Overhydration is a problem with the continuous use of heated jet nebulizers and USNs. With USNs capable of such extraordinarily high water outputs, they should never be used for continuous therapy. The risk for overhydration is highest for infants, small children, and patients with preexisting fluid or electrolyte imbalances. Even if used only to meet BTPS conditions, bland aerosol therapy effectively eliminates insensible water loss through the lungs and should be equated to a daily water gain (approximately 200 mL/d for an average adult). In addition to overhydration of the patient, inspissated pulmonary secretions can swell after high-density aerosol therapy, thus worsening airway obstruction. Careful patient selection and monitoring can prevent most potential problems with overhydration. Box 39.6 lists variables that should be recorded during the inspection and monitoring of humidification devices.

Bronchospasm

Bland water aerosols are irritating and can cause bronchospasm in some patients. Ultrasonic nebulization of distilled water is used in some pulmonary function laboratories to provoke bronchospasm and assess bronchial hyperactivity.[56] The patient's history and diagnosis should always be carefully reviewed before any bland aerosol, especially a hypotonic water solution, is administered. Patients receiving continuous bland aerosol therapy should initially be monitored carefully (including breath sounds and subjective responses) and reevaluated every 8 hours or with any change in clinical condition.[57] If bronchospasm occurs during therapy, treatment must be stopped immediately, O_2 provided, and appropriate bronchodilator therapy initiated as soon as possible. If the physician still requests bland aerosol therapy, pretreatment with a bronchodilator may be needed. Isotonic solutions (0.9% saline) instead of water may be better tolerated by these patients.

A problem unique to large-volume air-entrainment jet nebulizers is the noise they generate, especially at high flows. The American Academy of Pediatrics recommends that sound levels remain below 58 dB to avoid hearing loss in infants being cared for in incubators with O_2 hoods. Because many commercial nebulizers exceed this noise level, careful selection of equipment is necessary. However, the best way to avoid this problem and minimize infection risks further is to use heated pass-over humidification instead of nebulization.

SELECTING THE APPROPRIATE THERAPY

Fig. 39.20 provides a basic algorithm for selecting or recommending the appropriate therapy to condition a patient's inspired

BOX 39.6 Sputum-Induction Procedure

- Gather the necessary equipment: Ultrasonic nebulizer, aerosol mask, large-bore tubing, specimen container, 3% sterile saline, and stethoscope.
- Check the chart for order or protocol, diagnosis, history, and other pertinent information.
- Wash your hands and follow applicable standard, airborne, and tuberculosis precautions.
- Introduce yourself and identify your department, verify the patient's identity, and explain the procedure and verify that the patient understands it.
- Have the patient assume an upright, seated position if possible.
- Have the patient rinse his or her mouth with water, blow his or her nose, and clear any excess saliva.
- Perform pretreatment assessment, including vital signs, muscle tone, ability to cough, and auscultation.
- Assemble the nebulizer, fill the couplant chamber with tap water, plug the unit into a grounded electrical outlet, and attach the delivery tubing and mask.
- Aseptically fill the medication chamber of the nebulizer with 3% sterile saline.
- Turn the unit on and adjust the output control to achieve adequate flow and high density.
- Place the mask comfortably on the patient's face and instruct the patient to take slow, deep breaths, with an occasional inspiratory hold as tolerated.
- Periodically reassess the patient's condition (including breath sounds) throughout the application.
- Modify the technique and reinstruct the patient as needed based on his or her response.
- Terminate the treatment after 15–30 min, if significant adverse reactions occur, or when a sputum specimen has been obtained.
- Encourage the patient to cough and expectorate sputum into a specimen cup; observe for volume, color, consistency, odor, and the presence or absence of blood.
- Label the specimen container with patient identification and other required information and deliver it to the appropriate personnel.
- Chart the therapy according to departmental and institutional protocol.
- Notify the appropriate personnel of any adverse reactions or other concerns.

Modified from Butler TJ: *Laboratory exercises for competency in respiratory care*, ed 2, Philadelphia, 2009, FA Davis.

gas. Key considerations include (1) gas flow, (2) presence or absence of an artificial tracheal airway, (3) character of the pulmonary secretions, (4) need for and expected duration of mechanical ventilation, and (5) contraindications to using an HME unit.

Regarding delivery of O_2 to the upper airway, the American College of Chest Physicians advises against using a bubble humidifier at flow O_2 rates of 4 L/min or less because the entrained ambient gas provides sufficient humidity.[48] As O_2 flow increases, inhaled humidity decreases. For the occasional patient who complains of nasal dryness or irritation when he or she is receiving low-flow O_2, a humidifier should be added to the delivery system. Conversely, the relative inefficiency of unheated bubble humidifiers means that the clinician may have to consider heated humidification for patients receiving long-term O_2 at higher flow rates (>10 L/min without air entrainment).

HME units provide an inexpensive alternative to heated humidifiers when used for ventilation of patients who do not have complex humidification needs. However, passive HME units may not provide sufficient heat or humidification for long-term management of certain patients. When an HME unit is to be used, it should be selected based on the individual patient's needs and ventilatory pattern and the unit's performance, efficiency, and size. All patients using HME units should be reevaluated regularly to confirm the appropriateness of continued use.

RULE OF THUMB

HME units are better suited for short-term use and during transport, whereas heated humidifiers should be used for patients requiring long-term mechanical ventilation (>96 h) or for patients for whom the use of an HME unit is contraindicated.

MINI CLINI

Heat and Moisture Exchange Versus Heated Humidifier and Ventilator Outcomes

Problem

Do HME units reduce the incidence of ventilator-associated infections?

Solution

As HME units became more common in the ICU, some studies reported a lower incidence of infections associated with their use among hospital care workers than those associated with HHs. Comprehensive reviews and meta-analysis report no significant differences in the use of HHs and HME units on the incidence of VAP, ventilator days, days of ICU stay, and overall mortality rate. It was concluded that there is insufficient evidence to recommend the use of HME units for the prevention of hospital-acquired infections.

The following table compares illustrative costs associated with three humidification strategies in terms of circuit setup costs, water usage, and labor for a typical patient requiring 12 days of mechanical ventilation at a large acute-care hospital. Labor costs were calculated as the time required to perform setup or maintenance multiplied by the average salary. This example assumes no circuit changes for a patient over 14 days and that the HME unit is changed daily.

Components of Circuit Setup and Operating Costs	Heated Humidifier With Standard Circuit	Heated Humidifier With Heated-Wire Circuit	Heat Moisture Exchanger
Vent circuit	$3.00	$11.00	$3.00
Humidifier/water feed system	$12.00	$12.00	—
HME unit filter	—	—	$5.00
Setup cost (labor)	$18.00	$23.00	$8.00
Daily cost (labor)	$11.00	$1.50	$5.00
Total costs (5 days)	$62.00	$29.00	$28.00
Total costs (12 days)	$139.00	$39.50	$63.00

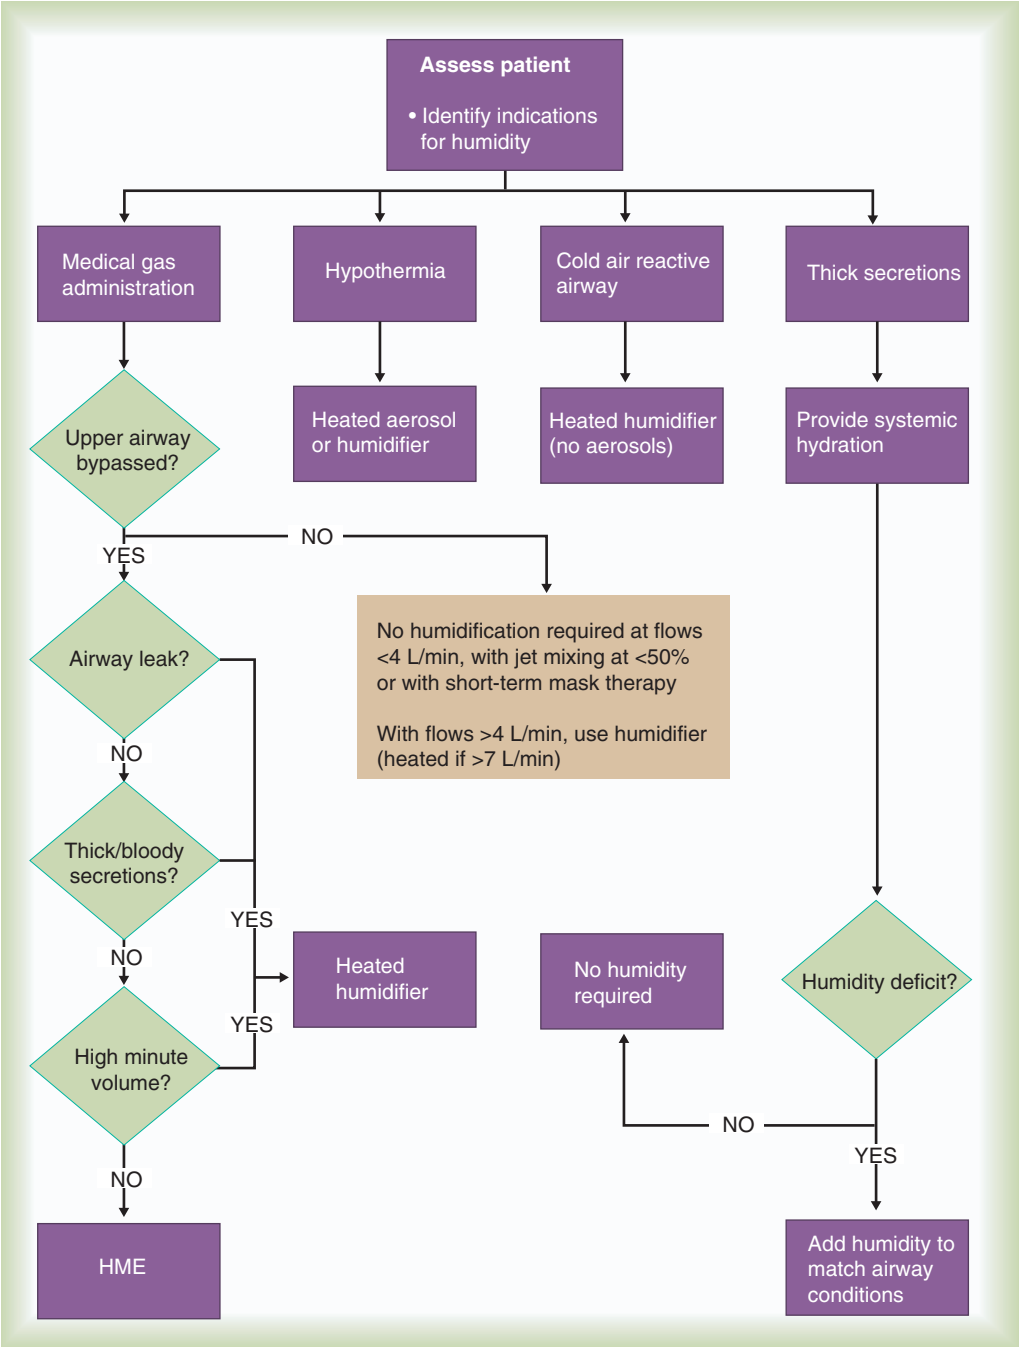

Fig. 39.20 Selection Algorithm for Humidity and Bland Aerosol Therapy. *HME,* Heat and moisture exchanger.

In this example, the standard circuit costs less than the heated-wire circuit but has twice the daily water usage, with an additional labor cost of $9.50 per day for adding and removing water from the system. The HME unit has the lowest setup cost, but after ventilator day 5, the total cost of daily filter replacement exceeds the cost associated with operation of the heated-wire circuit. However, most modern ventilator humidification systems require the purchase of their prepackaged water. This can markedly increase the cost of both unheated and heated-wire circuits. Although different component costs may shift the analysis, in general, there is no significant cost difference associated with the use of an HME, unheated-wire, and heated-wire systems. The final decision is generally based on the patient's clinical needs.

Mechanical Ventilation

Consideration of humidification device selection is patient specific. Reducing dead space with the use of a HH decreases $PaCO_2$; more importantly, if isocapnic conditions are maintained by

reducing tidal volume (V_T), this strategy improves respiratory system compliance as well as plateau airway pressure.

With heated humidity, maintaining temperature at one point in the inspiratory circuit (e.g., the Y piece), does not ensure adequate delivery of water vapor. Other factors (humidification system, expired minute volume [VE], gradient setting) are critical. At a given temperature, humidification may be significantly higher or lower than expected. Higher AH has been correlated to increased secretion volume, suggesting optimization of mucocilliary transport. This would support using a HH for patients with inspissated secretions.

Noninvasive Ventilation

NIV is often applied with a single-limb circuit with a fixed leak between the gas source and the patient's airway, typically with a mask interface. Analysis of the need for humidification during noninvasive mask ventilation (NIMV) should take into account the following parameters: air leaks, NIV interface, mechanical ventilator type, room temperature, inhaled gas temperatures and chamber vaporization, airflow and inlet pressure of the humidification system, and humidification system type. In addition, histopathologic changes in the nasal mucosa during NIV without a humidification system dictates that humidification should be considered even when short-term NIV use is expected.

The question becomes which to use: an HME or a HH during NIV? The increased dead space of an HME can affect ventilatory function and gas exchange negatively. The effect of the HME's dead space may decrease the efficiency of NIV in patients with autorespiratory failure (ARF).

When the use of HME units was randomly compared with that of HHs, minute ventilation was higher with HME units than with HHs despite similar PaCOs. The use of HME units was associated with a greater increase in WOB and other indexes of patient effort. NIV with an HME unit failed to decrease WOB compared with baseline. The addition of PEEP reduced the level of effort, but similar differences between the HME unit and HH were observed.[58] Use of an HME unit decreased CO_2 elimination during NIV despite increased minute ventilation, especially in hypercapnic subjects.[59-61] However, a multicenter randomized controlled trial reported no differences in intubation rates from NIV with HME units versus HHs (Fig. 39.21).[60]

The AH delivered to an oronasal mask during NIV is affected by gas flow and the amount of leak; moreover, it varies among patients at equivalent humidifier settings.[56] With a HH, the presence of condensate in the mask was associated with improved oral moistness and patient comfort. AH varied among the subjects, and some complained of oral dryness even with a HH. Oral breathing decreased oral moistness and worsened the feeling of dryness.[55]

High-Flow Nasal Oxygen

High-flow nasal oxygen (HFNC) use has been described in infants as well as in pediatric and adult patients. The need for heated humidity is even clearer than with NIV, as the high flow is directed into the nares, and use of an HME would not be practical. Use of heated high-flow gas in children has been reported to be more comfortable than MNIV or standard unheated nasal cannula.[62]

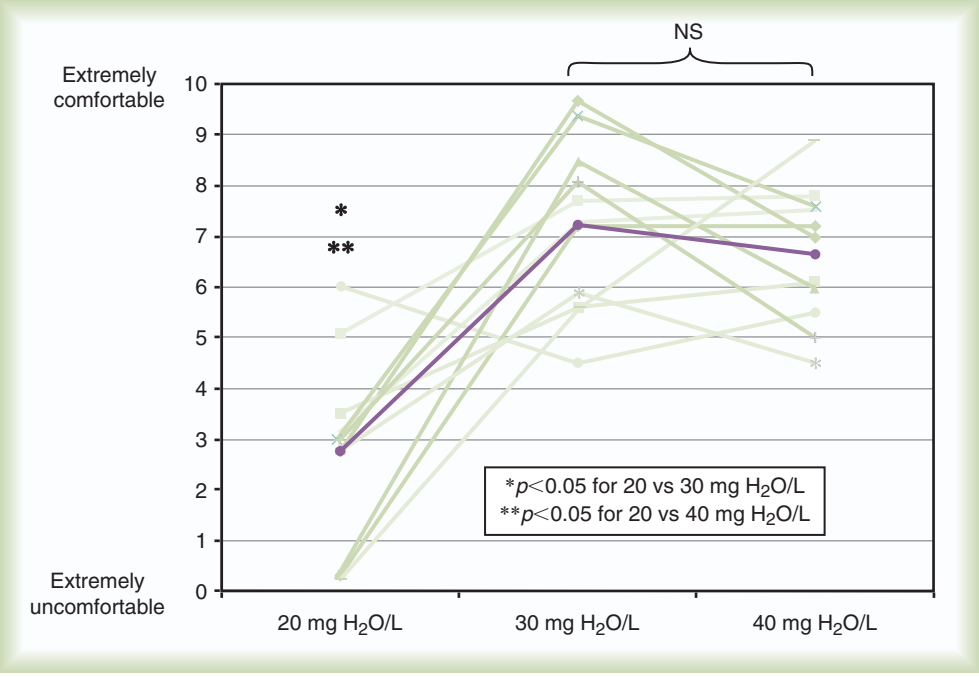

Fig. 39.21 Comfort levels with the administration of heated humidified noninvasive high-flow gas vary with absolute humidity. *NS,* Not significant. (Redrawn from Lellouche F, Bouchard PA: Hygrometry of gas delivered with different high flow oxygen humidifiers and impact on comfort of the level of hygrometry, *Intensive Care Med Exp* 3(Suppl 1):A805, 2015.)

In contrast, use of dry air has been reported to cause flow-dependent cooling of the brain in porcine models simulating adult conditions. The mechanism of cooling appears to be evaporation of nasal mucus as cooling is mitigated by humidifying the air at flows as low as 40 L/min.

Sputum Induction

As a diagnostic procedure, sputum induction (see Box 39.6) warrants separate attention from other modes of bland aerosol therapy. Sputum induction is a useful, cost-effective, and safe method for diagnosing tuberculosis, pneumocystis pneumonia (caused by *Pneumocystis jirovecii,* formerly *Pneumocystis carinii*), and lung cancer.[50,51]

The success rate of sputum induction and analysis is about 80%. Sputum induction involves short-term application of high-density hypertonic saline (3% to 10%) aerosols to the airway to help mobilize pulmonary secretions for evacuation and recovery. These high-density aerosols are often made using ultrasonic nebulization. Box 39.7 outlines a procedure for sputum induction using a 3% saline solution.[56]

To ensure a good sputum sample, every effort must be made to identify saliva from true respiratory tract secretions. Some protocols have patients brush their teeth and tongue surface thoroughly and rinse their mouths before sputum induction. Although the distinction between saliva and sputum can be made in the diagnostic laboratory, care during the collection procedure reduces the need for repeat inductions.

BOX 39.7 Monitoring

The humidifier should be inspected during the patient–ventilator system check and condensate should be removed from the circuit as needed. HMEs should be inspected and replaced if secretions have contaminated the insert or filter. The following should be recorded during equipment inspection:

- *Humidifier settings*: During routine use on an intubated patient, a HH should be set to deliver inspired gas at 34°C or greater but less than 41°C at the Y adapter in the circuit and should provide a minimum of 33 mg/L of water vapor.
- *Inspired gas temperature*: This should be monitored at or near the patient's airway opening (HH).
- *Location of probe:* For heated-wire circuits used with infants, the probe must be placed outside the incubator or away from the radiant warmer.
- *Temperature:* The high-temperature alarm should be set no higher than 41°C, and the low-temperature alarm should be set no lower than 2°C below the desired temperature at the circuit Y piece.
- *Water level and feed system:* Water level and function of automatic feed system (if applicable) should be monitored.
- *Quantity and consistency of secretions:* Quantity, consistency, and other characteristics of secretions should be noted and recorded., If secretions become copious or appear increasingly tenacious while an HME unit is being used, an HH should replace the unit.
- *Airway obstruction:* The presence of copious secretions increases the resistance of airflow through the HME unit. This may even increase peak pressures and induce changes of the flow waveforms consistent with those observed with airway obstruction. If these changes persist after changing the HME unit because of copious secretions, an HH should be used instead.

HH, Heated humidifier; *HME,* heat and moisture exchanger.

SUMMARY CHECKLIST

- Conditioning of inhaled and exhaled gas is accomplished primarily by the nose and upper airway. Bypassing the upper airway without providing similar levels of heat and humidity to inhaled gas can cause damage to the respiratory tract.
- Gases delivered to the nose and mouth should be conditioned to 20°C to 22°C with 10 mg/L water vapor (50% relative humidity).
- When being delivered to the trachea, gases should be warmed and humidified to 35°C to 40°C with 40 to 45 mg/L water vapor (>90% relative humidity).
- A humidifier is a device that adds invisible molecular water to gas.
- A nebulizer generates and disperses liquid particles in a gas stream.
- Water vapor cannot carry pathogens, but aerosols and condensate can do so.
- Temperature is the most important factor affecting humidifier output. The higher the temperature, the greater the water vapor content of the delivered gas.
- Bubble humidifiers, pass-over humidifiers, wick humidifiers, and HME units are the major types of humidifiers. Active humidifiers incorporate heating devices and reservoir and feed systems.
- At high flow rates, some bubble humidifiers can produce microaerosol particles, which can carry infectious bacteria.
- Most HME units are passive, capturing both heat and moisture from expired gas and returning it to the patient at approximately 70% efficiency. HME are not recommended for use with infants because of the increased mechanical dead space and use of uncuffed ETTs, which allow some exhaled gas to bypass the HME.
- HME are also not recommended for use in patients requiring lung-protective ventilation strategies because of the small tidal volume and increased levels of hypercapnia.
- Common problems with humidification systems include condensation, cross contamination, and ensuring proper conditioning of the inspired gas.
- Breathing circuit condensate must always be treated as infectious waste.
- Bland aerosol therapy with sterile water or saline is used to (1) treat upper airway edema, (2) overcome heat and humidity deficits in patients with tracheal airways, and (3) help obtain sputum specimens.
- Large-volume jet nebulizers and USNs are used to generate bland aerosols. Delivery systems include various direct airway appliances and mist tents.
- Common problems with bland aerosol therapy are cross contamination and infection, environmental safety, inadequate mist production, overhydration, bronchospasm, and noise.

Aerosol Drug Therapy

James B. Fink and Arzu Ari

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define the term *aerosol*.
- Describe how particle size, motion, and airway characteristics affect aerosol deposition.
- Describe how aerosols are generated.
- List the hazards associated with aerosol drug therapy.
- Describe how to select the best aerosol drug delivery system for a patient.
- Describe how to initiate and modify aerosol drug therapy.
- State the information patients need to know to self-administer drug aerosol therapy properly.
- Describe how to assess patient response to bronchodilator therapy at the point of care.
- Describe how to apply aerosol therapy in special circumstances.
- Describe how to protect patients and caregivers from exposure to aerosolized drugs.

CHAPTER OUTLINE

KEY TERMS

aerosol
aerosol output
aging

An **aerosol** is a suspension of solid or liquid particles in gas. Aerosols occur in nature as pollens, spores, dust, smoke, smog, fog, and mist. The upper airway and respiratory tract filter out larger particles to protect the lungs from invasion by these aerosols. In the clinical setting, medical aerosols are generated with **atomizers**, **nebulizers**, and inhalers. An atomizer convert liquid into droplets. Early atomizers were used for perfumes and later medical aerosol on a limited basis, using low volume gas pumps to draw liquid from a reservoir and disperse relatively large particles as individual puffs. Nebulizers produce finer aerosol particles from liquid-based formulations over greater periods of time using compressed gas (often with baffles) or electricity. Inhalers generate aerosolized medication from liquids or dry powders for a single inhalation. Aerosols can be used to deliver bland water solutions to the respiratory tract (see Chapter 39) or to administer drugs to the lungs, throat, or nose for local and systemic effect. This chapter focuses on the principles of medical aerosol drug therapy.

The aim of aerosol therapy is to deliver a therapeutic dose of the selected drugs to the desired site of action such as nose, throat, airways, or deep lung. The indication for any specific aerosol is based on the need for the specific drug.[1] Administration of drugs by aerosol offers higher local drug concentrations in the lung with lower systemic levels compared with other forms of administration. Improved therapeutic action with fewer systemic side effects provides a higher **therapeutic index** (TI).[2] A drug's TI identifies the margin of safety of the drug and is a ratio between the effective therapeutic dose (emergency department [ED]) and the toxic dose (TD) in 50% of humans. TI = TD50/ED50.

CHARACTERISTICS OF THERAPEUTIC AEROSOLS

Effective use of medical aerosols requires an understanding of the characteristics of aerosols and their effect on drug delivery to the desired site of action. Key concepts include aerosol output, particle size, deposition, and changes in the aerosol over time.

Aerosol Output

Aerosol output is the mass of fluid or drug produced by an aerosol generator per actuation or unit of time. Output varies greatly among different nebulizers and inhalers. For drug delivery systems, **emitted dose** describes the mass of drug exiting the mouthpiece of a nebulizer or inhaler as aerosol.

Aerosol output can be measured by collecting the aerosol that leaves the nebulizer on filters and measuring either their weight (gravimetric analysis) or quantity of drug (assay). Gravimetric measurement of aerosols is easier but less reliable than drug assay techniques because weight changes with water evaporation, whereas drug mass does not. A drug assay provides the most reliable measure of aerosol output.

A large proportion of particles that leave a nebulizer may never reach the lungs. The ability of aerosols to travel through the air, enter the airways, and become deposited in the lungs is based on many variables ranging from particle size to breathing pattern. Understanding and skillful manipulation of these variables can greatly improve pulmonary delivery of aerosols.

Particle Size

Aerosol particle size depends on the substance for nebulization, the method used to generate the aerosol, and the environmental conditions surrounding the particle.[3,4] It is impossible to determine visually whether a nebulizer is producing an optimal particle size. The unaided human eye cannot see particles less than 50 to 100 μm in diameter (equivalent to a small grain of sand). The only reliable way to determine the characteristics of an aerosol suspension is laboratory measurement. The two most common laboratory methods used to measure medical aerosol particle size distribution are cascade impaction and laser diffraction.[4] *Cascade impactors* are designed to collect aerosols of different size ranges on a series of stages or plates. The mass of aerosol deposited on each plate is quantified by drug assay, and a distribution of drug mass across particle sizes is calculated. In *laser diffraction,* a computer is used to estimate the range and frequency of droplet volumes crossing the laser beam.

Because medical aerosols contain particles of many different sizes (**heterodisperse**), the average particle size is expressed with a measure of central tendency, such as **mass median aerodynamic diameter (MMAD)** for cascade impaction or **volume median diameter (VMD)** for laser diffraction. These measurement techniques of the same aerosol may report different sizes, so it is important to know which measurement is used. The MMAD and VMD both describe the particle diameter in micrometers (μm). In an aerosol distribution with a specific MMAD, 50% of the particles are smaller and have less mass, and 50% are larger and have greater mass.

The **geometric standard deviation (GSD)** describes the variability of particle sizes in an aerosol distribution set at 1 standard deviation above or below the median (15.8% and 84.13%, respectively). Most aerosols found in nature and used in respiratory care are composed of particles of different sizes, described as heterodisperse. The greater the GSD, the wider the range of particle sizes and the more heterodisperse is the aerosol. Aerosols consisting of particles of similar size (GSD ≤1.2) are referred to as **monodisperse**. Nebulizers that produce monodisperse aerosols are used mainly in laboratory research and in nonmedical industries.

Deposition

When aerosol particles leave suspension in gas, they deposit on (attach to) a surface. Only a portion of the aerosol generated and emitted from a nebulizer (emitted dose) may be inhaled (inhaled dose). A fraction of the inhaled dose is deposited in the lungs (respirable dose). **Inhaled mass** is the amount of drug inhaled. The proportion of the drug mass in particles that are small enough **(fine-particle fraction)** to reach the lower respiratory tract is the **respirable mass**. Not all aerosol particles delivered to the lung are retained or deposited. A small percentage (1% to 5%) of inhaled drug may be exhaled. Whether aerosol particles that are inhaled into the lung are deposited in the respiratory tract depends on the size, shape, and motion of the particles and on the physical characteristics of the airways and breathing pattern. Key mechanisms of aerosol **deposition**

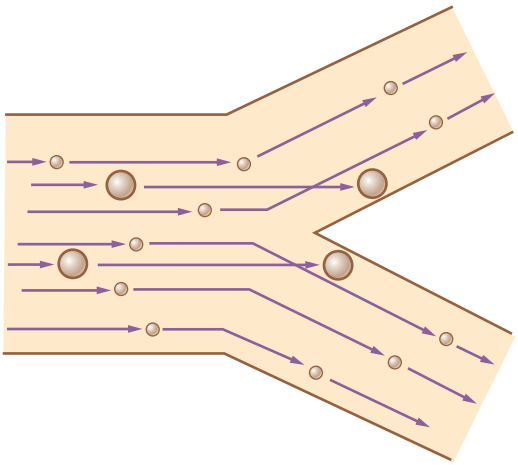

Fig. 40.1 Inertial impaction of large particles, the masses of which tend to maintain their motion in straight lines. As airway direction changes, the particles are deposited on nearby walls. Smaller particles are carried around corners by the airstream and fall out less readily.

