpose. These devices measure the pressure and allow air to be added or withdrawn from the cuff. There are two key considerations when making these adjustments. First, most manometers are calibrated in centimeters of water, with the "acceptable range" of pressure 20 to 30 cm H_2O.[44] Second, attaching the measurement system to the pilot tube evacuates some volume from the cuff (and decreases its pressure). For this reason, the clinician should always adjust the pressure to the desired level and never just measure it.

High cuff pressures are a result of the need to overinflate the cuff to seal the airway. This problem is common if the tube chosen is too small for the patient's trachea or positioned too high in the trachea or if the patient has developed tracheomalacia (softening of the tracheal tissue). Another cause of high cuff pressures is high airway pressures generated by mechanical ventilation, which may require adding air to the cuff to maintain an adequate tracheal seal. Intracuff pressure measurements should be done regularly to maintain the cuff pressure in the safe range to avoid tracheal wall injury and minimize risk for aspiration of oral secretions.

Devices are currently available to continuously monitor intracuff pressures via tubing connected directly to the pilot line. A target pressure is set by the RT. The machine will add or withdraw air to maintain that set pressure. In addition, proprietary ETTs include a subglottic suction line. Periodic irrigation and removal of contaminated secretions above the cuff are associated with decreased rates of ventilator associated pneumonia.[58] Additional care must be given to the tubing connecting the pilot line of the artificial airway to the controller box. The tubing depresses the spring-loaded valve in the pilot line. Upon disconnection at the proximal attachment point, the volume within the cuff will escape, potentially leading to frank aspiration of subglottic secretions.

Alternative Cuff Designs

Some different types of cuffs have been designed to minimize mucosal trauma. The foam cuff is one, which is designed to seal the trachea with atmospheric pressure in the cuff (Fig. 37.40). Before insertion, the foam cuff must be deflated by actively withdrawing air from the cuff with a cuff pressure device or syringe. When in position, the pilot tube is opened to the atmosphere, and the foam expands against the tracheal wall. Expansion of the cuff stops when the tracheal wall is encountered. If too much air leak and volume loss occur around the tube, the pilot tube can be placed in line with the ETT. Foam cuff tubes are not commonly used except in patients who have already developed tracheal injury. This cuff can minimize tracheal mucosal trauma but does not minimize the risk for aspiration of oral secretions and may make mechanical ventilation difficult.

Another cuff design is the TTS cuff on some TTs (Fig. 37.41). This is a low-volume, high-pressure cuff designed to maximize airflow around the tube when it is deflated. It should be inflated

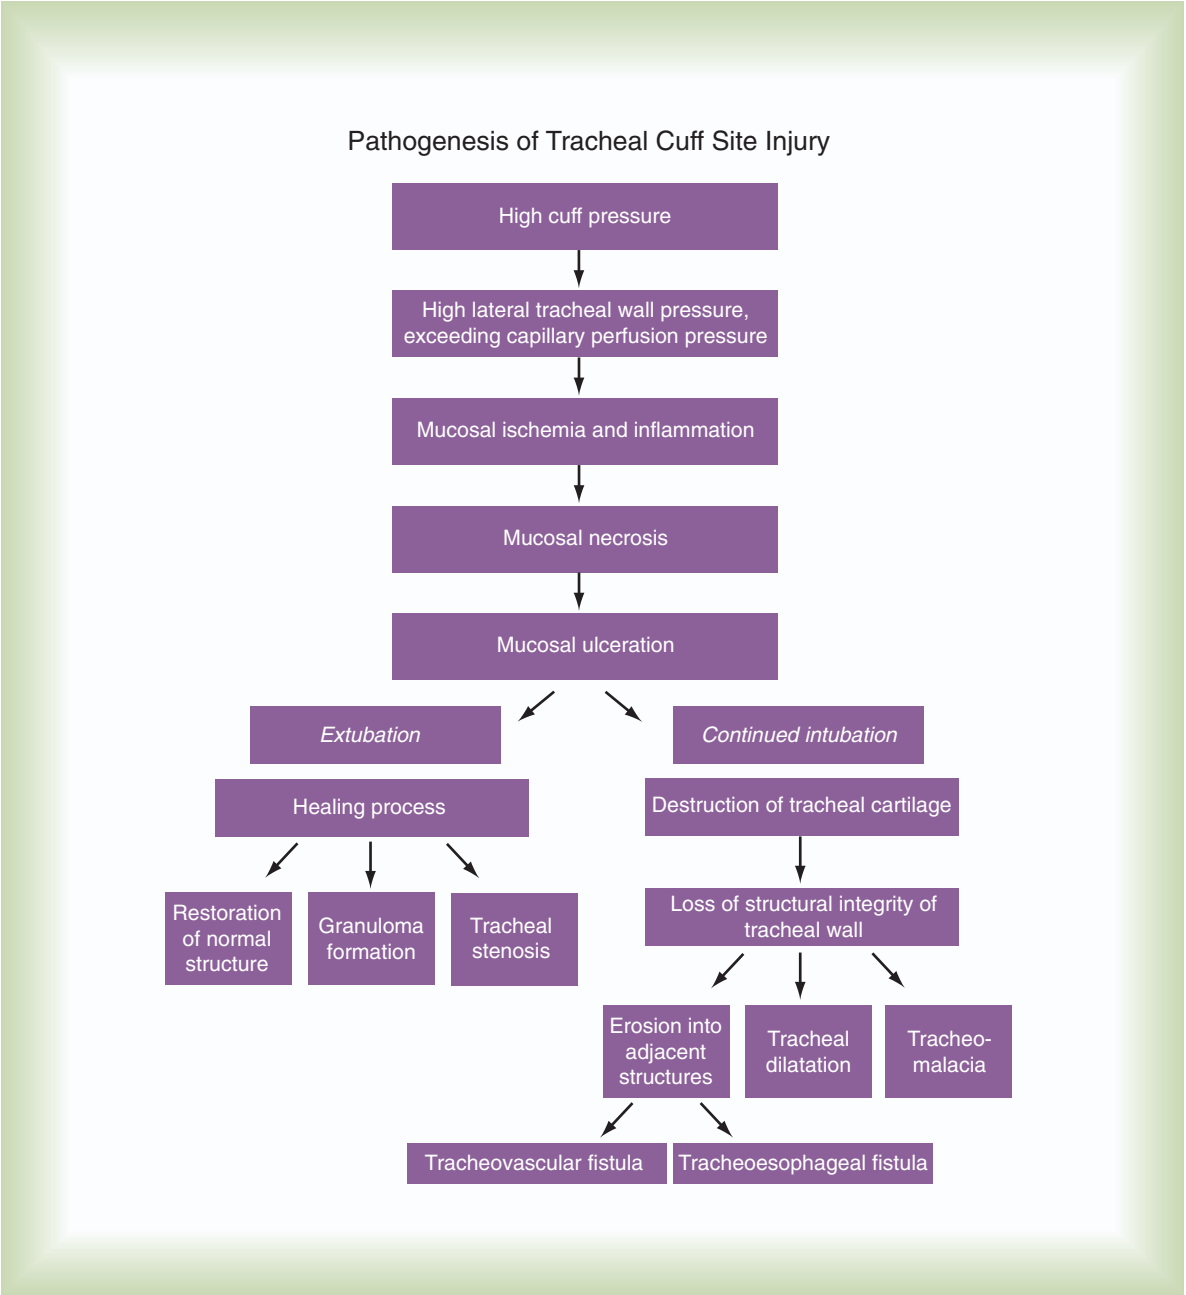

Fig. 37.38 Tracheal injury may occur secondary to trauma from the cuff. (Modified from Stauffer JL: Complications of endotracheal intubation and tracheostomy, *Respir Care* 44:828, 1999.)

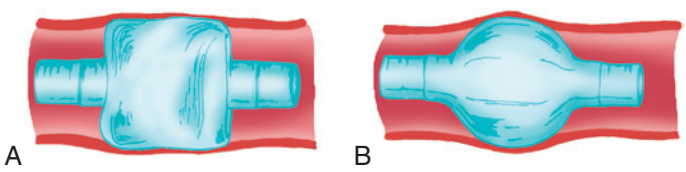

Fig. 37.39 Comparison of shapes of high-residual-volume, low-pressure cuff (A) and low-residual-volume, high-pressure cuff (B). (Modified from McPherson SP: *Respiratory therapy equipment*, ed 4, St. Louis, 1989, Mosby.)

only intermittently for airway protection or short-term ventilation. Because the cuff is made of a porous silicone material, it can be inflated only with sterile water and not air.

Prevention of silent aspiration is difficult because the current generation of cuffs when inflated properly create channels along the cuff in which secretions from above the cuff move by capillary action. Newer tubes with longer length ultrathin polyurethane cuffs form a cylinder shape or an inverted pear shape when inflated so that they do not form channels. These newer cuff designs and material seem to minimize silent aspiration that has been implicated in the development of VAP.[59]

Minimizing Likelihood of Aspiration

When judging the adequacy of a tracheal seal, the potential for aspiration should be taken into account. Keeping the cuff pressure between 20 and 30 cm H_2O helps to minimize aspiration and injury. In addition, aspiration is reported to be more common in spontaneously breathing patients than in patients receiving positive pressure ventilation; this may be due to the movement of pharyngeal secretions past the cuff during the negative pressure phase of a spontaneous inspiration.

A simple swallowing test can help to determine whether aspiration is occurring. These tests can be performed by various clinicians, including speech therapists, nurses, and RTs. To perform this test, blue food coloring is added to the patient's feedings or the patient swallows a small amount of blue food coloring in water. The patient's trachea is suctioned through the artificial airway. If blue-tinged secretions are obtained when performing suctioning, some aspiration is occurring. However, false-negative results can occur; the patient may still be aspirating despite no sign of blue coloring in suctioned secretions. For this reason, a modified barium swallow test may be needed to determine conclusively whether a patient is aspirating.[60]

If aspiration is confirmed, efforts must be made to minimize the aspiration. Ideally, the patient should be switched to a tube that continually aspirates subglottic secretions (see the previous section on Specialized Endotracheal Tubes). If it is impossible to make this switch, oropharyngeal suctioning (above the tube cuff) should be performed as needed. To decrease the possibility of aspiration with feedings, the head of the bed should be elevated 30 degrees or more when possible.[56] In addition, the feeding tube can be inserted into the duodenum, with its position confirmed by imaging. The use of slightly higher cuff pressure during and after feedings may minimize aspiration.

Care of Tracheostomy and Tube

TTs require daily care to clean the site and change the tie or holder securing the tube. The tubes also may be removed and replaced for routine cleaning or in an emergency, such as obstruction of the tube. The procedures for tracheostomy care and changing a TT are described in the following section.[61-63]

Tracheostomy Care

Step 1: Assemble and Check Equipment.

Box 37.8 lists the equipment needed for routine tracheostomy care. The equipment needed is for cleaning through the tube, around the tube, and the tube itself. Personal protective

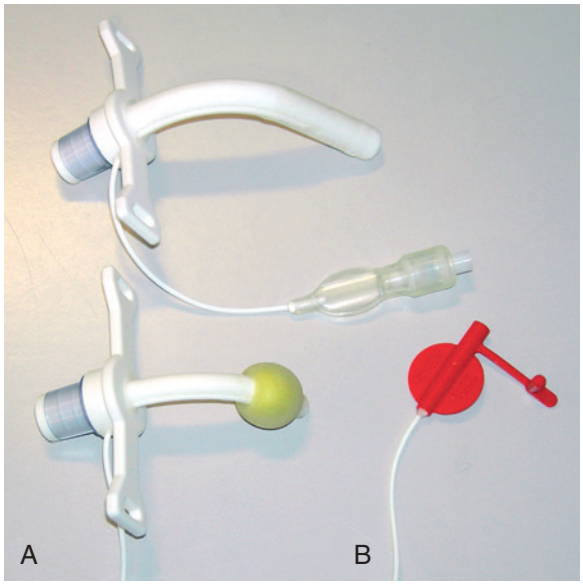

Fig. 37.40 Tracheostomy Tubes With Different Types of Cuffs. (A) Tight-to-shaft cuff. (B) Self-inflating foam cuff.

BOX 37.8 Equipment for Tracheostomy Care

- Personal protective equipment: Goggles and mask or face shield
- Sterile gloves
- Suction equipment
- Resuscitation bag
- Oxygen
- Tracheostomy care kit (basin and brush)
  - Spare inner cannula
  - Disposable inner cannula (if appropriate)
  - Hydrogen peroxide and sterile water
  - Cotton-tipped applicators
  - Precut gauze pad or precut foam dressing (to absorb excessive drainage)
  - New tracheostomy tube tie or Velcro tracheostomy tube (TT) holder
  - Another TT of the same size as backup
  - Additional equipment needed if changing TT
  - New TT with component parts and another tube one size smaller
  - Water-soluble lubricant
  - 10- or 12-mL syringe

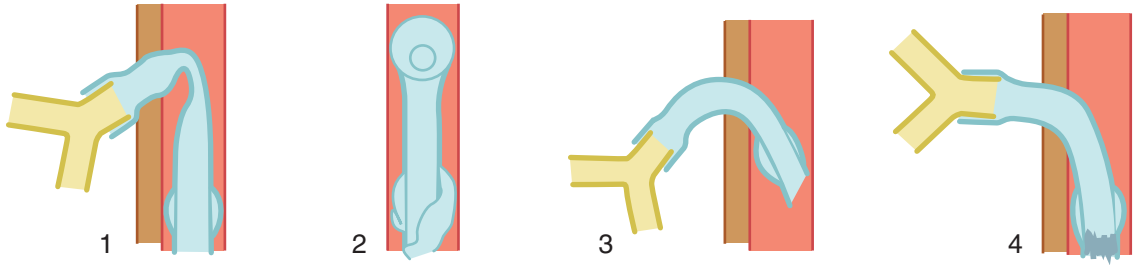

Fig. 37.41 Causes of Tube Obstruction. (See Text for Details.) (1) Kinked TT. (2) Cuff herniated over tip of TT. (3) Malpositioned TT where tip of tube is against posterior tracheal wall. (4) Properly positioned TT. (Modified from Sykes MK, McNichol MW, Campbell EJM: *Respiratory failure*, Philadelphia, 1969, FA Davis.)

equipment (face shield or mask and goggles) for the clinician is needed because stimulation of the trachea may result in coughing and expectorated secretions. Use of suction equipment to remove secretions from the tube before the procedure can decrease the possibility of secretions contaminating the environment. O_2 and a manual resuscitator are needed for the suctioning procedure and in case any problems such as desaturation occur. To clean around the tube, sterile water, cotton-tipped applicators, and tracheostomy sponges are needed along with a new tie or TT holder to secure the tube. A TT kit includes a basin and brush to clean the inner cannula of the tube. Alternatively, a disposable inner cannula may be used. The function of the manual resuscitator, O_2 flow, and suction control must be checked before starting.

Step 2: Explain Procedure to Patient.
Explain the procedure and confirm the patient understands what will be done.

Step 3: Suction Patient.
The procedures previously described for endotracheal suctioning are appropriate for this situation. A TT is much shorter than an ETT. The catheter is inserted just to the end of the TT to avoid causing mucosal injury to the carina.

Step 4: Clean Inner Cannula (If Present and Nondisposable).
The inner cannula is removed and placed in the basin. If appropriate, such as in the case of a ventilator-dependent patient, the spare inner cannula is inserted. Patients with certain types of TTs can be mechanically ventilated without an inner cannula in place. If the patient is not mechanically ventilated, the O_2 therapy device is reapplied as necessary. Sterile water is added to the basin, and the cannula is left to soak. A brush is used to remove any dried secretions from the inner lumen or the outside of the cannula. The cannula is rinsed with sterile water and allowed to air dry on sterile gauze.

Step 5: Clean and Examine Stoma Site.
The dressing (if present) is removed and disposed. Applicators that have been dipped in sterile normal saline are used to clean around the stoma site. After cleaning liquid, a skin barrier should be applied to protect the skin from moisture. A clean dressing, if needed to absorb drainage, is placed under the flange of the tube. An absorbent foam dressing, especially if there is excessive drainage around stoma, should be used. If the stoma site appears red or swollen, has pus around it, or is emitting a foul smell, the physician and nurse should be notified.

RULE OF THUMB Skin assessment around and underneath artificial airways should be completed frequently to prevent breakdown.

Step 6: Change Tie or Holder.
The clinician cuts the old tie or loosens the Velcro holder. One hand is kept on the flange of the TT to keep it secure. The old tie or holder is removed and discarded. The clinician replaces the tie or holder, keeping one finger-width of space between the neck and tie or holder.

Step 7: Replace Clean Inner Cannula (if present).
If the inner cannula is marked disposable and is not to be reused, a new one is inserted.

Step 8: Reassess Patient.
The clinician checks for adequate breath sounds, vital signs, and oxygenation and confirms no adverse effects.

RULE OF THUMB An extra tracheostomy tube of the same size and another, one size smaller, should be kept readily available in or near the patient's room in case of an accidental decannulation.

Changing a Tracheostomy Tube

A TT may need to be replaced in the case of long-term mechanical ventilation; if the current tube develops a problem, such as a mucous plug or damage to the cuff; or if a different size or type of tube is needed.[63] If a tube needs to be replaced before the stoma heals (7 to 10 days), it is best done by a physician. Intubation equipment should also be available. Because a single-cannula tube has no inner cannula to remove for cleaning, it may need to be replaced periodically.

Step 1: Assemble and Prepare Equipment.
In addition to the equipment described previously, the new tube, an extra tube one size smaller, and water-soluble lubricant are necessary. An additional TT that is one size smaller is necessary in the event of partial closure of the stoma site and difficulty reinserting initial size tube.

Step 2: Explain Procedure to Patient.

Step 3: Prepare Equipment.
Sterile technique must always be maintained for the distal portion of the cannula, which goes into the trachea. The inner cannula is removed and placed on a sterile surface. The obturator is inserted. The tie or TT holder is attached to one side of the flange of the tube. The clinician inflates the cuff, checks for leaks, and deflates the cuff. Lubricant is applied to the distal portion of the cannula.

Step 4: Prepare Patient.
The patient should be placed with the neck extended so that the tracheal stoma is accessible. The patient is suctioned and hyperoxygenated.

Step 5: Remove Old Tube.
The tie is cut, or the Velcro TT holder is opened. The cuff is deflated. The clinician removes the tube by following the curve of the tube. The clinician grasps the outer portion of the TT with one hand and rotates the wrist toward the chest. The stoma is inspected for any bleeding or other problems, such as granuloma or ulceration.

Step 6: Insert New Tube, Confirm Placement, and Assess Patient.
The new tube is picked up by the proximal portion. The surface that enters the trachea should not be touched. The tip of the obturator is inserted into the stoma, and the tube is advanced following the curve of the tube. While holding the flange of the tube against the neck, the clinician immediately removes the obturator. The clinician assesses for airflow through the tube. Coughing may reflect pressure on the outside of the trachea. The patient is assessed for proper tube placement and tolerance of the procedure. If extreme difficulty is encountered

inserting the new tube, insertion of the "stand-by" tube, which is one size smaller, is attempted.

Step 7: Secure Tube.

While still holding onto the flange, the clinician secures the TT tie or holder without overtightening. The inner cannula, if present, is inserted. If a cuff is present, it should be inflated to the appropriate pressure with the appropriate medium (air or sterile water, in the case of TTS cuff). The clinician reassesses for airflow and reapplies the O_2 therapy device or ventilator.

Step 8: Reassess Patient.

Suctioning may be required again. The clinician checks vital signs and SpO_2 and assesses the patient's overall tolerance of the procedure.

Troubleshooting Airway Emergencies

The areas discussed so far are routine aspects of airway care. Three emergency situations that may occur are tube obstruction, cuff leaks, and unplanned extubation. Clinical signs frequently encountered under these circumstances include various degrees of respiratory distress; changes in breath sounds; air movement through the mouth; or, if the patient is mechanically ventilated, changes in pressures.

Decreased breath sounds are a common finding in airway emergencies. The RT must try to identify specific indications of decreased breath sounds, such as the inability to pass a suction catheter (obstruction, occluded tube) or airflow around the tube (leaking cuff). Replacement airways, a manual resuscitator, mask, and gauze pads (for patients with tracheostomies) should be kept at the bedside.

Tube Obstruction

Obstruction of the tube is one of the most common causes of airway emergencies. Tube obstruction can be caused by: (1) the kinking of the tube or the patient biting on the tube, (2) herniation of the cuff over the tube tip,[64] (3) obstruction of the tube orifice against the tracheal wall, and (4) mucous plugging (see Fig. 37.41).

Different clinical signs are present depending on whether the tube obstruction is partial or complete.[41,65] A spontaneously breathing patient with partial airway obstruction exhibits decreased breath sounds and decreased airflow through the tube. If the patient is receiving volume-controlled ventilation, peak inspiratory pressures increase, often causing the high-pressure alarm to sound; during pressure-controlled ventilation, delivered V_Ts decrease. With complete tube obstruction, the patient exhibits severe distress, no breath sounds are heard, and there is no gas flow through the tube.

If the tube is kinked or positioned against the tracheal wall, the obstruction can be reversed by moving the patient's head and neck or repositioning the tube.[41] If this action does not relieve the obstruction, a herniated cuff may be blocking the airway. Deflating the cuff relieves the obstruction in such cases. If these steps fail to overcome the obstruction, the clinician can try to pass a suction catheter through the tube. The distance the catheter inserts before stopping helps to determine the site of obstruction. If the catheter does not travel much beyond the tube tip and insertion does not cause coughing, the likely problem is a herniated cuff or a mucous plug. In the case of mucous plugging, the clinician can attempt to remove the plug by suctioning the tube before considering more drastic action. Although instillation of sterile normal saline into the tube is not routinely needed during suctioning, it may facilitate mobilizing the mucous plug so that it can be more easily removed by suctioning. In addition, a mucus-shaving device may be used to clear thick, dried secretions from the inner lumen of the ETT. This device has a balloon at the end of the catheter. Once the catheter is inserted into the ETT, the balloon is inflated. When the catheter is withdrawn, the balloon scrapes the thick, dried mucus from the inside of the tube (Fig. 37.42).[66]

When the patient has a TT with an inner cannula, it should be removed and checked to see if the plug is lodged in the tube. O_2 should be provided to the patient through the outer cannula, or the inner cannula should be replaced with a spare one to facilitate manual ventilation.

If the obstruction cannot be cleared by using these techniques, the airway should be removed and replaced. In patients who have undergone recent tracheotomy (4 or 5 days earlier), the stoma may not be well established and may close when the tube is removed. If suture ties were left in place by the surgeon, they can be used to pull open the stoma.

After the obstructed airway is removed, the clinician should immediately try to restore adequate ventilation and oxygenation. For a patient with a tracheotomy stoma, the stoma may need to be covered with a gauze pad and the patient may need to be manually ventilated with a mask. Airway reinsertion by a properly trained RT or physician should be undertaken only after adequate ventilation and oxygenation are restored.

RULE OF THUMB If the patient exhibits respiratory distress and the cause is thought to be an obstructed tracheostomy tube, the inner cannula, if possible, should be promptly assessed for patency.

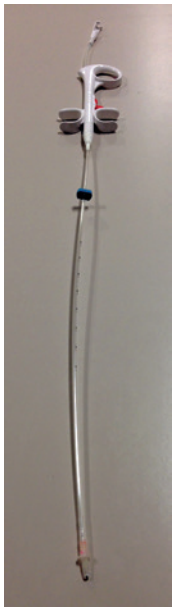

Fig. 37.42 Mucus-shaving device.

Cuff Leaks

A leak in the cuff, pilot tube, or one-way valve is a problem mostly for patients receiving mechanical ventilation. This leak causes a system leak, with a resultant loss of delivered volume or decreased inspiratory pressure or both.

A small cuff leak can be detected by noting decreasing cuff pressures over time. A large leak, such as occurs with a ruptured cuff, generally has a more rapid onset. Breath sounds are decreased, but a spontaneously breathing patient has air movement through the tube. With positive pressure breaths, airflow often is felt at the mouth. Under such circumstances, the RT should try to reinflate the cuff while checking the pilot tube and valve for leaks.[13] If the pilot tube or valve is leaking, the tube needs to be changed as soon as possible. However, a pilot valve (pilot balloon) repair kit, which permits the insertion of a replacement valve into the pilot tubing, can offer a safe and effective alternative until a replacement tube can be inserted.

A ruptured cuff requires extubation and reintubation emergently if the patient is being mechanically ventilated. This procedure can be done via the standard reintubation procedure or by using an ETT exchanger, which is a semirigid guide over which the damaged tube can be removed and the new tube promptly inserted. An ETT exchanger should be used only by an individual trained in its use, and all necessary intubation equipment and personnel should be available to perform a standard intubation if problems occur. An ETT that is positioned too high in the trachea and near the glottic opening can mimic a cuff leak. Before presuming a cuff leak, the RT should check the tube depth by noting the markings, and if the tube appears shallow, the RT should attempt to advance the tube slightly and reassess the leak. A leak around a tracheal tube can occur from a tube or cuff problem. Fig. 37.43 is a diagram of the process to investigate the source of a leak around a tube.[13]

MINI CLINI

Airway Cuff Problems

Problem

The RT is called to assist with a 220-lb, 6-ft 2-inch, male patient who is intubated with a 7-mm ETT and receiving positive pressure ventilation. The patient's nurse reports to the RT that over the past week it has been increasingly difficult to get a good seal with the tube cuff and that she has had to add "more and more air" to prevent gross leakage. When asked if the cuff pressures have been monitored, she says no. What is the likely problem and solution?

Discussion

"Low-pressure" cuffs can exert high pressure at high inflation volumes. The need for high volumes to get a good seal usually indicates that the ETT or tracheostomy tube is too small for the patient. This large man probably should have been intubated with at least an 8-mm tube. In addition, because cuff pressures were not monitored, it is possible that tracheal damage has already occurred. The fact that the nurse reports having to add "more and more air" to get a seal suggests tracheomalacia, which could be confirmed by radiographic or bronchoscopic examination.

Tracheomalacia can cause a vicious cycle in which high pressure causes more tracheal dilation, which requires higher pressures to seal the cuff, and so on. If tracheomalacia is confirmed and the patient still needs an artificial airway, the smaller tube should be replaced with a larger one that allows a good seal at acceptable cuff pressures. It also may be necessary to reposition the tube so that the cuff is not the original site of damage.

Unplanned Extubation

Partial displacement of an airway out of the trachea can be detected by noting decreased breath sounds, decreased airflow through the tube, and the ability to pass a catheter to its full length without meeting an obstruction or eliciting a cough. With positive pressure ventilation, airflow through the mouth or into the stomach may be heard and a decrease in delivered volumes or pressures occurs. In these cases, the tube should be completely removed and ventilatory support should be provided by manual resuscitator and mask as needed until the patient can be reintubated or the TT reinserted. To monitor trends and optimize quality outcomes associated with unplanned extubations, hospitals often require certain details of such incidents to be recorded.

RULE OF THUMB Resuscitation efforts differ greatly in patients with a tracheostomy tube versus a laryngectomy.

Tracheostomy—cover stoma with gauze; provide manual ventilation to upper airway.

Laryngectomy—provide manual ventilation via a small mask to the stoma site because there is no longer communication between the upper and lower airway.

Partial laryngectomy—may be able to ventilate via the upper airway because the separation was not complete. Attempts at both routes maybe necessary to determine which approach results in the best ventilation.

EXTUBATION OR DECANNULATION

For most patients, tracheal intubation is a temporary measure. The artificial airway should be removed when it is no longer needed. The process of removing an artificial tracheal airway is called **extubation** (ETT) or **decannulation** (TT). Although most patients eventually undergo extubation, a few need to maintain a permanent artificial route, usually by tracheostomy. Permanent tracheostomies are common among patients with surgically treated throat or laryngeal cancer and patients requiring long-term positive pressure ventilation. Advances in noninvasive mechanical ventilation have reduced the need for permanent tracheostomies in the latter group.

Assessing Patient Readiness for Extubation

A patient is ready to be extubated when the original need for the artificial airway no longer exists. Because artificial airways are inserted for many different reasons, several different criteria to establish readiness for extubation need to be considered. Some basic assessments include the ability to maintain adequate oxygenation and ventilation without mechanical support, ability of

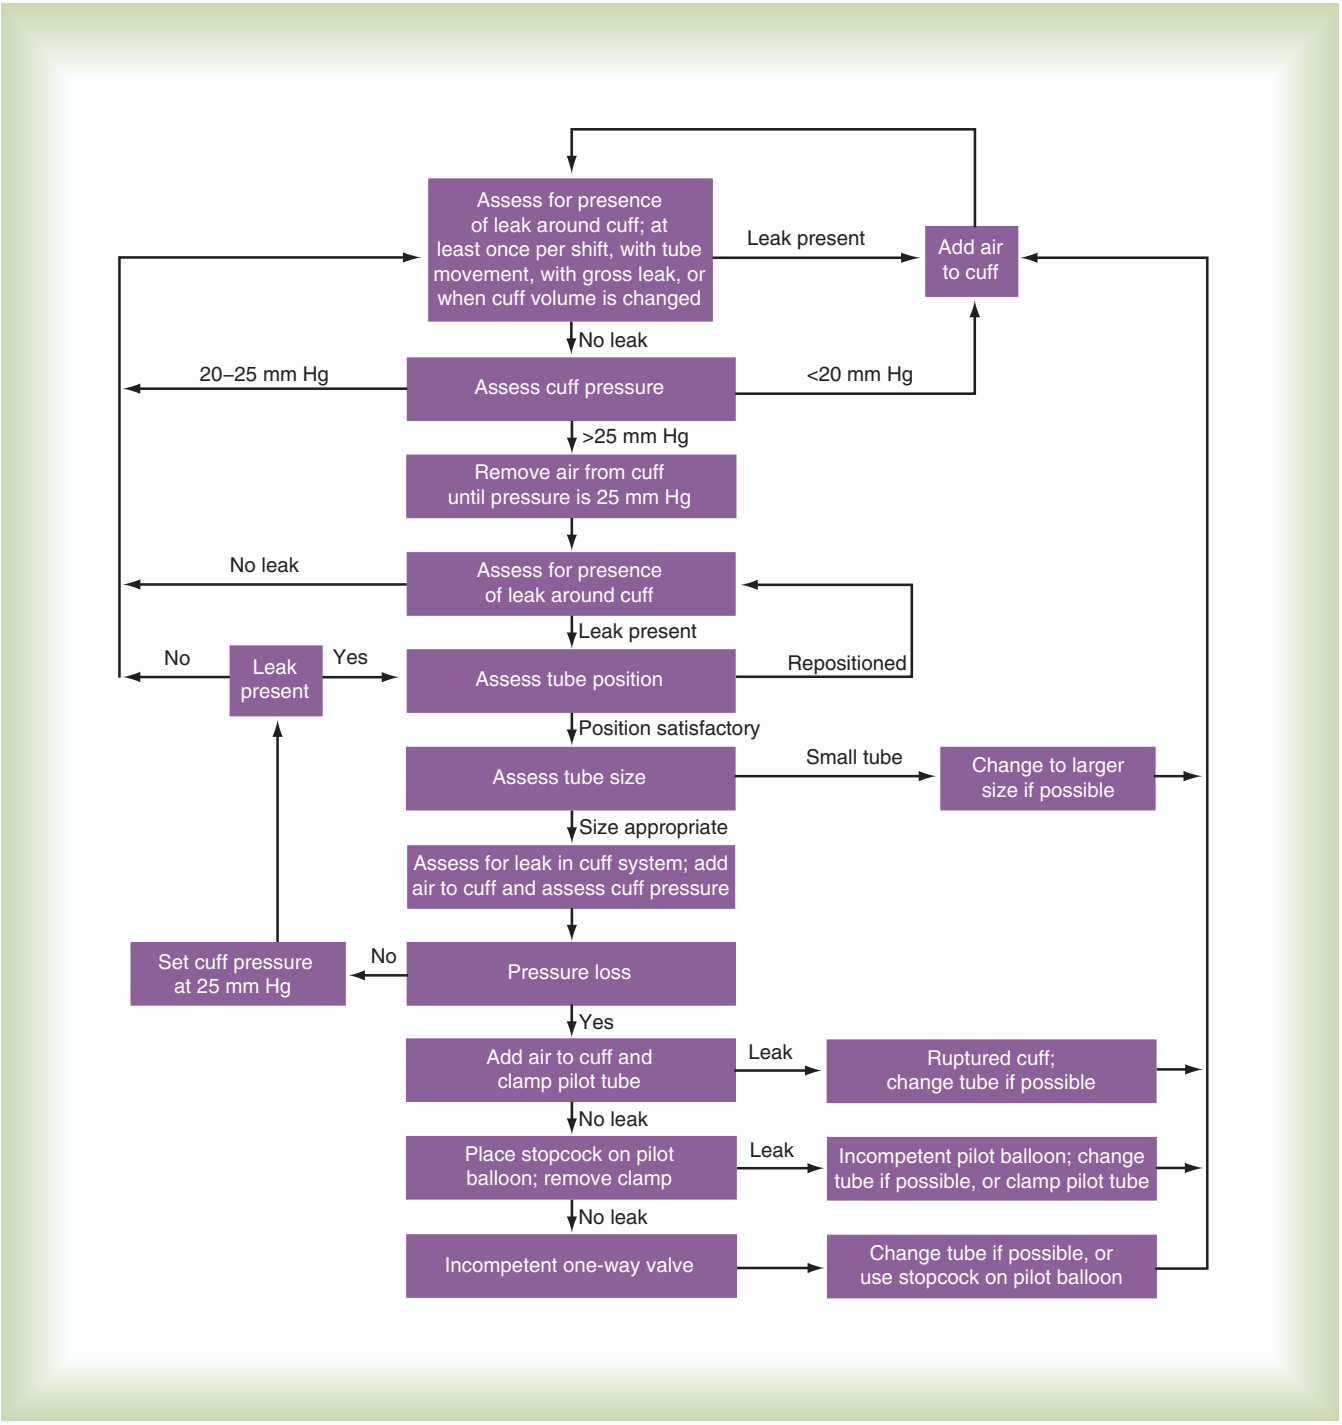

Fig. 37.43 Algorithm for solving leaking cuff problems. (From Hess D: Managing the artificial airway, *Respir Care* 44:759, 1999.)

the patient to protect the airway by the presence of a gag reflex, the ability to manage secretions based on cough strength, the quantity and thickness of secretions, and the patency of the upper airway.