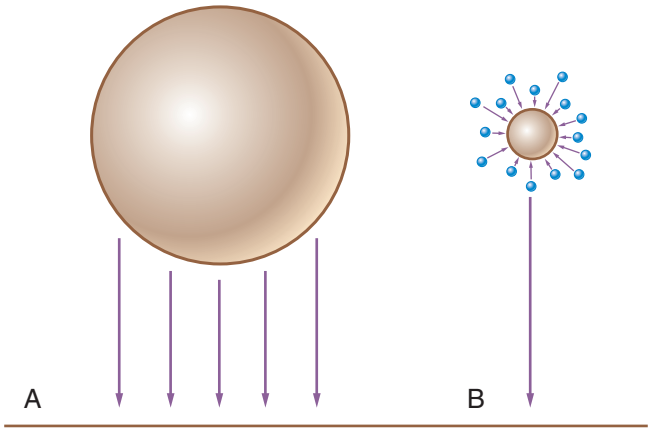

Fig. 40.2 Effect of Mass on Particle Size. Large particles (A) are more susceptible to the force of gravity than smaller particles (B), which are more affected by the bombardment of molecules deposited by diffusion.

include inertial impaction, gravimetric sedimentation, and **brownian diffusion**.[3,5]

Inertial Impaction

Inertial impaction occurs when suspended particles in motion collide with and are deposited on a surface; this is the primary deposition mechanism for particles larger than 5 µm. The greater the mass and velocity of a moving object, the greater its inertia and the greater the tendency of that object to continue moving along its set path (Fig. 40.1). When a particle of sufficient (large) mass is moving in a gas stream and that stream changes direction, the particle tends to remain on its initial path and collide with the airway surface.

Because inertia involves both mass and velocity, the higher the flow of a gas stream, the greater the tendency for particles to impact and be deposited in the airways. Turbulent flow patterns, obstructed or tortuous pathways, and inspiratory flow rates greater than 30 L/min are associated with increased inertial impaction. Turbulent flow and convoluted passageways in the nose cause most particles larger than 10 µm to impact and become deposited. This process produces an effective filter that protects the lower airway from particulates such as dust and pollen. However, particles 5 to 10 µm tend to become deposited in the oropharynx and hypopharynx, especially with the turbulence created by the transition of air as it passes around the tongue and into the larynx.

Sedimentation

Sedimentation occurs when aerosol particles settle out of suspension and are deposited owing to gravity. The greater the mass of the particle, the faster it settles (Fig. 40.2). During normal breathing, sedimentation is the primary mechanism for deposition of particles 1 to 5 µm. Sedimentation occurs mostly in the central airways and increases with time, affecting particles 1 µm in diameter. Breath holding after inhalation of an aerosol increases the residence time for the particles in the lung and enhances distribution across the lungs and sedimentation.

Diffusion

Brownian diffusion is the primary mechanism for deposition of small particles (<3 µm), mainly in the respiratory region, where bulk gas flow ceases and most aerosol particles reach the alveoli by diffusion. These aerosol particles have very low mass and are easily bounced around by collisions with carrier gas molecules. These random molecular collisions cause some particles to contact and become deposited on surrounding surfaces. Particles of size 1 to 0.5 µm are so stable that most remain in suspension and are cleared with the exhaled gas, whereas particles smaller than 0.5 µm have a greater retention rate in the lungs.

RULE OF THUMB Aerosol particle size ranging from 1 to 0.5 µm is so stable that most remain in suspension and may be cleared with the exhaled gas, whereas particles smaller than 0.5 µm have a greater retention rate in the lungs.

Fig. 40.3 summarizes the relationships between particle size and aerosol deposition in the respiratory tract. The depth of penetration and deposition of a particle in the respiratory tract tend to vary with size and tidal volume (V_T).[5] With this knowledge, it may be possible to target aerosol deposition to specific areas of the lung by using the proper particle size and breathing pattern.

RULE OF THUMB The site of deposition in the respiratory tract varies with the size of the particle. Use of nebulizers that produce particles in a specific size range improves the targeting of aerosols for deposition to a desired site in the respiratory tract, as follows:

Desired Location	Recommended MMAD
Upper airway: nose, larynx, trachea	5 to >50 µm
Lower airways	2–5 µm
Parenchyma: alveolar region	1–3 µm
Parenchyma	<0.1 µm

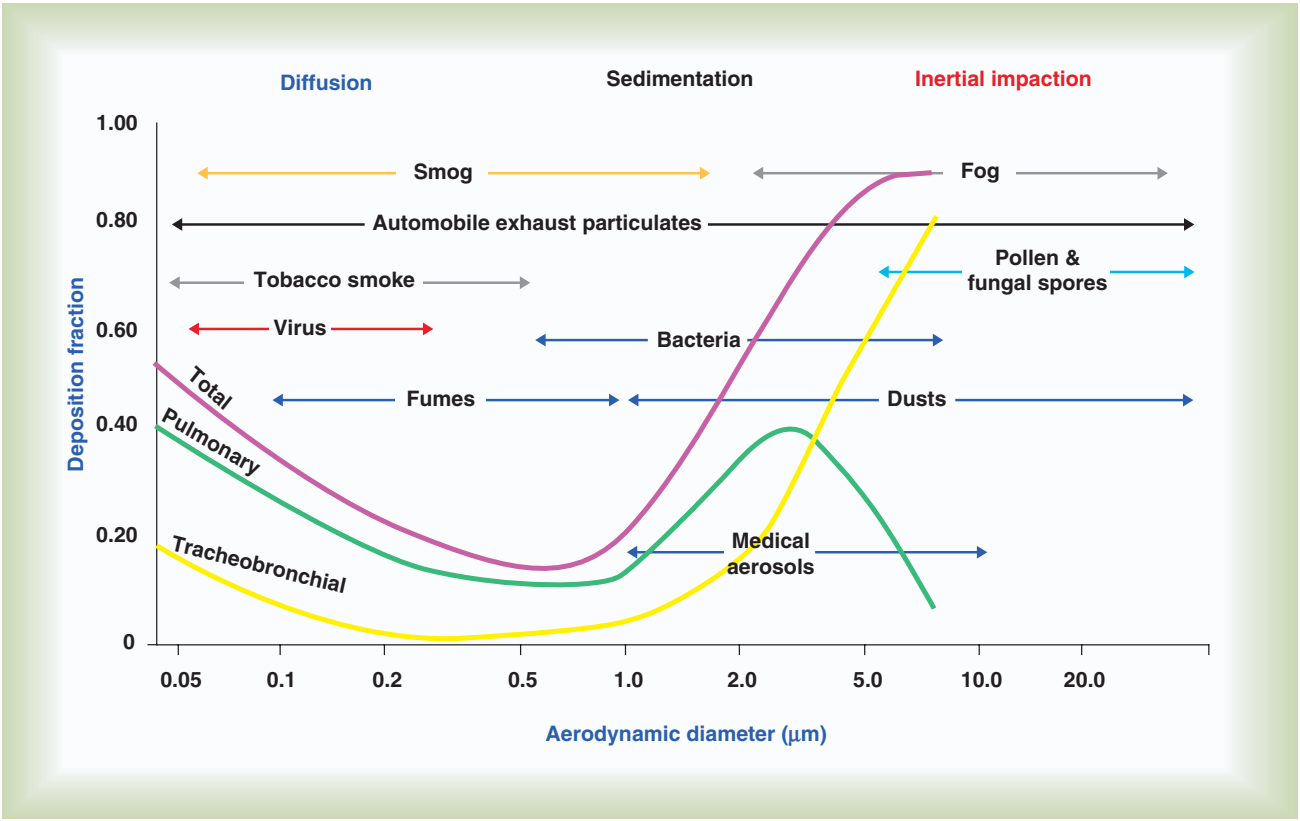

Fig. 40.3 Range of particle size for common aerosols in the environment and the influence of inertial impactions, sedimentation, and diffusion.

Aging

Aerosols are dynamic suspensions. Individual particles constantly grow, shrink, coalesce, and fall out of suspension. The process by which an aerosol suspension changes over time is called **aging**. How an aerosol ages depends on the composition of the aerosol, the initial size of its particles, the time in suspension, and the ambient conditions to which it is exposed.

Aerosol particles can change size as a result of either evaporation or **hygroscopic** water absorption. The relative rate of particle size change is inversely proportional to the size of a particle, so small particles grow or shrink faster than large particles. Small water-based particles shrink when exposed to relatively dry gas. Aerosols of water-soluble materials, especially salts, tend to be hygroscopic, absorbing water and growing when introduced into a high-humidity environment.[5]

Particle size is not the only determinant of deposition. Inspiratory flow rate, flow pattern, respiratory rate, inhaled volume, ratio of inspiratory time to expiratory time (I:E ratio), and breath holding all influence where a particle of any specific size is deposited. The presence of airway obstruction is one of the greatest factors influencing aerosol deposition. It has been shown that total pulmonary deposition is greater in smokers and patients with obstructive airway disease than in healthy persons (Fig. 40.4). Similarly, when inspiratory flow rates are constant, the deposition fraction of monodisperse aerosols increases with increased V_T, length of inspiration, and particle size.

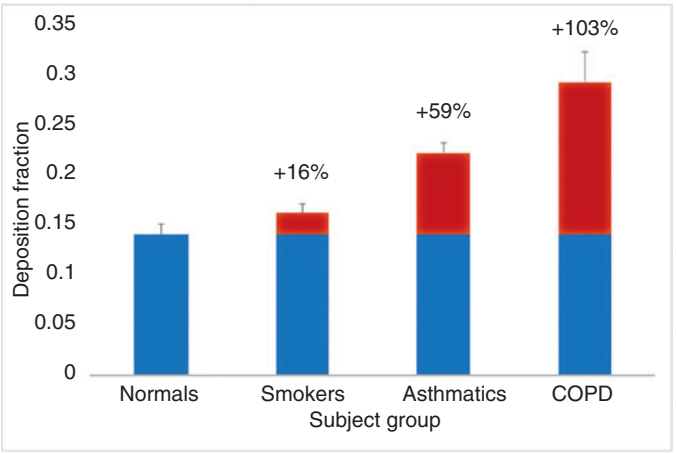

Fig. 40.4 Total lung deposition of a fine aerosol of particles 1 μm in diameter in healthy adults and in subjects with obstructive airway disease. The *red bars* indicate the percentage increase greater than normal value. *COPD,* Patients with chronic obstructive pulmonary disease.

These dynamic variables make it difficult to intuitively predict exactly what occurs to aerosol particles when they enter a gas stream and are inhaled. For this reason, prediction of actual aerosol deposition for an individual patient requires extensive computational analysis and testing.

Quantifying Aerosol Delivery

As mentioned in the preceding sections, many characteristics of aerosols can account for the variances in quantity of aerosolized medication delivered to the patient. Although the precise amount of drug delivered to the patient's airways can be difficult to determine, it can be measured in terms of the patient's clinical response to aerosol drug therapy, including the desired therapeutic effects and any unwanted adverse effects. The amount of aerosol deposited to a patient's airways can be quantified using specialized equipment and tests.

One approach used to quantify aerosol deposition involves **scintigraphy**, in which a drug is "tagged" with a radioactive substance (e.g., technetium), aerosolized, and inhaled. A scanner like those used in nuclear medicine counts the radiation distribution and intensity across the patient's head and thorax and the aerosol device. The result is a map of aerosol deposition in the upper airway, the stomach, and the lungs and device. Radiation counts are used to calculate the percentage of drug retained by the device and delivered to various areas in the patient.[6-8]

A less direct approach relates the systemic pharmacokinetic profile of a drug delivered by aerosol to an assay of the drug in a patient's blood or urine over time. This method does not directly estimate lung delivery but provides insight into systemic drug levels achieved after aerosol administration. Care must be taken to differentiate drug absorbed through the lungs from drug absorbed through the gastrointestinal tract. Simple laboratory bench, or in vitro, models, which simulate a range of V_T values, inspiratory flow rates, I:E ratios, and respiratory rates, have been useful in predicting inhaled mass of drug and relative performance of nebulizers.[9,10]

HAZARDS OF AEROSOL THERAPY

The primary hazard of aerosol drug therapy is an adverse reaction to the medication being administered (see Chapter 36). Other hazards to the patient include infection, airway reactivity, systemic effects of bland aerosols, drug concentration, and eye irritation. Care providers and bystanders risk these hazards as a result of exposure to secondhand aerosol drugs.

Infection

Aerosol generators can contribute to nosocomial infections by spreading bacteria by the airborne route.[11] The most common sources of bacteria are patient secretions, contaminated solutions (i.e., multiple-dose drug vials), and caregivers' hands. Various procedures can help to reduce contamination and infection associated with respiratory care equipment. Guidelines from the U.S. Centers for Disease Control and Prevention (CDC) state that nebulizers should be sterilized between patients, frequently replaced with disinfected or sterile units, or rinsed with sterile water (not tap water) and air dried between treatments (see Chapter 4). In addition, some recommend one nebulizer for one treatment. The Cystic Fibrosis Foundation recommends that standard small volume nebulizers (SVNs) should be discarded after each treatment to prevent infection in cystic fibrosis patients.

RULE OF THUMB Jet and ultrasonic nebulizers with medication reservoir open to the connection to the patient are susceptible to contamination. Therefore, they should be rinsed with sterile water and air dried between treatments. Tap water should not be used to clean jet nebulizers.

Airway Reactivity

Cold air and high-density aerosols can cause reactive bronchospasm and increased airway resistance, especially in patients with preexisting respiratory disease.[12] Medications such as acetylcysteine, antibiotics, steroids, ribavirin, and distilled water have been associated with increased airway resistance and wheezing during aerosol therapy. Administration of bronchodilators before or with administration of these agents may reduce the risk or duration of increased airway resistance.

The risk of inducing bronchospasm always should be considered when aerosols are administered. Monitoring for reactive bronchospasm should include auscultation for adventitious breath sounds; observation of the patient's breathing pattern before and after therapy; and most importantly, communication with the patient during therapy to determine the perceived work of breathing.

Pulmonary and Systemic Effects

Pulmonary and systemic effects are associated with the site of delivery and the drug being administered. Preliminary assessment should balance the need versus the risk of aerosol therapy, especially among patients at high risk, such as infants, patients who are prone to fluid and electrolyte imbalances, and patients with atelectasis or pulmonary edema. For patients unable to clear their own secretions, suctioning or other airway clearance techniques may be indicated as an adjunct to aerosol therapy. Care must be taken to ensure that patients are capable of clearing secretions when the secretions are mobilized by aerosol therapy. Appropriate airway clearance techniques should accompany any aerosol therapy designed to help mobilize secretions (see Chapter 44).

RULE OF THUMB Patients should be monitored continuously during aerosol treatment to avoid hazards such as reactive bronchospasm and accumulation of secretions and obstructing the airway. Patient monitoring should include auscultation for adventitious breath sounds; observation of the patient's breathing pattern and overall appearance before and after therapy; and, most essential, communicating with the patient during therapy to determine the perceived work of breathing.

Drug Concentration

During nebulization, the evaporation, heating, baffling, and recycling of drug solutions undergoing jet or ultrasonic nebulization increase solute concentrations.[9] This process can expose the patient to increasingly higher concentrations of the drug

over the course of therapy and result in a higher concentration of drug remaining in the nebulizer at the end of therapy. This increase in concentration is often time-dependent with the greatest effect occurring during nebulization over extended periods, as in continuous aerosol drug delivery.

Eye Irritation

Aerosol administration via a face mask may deposit drug in the eyes and cause eye irritation. In very rare cases, anticholinergic medications (see Chapter 36) have been suspected to worsen preexisting eye conditions, such as forms of glaucoma. Caution should be exercised when a face mask is used during aerosol drug therapy. In addition, special mask designs that have been shown to reduce drug deposition in the eyes or mouthpieces should be considered for at-risk patients.[13,14]

Secondhand Exposure to Aerosol Drugs

Workplace exposure to aerosols may be detectable in the plasma of bystanders and healthcare providers. Repeated secondhand exposure to bronchodilators is associated with increased risk of occupational asthma. Institutions should develop and implement an occupational health and safety policy to minimize the risk of secondhand aerosol exposure for care providers and bystanders.[15-17] Implementation of an occupational health and safety policy should include using systems that introduce less fugitive emissions of aerosol to the atmosphere generated by both aerosol devices and patients. These include filtering exhalation to contain aerosol, producing aerosol only during inspiration and using environmental controls. Up to 70% of aerosol generated by SVNs directly enter the environment. Unless filters are placed in the expiratory limb, 40% of aerosols produced during mechanical ventilation are exhausted to the air of the intensive care unit (ICU).[18]

AEROSOL DRUG DELIVERY SYSTEMS

Effective aerosol therapy requires a device that quickly delivers sufficient drug to the desired site of action with minimal waste and at a low cost.[19] Aerosol generators in use include pressurized metered dose inhalers (pMDIs) with or without spacers or valved holding chambers (VHCs), dry powder inhalers (DPIs), small and large volume (jet) nebulizers, hand-bulb atomizers and nasal spray pumps, ultrasonic nebulizers (USNs), and vibrating mesh (VM) nebulizers, as well as numerous emerging technologies.[2]

Pressurized Metered Dose Inhalers

The pMDI is the most commonly prescribed method of aerosol delivery in the United States (Fig. 40.5). The pMDI is portable, compact, and easy to use and provides multidose convenience. A uniform dose of drug is dispensed within a fraction of a second after actuation and is reproducible throughout the canister life. The pMDI and actuator are designed for the specific drug formulation, propellants, and dose volume to be delivered. The pMDI is used to administer bronchodilators, anticholinergics, and steroids. More formulations of these drugs are available for use by pMDIs than for use with nebulizers. When properly used, pMDIs are at least as effective as other nebulizers for drug delivery. For this reason, pMDIs often are the preferred method for delivering bronchodilators to spontaneously breathing patients and patients who are intubated and undergoing mechanical ventilation.[20-22]

Fig. 40.5 An Example of a Commonly Used Pressurized Metered Dose Inhaler.

Although pMDIs have relatively easy-to-use design, patients commonly misuse them during therapy. Most pMDIs are "press and breathe," but there is increasing presence of a variation known as *breath-actuated pMDIs*. The basic components of pMDI are similar regardless of type, manufacturer, or active ingredient; commonly used pMDIs are shown in Fig. 40.6.

The pMDI appears to be a simple device, but it represents sophisticated technology and engineering. A pMDI is a pressurized canister that contains the prescribed drug (a micronized powder or aqueous solution) in a volatile **propellant** combined with a surfactant and dispersing agent. Propellant is defined as a compressed inert gas that helps to dispense aerosolized medications when the pressure is released. When the canister is inverted (nozzle down) and placed in its actuator, or "boot," the volatile suspension fills a metering chamber that controls the amount of drug delivered. Pressing down on the canister aligns a hole in the metering valve with the metering chamber. The high propellant vapor pressure quickly forces the metered dose out through this hole and through the actuator nozzle.

Aerosol production takes approximately 20 ms. As the liquid suspension is forced out of the pMDI, it forms a plume, within which the propellants vaporize. Initially, the velocity of this plume is high (approximately 15 m/s). However, within 0.1 second, the plume velocity decreases to less than half its maximum as the plume moves away from the actuator nozzle. At the same time, propellant evaporation causes the initially large particles (35 μm) generated at the actuator orifice to decrease rapidly in size.

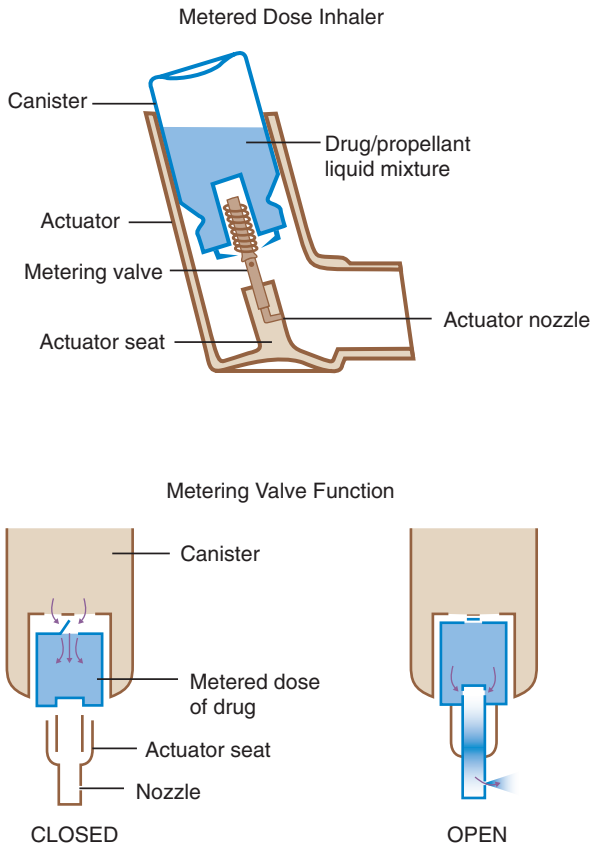

Fig. 40.6 Components of a Pressurized Metered Dose Inhaler, Including Function of the Metering Valve. (From Gardenhire DS: *Rau's respiratory care pharmacology*, ed 8, St. Louis, 2012, Mosby.)

The output volume of pMDIs ranges from 30 to 100 mcL. Approximately 60% to 80% by weight of this spray consists of the propellant, with only approximately 1% being active drug (50 mcg to 5 mg, depending on the drug formulation). For a chlorofluorocarbon (CFC) pMDI used in a standard actuator, loss of drug in the valve stem housing and on the actuator mouthpiece amounts to 10% to 15% of the nominal dose from the metering valve.

From their inception in the mid-1950s to the beginning of the 21st century, **chlorofluorocarbons (CFCs)** such as Freon were the propellants used in pMDIs. Manufacture of CFCs for most applications has now been prohibited because of the effect of these compounds on global warming, with a period of transition provided for pMDIs. A consortium of eight pharmaceutical companies developed **hydrofluoroalkane (HFA)**-134a to be more environment friendly and possibly clinically safer than CFCs.[23] Redesign of key components of the pMDI has resulted in improved performance.[23,24]

In addition to the propellant, pMDIs use dispersal agents to improve drug delivery by keeping the drug in suspension. The most common dispersal agents are surfactants, such as soy lecithin, sorbitan trioleate, and oleic acid. These agents help to keep the drug suspended in the propellant and lubricate the valve mechanism but may also cause adverse responses (coughing or wheezing) in some patients.[25,26]

Every pMDI should be primed by shaking and actuating the device to atmosphere one to four times (see label for the specific device) before initial use and after storage. Without priming, the initial dose actuated from a new pMDI canister contains less active substance than subsequent actuations.[25,26] This "loss of dose" from a pMDI occurs when drug particles rise to the top of the canister over time ("cream"). A reduction in emitted dose with the first actuation commonly occurs with a pMDI after storage, particularly with the valve pointed in the downward position. Loss of prime is related to valve design and occurs when propellant leaks out of the metering chamber during periods of nonuse (e.g., 4 hours). The result is reduced pressure and drug released with the next actuation.[25,26] Improved designs of metering valves developed for use with HFA propellants reduce these losses. It is recommended that a single dose be wasted before the next dose is inhaled when a CFC pMDI has not been used for 4 to 6 hours. An HFA pMDI requires no wasting of dose for periods exceeding 2 days.

Breath-Actuated Pressurized Metered Dose Inhaler

A variation of a pMDI is a **breath-actuated nebulizer**, which incorporates a trigger that is activated during inhalation. The trigger theoretically reduces the need for the patient or caregiver to coordinate pMDI actuation with inhalation.[26] Evaluation of the efficacy of breath-actuated pMDIs in children younger than 6 years is limited, and their use should be restricted to older children and adults. Oropharyngeal deposition of steroids using these devices is still very high.

RULE OF THUMB

- A pressurized metered dose inhaler (pMDI) has a press-and-breathe design; a breath-actuated pMDI incorporates a trigger that is activated with inspiration.
- Before initial use and after storage, every pMDI should be primed by shaking and actuating the device to atmosphere one to four times, depending on the label.

Dose Counters

A serious limitation of multidose inhalers is the lack of a "counter" to indicate the number of doses remaining in the canister. After the number of label doses has been administered, the pMDI may appear to give another 20 to 60 doses, which may deliver little or no medications as the doses "tail off." The *tail-off effect* refers to variability in the amount of drug dispensed toward the end of the life of the canister. The result of tail-off is swings from normal to almost no dose emitted from one breath to the next with no reliable indicator to the user. Without a dose counter, there is no viable method to determine remaining drug in a pMDI other than manually keeping a log of every dose taken. The US Food and Drug Administration (FDA) is requiring all new pMDIs to have counter technology to track pMDI actuations remaining. Third-party dose counters may be added to older pMDI models but may not have the accuracy of built-in technology (Fig. 40.7).

Fig. 40.7 Dose counters may be mounted on the top of a pressurized metered dose inhaler canister integrated in the actuator boot.

MINI CLINI

Using Universal Pressurized Metered Dose Inhaler Actuator or Boot

Problem

The association of CFCs with degradation of the earth's atmosphere and the ozone layer has resulted in an international treaty banning use of these compounds. As HFAs become the propellants of choice, a problem arises. If the CFC and HFA drug formulations are bioequivalent, can these compounds be used with the same (universal) pMDI actuator, or boot?

Discussion

In the case of HFA-based albuterol (e.g., Proventil HFA), the operating pressure and stem orifice differ from those used for the CFC formulation. The result is different plume geometries. When HFA albuterol is used in a universal adapter designed for CFC albuterol, the MMAD and GSD are greatly increased. The result is that significantly less drug is available to the patient. When possible, accessory devices that are used in the manufacturer's boot with the pMDI should be selected. If these devices are unavailable, the universal adapter device that is available should be evaluated to determine how much additional dose may be required to provide an equivalent dose through a third-party adapter.

Factors Affecting Pressurized Metered Dose Inhaler Performance and Drug Delivery

Temperature. Low temperature (<10°C) decreases the output of CFC pMDIs. Patients with cold air–induced bronchospasm who keep their pMDIs in outer coat pockets when outside in cold winter weather may receive only a small percentage of drug compared with that administered with the same pMDI at 25°C. This problem has been less serious with the newer HFA pMDIs.[25,26]

Nozzle size and cleanliness. Aerosol drug delivery is influenced by nozzle size and cleanliness. Nozzle size is pMDI specific. As debris builds up on the nozzle or actuator orifice, the emitted dose is reduced.[27,28] Manufacturer recommendations should be followed for cleaning. pMDI canisters should never be placed under water.

BOX 40.1 Optimal Technique for Use of a Pressurized Metered Dose Inhaler

1. Warm the pMDI canister to hand or body temperature and shake it vigorously.
2. Before first use of a new pMDI and when the pMDI has not been used for several days, prime the pMDI by pointing it into the air (away from people) and actuating a couple of times.
3. Assemble the apparatus and uncap the mouthpiece, ensuring there are no loose objects in the device.
4. Open-mouth technique: Open your mouth wide, keeping tongue down. Hold the pMDI with the canister oriented downward and the outlet aimed at your mouth. Position the pMDI approximately 4 cm (two fingerbreadths) away from your mouth.
5. Closed-mouth technique: Place mouthpiece between lips, with tongue out of the path of the outlet.
6. Breathe out normally.
7. As you slowly begin to breathe in (<0.5 L/s), actuate the pMDI.
8. Continue inspiration to total lung capacity.
9. Hold your breath for up to 10 s. Then relax and breathe normally.
10. Wait 1 min between puffs.
11. Disassemble the apparatus, and recap the mouthpiece.

pMDI, Pressurized metered dose inhaler.

Priming. Priming is defined as shaking the device and releasing one or more sprays into the air when the pMDI is new or has not been used for a while. It is done to mix the drug and the propellant, which can separate in the canister over time. Priming is required to provide an adequate dose, according to the manufacturer's guidelines.

Timing of actuation intervals. Manufacturers recommend 30 seconds to 1 minute between actuations. When propellants are released, the device cools, changing aerosol output. The pause allows the device to return to room temperature and recover normal output. However, previous research[29] showed that pMDI output is similar at 15-second intervals. Very rapid actuation of multiple puffs per breath reduces inhaled drug per puff.

Aerosol Delivery Characteristics

Although pMDIs can produce particles in the respirable range (MMAD 2 to 6 μm),[26] the initial velocity and dispersion of the aerosol plume generate larger particles that decrease in size as they leave the pMDI, resulting in approximately 80% of the dose leaving the actuator to impact and become deposited in the oropharynx. A significant proportion of this oropharyngeal deposition is swallowed and may be a factor in systemic absorption of some drugs. Pulmonary deposition ranges from 10% to 20% in adults and larger children (less in infants).[30] The exact amount of drug delivered to an individual patient is unpredictable because of high variability between patients and because pMDI drug administration is technique dependent.