The decision to remove the airway may not be the same as the decision to discontinue mechanical ventilation. The ventilator and airway may be removed simultaneously in the case of patients with normal lungs intubated for surgery. If a patient was intubated because of respiratory failure and has improved, but the upper airway problems remain (e.g., no gag reflex), the ventilator may be discontinued before extubation. In this scenario, it is customary to place a tracheostomy tube to assist with airway protection.

The cuff-leak test is designed to help predict the occurrence of glottic edema or stridor after extubation.[67,68] The clinician totally deflates the tube cuff and assesses the leak around the

MINI CLINI

Extubation Assessment

Problem

A physician informs the RT that a patient recently removed from a ventilator is maintaining adequate oxygenation and ventilation via spontaneous breathing through an oral ETT. She requests that the RT evaluate the patient for extubation. What would the RT assess and why?

Discussion

Because the patient is maintaining adequate oxygenation and ventilation off the ventilator, two key criteria for extubation have already been met. Further assessment is needed to determine (1) the risk for upper airway obstruction after extubation, (2) the level of protection against aspiration, and (3) the ability of the patient to clear secretions after extubation. First, the RT should perform a leak test to assess for upper airway edema. Second, the RT should determine the patient's level of consciousness and neuromuscular function by assessing the gag reflex or having the patient try to raise and hold his or her head off the bed. Third, the RT should determine the patient's ability to cough, using either subjective assessment (on suctioning) or measurement of maximum expiratory pressure or peak cough flow. Extubation should be recommended only if all three areas yield positive results.

tube during positive pressure ventilation in a volume-controlled mode. The percent of the cuff leak should be approximately 15% or greater, as determined by the difference between the measured expiratory V_T with the cuff inflated and then deflated.[67] If the exhaled volume is 500 mL with the cuff inflated and 400 mL with the cuff deflated, the difference is 100 mL. The percent cuff leak is 20% (100 mL divided by 500 mL), which suggests that there is no significant upper airway edema or obstruction. However, some data suggest that this test may not always be predictive of the presence of upper airway obstruction or edema.[68] This test may be most useful in patients who are at greatest risk for postextubation stridor, such as children, women, and patients intubated for more than 6 days.[69] Some patients who fail the test or who have questionable results may still be extubated, but they must be closely monitored with the appropriate personnel and equipment available to reestablish the airway if needed.

Procedures

Because RTs play a key role in extubation and decannulation and the techniques differ, the procedures for removing orotracheal or nasotracheal (extubation) and TTs (decannulation) are reviewed separately.

Orotracheal or Nasotracheal Tubes

The procedure for orotracheal or nasotracheal extubation is as follows.

Step 1: Assemble Needed Equipment.
Needed equipment includes suctioning apparatus; two suction kits with correct size sterile suction catheters and gloves; tonsillar suction tip (Yankauer); 10-mL or 12-mL syringe; O_2 and aerosol therapy equipment; manual resuscitator and mask; aerosol nebulizer with racemic epinephrine and normal saline (if concerns regarding postextubation edema); and intubation equipment (laryngoscope blades, handle, ETTs, stylets, water-soluble lubricant, syringe to inflate cuff, tape or holder to secure tube).

Step 2: Suction ETT and Pharynx Above Cuff.
Suctioning before extubation helps to prevent aspiration of secretions after cuff deflation. After use, the first suction kit should be discarded, and another should be prepared for use, or a rigid tonsillar (Yankauer) suction tip should be prepared to suction the oropharynx.

Step 3: Oxygenate Patient Well After Suctioning.
Extubation is a stressful procedure that can cause hypoxemia and unwanted cardiovascular side effects. To help avoid these problems, 100% O_2 should be administered for 5 minutes.

Step 4: Deflate Cuff.
The 10- or 12-mL syringe is attached to the pilot tubing. All the air is withdrawn from the cuff while applying positive pressure to direct any pooled secretions above the cuff up into the oropharynx, where they can immediately be suctioned with the tonsillar suction tip. The RT should listen for an audible leak around the tube. If no audible leak is present, the RT should reinflate the cuff and discuss with the physician how to proceed.

Step 5: Remove Tube.
The tape or holder that is securing the tube is removed. The technique used to remove the tube should help to avoid aspiration of pharyngeal secretions and maximally abduct the vocal cords. Clinicians use one of two different techniques to accomplish these goals. In the first method, a large breath is given with the manual resuscitator, and the tube is removed at peak inspiration (when the vocal cords are maximally abducted). In the second method, the patient coughs and the tube is pulled during the expulsive expiratory phase. This technique also results in maximal abduction of the vocal cords.

Step 6: Apply Appropriate Oxygen and Humidity Therapy.
Patients who have been receiving mechanical ventilation may still require O_2 therapy, usually at a higher FiO_2. Other patients may require some O_2 because this is a stressful procedure. If humidity or aerosol therapy is indicated, apply a cool mist immediately after extubation.

Step 7: Assess or Reassess Patient.
After extubation, auscultation is performed to check for good air movement. Stridor or decreased air movement after extubation indicates upper airway problems. Next, the patient's respiratory rate, breathing pattern, heart rate, blood pressure, and SpO_2 are checked. Mild hypertension and tachycardia immediately after extubation are common and resolve spontaneously in most cases. The patient should be monitored for nosebleed after nasotracheal extubation. The patient is encouraged to cough, with assistance as needed. Because laryngeal edema may worsen with time and stridor may develop, racemic epinephrine for nebulization should be available. Arterial blood gas (ABG) values should be sampled and analyzed as needed.

The most common problems that occur after extubation are hoarseness, sore throat, and cough.[43] These problems are benign and improve with time. A rare but serious complication associated with extubation is laryngospasm. Postextubation

laryngospasm is usually a transient event, lasting several seconds. If laryngospasm occurs, oxygenation can be maintained with a high FiO_2 and the application of positive pressure. If laryngospasm persists, a neuromuscular blocking agent may need to be given, which necessitates manual ventilation or reintubation.

Because the vocal cords have had limited function during the intubation period, they may not close fully as needed when the airway has been removed. To avoid aspiration, oral feedings, especially liquids, should be withheld for 24 hours after extubation. Patients may aspirate liquids even with an intact gag reflex.[50]

Extubation failure, defined as the sudden need for reinsertion of the airway because of airway problems, often occurs within 8 hours of extubation. Aspiration and edema are the most common problems. If the patient also is mechanically ventilated, reintubation may be required for work of breathing issues unrelated to the airway.

Fig. 37.44 Fenestrated tracheostomy tubes.

Tracheostomy Tube Removal (Decannulation)

Decannulation refers to removal of the TT. Several approaches exist to remove TTs. Patients who received a tracheostomy because of upper airway obstruction that has been resolved may have their tube removed in one step. Patients who have been on mechanical ventilation for an extended time may have problems with muscle weakness, problems adjusting to the increase in anatomic dead space, and upper airway problems with secretions and glottic closure. For these patients, a weaning process is used rather than abrupt removal of the tube. Weaning is accomplished by using fenestrated tubes, progressively smaller tubes, or tracheostomy buttons.[70]

Before decannulation, a comprehensive patient assessment is required. The patient should have sufficient muscle strength (peak expiratory pressure >40 cm H_2O) to generate an effective cough. Ideally, there should be no active pulmonary infection, and the volume and thickness of secretions should be acceptable. Patency of the upper airway can be assessed by bronchoscopy.[68] An adequate swallow must be present to decrease the risk for aspiration. After removal of the tube, the stoma closes on its own in a few days. After cleaning around the stoma, a sterile occlusive dressing should be applied over the stoma until it closes. The particular decannulation technique used depends on the patient's needs.

Fenestrated Tracheostomy Tubes

A **fenestrated** TT is a double-cannulated tube that has an opening in the posterior wall of the outer cannula above the cuff (Fig. 37.44). Removal of the inner cannula opens the fenestration, allowing air to pass into the upper airway. Capping or placing a speaking valve on the proximal opening of the tube's outer cannula, accompanied by deflation of the cuff, allows for assessment of upper airway function. Removal of the cap or speaking valve allows access for suctioning. If mechanical ventilation is needed, the inner cannula can be reinserted and the cuff reinflated.

One problem associated with this type of TT is malposition of the fenestration, such as between the skin and stoma or against the posterior wall of the larynx.[45] Customizing the fenestration or trying a fenestrated tube of a different size or by a different manufacturer can help to avoid this problem. Proper placement can be confirmed by using flexible bronchoscopy.

Case reports have shown granular tissue formation in some patients using a fenestrated TT. Granular tissue tends to form on the posterior tracheal wall, above the tube fenestration. This granular tissue may occlude the fenestration, cause bleeding (especially with tube changes), or result in airway obstruction on decannulation. Given the location of this granular tissue, these problems may be due to poor positioning of the fenestration within the airway.

Progressively Smaller Tubes

A second airway weaning technique is to use progressively smaller TTs. Similar to fenestrated tubes, this approach maintains the airway, but it allows for increasing use of the upper airway. This technique is also indicated in patients whose airway is too small for the available fenestrated tubes. The use of progressively smaller tubes may also allow for better healing of the stoma.

The problem with these techniques is the continued presence of a tube within the lumen of the airway.[69] The presence of the tube (cuffed or uncuffed) increases airway resistance. In patients with preexisting obstructive disorders, this added airway resistance may be too high to sustain spontaneous breathing, resulting in failed decannulation. These tubes also can impair coughing by preventing full compression of the inspired thoracic volume. The last factor to consider when using smaller tubes is the fit of the tube within the trachea. Smaller tubes have not only a smaller diameter but also a different length and angle of curvature; this may result in the tip of the tube impacting the posterior tracheal wall or the distal tip migrating into the subcutaneous space in the neck.

Tracheal Buttons

The tracheal button also may be used to maintain a tracheal stoma.[45] In contrast to the fenestrated tube, the tracheal button fits through the skin to just inside the anterior wall of the trachea

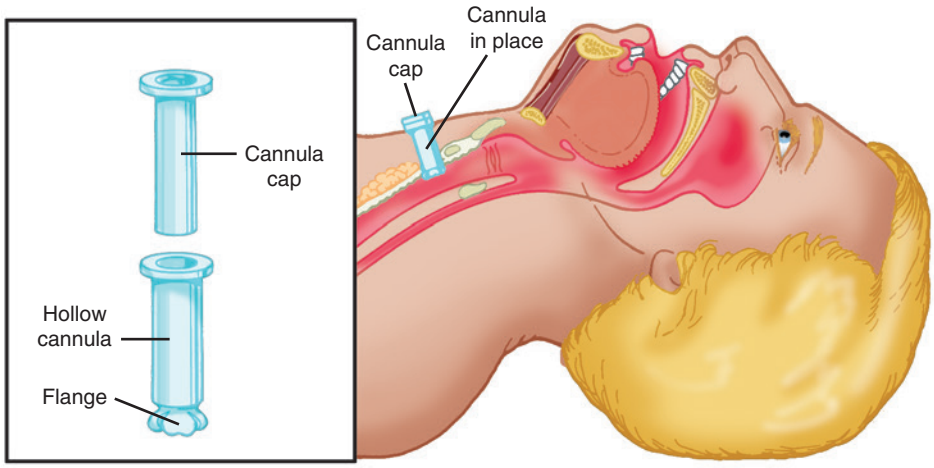

Fig. 37.45 Tracheostomy button.

(Fig. 37.45), which avoids the problem of added resistance. Because the tracheal button has no cuff, its use is limited to relieving airway obstruction and aiding the removal of secretions. When the inner cannula is removed, the clinician can suction through the outer cannula. However, when the inner cannula is removed, the clinician needs to hold the outer cannula in place to prevent it from being coughed out during suctioning.

Assessment After Tracheostomy Decannulation

After tracheostomy decannulation, the patient should be assessed for vocal cord responses.[69] Vocal cord abnormalities can result in either aspiration or acute airway obstruction. Symptoms such as stridor, retractions, and inability to feel airflow through the upper airway indicate upper airway obstruction. A replacement TT and suctioning equipment should be available in case the patient develops any of these symptoms of obstruction.

SUMMARY CHECKLIST

- Retained secretions or other semiliquid fluids are removed from the large airways via suctioning. Removal of foreign bodies or tissue masses beyond the mainstem bronchi requires bronchoscopy.
- To avoid or minimize the complications of suctioning, the RT needs to: (1) preoxygenate, (2) limit negative pressure and suction time, and (3) use sterile technique.
- The primary indications for an artificial tracheal airway are: (1) to relieve airway obstruction, (2) to facilitate secretion removal, (3) to protect against aspiration, and (4) to provide positive pressure ventilation.
- There are two basic types of tracheal airways: endotracheal (translaryngeal) tubes and TTs.
- Orotracheal intubation is the preferred route for establishing an emergency tracheal airway.
- Before intubation, adequate ventilation and 100% O_2 by manual resuscitator and mask should be provided.
- No more than 30 seconds should be devoted to any intubation attempt.
- There are many ways to assess ETT position; only laryngoscopy or bronchoscopy can definitively confirm positioning in the trachea.
- Serious complications of emergency airway management include acute hypoxemia, hypercapnia, bradycardia, and cardiac arrest.
- Nasotracheal intubation is the preferred route for intubation of patients with maxillofacial injuries.
- An LMA or a double-lumen airway (Combitube) can be used in a difficult intubation.
- The primary indication for tracheotomy is the continuing need for an artificial airway after a prolonged period of oral or nasal intubation; the decision when to switch from ETT to TT should be individualized.
- Cricothyroidotomy is performed when a patient cannot be intubated or ventilated.
- The most common laryngeal injuries associated with endotracheal intubation are glottic edema, vocal cord inflammation, laryngeal or vocal cord ulcerations, and vocal cord polyps or granulomas.
- Although laryngeal lesions occur only with oral or nasal ETTs, tracheal lesions can occur with any tracheal airway. The most common tracheal lesions are granulomas, tracheomalacia, and tracheal stenosis.
- To minimize or prevent trauma secondary to tracheal airways, the RT needs to: (1) select the correct size of airway, (2) avoid tube movement or traction, (3) maintain appropriate cuff pressures, and (4) use sterile techniques.
- To minimize the risk for infection, the RT needs to: (1) use closed suction devices, (2) use passive humidification, (3) monitor cuff pressure carefully, (4) use subglottic suction, and (5) keep the head of the bed elevated.
- ETT obstruction can be caused by: (1) kinking of or biting on the tube, (2) herniation of the cuff over the tube tip, (3) obstruction of the tube orifice against the tracheal wall, and (4) mucous plugging.
- If a tracheal airway appears to be completely obstructed, the RT needs to perform the following steps in order until the obstruction is relieved: (1) Reposition the patient's head and

neck, (2) deflate the tube cuff, (3) try passing a suction catheter, (4) try removing the inner cannula of the TT, and (5) remove the airway and provide bag-valve-mask ventilation and oxygenation.

- A patient is ready for extubation if the patient: (1) can maintain adequate spontaneous oxygenation and ventilation, (2) is at minimal risk for upper airway obstruction, (3) has adequate airway protective reflexes, and (4) can adequately clear secretions.
- Tracheostomy decannulation can be accomplished by using fenestrated tubes, progressively smaller tubes, or tracheostomy buttons.

Emergency Cardiovascular Life Support

Thomas A. Barnes

CHAPTER OBJECTIVES

After reading this chapter you will be able to

- List the causes of sudden cardiac arrest (SCA)
- List the signs of SCA, heart attack, and foreign body airway obstruction
- Describe how to perform cardiopulmonary resuscitation (CPR) on adults, children, and infants
- Describe how use a bag-valve-mask device without causing gastric inflation
- Describe how to perform defibrillation with automated external defibrillators and manual defibrillators
- State how to administer synchronized cardioversion
- Describe how to evaluate the quality and effectiveness of CPR
- List the complications that can occur as a result of resuscitation from SCA
- State when not to initiate CPR
- Describe how to apply key adjunct equipment during Advanced Cardiac Life Support (ACLS)
- State common drugs and drug routes used during ACLS
- Describe how to monitor patients before cardiac arrest, during CPR, and after cardiac arrest

CHAPTER OUTLINE

KEY TERMS

abdominal thrust
active compression/decompression (ACD)
active compression/decompression device
Advanced Cardiovascular Life Support (ACLS)
automated external defibrillators (AEDs)
Basic Life Support (BLS)
cardiopulmonary resuscitation
cardioversion
defibrillation
gastric inflation
impedance threshold device
Pediatric Advanced Life Support (PALS)
synchronized cardioversion

Respiratory therapists (RTs) play a vital role in emergency cardiovascular life support. In hospitals, RTs serve as key members of medical emergency teams, also known as *rapid response teams.* In addition to managing the airway, RTs often provide ventilatory and circulatory support; drug and electrical therapy; and monitoring immediately before, during, and after a cardiac arrest.

In the community, RTs also may be certified **cardiopulmonary resuscitation** (CPR) instructors, extending their knowledge to lay people through organizations such as the American Heart

Association (AHA) and the American Red Cross. Mastery of an extensive knowledge base and the development of various, sometimes difficult manual skills are required for teaching and performing CPR. The practitioner is encouraged to obtain further competencies by completion of formal courses in CPR, **Advanced Cardiovascular Life Support (ACLS)**, **Pediatric Advanced Life Support (PALS)**, and a neonatal resuscitation program.

CAUSES AND PREVENTION OF SUDDEN DEATH

Sudden cardiac arrest (SCA) is a leading cause of death among adults over the age of 40 in the United States and many other parts of the world.[1,2] In the United States, approximately 500,000 people per year experience SCA and receive an attempted resuscitation. Pulseless ventricular rhythms are the first manifestation of 23% of emergency medical services (EMS)–treated out-of-hospital cardiac arrests.[3] Each year, approximately 209,000 people are treated for in-hospital cardiac arrest.[4] In 2011, approximately 326,200 people experienced emergency medical services–assessed out-of-hospital cardiac arrests in the United States.[4] Successful resuscitation depends on immediate CPR and the delivery of a shock before pulseless ventricular rhythms deteriorate into asystole. In cases of SCA related to asphyxia due to trauma, drug overdose, or upper airway obstruction, CPR with chest compressions and ventilation before the shock is critical.

BASIC LIFE SUPPORT

The goal of **Basic Life Support (BLS)** is to restore ventilation and circulation to victims of airway obstruction and respiratory or cardiac arrest. These skills can be used by a single practitioner to restore ventilation and circulation until the victim is revived or until ACLS equipment and personnel are available. The steps for administering BLS by a single health care practitioner are as follows:

1. Check for lack of movement or response and no normal breathing or only gasping.
2. Activate the emergency response system (get and use an **automated external defibrillator [AED]** if available close to your location).
3. If no AED is available, start chest compressions and rescue breathing for adult cardiac arrest (use cycles of 30 compressions to 2 ventilations).
4. Open airway and check breathing.
5. If the person is not breathing, give two breaths that produce chest rise.
6. Immediately resume chest compressions (push hard and deep with a minimum depth of 2 inches [5 cm] and a rate of 100 to 120 per minute. Do not exceed 120 compressions/min because depth of compression and release of pressure during chest compression will be affected).
7. AED arrives with response team.

Steps 3 through 6 are referred to as the *CABDs* of resuscitation—circulation, airway, breathing, and defibrillation. Table 38.1 summarizes the CABDs of CPR for adults, children (1 year old to puberty), and infants (younger than 1 year).

Determining Unresponsiveness

BLS begins with immediate recognition of SCA and activation of the emergency response system based on assessment of unresponsiveness, not moving, and no normal breathing (only gasping). Check for a do-not-intubate/do-not-resuscitate (DNI/DNR) advanced directive if the resuscitative effort is in a medical setting or hospice at home and proceed accordingly.

Whatever the location, the victim's level of consciousness should be assessed quickly by checking for signs of life (e.g., movement and normal breathing). The rescuer should call for help and activate the emergency medical services (EMS) system if the patient is not moving or breathing or only gasping. Outside the hospital, someone may have to call 911 or the emergency number for the local EMS system. Within the hospital, specific protocols exist for "calling a code." All RTs must be familiar with the protocols of their institution for handling these emergency situations.

Restoring Circulation

Determining Pulselessness

For ease of training, the lay rescuer should be taught to assume that a cardiac arrest is present if the unresponsive victim is not breathing or only gasping; he or she should not take time to check for a pulse. Health care workers may also take too long for a pulse check and have difficulty determining whether a pulse is present. For this reason, if no pulse is found within 10 seconds, health care rescuers should immediately proceed with chest compressions.

RULE OF THUMB Assessment of the pulse of an unresponsive patient by health care providers should be limited to 10 s to avoid delaying chest compressions. Pulse checks are difficult to accomplish with any fidelity. Pulse and rhythm checks should not be done after a shock until five cycles of CPR have been completed. Pulse checks should not be done by lay rescuers.[5]

Pulselessness is evaluated by palpating a major artery. In adults and children older than 1 year, the carotid artery in the neck or femoral artery should be palpated. To locate the carotid artery, the rescuer should maintain the head-tilt with one hand while sliding the fingers of the other hand into the groove created by the trachea and the large neck muscles (Fig. 38.1). The carotid artery area must be palpated gently to avoid compressing the artery or pushing on the carotid sinus. Because the pulse may be slow, weak, or irregular, the artery may have to be assessed for approximately 10 seconds in order to confirm the presence or absence of a pulse.

For infants, the brachial artery is preferred for assessing pulselessness. To palpate the brachial artery, the rescuer must grasp the infant's arm with two or three fingers and, the thumb outward, slide his or her fingers down toward the antecubital fossa and press gently for 5 to 10 seconds to feel for a pulse (Fig. 38.2). The femoral artery can also be palpated; this may be done for an adult, a child, or an infant.

TABLE 38.1 Steps for Cardiopulmonary Resuscitation in Adults, Children, and Infants

Procedure	Adult[5]	Child[14]	Infant[11]
Compressions			
Where to check pulse (limit pulse check to <10 s)	Carotid artery	Carotid or femoral artery	Brachial artery
Hand placement	Heel of one hand on sternum in center of chest, between nipples. Second hand on top of first with hands overlapped and parallel	Lower half of sternum with heel of one hand or with two hands (for larger children). Do not compress over xiphoid	Sternum with two fingers placed just below nipple line in center of chest
Compression-to-ventilation ratio	One or two rescuers, 30:2	One rescuer, 30:2; two rescuers, 15:2	Neonatal: One rescuer 3:1 ratio of compressions to ventilation, with 90 compressions and 30 breaths to achieve approximately 120 events per minute to maximize ventilation at an achievable rate; 15:2 for cardiac origin
Cycles of compression-to-ventilation	5	5	n/a
Depth of compressions (push in hard and fast, allow chest to recoil fully)	Minimum of 2 in (5 cm)	At least one-third anteroposterior diameter of chest or 2 inches (5 cm)	At least one-third anteroposterior diameter of chest or 1½ inch (4 cm)
Compression rate	100–120/min (do not exceed 120/min)	100–120/min (do not exceed 120/min)	120/min
Breathing			
Obstructive procedure	*Responsive:* If mild, allow victim to clear the airway by coughing. If severe, repeat abdominal thrusts until foreign body is expelled or the choking victim becomes unresponsive. Consider chest thrusts if abdominal thrusts are ineffective, if rescuer is unable to encircle victim's abdomen, or if victim is in the late stages of pregnancy *Unresponsive:* Carefully move victim to the ground, immediately activate EMS system, and begin CPR (compressions first), then look into the mouth before giving breaths. If a foreign body is seen, it should be removed. Follow ventilation with chest compressions	Same as for adult	*Responsive:* If mild, allow infant to clear the airway by coughing. If infant is unable to make a sound (severe obstruction), deliver five back blows (slaps) followed by chest thrusts repeatedly until object is expelled or infant becomes unresponsive. Abdominal thrusts should not be done on infants because they may damage the largely unprotected liver *Unresponsive:* Activate EMS system and begin CPR, 30 chest compressions first, then look into the mouth before giving breaths. If a foreign body is seen, it should be removed. Follow ventilations with cycles of 30 chest compressions and 2 ventilations
Rescue Breathing (Pulse Present)			
Palpable pulse but no spontaneous breaths or inadequate breathing	10–12/min, 1 breath every 5–6 s	12–20/min, 1 breath every 3–5 s; if palpable pulse ≥60/min	40–60/min, 1 breath every 1–1.5 s; if palpable pulse ≥60/min to <100/min

In critical care settings within the hospital, bedside monitoring equipment may provide supporting or confirming information regarding the respiratory or circulatory status of a patient. However, information obtained from these devices should never be a substitute for careful clinical assessment.

If the patient has a pulse but is not breathing, ventilation must be started immediately at the appropriate rate of 8 to 10 breaths/min (every 6 to 8 seconds). If no pulse is palpable, external chest compressions must be interposed with ventilatory support. Deliver cycles of 30 compressions and 2 ventilations until an advanced airway is placed; then deliver uninterrupted chest compressions with asynchronous ventilations at a rate every 6 to 8 seconds (8 to 10 per minute) (see Table 38.1).

Providing Chest Compressions

Adequate circulation can be restored in a pulseless victim using external chest compressions. The rescuer manually compresses the lower half of the sternum (for an adult patient) at a minimum rate of 100 compressions/min without exceeding 120 per minute as a maximum recommended frequency of compressions. The duty cycle for downstroke and upstroke (release) is a 1:1 downstroke-to-upstroke ratio. It is very important to have a complete upstroke so as not to increase intrathoracic pressure during the diastolic phase. The best way to ensure that the upstroke is complete is for the rescuer to take his or her hand slightly off the chest between compressions and avoid leaning on the chest.[5-7] Cardiac output produced by external chest

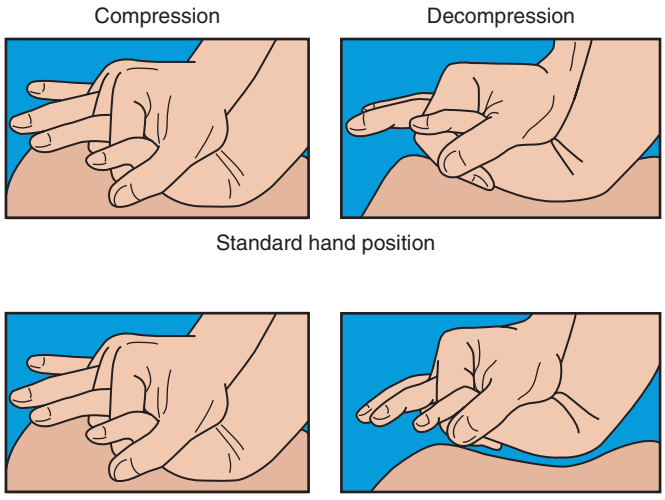

Fig. 38.4 Techniques for Hand Position.

compressions is approximately one-fourth of normal cardiac output, with arterial systolic blood pressures between 60 and 80 mm Hg. Blood flow during chest compression probably results from changes in the intrathoracic pressure. The American Heart Association (AHA) states that it is "reasonable to use physiologic parameters such as quantitative waveform capnography, arterial relaxation diastolic pressure, arterial pressure monitoring, and central venous O_2 saturation when feasible to monitor and optimize CPR quality, guide vasopressor therapy, and detect ROSC."[5] Quantitative capnography might be particularly beneficial. A persistent end-tidal PCO_2 less than 10 mm Hg during resuscitation is associated with a poor outcome. A sharp increase in end-tidal PCO_2 suggests return of spontaneous circulation (ROSC). A decreasing end-tidal PCO_2 suggests a worsening quality of CPR and the need to switch to a new person to perform compressions. An abrupt increase in end-tidal PCO_2 ≥40 mm Hg indicates ROSC.[8]

Adults. The procedure for providing chest compressions to adults is as follows (Figs. 38.3 and 38.4):

1. Place the victim in a supine position on a firm surface, because chest compressions are more effective when the victim is on a firm surface.
2. Choose a position close to the patient's upper chest so that the weight of your upper body can be used for compression. If the patient is on a bed or stretcher, stand next to it with the patient close to that side. If the bed is high or you are short, you may have to lower the bed, stand on a stool or chair, or kneel on the bed next to the victim. If the patient is on the ground, kneel at his or her side.
3. Identify the lower half of the victim's sternum, in the center of the chest between the nipples; place the heel of your hand on the sternum with your other hand on top and lock your elbows.[5]
4. Perform compression with the weight of your body exerting force on your outstretched arms, elbows held straight. Your shoulders should be positioned above the patient so that the thrust of each compression goes straight down onto the

sternum, using your upper body weight and the hip joints as a fulcrum (see Fig. 38.3). It is acceptable to let your hands leave the victim's chest ever so slightly to ensure a complete upstroke (see Fig. 38.4).

5. Compress the sternum 2 inches (5 cm) at a minimum rate of 100 compressions/min; however, do not exceed a rate of 120 per minute. The compression phase of the cycle should be equal in duration to the upstroke phase.
6. If CPR must be interrupted for transportation or advanced life support (ALS) measures, resume chest compressions as quickly as possible. Advanced airway placement presumes that the provider has the initial training, needed skills, and current experience to insert the airway and verify its proper position with minimal interruption in chest compressions.[8]

Children. Children who have reached puberty should receive chest compressions as outlined for adults. The procedure for younger children (1 year old to puberty) is as follows:

1. Place the victim in the supine position on a firm surface. Small children may require additional support under the upper body; this is particularly true when chest compressions are given with mouth-to-mouth ventilation because extension of the neck raises the shoulders. The head should be no higher than the body.
2. As with an adult, identify the lower half of the sternum. Because the liver and spleen of younger children lie higher in the abdominal cavity, take special care to ensure proper positioning as described previously. However, use only one hand to compress. Use the other hand to hold the head in position and maintain the airway.
3. Compress the chest at a rate of at least 100 compressions/min. Push with enough force to depress the chest one-third of the anteroposterior diameter, approximately 1½ inch (4 cm) in infants or at least 2 inches (5 cm) in children. Generally the heel of one hand is sufficient to achieve compression. Because children and rescuer hands come in all sizes, one or two hands can be used to deliver chest compressions to ensure that adequate compression depth and complete release occur. The use of two hands to compress the chest of a child will result in better release (less leaning) and less fatigue.[9,10] As with adults, compression and relaxation times should be equal in length and delivered smoothly.

Infants. The procedure for infants (1 year of age or younger) is as follows (Fig. 38.5):

1. Use the lower half of the sternum for compression in an infant. Proper placement is determined by imagining a line across the chest connecting the nipples. Place your index finger along this line on the sternum. Then place your middle and ring fingers next to the index finger. Raise your index finger and perform compressions with the middle and ring fingers. Use the other hand to maintain the infant's head position and airway.
2. Compress the sternum approximately 1.5 inch (4 cm) at a rate of at least 100 compressions/min. Compression and upstroke phases should be equal in length and delivered smoothly. Your fingers should remain on the chest at all times.

Neonates. Chest compressions are indicated if the neonate's heart rate decreases to less than 60 beats/min despite adequate ventilation with supplemental oxygen (O_2). Before starting chest compressions, the rescuer should ensure that the neonate is being ventilated optimally.[11] The oxygen concentration should be increased to 100% when chest compressions are provided.[11] To reduce the risk of complications associated with hyperoxia, the higher oxygen concentration should be weaned as soon as the heart rate improves. Neonatal chest compressions are delivered on the lower third of the sternum to a depth of approximately one-third of the anteroposterior diameter of the chest to achieve a 3:1 ratio of 90 compressions and 30 breaths for 120 events per minute; rescuers may consider using higher ratios (e.g., 15:2) if the arrest is believed to be of cardiac origin.[11] Coordinated chest compressions and ventilations should continue until the spontaneous heart rate is greater than 60 beats/min. The current measure for verifying progress in neonatal resuscitation is to assess the heart rate response.[11] Two methods have been described. The first method uses a "wraparound" technique (Fig. 38.6). To

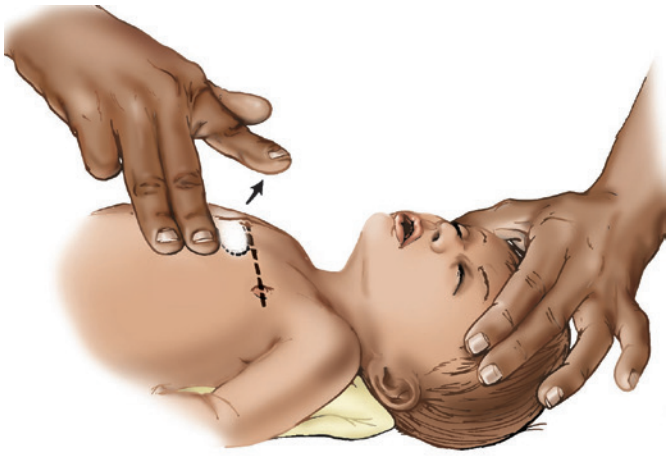

Fig. 38.5 Position for Chest Compression in Infants.

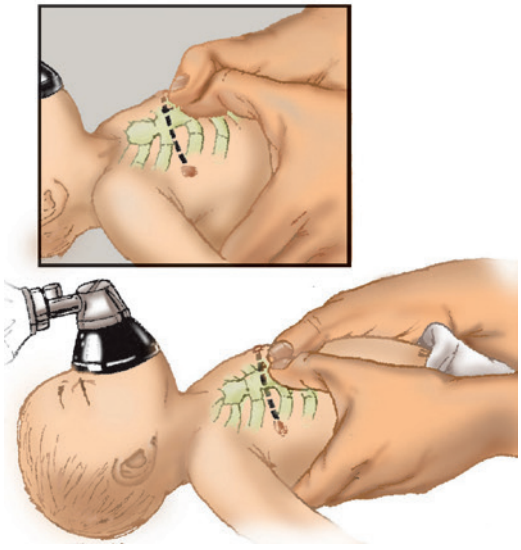

Fig. 38.6 Neonatal Chest Compression Using the Wraparound Technique.

use this method, the rescuer encircles the neonate's chest with both hands and compresses the sternum with two thumbs, using the other fingers of both hands to support the neonate's back. The rescuer should position the thumbs just below the victim's intermammary line, taking care not to compress the xiphoid process. Compression should be performed smoothly, with downstroke and upstroke times approximately equal. In all infants, the chest should be allowed to expand fully after a compression. After every third compression, the neonate should receive a breath of 100% O_2; this should be coordinated with compressions to avoid simultaneous delivery. The second method, the two-finger technique (see Fig. 38.4), may have advantages when access to the umbilicus is required.

Chest Compressions Under Special Circumstances

Two unique circumstances—near drowning and electrical shock—require modification of the normal procedures for applying cardiac compressions.

Near drowning. **Because of the hypoxemia caused by near drowning, use the ABC approach instead of CAB.** When cardiac arrest occurs as a result of drowning, the victim must be moved as quickly as possible to a firm surface. Cardiac compressions are difficult to perform while a victim is in the water and may be ineffective. Mouth-to-mouth ventilation in shallow water may be helpful when administered properly. Stabilization of the cervical spine is unnecessary unless circumstances leading to the incident indicate that trauma is likely. Manual cervical spine and spine immobilization equipment may restrict adequate opening of the airway and may delay the delivery of adequate ventilation.[5,12]

Suspected opioid-related life-threatening emergency. Isolated opioid toxicity is associated with central nervous system (CNS) and respiratory depression, which can advance to respiratory and cardiac arrest. For a patient with known or suspected opioid overdose who has a pulse but no normal breathing or only gasping should receive standard BLS care, and it is sensible for BLS health care providers to administer intramuscular or intranasal naloxone. Standard resuscitation, including activation of emergency medical services, should not be delayed for naloxone administration. For patients in cardiac arrest, medication administration is ineffective without concomitant chest compressions for drug delivery to the tissues, so naloxone administration should be considered only after initiation of CPR if there is high suspicion for opiate overdose.[5,13]

Restoring the Airway

After calling for help and activating the EMS system, the lay rescuer providing "hands only" CPR should not use a passive airway, such as hyperextending the neck. There is insufficient evidence indicating that a passive airway improves ventilation when chest compressions are being administered.[5,12]

After activating the emergency response system and sending someone for an automatic external defibrillator, the health care provider should deliver 30 chest compressions and use the head-tilt/chin-lift or jaw-thrust maneuver to open the airway (Figs. 38.7 and 38.8). The victim should quickly be inspected for any neck or facial trauma. If spinal cord trauma is suspected, the neck must be carefully positioned in a neutral in-line position and procedures requiring hyperextension must be avoided. In

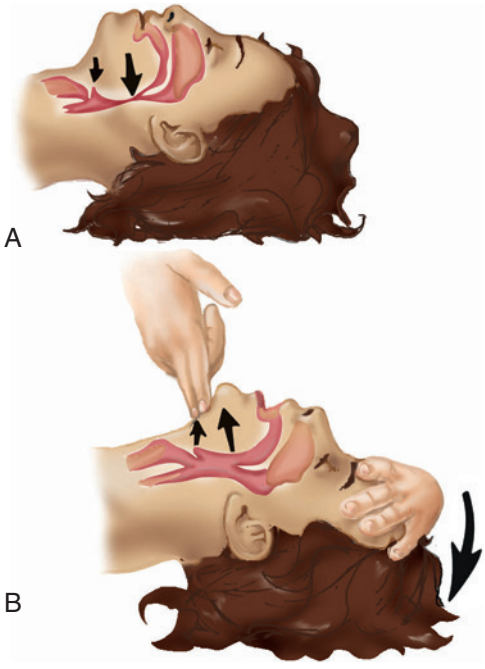

Fig. 38.7 Opening the Airway. (A) Airway obstruction produced by tongue and epiglottis. (B) Relief by head-tilt/chin-lift method.

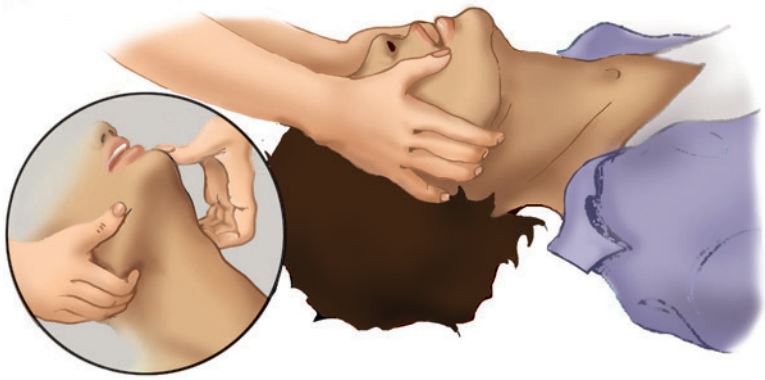

Fig. 38.8 Jaw-Thrust Maneuver.

addition, when a victim is found lying on his or her side or stomach, he or she should be moved to a supine position before airway procedures are begun. Manual in-line spinal motion restriction should be employed when the patient is being moved. The rescuer must ensure that the victim is positioned on a hard flat surface.[5]

One of two procedures can be used: (1) The head-tilt/chin-lift method is the primary procedure recommended when spinal trauma is not suspected. (2) The jaw thrust is used mainly by trained clinicians when spinal neck injuries are suspected. Health care providers should use the head-tilt/chin-lift procedure if the jaw-thrust maneuver does not open the airway.[5] After the airway is cleared and opened, the rescuer must immediately deliver two breaths.

Restoring Ventilation

Before attempting to provide artificial ventilation, the rescuer should assess for breathing. To determine breathlessness, the rescuer places his or her ear over the victim mouth and nose while simultaneously observing for spontaneous chest movement. Breathlessness exists if no chest movement or normal breath sounds are present or only gasping is present. This evaluation should take no longer than 3 to 5 seconds to complete. Delivery of chest compressions should always precede attempts to ventilate the patient using a ratio of 30 compressions to two breaths. Health care providers should provide chest compressions and ventilation for all adult patients in cardiac arrest from either a cardiac or noncardiac cause.[5]

RULE OF THUMB It is rational for health care providers to provide chest compressions and ventilation for all adult patients in cardiac arrest from a cardiac or noncardiac cause.[5] However, it is important to **restore circulation first,** with chest compressions, before attempting airway control. The sequence of rescue actions should be determined by the most likely cause of arrest. For example, if a lone health care provider sees an adolescent collapse, the provider may assume that the victim has had a sudden arrhythmic arrest; the provider should then call for help, get a nearby AED, and return to the victim to use the AED. Next, he or she should provide CPR starting with chest compressions at a 30:2 compression-to-ventilation ratio.

A team of highly trained rescuers may use an approach that undertakes multiple steps and assessments simultaneously rather than in the consecutive manner used by a single rescuer (e.g., one rescuer activates the EMS while retrieving a defibrillator, the second begins chest compressions, and a third provides airway control and ventilation with a bag-mask device for rescue breaths).[5]

Providing Artificial Ventilation

During respiratory arrest, the victim must be provided with O_2 within 4 to 6 minutes or biologic death will follow. The lay rescuer can restore O_2 supply to the victim's lungs by exhaling into the victim's mouth, nose, or tracheal stoma. These procedures can be used for any victim, with appropriate modification for the patient's age. Health care providers should provide ventilation with bag-mask ventilation that delivers 100% O_2. The routine use of passive oxygen administration without positive pressure during conventional CPR for adults is not recommended.[5] After placement of an advanced airway, it may be reasonable for the provider to deliver 1 breath every 6 seconds (10 breaths/min) while continuous chest compressions are being performed.[8]

Mouth-to-mouth ventilation. **Untrained lay rescuers should be encouraged to deliver hands-only (chest compression only) CPR** (i.e., continuous chest compression over the middle of the chest). Trained rescuers can restore adequate oxygenation through mouth-to-mouth ventilation. To do this, the rescuer should take a normal breath (500 to 600 mL) and exhale directly into the victim's mouth over 1 second to produce visible chest rise. Exhaled air provides approximately 16% O_2, which is sufficient to achieve an arterial O_2 tension (PaO_2) of 50 to 60 mm Hg. A tidal volume (V_T) of 500 mL should be delivered when chest compressions are being administered. Children require proportionally smaller volumes.

During resuscitation of a victim of cardiac arrest, two breaths should be given over a period of 1 second each. Excessive volumes (>500 mL) or an inspiratory rate that is too fast (>10 breaths/min) must be avoided because this can push air into the stomach, causing **gastric inflation,** and increase intrathoracic pressure. Increased intrathoracic pressure can decrease coronary and cerebral perfusion. Visible chest rise should be used to gauge the V_T needed in children and adults.

Adults. Thirty chest compressions should be delivered to unresponsive victims with apnea or abnormal breathing (gasping) before attempting mouth-to-mouth breathing. The exception would be a hypoxic event such as a near-drowning. The procedure for mouth-to-mouth ventilation of adults with spontaneous circulation (i.e., strong palpable pulses) is as follows (Fig. 38.9).[12]

1. Place the person on his or her back on a hard flat surface.
2. Kneel at the person's side, and open and clear the airway as previously described. Pinch the person's nose with your thumb and index finger close to the nares to prevent air from escaping during ventilation.
3. Take a normal breath and deliver 500 mL over 1 second while making a seal over the person's mouth and watching for chest

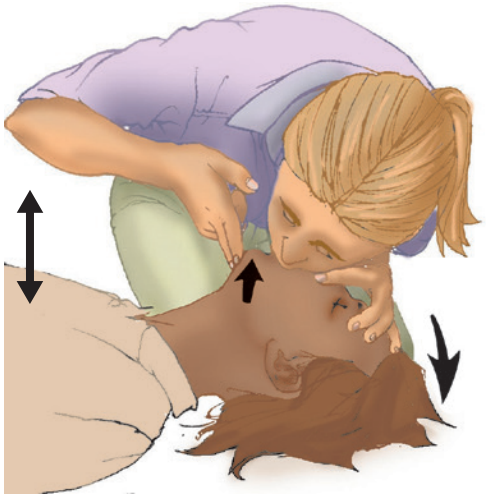

Fig. 38.9 Adult Mouth-to-Mouth Ventilation.

rise. A good seal over the person's mouth is essential. If a good seal cannot be obtained using this method, attempt mouth-to-nose ventilation.
4. Remove your mouth from the person's mouth and allow him or her to exhale passively. Provide a second breath after exhalation is complete.
5. After successfully delivering two breaths, immediately assess the circulatory status (take <10 seconds to accomplish this).
6. Should the initial attempt to ventilate fail, reposition the person's head and repeat the effort. If a second attempt at ventilation fails, the person may have foreign body airway obstruction (FBAO) and the procedures for handling such situations described elsewhere in this chapter should be followed.
7. Assuming that mouth-to-mouth ventilation is successful and the person remains apneic, continue the effort at a rate of 1 breath every 5 to 6 seconds to maintain the adult rate of 10 to 12 breaths/min.

Infants and children. Airway opening maneuvers for children and infants are similar to maneuvers for adults, but with several key differences. Anatomic differences in the infant's airway make it especially susceptible to occlusion by the tongue. The infant's head should be extended only slightly, or it should be tilted back gently into a neutral position when the head-tilt/chin-lift maneuver is used. The procedure for children and infants is as follows:
1. If the child is an infant (younger than 1 year), create an airtight seal by placing your mouth over the infant's nose and mouth (Fig. 38.10).
2. If the patient is a child between 1 year old and puberty, ventilate the child's lungs using the same technique as would be used for an adult (Fig. 38.11).
3. Provide an initial breath (over 1 second) sufficient to cause a visible rise in the chest. In infants, small puffs of air from the rescuer's cheeks are usually sufficient to achieve adequate ventilation.
4. Remove your mouth and allow the child to exhale passively. Provide a second breath after this deflation pause.
5. After successfully delivering two breaths, immediately assess the pulse (<5 seconds). Provide chest compressions if the pulse is less than 60 per minute despite adequate oxygenation and ventilation.
6. If the initial attempt to ventilate fails, reposition the child's head and repeat the effort. A child's head may have to be moved through a wide range of positions to secure an open airway. Hyperextension of a child's neck can cause obstruction and should be avoided. If a second attempt at ventilation fails, the victim may have FBAO, and the appropriate procedures outlined elsewhere in this chapter should be followed.
7. Assuming that mouth-to-mouth ventilation is successful and the child remains apneic, continue to provide one breath every 3 to 5 seconds to maintain a rate of 12 to 20 breaths/min. Recheck the pulse every 2 minutes.[14]

Mouth-to-nose ventilation. Mouth-to-mouth ventilation cannot be performed in some situations; these include trismus (involuntary contraction of the jaw muscles, also known as *lockjaw*) and traumatic jaw or mouth injury. Also, it is sometimes difficult to maintain a tight seal with the lips using the mouth-to-mouth method. In these situations, mouth-to-nose ventilation should be used. The procedure is as follows (see Fig. 38.11):
1. Place the person in a supine position.
2. Use the head-tilt/chin-lift maneuver to establish the airway, taking care to close the mouth completely.
3. Inhale normally and exhale into the person's nose. Greater force may have to be applied than would be used with mouth-to-mouth ventilation because the nasal passageways are smaller.
4. Remove your mouth from the person's nose to allow the person to exhale passively. If the person does not exhale through the nose (because of nasopharyngeal obstruction from the soft palate), open the mouth or separate his or her lips to facilitate exhalation.
5. If the person remains apneic, maintain ventilation at the rate appropriate for his or her age.

Mouth-to-stoma ventilation. Patients with tracheostomies or laryngectomies can be ventilated directly through the stoma or

Fig. 38.10 Mouth-to-Mouth and Nose Seal for Infants.

Fig. 38.11 Mouth-to-Nose Ventilation.

tube. These patients can be identified by an obvious stoma or a tracheostomy or laryngectomy tube in place. Some patients wear a medical alert tag or bracelet indicating that a stoma is present. The procedure for mouth-to-stoma ventilation is as follows:

1. Place the person on his or her back with the neck in vertical alignment. Usually, the neck does not need to be extended and the nose or mouth does not need to be sealed because oropharyngeal structures are bypassed by the stoma.
2. Ensure that the stoma is clear of any obstructing matter and breathe directly into the stoma (or tube). If the person has a cuffed tracheostomy tube in place, inflate the cuff to prevent air from escaping around the tube. If the tube is uncuffed, the mouth and nose may have to be sealed off with your hand or a tight-fitting face mask. A pediatric face mask may be used to create an adequate peristomal seal for bag-mask ventilation to persons with stomas without artificial airways.
3. After delivering two breaths, immediately assess circulatory status.
4. If the person remains apneic, maintain ventilation at the rate appropriate for his or her age.

One-Rescuer Versus Two-Rescuer Adult Cardiopulmonary Resuscitation

Outside the hospital, one-rescuer CPR is common. In such cases, the rescuer must assess the victim, call for help, and begin CPR without assistance from others. The rescuer must remain calm and remember the steps of one-rescuer CPR. The technique for performing chest compressions, opening the airway, and giving mouth-to-mouth breaths is the same regardless of the number of rescuers.

When CPR is being performed by only one rescuer, the lay rescuer must remember to give only compressions for adults, children, and infants until an AED arrives. When two rescuers are available, the second rescuer ventilates and evaluates the effectiveness of CPR. The other rescuer administers cardiac compressions. To facilitate movement, each rescuer should assume the appropriate rescue position on opposite sides of the victim.

RULE OF THUMB Lay rescuers should be taught to do 100 to 120 compressions/min (and not to exceed 120 per minute) for all age groups until the AED arrives because it is easier to remember.[5] Emphasis should be placed on teaching lay rescuers to "push hard and fast" on the sternum.

RULE OF THUMB Health care providers should use a 30:2 compression-to-ventilation ratio on adults and children.[5,14] For infants younger than approximately 1 year of age, use a 3:1 ratio of compressions to ventilation, with 90 compressions and 30 breaths to achieve about 120 events per minute in order to maximize ventilation at an attainable rate.[11] A 3:1 compression-to-ventilation ratio is used for neonatal resuscitation, where poor gas exchange is almost always the primary cause of cardiovascular failure, but rescuers may consider using 15:2 if the arrest is believed to be of cardiac origin.[11] When two health care providers work together to resuscitate a child or infant, the compression-to-ventilation ratio should be 15:2.[11,14] Use AED as soon as it is available.

When two health care providers resuscitate an adult patient, the individual providing compressions briefly pauses after 30 compressions so that the other person can administer two ventilations. The cycle is repeated without interruption of compressions to check for signs of circulation or response until an AED arrives or until the hospital code team takes over CPR. Health care providers should limit interruptions in chest compressions to no longer than 10 seconds.

To provide rest for the individual delivering cardiac compressions, the rescuers should change positions every five cycles (approximately 2 minutes). The individual doing cardiac compressions calls for the change, saying "we will change next time" in sequence with compressions. The switch should be accomplished in less than 5 seconds. The cycle continues with the two rescuers in their new positions. Alternatively, to avoid fatigue, teams of three health care providers can be assigned to do chest compressions, switching every five cycles of the 30:2 compression-to-ventilation ratio. The goal is to push "hard and fast" without letting fatigue diminish that rate.

RULE OF THUMB The person doing chest compressions should be changed every 2 minutes. Doing chest compressions is tiring, and fatigue occurs within a few minutes, leading to a compression rate less than 100 to 120 compressions/min, shallow chest compressions less than 1.6 inches or 4 cm, and incomplete chest recoil.[5] Health care providers should perform chest compressions to a depth of at least 2 inches or 5 cm for an average adult while avoiding chest compression depths that are greater than 2.4 inches or 6 cm.[5]

Rescue attempts continue until advanced life support is available, the rescuers note spontaneous pulse and breathing, or a physician pronounces the victim dead. A cardiopulmonary emergency is a crisis for the victim and his or her family, and appropriate support and intervention should be provided to all individuals affected. Victims who survive CPR should be transported quickly to tertiary care facilities, ideally only after advanced life support is instituted.

Automated External Defibrillation

Early Defibrillation

Since 1990 the AHA has recommended adding a fourth step to the treatment of cardiac arrest. This step involves early **defibrillation** after CPR has been initiated. The rationale is as follows:

1. The most common initial rhythm in witnessed sudden cardiac arrest is VF.
2. The treatment for VF is electrical defibrillation.
3. The probability of successful defibrillation diminishes rapidly over time.
4. VF tends to convert to asystole within a few minutes.

Studies have shown that survival rates are highest when immediate bystander CPR is provided and defibrillation occurs within 5 minutes after SCA.[15,16]

The AHA recommendation is that AEDs be made available to individuals expected to respond to emergencies, such as police, security personnel, ski patrol personnel, flight attendants, and first-aid volunteers (Fig. 38.12). Fig. 38.13 demonstrates how

Fig. 38.12 Automated External Defibrillator With Pads Attached. (From Chapleau W: *Emergency first responder, making the difference*, revised ed 2, St. Louis, 2011, Mosby JEMS.)

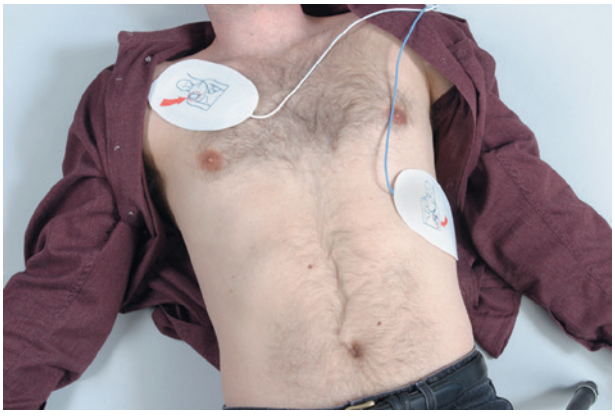

Fig. 38.13 Placement of Pads When Using Automated External Defibrillator. (From Chapleau W: *Emergency first responder, making the difference*, revised ed 2, St. Louis, 2011, Mosby JEMS.)

the AED is attached to the victim. Early defibrillation has already proved effective in saving lives of people who otherwise may not have been successfully resuscitated.[15,16] After appropriate training and implementation of the circulation, airway, and breathing (CAB), this last step is inserted as the letter *D*, for defibrillation. This step should be initiated within 2 minutes of beginning CPR. If the EMS provider witnesses the collapse or for in-hospital situations, the rescuer should use the defibrillator as soon as it is available.

Personnel employed at high-acuity hospitals may not be equipped with AEDs because access to ACLS is readily available, usually within minutes of the code being called. However, low-acuity hospitals, skilled nursing facilities, and other medical facilities that do not have a code team on the premises would benefit from AEDs. RTs working at such facilities should inquire whether an AED is on the premises; if so, they should determine where it is located and how it functions. If an AED is not present, a recommendation should be made to the administration of the facility to purchase one. RTs should know where AEDS are located in the hospitals and outpatient clinics where they work and know how to use them. The AHA recommends that an AED be available wherever CPR is likely to be performed. AEDs should be deployed in locations where there is a high incidence of witnessed SCA, such as airports, casinos, and sports facilities.

Ventricular fibrillation (VF) cardiac arrest is less common in children than in adults, accounting for 5% to 15% of pediatric and adolescent arrests.[12] The AHA recommends using an AED for children older than 1 year who are in cardiac arrest and recommends the use of a pediatric dose-attenuator system if one is available. If such a system is unavailable, a standard AED is recommended.[17] For infants, a manual defibrillator is chosen when a shockable rhythm is identified by a trained health care provider. The recommended first energy dose for defibrillation is 2 J/kg; a second dose should be doubled to 4 J/kg. If a manual defibrillator is not available, an AED equipped with a pediatric attenuator is preferred for infants.[17]

MINI CLINI

Problem

Health care colleagues are unsure whether, for adult patients, to deliver several stacked monophasic shocks at escalating higher energy levels to convert VF to sinus rhythm and what energy level should be used for each shock.

Solution

Research has shown that lower-energy (120 to 200 J) biphasic waveform shocks have equivalent or higher success in terminating VF than three stacked monophasic waveform shocks delivering escalating energy of 200, 300, and 360 J. The incremental benefit of another shock is low, and resumption of CPR is likely to confer a greater value than another shock.[18] There is no evidence indicating the superiority of one biphasic waveform or energy level for the termination of VF with the first shock (termination is defined as absence of VF at 5 s after shock).[8] All published studies support the effectiveness (consistently in the range of 85% to 98%) of the first biphasic shock using 200 J or less.[19] Biphasic waveforms are reported to be uniformly more effective in terms of first-shock success than monophasic across energy levels in a stacked-shock protocol.[19] An automated external defibrillator administering a high peak current at 150 J biphasic fixed energy can terminate initial and recurrent VF with a high rate of success.[8,20]

Automated External Defibrillators

AEDs function in a semiautomatic fashion; the device only recommends that a shock be delivered; it does not initiate one automatically. AEDs have pads that are placed on the chest in positions guided by diagrams (see Fig. 38.13). When all of the equipment is hooked up, the "Analyze" button should be pressed to begin. A rhythm recognition program then analyzes the patient's rhythm. If it detects VT or VF, it advises the rescuer through voice and visual prompts that a shock should be delivered. If a shock is indicated, the rescuer should "Clear" (all hands off to avoid being shocked) the patient and press the "Shock" button. Having done this, the rescuer should deliver five cycles of CPR beginning with chest compressions.

The rescuer should not delay chest compressions by stopping to recheck the rhythm or pulse. The rhythm is checked by the AED after five cycles (approximately 2 minutes) of CPR have been completed. The rescuers should be prepared to initiate another five cycles of CPR immediately after a second shock has

been delivered. The rescuer administering chest compressions should be changed every 2 minutes. The rescuer providing 2 minutes of chest compressions should be prepared to deliver a shock immediately after having removed his or her hands from the victim's chest. The second rescuer should be in position to start chest compressions as soon as the shock has been delivered. If no shock is advised by the AED, the AED voice prompt should instruct the rescuer to resume CPR immediately, starting with chest compressions. If the message reads "No shock indicated," CPR should be performed for 1 to 2 minutes and then the rhythm analysis should be repeated. A 1- to 2-minute period of CPR after a no-shock prompt from the AED delivers O_2 and metabolic substrates to the myocardium, increasing the probability that a perfusing rhythm will occur. The rescuer should not be concerned that chest compressions might trigger the return of VF in the presence of a postshock organized rhythm.[21]

RULE OF THUMB Patients in VF or pulseless VT cardiac arrest should receive only one shock followed immediately by five cycles of CPR before the next shock is delivered. Time should not be taken to check for a pulse or to ventilate the patient before delivering the second shock if needed. Biphasic AEDs have a 90% conversion rate of VF on the first shock, so it is unlikely that a second shock will be needed. Chest compressions immediately after the first shock increase O_2 delivery as well as the chance of VF converting to a normal rhythm.[8]

Evaluating the Effectiveness of Cardiopulmonary Resuscitation

CPR providers must continuously judge both the effectiveness of CPR and the victim's response. Ventilation can be evaluated by observing visible rise and fall of the victim's chest during mouth-to-mouth resuscitation. Air that is escaping can be heard and felt during exhalation.

Hazards and Complications

The most common complications that occur with CPR are worsening of existing neck or spine injuries, gastric inflation and vomiting, trauma to internal structures during chest compressions, and problems associated with the removal of foreign objects to clear an obstructed airway.

Neck and Spine Injuries

Health care providers can aggravate neck or spinal injuries by inappropriately moving the victim's head. However, only approximately 2% to 5% of victims with blunt trauma have a spinal injury. Spinal injury risk is greatest if the victim has craniofacial injury or a Glasgow Coma Scale score of less than 8 (see Chapter 52).[22] The victim should be carefully assessed for head, neck, or spinal injuries. If this type of injury is apparent, the head should be carefully supported and side-to-side motion avoided. In such situations, using the jaw-thrust maneuver rather than the head-tilt/chin-lift method to open the airway is recommended by the AHA.[5,12] If jaw thrust is unsuccessful in establishing an airway, the rescuer should try a slight head-tilt.[12]

Gastric Inflation

During prolonged mouth-to-mouth ventilation, air may enter the esophagus and stomach.[23,24] Severe gastric inflation puts pressure on the diaphragm, restricting lung expansion.[25]

RULE OF THUMB The best way to avoid gastric inflation during bag-mask ventilation is to deliver breaths with low to moderate flow (<30 L/min) over 1 second.[23,24,26] V_T size should be only large enough to cause visible chest rise. The health care provider should not ventilate and compress the chest simultaneously with a bag-mask device.

However, most important is the fact that severe gastric inflation prompts regurgitation. Because an unconscious patient lacks normal upper airway reflexes, regurgitated stomach contents can easily be aspirated into the lungs. Aspiration of stomach contents into the lungs may cause death by making ventilation virtually impossible or lead to severe lung injury such as aspiration pneumonia, which may cause death days or weeks later.

Internal Trauma

External cardiac compression is hazardous, and every attempt should be made to minimize trauma by using the correct technique. Complications associated with chest compression include rare incidents of gastric perforation, laceration of the liver, pneumothorax, hemothorax, cardiac tamponade, and soft tissue emphysema. More common complications are contusion of the lung and fractured ribs or sternum.[27] These complications are most often linked to improper hand position. Placement of the hands too far to either the left or the right can cause fractured ribs or a lacerated lung. Incorrect placement on the left can injure the heart. Placing the hands too high on the sternum can fracture the sternum; placing the hands too low can cause a fractured xiphoid process or a lacerated liver. Correct identification of landmarks and proper hand placement will minimize the likelihood of these complications.

Foreign Body Airway Obstruction

Manual removal of a foreign body from the upper airway also can be hazardous because of the possibility of forcing the object deeper into the airway or traumatizing the airway. This hazard can be minimized by attempting to remove foreign body only when the provider can see solid material obstructing the airway in an unresponsive patient and using extreme care in removing it.[12]

Contraindications to Cardiopulmonary Resuscitation

A pulseless apneic patient dies within 4 to 6 minutes without intervention. Fear of further harm should never influence the decision to begin CPR. CPR is contraindicated only when the patient is obviously biologically dead (as noted by such findings as rigor mortis). In the hospital, CPR is contraindicated when a valid do-not-resuscitate order is in effect or when a properly executed living will (advance directive) specifically requests that CPR not be initiated.

Health Concerns and Cardiopulmonary Resuscitation

The actual risk for disease transmission during mouth-to-mouth ventilation is very small. However, the reluctance to initiate CPR poses a clear threat to the effectiveness of early intervention in life-threatening emergencies. A bystander should provide hands-only (chest compression only) CPR, with an emphasis on "push hard and fast" or follow the directions of the emergency medical dispatcher.[5]

RULE OF THUMB Rescuers of adult VF cardiac arrest should provide chest compressions at a rate of 100–120 per minute with an emphasis on "push hard and fast." Periodic gasps and chest recoil in victims of adult cardiac arrest may provide some ventilation if the airway is open. Most children and infants with cardiac arrest require both prompt ventilations and chest compressions.