Technique

The successful administration of aerosol drugs by pMDI is highly technique dependent. Two-thirds of patients and healthcare professionals who teach pMDI use do not perform the procedure properly.[31] Box 40.1 outlines the recommended steps for

self-administering a bronchodilator by pMDI. Patient instruction requires 10 to 30 minutes and should include demonstration, practice, and confirmation of patient performance (demonstration pMDIs with placebo are available from manufacturers for this purpose). Repeated instruction improves performance; repeat instruction is done most appropriately with follow-up clinic or home visits. Demonstration and return demonstration must occur several times for best patient adherence to device use.

For best effect, the pMDI should be actuated once at the beginning of inspiration. Common hand–breath coordination problems include actuating the pMDI before or after the breath. Some patients, especially infants, young children, elderly adults, and patients in acute distress, may be unable to coordinate actuation of the pMDI with inspiration. Some patients exhibit a "cold Freon effect," which occurs when the cold aerosol plume reaches the back of the mouth and the patient stops inhaling. All of these problems reduce aerosol delivery to the lung to the point that the patient does not benefit from the medication, but they can be corrected entirely or in part by use of the proper pMDI accessory device.

Most pMDI labels call for placing the mouthpiece between the lips. However, positioning the outlet of the pMDI approximately 4 cm (two finger lengths) in front of the mouth improves lung deposition by decreasing oropharyngeal impaction.[32] Holding the canister outside the open mouth (at two finger lengths) provides a space for the particles to decelerate while evaporating, allowing particle size to reduce to respirable size. Using the open-mouth technique with a low inspiratory flow rate can result in a doubling of the dose delivered to the lower respiratory tract of an adult from approximately 7% to 10% to 14% to 20%. However, this technique is more difficult for patients to perform reliably than the closed-mouth technique. Although it may reduce oropharyngeal deposition, the technique has not been shown to improve the clinical response to pMDI bronchodilators.

MINI CLINI

High Oral Deposition With Pressurized Metered Dose Inhalers

Problem

High oral deposition with pMDIs.

Discussion

The manufacturer labels for pMDIs call for placing the mouthpiece between the lips. However, positioning the outlet of the pMDI approximately 4 cm (two finger widths) in front of the mouth improves lung deposition up to twofold in adults from approximately 7%–10% to 14%–20% by decreasing oropharyngeal impaction.[32] Holding the canister outside the open mouth provides a space for the particles to decelerate while evaporating, allowing particle size to reduce to a more respirable size. Although it may reduce oropharyngeal deposition, the technique is more difficult for some patients and has not been shown to improve the clinical response to pMDI bronchodilators.

Concerns have been raised about use of the open-mouth technique with ipratropium bromide because poor coordination can result in drug being sprayed into the eyes. Use of anticholinergic agents has been associated with increased ocular pressure, which could be dangerous for patients with glaucoma. For avoidance of ocular exposure, the drug manufacturer recommends that patients use the closed-mouth technique with ipratropium.

The high percentage of oropharyngeal drug deposition with use of steroid pMDIs can increase the incidence of oral yeast infection (thrush) and changes in the voice (dysphonia). Rinsing the mouth after steroid use can help to avoid this problem, but most pMDI steroid aerosol impaction occurs deep in the hypopharynx, which cannot be easily rinsed with gargling. For this reason, steroid pMDIs should not be used alone but always in combination with a spacer or VHC. See Box 40.2 for instructions for determining dosage left in the pMDI.

BOX 40.2 Determining Dose Left in Pressurized Metered Dose Inhaler

Tracking the number of actuations (puffs) remaining in a pMDI can be done with or without dose counters (see Fig. 40.7).

With Dose Counters

The user should:[29]

1. Determine how many puffs of drug the pMDI has when full.
2. Learn to read the counter display, because each dose counter has a different way of displaying doses left in the canister.
3. Check the counter display to track the pMDI actuations remaining in the canister.
4. Reorder the pMDI when there are a few days of drug remaining.
5. Dispose of the pMDI properly, after the last dose is dispensed.

Without Dose Counters

The user should:[29]

1. Read the label to determine how many puffs of drug the pMDI has when full.
2. Calculate how long the pMDI will last by dividing the total number of puffs in the pMDI by the total puffs used per day. If the pMDI is used more often than planned, it will run out sooner.
3. Identify the date that the medication will run out, and mark it on the canister or on a calendar.
4. For drugs that are prescribed to be taken as needed, track the number of puffs of drug administered on a daily log sheet and subtract them from the remaining puffs to determine the amount of medication left in the pMDI.
5. Keep the daily log sheet in a convenient place, such as taped to the bathroom mirror.
6. Refill the pMDI prescription when there are a few days of use remaining in the pMDI.
7. Dispose of the pMDI properly when the last dose is dispensed.

pMDI, Pressurized metered dose inhaler.

Pressurized Metered Dose Inhaler Accessory Devices

Various pMDI accessory devices have been developed to overcome the two primary limitations of these systems: hand–breath coordination problems and high oropharyngeal deposition. Accessory devices include spacers and VHCs.

Spacers and valved holding chambers. Spacers and VHCs are designed to reduce both oropharyngeal deposition and the need for hand–breath coordination. A spacer is a simple valveless extension device that adds distance between the pMDI outlet and the patient's mouth. This distance allows the aerosol plume

Fig. 40.8 Pressurized metered dose inhaler and accessory devices consisting of spacer and holding chambers. All of the accessory devices reduce oropharyngeal deposition. Small volume spacers such as (A) the unidirectional spacer (RTC 15-D) (Courtesy Instrumentation Industries, Bethel Park NC) and (B) the bidirectional spacer (Dual Spray Mini Spacer) (Courtesy Thayer Medical, Tucson, AZ) offer no additional advantage, but the large volume spacers, (C) Aerovent (Courtesy Monaghan/Trudell Medical) and (D) Aerochamber Plus Z Stat (Courtesy Monaghan/Trudell Medical, London, Canada), improve inhaled aerosol with delay between actuation and inspiration. Different colors of AeroChamber Plus Z Stat represent different patient populations. For instance, *orange* is for infants, while *yellow* is for children and *blue* is for adults.

to expand and the propellants to evaporate before the medication reaches the oropharynx. Larger particles leaving the pMDI tend to impact on the spacer walls. In combination, this phenomenon reduces oropharyngeal impaction and increases pulmonary deposition. VHCs incorporate one or more valves that prevent aerosol in the chamber from being cleared on exhalation. This allows patients with a small V_T to empty the aerosol from the chamber over two or more successive breaths. In general, holding chambers provide less oropharyngeal deposition, higher respirable drug dosages, and better protection from poor hand-breath coordination than simple spacers. VHCs protect the patient from poor hand–breath coordination, with exhaled gas venting to the atmosphere, allowing aerosol to remain in the chamber, available to be inhaled with the next breath. VHCs allow infants, small children, and adults who cannot control their breathing pattern to be treated effectively with pMDIs.

Types of accessory devices. Basic concepts for spacer devices include: (1) small volume adapters, (2) open tube designs, (3) bag reservoirs, and (4) VHCs (Fig. 40.8). More than a dozen different devices with volumes ranging from 15 to 750 mL have been developed over the past 30 years. Despite differences in design, all spacers add distance between the pMDI and the mouth, reducing the initial forward velocity of the pMDI droplets, which occurs with partial evaporation of propellant in the time the aerosol traverses the length of the spacer. The reduction in initial forward velocity decreases the number of nonrespirable particles reaching the airway. The same drug used with different accessory devices may produce differences in MMAD, GSD, and fine-particle fraction. The quantity of respirable drug available at the spacer or VHC depends on spacer volume and design and formulation. The placement of a valve between the pMDI, the chamber, and the mouthpiece works like a baffle, reducing the size of particles inhaled. A simple tube spacer may reduce oral deposition by 90%, whereas a VHC can reduce oral deposition by 99%.

It is increasingly common practice to provide asthmatic patients an accessory device to use with the pMDI and to teach them how to use the pMDI with and without the accessory device. Patients are instructed to use the device with the pMDI whenever they feel short of breath. Many of these patients find that they get much better relief from the pMDI with an accessory device than with the pMDI alone.

Proper use of a simple open-tube spacer still requires some hand–breath coordination because a momentary delay between triggering and inhaling the discharged spray results in a substantial loss of drug and reduced lung delivery. Exhalation into a simple spacer after pMDI actuation clears the aerosol from the device and wastes most of the dose to the atmosphere. This reduction in dose also occurs with small volume reverse-flow design spacers if there is no provision for "holding" the aerosol in the device.[33]

The MMAD of the aerosol emitted from the pMDI exiting a spacer decreases approximately 25%, whereas the fraction containing particles less than 5 μm in diameter increases. This change is largely due to rapid evaporation of propellant in the spacer. With VHCs, in addition to evaporation of the plume, the valves act as baffles of larger particles, increasing the respirable fraction further.

VHCs produce a finer, slower moving, more "respirable" aerosol with less impaction of drug in the oropharyngeal area (1% of dose) than simple spacers (10%) or a pMDI alone (80% of dose). Research suggests that a properly used pMDI and aerochamber can significantly reduce oropharyngeal deposition versus an

open-mouth technique while maintaining drug dose delivery to the lungs. This finding was true for both healthy subjects and patients with chronic obstructive pulmonary disease (COPD).[34] The advantage of reduced oropharyngeal deposition is fewer side effects from steroid aerosols. Multiple actuations of one or more drugs into a spacer reduce both the total dose and the respirable dose of drug available for inhalation. The extent of these losses may vary for different drugs and spacer designs.[35,36]

VHCs with masks are available for use in the care of infants, children, and adults. These units allow effective administration of aerosol from a pMDI to patients who are unable to use a mouthpiece device (because of their size, age, coordination, or mentation). VHCs are helpful in administering pMDI steroids because deposition of the drug in the mouth is largely eliminated, and systemic side effects can be minimized.

Even with a VHC, respirable particles containing drug settle out and become deposited within the device, causing a whitish buildup on the inner chamber walls. This residual drug poses no risk to the patient but should be rinsed out periodically. Plastic spacers decrease drug output due to the presence of an electrostatic charge. With these devices, a buildup of material can be seen on the walls of the chamber. As more material builds up on the wall of the chamber, the charge is dissipated, and more drug is inhaled by the patient. Washing the chamber with water (without soap) causes the electrostatic charge to be reestablished, making the device less effective for the next few puffs, until the static charge in the chamber (which attracts small particles) is again reduced.[37] Optimal technique is outlined in Box 40.3.

Use of conductive metal or nonelectrostatic plastic chambers or washing the plastic chamber periodically with deionizing detergent (liquid dishwashing soap) can overcome the loss of fine-particle mass owing to electrostatic charge and increase the inhaled mass from 20% to 50% of the emitted dose of the pMDI, even in children.[1] The effect of washing the chamber with conventional dishwashing soap reduces this static charge for up to 30 days. All manufacturers recommend that VHCs and spacers should be cleaned regularly, typically monthly, using dilute liquid dishwashing soap, with or without rinsing, and allowing them to air dry.

The addition of a one-way valve to convert an open tube into a reservoir for the aerosol, the incorporation of the actuator in the pMDI, the shape of the device, flow of air through the device, edge effects, masks, and manufacturing materials all affect aerosol characteristics. The inhalation valve, which is used to contain the aerosol, also acts as a baffle to reduce oropharyngeal deposition. This valve must be able to withstand the initial pressure from the pMDI when the device is triggered to retain aerosol and have sufficiently low resistance to open readily when the user inhales, in particular when the user is a child or an infant. Exhalation valves in a face mask attached to a spacer device must also provide low resistance. Issues of spacer volume, V_T, frequency of breathing, and mechanical dead space between the spacer and mouth are of particular concern when these devices are used by children.[37] There are twofold to threefold differences in the amount of drug available at the mouth when different spacers are used to treat infants. Clinicians should determine the delivery efficiencies of spacer devices before using the device in a particular population.

Accessory devices are used with either the manufacturer-designed boot that comes with the pMDI or with a "universal adapter" that triggers the pMDI canister. Formulations of pMDI drugs operate at varying pressures and have a different-sized orifice in the boot that are specifically designed by the manufacturer for use exclusively with that pMDI. The output characteristics of a pMDI change when an adapter with a different-sized orifice is used. With HFA pMDIs, the diameter of the actuator orifice is smaller and the spray is predictably finer. When the HFA pMDI is used in an actuator designed for use with CFC pMDIs, output is reduced. When these HFA formulations are used with any particular spacer, it is important to know how comparable the available dose and particle size distribution are to the dose and particle size from an existing CFC pMDI.

BOX 40.3 Optimal Technique for Use of a Metered Dose Inhaler With a Valved Holding Chamber

1. Warm the pMDI to hand or body temperature.
2. Assemble the apparatus, ensuring there are no objects or coins in the chamber that could be aspirated or obstruct outflow.
3. Hold the canister vertically and shake it vigorously. Prime if necessary.
4. Place the pMDI in the holding chamber inlet, position chamber outlet in the mouth (or place the mask over nose and mouth), and encourage the patient to breathe through the mouth. Visually inspect for proper valve function.
5. With normal breathing, actuate the pMDI once and have the patient breathe through the device for three to seven breaths (three breaths for adults and seven breaths for infants).[a]
6. Allow 30 to 60 s between actuations.

[a]For a cooperative patient, synchronizing actuation at the beginning of larger breaths with breath holding may be encouraged. However, this maneuver has not been shown to increase clinical response to inhaled bronchodilators.

pMDI, Pressurized metered dose inhaler.

Cost

Many hospitals are moving away from the use of HFA pMDIs because of the high cost of these devices. Regardless of drug delivered, these devices cost between $200 and $300 in the United States compared with pennies a dose for the same drug in a liquid preparation to be used in a nebulizer. The use of these less expensive preparations with a VM nebulizer (see later discussion) has now become the norm in many hospitals because of cost.

Dry Powder Inhalers

A DPI is typically a breath-actuated dosing system. With a DPI, the patient creates the aerosol by drawing air though a dose of finely milled drug powder with sufficient force to disperse and suspend the powder in the air. DPIs are inexpensive, do not need propellants, and do not require the hand–breath coordination needed for pMDIs. However, dispersion of the powder into respirable particles depends on the creation of turbulent flow in the inhaler. Turbulent flow is a function of the ability of the

patient to inhale the powder with a sufficiently high inspiratory flow rate (Fig. 40.9). In terms of both lung deposition and drug response, DPIs are as effective as pMDIs.[38,39]

RULE OF THUMB

- Unlike pMDIs, DPIs do not require hand–breath coordination but require patients to generate a high inspiratory flow to disaggregate and disperse drug powder into respirable particles.

Equipment Design and Function

Most passive dry powder–dispensing systems require the use of a carrier substance (lactose or glucose) mixed into the drug to enable the drug powder to disaggregate more readily and flow out of the device. Reactions to lactose or glucose seem to be fewer than reactions to the surfactants and propellants used in pMDIs, even though the amount of these substances is substantially greater than the amount of the drug and can represent 98% or more of the weight per inhaled dose in some formulations.

As shown in Fig. 40.10A to C, there are numerous DPIs on the market, which can be divided into three categories based on the design of their dose containers: (1) unit-dose DPI, (2) multiple unit-dose DPI, and (3) multiple-dose drug reservoir DPI.

Unit-dose DPIs, such as the Aerolizer (Schering-Plough, Kenilworth, NJ), Arcarta Neohaler (Sunovion Pharmaceuticals Inc, Marlborough, MA), and the HandiHaler (Boehringer Ingelheim, Ingelheim am Rhein, Germany), dispense individual doses of drug from punctured gelatin capsules. Multiple unit-dose DPIs (Diskhaler; GlaxoSmithKline, Philadelphia) contain a case of four or eight individual blister packets of medication on a disk inserted into the inhaler. Multiple-dose DPIs include the Twisthaler (Schering-Plough), Flexhaler (AstraZeneka, London, UK), and the Diskus (GlaxoSmithKline). The Twisthaler and Flexhaler have a multidose reservoir powder system preloaded with a quantity of pure drug sufficient for dispensing 120 doses of medication, and the Diskus incorporates a tape system that contains up to 60 sealed single doses (Fig. 40.11).

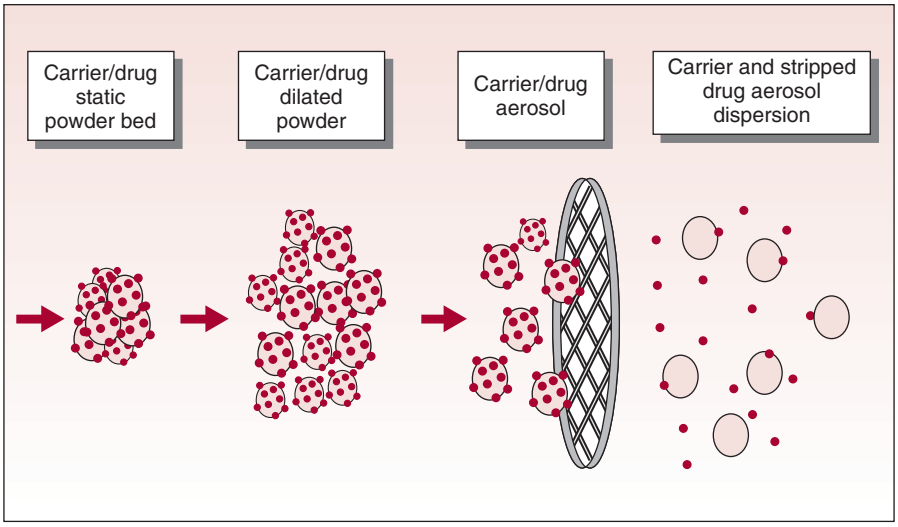

Fig. 40.9 Aerosolization of Dry Powder.

Fig. 40.10 Some currently available dry powder inhalers *(DPIs)*: (A) unit-dose DPI (Courtesy Arcapta Neohaler, Sunovion Pharmaceuticals), (B) multiple unit-dose DPI (Dishaler) (Courtesy GlaxoSmithKline), and (C) multiple-dose DPI (Discus) (Courtesy GlaxoSmithKline).

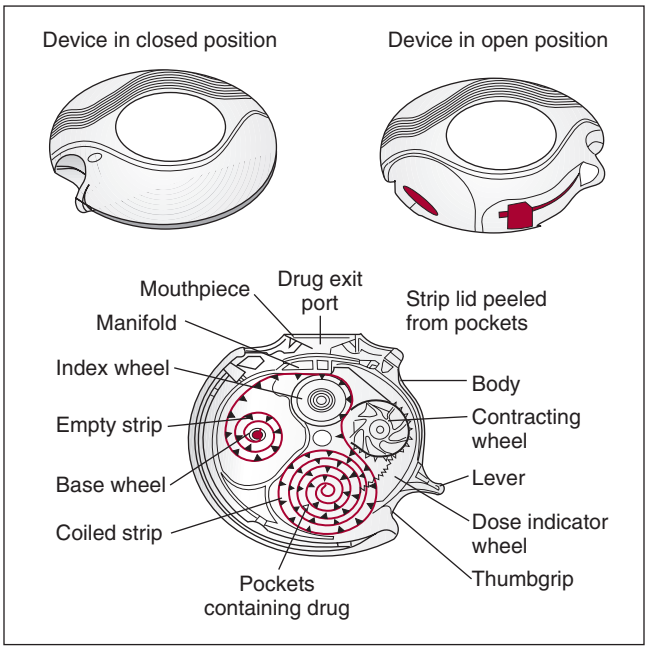

Fig. 40.11 Diskus Dry Powder Inhalers (Modified from Dhand R, Fink J: Dry powder inhalers. Resir Care 44:940, 1999).

The particle size of the dry powder particles of drug ranges from 1 to 3 µm. However, the size of the lactose or glucose particles can range from approximately 20 to 65 µm, so most of the carrier (≤80%) is deposited in the oropharynx.

Factors Affecting Dry Powder Inhaler Performance and Drug Delivery

Intrinsic resistance and inspiratory flow rate. Optimal performance for each DPI design occurs at a specific inspiratory flow rate. The fine-particle fraction of respirable drug from existing DPIs ranges from 10% to 60% of the nominal dose. The amount varies with inspiratory flow and device design. The higher the resistance or the greater the flow requirement of a DPI device, the more difficult it is for a compromised or young patient to generate inspiratory flow sufficient to obtain the maximum dose of drug from the device.

Exposure to humidity and moisture. The emitted dose of DPI decreases in a humid environment, likely because of powder clumping. The longer the exposure and the greater the level of absolute humidity, the lower the dose emitted. New DPIs with multiple unit-doses minimize the effects of moisture on the powder as long as individual doses are inhaled as soon as the seal is broken.

Patient's inspiratory flow ability. High peak inspiratory flow rates (>60 L/min) are required to dispense the drug powder from most current DPI designs and result in a pharyngeal dose comparable with the dose received from a typical pMDI without an add-on device. If a patient does not inhale at the optimal inspiratory flow rate for a particular device, delivery to the lung decreases as the dose of drug dispensed decreases and the particle size of the powder aerosol increases.[39,40]

Passive, or patient-driven, DPIs rely on the patient's inspiratory effort to dispense the dose. The result is differences in lung delivery and clinical response. Active or powered DPI devices, which disaggregate the powder before inhalation, are independent of patient effort. Active DPIs use an energy source to disaggregate the powder and suspend the powder into an aerosol, allowing the dose to be suspended independent of patient inspiratory flow rates.

BOX 40.4 Optimal Technique for Use of a Dry Powder Inhaler

1. Assemble the apparatus.
2. Load dose, keeping device upright.
3. Exhale slowly to functional residual capacity.
4. Seal lips around the mouthpiece.
5. Inhale deeply and forcefully (>60 L/min). A breath hold should be encouraged but is not essential.
6. Repeat the process until dose is completed.
7. Monitor adverse reactions.
8. Assess beneficial effects.

Modified from Pedersen S: How to use a Rotahaler, *Arch Dis Child* 61:11, 1986; and Hansen OR, Pedersen S: Optimal inhalation technique with terbutaline, *Turbuhaler Eur Respir J* 2:637, 1989.

Technique. Proper technique is essential to derive the maximum benefit from a DPI. Box 40.4 outlines the basic steps for ensuring optimal drug delivery. The most critical factor in using a passive DPI is the need for high inspiratory flow. Patients must generate an inspiratory flow rate of at least 40 to 60 L/min to produce a respirable powder aerosol. Because infants, small children (<5 years old), and patients who are unable to follow instructions cannot develop inspiratory flows this high, these patients cannot use DPIs. Because patients with severe airway obstruction may be unable to achieve the required flow, they should not use DPIs during acute bronchospasm.

Exhalation into a DPI before inspiration can result in loss of drug delivery to the lung. Some DPIs also require assembly, which can be cumbersome or difficult for some patients, especially in an emergency. It is important that patients receive demonstrations with their inhalers and have the opportunity to assemble and use the DPI (return demonstration) before self-administration. Although the DPI may require cleaning in accordance with the product label, the device should never be submerged in water. Moisture in the device dramatically reduces available dose. Table 40.1 provides methods to determine the dose of the different types of DPI.

RULE OF THUMB

- DPIs should be used for patients who can generate an inspiratory flow rate at least 40 to 60 L/min in order to produce a respirable powder aerosol.

New Dry Powder Inhaler Technologies

As shown in Fig. 40.12, new DPI technologies include the Easyhaler, Ellipta, Podhaler, Tudorza Pressair, and Spiromax.

Easyhaler. The Easyhaler (Orion Corporation, Espoo, Finland) is approved for marketing in Europe for delivery of beclomethasone, albuterol, formoterol, and budesonide. The device is similar to the pMDI in terms of its shape and operation. However, it is

TABLE 40.1 Determining Doses Left in the Dry Powder Inhaler

		Drug Container	Doses	Type Indicator	Meaning of Dose Indicator
Unit-dose DPI	Aerolizer or HandiHaler	Single capsule	1	None	Check capsule to ensure full dose was inhaled. Repeat to empty capsule
Multiple unit-dose DPI	Diskhaler	Dose blisters	4 or 8	None	Inspect visually to confirm use of all blisters
	Diskus	Blister strip	60	Red numbers	Red numbers indicate that ≤5 doses are left in DPI
Multiple-dose DPI	Flexhaler	Reservoir	60 or 120	"0"	Marked in intervals of 10 doses; "0" indicates empty
	Twisthaler	Reservoir	30	"01"	"01" indicates last dose

DPI, Dry Powder Inhaler.

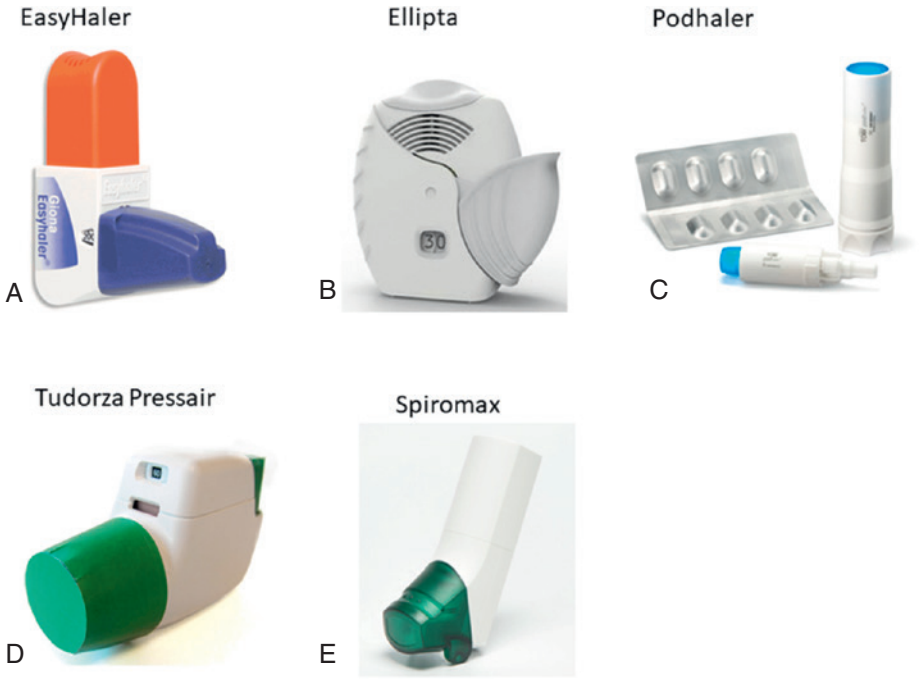

Fig. 40.12 New Dry Powder Inhalers. (A) Easyhaler (Courtesy Orion Corporation, Espoo, Finland), (B) Ellipta (Courtesy GlaxoSmithKline, Research Triangle Park, NC), (C) Podhaler (Courtesy Novartis Pharmaceutical Corporation, San Carlos, CA), (D) Tudorza Pressair (Courtesy Forest Laboratories, St Louis, MO), and (E) Spiromax (Courtesy Teva Pharmaceuticals).

a DPI and has a dose counter that gives a red signal when 20 doses are left in the device.

Ellipta. The Ellipta (GlaxoSmithKline, Research Triangle Park, NC) is a disposable multidose DPI in which the drug is stored in double-foil blister strips. The device has a three-step technique (open-inhale-close) and provides auditory feedback with the opening of the inhaler that results in loading the dose and an advancement in the dose counter. When a patient does not inhale the dose from the Ellipta, the drug is dumped internally to prevent overdosing. The Ellipta has four categories that provide different drugs or drug combinations: (1) Incruse Ellipta delivers umeclidinium, a long-acting muscarinic antagonist that is used in the treatment of COPD, (2) Breo Ellipta has a combination of fluticasone furoate and vilanterol (long-acting β2-agonist), (3) Anoro Ellipta includes a combination of umeclidinium and vilanterol, (4) Arnuity Ellipta delivers fluticasone furoate, and (5) Relvar Ellipta includes fluticasone furoate and vilanterol.

RULE OF THUMB

- Moisture in DPIs decreases aerosol delivery.
  - Do not exhale into your DPI.
- Do not store your DPI in the bathroom.
- Never submerge in water.

Podhaler. As a single-dose reusable DPI, the Podhaler (Novartis Pharmaceutical Corporation, San Carlos, CA) delivers Tobramycin (TOBI) for the treatment of chronic infection in patients with cystic fibrosis. The device produces light porous particles with improved flow and dispersion characteristics by using the PulmoSphere technology that has less interparticle cohesive forces. When using the Podhaler, a patient opens the mouthpiece, inserts the capsule in the device, and then inhales. The manufacturer suggests disposing of the device after 7 days of use.

Tudorza pressair. The Tudorza Pressair (Forest Laboratories, St Louis, MO) is a multidose DPI that delivers aclidinium bromide, a long-acting anticholinergic. The device has a dose counter that decreases by 10 doses and shows a red mark with a "0" sign when it is empty. It also has a lockout system at the end of the dose. The Tudorza Pressair provides both visual feedback and auditory feedback during therapy. The visual feedback displays red color in the control window with incorrect technique and shows green color when the patient inhales the dose completely with the correct use of the device.