Health care providers with a duty to provide CPR should follow the guidelines established by the US Centers for Disease Control and Prevention (CDC) and the Occupational Safety and Health Administration (OSHA). These recommendations include the use of latex gloves, masks, and goggles. Mechanical barrier aids to ventilation (e.g., masks, filters, valves, bag-mask device) have also been suggested to allay fear and protect the rescuer. However, these devices require training to be used properly.[28]

Equipment contaminated with blood or other body fluids during a resuscitation effort should always be discarded in appropriate receptacles or thoroughly cleaned and disinfected according to hospital protocols.

Treating Foreign Body Airway Obstruction

Early recognition of FBAO is critical. Foreign bodies may cause partial or complete obstruction. Partial obstruction may allow nearly adequate air exchange, in which case the patient remains conscious and coughing. If air exchange is present, the patient should be reassured and allowed to clear his or her own airway by coughing. If partial obstruction persists or air exchange worsens, the EMS system should be activated. Poor air exchange exists when the patient has a weak or ineffective cough, increased inspiratory difficulty, or cyanosis.

With a completely obstructed airway, the patient commonly clutches at his or her throat. This is known as the *universal distress signal for foreign body obstruction.* A person with a complete obstruction cannot talk, cough, or breathe and is in dire need of emergency intervention using abdominal thrusts, chest thrusts, back blows, or a combination of two or more such maneuvers.[12]

Several procedures can be used to obtain a clear passageway if attempts to open a victim's airway are unsuccessful or if a foreign body is observed but cannot be removed from the mouth or pharynx. For adults and children, the procedure for health care providers for clearing a foreign body is the *abdominal thrust.* The rescuer should attempt back blows first for infants with an obstructed airway; if these are unsuccessful, the rescuer should try chest thrusts.[17] *Chest thrusts* may be used in place of abdominal thrusts on women in advanced stages of pregnancy and on markedly obese individuals. Both abdominal thrusts and chest thrusts are normally followed by a visual check and manual removal of any observed obstructing foreign material.[12]

Abdominal Thrusts (Heimlich Maneuver)

Forceful thrusts applied to the epigastrium can dislodge an obstruction caused by a food bolus, vomitus, or other foreign body. Quick thrusts to the abdomen rapidly displace the diaphragm upward, increasing intrathoracic pressure and creating expulsive expiratory airflow. As with a normal cough, this expulsive airflow may be sufficient to expel the foreign body from the airway. The procedure for performing abdominal thrusts on adults and children is as follows (Fig. 38.14): (1) If the victim is sitting or standing, stand behind the victim and wrap your arms around his or her waist. (2) Make a fist with one hand and place the thumb side midline on the abdomen slightly above the navel and well below the tip of the xiphoid process (see Fig. 38.14). (3) Grasp the fist with the other hand and deliver a quick upward and inward thrust. Each thrust should be a separate and distinct movement. (4) Repeat the process until the obstruction is removed or the victim loses consciousness.

If an adult victim with FBAO becomes unresponsive, the rescuer should move the patient to the ground, activate the EMS system, and begin CPR. Each time the mouth is opened during cycles of compressions and ventilation, the rescuer should look into the victim's mouth for the foreign body and remove it; this should be done without increasing the time to deliver 2 breaths (~6 seconds). The routine use of blind finger sweeps to remove foreign bodies in adults, children, and infants is not recommended by the AHA.[12,17]

A conscious victim who is alone can attempt to dislodge the foreign body with self-administered abdominal thrusts, performed by pressing his or her fist into the abdomen or pushing the abdomen against a firm surface such as a countertop, sink, chair back, railing, or tabletop.

Fig. 38.14 Abdominal Thrusts, Adult Victim Standing. (From Chapleau W: *Emergency first responder, making the difference*, revised ed 2, St. Louis, 2011, Mosby JEMS.)

Vomiting

Vomiting is another complication associated with **abdominal thrusts and gastric inflation;** it is impossible to avoid in some victims. The hazard is the aspiration of vomitus into the lung. Aspiration can be prevented by using advanced airway devices such as an endotracheal tube, laryngeal mask airway, or esophageal-tracheal double-lumen airway (Combitube, Medtronic, Minneapolis, MN). During bag-mask ventilation, vomiting and aspiration can be lessened by limiting gastric inflation. Using a 1-second inspiratory time and tidal volumes limited to 500 mL may reduce the incidence of gastric inflation and the aspiration of vomitus.[23,24]

Internal organ damage. The major hazard associated with abdominal thrusts that are performed when an individual has choked and lost consciousness is possible damage to internal organs, such as laceration or rupture of abdominal or thoracic viscera.[29] The body of clinical data regarding choking is largely retrospective and anecdotal. Abdominal thrusts have been recommended for the relief of FBAO in adults and children since 1975, based mostly on early anecdotal case reports. Abdominal thrusts are recommended by the AHA and several other resuscitation councils for use for *unresponsive* adult and child (but not infant) victims. Abdominal thrusts are not recommended for infants younger than 1 year of age because of their relatively unprotected abdomens and large livers. Rational conjecture and common practices suggest that back blows may loosen an obstruction, so that subsequent abdominal or chest thrusts may relieve obstruction. The risk for internal organ damage from abdominal thrusts in a conscious patient can be minimized by the rescuer placing his or her arms and fist below the victim's xiphoid process and the lower margin of the ribs.

Back Blows and Chest Thrusts

Because an abdominal maneuver can easily cause abdominal injury when applied to infants, a combination of back blows and chest thrusts should be used to clear foreign bodies from the upper airway. Back blows alone may create sufficient force to dislodge trapped objects, but if this is ineffective, the back blows should be followed with five chest thrusts. The rescuer should continue inspecting the airway until it has been cleared. This procedure is as follows:

1. Back blows can be administered to infants more efficiently if the child is held straddled over one arm with the head lower than the body (Fig. 38.15).
2. Use the flat portion of your hand to deliver gently but quickly five back blows between the shoulder blades.
3. If the back blows do not clear the infant's airway, turn the infant over and institute a series of five chest thrusts (see Fig. 38.15). Similar to abdominal thrusts, chest thrusts create a rapid increase in intrathoracic pressure, aiding expulsion of the foreign body. Chest thrusts for infants are performed in the same manner and at the same location as cardiac compressions but at a slower rate.
4. Try to clear the airway between attempts to expel the foreign body. Visually inspect the oral cavity and remove any foreign matter that can be seen.

Fig. 38.15 Use of Back Blows and Chest Thrusts to Clear Foreign Bodies From Infant Airway.

Evaluating the Effectiveness of Foreign Body Removal

After each airway restoration maneuver, the rescuer must determine whether the foreign body has been expelled and the obstructed airway cleared. If the foreign body has not been dislodged, the appropriate sequence (abdominal thrusts or chest thrusts for adults and children, back blows and chest thrusts for infants) should be repeated until they have succeeded. Successful removal of an obstructing body is indicated by the following:

- Confirmed expulsion of foreign body
- Clear breathing and ability to speak
- Return of consciousness
- Return of normal color

If successive attempts to clear the airway fail, more aggressive techniques are indicated if available. These include direct laryngoscopy and foreign body removal with Magill forceps, transtracheal catheterization, cricothyrotomy, and tracheotomy. These methods require specially trained health care professionals and equipment, and they are aptly categorized as advanced life-support techniques. Transtracheal catheterization and cricothyrotomy are discussed later in this chapter, and laryngoscopy, bronchoscopy, and tracheotomy are described in Chapter 37.

ADVANCED CARDIOVASCULAR LIFE SUPPORT

ACLS extends BLS capabilities by providing additional measures beyond immediate ventilatory and circulatory assistance. These measures include using accessory equipment to support ventilation

and oxygenation, monitoring the electrocardiogram (ECG), establishing an intravenous route for drug administration, and applying selected pharmacologic agents and electrical therapies (Fig. 38.16). The AHA claims that "the foundation of ACLS is good BLS care, beginning with prompt high-quality bystander CPR and, for pulseless ventricular rhythms, attempted defibrillation within minutes of collapse."[30]

During ACLS in the hospital, the RT assumes primary responsibility for supporting oxygenation, establishing and maintaining the airway, and providing ventilation. RTs must demonstrate high levels of proficiency in these advanced life support skills and other ACLS skills that may be assigned by the resuscitation team leader.

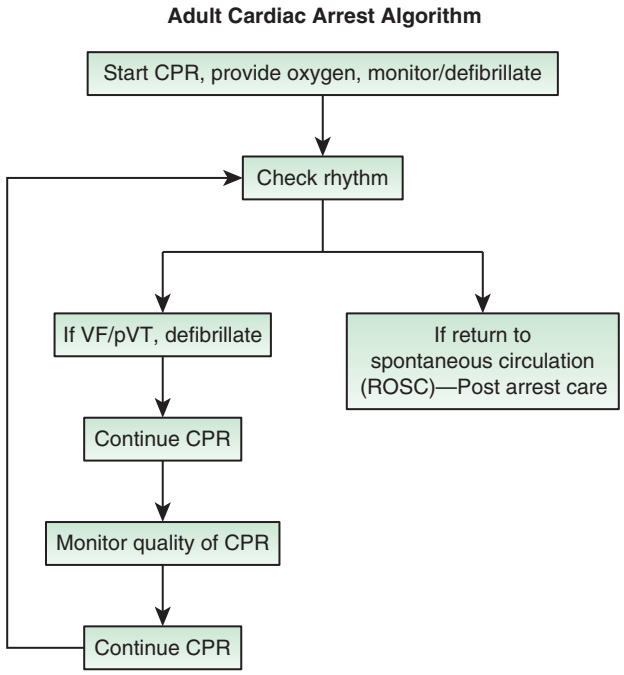

Fig. 38.16 Adult Cardiac Arrest Algorithm. (Information from Link MS, Berkow LC, Kudenchuk PJ, et al. Part 7: Adult advanced cardiovascular life support. 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 132(18 suppl 2):S444–S464, 2015; Wyckoff MH, Aziz K, Escobedo MB, et al. Part 13: Neonatal resuscitation: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 132(18 Suppl 2):S543–560, 2015.)

Support for Oxygenation

Although expired air ventilation provides an acceptable level of oxygenation, other factors—including low cardiac output, pulmonary shunting, and abnormalities during CPR—may lead to hypoxia. Hypoxia results in anaerobic metabolism and metabolic acidosis. Metabolic acidosis impedes the action of certain drugs and can diminish the effectiveness of electrical therapies. For these reasons, the highest possible concentration of O_2 should be administered as soon as possible to adults and children.[8] Concerns about O_2 toxicity are not valid during this period of resuscitation. Less than 100% O_2 may be used during neonatal resuscitation at birth.[11]

During ACLS, supplemental O_2 is normally given through accessory devices designed to support ventilation. The ability of these devices to provide high fractional inspired O_2 (F_iO_2) is a key factor in judging their performance.[31,32]

Airway Management

Accessory equipment designed to provide airway management during ACLS includes a variety of masks and artificial airways.

Pharyngeal Airways

Pharyngeal airways can help to restore airway patency and maintain adequate ventilation, in particular when using a bag-mask device. A properly placed pharyngeal airway may also help to provide access for suctioning. Pharyngeal airways should be used only after BLS methods have opened and cleared the airway.

Pharyngeal airways restore airway patency by separating the tongue from the posterior pharyngeal wall. Two types of pharyngeal airways are used in clinical practice: the oropharyngeal airway and the nasopharyngeal airway.

Oropharyngeal airways come in many different sizes to fit adults, children, and infants. Fig. 38.17 shows the two most common oropharyngeal airway designs: the Guedel airway (Flexicare, Irvine, CA; see Fig. 38.17A) and the Berman airway

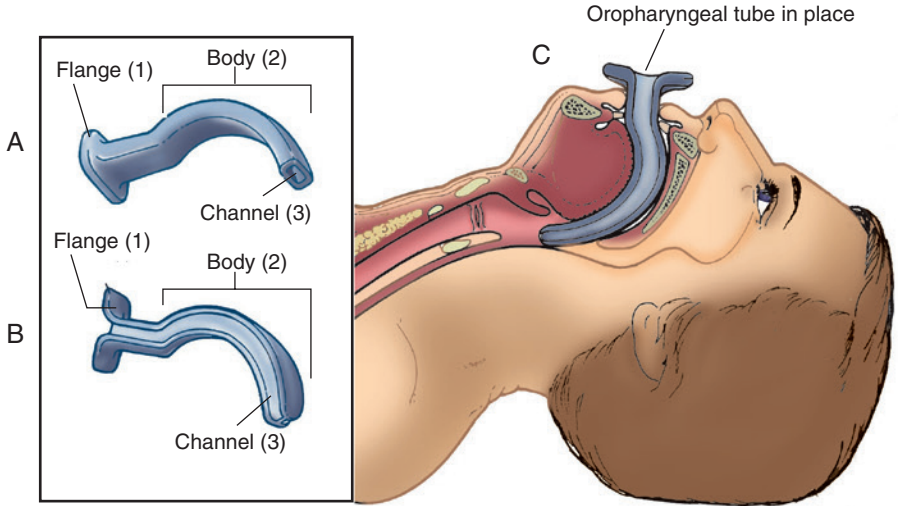

Fig. 38.17 Oropharyngeal Airways. (A) Guedel airway. (B) Berman airway. (C) Airway in place.

(Medline, Mundelein, IL; see Fig. 38.17B). Both types have an external flange, a curved body that conforms to the shape of the oral cavity, and one or more channels. The Guedel airway has a single center channel, whereas the Berman airway uses two parallel side channels.

To choose an airway of the correct size, the clinician should place the devices on the side of the patient's face with the flange even with the patient's mouth. The correct size airway measures from the corner of the patient's mouth to the angle of the jaw following the natural curve of the airway.

Because insertion of an oropharyngeal airway can provoke a gag reflex, vomiting, or laryngeal spasm, these devices are generally contraindicated for conscious or semiconscious patients. They also are contraindicated when there is trauma to the oral cavity or the mandibular or maxillary areas of the skull. These airways should never be placed when either a space-occupying lesion or a foreign body obstructs the oral cavity or pharynx.

Two techniques may be used to insert an oropharyngeal airway. In the first method, the tongue is displaced away from the roof of the mouth with a tongue depressor. The curved portion of the airway is slipped over the tongue, following the curve of the oral cavity.

In the second approach, the jaw-lift technique is used to help displace the tongue. The oropharyngeal airway is rotated 180 degrees before insertion. In this manner, the airway itself helps separate the tongue from the posterior wall of the pharynx. As the tip of the airway reaches the hard palate, it is rotated 180 degrees, aligning it in the pharynx.

In either approach, incorrect placement can displace the tongue, pushing it farther back into the pharynx and worsening the obstruction. Oropharyngeal airways must be inserted carefully and by trained personnel only. As shown in Fig. 38.17C, when properly inserted, the tip of an oropharyngeal airway lies at the base of the tongue above the epiglottis, with the flange portion extending outside the teeth. Only in this position can the device properly maintain airway patency.

Nasopharyngeal Airways

Nasopharyngeal airways are inserted through the nose instead of the mouth. A properly inserted nasopharyngeal airway provides a passageway from the external nares to the base of the tongue. As with the oropharyngeal airway, the nasopharyngeal airway helps restore airway patency by separating the tongue from the posterior pharyngeal wall.

The nasopharyngeal airway is generally indicated when placement of an oropharyngeal airway is impossible. The nasopharyngeal airway is also used when the jaws of a victim cannot be separated, as may occur with seizures. A nasopharyngeal airway should not be used when there is trauma to the nasal region or when a space-occupying lesion or foreign object blocks the nasal passages. Because the nasal passageway in children and infants is small, the use of nasal airways is generally limited to adults.

Most nasal airways are made from either rubber or plastic polymers and sized by external diameter according to the French scale, with 26F to 32F being the usual range for adults. Anatomically, the length of the airway is more critical than the diameter. The appropriate length can be estimated by measuring the distance from the patient's earlobe to the tip of the nose.

To insert a nasopharyngeal airway, the victim's head is tilted slightly backward. The airway is lubricated with a water-soluble agent to ease insertion, and it is positioned perpendicular to the frontal plane of the victim's face. The airway is advanced slowly through the inferior meatus of either the right or left nasal cavity, with the bevel edge facing the septum. If an obstruction is felt during insertion, gentle twisting may facilitate placement. If the resistance continues, the most likely cause is a deviated nasal septum. In this case, an attempt may be made to insert the airway through the other naris or a smaller-diameter tube may be tried.

After the airway has been inserted, the rescuer must try to visualize and confirm its correct position quickly, using a tongue depressor if necessary. When properly positioned, a nasopharyngeal airway is usually stabilized by its own flange.

Masks

A mask that fits the patient is a useful tool for the application of artificial ventilation by appropriately trained rescuers. An ideal mask should be made of transparent material, be capable of sealing tightly against the face, provide an inlet for supplemental O_2, and have a standard 22-mm port for connection to a bag-mask device. Masks should be available in various sizes to accommodate adults, children, and infants. Infant masks often have a 15-mm male connector instead of a 22-mm port. The use of masks to support ventilation presumes that the airway can be maintained by conventional BLS techniques. Which mask should be used in a given situation depends on careful assessment of the status of the victim and an in-depth knowledge of the capabilities and limitations of the equipment on hand.

Endotracheal Intubation

An advanced airway allows the rescuer to achieve one or more of the following goals:

1. Deliver ventilations that are not synchronous with chest compressions
2. Restore airway patency
3. Maintain adequate ventilation
4. Isolate and protect the airway from aspiration
5. Provide access for clearance of secretions

Endotracheal intubation is used for securing the airway during CPR. When positioned properly, endotracheal tubes can maintain a patent airway, prevent aspiration of stomach contents, permit suctioning of the trachea and mainstem bronchi, facilitate ventilation and oxygenation, and provide a route for drug administration.

Attempts to intubate the trachea must never interfere with providing adequate ventilation and oxygenation by other means, such as a bag-mask resuscitator. Advanced airway placement presumes that the provider has the initial training and skills as well as current experience to insert the airway and verify its proper position with minimal interruption in chest compressions.[8] Bag-mask ventilation also requires skill and proficiency. The choice of a bag-mask device versus advanced airway insertion, then, will be determined by the skill and experience of the provider. Only highly trained personnel should perform endotracheal intubation, and each attempt ideally should not exceed 10 seconds, because chest compressions will not be possible during the procedure.

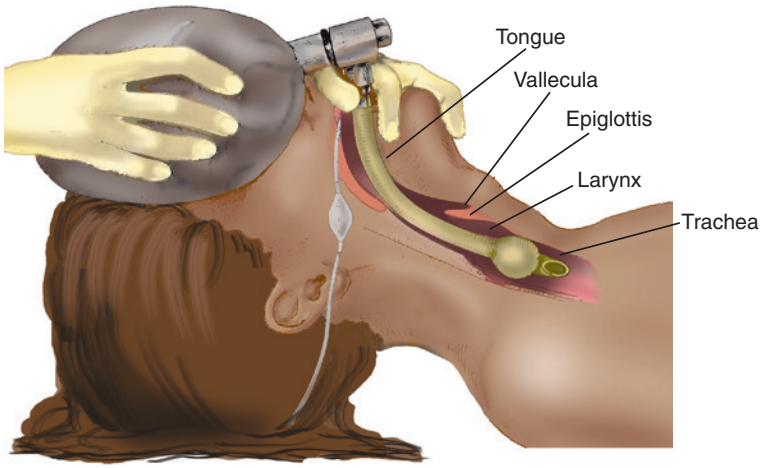

Fig. 38.18 Orotracheal Tube in Place, Being Used With a Bag-Valve Resuscitator.

Continuous waveform capnography is recommended by the AHA guidelines in addition to physical assessment as the initial method for confirming and monitoring correct placement of an endotracheal tube.[8] When capnometry is not available, auscultation and direct visualization should be used to confirm the position of the endotracheal tube. Adequate ventilation and oxygenation must be provided between attempts. Fig. 38.18 shows a cuffed orotracheal tube properly positioned in the trachea. It is being used with a manual bag-mask device to provide ventilation and oxygenation. Adequate ventilation and oxygenation can be provided with 10 to 12 breaths/min.

RTs should be trained in endotracheal intubation techniques as applied in both emergency life support and mechanical ventilation situations. Details about the necessary equipment, procedures, and short- and long-term complications of endotracheal intubation are provided in Chapter 37.

Accessory equipment used to support ventilation in advanced life support includes manual and O_2-powered resuscitators. Bag-mask devices, also called manual resuscitators, are available for adults, children, and infants. Conversely, O_2-powered resuscitators are strictly limited to adult application and are not discussed in this chapter.

Bag-Mask Devices

One-way valves on bag-mask devices should be simple, dependable, and jam-free. All health care professionals responding to a cardiac arrest call should be familiar with and skilled in the use of such a device for the support of ventilation and oxygenation. Application of the bag-mask device is best performed with the practitioner positioned at the head of the victim, using the head-tilt maneuver to maintain the airway (Fig. 38.19). The rescuer delivers V_T adequate to produce visible chest rise (6 to 7 mL/kg predicted body weight or 400 to 500 mL) over 1 second. Using this smaller V_T decreases airway pressure and minimizes the risk for gastric inflation.

After an advanced airway replaces the face mask, the ventilatory rate should be 10 breaths/min during CPR. Slower rates of 6 to 8 breaths/min might be needed for patients with chronic obstructive pulmonary disease (COPD) to prevent air trapping and the development of auto-positive end expiratory pressure (auto-PEEP). Ventilatory rates greater than 12 breaths/min are not recommended during CPR because they lead to increased intrathoracic pressure, impeding venous return to the heart during chest compressions and hyperventilation.[33]

Fig. 38.19 Ventilation Using a Bag-Mask Device and Head-Tilt/Chin-Lift Method to Open the Airway. (From Henry MC, Stapleton ER: *EMT prehospital care*, revised ed 4, St. Louis, 2009, Mosby.)

The rescuer delivers a breath every 6 seconds with a 1 second inspiratory time and should not attempt to synchronize ventilations with the chest compressions. Nonsynchronized delivery of ventilation and compressions allows the number of chest compressions delivered per minute to increase to 100 to 120 per minute and breaths delivered to 10 per minute. After restoration of a perfusing rhythm, the ventilation rate should be 10 to 12 breaths/min delivered with a 1 second inspiratory time.

RULE OF THUMB

Rescuers should not hyperventilate victims of cardiac arrest. Once an advanced airway is placed, ventilations should be delivered with a 1 s inspiratory time at a rate of 10 breaths/min (every 6 s). Do not attempt to synchronize ventilations with chest compressions. Ventilation for patients with a perfusing rhythm should be at a rate of 10–12 breaths/min (1 breath every 5–6 s). Patients with COPD may need ventilation rates of 6–8 breaths/min to prevent auto-PEEP.

Bag-mask devices combine a mask with a self-inflating bag and a nonrebreathing valve mechanism. These devices may be used to ventilate patients by applying the mask over the patient's mouth and nose or by attaching the self-inflating bag directly to an endotracheal tube or other advanced airway. All devices can provide ventilation with air or with supplemental O_2. Bag-mask devices provide 100% O_2 when properly applied. Although initially designed as adjuncts for emergency life support, they are used extensively in other respiratory care settings, particularly in the areas of airway management and continuous mechanical ventilation.

Design

Fig. 38.20 is a schematic of a typical bag-mask device, showing gas movement and valve action during both the inhalation-compression and exhalation-relaxation phases. The key components shown in this schematic are the nonrebreathing valve *(left)*, the bag itself, the O_2 inlet and bag inlet valve *(to the right of the bag)*, and the O_2 reservoir tube *(far right)*.

During exhalation (see Fig. 38.20A), gas flows out from the patient's lungs through the nonrebreathing valve into the atmosphere. At the same time (while the bag expands), the intake valve opens and 100% O_2 flows into the bag from both the reservoir and the O_2 inlet.

During the inhalation phase (see Fig. 38.20B), the bag is compressed manually, causing bag pressure to increase. This increase in bag pressure simultaneously closes the inlet valve and opens the nonrebreathing valve, forcing gas into the patient. While the bag inlet valve is closed, O_2 coming in through the O_2 inlet goes into the reservoir tube, where it is stored for the next breath.

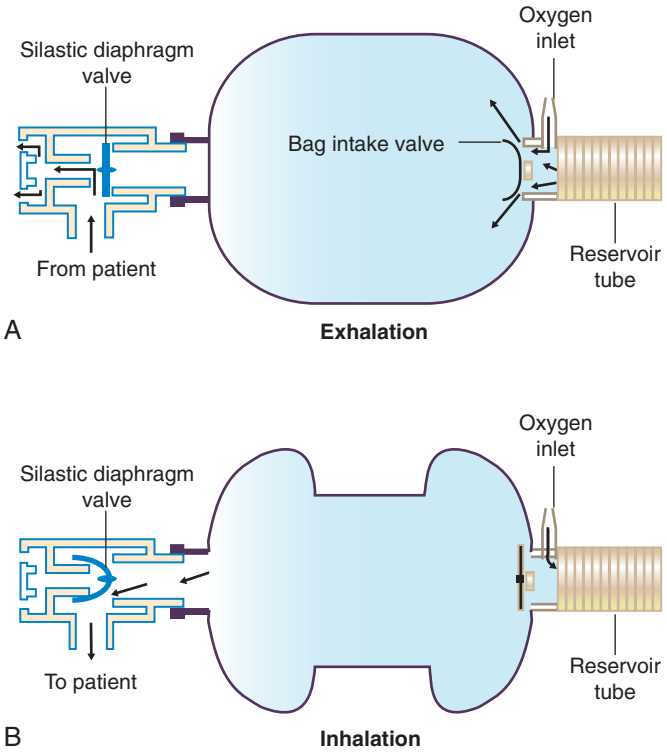

Fig. 38.20 Components of Bag-Mask Device.

Use

To use a bag-mask device, the health care provider is positioned at the head of the patient's bed. Ideally, an oral airway is inserted, and the head-tilt method is used to keep the airway open (assuming that there are no neck injuries). While using one hand to keep the patient's head extended and the mask tightly sealed to the patient's face, the health care provider uses the other hand to compress the bag (see Fig. 38.19).

In addition to providing adequate ventilation, bag-mask devices can provide high FiO_2. Theoretically, all such devices on the market can deliver 100% O_2; however, the actual FiO_2 provided at the bedside depends on several factors, including O_2 input flow, reservoir volume, delivered volume and rate, and bag refill time. As a guideline to achieve the highest possible FiO_2 with a bag-mask device, the following always should be done:

1. Use an O_2 reservoir of adequate size.
2. Set the O_2 input flow at 10 to 15 L/min.
3. Deliver appropriate V_T for a 1-second period (when using a mask).
4. Ensure the longest possible bag refill time.

Hazards and Troubleshooting

Bag-mask devices are simple and safe advanced life support devices. However, several major hazards are associated with their use. The first and most common problem is unrecognized equipment failure. Knowledge of how such devices operate can help clinicians understand the operational testing of and troubleshooting for these devices. Gastric inflation is another common hazard encountered when using a bag-valve device with a face mask. Gastric inflation can be minimized by providing low to moderate inspiratory flows (<30 L/min).[23,24,26] For an adult, a full 1 s should be used to deliver V_T of 500 mL.[23,24]

MINI CLINI

Ventilation During Cardiopulmonary Resuscitation

Problem

A student is observing a code blue in progress in the intensive care unit. The patient has had a cardiac arrest, and CPR is being administered. The student notices that the RT is ventilating the patient's lungs with a bag-valve device through an endotracheal tube at a considerably higher rate and minute ventilation than would normally be established on a mechanical ventilator for a patient of this size. Is this increased minute ventilation needed?

Solution

No, it is not. The ventilation rate should be 10 breaths/min, and V_T should be limited to achieve no more than a visible chest rise so as to avoid excessive ventilation.[34,35] Ventilation rates greater than 12 breaths/min and large V_T (>6 to 7 mL/kg) increase intrathoracic pressure and impede venous return to the heart during chest compressions.[33] During CPR, hyperventilation reduces cardiac output and decreases coronary and cerebral perfusion and markedly decreases coronary perfusion pressure and survival rates.[33] Overzealous ventilation with high rates (>12 breaths/min) during resuscitation of cardiac arrest increases intrathoracic pressure, impedes venous return, decreases cardiac output, decreases coronary artery perfusion pressure, increases gastric inflation, and provides more ventilation than is needed.

MINI CLINI

Problem

Inadequate refilling of the heart during the decompression phase of CPR.

Solution

If the depth of chest compression for adults is not 2 inches (5 cm), chest recoil can be impaired.[5] Chest wall recoil creates a relative negative intrathoracic pressure that promotes venous return and cardiopulmonary blood flow. Incomplete recoil could increase intrathoracic pressure and reduce venous return, coronary perfusion pressure, and myocardial blood flow and could potentially influence resuscitation outcomes.[10] It has been demonstrated that when compressions are too rapid, the compression depth is too shallow. When CPR is performed according to the AHA's recommendations, at 100–120/min, using either both hands or an **active compression/decompression device (ACD)** CPR device (Fig. 38.21), the addition of the **impedance threshold device** (ITD) (Fig. 38.22) provides important hemodynamic and survival benefits.[5,36,37] The small negative intrathoracic pressure generated within the thorax during the chest wall recoil phase is critical for refilling the heart during the decompression phase of CPR.[38] The ITD is designed to enhance venous return and cardiac output during CPR by increasing the amount of negative intrathoracic pressure.[39,40] The ITD (ResQPOD) (see Fig. 38.22) prevents the influx of respiratory gases into the chest during the chest wall recoil (relaxation or decompression) phase, which lowers the intrathoracic pressure and draws more venous blood back to the heart. Improved blood return to the heart (preload) results in improved blood flow out of the heart (cardiac output) during the subsequent compression. The ITD cannot function to enhance negative intrathoracic pressure during the decompression phase of CPR without adequate chest wall recoil. Active compression-decompression CPR uses a handheld device with a suction cup (ACD device) to perform closed-chest cardiac massage. The ACD is applied to the midsternum to compress the chest and then to actively decompress the chest after each compression. This differs from traditional manual CPR, where the chest can recoil passively. A meta-analysis review comparing ACD and standard chest compression techniques reported active chest compression-decompression to have no advantage and some drawbacks compared with standard CPR.[41] To the contrary, a large study found strong evidence that the application of ACD plus ITD in a wide spectrum of patients with out-of-hospital cardiac arrest can significantly increase long-term survival with restoration of baseline neurologic function at 1 year after arrest.[42] The 2015 ACLS guidelines recommend that the combination of ITD with active compression decompression CPR may be an acceptable alternative to conventional CPR in settings with available equipment and properly trained personnel.[36]

Increases in central venous pressure, because of increased intrathoracic pressure, can decrease cerebral blood flow. Increased airway pressures and auto-PEEP generated by hyperventilation should be avoided. The AHA consensus statement, "Cardiopulmonary Resuscitation Quality: Improving Cardiac Resuscitation Outcomes Both Inside and Outside the Hospital," recommends avoiding excessive ventilation during and after cardiac arrest.[34] Methods have been developed that decrease ventilation rate using electronic metronomes.[35] However, methods to limit excessive tidal volume and inspiratory pressure are less well developed but may include the use of smaller resuscitation bags, bags with manometers, and direct observation of chest rise.

Barotrauma has long been recognized as a potential hazard when a bag-mask device is used. However, with the full-bag volume of adult-size devices (generally ≤2000 mL), the potential for barotrauma is small if the nonrebreathing valve is working properly and a bronchial intubation has not occurred. The average mask leak with bag-mask devices ranges from 20% to 40% of stroke volume and substantially reduces the risk for barotrauma, especially if no more than visible chest rise is used to determine adequate V_T. Some pediatric bag-mask devices have bag volumes of more than 500 mL, and rescuers may cause barotrauma to small children or infants if they do not adjust stroke volume by squeezing the bag so that only half to one-third of the volume is delivered to the mask.

Restoring Cardiac Function

Perfusion support techniques, such as chest compressions, can restore circulation only temporarily. ACLS must go beyond simple perfusion support to identify, remove, or relieve the underlying cause of cardiac failure; this is done by combining ECG monitoring with pharmacologic and electrical therapies.

Fig. 38.21 Active Compression-Decompression Device. (Courtesy Zoll.)

Electrocardiogram Monitoring

Because most cases of cardiac arrest are caused by arrhythmias, ECG monitoring should be started as soon as the necessary equipment and personnel arrive. Monitoring may be done with either standard ECG equipment or the quick-look paddles now available on most defibrillators.

Given their important role in ACLS, RTs must be skilled in recognizing arrhythmias. Although an RT may be able to quickly

interpret gross arrhythmias appearing on ECG monitors at the bedside, these skills develop only after much practice with actual rhythm strips. Chapter 18 presents a review of ECG interpretation. The reader should focus on the following arrhythmias:

- VT
- VF
- Sinus tachycardia
- Sinus bradycardia
- Sinus arrest
- Premature atrial contractions
- Supraventricular tachycardia (SVT)—a classification of arrhythmias including but not limited to sinus tachycardia, atrial flutter, and atrial fibrillation
- Atrioventricular blocks—first degree, second degree types I and II, and third degree
- Premature ventricular contractions (PVCs)
- Pulseless electrical activity (PEA)
- Systole

Fig. 38.22 Impedance Threshold Device (ZOLL, Chelmsford, MA). (Courtesy ResQPOD.)

This section briefly discusses the arrhythmias closely associated with CPR conditions, including SVT, VT, VF, and PEA.

Supraventricular tachycardia. The term *supraventricular tachycardia* is commonly used to describe any tachycardia not of ventricular origin. This grouping can include sinus tachycardia, atrial tachycardia, junctional tachycardia, atrial flutter, and atrial fibrillation (with rates >100 beats/min). These individual supraventricular arrhythmias are identified by ECG and treated accordingly (Fig. 38.23).

A more specific form of SVT involves rapid impulse formation caused by a reentry mechanism that develops in the atria or atrioventricular junction. Normally, a single impulse from the sinoatrial node traverses the atria and continues down into the ventricles, causing depolarization and contraction. In reentry, an ectopic focus disrupts this normal conduction. The impulse not only moves down to the ventricles but also returns to the atria. This pattern repeats in a self-perpetuating, or circular, manner.

Typically, this form of SVT results in heart rates between 160 and 220 beats/min. The rhythm is regular, which distinguishes it from rapid atrial fibrillation. However, because of its rapid rate, P waves may not be seen. If identifiable, the P waves appear abnormal. In addition to the rate and regular rhythm, SVT is characterized by a normal QRS complex. At very high rates, the ventricles may not have enough time to fill completely. Incomplete ventricular filling can result in decreased cardiac output, congestive heart failure, and tissue hypoxia. SVT may deteriorate to VT if it is not recognized and treated in a timely manner.

The treatment of SVT varies according to the clinical situation (Fig. 38.24). If a patient with SVT is ill or unstable, the treatment of choice is immediate synchronized electrical **cardioversion**, as described elsewhere in this chapter. If the patient is stable, other interventions are tried before cardioversion is considered. The most common nonelectrical treatment for SVT is vagal stimulation by carotid artery massage or Valsalva maneuver. If these attempts are ineffective and the patient remains stable, drugs such as adenosine, diltiazem, verapamil, or β blockers (as a second-line agent) may halt SVT. These drugs work primarily on the nodal tissue by slowing ventricular response to atrial arrhythmias, or they block the reentry SVT that travels through the atrioventricular node.[30]

Ventricular tachycardia. VT occurs when one or more irritable foci within the ventricle discharge at rapid rates, creating the appearance of a prolonged chain of PVCs. Rates typically range from 140 to 220 beats/min and are usually regular (Fig. 38.25). Although VT may come and go in brief episodes, or *paroxysms,* it is always a sign of a serious underlying pathologic

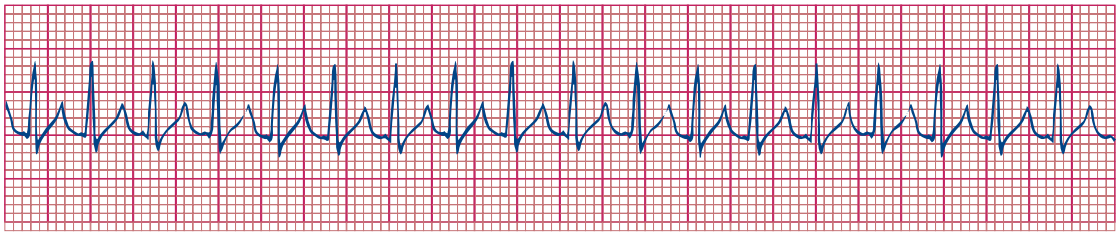

Fig. 38.23 Supraventricular Tachycardia, Lead II.

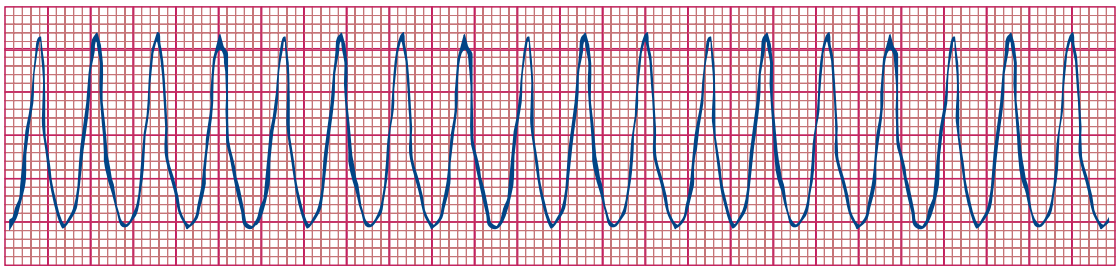

Fig. 38.25 Ventricular Tachycardia, Lead II (St. Louis, 2017, Mosby.)

condition and should be treated immediately. In stable patients, VT is managed with amiodarone, procainamide, and/or sotalol.[30] Procainamide and sotalol should be avoided in patients with a prolonged QT.[30] For patients with sustained VT who exhibit hypotension, ischemic chest pain, shortness of breath, decreased consciousness, or signs of pulmonary edema, immediate **synchronized cardioversion** is indicated (Fig. 38.26). Patients with sustained VT in full cardiac arrest are treated similarly to patients with VF.

Ventricular fibrillation. VF is a rapid, sustained, uncontrolled depolarization of the ventricles. During VF, the ECG is characterized by irregular, widened, poorly defined QRS complexes, known as *coarse* VF (Fig. 38.27A). These complexes widen farther and lose amplitude, resembling a coarse asystole, which now is defined as *fine* VF (see Fig. 38.27B). Rather than exhibiting coordinated contractions, the ventricles quiver in a totally disorganized manner. Cardiac output during VF is zero. The rapid decrease in cardiac output produces acute cerebral hypoxia, often

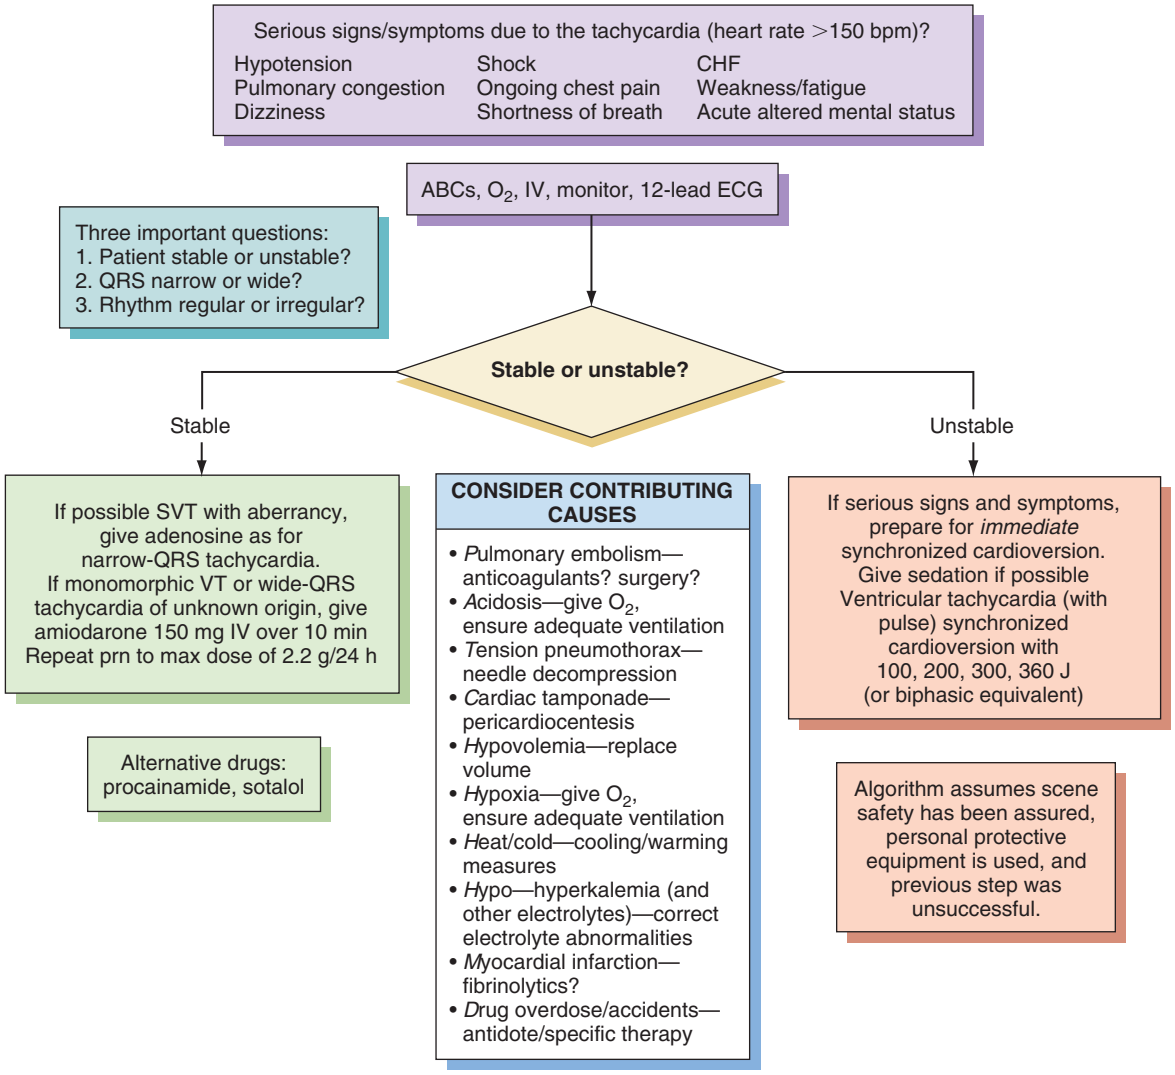

Fig. 38.26 Wide-Complex QRS Tachycardia Algorithm. (From Aehlert B: *ACLS study guide*, ed 5.)

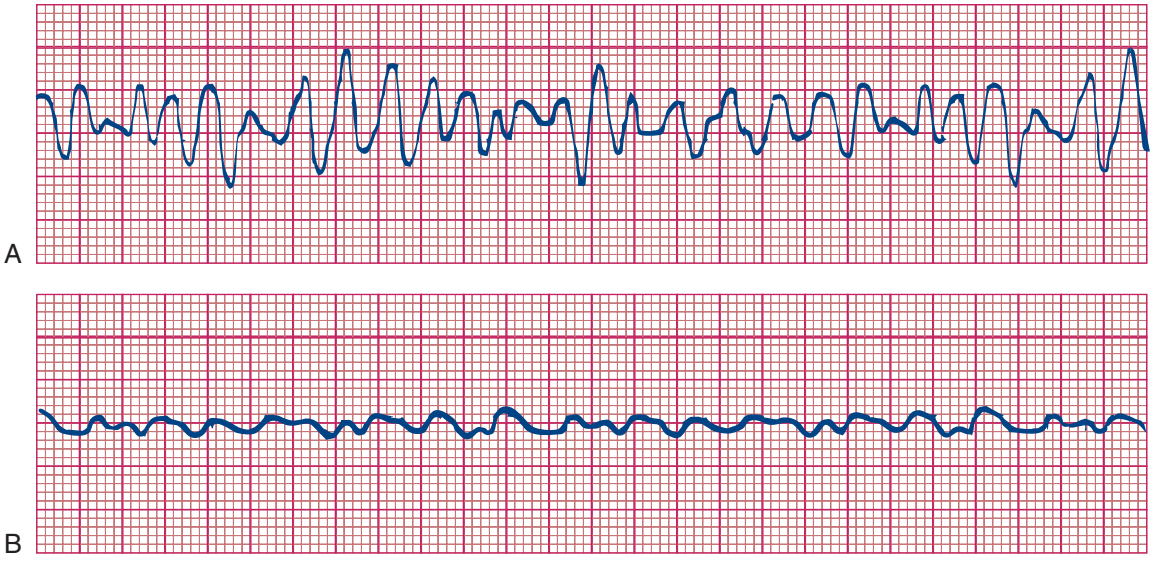

Fig. 38.27 Ventricular Fibrillation. (A) Coarse VF. (B) Fine VF, lead II.

manifested by seizures. VF is uniformly fatal if not corrected immediately.

Many conditions cause VF. The most common causes include hypoxemia, hypovolemia, acidosis, hypokalemia and hyperkalemia, hypothermia, toxins, cardiac tamponade, tension pneumothorax, pulmonary thrombosis, and coronary thrombosis.[30] Regardless of the cause, VF constitutes a true emergency. Patient survival depends on immediate provision of ACLS, especially electrical defibrillation. Early defibrillation is the major determinant of survival in cardiac arrest caused by VF.

Pulseless electrical activity. PEA that is not shockable can result from several reversible causes (Fig. 38.28). The immediate primary treatment is uninterrupted CPR for approximately 2 minutes with epinephrine administered as soon as feasible after the onset of cardiac arrest due to an initial nonshockable rhythm.[8] The best secondary approach is to identify and treat reversible causes (e.g., for hypovolemia, replace volume; for tension pneumothorax, use needle decompression).

Pharmacologic Intervention

Although the full range of drug use in ACLS is beyond the scope of this chapter, RTs must have a general knowledge of both the various drug categories and the specific agents used in emergency situations.[43] Table 38.2 summarizes the major drug categories and primary agents currently used in ACLS.

Routes of administration. Unless a central vein is already cannulated, the ideal route for drug administration in emergency situations is a peripheral intravenous line. Intravenously administered drugs should be given by rapid bolus injection, followed by a 20-mL bolus of intravenous fluid and elevation of the extremity.

Selected drugs—such as epinephrine, lidocaine, and atropine—may also be given through intraosseous access when intravenous access is not readily available.[44]

The intraosseous route is always an option, especially in small children or infants.[44] Chapter 36 provides information about some pharmacologic agents often used in ACLS.

Electrical Therapy

The following three general types of electrical therapy are used in emergency cardiac care: (1) unsynchronized countershock, or defibrillation; (2) synchronized countershock, or cardioversion; and (3) electrical pacing.

Unsynchronized countershock (defibrillation). When an electrical shock of appropriate strength is applied to the myocardium, all myocardial fibers depolarize simultaneously. Theoretically, when all cells depolarize, the cells that fire spontaneously at the fastest rate should be able to regain control and pace the heart. Normally, the sinus node spontaneously depolarizes most rapidly. After electrical shock, the sinus node should discharge first and capture all parts of the myocardium as the depolarization wave travels through the still silent heart.

Defibrillation is an unsynchronized shock used to depolarize all the myocardial fibers simultaneously. It is the definitive treatment for both VF and pulseless VT. If one of these arrhythmias is present and the proper equipment and trained personnel are available, defibrillation of the patient should be performed immediately.

MINI CLINI

Route of Drug Administration During Advanced Cardiovascular Life Support

Problem

An RT working in a small rural hospital is called to the emergency department, where a patient is in cardiac arrest. The RT is able to intubate and ventilate the patient, using a bag-valve device with 100% O_2.

Nurses are performing cardiac compressions and attempting unsuccessfully to start a peripheral intravenous line. The ECG monitor reveals a fine VF pattern. Electrical defibrillation is unsuccessful on the first attempt, and five cycles of 30 compressions to 2 ventilations are in progress. Immediate administration of epinephrine without interrupting CPR is indicated before or after the next shock. Attempts to secure an intravenous line continue to be unsuccessful. What action is appropriate at this time?

Solution

Because of its strong inotropic and α-adrenergic effects, epinephrine should be the first drug administered during resuscitation from cardiac arrest, and it should be administered as soon as possible. Drugs given via a peripheral vein take 1 to 2 minutes to reach the central circulation. Epinephrine can convert fine VF to coarse VF and improves the chance for successful electrical defibrillation. In this case, because intravenous routes are unavailable, epinephrine should be administered by the intraosseous route, which can quickly be established with minimal complications by providers with varied levels of training.[44,45]

If a biphasic defibrillator is available, the AHA recommends an initial energy level of 120 to 200 J for the defibrillation of adults and 2 to 4 J/kg for the defibrillation of children and infants.[8,17,20] For children older than 1 year, if a shockable rhythm persists after five cycles of CPR, the rescuer should give one shock (4 J/kg) and resume compressions immediately. For adults, a 360-J shock should be used with monophasic defibrillators for the first and subsequent shocks with 2 minutes of CPR between shocks.[8] If VF recurs, and compressions should be resumed immediately.

The size and placement of electrode paddles are important to ensure that the full energy of the countershock is applied. Many AEDs have pads that are placed on the chest in positions guided by diagrams. Such pads are connected to the defibrillator, so that paddles are not actually used in this circumstance (see Fig. 38.12). For adults, paddles should be 8 to 12 cm in diameter to decrease resistance; adult paddles are of adequate size for children older than 1 year. Normally, one paddle is placed below the clavicle and just to the right of the upper portion of the sternum with the other positioned on the midaxillary line to the left of the left nipple. Alternatively, one paddle may be placed on the left precardium with the other positioned posteriorly under the patient, behind the heart. Paddles should be prepared with conducting gel and applied with firm pressure (approximately 25 lb).

Synchronized countershock (cardioversion). **Cardioversion** is like defibrillation with two major exceptions. First, the countershock is synchronized with the heart's electrical activity (the R wave). Synchronization is necessary because electrical stimulation during the refractory phase (part of the T wave) can cause

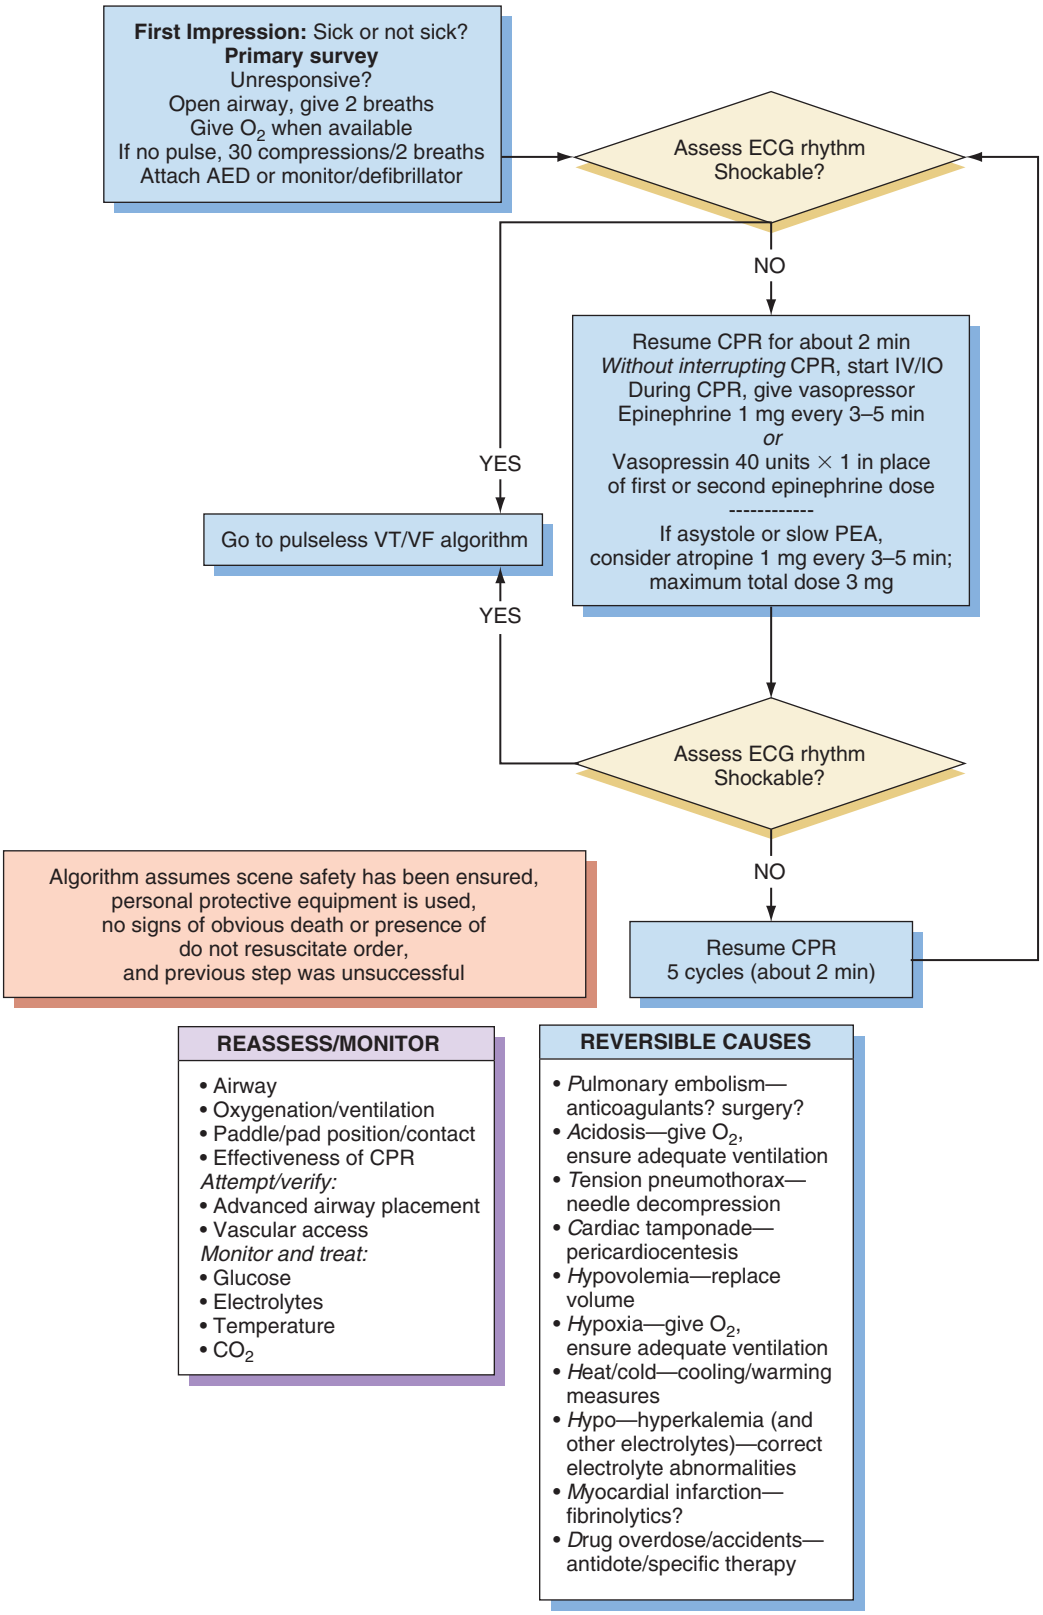

Fig. 38.28 Asystole or Pulseless Electrical Activity Algorithm. (From Aehlert B: *ACLS study guide*, ed 5, St. Louis, 2017, Mosby.)

TABLE 38.2 Drugs Used in Advanced Cardiovascular Life Support

Drug	Indications	Contraindications	Route	Dosage[8]	Pharmacologic Effects
Adenosine	PSVT; recommended as a safe and potentially effective therapy in the initial management of stable undifferentiated regular monomorphic wide-complex tachycardia	Use with caution if patient has asthma; may precipitate atrial fibrillation; poison-induced or drug-induced tachycardia; second-degree or third-degree heart block	IV bolus	6 mg IV for 1–2 s followed by 20-mL saline bolus; repeat twice with 12 mg in 1–2 min if needed	Decrease in AV node conduction
Amiodarone	Stable regular narrow-complex tachycardia to control rapid ventricular rate secondary to accessory pathway conduction in preexcited atrial arrhythmias	Prolonged QT interval	IV; IO	First dose: 300 mg bolus. Second dose: 150 mg	Multichannel blocker (calcium, potassium); inhibited α- and β-adrenergic responses
Atropine sulfate	Acute symptomatic bradycardia	Sinus, atrial, and ventricular tachycardia; hypothermic bradycardia; infranodal (type II) AV block; new third-degree with wide QRS complexes	IV bolus; IO	0.5–1 mg IV repeated every 3–5 min to total dose of 3 mg	Increased heart rate; increased force of atrial contractions
Dopamine	Hypotension with signs and symptoms of shock; second-line drug for symptomatic bradycardia	Use with caution in cardiogenic shock with accompanying CHF	IV infusion	2–20 mcg/kg/min	Increased renal and splenic flow at low doses (1–5 mcg/kg/min); β-adrenergic effects at moderate doses (5–10 mcg/kg/min); α-adrenergic effects at high doses (>10 mcg/kg/min)
Epinephrine	Cardiac arrest; VF; pulseless tachycardia; asystole; PEA; symptomatic bradycardia; severe hypotension; anaphylaxis; severe allergic reaction	VT and frequent PVCs	IV bolus; IO; endotracheal[a] use only if IV or IO cannot be established; IV infusion	1 mg every 3–5 min in cardiac arrest, up to 0.2 mg/kg; High-dose epinephrine is not recommended for routine use in cardiac arrest	Increased heart rate; increased force of contractions; vasoconstriction; increased coronary perfusion pressure; increased myocardial irritability; increased myocardial O_2 consumption
Isoproterenol	Alternative when a bradyarrhythmia is unresponsive to or inappropriate for treatment with atropine, or as a temporizing measure while awaiting the availability of a pacemaker. Refractory torsade de pointes[b] unresponsive to magnesium sulfate	Cardiac arrest; VT; frequent PVCs	IV infusion	2–10 mcg/min, titrate to adequate heart rate	Increased heart rate; increased force of contractions; vasodilation
Lidocaine	Second-line prophylactic antiarrhythmic therapy for monomorphic VT; lidocaine may be considered immediately after ROSC from cardiac arrest due to VF/pVT	Signs of lidocaine toxicity; prophylactic use in acute MI	IV bolus; IV infusion; IO; endotracheal[c]	1–1.5 mg/kg bolus every 5–10 min up to 3 mg/kg	Increased electrical stimulation threshold; depressed ventricular electrical activity
Propranolol	Suspected MI and unstable angina; SVTs	Bronchospastic disease; severe bradycardia; hypotension; second-degree or third-degree heart block; cocaine-induced acute coronary syndrome	IV	Total dose: 0.1 mg/kg by slow IV push, divided into 3 equal doses at 2- to 3-min intervals. Do not exceed 1 mg/min, repeat in 2 min to a total dose of 0.1 mg/kg if required	Reduce heart rate; decreased stroke volume; decreased myocardial O_2 consumption; increased LVEDP

Continued

TABLE 38.2 Drugs Used in Advanced Cardiovascular Life Support—cont'd

Drug	Indications	Contraindications	Route	Dosage[8]	Pharmacologic Effects
Verapamil, diltiazem	Alternative drug (after adenosine or vagal maneuvers) to terminate PSVT with narrow QRS complex, adequate blood pressure, and preserved left ventricular function; control ventricular rate in patients with atrial fibrillation or atrial flutter	Wide-complex QRS tachycardias of uncertain origin, Wolff-Parkinson-White syndrome and AF, sick sinus syndrome, second-degree or third-degree block without pacemaker, concurrent IV administration with IV β blockers	IV bolus	*First dose:* Verapamil: 2.5–5-mg IV bolus over 2 min (over 3 min in older patients) *Second dose:* 5–10 mg, if needed, every 15–30 min; maximum dose 20 mg *Alternative:* 5-mg bolus every 15–30 min to a total dose of 20–30 g *Diltiazem:* initial dose 15–20 mg (0.25 mg/kg) IV over 2 min; an additional 20–25 mg (0.35 mg/kg) IV in 15 min if needed; 5–15 mg/h IV titrated. Maintenance infusion titrated AF heart rate (if given for rate control)	Decreased sinoatrial node automaticity; slowed AV node conduction

[a]Endotracheal tube dosage is usually double the intravenous dosage.
[b]*Torsade de pointes* is a specific form of ventricular tachycardia in patients with a long QT interval. It is characterized by rapid and irregular QRS complexes, which may cease spontaneously or degenerate into ventricular fibrillation; In *Wolff-Parkinson-White* (WPW) syndrome, an extra electrical pathway between the heart's atria and ventricles causes a rapid heartbeat. The extra pathway is present at birth and the condition is rare.
[c]Dose of lidocaine via an endotracheal tube is 2.0–2.5 times the normal intravenous dose diluted in 10 mL of normal saline or sterile water to be used only when intravenous and intraosseus access is unavailable.
AF, Atrial fibrillation; *AV,* atrioventricular; *CHF,* congestive heart failure; *IO,* intraosseous; *LVEDP,* left ventricular end-diastolic pressure; *MI,* myocardial infarction; *PSVT,* paroxysmal supraventricular tachycardia; *PEA,* pulseless electrical activity; *PVC,* premature ventricular contraction; *SVT,* supraventricular tachycardia; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

VF or VT. Second, the energy used during cardioversion is usually less than the energy applied during defibrillation.

Cardioversion is considered when a patient with an organized arrhythmia producing a high ventricular rate exhibits signs or symptoms of cardiac decompensation. These so-called *tachyarrhythmias* include SVT, atrial flutter, atrial fibrillation, and monomorphic VT with pulses. Cardioversion is ineffective for the treatment of junctional tachycardia or multifocal atrial tachycardia.[18]

If the arrhythmia is not causing serious signs or symptoms, drug therapy is used first. However, if the patient is hypotensive, exhibits signs of decreased consciousness or pulmonary congestion, or complains of chest pain, cardioversion is indicated.

Electrical pacing. Another application of electrical therapy uses intermittently timed low-energy discharges to replace or supplement the natural pacemaker of the heart. There are two primary types of electrical pacing. First, the electrical discharge can be delivered from an external power pack through wires inserted into the patient's chest wall (transcutaneous, or transthoracic, pacing). Alternatively, wire electrodes may be floated through the large veins and implanted directly inside the heart (transvenous pacing). Because it can be started quickly, transcutaneous pacing is the method used most often in emergency cardiac care.

Pacemaker therapy is used to treat sinus bradycardias that produce serious signs and symptoms and that do not respond to atropine (Fig. 38.29). Electrical pacing is also used to manage second-degree type II and third-degree heart block.

Because defibrillation can cause damage to permanent pacemakers, care should be taken not to place the electrode paddles or AED pads near these devices. After a patient with a permanent pacemaker undergoes either cardioversion or defibrillation, the device should be checked for proper functioning. Pacing is not recommended by the AHA for patients in asystolic cardiac arrest because it is ineffective and may delay or interrupt the delivery of chest compressions.[18]

The ECG is the most common and one of the most useful types of monitoring used during ACLS. The ECG provides the basis for selecting various drug and electrical therapies during CPR and helps to indicate patient response to these interventions. However, an acceptable ECG rhythm does not mean that cardiac output is adequate. Other indices of perfusion—such as pulse, blood pressure, and skin temperature—are needed to confirm adequate cardiac output.