Spiromax. As a multidose passive DPI, the Spiromax (Teva Pharmaceuticals, Petah Tikva, Israel) is used to deliver albuterol, fluticasone/salmeterol, and budesonide/formoterol in the treatment of pulmonary diseases in Europe. When the patient opens the cap on the mouthpiece, the dose is loaded to the DPI, and then it is ready for the patient to inhale the medication.

Nebulizers

Nebulizers generate aerosols from solutions and suspensions. The three categories of commonly used medical nebulizers include: (1) pneumatic jet nebulizers, (2) USNs, and (3) VM nebulizers. Nebulizers are also described in terms of their reservoir size. SVNs most commonly used for medical aerosol therapy hold 5 to 20 mL of medication. Large volume nebulizers hold up to 200 mL and may be used for either bland aerosol therapy (see Chapter 39) or continuous drug administration.

Pneumatic (Jet) Nebulizers

Gas-powered jet nebulizers (Fig. 40.13A) have been in clinical use for longer than 100 years. Most modern jet nebulizers are powered by high-pressure air or oxygen (O_2) provided by a portable compressor, compressed gas cylinder, or 50-psi wall outlet.

Factors affecting nebulizer performance. Nebulizer design, gas pressure, gas density, and medication characteristics affect SVN performance (Box 40.5).

Nebulizer design. As shown in Fig. 40.13B, a typical SVN is powered by a high-pressure stream of gas directed through a restricted orifice (the jet). The gas stream leaving the jet passes by the opening of a capillary tube immersed in solution. Because it produces low lateral pressure at the outlet, the high jet velocity draws the liquid up the capillary tube and into the gas stream, where it is sheared into filaments of liquid that break up into droplets. This primary spray produces a heterodisperse aerosol with droplets ranging from 0.1 to 500 µm.

This spray is directed against one or more baffles. A **baffle** is a surface on which large particles impact and fall out of suspension, whereas smaller particles remain in suspension, reducing the size of particles remaining in the aerosol. In many designs, droplets that impact baffles in the SVN return to the medication reservoir for nebulization again.

Baffles are key elements in nebulizers; well-designed baffling systems decrease both the MMAD (size) and the GSD (range of sizes) of the generated aerosol. **Atomizers** operate with the same basic principles as nebulizers without baffling and produce aerosols with larger MMAD and GSD. **Residual drug volume**,

or dead volume, is the medication that remains in the SVN after the device stops generating aerosol and "runs dry."[9] The residual volume of a 3-mL dose can range from 0.5 to more than 2.2 mL, which can be more than two-thirds of the total dose. The greater the residual drug volume, the more drug that is unavailable as aerosol and the less efficient the delivery system. Residual volume also depends on the position of the SVN. Some SVNs stop producing aerosol when tilted 30 degrees from vertical. Increasing the fill volume allows a greater proportion of active medication to be nebulized. In a nebulizer with a residual volume of 1.5 mL, a fill of 3 mL would leave only 50% of the nebulizer volume (nominal dose) available for nebulization. In contrast, a fill of 5 mL would make 3.5 mL, or more than 70% of the medication, available to be inhaled. The unit-dose volumes of drugs were based on clinical response of patients using nebulizers with substantial residual drug volumes. Although increasing dose volume may increase available dose, it should be considered off-label administration, and there is no significant difference in clinical response with varying diluent volumes and flow rates.

Flow. Droplet size and nebulization time are inversely proportional to gas flow through the jet. The higher the flow of gas to the nebulizer, the smaller the particle size generated and the shorter is the time required for nebulization of the full dose. Nebulizers that produce smaller particle sizes by use of baffles, such as one-way valves, may reduce total drug output per minute compared with the same nebulizer without baffling and require more time or nominal dose to deliver a standard dose of medication to the lungs.

Gas source (hospital versus home). Gas pressure and flow through the nebulizer affect particle size distribution and output. Within operating limits, the higher the pressure or flow means the smaller the particle size and the greater the output correlates to a shorter treatment time. A nebulizer that produces an MMAD of 2.5 μm when driven by a gas source of 50 psi at 6 to 10 L/min may produce an MMAD of more than 5 μm when operated on a home compressor (or ventilator) developing 10 psi. Too low a gas pressure or flow can result in negligible nebulizer output. Consequently, nebulizers used for home care should be matched to the compressor according to data supplied by the manufacturer. Thus the combination of specific equipment improves efficient nebulization of the desired medications prescribed for the patient.

Other concerns in the use of disposable nebulizers with compressors at home involve possible degradation of performance of the plastic device over multiple uses. One study showed that repeated use of nebulizers did not alter MMAD or output as long as the nebulizer was cleaned properly. Failure to clean the nebulizer properly caused degradation of performance because of clogging of the jet orifice, reduction of the output flow, and a buildup of electrostatic charge in the device.

Density. Gas density affects both aerosol generation and delivery to the lungs. The lower the density of the carrier gas, the less aerosol impaction as gas passes through the airways, and the greater the deposition of aerosol in the lungs.[41] However, when heliox is used to drive a jet nebulizer at standard flow rates, aerosol output is substantially less than with air or O_2, and aerosol particles are considerably smaller. When driving a nebulizer with heliox, twofold to threefold greater flow is required to produce a comparable aerosol output. Heliox concentrations of 40% or greater have been shown to improve aerosol deposition.[41-43]

Humidity and temperature. Humidity and temperature can affect particle size and the concentration of drug remaining in the nebulizer. Evaporation of water and adiabatic expansion of gas can reduce the temperature of the aerosol to 10°C less than ambient temperature. This cooling may increase solution viscosity and reduce the nebulizer output while decreasing particle MMAD.[9] Aerosol particles entrained into a warm and fully saturated gas stream increase in size. These particles also can coalesce (stick together), increasing the MMAD further and, in the case of a DPI, can severely compromise the output of respirable particles. How much these particles enlarge depends primarily on the tonicity of the solution. Aerosols generated from isotonic solutions probably maintain their size as they enter the respiratory tract. Hypertonic solutions tend to enlarge, whereas evaporation can cause hypotonic droplets to evaporate and shrink.

Characteristics of drug formulation. The viscosity and density of a drug formulation affect both output and particle size. Some drugs, such as antibiotics, are so viscous that they cannot be used effectively for nebulization in some standard SVNs. In addition, in some suspensions, some aerosolized particles contain no active drug, whereas other particles, generally larger, carry the active medication.

Small Volume Nebulizers

Four categories of jet SVNs include: (1) continuous nebulizer with simple reservoir, (2) continuous nebulizer with collection reservoir bag, (3) breath-enhanced nebulizer, and (4) breath-actuated nebulizer (Fig. 40.14A, B, C, and D, respectively). The most commonly used SVN is the constant output design. Aerosol is generated continuously, with 30% to 60% of the nominal dose being trapped as residual volume in the nebulizer and more than 60% of the emitted dose wasted to the atmosphere. Continuous nebulization wastes medication because the aerosol is produced throughout the respiratory cycle and is largely lost to the atmosphere. Patients with an I:E ratio of 40:60 (or 1:1.5) lose 60% of the aerosol generated to the atmosphere. If 50% of the total dose is emitted from the nebulizer, and 50% of that aerosol is in the respiratory range and 40% of that is inhaled by the patient, less than 10% deposition is commonly measured in adults receiving continuous nebulizer therapy. In neonates and infants, given the small minute volumes and small airways with increased impaction and reduced sedimentation, deposition can be only 0.5%.

Aerosolized medication can also be conserved with reservoirs. A reservoir on the expiratory limb of the nebulizer conserves drug aerosol.

Small volume nebulizer with a reservoir. Many types of disposable SVNs are packaged with a 6-inch (15-cm) piece of aerosol tubing to be used as a reservoir (Fig. 40.14A).

Continuous small volume nebulizer with collection bag. As shown in Fig. 40.14B, bag reservoirs hold the aerosol generated during exhalation and allow the small particles to remain in suspension for inhalation with the next breath, while larger particles rain out. These additions have been attributed with a 30%

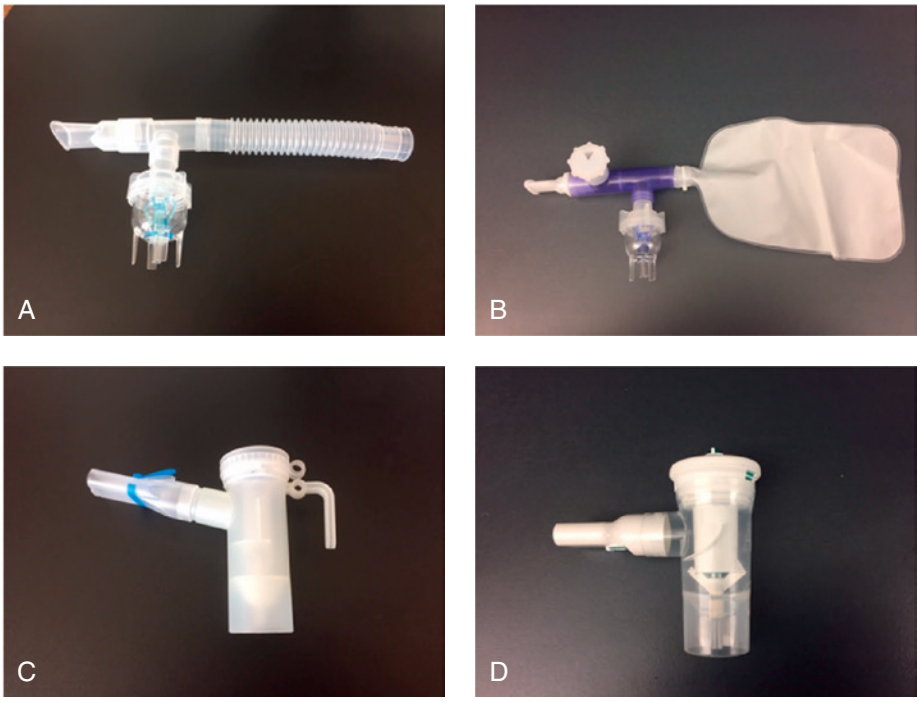

Fig. 40.14 Four categories of jet small volume nebulizers include: (A) continuous nebulizer with simple reservoir, (B) continuous nebulizer with collection reservoir bag, (C) breath-enhanced nebulizer, and (D) breath-actuated nebulizer.

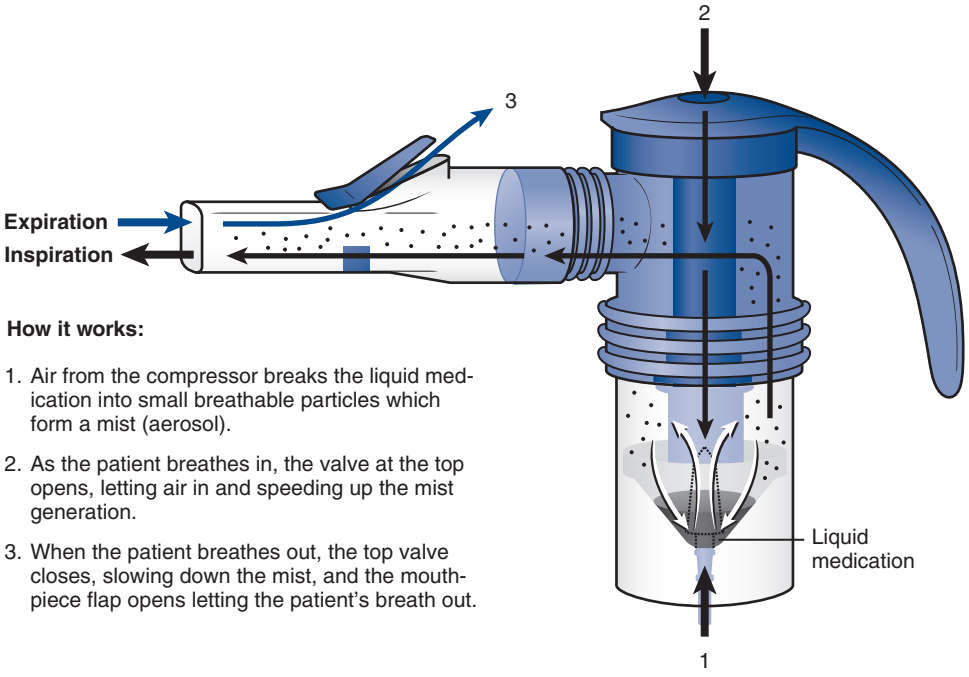

Fig. 40.15 Operating Principles of the Sprint (Pari, Midlothian, VA) Breath-Enhanced Nebulizer. (From Cairo JM, Pilbeam SP: *Mosby's respiratory care equipment*, ed 8, St. Louis, 2009, Mosby.)

to 50% increase in inhaled dose.[44] A collection bag is attached on the expiratory side of the nebulizer "T," which collects aerosol leaving the SVN when the patient is not actively inhaling. Some of the aerosol in the bag is inhaled with the next inspiration, increasing total dose efficiency.

Breath-enhanced nebulizers. **Breath-enhanced nebulizers** (Fig. 40.14C) generate aerosol continuously, using a system of vents and one-way valves to minimize aerosol waste.[44] In the Pari LC Sprint (Pari, Midlothian, VA) breath-enhanced nebulizer (Fig. 40.15), an inspiratory vent allows the patient to draw in

air through the nebulization chamber that generates and contains the aerosolized drug. On exhalation, the inlet vent closes and the aerosol exits by a one-way valve near the mouthpiece. This process can increase inhaled mass by 50% over standard continuous nebulizers and can reduce waste to the atmosphere.

MINI CLINI

Home Nebulizer Therapy

Problem

Many patients are sent home with a prescription for home nebulizer therapy prescribed with the intention of giving the patient the same quality of aerosol therapy he or she received in the hospital. However, the patient often is given the same type of nebulizer used in the hospital because it is inexpensive. These nebulizers provide an aerosol that is too large for optimal deposition in the lungs. What should be done instead?

Discussion

Home nebulizers designed for use with compressors should be matched to ensure an MMAD of 1 to 5 μm with the medication being administered. Nebulizer manufacturers such as Pari and Medic-Aid offer matched nebulizer–compressor systems for home use. Although these devices cost a little more, they are more likely to meet therapeutic objectives.

Breath-actuated nebulizers. Breath-actuated nebulizers (Fig. 40.14D) synchronize aerosol generation with inspiration, reducing waste of aerosol during exhalation and increasing inhaled dose up to threefold more than continuous and breath-enhanced nebulizers. Dosimeters, used in pulmonary function laboratories, sense inspiration and pulse airflow to the jet orifice and transform a conventional nebulizer into a breath-actuated system. Manual systems allow the user to cover a thumb port directing, compressed gas to the jet nebulizer.

AeroEclipse (Trudell Medical International, London, ON, Canada) is a breath-actuated SVN. A unique, spring-loaded, one-way valve design draws the jet to the capillary tube during inspiration and causes nebulization to cease when the patient's inspiratory flow decreases below the threshold or the patient exhales into the device (Fig. 40.16). Expiratory pressure on the valve at the initiation of exhalation moves the nebulizer baffle away from its position directly above the jet orifice, reduces the pressure, and stops aerosolization. Because aerosol is generated only during inhalation, exhaled aerosol and contamination of the environment during the expiratory phase of the breathing cycle are largely reduced.

It can be difficult to determine when a nebulizer treatment is complete. Aerosol delivery from a jet nebulizer ceased after the onset of inconsistent nebulization (sputtering).[45] Aerosol output declined by one-half within 20 seconds of the onset of sputtering. The concentration of albuterol in the nebulizer cup increased significantly when the aerosol output declined, and further weight loss in the nebulizer was caused primarily by evaporation. Most consider aerosolization past the point of initial nebulizer sputter ineffective.

Table 40.2 summarizes some of these key factors for many commercially available SVNs.[9] Numerous SVNs are on the market, and they vary widely in design and performance. SVNs of the same design and lot number can exhibit variable performance, even to the point that some nebulizers of the same model number do not work at all.[46] Managers and clinicians always must evaluate SVNs carefully before purchasing or using them. Manufacturers should provide data on the performance of their nebulizers under common use conditions.

Technique. Box 40.6 outlines the optimal technique for using an SVN for aerosol drug delivery. Use of an SVN is less technique-dependent and device-dependent than use of a pMDI or DPI

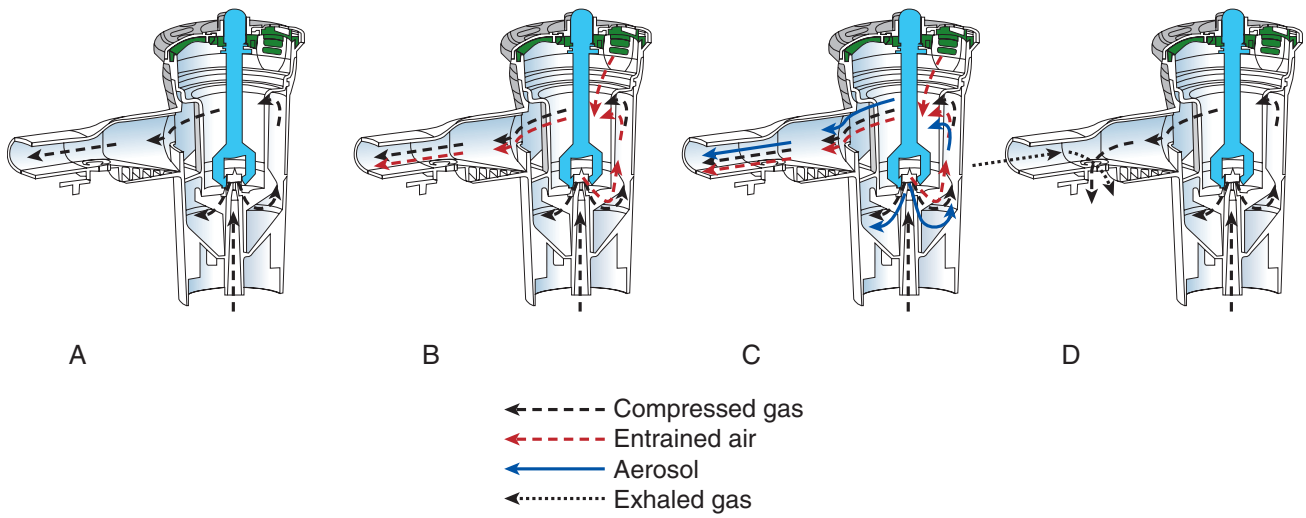

Fig. 40.16 Breath-Actuated Pneumatic Nebulizer (AeroEclipse BANII) Flow Path Diagram. (A) Before inhalation, actuator is up and compressed gas freely circulates with no aerosol produced. (B) Patient inhales, and actuator starts to move down. (C) Negative pressure pulls the diaphragm down (with actuator moved down sealing around the nozzle cover), producing aerosol. (D) Patient exhales through valve in mouthpiece; as pressure increases, the diaphragm and actuator move up, stopping aerosol production. (Courtesy Trudell Medical International, London, ON, Canada.)

TABLE 40.2 Comparison of Different Nebulizers

	Jet Nebulizer	Ultrasonic Nebulizer	Mesh Nebulizer	Smart Nebulizer
Power source	Compressed gas or electrical mains	Electrical mains	Batteries or electrical mains	Batteries or electrical mains
Portability	Restricted	Restricted	Portable	Portable
Treatment time	Long	Intermediate	Short	Short
Output rate	Low	Higher	Highest	Highest
Residual volume	0.8–2.0 mL	0.8–2 mL	≤0.2 mL	≤0.2 mL
Performance variability	High	Intermediate	Low	Low
Temperature	Decreases[a]	Increases[b]	Minimum change	Minimum change
Concentration	Increases	Variable	Minimum change	Minimum change
Cleaning	Required after single use	Required after multiple use	Required after single use	Required after single use
Cost	Very low	High	High	High

[a]For jet nebulizers, the temperature of the reservoir fluid decreases approximately 15°C during nebulization because of evaporation.
[b]For ultrasonic nebulizers, vibration of the reservoir fluid causes a temperature increase during aerosol generation, which can be 10°C to 15°C.

BOX 40.6 Optimal Technique for Using a Small Volume Nebulizer

1. Assess the patient for need (clinical signs and symptoms, breath sounds, peak flow, $\%FEV_1$).
2. Select mask or mouthpiece delivery (nose clips may be needed with mouthpiece).
3. Use conserving system (thumb port, breath actuator, or reservoir) if indicated.
4. Place drug in the nebulizer. If using a multidose vial, add saline to approved dose volume (per drug label).
5. Set gas flow to nebulizer at 6 to 10 L/min (per manufacturer label).
6. Coach patient to breathe slowly through the mouth at normal V_T.
7. Continue treatment until nebulizer begins to sputter.
8. Rinse the nebulizer with sterile water and air dry, or discard, between treatments.
9. Monitor patient for adverse response.
10. Assess outcome (change in peak flow, $\%FEV_1$).

$\%FEV_1$, Percentage forced expiratory volume in 1 s; *V_T*, tidal volume.

delivery system. Slow inspiratory flow optimizes SVN aerosol deposition. However, deep breathing and breath holding during SVN therapy do little to enhance deposition over normal tidal breathing.[47] Because the nose is an efficient filter of particles larger than 5 µm, many clinicians prefer not to use a mask for SVN therapy. As long as the patient is mouth breathing, there is little difference in clinical response between therapy given by mouthpiece and therapy given by mask. The selection of delivery method (mask or mouthpiece) should be based on patient ability, preference, and comfort.

Infection control issues. The CDC recommends that nebulizers be cleaned and disinfected, rinsed with sterile water, or air dried between uses. Jet SVNs have reservoirs that are open to and positioned below the mouthpiece or mask. This allows secretions from the patient to enter the medication cup, contaminating medication.

Multidose drug containers have been associated with contamination. After 7 days of nebulizer use, five of six multidose containers of medication solutions were found to be contaminated.[11,48] Refrigerating solutions and discarding syringes every 24 hours eliminated bacterial contamination.

RULE OF THUMB Multidose drug bottles have been associated with contamination. Therefore, single-dose amp should be preferred for aerosol drug delivery to patients with pulmonary diseases. When a multidose drug bottle is used, the solution should be refrigerated, and syringes should be discarded every 24 h to eliminate bacterial contamination.

Large Volume Jet Nebulizers

Large volume jet nebulizers are also used to deliver aerosolized drugs to the lung and are particularly useful when traditional dosing strategies are ineffective in the management of severe bronchospasm. When a patient with airway obstruction does not respond to a standard dosage of bronchodilator, it is common to repeat the treatment every 15 minutes. An alternative approach is to provide continuous nebulization with a specialized large volume nebulizer.

The high-output extended aerosol respiratory therapy nebulizers HEART (Cardinal Health, Dublin, OH) and HOPE (B & B Medical Technologies, Carlsbad, CA) are examples of devices designed for this purpose. These nebulizers have a reservoir greater than 200 mL that produces an aerosol with an MMAD of 2.2 to 3.5 µm. Actual output and particle size vary with the pressure and flow at which the nebulizer operates. A concern with continuous bronchodilator therapy (CBT) is increased drug concentration. Patients receiving CBT need close monitoring for signs of drug toxicity (e.g., tachycardia and tremor). An additional strategy is to use an intravenous (IV) infusion pump to drip premixed bronchodilator solution into a standard SVN. Although this is an equipment-intensive approach, this technique can provide dosing equivalent to intermittent nebulization for the treatments of adults with acute asthma.[49]

Another special-purpose large volume nebulizer is a *small particle aerosol generator (SPAG)* (Fig. 40.17). The SPAG was developed in the 1940s to study pathogen aerosols and subsequently manufactured by ICN Pharmaceuticals specifically for administration of ribavirin (Virazole) to infants with respiratory syncytial virus infection. The device is unique in clinical respiratory care practice. It incorporates a drying chamber with its own flow control to produce a stable aerosol. The SPAG reduces medical gas source from the normal 50 *pounds per square inch*

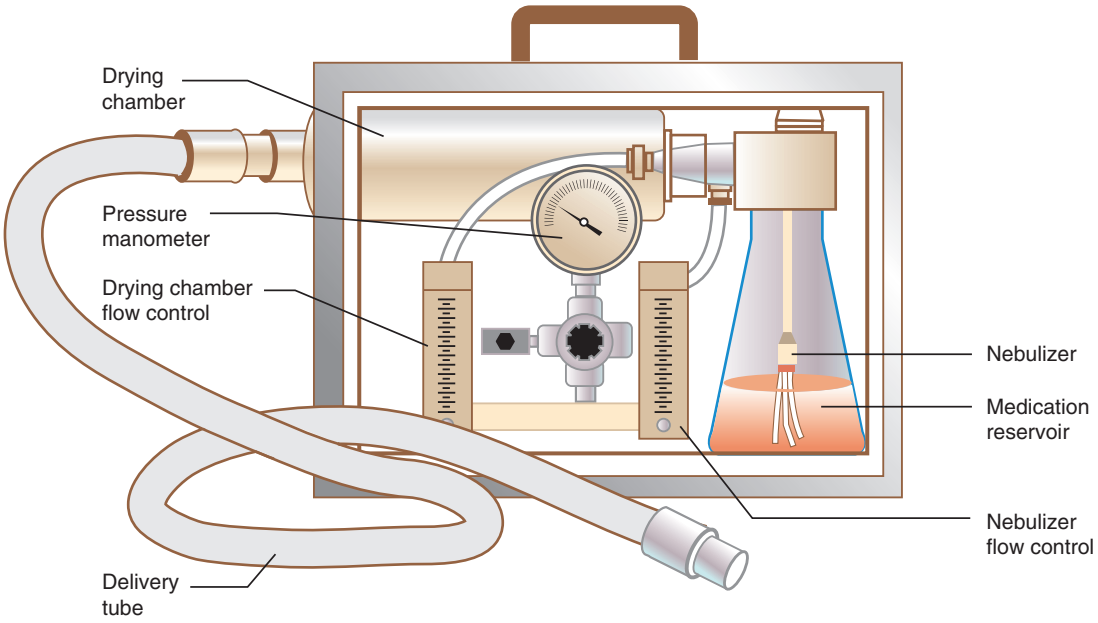

Fig. 40.17 Small-Particle Aerosol Generator.

gauge (psig) line pressure to 26 psig with an adjustable regulator. The regulator is connected to two flowmeters that separately control flow to the nebulizer and flow through the drying chamber. The nebulizer is located within the glass medication reservoir, the fluid surface and wall of which serve as primary baffles. As it leaves the medication reservoir, the aerosol enters a long, cylindrical drying chamber. Here the second (separate) flow of dry gas is added, reducing particle size by evaporation, creating a monodisperse aerosol with an MMAD of 1.2 to 1.4 µm. Nebulizer flow should be maintained at approximately 7 L/min with total flow from both flowmeters not less than 15 L/min. The latest model operates consistently even with back pressure and can be used with masks, hoods, tents, or ventilator circuits.

Two specific problems are associated in the delivery of ribavirin with SPAG. The first is caregiver exposure to the drug aerosol. Approaches to limit caregiver exposure are discussed later (see the section on Controlling Environmental Contamination). The other problem occurs only when the SPAG is used to deliver ribavirin through a mechanical ventilator circuit. Drug precipitation can jam breathing valves or occlude the ventilator circuit. This problem can be overcome by: (1) placing a one-way valve between the SPAG and the circuit, (2) filtering out the excess aerosol particles before they reach the exhalation valve, and (3) changing filters frequently to avoid increasing expiratory resistance.[47]

Hand-Bulb Atomizers and Spray Pumps

Hand-bulb atomizers and nasal spray pumps are used to administer sympathomimetic, anticholinergic, antiinflammatory, and anesthetic aerosols to the upper airway, including nasal passages, pharynx, and larynx (see also Chapter 36). These agents are used to manage upper airway inflammation and rhinitis, to provide local anesthesia, and to achieve systemic effects.

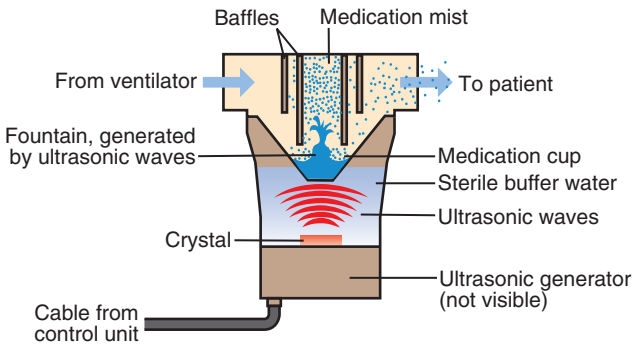

Fig. 40.18 Small volume ultrasonic nebulizers designed for use with mechanical ventilation. A vibrating piezoceramic crystal generates ultrasonic waves that pass through couplant (sterile buffer water) and the medication cup to generate a fountain (or *standing wave*) of medication that produces aerosol particles.