Few criteria can predict the effectiveness of continued resuscitation. Considering this doubt, all pediatric and adult patients who experience cardiac arrest in the hospital setting should have resuscitative attempts initiated unless the patient has a valid

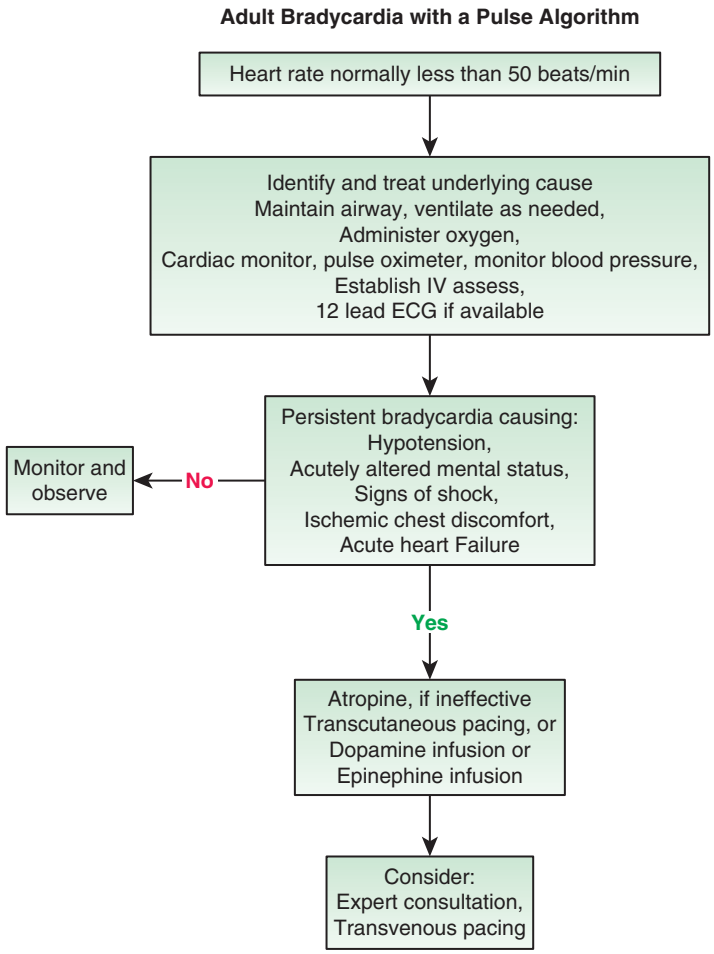

Fig. 38.29 Symptomatic Bradycardia Algorithm. (From Aehlert B: *ACLS study guide*, ed 5, St. Louis, 2017, Mosby.)

MINI CLINI

Problem

The code team is unsure when to discontinue resuscitation of a pediatric or adult cardiac arrest victim and whether family members should be allowed into the room.

Solution

First understand the principle of futility:

> "Patients or families may ask for care that is highly unlikely to improve health outcomes. Health care providers, however, are not obliged to provide such care when there is scientific and social consensus that the treatment is ineffective. If the purpose of a medical treatment cannot be achieved, the treatment can be considered futile."[46]

DNR order or has objective signs of irreversible death (e.g., hypostasis of the blood following death, which causes a purplish red discoloration of the skin).[46] In the hospital the decision to terminate resuscitative efforts rests with the treating physician and is based on attention to many factors including witnessed versus unwitnessed arrest, time to CPR, initial arrest rhythm, time to defibrillation, comorbid disease, prearrest state, and whether there is ROSC at some point during the resuscitative efforts.[46] In pediatric in-hospital cardiac arrest the clinician should consider stopping resuscitation using the following arrest characteristics: duration of CPR, witnessed event, number of doses of epinephrine, etiology of arrest, first and subsequent rhythm, and age.[46] Multiple variables should be considered in attempting to predict outcomes during cardiac arrest. Although there are factors associated with better or worse outcomes, no single factor studied predicts outcome with sufficient accuracy to recommend termination or prolongation of CPR.[47]

It may be helpful to offer limited family members the opportunity to be present during a resuscitation (assuming that the patient, if an adult, has not raised a prior objection).[46] Parents and other family members should be encouraged to do so by health care providers. Resuscitation team members should be sensitive to the presence of family members during resuscitative efforts, assigning a team member to remain with the family to answer questions, clarify information, and otherwise offer comfort (see "end of life," discussed in Chapter 58).[46]

Patient Care After Resuscitation

The key principles of postarrest care are (1) to identify and treat the core etiology of the cardiac arrest, (2) to lessen ischemia-reperfusion injury and avert secondary organ injury, and (3) to

make accurate appraisals of prognosis to guide the clinical team and to advise the family when they are selecting goals for continued care.[36]

After cardiac arrest, a patient may exhibit an optimal response, in which case the patient regains consciousness, is responsive, and breathes spontaneously. More often, however, the patient requires support of one or more organ systems. Acidemia associated with cardiac arrest usually improves when normal ventilation and perfusion are restored.

If the patient is conscious and breathing spontaneously after resuscitation, supplemental O_2, maintenance of an intravenous infusion, and continuous cardiac and hemodynamic monitoring may be all that is necessary. A 12-lead ECG, chest x-ray, arterial blood gas (ABG) analysis, and clinical chemistry profile should be performed as soon as possible. Providers of care after cardiac arrest should do the following to optimize survival and neurologic recovery:

> *"(1) maintain constant body temperature between 32°C and 36°C for at least 24 hours after achieving target temperature; (2) actively prevent fever in comatose patients after targeted temperature management.; (3) identify and treat acute coronary syndromes; (4) avoid and immediately correct hypotension and hypoxemia by using the highest available oxygen concentration until the arterial oxyhemoglobin saturation or the partial pressure of arterial oxygen can be measured; (5) optimize mechanical ventilation to minimize lung injury; (6) reduce the risk for multiorgan injury and support organ function if required; (6) objectively assess prognosis for recovery; and (7) assist survivors with rehabilitation services when required."*[36,48]

The patient should be closely supervised in an intensive care or coronary care unit, especially during the first 24 hours after a cardiac arrest.

Only in this setting can underlying organ system insufficiency or failure be properly identified and managed. The organs most likely to exhibit failure after resuscitation are the lung, heart, vasculature, and kidneys. Central nervous system failure is an ominous sign and generally indicates a failed resuscitation attempt.

Respiratory Management

If the patient remains apneic or exhibits irregular breathing after resuscitation, mechanical ventilation is instituted through a properly positioned endotracheal tube with an initial O_2 concentration of 100%. ABGs, preferably obtained through an arterial line, are analyzed as needed until the oxygenation and acid-base status of the patient stabilize. ABG analysis also helps differentiate between pulmonary and nonpulmonary (or cardiac) causes of hypoxemia and tissue hypoxia. Mechanical ventilation is adjusted to maintain a normal $PaCO_2$ level. Hyperventilation is detrimental and should be avoided. Higher ventilatory rates and larger V_T may cause hyperventilation. This hyperventilation may generate increased airway pressures and auto-PEEP, leading to an increase in cerebral venous and intracranial pressures and a decrease in coronary artery and cerebral arterial pressures.[49] If hyperventilation results in increased intrathoracic pressure, cerebral blood flow may decrease, causing increased brain ischemia. For details of the selection and use of mechanical ventilators and appropriate patient monitoring procedures, see Chapters 46 to 49, 52, and 53.

Cardiovascular Management

The 12-lead ECG, chest x-ray, clinical chemistry profile, cardiac enzyme results, and current and past drug histories should be reviewed. Invasive hemodynamic monitoring may be needed to monitor blood pressure and cardiac output. Such monitoring provides needed data on the adequacy of vascular volumes, left ventricular performance, and overall tissue perfusion. Based on these data, judgments can be made regarding the need for fluid therapy and the selection and use of appropriate drugs.

SUMMARY CHECKLIST

- The most common cause of sudden death in adults is coronary artery disease; accidents are the most common cause of death in young people.
- The fundamental steps of basic CPR implemented by health care providers for a witnessed cardiac arrest are as follows:
  1. Confirm unresponsiveness.
  2. Call for help and activate the EMS system.
  3. Check for a pulse (<10 seconds).
  4. Perform 30 cardiac compressions.
  5. Give two 1-second breaths to produce visible chest rise.
  6. Initiate automated external defibrillation immediately (perform defibrillation as soon as possible).
- In CPR for adults, five cycles of 30 compressions to 2 ventilations should be given between attempts at defibrillation using only one shock followed immediately by chest compressions.
- Evaluating the effectiveness of CPR is important and requires rescuers to watch for visible chest rise and fall with ventilation and to push hard and fast when they are delivering chest compression.
- Complications of CPR include worsening of potential neck injuries, gastric inflation and vomiting, and internal trauma during chest compressions. Correct technique minimizes the risk for such complications.
- The RT is most often called on to establish an airway and ventilation with elevated FiO_2 during ACLS of hospitalized patients. Most often, knowledge and skill with bag-valve devices and oropharyngeal airways is required. Special care should be taken not to hyperventilate the patient during or after cardiac arrest.
- Common pharmacologic agents used during ACLS include atropine for bradycardia, epinephrine and amiodarone or lidocaine (less effective than amiodarone) for ventricular arrhythmias, and epinephrine for cardiac arrest and hypotension.
- The RT is often involved in the care of a patient after cardiac arrest who has responded favorably to CPR. In the postresuscitative phase, the RT may have to maintain normal ventilation and oxygenation and assist the physician and nurses in monitoring the patient's condition.

Humidity and Bland Aerosol Therapy

James B. Fink and Arzu Ari

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how airway heat and moisture exchange normally occurs
- State the effect dry gases have on the respiratory tract
- State when to humidify and warm inspired gas
- Describe how various types of humidifiers work
- Describe how to enhance humidifier performance
- State how to select and use humidifier heating and feed systems safely
- Identify the indications, contraindications, and hazards that pertain to humidification during mechanical ventilation
- Describe how to monitor patients receiving humidity therapy
- Describe how to identify and resolve common problems with humidification systems
- State when to apply bland aerosol therapy
- Describe how large-volume aerosol generators work
- Identify the delivery systems used for bland aerosol therapy
- Describe how to identify and resolve common problems with aerosol delivery systems
- Describe how to perform sputum induction
- State how to select the appropriate therapy to condition a patient's inspired gas

Vapors and mists have been used for millennia to treat respiratory disease. Modern respiratory care still uses these treatments at the bedside in the form of water vapor (humidity) and bland water aerosols. Concepts of absolute and relative humidity are essential for understanding humidity therapy; they are covered in Chapter 6. This chapter reviews the principles, methods, equipment, and procedures for using these concepts appropriately.

HUMIDITY THERAPY

Humidity therapy involves adding water vapor and (sometimes) heat to the inspired gas. Simply put, humidity is water in its gaseous or molecular form and its quantity depends on the temperature of the gas and is expressed as **absolute humidity** (AH) and relative humidity (RH).

AH, the amount of water in a given volume of gas, is usually expressed in milligrams per liter (mg/L). RH, the amount of water vapor in a volume of gas, is expressed as a percentage of the amount of water vapor required to fully saturate that gas at the same temperature and pressure. To understand the need for humidity therapy, clinicians must understand the normal control of heat and moisture exchange (HME).

Physiologic Control of Heat and Moisture Exchange

HME is a primary function of the upper respiratory tract, mainly the nose.[1-4] The nose heats humidifies gas on inspiration; it cools the gas and reclaims water the gas that is exhaled. The nasal mucosal lining is kept moist by secretions from mucous glands, goblet cells, transudation of fluid through cell walls, and condensation of exhaled humidity. The nasal mucosa is very vascular, actively regulating temperature changes in the nose and serving as an active element in promoting effective heat transfer. Similarly, the mucosa lining the sinuses, trachea, and bronchi aid in heating and humidifying inspired gases.

During inspiration through the nose, the tortuous path of gas passing through the turbinates increases surface area contact between the inspired air and the mucosa. As the inhaled ambient air enters the nose, it warms to 28.5°C *(convection)* and picks up water vapor from the moist mucosal lining *(evaporation),* cooling the mucosal surface to 30.2°C at the end of inspiration.[5]

During exhalation, the expired gas (34.1 7°C) transfers heat back to the cooler tracheal and nasal mucosa, which is 32.2°C at the end of expiration. As the saturated gas cools, it holds less water vapor. Condensation occurs on the mucosal surfaces during exhalation, and water is reabsorbed by the mucus *(rehydration).* In cold environments, the formation of condensate may exceed the ability of the mucus to reabsorb water (resulting in a "runny nose").

The mouth is less effective at HME than the nose because of the low ratio of gas volume to moist and warm surface area and the less vascular squamous epithelium lining the oropharynx and hypopharynx. When a person inhales through the mouth at normal room temperature, pharyngeal temperatures are approximately 3°C less than when the person breathes through the nose, with 20% less RH. During exhalation, the RH of expired gas varies little between mouth breathing and nose breathing, but the mouth is much less efficient in reclaiming heat and water.[2]

As inspired gas moves into the lungs, it achieves body temperature and pressure saturated (BTPS) conditions (i.e., body temperature, 37°C; barometric pressure; saturated with water vapor [100% RH at 37°C]) (Fig. 39.1). This point, normally approximately 5 cm below the carina, is called the **isothermic saturation boundary** (ISB).[6] Above the ISB, temperature and humidity decrease during inspiration and increase during exhalation. Below the ISB, temperature and RH remain constant (BTPS).

Numerous factors can shift the ISB deeper into the lungs. The ISB shifts distally when a person breathes through the mouth rather than the nose; when the person breathes cold dry air; when the upper airway is bypassed (breathing through an artificial tracheal airway); or when the minute ventilation is higher than normal. When this shift of ISB occurs, additional surfaces of the airway are recruited to meet the heat and humidity requirements of the lung. This recruitment of airways that do not typically provide this level of heat and humidity can have a negative impact on epithelial integrity. These shifts of the ISB can compromise the body's normal HME mechanisms, in which case humidity therapy is indicated.

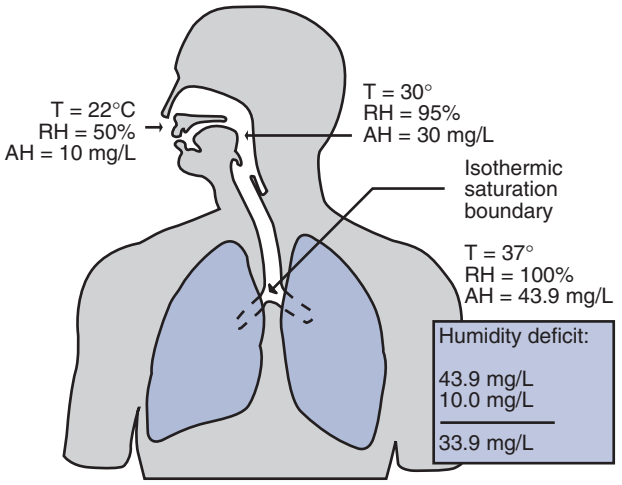

Fig. 39.1 As a person breathes typical ambient air, the upper airway adds 20 mg/L of water vapor and the lower airway adds 13.9 mg/L. If all of that humidity were exhaled, it would represent a humidity deficit of 33.9 mg/L. *AH,* Absolute humidity; *RH,* relative humidity; *T,* temperature. (From Fink J: Humidity and aerosol therapy. In Cairo J, Pilbeam S, editors: *Mosby's respiratory equipment*, ed 8, St. Louis, 2010, Mosby.)

RULE OF THUMB

The heat and humidity (AH) of a medical gas should be targeted to match conditions found in normal airways at the part of the airway where the gas is being introduced.

Indications for Humidification and the Warming of Inspired Gases

The primary goal of humidification is to maintain normal physiologic conditions in the lower airways. Proper levels of heat and humidity help to ensure normal function of the mucociliary transport system. Humidity therapy is also used to treat abnormal conditions. Box 39.1 summarizes the indications and contraindications for humidity therapy.

Administration of dry medical gases at flows greater than 4 L/min to the upper airway causes immediate heat and water loss and, if prolonged, causes structural damage to the epithelium. As the airway is exposed to relatively cold dry air, ciliary motility is reduced, airways become more irritable, mucus production increases, and pulmonary secretions become **inspissated** (thickened and dried, owing to dehydration).[7]

As listed in Box 39.2, the hazard of breathing dry gas is even greater when the normal heat- and water-exchange capabilities

BOX 39.1 Indications for Humidification Therapy

Primary

- Humidifying dry medical gases
- Overcoming humidity deficit created when the upper airway is bypassed

Secondary

- Treating bronchospasm caused by cold air
- With thick, copious, or bloody secretions.
- With an expired tidal volume (V_T) less than 70% of the delivered V_T (e.g., patients with large bronchopleural fistulas or incompetent or absent endotracheal tube cuffs).
- With a body temperature below 32°C.
- With high spontaneous minute volumes (>10 L/min).
- Receiving noninvasive ventilation with large mask leaks, because the patient does not exhale enough V_T to replenish heat and moisture to adequately condition the inspired gas. Also, the resistance and dead space of the HME may negate the effects of the noninvasive positive pressure and add additional work of breathing.
- Receiving lung-protective ventilation strategies, as in acute respiratory distress syndrome (the additional dead space of HME may increase the ventilation requirement and $PaCO_2$).
- Receiving in-line aerosol drug treatments (a standard HME must be removed from the patient circuit during treatments. An HME designed for aerosol delivery must be switched to the aerosol bypass mode).

HME, Heat and moisture exchanger.

BOX 39.2 Hazards and Complications for Humidification Therapy

Hazards and complications associated with use of HH and HME units during mechanical ventilation include the following:

- Potential electrical shock (HH)
- Potential for burns to caregivers from hot metal (HH)
  - Hypothermia (HME unit or inadequately set HH)
  - Hyperthermia (HH)
  - Thermal injury (HH)
- Underhydration and mucous impaction (HME unit or HH)
  - Hypoventilation and/or alveolar gas trapping, resulting from mucus plugging of airways (HME unit or HH)
  - Hypoventilation secondary to hypercapnia caused by the increase in dead space (HME unit)
  - Increased work of breathing (HME unit)
  - Possible hypoventilation resulting from hypercapnia caused by the increase in dead space (HME unit)
  - Inadvertent overfilling or pooled condensate, resulting in unintentional tracheal lavage (HH)
  - High flow rates during disconnect, which can aerosolize contaminated condensate (HH)
  - Elevated airway pressures caused by condensation (HH)
  - Ineffective low-pressure alarm during disconnection (HME unit)
  - Patient–ventilator dysynchrony and improper ventilator function caused by condensation in the circuit (HH)
  - Airway burns or tubing meltdown if heated-wire circuits are covered or incompatible with humidifier (HH)

HH, Heated humidifier; *HME,* heat and moisture exchanger.

BOX 39.3 Clinical Signs and Symptoms of Inadequate Airway Humidification

- Atelectasis
- Dry, nonproductive cough
- Increased airway resistance
- Increased incidence of infection
- Increased work of breathing
- Patient complaint of substernal pain and airway dryness
- Thick, dehydrated secretions

TABLE 39.1 Recommended Heat and Humidity Levels

Delivery Site	Temperature Range (°C)	Relative Humidity (%)	Absolute Humidity (mg/L)
Nose/mouth	20–22	50	10
Hypopharynx	29–32	95	27–32
Trachea/carina	32–35	100	34–40
Lungs (ISB)	37	100	44

ISO, Isothermic saturation boundary.

of the upper airway are lost or bypassed, as occurs with endotracheal intubation. Breathing dry gas through an endotracheal tube (ETT) can cause damage to tracheal epithelium within minutes. However, as long as the inspired humidity is at least 60% of BTPS conditions, no injury occurs in normal lungs. Prolonged breathing of improperly conditioned gases through a tracheal airway can result in **hypothermia** (reduced body temperature), inspissation of airway secretions, mucociliary dysfunction, destruction of airway epithelium, and atelectasis.[6-8] Delivery of inspired gas at 30°C or even 34°C with 100% RH may not be sufficient to prevent epithelial damage occurring during a 6-hour exposure.[7]

Box 39.3 summarizes the signs and symptoms associated with breathing cold dry gases. A reduction of 20 mg/L below BTPS (44 mg/L) is less than 60% RH at BTPS.

The amount of heat and humidity that a patient needs depends on the site of gas delivery (e.g., nose or mouth, hypopharynx, trachea). Table 39.1 summarizes the recommended levels based on current standards.

RULE OF THUMB

Despite minimal levels in the standards, delivery of inspired gas to the lower airways at 30°C or even 34°C with 100% RH may not be sufficient to prevent the occurrence of epithelial damage during a 6-hour exposure.[7]

Warmed, humidified gases are used to prevent or treat various abnormal conditions. In the treatment of hypothermia, heating and humidifying the inspired gas is one of several techniques used to raise core temperatures back to normal.[8-10] Heated humidification is used to reduce intraoperative hypothermia.[9]

MINI CLINI

Stabilization of Preterm Infants at Birth With Conditioned or Unconditioned Gas

Problem

A preterm infant is delivered and requires oxygen, bagging, and continuous positive airway pressure (CPAP) during stabilization and transport to the nursery, but heated humidified gas is not ready. What is the risk of using unconditioned gas?

Solution

Use of heated humidity from delivery to arrival at the nursery improves admission temperatures, whereas inadequate humidification and heating of inspired gases increases heat loss and can lead to mild hypothermia. Cold inspired gases can also cause distal airway and alveolar damage, and even a brief exposure to dry and cold respiratory gases can decrease lung compliance and increase work of breathing (WOB).

However, transient use of dry cold gases during resuscitation did lower temperature, but no detectable differences in acute or longer-term respiratory outcomes—including level of respiratory support, bronchopulmonary dysplasia or mortality—were reported. Although transient administration of unconditioned gas did no apparent harm, additional studies are required to support a practice change.

Of possibly greater clinical significance, warming and humidifying the inspired gas can help to alleviate bronchospasm in patients who develop airway narrowing after exercise or when they breathe cold air. Although the cause of this condition is not known for certain, the primary stimulus is probably a combination of airway cooling and drying, which leads to the hypertonicity of airway lining fluid and the release of chemical mediators.[11] The incidence of cold air–induced bronchospasm can be reduced by wearing a scarf over the nose and mouth in cold weather; the scarf becomes a crude passive HME device.

The delivery of cool humidified gas is used to treat upper airway inflammation resulting from croup, epiglottitis, and postextubation edema. This technique is used most often in conjunction with bland aerosol delivery (see the later section titled "Bland Aerosol Therapy").[12]

Equipment

A **humidifier** is a device that adds molecular water to gas. This process occurs by evaporation of water from a surface to a gas that is not 100% saturated with water vapor (see Chapter 6), whether the water is in a reservoir, a wick, or a sphere of water in suspension (aerosol).

Physical Principles Governing Humidifier Function

The following four variables or principles affect the performance of a humidifier: (1) temperature, (2) surface area, (3) time of contact, and (4) thermal mass.[13] These factors are exploited to various degrees in the design of humidification devices (Box 39.4).

Temperature. Temperature is an important factor affecting humidifier performance. The higher the temperature of a gas, the more water vapor it can hold (increased capacity). As gas expansion and evaporation cool water in unheated humidifiers to 10°C below ambient temperature, the humidifiers become less efficient.

Fig. 39.2 shows this concept, where—owing to evaporative cooling—the unheated humidifier on the left is operating at 10°C. Although the humidifier fully saturates the gas, the low operating temperature limits total water vapor capacity to approximately 9.4 mg/L, equivalent to approximately 21% of **body humidity**. Simply heating the humidifier to 40°C (see Fig. 39.2, right) increases its output to 51 mg/L, which is sufficient to meet BTPS conditions.

Surface area. The greater the area of contact between water and gas, the more opportunity there is for evaporation to occur. Pass-over humidifiers pass gas over a large surface area of water. More space-efficient ways to increase the ratio of water to gas surface area include bubble diffusion, aerosol, and wick technologies.

Bubble-diffusion directs a stream of gas under water, where it is broken up into small bubbles. As the gas bubbles rise to the surface, evaporation increases the water vapor content within the bubble. The smaller the bubble, the greater the ratio of water to air surface area.

An alternative to dispersing gas bubbles in water is spraying water particles (aerosol) into the gas. The higher the aerosol density (number of particles per volume of gas), the greater the gas-to-water surface area available for evaporation.

Wicks use porous water-absorbent materials to draw water (similar to a sponge) into its fine honeycombed structure by means of capillary action. The surfaces of the wick increase the area of contact between the water and gas, which aids evaporation.

Contact time. The longer a gas remains in contact with water, the greater the opportunity for evaporation to occur. For bubble humidifiers, contact time depends on the depth of the water column; the deeper the column, the greater the time of contact as the bubbles rise to the surface. In pass-over and wick-type humidifiers, the flow rate of gas through the humidifier is inversely related to contact time, with high flow rates reducing the time available for evaporation to occur. Aerosols suspended in a gas stream have extended contact time (and opportunity for evaporation) as the aerosol and gas travel to the patient.

Thermal mass. The greater the amount of water in a humidifier, the greater the thermal mass. Increased thermal mass equates to increased capacity to hold and transfer heat to therapeutic gases. Larger-reservoir humidifiers can provide more consistent heat and humidification with a broader range of gas flow.

BOX 39.4 Physical Principles Governing Humidifier Function

Temperature: The higher the temperature of a gas, the more water vapor it can hold (increased capacity), and vice versa.

Surface area: The greater the surface area of contact between water and gas, the more opportunity for evaporation to occur.

Contact time: The longer a gas remains in contact with water, the greater the opportunity for evaporation to occur.

Thermal mass: The greater the mass of water or the core element of a humidifier, the greater its capacity to hold and transfer heat.

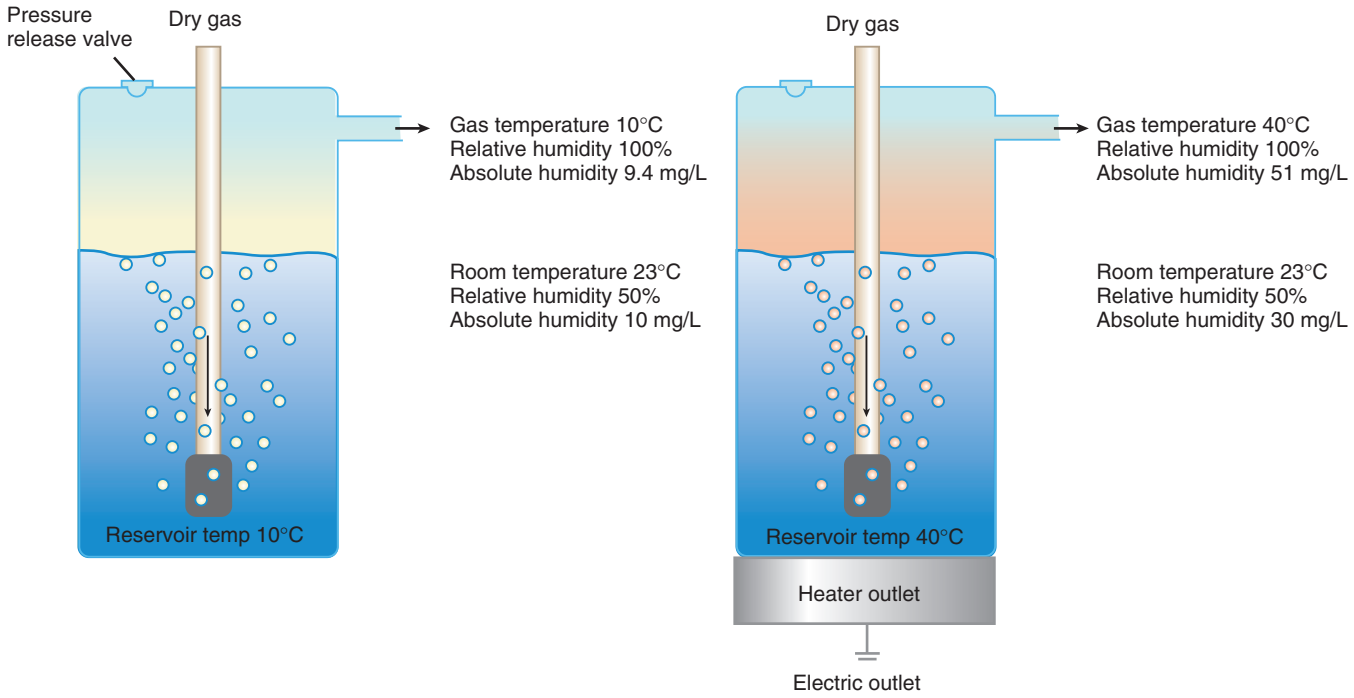

Fig. 39.2 Effects of reservoir temperature on humidity output with unheated *(left)* and heated *(right)* bubble-type humidifiers. (Modified from Fink J, Cohen N: Humidity and aerosols. In Eubank D, Bone R, editors: *Principles and applications of cardiorespiratory care equipment*, St. Louis, 1994, Mosby.)

Types of Humidifiers

Humidifiers are either *active* (actively adding heat, water, or both to the device–patient interface) or *passive* (recycling exhaled heat and humidity from the patient). Active humidifiers typically include (1) bubble humidifiers, (2) pass-over humidifiers, (3) nebulizers of bland aerosols, and (4) vaporizers. Passive humidifiers are typical **heat and moisture exchangers**. Specifications covering the design and performance requirements for medical humidifiers are established by the **American Society for Testing and Materials** (ASTM).[14]

Active humidifiers

Bubble. A bubble humidifier breaks (diffuses) an underwater gas stream into small bubbles (Fig. 39.3). Use of a foam or mesh diffuser produces smaller bubbles than an open lumen, allowing greater surface area for gas–water interaction. Unheated bubble humidifiers are commonly used with oxygen (O_2) delivery systems (see Chapter 41) to raise the water vapor content of the gas to ambient levels.

As indicated in Table 39.2, unheated bubble humidifiers can provide AH levels between approximately 15 and 20 mg/L.[13,14] At room temperature, 10 mg/L AH corresponds to approximately 80% RH but only approximately 25% body humidity (see Chapter 6). As gas flow increases, the reservoir cools and contact time is reduced, limiting effectiveness at flow rates greater than 10 L/min. Heating the reservoirs can increase humidity content, but this is not recommended because cooling produces a condensate that obstructs small-bore delivery tubing.

To warn of flow-path obstruction and prevent bursting of the humidifier bottle, bubble humidifiers incorporate a simple pressure-relief valve, or *pop-off*. The pop-off is commonly a gravity- or spring-loaded valve that releases pressures greater than 2 psi. Humidifier pop-offs should provide both an audible and a visible alarm and resume normal position when pressures return to normal.[14] The pop-off can be used to test an O_2 delivery system for leaks by obstructing delivery tubing at or near the patient interface. If the pop-off sounds, the system is leak free; failure of the pop-off to sound may indicate a leak (or a faulty pop-off valve).

As gas flow increases, bubble humidifiers can produce aerosols. Although invisible to the naked eye, these water droplet suspensions can transmit pathogenic bacteria from the humidifier reservoir to the patient.[15] Because any device that generates an aerosol poses a high risk for spreading infection, strict infection-control procedures must be followed when these systems are used (see Chapter 4).

TABLE 39.2 Types, Mechanisms, and Absolute Humidity Range of Passive Heat and Moisture Exchangers

	Mechanism	Absolute Humidity Range
HME	Hydrophobic	10–14 mg H_2O/L
HMEF	Hydrophobic + filter	18–28 mg H_2O/L
HHME	Hydrophobic + hygroscopic	22–34 mg H_2O/L
HHMEF	Hydrophobic + hygroscopic + filter	23–35 mg H_2O/L

HME, Heat and moisture exchanger; *HMEF,* heat and moisture exchanging filter; *HHME,* hydrophobic hydroscopic heat and moisture exchanger; *HHMEF,* hydrophobic hydroscopic heat and moisture exchanging filter.