Because the spray pump generates relatively low pressure and does not have baffles, it produces an aerosol with large particle size (high MMAD and GSD), ideal for upper airway deposition. (Nasopharyngeal deposition is greatest for particles 5 to 40 µm.) Deposition with the hand-bulb atomizer applied to the nose occurs mostly in the anterior nasal passages with clearance to the nasopharynx. The 100-mcL puffs appear to deposit more medication than 50-mcL puffs, and deposition to a greater surface area occurs with a 35-degree spray angle than with a 60-degree angle.

Ultrasonic Nebulizers

The USN uses a piezoelectric crystal to generate an aerosol. The crystal transducer converts an electrical signal into high-frequency (1.2- to 2.4-MHz) acoustic vibrations. These vibrations are focused in the liquid above the transducer, where they disrupt the surface and create oscillation waves (Fig. 40.18). If the frequency of the

signal is high enough and its amplitude strong enough, the oscillation waves form a standing wave that generates a geyser of droplets that break free as fine aerosol particles.

USNs are capable of higher aerosol outputs (0.2 to >1.0 mL/min) and higher aerosol densities than conventional jet nebulizers. Output is determined by the amplitude setting (sometimes user selected). The greater the signal amplitude, the greater the nebulizer output. Particle size is inversely proportional to the frequency of vibrations. Frequency is device specific and is not user adjustable. For example, the DeVilbiss (Somerset, PA) Portasonic nebulizer operating at a frequency of 2.25 MHz produces particles with an MMAD of 2.5 μm, whereas the DeVilbiss Pulmosonic nebulizer operating at 1.25 MHz produces particles in the 4- to 6-μm range. Particle size and aerosol density also depend on the source and flow of gas conducting the aerosol to the patient.

Large volume ultrasonic nebulizers. Large volume USNs (used mainly for bland aerosol therapy or sputum induction) incorporate air blowers to carry the mist to the patient (see Chapter 39). Low flow through the USN is associated with higher mist density. In contrast to jet nebulizers, the temperature of the solution placed in a USN increases during use. As the temperature increases, the drug concentration increases, and proteins can be denatured.

Small volume ultrasonic nebulizers. Many small volume USNs have been marketed for aerosol drug delivery (see Fig. 40.18). In contrast to the larger units, some of these systems do not use a couplant compartment; the medication is placed directly into the manifold on top of the transducer. The transducer is connected by a cable to a power source, often battery-powered to increase portability. These devices have no blower; the patient's inspiratory flow draws the aerosol from the nebulizer into the lung.

Small volume USNs administer a wide variety of formulations ranging from bronchodilators to antiinflammatory agents and antibiotics.[9] Suspensions such as budesonide may not nebulize well with USNs, because large suspension aerosol particles that are larger than the aerosol particles remain in the medication cup. Use of a small volume USN may increase available respirable mass for designs with less residual drug volume than SVNs; this may reduce the need for a large quantity of diluent to ensure delivery of the drugs. The contained portable power source adds a great deal of convenience in mobility. However, sometimes the theoretical advantages of the ultrasonic devices are outweighed by relatively high purchase costs and poor reliability.

Small volume USNs have been used to administer undiluted bronchodilators to patients with severe bronchospasm.[50] Because the nebulizers have minimal residual drug volume, the treatment time is reduced with smaller volumes; however, it may be increased with standard dosing volumes. Some ventilator manufacturers (e.g., Maquet, Rastatt, Germany) have promoted the use of USNs for administration of aerosols during mechanical ventilation. In contrast to SVNs, USNs do not add extra gas flow to the ventilator circuit during use. This feature reduces the need to change and reset ventilator and alarm settings during aerosol administration.

Vibrating Mesh Nebulizers

The two types of commercially available VM nebulizers are active and passive.[9,51] Active VM nebulizers use a dome-shaped aperture plate, containing more than 1000 funnel-shaped apertures. The dome is attached to a plate that is also connected to a piezoceramic element surrounding the aperture plate. Electrical energy applied to the piezoceramic element vibrates the aperture plate at a frequency of approximately 130 kHz (or one-tenth that of a USN), moving the aperture plate up and down by approximately 1 to 2 μm and acting as an electronic micropump. The plate actively pumps the liquid through the apertures, where it is broken into fine droplets. The exit velocity of the aerosol is low (<4 m/s), and the particle size can range from 3 to 4 μm (MMAD), varying with the exit diameter of the apertures. Examples of an active VM nebulizer (Fig. 40.19A to C) include the Aeroneb Solo nebulizers (Aerogen, Ltd, Galway, Ireland) and the eFlow nebulizers (Pari) and Innospire Go (Phillips Respironics, Murraysville, PA, USA). An active VM nebulizer can nebulize single drops of 15 mcL of formulations containing small and large molecules, suspensions, microsuspensions, and liposomes.

Passive VM nebulizers (see Fig. 40.19D) use a mesh separated from an ultrasonic horn by the liquid solution for nebulization. A piezoelectric transducer vibrates the ultrasonic horn, which pushes fluid through the mesh. Passive VM nebulizers include the MicroAir U100, the NEU-22 (Omron, Kyoto, Japan), and the I-Neb (Philips Respironics, Murrysville, PA).

The residual drug volumes with either type of VM nebulizer range from 0.1 to 0.4 mL, in contrast to other types of liquid aerosol generators with residual drug volumes of 0.8 to 1.5 mL. Because a greater percentage of standard unit doses is emitted as aerosol, care should be exercised when transitioning to these devices to ensure that the higher dose does not create adverse effects.

Smart Nebulizers

Low-velocity (soft mist) aerosol, smaller particle size distribution, and systems that minimize residual volume of medication left in the nebulizer substantially improve aerosol device efficiency. Along with improved performance, some "smart" nebulizers have the capability to monitor patient compliance and aid in managing the patient's treatment schedule.

With pulmonary deposition increased from the old standard of approximately 10% to more than 60% of the nominal dose, these recent device improvements may be accompanied by greater systemic side effects, unless the delivered dose is reduced. The key is to be able to target an effective delivered dose to the lungs.

The I-Neb (Philips Respironics) is a breath-actuated passive VM nebulizer with *adaptive aerosol delivery* that monitors pressure changes and inspiratory time for the patient's first three consecutive breaths (Fig. 40.20).[52,53] Drug is then aerosolized over 50% of the inspiratory maneuver during the fourth and all subsequent breaths. *Targeted inhalation mode* guides the patient to take serially longer inspirations to achieve optimal inhalation duration, reducing the time for administration. When the prescribed emitted dose has been aerosolized, the system provides an audible signal indicating the treatment should be stopped and the remaining medication discarded. Built-in electronics monitor patient treatment schedules and delivered doses with the goal to improve compliance with therapy. The I-Neb has been released for delivery of prostacyclin.

Fig. 40.19 Variety of Available Mesh Nebulizers. (A) Aerogen Solo (Courtesy Aerogen, Galway, Ireland), (B) PARI e-Flow (Courtesy Pari, Midlothian, VA), (C) Innospire Go (Courtesy Philips Healthcare, Murrysville, PA), and (D) iNeb (Courtesy Phillips Healthcare, Murrysville, PA). A and B are active mesh nebulizers, while C and D are examples of passive mesh nebulizers. Active vibrating mesh (VM) nebulizer has an aperture plate with funnel-shaped holes vibrated by a piezoelectric transducer surrounding the aperture plate found in the nebulizer. Passive VM nebulizer uses an ultrasonic horn to push fluid through a stationary mesh found in the nebulizer.

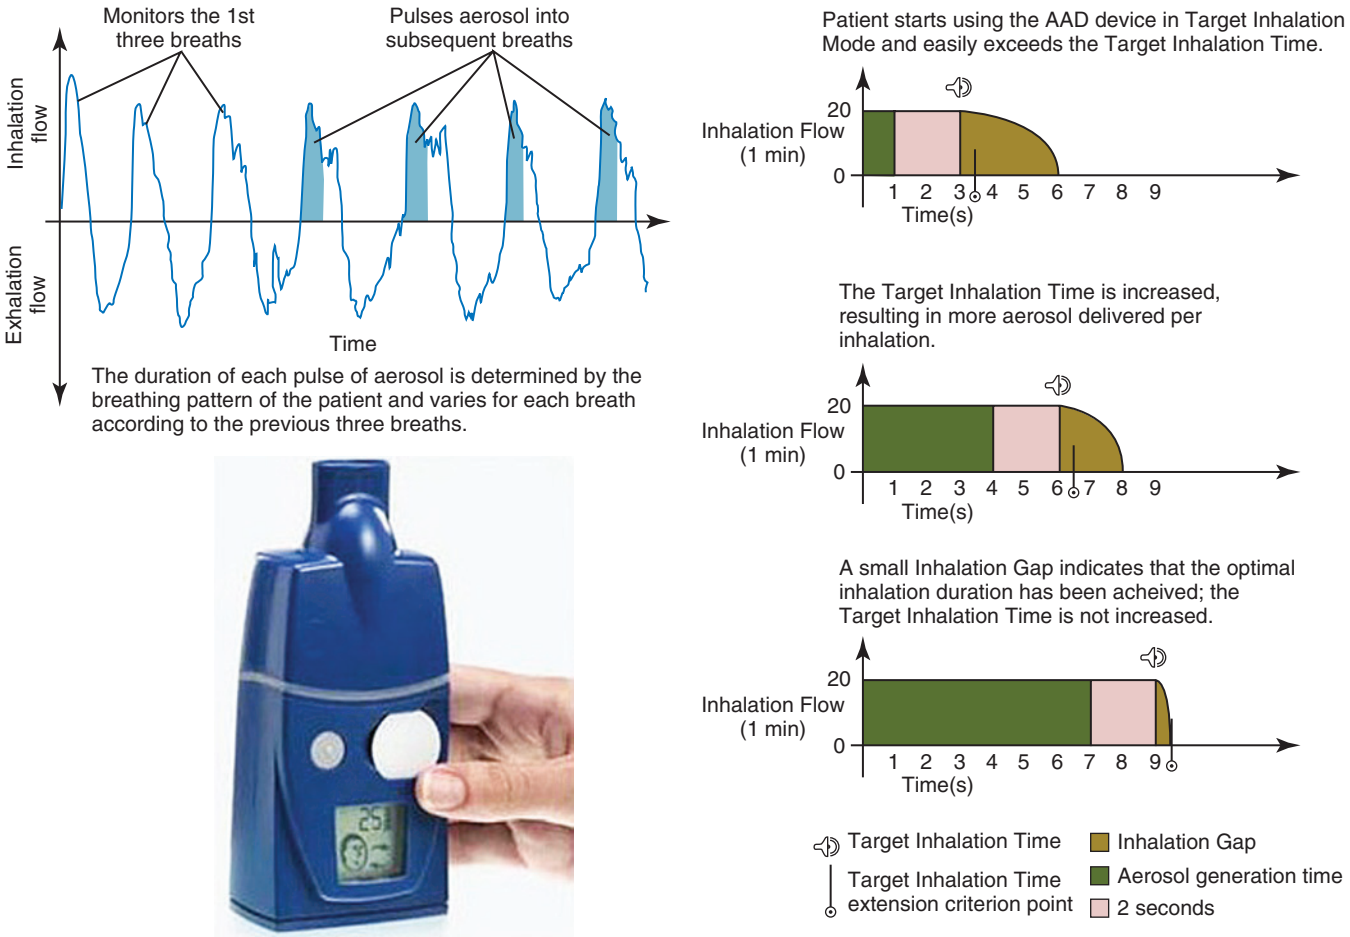

Fig. 40.20 The iNeb *(bottom left)* is a smart nebulizer with adaptive aerosol delivery (AAD) and targeted inhalation mode (TIM). AAD delivers a precise preset dose with variation between patients. A microprocessor tracks the patient's breathing pattern on a running average of the previous three breaths, generating aerosol for 50% of the predicted inspiration *(upper left)*. TIM progressively guides the patient to take longer inspirations, increasing to achieve optimal inhalation duration *(right)*.

The Akita (Activaero, Gemuenden/Wohra, Germany) allows controlled inhalation of aerosol produced by either a jet or VM nebulizer (Fig. 40.21). The Akita controls inspiratory flow to keep it slow (12 to 15 L/min), reducing impaction loss of aerosols in the upper airways. Patient pulmonary function is stored on a smart card programmed to tell the device when to generate aerosol during inspiration. Aerosol generated early targets distal airways, whereas aerosol generated later in the breath targets larger, more central airways.[54] Smart nebulizers can track the actual time, duration, and dose administered for each treatment and provide logs of use that can be downloaded for the medical or research record.

Fox. The Fox inhalation system (Vectura Group, Wiltshire, UK) is an active VM nebulizer with a flow- and volume-controlled inhalation system that increases intrapulmonary deposition. The device targets aerosol deposition in the peripheral and central airways by controlling the time of aerosol release during therapy. Although releasing the aerosol at the beginning of inspiration leads to peripheral deposition, the release of aerosols in the middle of inhalation results in aerosol deposition in central airways. The Fox inhalation system is approved for delivery of different medications in Europe but not available in the United States.

Fig. 40.21 The AKITA Smart Nebulizer.

Dance 501. The Dance 501 (Dance Biopharm, San Francisco, CA) is a VM nebulizer (Aerogen Ltd, Galway, Ireland) that is designed for the treatment of patients with diabetes. Because it generates aerosol only when inspiratory flow is between 7 and 14 L/min, it reduces impaction losses and provides optimal lung deposition.[55] Dance 501 is a small, silent, hand-held smart nebulizer that is portable and easy to use. The nebulizer has a mouthpiece with reservoir that needs to be cleaned between doses.

New nebulizer designs for liquid medications.

InnoSpire Go. The InnoSpire Go (Philips Healthcare, Newark, NY) is a hand-held mesh nebulizer that is small, silent portable, and easy to use and clean with two parts assembly. The treatment time of the InnoSpire Go is 4 minutes with salbutamol of 2.5 mL. It is battery operated with a built-in rechargeable battery that operates for up to 30 treatments. The InnoSpire Go provides audible and visual signals to patients when the treatment is complete.

Examples of nebulizers with drug device combinations.

Lonhana magnair. The Lonhana Magnair (Sunovion Pharmaceuticals Inc) delivers glycopyrrolate, which is a long-acting muscarinic antagonist (anticholinergic) used for maintenance treatment of COPD twice daily (Fig. 40.22A). It is a drug/device combination that is portable, battery powered and silent. The Lonhana Magnair is combined with a mesh nebulizer that does not require any specific breathing technique and complete dosing in 2 to 3 minutes. The device also provides two audio beeps and visual feedback with a green LED light that indicates the nebulization is complete.

Tyvaso. The Tyvaso Inhalation System (United Therapeutic Corperation, Research Triangle Park, NC) is a pulsed USN that is used for delivery of treprostinil. Device preparation requires assembly of different parts of the device including dome, inhalation piece, filters, and mouthpiece (see Fig. 40.22B). A couplant chamber is filled with water between the piezo and the medication

Fig. 40.22 New Nebulizer Technologies. Tyvaso Inhalation System. (Courtesy Tyvaso® Inhalation Device (TD-300/A) and supplier, United Therapeutics Corporation.)

cup. A daily dose is placed in the medication cup, and patients are instructed to take a set number of breaths per treatment, at set intervals during the day, with the device cleaned at the end of the day. The Tyvaso Inhalation System provides auditory and visual feedback on the patient's inhalation technique. In addition, if a patient stops inhalations during therapy, the device shows the remaining breaths in the numerical display that are needed to complete the treatment.

Cayston Altera eFlow

The Cayston Altera eFlow (Gilead Pharmaceuticals, Foster City, CA) is a mesh nebulizer with a piezoelectric element that is used to deliver aztreonam lysine (AZLI) to patients with cystic fibrosis. It is battery powered and does not require a compressor to operate.

Staccato. The Staccato (Alexza Pharmaceuticals, Mountain View, California) uses a thermal aerosol technology that has three components, including a heating substrate, a thin film of pure drug, and a channel where aerosol forms. It is a small, portable, breath-actuated device that does not require any type of special breathing technique. Therefore, unlike other DPIs, the Staccato is insensitive to patient inhalation rates. The device generates aerosols by heating a thin film of drug to form pure drug vapor. When the patient inhales, the vapor cools and condenses into 1- to 3-μm-diameter particles. Thus pure drug can be delivered to the alveoli without extensive thermal degradation and with the optimal range of particle diameter, promoting very fast systemic drug absorption. The Staccato has been approved in the United States for delivery of loxapine.

Soft Mist Inhalers

Respimat. The Respimat soft mist inhaler (Boehringer Ingelheim) is a small hand-held inhaler that uses mechanical energy to create an aerosol from liquid solutions to produce a low-velocity spray (10 mm/s) that delivers a unit dose of drug in a single actuation. To operate the device, patients twist the body of the device to load an internal spring, place the mouthpiece of the Respimat between the lips, and press a button to release the drug through a uniblock to create the aerosol, which is released over 1.1 to 1.4 seconds, depending on the formulation configuration.[56,57] The Respimat requires hand–breath coordination on the part of the patient, as does a pMDI, but because of the longer aerosolization time, it seems more likely that the patient will get a greater percentage of emitted dose despite coordination issues. Because of the small particle size and low-velocity spray, pulmonary deposition of 40% is independent of inspiratory flows with oral deposition (40%) half the oral deposition with most pMDIs and DPIs (80%). The Stiolto Respimat (tiotropium bromide and olodaterol) and the Spiriva Respimat are currently available in the United States and have been prescribed for patients with COPD.

Aqueous droplet inhaler liquid inhaler device. The Aqueous Droplet Inhaler (ADI) liquid inhaler device (Pharmaero, Copenhagen, Denmark) is a soft mist inhaler that delivers small or large volumes of liquid medications in a low-velocity aerosol mist. The ADI liquid inhaler device does not require any source of power to operate and has a five-step operation system including insert the syringe, wind up, push button, inhale, and repeat. The treatment time with the IDA liquid inhaler is 2 minutes. In addition, cleaning after treatment is not needed with the ADI liquid inhaler device because the mouthpiece used with the device is disposable.

Advantages and Disadvantages of Aerosol Systems

Knowledge of the advantages and disadvantages of various aerosol drug delivery systems is crucial for proper selection and application. Table 40.3 compares pMDI, DPI, SVN, and USN delivery systems.

Special Medication Delivery Issues for Infants and Children

Children and infants have a smaller airway diameter than adults. In addition, their breathing rate is faster, and nose breathing

TABLE 40.3 Advantages and Disadvantages of Aerosol Drug Delivery Systems

	Advantages	Disadvantages
pMDI	Convenient	Patient coordination required
	Inexpensive	Patient activation required
	Portable	High percentage of oropharyngeal deposition
	No drug preparation required	Not all medications are available
	Difficult to contaminate	Expensive
pMDI with accessory device	Less patient coordination required	More expensive than pMDI alone
	Less oropharyngeal deposition	More complex than pMDI alone
	No drug preparation needed	Less portable than pMDI alone
DPI	Less patient coordination required	Required high inspiratory flow
	Breath activated	Most units are single dose
	Breath hold not required	Risk of oropharyngeal deposition
	Built-in dose counters	Expensive
SVN	Inexpensive	Large residual volume
	Less patient coordination required	Drug preparation required
	High doses possible (even continuous)	Compressed gas or compressor required
		Long treatment time
		Contamination possible if device is not cleaned carefully
USN	Quiet	Expensive
		Drug preparation required
		Prone to electrical or mechanical breakdown
		Large residual volume
VM nebulizer	Quiet	Expensive
	Small residual volume	Drug preparation required

DPI, Dry powder inhaler, *pMDI*, pressurized metered dose inhaler; *SVN*, small volume nebulizer; *USN*, ultrasonic nebulizer; *VM*, vibrating mesh.

filters out large particles and deposits more medication in the upper airway. Furthermore, mouthpiece administration often cannot be used before 3 years of age.[58] Patient cooperation and ability vary with age and developmental level. Finally, infants and small children have lower minute volumes than adults and so inhale a smaller proportion of the output of continuous nebulizers than adults.[59]

Normal tidal breathing is the most effective method for administering aerosols to an infant. Mouth breathing enhances medication delivery to the airways of adults, but there is little evidence to show that this is true for infants, who are preferential nose breathers up to 1 year of age. Crying greatly reduces lower airway deposition of aerosol medication; therefore aerosols should not be administered to a crying child (Fig. 40.23).

MINI CLINI

Aerosol Drug Delivery and Crying Infants

Problem

Child cries during aerosol therapy.

Discussion

Crying greatly reduces inhaled dose, making aerosol ineffective. Many infants and toddlers (up to 49%) do not tolerate aerosol masks without crying and fussing. Aerosol delivery should be avoided when the infant or toddler is crying, because it just wastes the medication. Efforts can be made to turn the aerosol mask into a "toy" and treatments into playtime so the child is entertained rather than scared. Alternatively, interfaces such as tents, hoods, or nasal cannula may be better tolerated by the infant. Caution: Blow-by may be tolerated but is associated with very poor deposition and should be avoided.

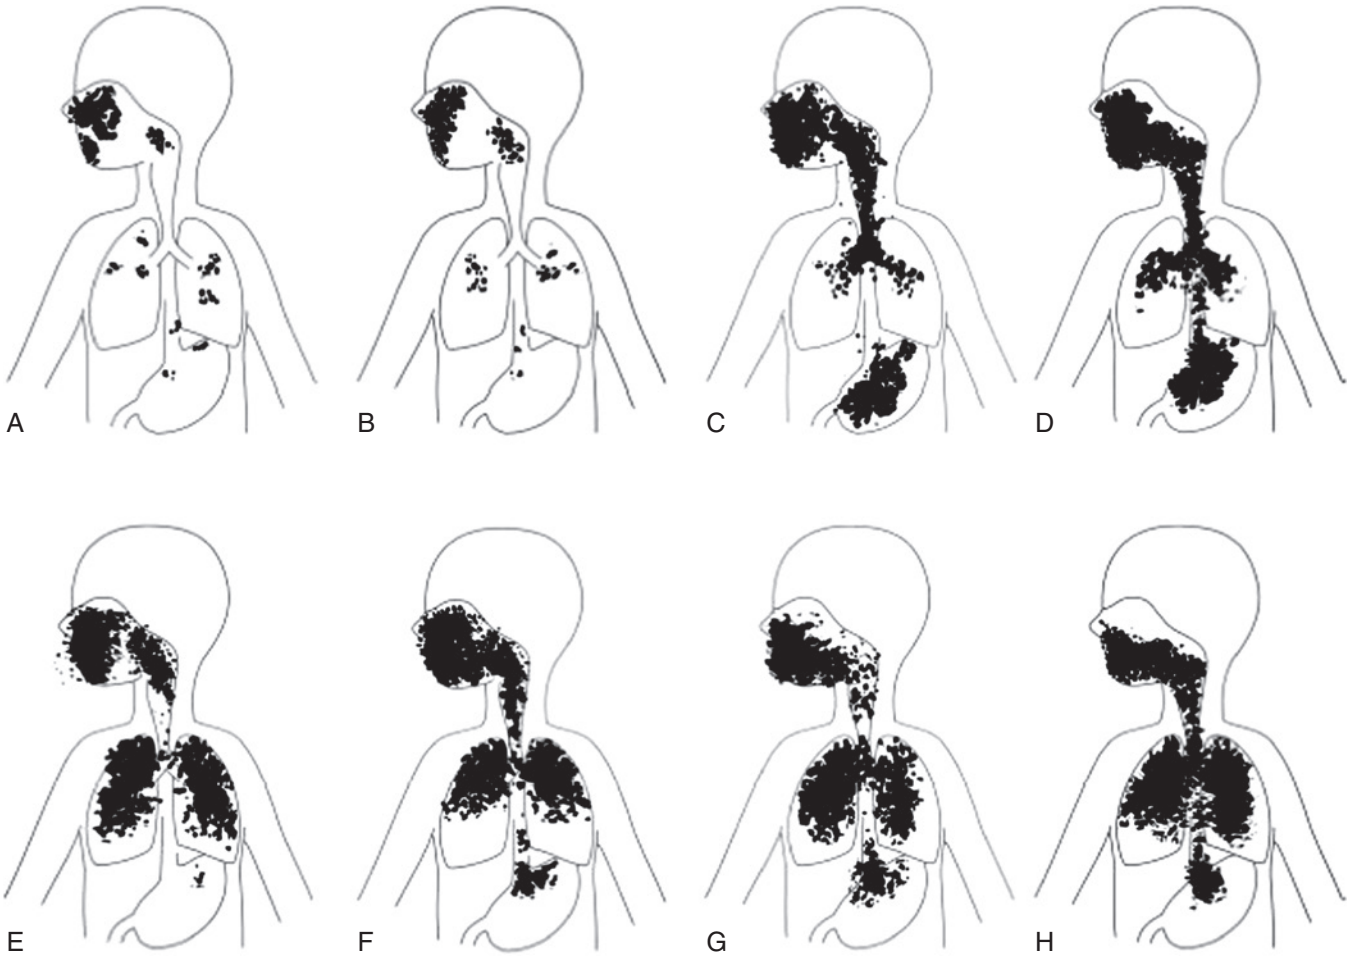

Fig. 40.23 Drug deposition of radiolabeled albuterol in a young child (A) inhaling with a pressurized metered dose inhaler (pMDI)/space through a non–tightly fitted facemask; (B) inhaling with a nebulizer through a non–tightly fitted facemask; (C and D) inhaling with a pMDI/spacer through a tightly fitted facemask, screaming during inhalation; (E and F) inhaling with a pMDI/spacer through a tightly fitted facemask, quietly inhaling; and (G and H) inhaling from a nebulizer through a tightly fitted facemask, quietly inhaling. (Redrawn from Erzinger, S, Schueepp, KG, Brooks-Wildhaber, J, et al: Facemasks and aerosol delivery in vivo, *J Aerosol Med* 20(Suppl 1.):S78–S84, 2007.)

For infants and children who can tolerate a mask, a medication nebulizer can be fitted to an appropriately sized aerosol mask. There is no difference in clinical response between mouthpiece and close-fitting mask treatment, so patient tolerance, compliance, and preference should guide selection of the device. There is evidence that the aerosol available to the patient is substantially less when a loosely fitting mask (>1 cm leak) is used rather than a snug mask or mouthpiece with either a nebulizer or a pMDI with a holding chamber.[54,58,60] If a patient cannot tolerate mask treatment (e.g., will not wear a close-fitting mask without agitation), a commonly used strategy is the "blow-by" technique, in which the practitioner directs the aerosol from the nebulizer toward the patient's nose and mouth from a distance of several inches from the face. Studies suggest a greatly reduced inhaled dose with blow-by. Rather than "blow-by," it may be more efficient to take the time to condition the infant or child to tolerate the mask without crying or to deliver medication with a close-fitting mask when the patient is asleep.[61]

As shown in Fig. 40.24, a pediatric mask with an integrated pacifier uses the infant's pull on the pacifier to hold the mask in place with improved face-mask seal which may reduce agitation and crying associated with standard masks (Soother Mask, InspiRx Inc, Somerset, NJ). Given the cognitive and functional limitations of very young patients, not all delivery devices are suitable for these patients. To help guide clinicians, the accompanying Rule of Thumb outlines age-specific guidelines for using aerosol devices in pediatric and neonatal patients.

RULE OF THUMB: Guidelines for Use of Aerosol Devices in the Care of Infants and Children

Device	Age Group
Small volume nebulizer	Neonate to all ages
Valved chamber with mask	Neonate/infant/toddler
Valved chamber with mouthpiece	>3 years
Pressurized metered dose inhaler alone	>4 years
Breath-actuated nebulizer	>4 years
Dry powder inhaler	≥4 years

Fig. 40.24 The SootherMask. (Courtesy of InspiRx, Somerset, NJ).

Spontaneous breathing in all patient populations results in greater deposition of aerosol from an SVN than occurs with positive pressure breaths (e.g., intermittent positive pressure ventilation [IPPB]). IPPB reduces aerosol deposition more than 30% compared with spontaneously inhaled aerosols.[62]

Selecting an Aerosol Drug Delivery System

pMDIs, DPIs, and nebulizers all work with comparable clinical results, as long as they are prescribed for the appropriate patients and are used properly.[1,38,63] Consequently, clinicians need to know the strengths and limitations of each type of device, match the device to each patient, and ensure that the patient or caregiver is trained to use the device properly.[30] Fig. 40.25 is an algorithm that provides guidance regarding device selection.

Regardless of the device used, the clinician must be aware of the limitations of aerosol drug therapy. Depending on the device and the patient, 10% or less of drug emitted from an aerosol device may be deposited in the lungs (Fig. 40.26). As indicated in Box 40.7, additional reductions in lung deposition can occur in many clinical situations that sometimes necessitate the use of higher dosages. Clinical efficacy varies according to both patient technique and device design. For these reasons, the best approach to aerosol drug therapy is to use an assessment-based protocol that emphasizes individually tailored therapy modified according to patient response.