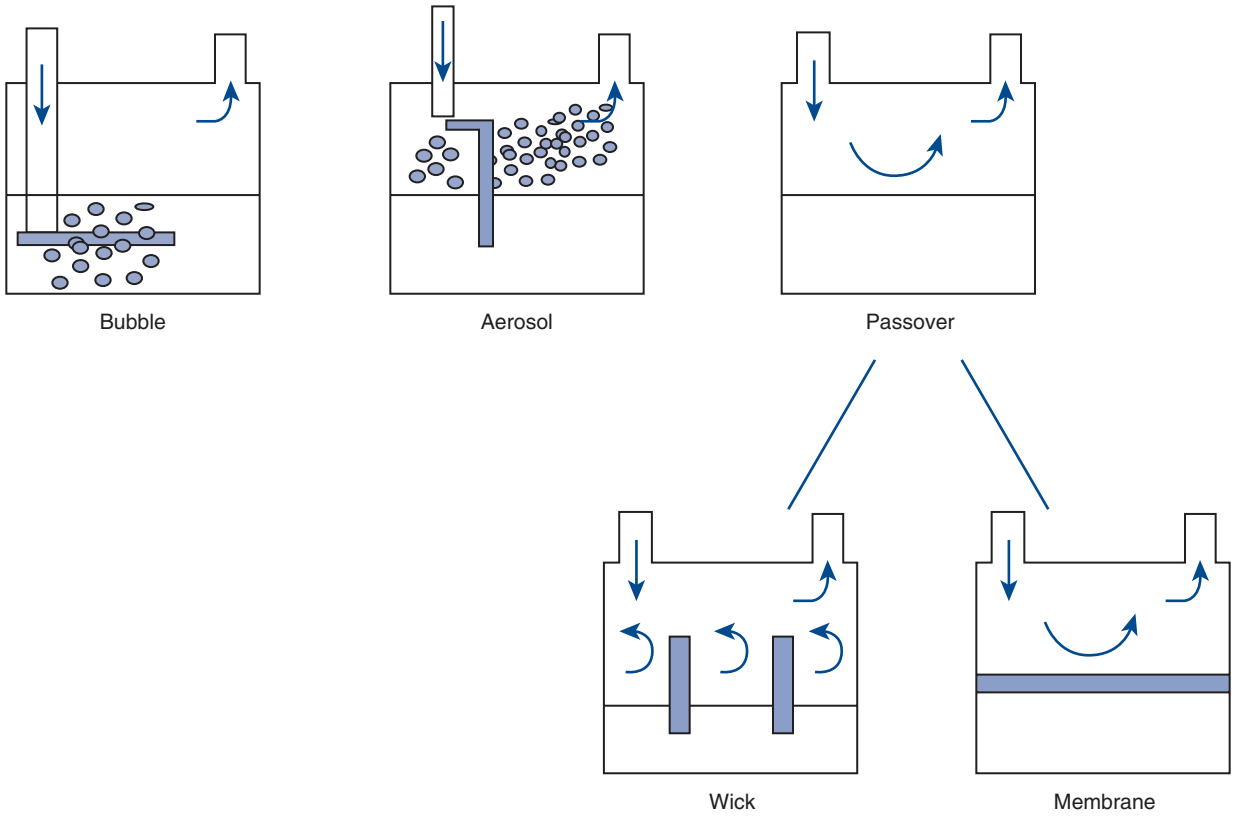

Fig. 39.3 Primary Types of Active Humidifiers. Gas passes through the water *(bubble)*, around drops of water *(aerosol)*, or over the surface of water *(pass-over)*, a saturated material *(wick)*, or a semipermeable membrane *(membrane)*. (From Fink J: Humidity and aerosol therapy. In Cairo J, Pilbeam S, editors: *Mosby's respiratory equipment*, ed 8, St. Louis, 2010, Mosby.)

RULE OF THUMB

Jet, bubble, and ultrasonic humidifiers produce aerosols that can carry bacteria from the reservoir to the patient. Minimize contamination of the reservoir by draining condensate away from the humidifier, and rinse, wash, sterilize, or replace frequently.

Pass-over. Pass-over humidifiers direct gas over a surface containing water. There are three common types: (1) simple reservoir type, (2) wick type, and (3) membrane type (see Fig. 39.3).

The simple reservoir device directs gas over the surface of a volume of water (or fluid). The surface for gas–fluid interface is limited. Typically used with heated fluids during invasive mechanical ventilation, room-temperature fluids may be used with noninvasive ventilatory support (nasal CPAP or bilevel ventilation).

A wick humidifier uses an absorbent material to increase the surface area for dry air to interface with heated water. Typically a wick is placed upright with the gravity-dependent end in a heated water reservoir. Heating elements might be below or surrounding the wick. Capillary action draws water up from the reservoir and keeps the wick saturated. As dry gas enters the chamber, it flows around the wick, quickly picking up heat and moisture and leaving the chamber saturated with water vapor. No bubbling occurs, so no aerosol is produced.

Membrane-type humidifiers separate heated water from the gas stream by means of a **hydrophobic** membrane. Hydrophobic

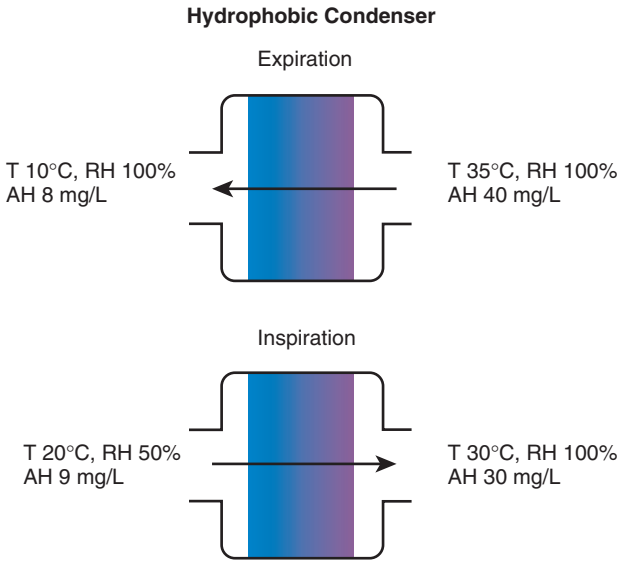

Fig. 39.4 Process of Humidification With a Hydrophobic Condenser Humidifier. *AH,* Absolute humidity; *RH,* relative humidity; *T,* temperature.

("water hating") membranes have little or no tendency to absorb water, typically having a nonpolar surface that repels water (Fig. 39.4). Water vapor (molecules) pass through the pores in the membrane, but liquid water (and pathogens) cannot.

Compared with bubble humidifiers, pass-over, wick, and membrane humidifiers offer several advantages.[15,16] First, they

maintain heat and saturation at higher flow rates than bubbling or jet humidifiers. Second, they add little or no flow resistance to spontaneous breathing circuits.[16,17] Third, they do not generate any aerosols and pose minimal risk for spreading infection.[15]

Vaporizer humidifiers. Simple vaporizers heat water to the point of expansion as a gas. Simple room vaporizers have been used in ambulatory settings for years as room humidifiers. A capillary force vaporizer is a thin-film, high-surface-area boiler that combines capillary force and phase transition to impart pressure onto an expanding gas (water vapor) and ejects it into the gas stream.

Heat and moisture exchangers. Heat and moisture exchange (HME) units typically comprise a passive humidifier, also described as an "artificial nose." Similar to the nose, such a device captures exhaled heat and moisture and returns up to 70% of the heat and humidity to the patient during the next inspiration. In contrast to the nose, with its rich vasculature and endothelium, most HME units do not actively add heat or water to the system.[13]

Traditionally, HME units have been mainly used to provide humidification to patients receiving ventilatory support via endotracheal or tracheostomy tubes. More recently, they have been used successfully in meeting the short-term humidification needs of spontaneously breathing patients with tracheostomy tubes[16-19] and long-term needs with laryngectomies where a significant decrease in the frequency of coughing, forced expectoration, and stoma cleaning were reported with a decrease in pulmonary symptoms and improvement of speech and sleeping regardless of country or climate.[20]

Reports of an increased incidence of blocked tracheal tubes associated with the long-term use of HME deices in the intensive care unit[21] are in contrast to evidence supporting their long-term use in spontaneously breathing patients.[22-25]

The three basic types of HME units are (1) simple condenser humidifiers, (2) hygroscopic condenser humidifiers, and (3) hydrophobic condenser humidifiers. Simple condenser units contain a condenser element with high thermal conductivity; the latter usually consists of metallic gauze, corrugated metal, or parallel metal tubes. Inspired air cools the condenser element, and expired water vapor condenses directly on its surface and rewarms it. On the next inspiration, cool dry air is warmed and humidified as it passes over the condenser element. Simple condenser humidifiers can recapture only some 50% of a patient's exhaled moisture.

Hygroscopic materials absorb moisture from the air. Hygroscopic condenser HME units use materials that (1) incorporate a condensing element of low thermal conductivity (e.g., paper, wool, or foam) and (2) impregnate this material with a hygroscopic salt (calcium or lithium chloride). By using an element with low thermal conductivity, hygroscopic condenser HME units can retain more heat than simple condenser systems, while hygroscopic salt helps capture extra moisture from the exhaled gas. The lower water vapor pressure in the inspired gas liberates water molecules directly from the hygroscopic salt without cooling. Fig. 39.5 depicts the overall process of humidification with a hygroscopic condenser humidifier, showing the changes in temperature and the RH and AH occurring during the cycle of breathing. As shown, these units typically achieve approximately 70% efficiency (40 mg/L exhaled, 27 mg/L returned).

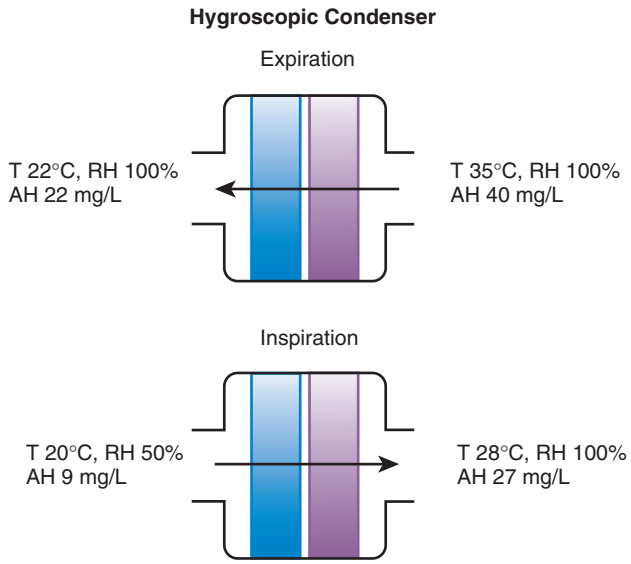

Fig. 39.5 Process of Humidification With a Hygroscopic Condenser Humidifier. *AH,* Absolute humidity; *RH,* relative humidity; *T,* temperature

Hydrophobic condenser HME units use a water-repellent element with a large surface area and low thermal conductivity (see Fig. 39.4). During exhalation, the condenser temperature increases to approximately 25°C because of conduction and the latent heat of condensation. On inspiration, cool gas and evaporation reduce the condenser temperature down to 10°C. This large temperature change results in the conservation of more water to be used in humidifying the next breath. The efficiency of these units is comparable to that of hygroscopic condenser HMEs (approximately 70%). However, some hydrophobic HMEs that provide bacterial filtration may reduce the risk for pneumonia but be unsuitable for patients with limited respiratory reserve or those are prone to airway blockage because they may increase artificial airway occlusion.[26] HME units that deliver at least 30 mg H_2O/L should be used because they are associated with a lower incidence of ETT occlusion.[21]

Design and performance standards for HME units are set by the **International Organization for Standardization** (ISO).[27,28] The ideal HME unit should operate at 70% efficiency or better (providing at least 30 mg/L water vapor); use standard connections; have a low compliance; and add minimal weight, dead space, and flow resistance to a breathing circuit.[29] HME performance varies from brand to brand and may differ from manufacturers' specifications.[21] Insufficient heat and humidification can occur with some HME units, causing complications. Table 39.3 compares performance of several commercially available HME units according to their moisture output, flow resistance, and dead space.[21]

RULE OF THUMB

As many as 50% of HME units do not provide the recommended inspired AH of 30 mg H_2O/L. Check manufacturing performance specifications and independent bench studies before adopting an HME unit for clinical use.

As shown in Table 39.4, the moisture output of HME units tends to decrease with high volumes and rates of breathing. In addition, high inspiratory flows and high FiO_2 levels can decrease the efficiency of such a device.[30] Flow resistance through the HME also is important. When they are dry, resistance across most devices is minimal. However, because of water absorption, flow resistance increases after several hours of use.[31] For some patients, the increased resistance imposed by the HME may not be well tolerated, particularly if the underlying lung disease has already increased WOB. An increase in WOB through the HME may lead to elevated airway pressures and a possible disconnect.[32]

Because HME units eliminate the problem of condensation in the breathing circuit, many clinicians consider these devices (especially hydrophobic filter HME units) to be helpful in preventing nosocomial infections and ventilator-associated pneumonia (VAP).[33-38] Compared with active humidification systems, HME units reduce bacterial colonization of ventilator circuits.[34] However, if usual maintenance precautions are applied, circuit colonization plays a minor role in the development of nosocomial infections.[35] Further, there is no evidence of an overall difference between HME units and heated humidifiers in preventing mortality and other complications in patients who are mechanically ventilated,[26] and previous research indicates no difference in the incidence of ventilator-associated infections with HME units versus heated humidifiers.[26,29,33-40] The position of the HME relative to the patient's airway can affect its ability to heat and humidify inhaled gas. Secretions can foul HME units attached directly to the airway. The use of devices such as closed suction catheters and airway monitor ports requires placement of the HME closer to the ventilator. Previous research has tested the performance of HME units placed directly at the airway, 10 cm away from the ETT, and proximal to the ventilator circuit.[41] It was then reported that the performance of the HME unit was best when placed directly at the airway (Fig. 39.6).[41] Clinicians should select HME units that perform adequately when placed at the intended position. Although use of these devices has been associated with a thickened and increased volume of secretions in some patients, the incidence of ETT occlusion when HME units are used is equivalent to that with heated humidifiers.[37,42]

HME units are not recommended for use with infants and small children because they add 5 to 90 mL of mechanical dead space, exceeding the tidal volume of the preterm infant. In addition, infants are commonly ventilated through uncuffed ETTs, which allow exhaled gas to leak around the tube and bypass the HME, thus reducing recovered heat and humidity. Similarly, for other populations, HME units are not recommended for patients requiring lung-protective ventilation. The greater dead space frequently results in hypercapnia in patients with small tidal volumes.[43]

Active heat and moisture exchangers. Active HME units add humidity, heat, or both to inspired gas by chemical or electrical means.[44] The Humid-Heat (Louis Gibeck AB, Upplands Väsby, Sweden) consists of a supply unit with a microprocessor, water pump, and humidification device, which is placed between

TABLE 39.3 Comparison of Active Heated Humidity Units With Passive Heat and Moisture Exchangers

Humidifier	Advantages	Disadvantages
Active heated humidity	Wide application	Cost—setup
	Reliability	Water use
	Temperature monitoring and alarms	Condensation
	Control over range of temperatures	Risk of contamination
	Optimal absolute humidity	Risk of burns or electrical shock (low)
Passive—heat and moisture exchanger	Cost—low per unit	Limited applications—not for all patients
	No power required	Added mass at airway
	No added water	Increased dead space
	Minimal condensation	Increased resistance and work of breathing
	Ease of use	Potential occlusion
		Limited temperature and absolute humidity
		Breaking circuit to change and administer aerosol

HME, Heat and moisture exchange.

the Y piece and the ETT. The humidification device is based on a hygroscopic HME unit, which absorbs the expired heat and moisture and releases it into the inspired gas. External heat and water are added to the patient side of the unit in order to increase temperature. The external water is delivered to the humidification device via a pump onto a wick and evaporated into the inspired air by an electrical heater. The microprocessor controls the water pump and heater by an algorithm using the minute ventilation (which is fed into the microprocessor) and the airway temperature measured by a sensor mounted in the flex-tube on the patient side of the humidification device. The HME Booster (King Systems, Noblesville, IN) has a T piece containing an electrically heated element designed for use as an adjunct to a passive HME. The heating element heats water, so that water vapor passes into the airway between the artificial airway and ETT via a Gore-Tex membrane and aluminum. Using gravity feedbag via a flow regulator that limits flow to 10 mL/h, water is fed to the heater, which operates at 110°C and adds 3 to 5.5 mg/L of humidity and 3°C to 4°C to inspired gas compared with the HME alone. The Humid-Booster was designed for patients with minute volumes of 4 to 20 L and is not appropriate for use with pediatric patients or infants. Active HME units add weight and complexity at the patient airway (Table 39.5).

The Performer (StarMed, Mirandola, Italy), similar to a common hygroscopic-hydrophobic HME unit, has the ability (in active mode) to add water and heat to the inspired gas circuit. The water is continuously added from an external source, wetting the hygroscopic-hydrophobic membrane; the membrane is heated,

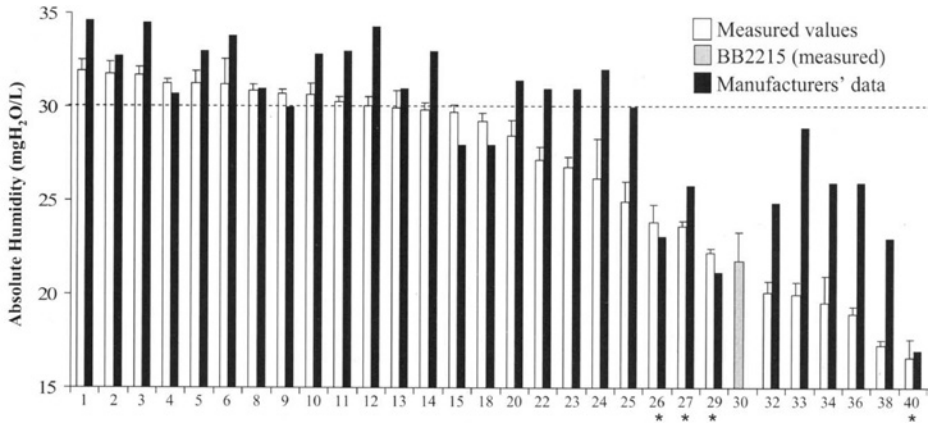

Fig. 39.7 Inspired absolute humidity values obtained using the bench test apparatus compared with manufacturer data when available (29 devices). Results of the hydrophobic heat and moisture exchange Pall BB2215 are also displayed. The asterisks indicate the devices that are proposed as antimicrobial filters. (From Lellouche F, Taillé S, Lefrançois F, et al: Humidification performance of 48 Passive Airway Humidifiers: comparison with manufacturer data, *Chest* 135(2): 276–286, 2009.)

yielding water from evaporation. In passive mode, it produced AH 28.9 ± 0.9 mg H_2O/L in vitro during normothermic conditions and 30.7 ± 1.6 mg H_2O in vivo. In active mode, AH ranged from 30 to 36 mg H_2O/L, independent of minute ventilation and expiratory AH without loss of efficiency after 12 hours, reaching a steady state of temperature and humidity after only 15 minutes of use (Fig. 39.7). Although active heat moisture exchangers can increase the temperature and AH of the inspired gases compared to the commonly used heat moisture exchangers, the use of active heat moisture exchangers should be restricted in patients with variable minute ventilation or in presence of thickened secretions or hypothermia (Fig. 39.8).

RULE OF THUMB

HME units should be replaced if secretions have contaminated the filter and/or if flow resistance has increased, causing an increase in the WOB.

Heated Humidifiers

Heat improves the water output of humidifiers. Heated humidifiers are used to increase the heat and water content of inspired gas for patients with bypassed upper airways and those receiving noninvasive mechanical ventilatory support.[12] Humidifier heating systems generally have a controller that regulates the power to the heating element by monitoring it, which matches a preset or adjustable temperature. They also may use a thermistor placed at the outlet of the humidifier, with a heater set to control output temperature. Servo-controlled heating systems monitor the temperature at the humidifier's outlet and at the patient's airway using a thermistor probe. The controller adjusts the heater power to reach the desired airway temperature and incorporates alarms and an alarm-activated heater shutdown function.[13]

An electrical heating element provides the needed energy. Five types of heating elements are common: (1) a hotplate element at the base of the humidifier; (2) a wraparound type that surrounds the humidifier chamber; (3) a yoke, or collar, element that sits between the water reservoir and the gas outlet; (4) an immersion-type heater, with the element placed in the water reservoir; (5) a heated wire in the inspiratory limb warming a saturated wick or hollow fiber; and (6) a thin-film high-surface-area broiler.

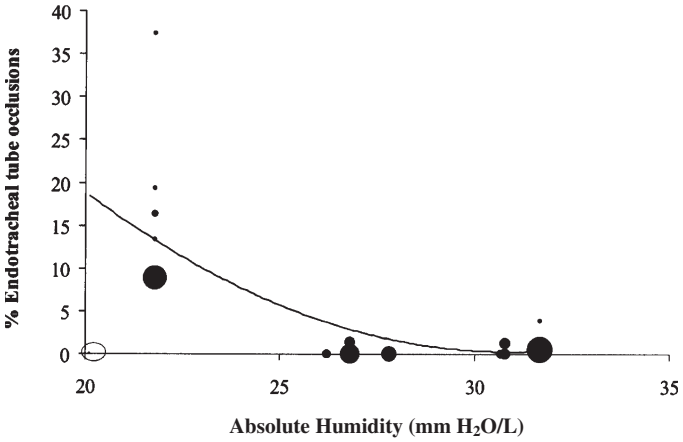

Fig. 39.8 Reported incidence of airway occlusion *(circles)* correlated with absolute humidity determined from in vitro testing of the same heat and moisture exchangers (HME units). A hydrophobic HME unit that delivered an absolute humidity of 21.8 ± 1.5 mg H_2O/L in the bench study was associated with high rates of endotracheal tube occlusion in five published studies. (From Lellouche F, Taillé S, Lefrançois F, et al: Humidification performance of 48 Passive Airway Humidifiers: comparison with manufacturer data, *Chest* 135(2):276–286, 2009.)

Humidifier heating systems have a controller that regulates the element's electrical power. In the simplest systems, the controller monitors the heating element, varying the delivered current to match either a preset or an adjustable temperature. In these systems, the temperature of the patient's airway has no effect on the controller. Conversely, a **servo-controlled heating system** monitors temperature at or near the patient's airway using a thermistor probe. The controller adjusts heater power to achieve the desired airway temperature. Systems usually have alarms and alarm-activated heater shutdown. Box 39.5 outlines key features of modern heated humidification systems.

BOX 39.5 Key Features of Heated Humidification Systems

- Gas temperature delivered to the patient should not be greater than 40°C. When temperatures greater than 40°C are reached, audible and visual alarms should indicate an overly high temperature condition and interrupt power to the heater.
- Audible and visual alarms should indicate when remote temperature sensors are disconnected, absent, or defective, and power to the heater should be interrupted to prevent overheating.
- Temperature overshoot should be minimized. Overshoot can occur when servo-controlled units warm up without flow through the circuit, when the temperature probe is not inserted in the circuit (or becomes dislodged), or when flow changes during normal operation. Non–servo-controlled units can overshoot when temperature controls are set too high or when gas flow is abruptly reduced.
- Indicators for delivered gas temperature should be accurate to ±3°C of the indicated value.
- Humidifier temperature output should not vary more than 2°C from the set value (proximal to the patient).
- Warmup time should not exceed 15 min.
- The water level should be readily visible in either the humidifier or the remote reservoir.
- Humidifiers should be able to withstand ventilation pressures greater than 100 cm H_2O.
- Internal compliance should be low and stable so that changes in the water level do not significantly alter the delivered tidal volume.
- The exposed surface of a humidifier should not be too hot to touch during operation. Readily accessible surfaces should not be warmer than 37.5°C. A warning label is needed for hotter surfaces.
- Operator, or feed, systems must not be able to overfill the humidifier to the point that water can block gas flow through the humidifier or ventilator circuit. Humidifiers should not be damaged by spilled fluids.
- Electromagnetic interference from other devices should not affect humidifier performance. The unit should not be damaged by 95–135 volts.
- Fuses or circuit breakers should be clearly labeled and easily reset or replaced. The unit should have adequate overcurrent protection to prevent ventilator shutdown or loss of power to other equipment on the same branch circuit because of internal equipment failures.
- It should be impossible to assemble the unit in a way that would be hazardous to the patient. The direction of gas flow should be indicated on interchangeable components, for which proper direction is essential.
- The humidifier should be assembled and filled in a manner that minimizes the introduction of infectious materials or foreign objects.
- Service and operation manuals should be provided with the humidifier and should cover all aspects of its use and service.

Modified from Emergency Care Research Institute: Heated humidifiers, Health Devices. 1987. http://www.fda.gov/oc/po/firmrecalls/Vapotherm2000i_01_06.html. Accessed March 2, 2011.

RULE OF THUMB

Place heated humidifier thermistor probes in the inspiratory limb of a ventilator circuit far enough from the patient's Y adaptor to ensure that warm exhaled gas does not fool the controller system. Never place a thermistor probe in an isolette or a radiant warmer, where the probe is warmed externally and the humidifier is fooled into shutting down, reducing the humidity available to the patient.

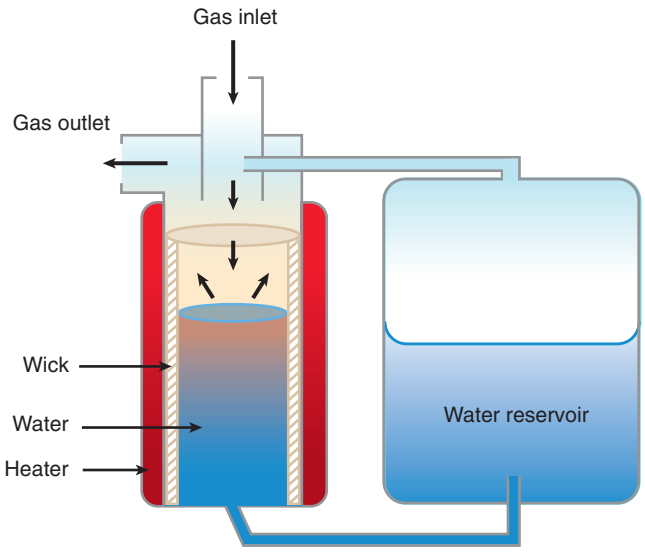

Fig. 39.9 Schematic of the Concha-Column wick-type humidifier with a level-compensated reservoir feed system (Hudson RCI, Temecula, CA). (Modified from Fink J, Cohen N: Humidity and aerosols. In Eubank D, Bone R, editors: *Principles and applications of cardiorespiratory care equipment*, St. Louis, 1994, Mosby.)

Reservoir and Feed Systems

Heated humidifiers operating continuously in breathing circuits can evaporate more than 1 L of water per day. An ideal reservoir or feed system should be safe, dependable, easy to set up, and allow continuity of therapy, even when the reservoir is being replenished.

Manual systems. Simple large-reservoir systems are manually refilled (with sterile or distilled water). If a manual system is used, momentary interruption of humidifier operation and mechanical ventilation is required for refilling. Because the system must be "opened" for refilling, cross contamination can occur. Water levels in manually filled systems are constantly changing, and changes in the humidifier fill volume alter the gas compression factor and the delivered volume during mechanical ventilation.

A small inlet that can be attached to a gravity-fed intravenous bag and line allows refilling without interruption of ventilation. Such systems still require constant checking and manual replenishment by opening the line valve or clamp. If not checked regularly, the reservoir in these systems can go dry, placing the patient at considerable risk.

Automatic systems. Automatic feed systems avoid the need for constant checking and manual refilling. The simplest type of automatic feed system is the level-compensated reservoir (Fig. 39.9). In these systems, an external reservoir is aligned horizontally with the humidifier, maintaining relatively consistent water levels between the reservoir and the humidifier chamber.

With flotation-type systems (Fig. 39.10), a float rises and falls with the water level. As the water level falls below a preset value, the float opens the feed valve; as the water rises back to the set fill level, the float closes the feed valve. Alternatively, optical sensors can be used to sense water level, driving a solenoid valve to allow refilling of the humidifier reservoir.

MINI CLINI

Selecting the Appropriate Therapy to Condition a Patient's Inspired Gas: Hypothermia

Problem

A survivor of near drowning has just been intubated and placed on mechanical ventilatory support. Her body temperature is 31°C and her minute ventilation is high. What would be the appropriate humidification system to recommend for this patient?

Solution

Normally, patients without chronic obstructive pulmonary disease supported by mechanical ventilation can be started with an HME unit unless its use is contraindicated. Using an HME unit with this patient is contraindicated because (1) she is hypothermic and (2) she has a high minute ventilation. Based on this assessment, the best choice is a heated humidifier, preferably with servo-controlled airway temperature. A gas temperature above 41°C may lead to a potential thermal injury to the patient; high-temperature alarms protect the patient from thermal injury.

Membrane-type humidifiers require no water-feed control system because the liquid water chamber feeding the membrane cannot overfill, so only an open gravity feed system is required. The Vapotherm humidifier (Vapotherm, Stevensville, MD; Fig. 39.11) utilizes a membrane cartridge system whereby blended gas passes through the lumens of hundreds of parallel hollow fibers made of a polymer that allows molecules of heated water surrounding the fibers to pass to the air within the fibers with no direct contact with the water. The warmed humidified gas enters the center of a triple-lumen heated delivery tube, where it is surrounded by two outer lumens circulating warmed water to maintain the temperature of the inner lumen and minimize rain-out. There are separate cartridges for infants (delivering up to 8L/min) and children/adults (delivering up to 5 to 40 L/min) with a temperature range from 33°C to 43°C.

RULE OF THUMB

Humidification of inspired gas is critical for mechanically ventilated patients with ETTs or tracheostomy tubes. During noninvasive ventilation (NIV), active humidification is suggested to improve patient comfort.

Setting Humidification Levels

The American National Standards Institute (ANSI) recommends *minimum* levels of humidity for intubated patients (>30 mg/L). However, optimum humidity targets the temperature and humidity for normal conditions at the point that the gas is entering the airway. For example, the humidity of air entering the carina is typically 37 to 40 mg/L. When humidifiers run too cold (<32°C), humidity can be reduced to the point of increased airway plugging. Not all active heated humidifiers perform the same under all conditions. Previous research emphasizes the need to set humidifiers to maintain airway temperatures between 35°C and 37°C.

Controversy exists regarding the appropriate temperature and humidity of inspired gas delivered to mechanically ventilated patients with artificial airways. The current clinical practice guideline of the American Association for Respiratory Care (AARC) recommends 33°C, within 2°C, with a minimum of 30 mg/L of water vapor.[1] In a comprehensive review, Williams[45] suggested that inspired humidity be maintained at an optimal level, 37°C with 100% RH and 44 mg/L, to minimize mucosal dysfunction. Theoretically, optimal humidity offers improved mucociliary clearance. The benefits of this strategy are based on theory and have yet to be demonstrated conclusively in the clinical setting. Further controlled studies are needed to better support the need for optimal humidity.

MINI CLINI

Selecting the Appropriate Therapy to Condition a Patient's Inspired Gas: Noninvasive High Gas Flow

Problem

A patient is prescribed to receive high-flow oxygen at greater than 30 L/min via face mask. What temperature would be most comfortable for the patient?

Solution

Gas applied to an intact upper airway, whether via mask or nasal cannula, should be conditioned to normal ambient temperature and RH. Normal room temperature at 50% to 55% RH approximates an AH of 20 mg/L. However, patients receiving high-flow gas for extended periods may complain of airway dryness and discomfort. However, patients receiving gas with an AH of 40 mg/L also complain of discomfort (too warm or claustrophobic). An AH of 30 mg/L has been reported to be more comfortable.

MINI CLINI

When Is Sterile Water Essential?

Problem

Sterile water is back ordered. Your department is running low and there is not enough to support all of the humidifiers in use, but your hospital does have an unlimited supply of distilled water.

Solution

Pass-over, wick, and membrane humidifiers produce water vapor, or molecules, that are too small to carry bacteria, so distilled water would be fine for those humidifiers. In contrast, bubbling and jet humidifiers produce aerosols that *can* carry bacteria, so sterile water should be used in those.

Caution: Tap water should not be used with any humidifier, as chemicals used in public water supplies may vaporize and irritate patients' airways.

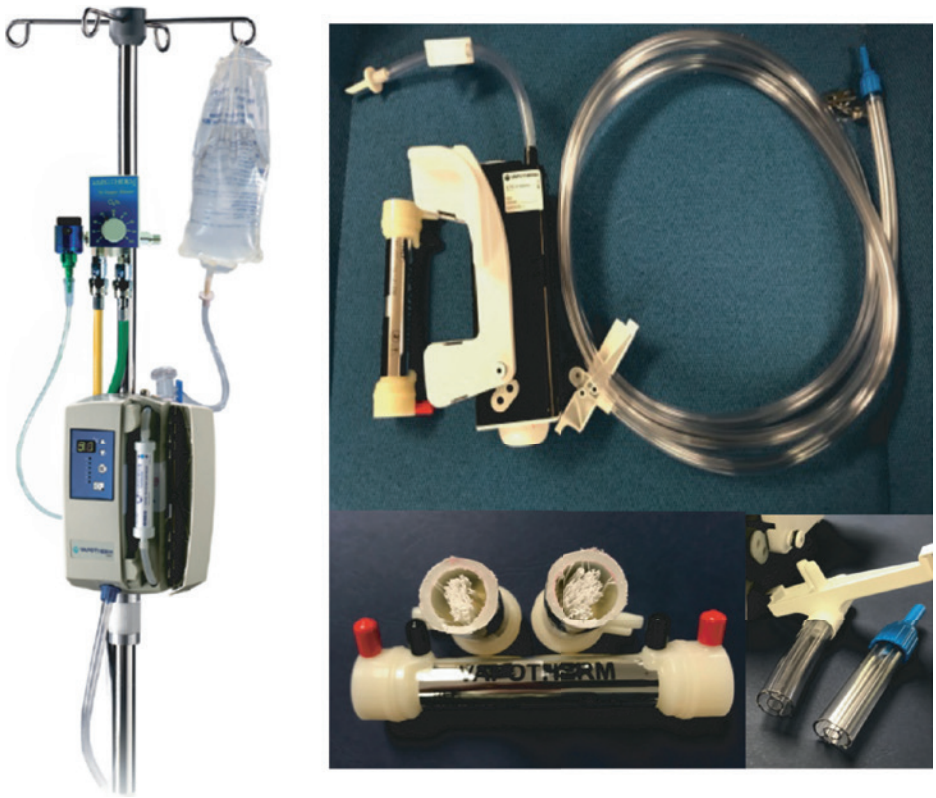

Fig. 39.11 Example of a membrane humidifier—Vapotherm humidifier with cartridge. Single-patient disposable circuit with heating block, cartridge, and circuit. Cartridge and cross section showing bundle of fibers that carry blended gas and space between the fibers where warm water heats and humidifies the gas in the fibers. Cross section of circuit with triple lumen. The central lumen carries heated humidified gas; the other two lumens carry warm water, increasing thermal mass of circuit and reducing condensate formation. (Left, Courtesy of Vaportherm.)

Problem Solving and Troubleshooting

Common problems with humidification systems include condensation, avoiding cross contamination, and ensuring proper conditioning of the inspired gas.

Condensation

In standard heated humidifier systems, saturated gas cools as it leaves the point of humidification and passes through the delivery tubing en route to the patient. As gas cools, water vapor capacity decreases, resulting in condensation or "rain out." Factors influencing the amount of condensation include (1) the temperature difference across the system (humidifier to airway); (2) the ambient temperature; (3) the gas flow; (4) the set airway temperature; and (5) the length, diameter, and thermal mass of the breathing circuit.

Fig. 39.12 illustrates the condensation process. Because cooling occurs as gas transits the circuit, the humidifier is set to a higher temperature (50°C) than desired at the airway. At 50°C, saturated gas has an AH level of 84 mg/L of water. As cooling occurs along the tubing, the capacity of the gas to hold water vapor decreases as temperature decreases to 37°C, holding only 44 mg/L of water vapor. Although BTPS conditions have been achieved at 40 mg/L, half the total output of the humidifier (84 mg/L to 44 mg/L = 40 mg/L) condenses in the inspiratory limb of the circuit.

This condensation poses risks to patients and caregivers and can waste a lot of water. Condensation can disrupt or occlude gas flow through the circuit, potentially altering ventilator function. Because condensate can enter the patient's airway and be aspirated, circuits must be positioned to drain condensate away from the patient and checked often, with condensate drained from breathing circuits regularly.

Patients contaminate ventilator circuits within hours; thus condensate colonized with bacteria poses a risk for infection.[45] Health care personnel should treat all breathing circuit condensate as infectious waste. See Chapter 4 for more detail on control procedures used with breathing circuits, including the AARC's Clinical Practice Guideline on changing ventilator circuits.

RULE OF THUMB

Always treat breathing circuit condensate as infectious waste. Use standard precautions, including wearing gloves and goggles. Always drain the tubing away from the patient's airway into an infectious waste container and dispose of the waste according to the policies and procedures of the institution.

A common method to minimize problems with condensate is to place water traps at low points in the circuit (both the inspiratory and expiratory limbs of ventilator circuits) to collect

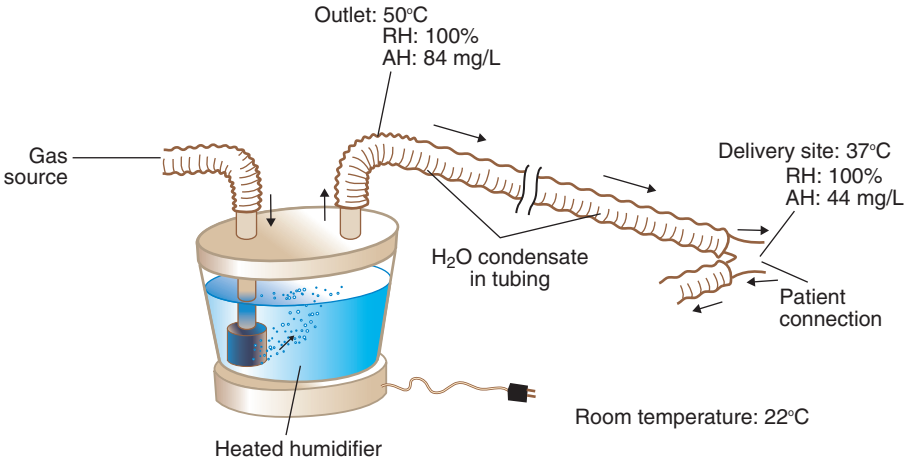

Fig. 39.12 Gas leaving a standard bubbling heated humidifier is cooled en route to the patient. Although the gas remains saturated (100% relative humidity *[RH]*), cooling reduces its water vapor capacity and condensation forms. Almost half of the original water (500 mL/d) is lost to condensation. The temperature at the patient connection (37°C) shown here is for illustrative purposes only. Heated humidifiers should be set to deliver inspired gas at 35°C ± 2°C. *AH,* absolute humidity.

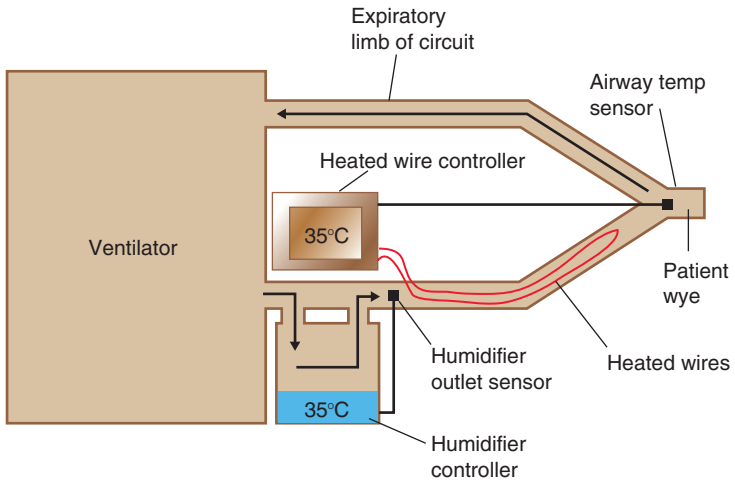

Fig. 39.13 Heated-wire humidifier system. The dual sensor system keeps the temperature constant throughout the inspiratory limb of the ventilator circuit, minimizing condensation. Cooling of exhaled gas in the expiratory limb can cause condensation unless it also is heated.

condensate and reduce the likelihood of gas flow obstruction. Water traps should have little effect on circuit compliance, allow emptying without disrupting ventilation, and not be prone to leakage.

A nebulizer, with a medication reservoir positioned below the ventilator circuit, can act as a "water trap," collecting contaminated condensate. This creates a risk that contaminated aerosols can be generated and pathogens delivered to deep into the lung. To minimize this risk, nebulizers should be placed in a superior position so that any condensate travels downstream from the nebulizer. In addition, nebulizers should be rinsed and air dried, washed and sterilized, or disposed of and replaced between treatments.

One way to avoid condensation problems is to prevent condensation from forming. Because the decrease in temperature in gas traveling from the humidifier to the airway causes condensation, maintenance of heat in the circuit can prevent the formation of condensate. Several methods, such as insulation or increasing the thermal mass of the circuit, can reduce circuit cooling by keeping the circuit at a constant temperature. The most common approach uses wire heating elements that are inserted into the ventilator circuit.

Most heated-wire circuits use dual controllers with two temperature sensors: one monitoring the temperature of gas leaving the humidifier and the other placed at or near the patient's airway (Fig. 39.13). The controller regulates the temperature difference between humidifier output and patient airway. When heated-wire circuits are used, the humidifier heats gas to a lower temperature (32°C to 40°C) than with conventional circuits (45°C to 50°C). Reduction in condensate in the tubing results in less water use, reduced need for drainage, and less infection risk for patients and health care workers.

RULE OF THUMB

Heated humidifiers should be set to deliver an inspired gas temperature of 34°C or greater but less than 41°C at the inspiratory limb near the Y adaptor during invasive mechanical ventilation. Gas temperatures in patients receiving NIV should be selected based on patient comfort, tolerance, adherence, and the underlying pulmonary condition.

Unwanted levels of condensate can still occur with heated wires. Absorptive material in the inspiratory limb of the ventilator circuit acts as a wick warmed by the heated wire system (Fisher & Paykel Healthcare, Irvine, CA).

Use of heated-wire circuits in neonates is complicated by incubators and radiant warmers.[46] Incubators provide a warm environment surrounding the infant and radiant warmers use radiant energy to warm objects that intercept radiant light. In both cases, a temperature probe placed in the heated environment would affect humidifier performance, resulting in reduced humidity received by the patient. Fig. 39.14 shows the impact of temperature probe placement, in or out of the incubator, on AH delivered to the neonate. Consequently temperature probes should always be placed outside of the radiant field or incubator (Fig. 39.15).

Cross Contamination

Aerosol and condensate from ventilator circuits are known sources of bacterial colonization.[45] However, advances in both circuit and humidifier technology have reduced the risk for nosocomial

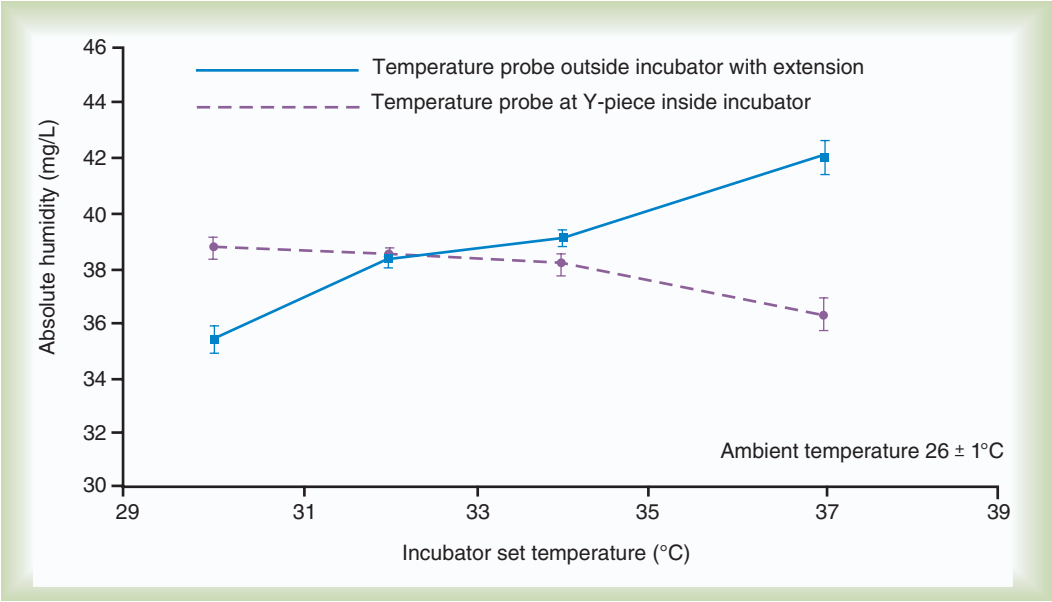

Fig. 39.14 Humidity achieved at the Y piece of a neonatal humidification system when used inside an incubator *(dotted line)* and outside or under an incubator *(solid line)*.

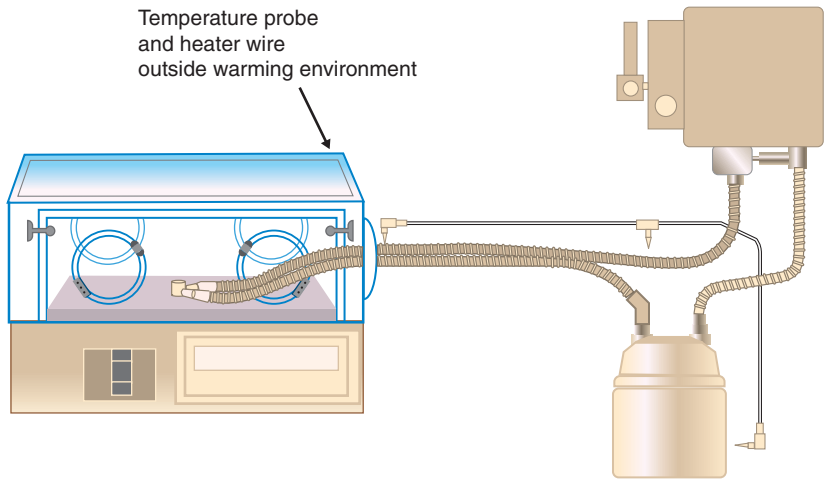

Fig. 39.15 Neonatal breathing circuit configuration used with an incubator, with the temperature probe placed outside of the warming environment and an unheated portion of the inspiratory circuit delivering the gases to the Y piece.

infection when these systems are used. Wick-type or membrane-type pass-over humidifiers prevent the formation of bacteria-carrying aerosols. Heated-wire circuits reduce the production and pooling of condensate within the circuit. In addition, the high reservoir temperatures in humidifiers tend to be bactericidal. In ventilator circuits using wick-type humidifiers with heated wire systems, circuit contamination usually occurs from the patient to the circuit rather than vice versa.

For decades, the traditional way to minimize the risk for circuit-related nosocomial infection in critically ill patients receiving ventilatory support was to change the ventilator tubing and its attached components daily. It is now known that such frequent changes increase the risk for nosocomial pneumonia.[47] There is minimal risk for VAP with weekly circuit changes, and there may be no need to change circuits at all unless they are visibly soiled. In addition, substantial cost savings can accrue with fewer circuit changes.

Proper Conditioning of Inspired Gas

All respiratory therapists (RTs) are trained to measure patient inspired FiO_2 levels regularly and, in ventilatory care, to monitor selected pressures, volumes, and flows. However, few clinicians take the steps needed to ensure proper conditioning of the gas to be inspired by the patients.

The most accurate and reliable way to ensure that patients are receiving gas at the expected temperature and humidity level is to measure these parameters. Portable battery-operated digital **hygrometers**, which measure temperature and RH, are available for less than $300 and are invaluable in ensuring proper conditioning of the inspired gas. When high-humidity environments are being assessed, hygrometers become saturated and nonresponsive over time and so should be used for spot checks only.

Many heated wire humidification systems have a humidity control. This control does not reflect either AH or RH but only the temperature differential between the humidifier and the airway sensor. If the heated wires are set warmer than the humidifier, less RH will be delivered to the patient. To ensure that the inspired gas is being properly conditioned, clinicians should always adjust the temperature differential to the point at which a few drops of condensation form near the patient connection, or "wye." Lacking direct measurement of humidity, observing this minimal condensate is the most reliable indicator that the gas is fully saturated at the specified temperature. If condensate cannot be seen, there is no way of knowing the level of RH without direct measurement—it could be anywhere between 99% and 0%. An HME unit's performance can be evaluated in a similar manner.[48]

RULE OF THUMB

You can estimate whether an HME unit is performing well at the bedside by visually confirming condensation in the flex tube or HME housing between the device and the patient's airway. Lack of condensate may be a clue that humidification is inadequate and that an alternative system may be more appropriate for use with the patient. This can be applied to heated humidifiers as well.

BLAND AEROSOL THERAPY

Humidity is simply water in the gas phase, whereas a bland aerosol consists of liquid particles suspended in a gas (see Chapter 40 for details on aerosol physics). Bland aerosol therapy involves the delivery of sterile water or hypotonic, isotonic, or hypertonic saline aerosols. Bland aerosol administration may be accompanied by O_2 therapy.[49]

Equipment

The equipment needed for bland aerosol therapy includes an aerosol generator and a delivery system. Devices used to generate bland aerosols include large-volume jet nebulizers and **ultrasonic nebulizers** (USNs). Delivery systems include various direct airway appliances and enclosures (mist tents).

Aerosol Generators

Large-volume jet nebulizers. A large-volume jet nebulizer is the most common device used to generate bland aerosols. As depicted in Fig. 39.16, these devices are pneumatically powered, attaching directly to a flowmeter and compressed gas source. Liquid particle aerosols are generated by passing gas at a high velocity through a small "jet" orifice. The resulting low pressure at the jet draws fluid from the reservoir up to the top of a siphon tube, where it is sheared off and shattered into liquid particles. The large unstable particles fall out of suspension or hit on the internal surfaces of the device, including the fluid surface; these act as **baffles** (surfaces that affect aerosol by removing large particles from suspension). The remaining small particles leave the nebulizer carried in the gas stream through the outlet port.

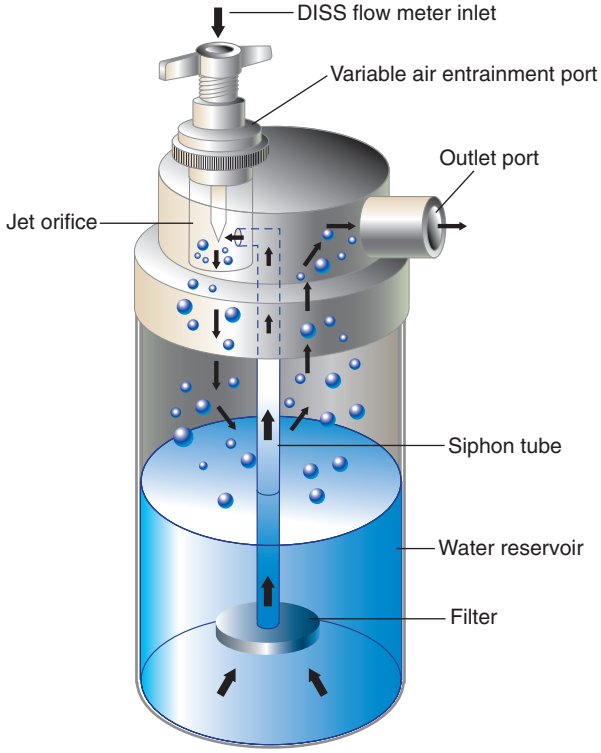

Fig. 39.16 All-Purpose Large-Volume Jet Nebulizer.

A variable air-entrainment port allows air mixing to increase flow rates and to alter FiO_2 levels (see Chapter 42).

If heat is required, as in the case of humidifiers, a hot plate, wraparound, yoke collar, or immersion element can be added (Fig. 39.17). These devices rarely have sophisticated servo-controlled systems to control delivery temperature. They may not shut down when the reservoir empties, resulting in the delivery of hot, dry gas to the patient. Failure of the heating element can also cause a loss of heating capacity without warning to the clinician.

Depending on the design, input flow, and air-entrainment setting, the total water output of unheated large-volume jet nebulizers varies between 26 and 35 mg H_2O/L. When heated, output increases to between 33 and 55 mg H_2O/L, mainly because of increased vapor capacity. Larger versions of these devices (with reservoirs holding 2 to 3 L of water) are used to deliver bland aerosols into mist tents. These enclosure systems can generate flow rates greater than 20 L/min, with water outputs of 5 mL/min (300 mL/h). Because heat buildup in enclosures is a problem, these systems are always run unheated.

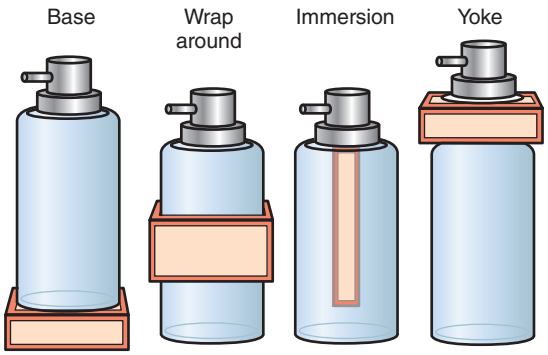

Fig. 39.17 Methods used to heat jet and bubble humidifiers with placement of electrical heating elements.

Ultrasonic nebulizers. A USN is an electrically powered device that uses a **piezoelectric crystal** to generate an aerosol. This crystal transducer converts radio waves into high-frequency mechanical vibrations (sound), which are transmitted to a liquid surface. There the intense mechanical energy creates a cavitation in the liquid, forming a standing wave, or "geyser," that sheds aerosol droplets. Fig. 39.18 is a schematic view of a large-volume USN. Output from a radiofrequency generator is transmitted over a shielded cable to the piezoelectric crystal. Vibrational energy is transmitted either indirectly through a water-filled couplant reservoir or directly to a solution chamber. Gas entering the chamber inlet picks up the aerosol particles and exits through the chamber outlet.

The properties of the ultrasonic signal determine the characteristics of the aerosol generated by these nebulizers. The frequency at which the crystal vibrates, preset by the manufacturer, determines the size of the aerosol particles. Particle size is inversely proportional to signal frequency. A USN operating at a frequency of 2.25 MHz may produce an aerosol with a mass median aerodynamic diameter (MMAD) of approximately 2.5 µm, whereas another nebulizer operating at 1.25 MHz produces an aerosol with MMAD between 4 and 6 µm. Signal amplitude directly affects the amount of aerosol produced; the greater the amplitude, the greater the volume of aerosol output. In contrast to frequency, signal amplitude can be adjusted by the clinician.

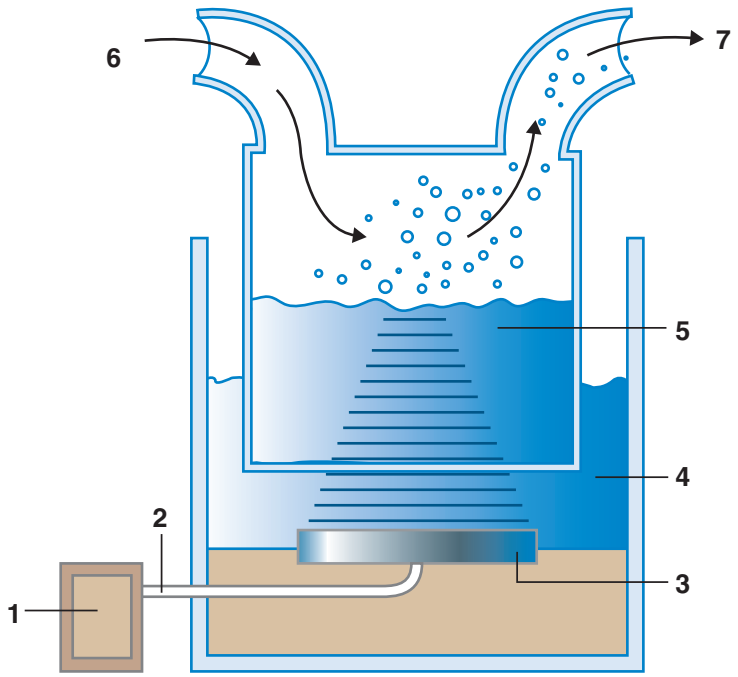

Fig. 39.18 Functional schematic of a typical large-volume ultrasonic nebulizer. *1,* Radiofrequency generator; *2,* shielded cable; *3,* piezoelectric crystal transducer; *4,* water-filled couplant reservoir; *5,* solution chamber; *6,* chamber inlet; and *7,* chamber outlet. (Modified from Barnes TA: *Core textbook for respiratory care practice*, ed 2, St. Louis, 1994, Mosby.)

Particle size and aerosol density delivered to the patient are also affected by the source and flow of gas through the aerosol-generating chamber. Some large-volume USNs have built-in fans that direct room air through the solution chamber conducting the aerosol to the patient. The airflow may be adjusted by changing the fan speed or using a simple damper valve. Alternatively, compressed anhydrous gases can be delivered to the chamber inlet through a flowmeter. For precise control over delivered O_2 concentrations, clinicians can attach a flowmeter with an O_2 blender or air-entrainment system to the chamber inlet.

The flow and amplitude settings interact to determine aerosol density (mg/L) and total water output (mL/min). Amplitude affects water output. At a given amplitude setting, the greater the flow through the chamber, the less the density of the aerosol. Conversely, low flows result in aerosols of higher density. Total aerosol output (mL/min) is greatest when both flow and amplitude are set at the maximum. With these settings, some units can achieve total water outputs of 7 mL/min.

Particle size, aerosol density, and output are also affected by the RH of the carrier gas (see Chapter 40). In contrast to jet nebulizers, the temperature of the solution placed in a USN increases up to 10°C during use. Although this increase in temperature affects water vapor capacity, its impact on aerosol output is minimal.

RULE OF THUMB

To produce a high-density aerosol using a USN (useful for sputum induction), set the amplitude high and the flow rate low. To maximize aerosol delivery per minute (in trying to help mobilize secretions), set the flow rate to match and slightly exceed the patient's inspiratory flow rate and set the amplitude at the maximum.

Although USNs have some unique capabilities, their relative advantages over jet nebulizers in most cases of bland aerosol administration are outweighed by their high cost and erratic reliability. Exceptions include the use of a USN for sputum induction, where the high output (1 to 5 mL/min) and aerosol density seem to yield sputum specimens of higher quantity and quality, although at some cost in increased airway reactivity.[50,51] Although a major manufacturer of USNs (DeVilbiss, Scottsdale, AZ) has discontinued this product line, other companies in both the United States and Europe still manufacture USNs for clinical use.

Commercially available USNs (usually marketed as "cool-mist" devices) have found a place in the home, being used as room humidifiers. As with any nebulizer, the reservoirs of these devices can easily become contaminated, resulting in the airborne transmission of pathogens. Care should be taken to ensure that these units are cleaned according to the manufacturer's recommendations and that water is discarded from the reservoir periodically between cleanings. In the absence of a manufacturer's recommendation, these units should undergo appropriate disinfection at least once daily. Generally, pass-over and wick-type humidifiers present less risk than USNs as room humidifiers.

Airway Appliances

Airway appliances used to deliver bland aerosol therapy include the aerosol mask, face tent, T tube, and tracheostomy mask (Fig. 39.19). The aerosol mask and face tent are used for patients with intact upper airways. The T tube is used for patients who are orally or nasally intubated or have a tracheostomy. The tracheostomy mask is used only for patients who have a tracheostomy. In all cases, large-bore tubing is required to minimize flow resistance and prevent occlusion by condensate.

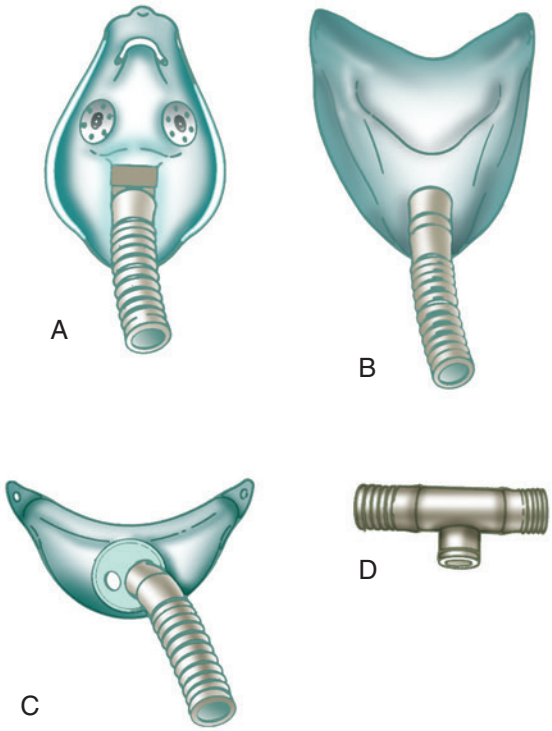

Fig. 39.19 Airway Appliances Used to Deliver Bland Aerosol Therapy. *A,* Aerosol mask. *B,* Face tent. *C,* Tracheostomy mask. *D,* T tube.

For short-term therapy to patients with intact upper airways, the aerosol mask is the device of choice. However, some patients cannot tolerate masks and may do better with a face tent. No data support preferential use of an open aerosol mask versus a face tent.

Although the T tube is the most common application for tracheostomy patients, a tracheostomy mask is a better choice unless moderate to high FiO_2 levels are needed. In contrast to T tubes, tracheostomy masks exert no traction on the airway and allow secretions and condensate to escape from the airway, thus reducing airway resistance.

Enclosures (Mist Tents and Hoods)

Infants and small children may not readily tolerate direct airway appliances such as masks, so enclosures such as mist tents and aerosol hoods are used to deliver bland aerosol therapy to these patients. More recent studies have shown that aerosol hoods can provide aerosol delivery with efficiency similar to that of a properly fitted aerosol mask in infants, and with less patient discomfort.[52]

Mist tents were used for more than 40 years mainly to treat croup and thus were called *croup tents*. The cool aerosol provided through these enclosures promotes vasoconstriction, decreases edema, and reduces airway obstruction.

All body enclosures pose two problems: carbon dioxide (CO_2) buildup and heat retention. CO_2 buildup can be reduced by providing sufficiently high gas flow rates. These high flows of fresh gas circulate continually through the enclosure and "wash out" CO_2 while helping to maintain the desired O_2 concentrations. Heat retention may be handled with high fresh gas flows to prevent heat buildup or use of a separate cooling device such as a simple ice compartment to cool the aerosol.[53,54] The Ohmeda Ohio Pediatric Aerosol Tent (Ohmeda Ohio, Gurnee, IL) and other similar units use electrically powered refrigeration units to cool the circulating air.

The cooling produces a great deal of condensation, which must be drained into a collection bottle outside of the tent. Units such as the Mistogen CAM-3M (Mercury Medical, Clearwater, FL) have overcome some of these problems with a thermoelectric cooling system in which an electrical current passing through a semiconductor augments heat absorption and release. As warm air is taken from the tent, heat is transferred and released into the room, and cool air is returned to the tent.

Problem Solving and Troubleshooting

The most common problems with bland aerosol delivery systems are cross contamination and infection, environmental safety, inadequate mist production, overhydration, bronchospasm, and noise.

Cross Contamination

Rigorous adherence to the infection control guidelines detailed in Chapter 4, especially guidelines covering solutions and equipment processing, should help to minimize the cross contamination and infection risks involved in using these systems. In addition, the water should be changed regularly, and the couplant compartments and nebulizer chambers of USNs should be disinfected or replaced regularly.

Environmental Exposure

Environmental safety issues from secondhand and exhaled aerosol arise mainly when aerosol therapy is prescribed for immunosuppressed patients or for patients with tuberculosis. A survey suggested that RTs may be at increased risk for developing asthma-like symptoms attributed partly to secondhand exposure to aerosols such as ribavirin or albuterol.[55] To minimize problems in this area, all clinicians should strictly follow the standards and airborne precautions published by the US Centers for Disease Control and Prevention, including precautions specified for the control of exposure to tuberculosis (see Chapter 4). Additional methods for dealing with the environmental control of drug aerosols are described in Chapter 40.

Inadequate Aerosol Output

Inadequate mist production is a common problem with all nebulizer systems. With pneumatically powered jet nebulizers, poor mist production can be caused by inadequate input flow of driving gas, siphon tube obstruction, or jet orifice misalignment. With the exception of inadequate driving gas flow, these problems require unit repair or replacement. If a USN is not functioning properly, the electrical power supply (cord, plug, and fuse or circuit breakers) should be checked first. The clinician next should check to confirm that (1) carrier gas is flowing through the device and (2) the amplitude, or output, control is set above minimum. If there is still no visible mist output, the clinician should inspect the couplant chamber to confirm proper fill level and the absence of any visible dirt or debris. Finally, the clinician must ensure that the couplant chamber solution meets the manufacturer's specifications (most units do not function properly with distilled water).

Overhydration