MINI CLINI

Device Selection in Aerosol Therapy

Problem

The variety of aerosolized medications continues to expand, but many are limited to a specific pMDI, DPI or nebulizer. Even when we have an effective medication with excellent molecular structure, we may not be able to administer the medication because clinicians did not make the right device selection for their patient or they do not know how to use aerosol delivery devices properly.

Discussion

It is essential for clinicians to understand the characteristics of the available device, select the best device/interface combination, and know how to use them effectively. When selecting an aerosol delivery device, clinicians should use a patient-focused approach and individualize device and interface selection based on patients' age, physical and cognitive abilities, as well as patient preference and acceptance. As clinicians become familiar with the characteristics of aerosol delivery devices and know how to overcome challenges associated with aerosol therapy, they will be able to optimize aerosol drug delivery to patients.

BOX 40.7 Factors Associated With Reduced Aerosol Drug Deposition in the Lung

- Mechanical ventilation
- Artificial airways
- Reduced airway caliber (e.g., infants and children)
- Severe airway obstruction
- High gas flows
- Low minute volumes
- Poor patient compliance or technique
- Limitation of specific delivery device

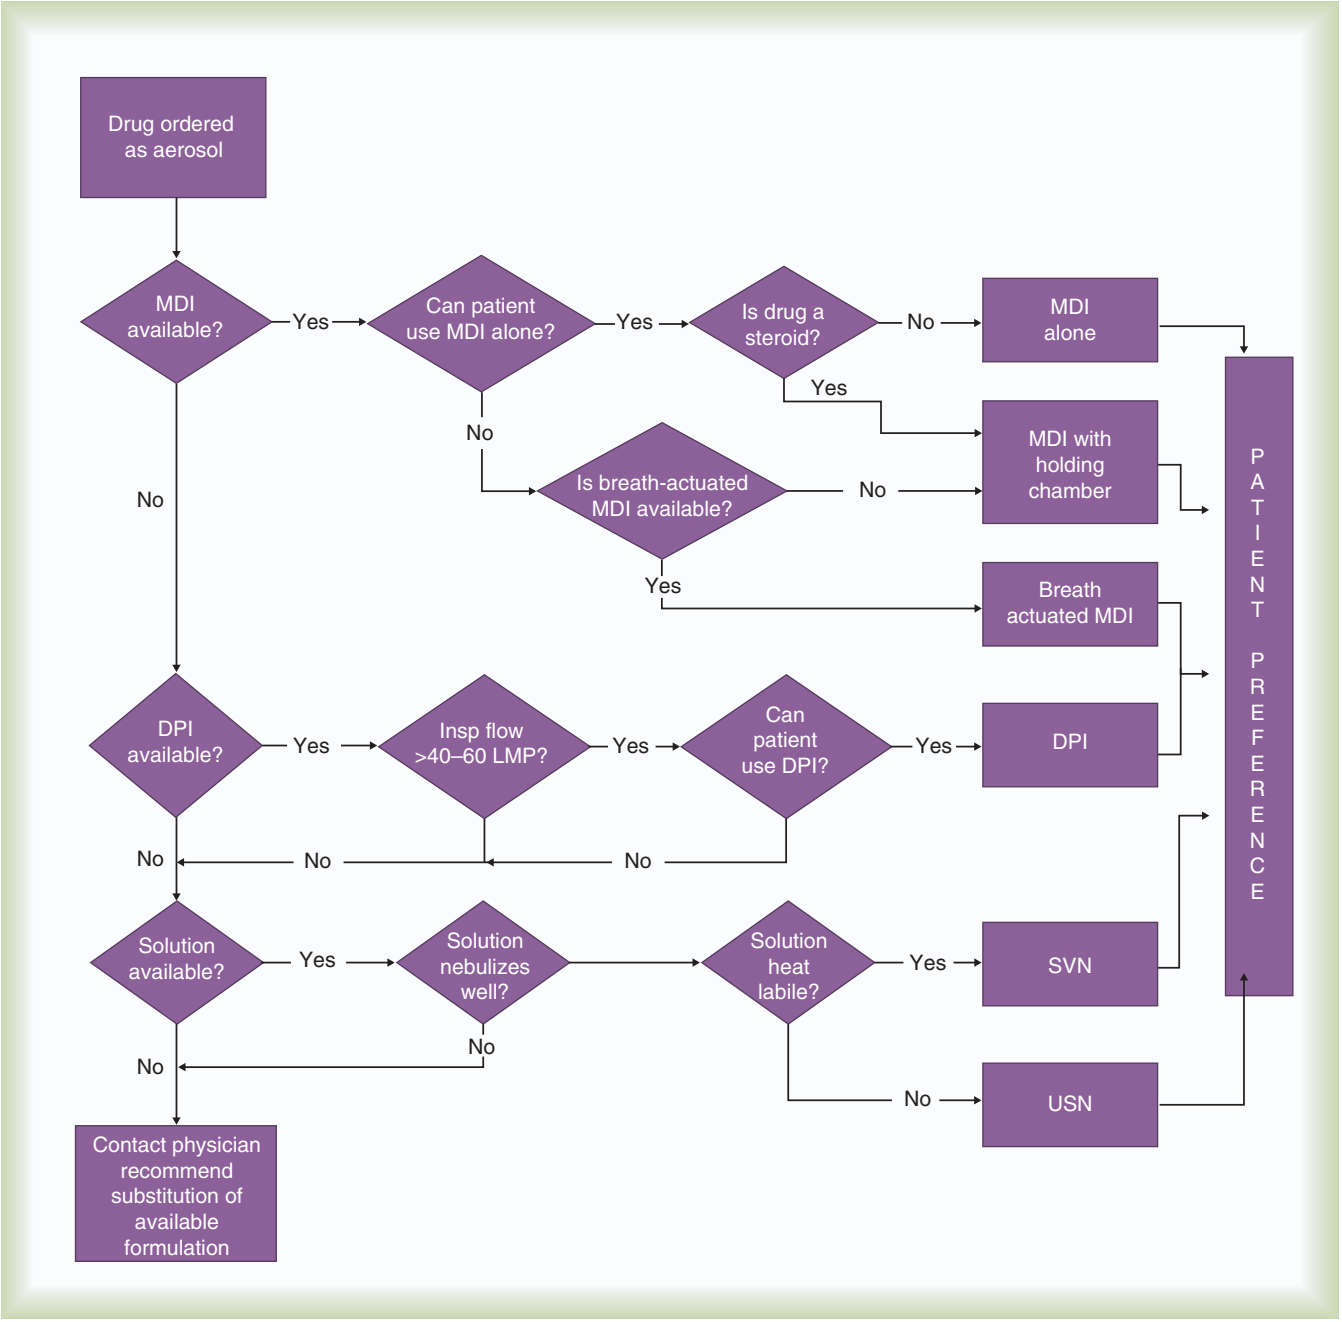

Fig. 40.25 Selecting an Aerosol Drug Delivery System. When the need is established for aerosol drug delivery, the formulations available for the prescribed medication should be determined. If a pressurized metered dose inhaler is available, it is the first choice for cost and convenience. The patient's ability to coordinate actuation with inspiration and the need to reduce oropharyngeal deposition (e.g., steroids) determine need for a holding chamber or a breath-actuated unit. Nebulizers are the first choice when the formulation is available only as a solution. When the ordered medication is unavailable for inhalation use, the respiratory therapist should recommend a substitution to the ordering physician.

ASSESSMENT-BASED BRONCHODILATOR THERAPY PROTOCOLS

Although the choice of delivery system affects how well an aerosolized drug works, it is ultimately the patient's response that determines the therapeutic outcome. Because patients vary markedly in response to the dose and route of drug administration, it makes sense to tailor aerosol drug therapy to each patient. This approach is best determined with an assessment-based protocol.

Sample Protocol

Fig. 40.27 illustrates the setup that can be used for continuous nebulization for acutely ill adults or children admitted to an emergency department. Continuous nebulization relies heavily on bedside assessment of the severity of airway obstruction based on the patient's response to varying drug dosages.

According to the algorithm, a patient with acute airway obstruction (wheezing, cough, dyspnea, and peak expiratory flow rate [PEFR] <60% of predicted value) would receive up to three SVN treatments with a standard dose of albuterol, repeated at 20-minute intervals, or four puffs of pMDI albuterol with a holding chamber (up to 12 puffs). Each treatment is followed by a dose-response assessment to determine the "best" dose. Once determined, this best dose, with the pMDI or SVN, is repeated 1 hour later, then every 4 hours as needed, supplemented with patient education. If use of the SVN or pMDI with holding chamber fails to relieve the symptoms, CBT with 15 mg/h albuterol is generally started.

Assessing Patient Response

Careful, ongoing patient assessment is key to an effective bronchodilator therapy protocol.

Use and Limitations of Peak Flow Monitoring

Because the peak flow measurement is effort dependent and volume dependent, evaluation of patient performance is subjective, and there are no good acceptability criteria. In addition, agreement between conventional spirometry values, such as forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV_1), and bedside PEFR values are poor for individual patients. Although peak flow measurement can be used at the bedside to assess treatment effectiveness and to monitor trends, conventional spirometry remains the standard for determining bronchodilator response.

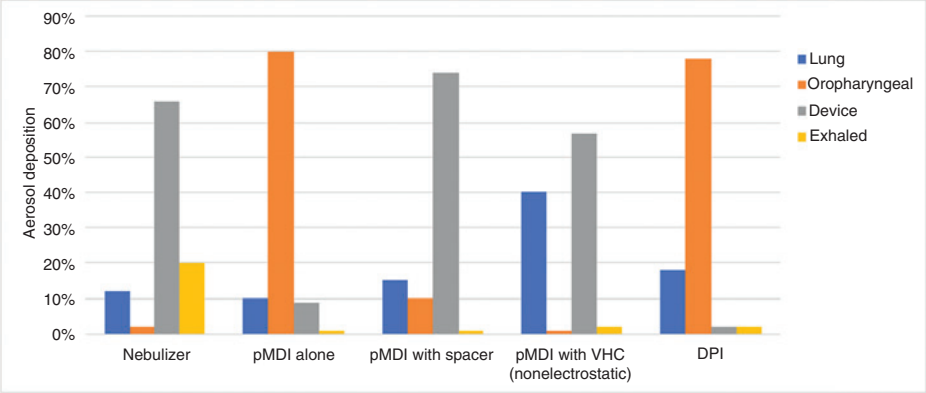

Fig. 40.26 Distribution of albuterol via nebulizer, pressurized metered dose inhaler (pMDI), pMDI with a holding chamber, and dry powder inhaler.

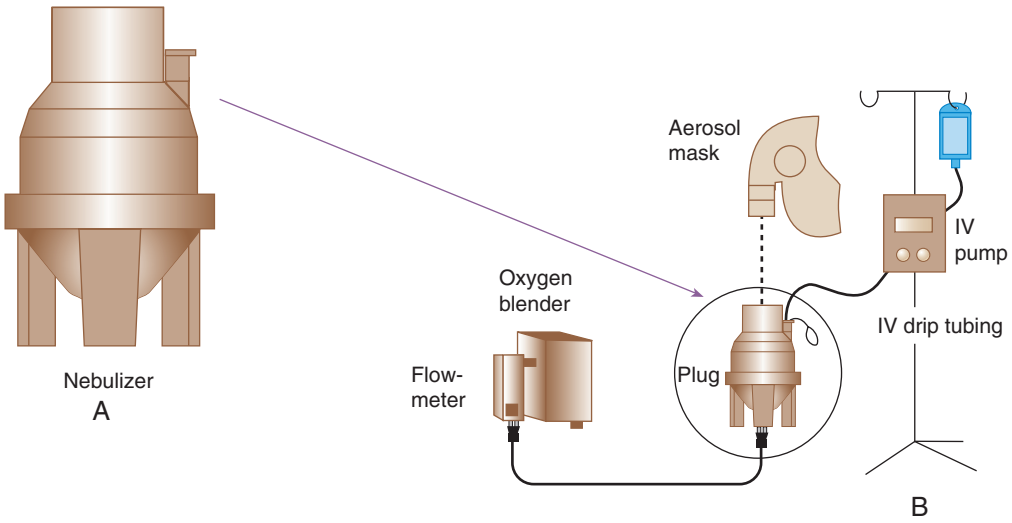

Fig. 40.27 The Setup That Can Be Used for Continuous Nebulization.

Some peak flowmeters are more accurate and reliable than others. Even different units of the same model may give variable results. For this reason, when monitoring trends, the same unit should be used for a given patient, and the patient's range should be reestablished if a different flowmeter is used.

RULE OF THUMB

- It is important to use the same flowmeter when monitoring the patient's flow rates due to variation in results among different peak flowmeters.

MINI CLINI

Spirometry and Peak Flows During Exacerbation

Problem

A patient in the emergency department presents with asthma and is having difficulty breathing. A peak flow measurement is attempted before administration of aerosol bronchodilator, but patient does not appear to be able to complete the maneuver. Do you repeat or treat?

Discussion

Definitely proceed to treat. When patients with asthma or COPD are short of breath, use of spirometry and peak flow may not be possible or reliable. Rather than repeating the test, which may further irritate or tire the patient, it is better to proceed with the bronchodilator therapy, and document that patient was unable to perform the peak flow.

Other Components of Patient Assessment

Tests of expiratory airflow for assessing patient response to therapy are commonly used, but not all patients can perform these maneuvers. Other components of patient assessment useful in evaluating bronchodilator therapy include patient interviewing and observation, measurement of vital signs, auscultation, blood gas analysis, and oximetry.

When possible, the patient should be interviewed to determine the pertinent respiratory history and current level of dyspnea. A validated dyspnea rating scale may be useful for this purpose. Initial determination of patient age and level of consciousness is helpful in selecting both delivery device and starting drug dosage. Observing the patient for signs of increased work of breathing (e.g., tachypnea, accessory muscle use) provides a baseline for assessing status as therapy progresses. Restlessness, diaphoresis, and tachycardia also may indicate severity of airway obstruction but must not be confused with bronchodilator overdose.

Increased cough has been associated with the onset of asthma. The frequency, severity, and effectiveness of cough should be assessed before and after therapy.

In terms of breath sounds, a decrease in wheezing accompanied by an overall decrease in the intensity of breath sounds indicates worsening airway obstruction or patient fatigue. Improvement is indicated when wheezing decreases and the overall intensity of breath sounds increases.

All patients with acute airway obstruction should be monitored for oxygenation status with pulse oximetry. This value can be used in conjunction with observational assessment to titrate the level of inspired O_2 given to the patient (see Chapter 42). Arterial blood gases are not essential for determining patient response to bronchodilator therapy but may be needed for patients in severe distress to assess for hypercapnic respiratory failure.

Dose-Response Assessment

Poor patient response to bronchodilator therapy often occurs because an inadequate amount of drug reaches the airway. To determine the "best" dose for patients with moderate obstruction, the respiratory therapist (RT) should conduct a dose-response titration.

A simple albuterol dose-response titration involves giving an initial four puffs (90 mcg/puff) at 1-minute intervals through a pMDI with a holding chamber. After 5 minutes, if airway obstruction is not relieved, the RT gives one puff per minute until symptoms are relieved, heart rate increases by more than 20 beats/min, tremors increase, or 12 puffs are delivered. The best dose is the dose that provides maximum relief of symptoms and the highest PEFR without side effects.

Frequency of Patient Assessment

How frequently patients should undergo assessment for bronchodilator therapy depends primarily on the acuity of the condition. An unstable patient in acute distress should undergo closer and more frequent scrutiny than a patient in stable condition. Box 40.8 provides guidance regarding the frequency of assessment according to acuity.

BOX 40.8 Frequency of Assessment of Bronchodilator Therapy

For Patient With an Acute Disorder Who Is in Unstable Condition

- Whenever possible, perform a full assessment and obtain a pretreatment baseline.
- Assess and document all appropriate variables before and after each treatment (breath sounds, vital signs, side effects during therapy, and PEFR or FEV_1).
- The frequency with which physical examination and PEFR or FEV_1 are repeated should be based on the acuteness of the disorder and the severity of the patient's condition.
- SpO_2 should be monitored continuously, if possible.
- Assessment should continue as dosages are changed to optimize patient response (e.g., if an asthmatic patient achieves 70%–90% of predicted or "personal best" or becomes symptomfree).

For Stable Patient

- In the hospital, PEFR should be measured initially before and after each bronchodilator administration. Thereafter, twice-daily determinations may be adequate.
- In the home, PEFR ideally should be measured three or four times a day: on rising, at noon, between 4 PM and 7 PM, and at bedtime.
- For a stable COPD patient at home, measuring PEFR twice a day may be adequate.
- Patients with asthma should adjust the frequency of PEFR measurement according to the severity of symptoms.
- PEFR levels before and after bronchodilator use, medication dose, date and time, and dyspnea score should be documented.
- The patient should be reevaluated periodically for response to therapy.

COPD, Chronic obstructive pulmonary disease; *FEV_1*, forced expiratory volume in 1 s; *PEFR*, peak expiratory flow rate; *SpO_2*, oxygen saturation by pulse oximeter.

Patient Education

The desired outcome of all bronchodilator protocols is restoration of normal airflow and cessation of therapy. For patients who need ongoing maintenance therapy after the acute phase of illness, the goal should be effective self-administration. An effective program of aerosol drug self-administration depends on thorough patient education. Patient education on aerosol therapy should be individualized by providing one-on-one training, using a device preferred by the patient, keeping the device consistent, and developing psychomotor skills of patients with teaching devices.

Through one-on-one training sessions, clinicians can individualize the education session to a specific patient and increase adherence to therapy and improve clinical outcomes.[64,65] The patient's ability to understand the therapy and its goals significantly affects the therapeutic efficacy of any treatment. Whenever possible, patients should be taught to understand the basic administration techniques, to keep track of dosing requirements, to recognize undesirable side effects, and to understand the options and actions required to reduce or eliminate these effects. Previous research showed a relationship between proper inhalation technique and a greater degree of satisfaction with therapy.[66,67] Therefore it is important to choose an aerosol device based on patient preference and use the same type of device for different medications to eliminate patient confusion and increase patient adherence to aerosol therapy.[63] In addition, patients should be able to demonstrate good technique regarding the use of each aerosol device that they are expected to use in self-care. Patient technique with aerosol devices can be assessed and improved through teaching devices such as the 2 Tone, Mag-Flo, or InCheckDial (Fig. 40.28). Although these teaching devices provide an objective evaluation of the patient's inhalation technique, they cannot assess the patient's preparation and handling of the device at home.[68] Practitioner demonstration followed by repeated patient return demonstration is a must and should be done frequently, with each office or clinic visit.

MINI CLINI

Patient Education Continuum—Home to Hospital to Home

Problem

A patient uses inhalers at home and presents to the ED with severe symptoms of shortness of breath and bronchospasm. The ED staff begins aerosol therapy with a jet nebulizer, which is continued in the ICU and the hospital floor until discharge, where the patient goes back to use his inhaler. He may feel better, but when he goes home, he might not be effectively self-administering his inhalers, which brings him back to the ED and hospital more frequently.

Discussion

Does the patient effectively use his inhalers at home? Up to 60% of patients do not use their inhalers well enough to benefit from the medication. When the patient goes to the hospital and receives a nebulizer that is not used at home, we have not addressed a common and obvious problem. Does the patient use their inhaler properly?

It is difficult to learn and retain education when you are fighting for breath, but once the crisis is resolved, there is a "teachable moment" in which the clinician can transfer patients to the medications they use at home, observe how they self-administer, and provide teaching to improve their self-administration skill. A little teaching time can greatly reduce costs of frequent readmissions.

It is also important to monitor patient adherence, because there is a strong association between poor adherence and hospital admission due to exacerbations.[69] In addition, nonadherence to aerosol therapy results in poor disease management, an increase in school and work absenteeism, unscheduled healthcare use, morbidity, and mortality.[69-72] Patient adherence to aerosol therapy can be monitored through patient diaries, clinical judgment, pharmacy data, biochemical measures, and electronic monitoring.[73] Monitoring adherence with patient self-reports and clinical judgment is fast and inexpensive but overestimates patient adherence to prescribed medications.[74,75] Although pharmacy data are

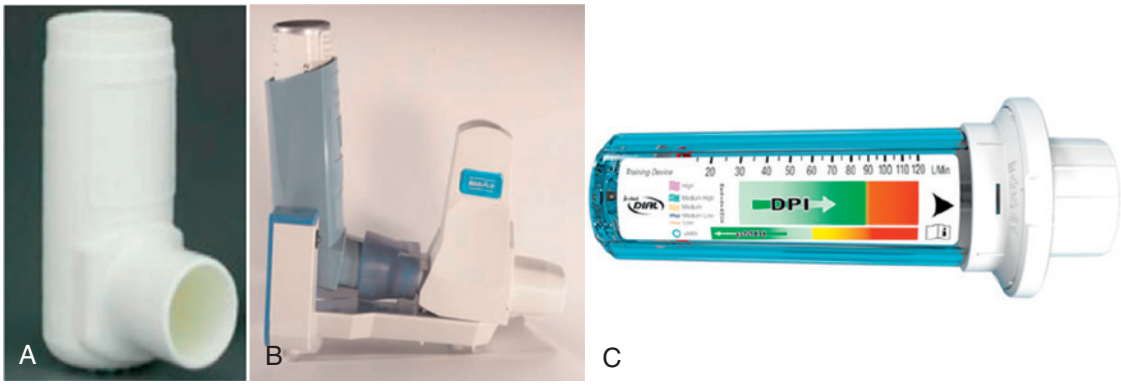

Fig. 40.28 Teaching Devices That Can Be Used for Patient Training and Assessment of Inhalation Technique. (A) 2Tone (Courtesy of Canday Med Ltd, London, UK), (B) MagFlo (Courtesy Dr Mark Levy www.animalswild.com), and (C) InCheckDial (Courtesy of ClementClark International Ltd, San Francisco, CA).

objective, valid, and inexpensive, they provide only the dates of medication dispensing and do not guarantee that the medication was taken as prescribed. Biologic measures confirm the presence of the medication in blood, urine, or saliva with a limited number of medications, and repeated analysis may be needed because it is hard to detect the presence of inhaled drugs. Electronic device monitoring provides accurate data about patient's adherence to therapy, but it is expensive.[76,77]

SPECIAL CONSIDERATIONS

Aerosol Therapy for Treatment of Pulmonary Arterial Hypertension

Iloprost (Ventavis, Actelion Pharmaceuticals US, Inc, South San Francisco, CA) and treprostinil (Tyvaso) are inhaled prostacyclins approved for treatment of pulmonary arterial hypertension. They are administered with specific nebulizers in discrete doses that are repeated throughout the day. Iloprost and treprostinil have a half-life of 60 to 90 minutes, allowing more convenient dosing to ambulatory patients.

Other formulations of epoprostenol (Veletri, Actelion Pharmaceuticals US, Inc) and epoprostenol sodium (Flolan, GlaxoSmithKline) have been administered as aerosol in the acute care setting for more than 20 years but they are only approved for IV use, not inhalation. Epoprostenol administration is associated with positive effects on symptoms, hemodynamics, exercise capacity, disease progression, and survival.[78-80] Due to their short half-life of 30 to 90 seconds, continuous nebulization is used. It is important to select an appropriate nebulizer and delivery method to improve the effectiveness of aerosol therapy in pulmonary hypertension. In the past, a variety of jet and USNs were used to administer prostaglandin I_2 (PGI_2). The particle size ranged from 2.1 μm to 5.2 μm at 6 L/min, and it was between 2.5 μm and 4 μm with the USN.[81] Jet and USNs gradually concentrate the drug solution due to the evaporation of solvent. In addition, USNs increase the temperature of the medication up to 55°C, resulting in higher evaporation and concentration effects. In contrast, mesh nebulizers generate a constant aerosol output of small particles without generating significant heat or evaporation, reducing issues with dose variability and solvent evaporation. One other advantage of mesh nebulizers is that they consistently nebulize small volumes of drug, as small as single drops and do not interfere with ventilator functions during mechanical ventilation. During drug delivery to ventilator dependent patients, filters should be placed on the expiratory limb of the ventilator circuit and changed frequently.

Acute Care and Off-Label Use

Every drug approved for inhalation to date has been designed for and tested in populations of ambulatory patients with moderate disease. As patients with lung disease become acutely and critically ill, the approved label doses, frequency of administration, and devices may not be practical or effective, especially for treatment of patients requiring ventilatory support. In such cases, clinicians may explore and consider nonstandard methods (doses, frequency, and devices) for administration of approved inhaled drugs to patients in the acute care environment, known as *off-label use*. For example, epoprosterenol and iloprost are approved for treatment of ambulatory patients with pulmonary hypertension; physicians may use them in ventilator-dependent patients, right heart failure, or hypoxemic respiratory failure because they improve right heart function, increase oxygenation, and decrease pulmonary artery pressure. Another type of off-label use involves drugs that have not been approved for inhalation, ranging from heparin to certain antibiotics. Although physicians may order such drugs via inhalation, the risk to the patient and institution is greater when the administration of such drugs via inhalation has not been thoroughly studied. All forms of off-label use should be avoided when approved, effective, and viable alternatives exist. Likewise, off-label administration should always be backed by appropriate departmental or institutional policies and procedures.

Continuous Nebulization for Refractory Bronchospasm

Patients in the emergency department with severe exacerbation of asthma or acute bronchospasm often have been taking standard doses of their bronchodilators for 24 to 36 hours before admission without response. Giving nebulizer treatments with standard bronchodilator doses and repeating the treatments until the symptoms are relieved can require hours of staff time. Administering higher doses of albuterol in short time frames can be accomplished by nebulization of undiluted albuterol or by protocol titration with a pMDI and holding chamber (up to 12 puffs). If these strategies fail to provide relief, CBT with albuterol nebulization doses ranging from 5 to 20 mg/h have proven safe and effective for adult and pediatric patients (Fig. 40.29. Recently, CBT has been used for the treatment of ventilator-dependent patients.

Fig. 40.30 shows a treatment algorithm used for high-dose therapy and CBT for pediatric patients with status asthmaticus who are unable to perform peak flow maneuvers.[82] Candidates for this protocol are children who, despite frequent β-agonist treatments, remain in extremis with bronchospasm, dyspnea, cough, chest tightness, and diminished breath sounds.

According to this protocol, children older than 6 years with tachypnea, hypoxemia, increased work of breathing, and

Fig. 40.29 Continuous Drug Delivery Line From a Syringe Pump Attached to a Nebulizer.

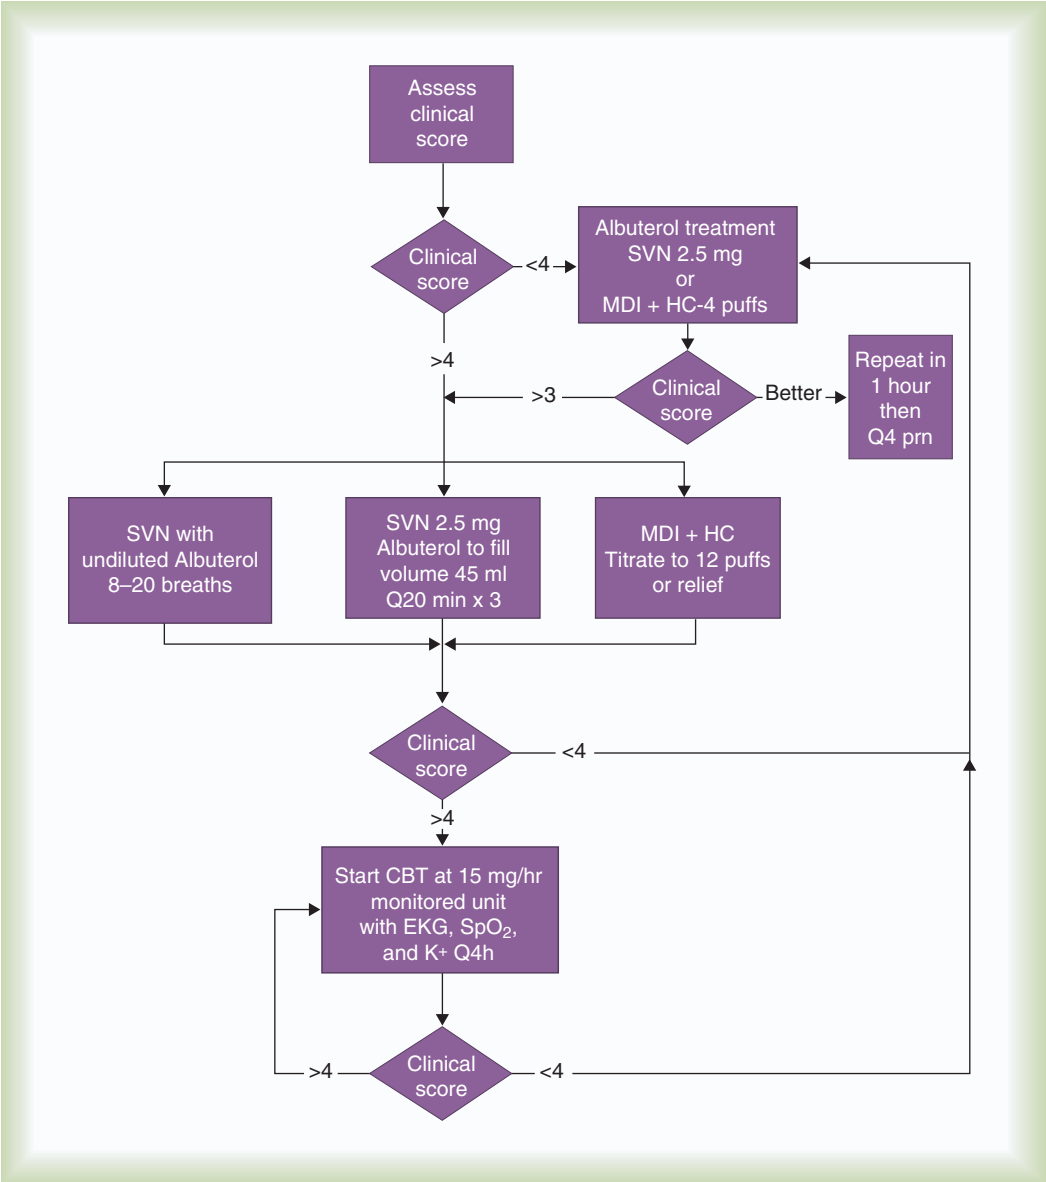

Fig. 40.30 Algorithm for continuous bronchodilator therapy (CBT) for patients younger than 5 years with pediatric asthma in extremis.

restlessness who do not respond to standard therapy are given CBT with a large volume nebulizer or SVN at a dose rate of 15 mg/h (see the accompanying Mini Clini "CBT Dosage Computations" for dosage computations). A standardized asthma score is used to evaluate children younger than 6 years for the severity of the condition (Table 40.4). Patients with an asthma score of 4 or higher are given CBT.

After CBT is started, the patient is carefully assessed every 30 minutes for the first 2 hours and thereafter every hour. A positive response is indicated by an increase in PEFR of at least 10% after the first hour of therapy. The goal is at least 50% of the predicted value. For small children, improved oxygenation (oxygen saturation by pulse oximeter [SpO_2] >92% on room air) with evidence of decreased work of breathing indicates a favorable response. Once the patient "opens up," intermittent SVN administration is resumed, or a pMDI dose-response assessment is conducted.

The patient has responded poorly to CBT if any of the indicators listed in Table 40.4 worsen. The patient must be observed for adverse drug responses, including worsening tachycardia, palpitations, and vomiting. In these situations, the attending physician must be contacted immediately.

As an alternative to large volume drug nebulizers, some protocols are based on high-dose pMDI therapy (12 to 24 puffs per hour).[83] To provide an extra margin of safety, some clinicians recommend that patients receiving CBT undergo continuous electrocardiogram monitoring and measurement of serum potassium level every 4 hours.

TABLE 40.4 Pediatric Asthma Score

	ASTHMA SCORE		
Variable	**1 Point**	**2 Points**	**3 Points**
Respiratory Rate			
2–3 years	≤34	35–39	≥40
4–5 years	≤30	31–35	≥36
6–12 years	≤26	27–30	≥31
>12 years	≤23	24–27	≥28
Oxygen saturation (%)	>95 with room air	90–95 with room air	<90 with room air or supplemental oxygen
Auscultation	Normal breathing or end-expiratory wheezing	Expiratory wheezing	Inspiratory and expiratory wheezing, diminished breath sounds, or both
Retractions	None or intercostal	Intercostal and substernal	Intercostal, substernal and supraclavicular
Dyspnea	Speaks in sentences or coos and babbles	Speaks in partial sentences or utters short cries	Speaks in single words or short phrases or grunts

MINI CLINI

Continuous Bronchodilator Therapy Dosage Computations

Problem

Dosages for CBT are ordered in milligrams per hour, and delivery depends on both drug concentration and nebulizer output. Compute the volume of 1:200 (0.5%) albuterol and the volume of diluent (normal saline solution) needed to provide 4 hours of CBT with 15 mg/h of albuterol in a nebulizer with an output of 25 mL/h.

Discussion

Step 1: Compute the volume of albuterol given per hour (mg/h × mL/mg).

$$15.0\ \text{mg/h} \times 0.2\ \text{mL/mg} = 3.0\ \text{mL/h albuterol}$$

Step 2: Compute the volume of albuterol for the treatment period (hours × mL/h).

$$4\ \text{hours} \times 3.0\ \text{mL/h} = 12\ \text{mL/4 h albuterol}$$

Step 3: Compute the volume of nebulization solution (mL/h nebulizer output × hours).

$$25\ \text{mL/h} \times 4\ \text{hours} = 100\ \text{mL}$$

Step 4: Compute the volume of diluent required.

$$100\ \text{mL} - 12\ \text{mL} = 88\ \text{mL normal saline solution}$$

To prepare this dosage, mix 12 mL of 0.5% albuterol with 88 mL of normal saline solution, for a total nebulizer solution volume of 100 mL. In this example, residual volume of the nebulizer decreases total treatment time and dose.

Transnasal Pulmonary Aerosol Delivery

Transnasal pulmonary aerosol delivery through nasal cannula has gained increasing popularity.[84] Pediatric patients with bronchiolitis or asthma were found to become less anxious and more comfortable when inhaling bronchodilator via nasal cannula.[85-87] This route makes the long duration of aerosol inhalation feasible, as the traditional nebulizer and interface (mask or mouthpiece) are unlikely to be tolerated for extended periods of time. Aerosol delivery via high-flow nasal cannula (HFNC) has been clinically described and used for administration of bronchodilators for asthma or COPD[88] and inhaled epoprostenol for pulmonary hypertension or hypoxemia.[89]

Radiolabeled in vivo studies report aerosol lung deposition via HFNC is less than 1% in models of pediatric population[90] and less than 4% in adult population.[91,92] In vitro reports investigated influential factors, such as delivery gas type and flow, nebulizer type and placement, breathing pattern, size of nasal cannula, and role of heated humidification with a consensus that flow plays a key role in aerosol delivery via HFNC.[42,43,91-98] Previous studies report aerosol deposition to be inversely related to the HFNC flow in quite breathing.[42,43,91,95] However, distressed breathing with higher inspiratory flows (required for sicker patients) increased lung deposition at higher HFNC gas flow (≥30 L/min) but not at low flow (10 L/min). Lower gas flows result in greater lung deposition making transnasal pulmonary aerosol delivery attractive for continuous nebulization over multiple hours.

Aerosol Administration During Ventilator Support

Since the advent of modern mechanical ventilation, clinicians have administered aerosols to critically ill mechanically ventilated patients. Four primary forms of aerosol generator are used to deliver aerosols during mechanical ventilation: SVN, USN, VM nebulizer, and pMDI with third-party adapter. Table 40.5 summarizes the factors affecting aerosol drug delivery to mechanically ventilated patients. Techniques to optimize delivery to patients receiving ventilatory support are described.[99]

Regarding doses, the amount of drug required to achieve the same therapeutic end point is substantially similar for medications delivered by pMDI to intubated patients (8%) and patients who are not intubated (8% to 10%). In stable patients with COPD receiving ventilatory support, four puffs of albuterol via pMDI with chamber and 2.5 mg via SVN were shown to produce maximum bronchodilation with effects lasting for 4 hours. However, some differences in response were noted that may have been due to the level of airway obstruction and the techniques used for assessing response.

Techniques for assessing the response to a bronchodilator in intubated patients undergoing mechanical ventilation differ from techniques used in the care of spontaneously breathing patients because expiration is passive during mechanical ventilation, and forced expiratory values (PEFR, FVC, FEV_1) cannot normally be obtained. Additional techniques can be used for mechanically ventilated patients because: (1) a change in the differences between peak and plateau pressures (volume ventilation with constant flow, the most reliable indicator of a change in airway resistance during continuous mechanical ventilation) can be measured, (2) automatic positive end expiratory pressure levels may decrease in response to bronchodilators, and (3) breath-to-breath variations make measurements more reliable when the patient is not actively breathing with the ventilator.[100]

TABLE 40.5 Factors Affecting Aerosol Drug Delivery During Mechanical Ventilation

Category	Factor
Ventilator related	Mode of ventilation
	V_T
	Respiratory rate
	Duty cycle
	Inspiratory waveform
	Breath-triggering mechanism
Circuit related	Size of endotracheal tube
	Type of humidifier

Techniques for aerosol administration vary by type of aerosol generator and device used. The optimal technique for drug delivery to mechanically ventilated patients with each type of aerosol generator is described in Box 40.9.

MINI CLINI

Use of Heat Moisture Exhchangers During Aerosol Administration

Problem

Guidelines recommend removing heat moisture exchangers (HMEs) from between the aerosol generator and the patient airway. However, not all HMEs work the same, and some nonfiltering may be left in line.

Discussion

Filter HMEs are known to filter out the majority of aerosol passing through them. However, studies have shown that nonfilter HMEs may pass up to 60% of aerosol on to the patient.[101] If you use a nonfilter HME that is known to work with aerosol delivery, then it can remain in line, reducing the need to disconnect that patient from the ventilator before and after aerosol therapy. Because HMEs can allow aerosol to pass, they are not a substitute for high-efficiency particulate air (HEPA) filters placed in the expiratory line of the ventilator circuit. Over time, aerosol can build up an HME, increasing resistance to expiratory flow, causing increased expiratory time, air trapping, and increased work of breathing. Assess HMEs periodically, and change as appropriate.

BOX 40.9 Optimal Technique for Aerosolized Drug Delivery to Mechanically Ventilated Patients

1. Review order, identify the patient, gather equipment, and assess the need for bronchodilators.
2. Clear the airways as needed by suctioning the patient as needed.
3. If using a circuit with HME, remove HME from between the aerosol generator and the patient.
4. If using heated humidifier, do not turn off or disconnect before or during treatment.
5. Assemble equipment (tubing, nebulizer, circuit adapter).
6. Fill the nebulizer with recommended volume and medication per physician order and label.
7. Place adapter in the inspiratory limb, 6 inches from the "wye," and connect aerosol generator.
8. Turn off or minimize bias flow during treatment.
9. Connect the nebulizer to a gas or power source, as appropriate.

10a. For jet nebulizer (including SVN): Use gas source on ventilator to synchronize nebulization with inspiration, if available; otherwise, set gas flow 6 to 10 L/min as recommended on nebulizer label, and adjust ventilator volume or pressure limit and alarms to compensate for added flow and volume.

10b. For USN and VM nebulizer: Attach power source and cable from controller.

10c. For pMDI: Shake canister and connect to spacer or adapter; actuate at beginning of inspiration.

11. Observe aerosol cloud for adequate aerosol generation during nebulization.
12. After appropriate dose is administered, remove aerosol generator from the ventilator circuit.
13. Reconnect HME, as appropriate.
14. Return ventilator settings and alarms to previous values.
15. Ensure there is no leak in the ventilator circuit.
16. Rinse the nebulizer with sterile or distilled water, shake off excess water, and allow to air dry.
17. Store aerosol device in a clean, dry place.
18. Monitor heart rate, SpO_2, blood pressure, and patient-ventilator synchronization.
19. Monitor the patient for adverse response.
20. Assess the airway, and suction as needed; document findings.

HME, heat and moisture exchanger; *MDI*, pressurized metered dose inhaler; *SpO_2*, oxygen saturation by pulse oximeter; *SVN*, small volume nebulizer; *USN*, ultrasonic nebulizer; *VM*, vibrating mesh.

Use of a Small Volume Nebulizer During Mechanical Ventilation

The aerosol administered by SVN to intubated patients receiving mechanical ventilation tends to be deposited mainly in the tubing of the ventilator circuit and expiratory filter. Under normal conditions with heated humidification and standard jet nebulizers, pulmonary deposition ranges from 1.5% to 3.0%.[102] When nebulizer output, humidity level, V_T, flow, and I:E ratio are optimized, deposition can increase to 15%.

There are several disadvantages with SVN use during mechanical ventilation. Although in vitro models showed 40% higher aerosol delivery with an unheated, nonhumidified circuit compared with heated humidity, these effects have not been shown in patients. The risks associated with administering cold and

dry gas through an endotracheal tube include drying of secretions, bronchospasm, and airway obstruction. A heat and moisture exchanger should be considered a barrier to aerosol administration and should always be removed if placed between the nebulizer and the patient airway. When available with the specific ventilator being used, breath actuation can increase aerosol delivery by 30%, but it may extend administration time by more than threefold. Introducing additional flow into the ventilator circuit may change parameters of flow and delivered volumes and require changes to V_T and alarm settings during and after nebulization. The smaller the patient, the greater the impact of added flow into the ventilator circuit, where 6 L/min of additional gas flow can more than double V_T and inspiratory pressure, placing the patient at risk. Risk is high for not changing ventilator parameters and not returning parameters to pretreatment levels after administration. There is also a tendency for condensate and secretions to drain into the nebulizer reservoir, contaminating medication being delivered to the lungs.

MINI CLINI

Never Emptying Nebulizer

Problem

Jet nebulizers and ultrasonic nebulizers are frequently used to administer aerosol to patients during mechanical ventilation. Commonly, a nebulizer is filled with a standard unit dose of 3 mL of medication at the beginning of the aerosol treatment, and the RT finds as much or more fluid in the medication reservoir 20 to 30 min later. The additional fluid is usually condensate (often contaminated from patient secretions), which drains from the inspiratory limb into the gravity-dependent reservoir of the nebulizer. Even heated wire circuits may have condensate. Although pathogens in a dry circuit have minimal chance of contaminating the patient's airway, aerosolizing the pathogens provides a vehicle for infectious material to enter the airway and the lung parenchyma.

Solution

The nebulizer should be positioned so that the upper end of the reservoir is superior to (higher than) the ventilator tubing attached to both ends of the nebulizer. This position allows the condensate and secretions to drain away from the nebulizer. Alternatively, nebulizers with physical barriers between the ventilator circuit tubing and the medication reservoir can be used. These options include use of a pMDI with spacer or a VM nebulizer.

Use of a Vibrating Mesh Nebulizer During Mechanical Ventilation

Aerosol administration by a VM nebulizer has been estimated to deliver greater than 10% deposition in adults and infants without the addition of gas into the ventilator circuit. The low residual drug volume and small particle size are associated with higher efficiency. Similar to the USN, the VM nebulizer does not add gas flow into the ventilator circuit, so ventilator parameters and alarms do not need to be adjusted before, during, or after nebulization. In contrast to jet SVNs and USNs, the medication reservoir of the VM nebulizer is above the circuit and separated from the ventilator tubing by the mesh, reducing the risk of retrograde contamination of medication in the reservoir from the ventilator circuit. Because of the nature of the mesh, the reservoir can be opened and medication can be added to the nebulizer without creating a perceptible leak during ventilation. When using VM nebulizers in ventilator-dependent patients, HMEs should be removed before treatment.

Use of a Pressurized Metered Dose Inhaler During Mechanical Ventilation

Results of in vitro studies show that effective aerosol delivery by pMDIs during mechanical ventilation can range from 2% to 30%. Direct pMDI actuation by simple elbow adapters typically results in the least pulmonary deposition, with most of the aerosol impacting in either the ventilator circuit or the tracheal airway. Higher aerosol delivery percentages occur only when an actuator or spacer is placed in-line in the ventilator circuit. These spacers allow an aerosol "plume" to develop before the bulk of the particles impact on the surface of the circuit or endotracheal tube. The result is a more stable aerosol mass that can penetrate beyond the artificial airway and be deposited mainly in the lung. This situation leads to a better clinical response at lower doses.[26,39]

Aerosol Generator Placement

Placement of aerosol generators in the ventilator circuit can have a substantial impact on the available lung dose of drug. During adult ventilation without bias flow, placement of aerosol generators 18 to 24 inches from the patient in the inspiratory limb increases inhaled dose for jet nebulizers, where continuous gas flow acts to clear the inspiratory limb of the ventilator circuit of aerosol. In contrast, pMDI, USN, and VM nebulizer devices are more efficient when placed close to the patient at the circuit wye.[103,104] With continuous or bias flow through the adult and pediatric ventilator circuit, the delivery is reduced as flow increases, whereas placement of a VM or USN nebulizer near the ventilator increases delivery (Fig. 40.31).[104,105] For PCV with and without bias flow, as well as airway pressure release ventilation (APRV), with and without spontaneous ventilation, delivered dose was greatest with VM at the humidifier inlet. In contrast, with infant circuits, placement in the inspiratory limb closer to the patient was most efficient.

Placement During Noninvasive Ventilation

Noninvasive ventilation may be administered with standard and bilevel ventilators. Bilevel ventilators often use a flow turbine, with a fixed leak in the circuit that permits excess flow to vent to atmosphere. Placement of the aerosol generator between the leak and the patient's airway seems to provide the highest aerosol delivery efficiency.[106-108] A VM nebulizer delivers a greater inhaled dose than an SVN during noninvasive ventilation, presumably because of the lower residual drug volume and lower total flow in the circuit.[107,109,110] Delivery efficiency of aerosol devices during noninvasive ventilation ranges from 2% to 29% depending on patient population, the ventilator parameters, aerosol devices, and interfaces used in patients receiving noninvasive ventilation.[106,107,109-111] It is important to note that high flows and leakage of gas decrease aerosol delivery to patients receiving noninvasive ventilation.

Placement During Transnasal Pulmonary Delivery of Aerosol With High-Flow and Low-Flow Nasal Cannula

Transnasal delivery of aerosol to the lung via a nasal cannula with infant, pediatric, and adult models has been quantified

	Percent of nominal or emitted dose (mean ± SD %)							
	Adult lung model				Pediatric lung model			
	Position 1		Position 2		Position 1		Position 2	
	Bias flow 2 L/min	Bias flow 5 L/min	Bias flow 2 L/min	Bias flow 5 L/min	Bias flow 2 L/min	Bias flow 5 L/min	Bias flow 2 L/min	Bias flow 5 L/min
Jet nebulizer	4.7 ± 0.1*	4.0 ± 0.1*	5.2 ± 0.2*	4.7 ± 0.4*	4.2 ± 0.2*	3.8 ± 0.3*	5.2 ± 0.3*	4.1 ± 0.4*
Vibrating-mesh nubulizer	13.4 ± 1.1	9.7 ± 0.6	23.8 ± 1.0	21.4 ± 0.4	11.4 ± 0.7	8.4 ± 0.2	13.6 ± 1.3	10.6 ± 0.3

*Significant difference between jet nebulizer and vibrating-mesh nebulizer ($p < 05$).

Fig. 40.31 Placement of small volume nebulizer and vibrating mesh nebulizer aerosol generators in two positions in the ventilator circuit with 2 L/min and 5 L/min of bias flow results in different deposition efficiency.

with aerosol delivery efficiency negatively correlated with the flow of gas administered.[42,43,84,98] Use of SVN has been described, with lower delivery efficiency than VMN and greater flow in the circuit for nebulizer operation, presenting a problem with infants and children. Fig. 40.32 shows the setup with HFNC, including the location of the VM nebulizer. Placement of the VM nebulizer prior to the humidifier increases aerosol deposition with HFNC.[93] In addition to the location of the nebulizer with HFNC, the inhaled dose varies with cannula size, respiratory pattern, gas flow, and gas density. Heliox (80:20) appears to improve aerosol delivery at higher flow rates.[93] The administration of aerosolized medications via HFNC is marginally less efficient than removing the HFNC cannula during administration.[97] Administering aerosol via mouth during HFNC results in virtually no drug reaching the lungs. When delivering aerosolized medications by mask, the benefit of increased aerosol delivery must be weighed against the risk of desaturation when nasal prongs are removed. According to previous in vitro studies, aerosol drug delivery with HFNC ranged from 0.2% to 32% depending on nebulizer type, position, and flow rate used with pediatric and adult lung models.[42,43,84,93,98,112]

MINI CLINI

Aerosol by Mouth or Mask During High Flow Nasal Cannula

Problem

HFNC is prescribed to maintain FiO_2, help clear CO_2, and incrementally increase positive airway pressure with flows that exceed a patient's inspiratory flow. What happens when you administer aerosol via mouthpiece or mask during HFNC?

Discussion

Nothing good! In vitro models of infants and adults show only trace inhaled doses when aerosol is administered while HFNC is in place. It appears that the high flow from the cannula acts to blow the aerosol away from the patient, so only a small proportion of gas containing aerosol is inhaled. Transnasal pulmonary delivery or aerosol via nasal cannula has proven more efficient and more readily tolerated by patients.

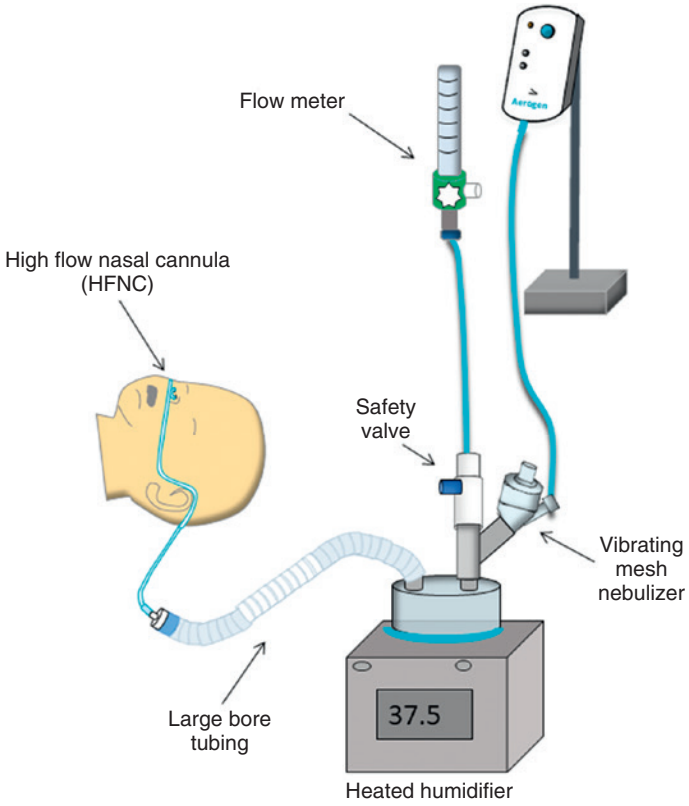

Fig. 40.32 The Setup That Will Be Used to Deliver Aerosolized Medications Through High Flow Nasal Cannula. (From *Current Pharmaceutical Biotechnology* 2017; 18(11): 877–882.)

Placement During Intrapulmonary Percussive Ventilation

Intrapulmonary percussive ventilation provides high-frequency oscillation of the airway while administering aerosol particles. During intrapulmonary percussive ventilation, the aerosol generator should be placed in the circuit as close to the patient's airway as practical. A comparison study found the MMAD was smaller with intrapulmonary percussive ventilation than with the jet (0.2 μm vs. 1.89 μm), and the fine-particle fraction was lower (16.2% vs. 67.5%). However, lung dose was similar (2.49% with intrapulmonary percussive ventilation vs. 4.2% with the jet nebulizer). It was concluded that intrapulmonary percussive ventilation was too variable and too unpredictable to recommend for drug delivery to the lung.[113]

Placement During High-Frequency Oscillatory Ventilation

When used in conjunction with high-frequency oscillatory ventilation, administration of albuterol sulfate via a VM nebulizer placed between the ventilator circuit and the patient airway has been reported to deliver greater than 10% of dose to both infants and adults.[114,115] A pMDI with adapter placed immediately proximal to the endotracheal tube achieved similar results in adult patients ventilated via high-frequency oscillatory ventilation.[116]

CONTROLLING ENVIRONMENTAL CONTAMINATION

Drugs for nebulization that escape from the nebulizer into the atmosphere or are exhaled by the patient can be inhaled by anyone in the vicinity of the treatment. The risk imposed by this environmental exposure is clear and is associated with a range of drugs and patients with infectious disease. Pentamidine and ribavirin were associated with health risks to healthcare providers even when used in conjunction with filters on exhalation ports of nebulizers, containment and scavenger systems, and *HEPA* filter hoods and ventilation systems. In addition, the aerosolization of any antibiotic should be treated in a similar manner.

Continuous pneumatic nebulizers produce the greatest amount of secondhand aerosol, with most (60%) of the aerosol produced passing directly into the environment. The Respirgard II (Vital Signs, Totowa, NJ) nebulizer was developed for administration of pentamidine, adding one-way valves and an expiratory filter to contain aerosol that is exhaled and not inhaled. Breath-actuated nebulizers, DPIs, and pMDIs tend to generate less secondhand aerosol.

A survey found that RTs were more than twice as likely as physical therapists to develop asthma-like symptoms during the course of their careers. The authors associated this with administration of ribavirin and exposure to gluteraldehyde.[16] There have been anecdotal reports of respiratory care clinicians who have developed a sensitivity to secondhand aerosol from bronchodilators. Further research is required to understand more thoroughly the hazards of secondhand exposure to aerosols in the clinical setting. Most nebulizer therapy currently delivered does not include filtering systems.

There is a requirement for caregiver protection and patient respiratory isolation when they are exposed with infectious and resistant organisms, such as tuberculosis, severe acute respiratory syndrome (SARS), and H1N1 virus. RTs have a duty to take appropriate steps to protect themselves and their patients. In these cases, the aerosols generated by the patient from coughing, speaking, or laughing can transmit disease. These aerosols can travel substantial distances between rooms and floors in institutions. Although exposure to secondhand aerosol generated by a nebulizer is undesirable, it poses less risk than the infected aerosols produced by mucosa of patients.[117] In essence, it is unlikely that any medical aerosol that is inhaled by the patient would be contaminated. Nonetheless, during the SARS outbreak, some centers outlawed use of medical aerosols to reduce exposure. Efforts should be taken to reduce transmission of both nebulizer aerosols and patient-generated aerosols to the environment.

Various techniques are available for protecting patients and caregivers from environmental exposure during aerosol drug therapy. The greatest occupational risk for RTs has been associated with the administration of ribavirin and pentamidine. Conjunctivitis, headaches, bronchospasm, shortness of breath, and rashes have been reported among individuals administering these drugs.[17,118] Patients given aerosolized ribavirin or pentamidine must be treated in a private negative room, booth, or tent or at a special station designed to minimize environmental

contamination with the caregiver wearing an N95 mask during all periods in the room during administration and for at least 10 minutes after completion of administration of the aerosol.

MINI CLINI

When to Change Expiratory Filter During Aerosol Therapy

Problem

Filters in the expiratory limb of ventilator circuits should be periodically replaced during aerosol therapy. How do you determine that period?

Discussion

Filters are often placed in the expiratory limb to protect the expiratory valves and sensors of the ventilator and reduce fugitive emissions. Over time, aerosol can build up on the filter, increasing resistance to expiratory flow, causing increased expiratory time, air trapping, and increase work of breathing. However, changing filters can be expensive, and breaking circuits can cause derecruitment of the lung.

Fig. 40.33 Emerson Treatment Booth Provides Containment of Aerosol During Therapy.

To determine filter change times during use: A test setup consisting of a high-flow flow meter running a known flow of gas (30 L/min) with a manometer positioned between flow source and filter. Measure a new filter, then place into the expiratory limb. After four treatments (or 4 hours continuous nebulization), remove the filter and retest. You can then return the filter to the circuit and repeat at regulator intervals. Plotting the increasing pressures can identify buildup drug on the filter. Substantial increase means time to change the filter. Repeating this experiment on a few patients for the different way you administer aerosol can help you to establish a filter change policy that is safe and cost efficient.

Negative-Pressure Rooms

When any antibiotic, ribavirin, or pentamidine is given, the treatment is provided in a private room. The room should be equipped for negative-pressure ventilation with adequate air exchanges (at least six per hour) to clear the room of residual aerosols before the next treatment. HEPA filters should be used to filter room or tent exhaust, or the aerosol should be scavenged to the outside.

Booths and Stations

Booths or stations should be used for sputum induction and aerosolized medication treatments given in any area where more than one patient is treated. The area should be designed to provide adequate airflow to draw aerosol and droplet nuclei from the patient into an appropriate filtration system or an exhaust system directly to the outside. Booths and stations should be adequately cleaned between patients.

A variety of booths and specially designed stations are available for delivery of pentamidine or ribavirin. The Emerson containment booth (Fig. 40.33) is an example of a system that completely isolates the patient during aerosol administration. The AeroStar aerosol protection cart (Respiratory Safety Systems, San Diego, CA) is a portable patient isolation station for administration of hazardous aerosolized medication. It has been used during sputum induction and for pentamidine treatment. The patient compartment is collapsible with a swing-out counter and three polycarbonate walls. Captured aerosols are removed with a HEPA filter. A prefilter is used to retain larger dust particles and to prevent early loading of the more expensive HEPA filter.

Filters and nebulizers used in treatments with antibiotics, pentamidine, and ribavirin should be treated as hazardous wastes and disposed of accordingly. Goggles, gloves, and gowns should be used as splatter shields to reduce exposure to medication residues and body substances. Staff members should be screened for adverse effects of exposure to the aerosol medication. The risks and safety procedures should be reviewed regularly.

In addition to the risks associated with administration of aerosol medication, risk of tuberculosis transmission has become a great concern because of an increase in case numbers and the development of multidrug-resistant strains of the organism. Tuberculosis is transmitted in the form of droplet nuclei (0.3 to 0.6 μm) that carry tuberculosis bacilli. Patients with known or suspected tuberculosis need private rooms with negative pressure ventilation that exhausts to the outside. If environmental isolation is impossible or the healthcare worker must enter the patient's room, personal protective equipment should be used.

Personal Protective Equipment

Personal protective equipment is recommended when caring for any patient with a disease that can be spread by the airborne route.[119] The greatest risk is communication of tuberculosis or chickenpox. Although environmental controls should be instituted in the care of these patients, standard and airborne precautions should also be implemented. Various masks and respirators have been recommended for use when caring for a patient with tuberculosis or other respiration-transmitted diseases. Traditional surgical masks, particulate respirators, disposable and reusable HEPA filters, and powered air-purifying respirators (PAPRs) have been used. No data are available for determining the most effective and most clinically useful device to protect healthcare workers and others, although the U.S. Occupational Safety and

Health Administration requires specific levels of protection (HEPA filters and PAPRs). Guidelines from the World Health Organization recommend surgical masks for all patient care with the exception of N95 masks for aerosol-generating procedures such as sputum induction. Evidence from laboratory studies of potential airborne spread of influenza from contagious patients indicates that guidelines related to the current 1-m respiratory zone may need to be extended to a larger respiratory zone and include eye protection.[120]

SUMMARY CHECKLIST

- An aerosol is a suspension of solid or liquid particles in gas. In the clinical setting, therapeutic aerosols are made with atomizers or nebulizers.
- The general aim of aerosol drug therapy is delivery of a therapeutic dose of the selected agent to the desired site of action.
- Where aerosol particles are deposited in the respiratory tract depends on their size, shape, and motion and on the physical characteristics of the airways. Key mechanisms causing aerosol deposition include inertial impaction, sedimentation, and brownian diffusion.
- For targeting aerosols for delivery to the upper airway (nose, larynx, trachea), particles in the 5- to 20-μm MMAD range are used; for the lower airways, 2- to 5-μm particles are used; and for the lung parenchyma (alveolar region), 1- to 3-μm particles are used.
- The primary hazard of aerosol drug therapy is an adverse reaction to the medication being administered. Other hazards include infection, airway reactivity, systemic effects of bland aerosols, and drug reconcentration.
- Drug aerosol delivery systems include pMDIs, DPIs, SVNs, large volume jet nebulizers, hand-bulb atomizers (nasal spray pumps), USNs, and VM nebulizers.
- MDIs are the preferred method for maintenance delivery of bronchodilators and steroids to spontaneously breathing patients. The effectiveness of this therapy is highly technique dependent.
- Accessory devices, spacers, and holding chambers are used with pMDIs to reduce oropharyngeal deposition of a drug and to overcome problems with poor hand–breath coordination.
- Effective use of DPIs does not require hand–breath coordination, but it does require high inspiratory flows. Some patients in stable condition prefer DPI delivery systems.
- Compared with pMDI and DPI delivery systems, use of an SVN is less technique-dependent and is more commonly used in acute care.
- Large volume drug nebulizers can be used to provide continuous aerosol delivery when traditional dosing strategies are ineffective in controlling severe bronchospasm.
- Small volume USNs can be used to administer bronchodilators, antiinflammatory agents, and antibiotics.
- Because patients vary in their response to a particular drug dose and route of administration, aerosol drug therapy should be tailored to each patient with an assessment-based protocol.
- Careful, ongoing patient assessment is the key to an effective bronchodilator therapy protocol. Components of the assessment include a patient interview, observation, expiratory airflow tests, vital sign measurements, auscultation, blood gas analysis, and oximetry.
- Protocols for CBT have proven safe and effective in the management of refractory bronchospasm in both adults and children.
- Many factors affect the efficiency of aerosol drug delivery during mechanical ventilation. Proper selection of aerosol generator type, position in the circuit, dose, and accessory equipment is needed to optimize deposition and achieve the desired clinical outcome.
- Various techniques are available to protect patients and caregivers from environmental exposure during aerosol drug therapy.

Storage and Delivery of Medical Gases

David L. Vines

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe how medical gases and gas mixtures are produced.
- Discuss the clinical applications for medical gases and gas mixtures.
- Distinguish between gaseous and liquid storage methods.
- Calculate the duration of gas flow remaining in a compressed oxygen cylinder.
- Calculate the duration of gas flow remaining in a liquid oxygen cylinder.
- Describe how to store, transport, and use compressed gas cylinders properly.
- Distinguish between gas supply systems.
- Describe what to do if a bulk oxygen supply system fails.
- Differentiate among safety systems that apply to various equipment connections.
- Select the appropriate devices to regulate gas pressure or control flow in various clinical settings.
- Regarding gas delivery equipment, describe how to assemble it, check it for proper function, and identify malfunctions.
- Identify and correct common malfunctions of gas delivery equipment.

CHAPTER OUTLINE

KEY TERMS

American standard safety system
Bourdon gauge

downstream
filling density
flammable
flow meter
fractional distillation
heliox
manifold
nonflammable
oxidizing
pin-index safety system
psig
reducing valve
regulator
Thorpe tube
upstream
zone valves

The current field of respiratory care evolved from the hospital "oxygen service." Although respiratory therapists (RTs) have assumed many more challenging roles, ensuring the safe and uninterrupted supply of medical gases remains an important responsibility.

Medical gases (Table 41.1) are classified as laboratory gases, therapeutic gases, or anesthetic gases. *Laboratory gases* are used for equipment calibration and diagnostic testing. *Therapeutic gases* are used to relieve symptoms and improve the oxygenation of patients with hypoxemia. *Anesthetic gases* are combined with oxygen (O_2) to provide anesthesia during surgery. It is important for RTs to be familiar with all aspects of gases used in the clinical setting, especially their chemical symbols, physical characteristics, ability to support life, and fire risk. In regard to fire risk, medical compressed gases are classified as either **nonflammable** (do not burn), nonflammable but supportive of combustion (also termed **oxidizing**), or **flammable** (burns readily, potentially explosive).[1] This chapter focuses on the therapeutic gases.

TABLE 41.1 Physical Characteristics of Medical Gases

Gas	Chemical Symbol	Color	Taste	Odor	Can Support Life	Flammability
Laboratory Gases						
Nitrogen	N	Colorless	Tasteless	Odorless	No	Nonflammable
Helium	He	Colorless	Tasteless	Odorless	No	Nonflammable
Carbon dioxide	CO_2	Colorless	Slightly acidic	Odorless	No	Nonflammable
Therapeutic Gases						
Air	AIR	Colorless	Tasteless	Odorless	Yes	Supports combustion
Oxygen	O_2	Colorless	Tasteless	Odorless	Yes	Supports combustion
Helium/oxygen (heliox)	He/O_2	Colorless	Tasteless	Odorless	Yes	Supports combustion
Carbon dioxide/oxygen	CO_2/O_2	Colorless	Slightly acidic	Odorless	No	Supports combustion
Nitric oxide	NO	Colorless	Tasteless	Metallic	No	Supports combustion
Anesthetic Gas						
Nitrous oxide	N_2O	Colorless	Slightly sweet	Slightly sweet	No	Supports combustion

CHARACTERISTICS OF MEDICAL GASES

Oxygen

Characteristics

O_2 is a colorless, odorless, transparent, and tasteless gas.[1] It exists naturally as free molecular O_2 and as a component of a host of chemical compounds. At *standard temperature, pressure, and dry (STPD)*, O_2 has a density of 1.429 g/L, being slightly heavier than air (1.29 g/L). O_2 is not very soluble in water. At room temperature and 1 atm pressure, only 3.3 mL of O_2 dissolves in 100 mL of water.

O_2 is nonflammable, but it greatly accelerates combustion. Burning speed increases with either (1) an increase in O_2 percentage at a fixed total pressure or (2) an increase in total pressure of O_2 at a constant gas concentration. Both O_2 concentration and partial pressure influence the rate of burning.[1,2]

Production

O_2 is produced by one of several methods. Chemical methods for producing small quantities of O_2 include *electrolysis of water* and *decomposition of sodium chlorate* ($NaClO_3$). Most large quantities of medical O_2 are produced by fractional distillation of atmospheric air.[1] Small quantities of concentrated O_2 are produced by physical separation of O_2 from air.

Fractional distillation. **Fractional distillation** is the most common and least expensive method for producing O_2. The process involves several related steps. First, atmospheric air is filtered to remove pollutants, water, and carbon dioxide (CO_2). The purified air is liquefied by compression and cooled by rapid expansion *(Joule-Thompson effect)*.

The resulting mixture of liquid O_2 and nitrogen (N, N_2) is heated slowly in a distillation tower. N_2, with its boiling point of 195.8°C (320.5°F), escapes first, followed by the trace gases of argon, krypton, and xenon. The remaining liquid O_2 is transferred to specially insulated **cryogenic** (low-temperature) storage cylinders. An alternative procedure is to convert O_2 directly to gas for storage in high-pressure metal cylinders. These methods produce O_2 that is approximately 99.5% pure. The remaining 0.5% is mostly N_2 and trace argon. US Food and Drug Administration (FDA) standards require an O_2 purity of at least 99.0%.[3]

Physical separation. Two methods are used to separate O_2 from air.[4] The first entails the use of molecular "sieves" composed of inorganic sodium aluminum silicate pellets. These absorb N_2, "trace" gases and water vapor from the air, providing a concentrated mixture of more than 90% O_2 for patient use. The second method entails use of a vacuum to pull ambient air through a semipermeable plastic membrane that allows O_2 and water vapor to pass through at a faster rate than N_2 from ambient air. This system can produce an O_2 mixture of approximately 40%. These devices, called *oxygen concentrators*, are used primarily for supplying low-flow O_2 in the home care setting. Details about their principles of operation and appropriate use are discussed in Chapter 57.

RULE OF THUMB O_2 from a liquid source or cylinder is over 99% pure, whereas O_2 from a concentrator will be 90% to 96% pure. Changing from a cylinder to a concentrator may require an increase in liter flow to maintain the patient's arterial O_2 saturation.

Air

Atmospheric air is a colorless, odorless, naturally occurring gas mixture that consists of 20.95% O_2, 78.1% N_2, and approximately 1% "trace" gases, mainly argon. At STPD, the density of air is 1.29 g/L; this is used as the standard for measuring the specific gravity of other gases. O_2 and N_2 can be mixed to produce a gas with an O_2 concentration equivalent to that of air. Medical-grade air is usually produced by filtering and compressing atmospheric air.[1,5]

Fig. 41.1 shows a typical large medical *air compressor system*. In these systems, an electric motor is used to power a piston in a compression cylinder. On its downstroke, the piston draws air through a filter system with an inlet valve. On its upstroke, the piston compresses the air in the cylinder (closing the inlet valve) and delivers it through an outlet valve to a reservoir tank. Air from the reservoir tank is reduced to the desired working

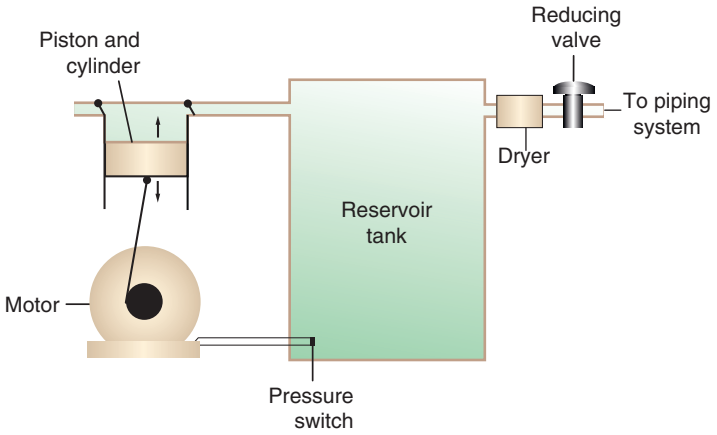

Fig. 41.1 Large Medical Air Compressor. The compressor sends gas to the reservoir at higher than line pressure. When the preset pressure level is reached, the pressure switch shuts off the compressor. Gas leaves the reservoir and passes through the dryer to remove moisture, and the reducing valve reduces gas to the desired line pressure. When reservoir pressure has decreased to near line pressure, the pressure switch turns the compressor back on. (Modified from McPherson SP, Spearman CB: *Respiratory Therapy Equipment*, ed 5, St Louis, 1995, Mosby.)

Fig. 41.2 Small portable compressor used with a handheld nebulizer to aerosolize medication.

pressure by a pressure-reducing valve before being delivered to the piping system.

For medical gas use, air must be dry and free of oil or particulate contamination.[5] The most common method used for drying air is cooling to produce condensation. For avoidance of oil or particulate contamination, medical air compressors have air inlet filters and polytetrafluoroethylene (Teflon) piston rings as opposed to oil lubrication. Large medical air compressors must provide high flow (at least 100 L/min) at the standard working pressure of 50 *pounds per square inch gauge* (**psig**) for all equipment in use. The psig is the pressure read on the gauge, which reads the pressure above atmosphere pressure. See Chapter 6 for more information on this concept.

Smaller compressors (Fig. 41.2) are available for bedside or home use. These have a diaphragm or turbine that compresses the air and generally do not have a reservoir. This design limits the pressure and flow capabilities of these devices. For this reason, small compressors must never be used to power equipment that needs unrestricted flow at 50 psig, such as pneumatically powered ventilators (see Chapter 46). However, small-diaphragm or turbine compressors are ideal for powering devices such as small-volume medication nebulizers (see Chapter 40).

RULE OF THUMB Medical air compressors must produce 50 psig of a dry gas at 100 L/min to power pneumatically driven equipment such as mechanical ventilators.

Carbon Dioxide

At STPD, CO_2 is a colorless and odorless gas with a specific gravity of 1.52 (approximately 1.5 times heavier than air).[1] CO_2 does not support combustion or life. For medical use, CO_2 is usually produced by heating limestone in contact with water. The gas is recovered from this process and liquefied by compression and cooling. The FDA purity standard for CO_2 is 99%.[6]

Mixtures of O_2 and 5% to 10% CO_2 are occasionally used for therapeutic purposes. Therapeutic uses include the management of singultus (hiccups), prevention of the complete washout of CO_2 during cardiopulmonary bypass, and regulation of pulmonary vascular pressures in some congenital heart disorders. However, CO_2 mixtures are more commonly used for the calibration of blood gas analyzers (see Chapter 19) and for diagnostic purposes in the clinical laboratory.

Helium

Helium (He) is second only to hydrogen as the lightest of all gases; it has a density at STPD of 0.1785 g/L. It is odorless, tasteless, nonflammable, and chemically and physiologically inert. Although He is present in small quantities in the atmosphere, it is commercially produced from natural gas through liquefaction to purity standards of at least 99%.[1,7]

Breathing 100% He would cause suffocation and death. For therapeutic use, He must always be mixed with at least 20% O_2. **Heliox** (a gas mixture of O_2 and He) may be used clinically to

manage severe cases of airway obstruction. Its low density decreases the work of breathing by making gas flow more laminar. It is discussed in more detail in Chapter 42.

RULE OF THUMB He lium must always be combined with at least 20% O_2. The higher the concentration of O_2 used in a heliox mixture, the less likely it is that heliox will be beneficial. Heliox mixtures of less than 60% He are rarely used clinically.

Nitric Oxide

Nitric oxide (NO) is a colorless, nonflammable, toxic gas that supports combustion. It is produced by oxidation of ammonia at high temperatures in the presence of a catalyst. In combination with air, NO forms brown fumes of nitrogen dioxide (NO_2). Together, NO and NO_2 are strong respiratory irritants that can cause chemical pneumonitis and a fatal form of pulmonary edema. Exposure to high concentrations of NO alone can cause methemoglobinemia (see Chapter 42). High levels of methemoglobin can cause tissue hypoxia.

NO is approved by the FDA for use in the treatment of term and near-term infants for hypoxemic respiratory failure. A systematic review supports the recommendation that inhaled NO at 20 ppm is beneficial in term and near-term infants with severe hypoxemia who do not have a diaphragmatic hernia (see Chapter 35).[8] Inhaled NO has not been shown to be beneficial in improving outcomes in preterm infants or adult patients with hypoxemia, and it is expensive to use clinically.

RULE OF THUMB Inhaled NO is a pulmonary vasodilator that has been shown beneficial in treating term or near-term infants with severe hypoxia who do not have a diaphragmatic hernia. Inhaled NO has not been shown to be beneficial in improving outcomes in preterm infants or adult patients with severe hypoxemia. NO is also costly.

Nitrous Oxide

Nitrous oxide (N_2O) is a colorless gas with a slightly sweet odor and taste; it is used clinically as an anesthetic agent. Similar to O_2, N_2O can support combustion. However, N_2O cannot support life and must always be mixed with at least 20% O_2. N_2O is produced by thermal decomposition of ammonium nitrate.[1]

The use of N_2O as an anesthetic agent is based on its central nervous system depressant effect. However, only dangerously high levels of N_2O provide true anesthesia. N_2O/O_2 mixtures are almost always used in combination with other anesthetic agents.

Long-term human exposure to N_2O has been associated with a form of neuropathy. In addition, epidemiologic studies have linked chronic N_2O exposure with an increased risk for fetal disorders and spontaneous abortion.[1] Based on these findings, the National Institute for Occupational Safety and Health set an upper exposure limit for hospital operating rooms of 25 ppm N_2O.[1]

STORAGE OF MEDICAL GASES

Medical gases are stored either in portable high-pressure cylinders or in large bulk reservoirs. Bulk reservoirs require a separate distribution system to deliver the gas to the patient.

Gas Cylinders

The containers used to store and ship compressed or liquid medical gases are high-pressure cylinders. The design, manufacture, transport, and use of these cylinders are carefully controlled by both industrial standards and federal regulations. Gas cylinders are made of seamless steel and are classified by the US Department of Transportation (DOT) according to their fabrication method. DOT type 3A cylinders are made from carbon steel, and DOT type 3AA containers are manufactured with a steel alloy tempered for higher strength.[1]

Markings and Identification

Medical gas cylinders are marked with metal stamping on the shoulders—stamps that supply specific information (Fig. 41.3).[1,9] Although the exact location and order of these markings vary, the practitioner should be able to identify several key items of information.

The letters *DOT* or *ICC* (Interstate Commerce Commission) are followed by the cylinder classification (*3A* or *3AA*) and the normal filling pressure in pounds per square inch (psi). Below this information there is usually the letter size of the cylinder (*E*, *G*, *H*, and so on). followed by the cylinder serial number. A third line provides a mark of ownership, often followed by the manufacturer's stamp or a mark identifying the inspecting authority. An abbreviation indicating the method of cylinder manufacturer is usually on the opposite side of the cylinder. Also in this area is information about the original safety test as well as the dates of all subsequent tests.

Safety tests are conducted on each cylinder every 5 or 10 years, as specified in DOT regulations.[1,9] During these tests, cylinders are pressurized to five-thirds of their service pressure. While the cylinder is under pressure, technicians measure cylinder leakage, expansion, and wall stress. The notation *EE* followed by a number indicates the elastic expansion of the cylinder in cubic centimeters under the test conditions. An asterisk (*) next to the test date indicates DOT approval for 10-year testing. A plus sign (+) means that the cylinder is approved for filling to 10% greater than its service pressure. An approved cylinder with a service pressure of 2015 psi can be filled to approximately 2200 psi. After hydrostatic testing, cylinders are subjected to internal inspection and cleaning.

In addition to these permanent marks, all cylinders are color-coded and labeled for identification of their contents.[1,10] Table 41.2 lists the color codes for medical gases as adopted by the Bureau of Standards of the US Department of Commerce.[10,11] For comparison, the color codes adopted by the Canadian Standards Association are also included. Color codes are not standardized internationally. For this reason, cylinder color should be used only as a guide. As with any drug agent, the cylinder's contents must always be identified by careful inspection of the label. It has been reported that gas mixtures such as heliox can become unmixed.[12] To be absolutely sure about the O_2 concentration provided by a cylinder, the user must analyze the gas before administering it (see Chapter 19).

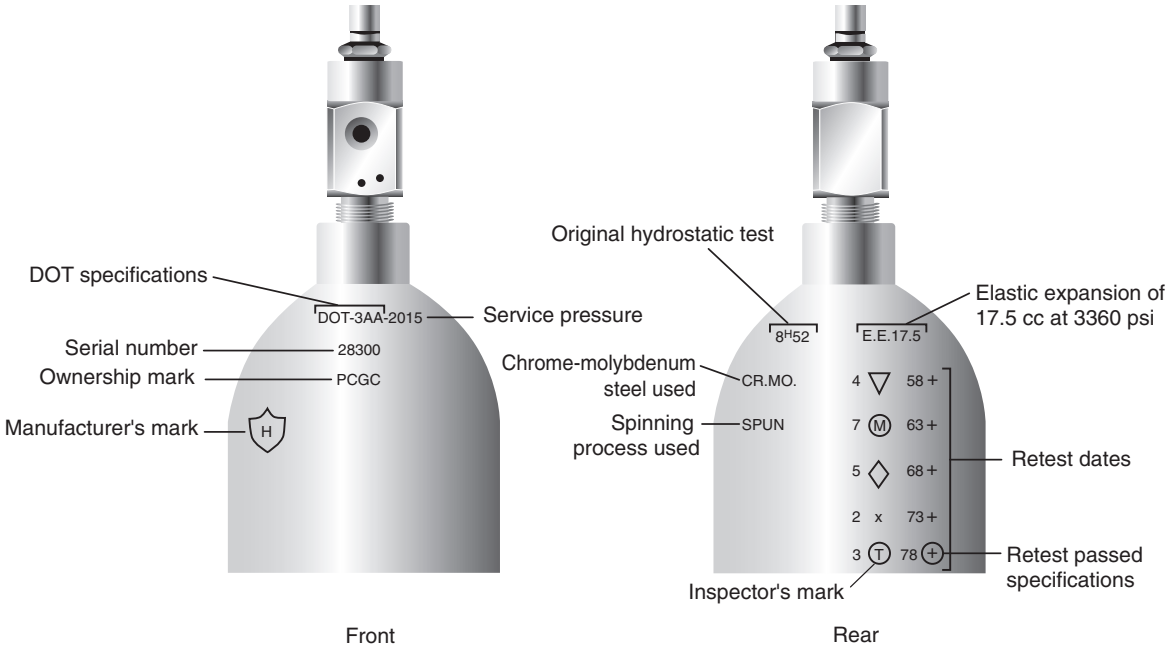

Fig. 41.3 **Typical Markings of Cylinders Containing Medical Gases.** Front and back views are for illustration purposes only; exact location and order of markings will vary. *DOT,* Department of Transportation.

TABLE 41.2 Color Codes for Medical Gas Cylinders

Gas	United States	Canada
O_2	Green	White[a]
CO_2	Gray	Gray
N_2O	Blue	Blue
Cyclopropane	Orange	Orange
He	Brown	Brown
C_2H_4	Red	Red
CO_2–O_2	Gray/green	Gray/white
He–O_2	Brown/green	Brown/white
N_2	Black	Black
Air	Yellow[a]	Black/white
N_2–O_2	Black/green	Pink

[a]Vacuum systems historically are identified as white in the United States and yellow in Canada. for this reason, the Compressed Gas Association (CGA) recommends that white not be used for any cylinders in the United States and that yellow not be used in Canada. C_2H_4, Ethylene.

RULE OF THUMB Cylinders with a service pressure of 2015 psi are usually filled to approximately 2200 psi.

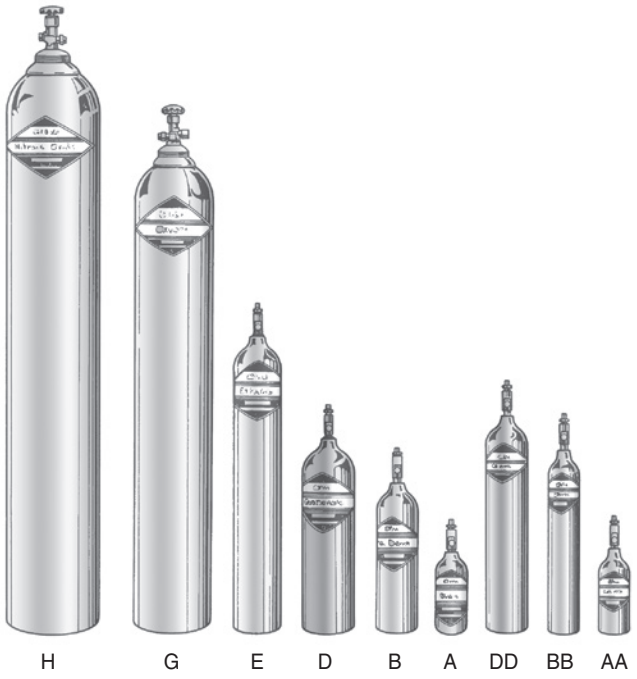

Fig. 41.4 Cylinder sizes are identified by letter designations.

Cylinder Sizes and Contents

Letter designations are used for different sizes of cylinders (Fig. 41.4). Sizes E through AA are referred to as "small cylinders" and are used most often for transporting patients and anesthetic gases. These small cylinders are easily identified because of their unique valves and connecting mechanisms. Small cylinders have a post valve and yoke connector. Large cylinders (F through H and K) have a threaded valve outlet (Fig. 41.5).

Cylinder Safety Relief Valves

In a closed cylinder, any increase in gas temperature increases gas pressure. Should the temperature increase too much (as in a fire), the high gas pressure could rupture and explode the cylinder. To prevent this type of accident, all cylinders have high-pressure relief valves of three basic designs: frangible disk, fusible plug, and spring-loaded. The *frangible metal disk* ruptures at a specific pressure. The *fusible plug* melts at a specific temperature. The *spring-loaded valve* opens and vents gas at a set high

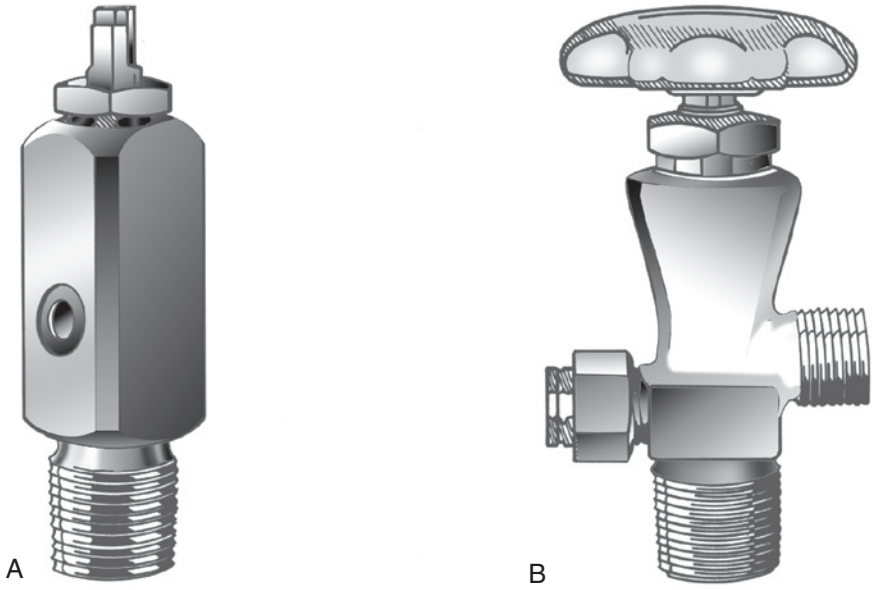

Fig. 41.5 (A) Post valve for yoke connector used with small cylinders (E through AA). (B) Large, threaded valve outlet used with large cylinders (H/K, G, and M).

pressure. In each case, the activated valve vents gas from the cylinder and prevents pressure from becoming too high.

Most small cylinders have a fusible plug relief valve. Most large cylinders have a spring-loaded relief valve. These safety relief valves are always located in the cylinder's valve stems.

Filling (Charging) Cylinders

How a cylinder is filled depends on whether its contents will be gaseous or liquid. Some gases stored in liquid form can remain at room temperature, but others must be maintained in a cryogenic (low-temperature) state.

Compressed gases. A gas cylinder is normally filled to its service pressure (the pressure stamped on the shoulder) at 21.1°C (70°F). However, approved cylinders can be filled to 10% greater than the service pressure.

Liquefied gases. Gases with critical temperatures greater than room temperature—including CO_2 and N_2O—can be stored as liquids at room temperature (see Chapter 6). Rather than being filled to filling pressure, cylinders of these gases are filled according to a specified filling density. The **filling density** is the ratio between the weight of liquid gas put into the cylinder and the weight of water the cylinder could contain if full. The filling density for CO_2 is 68%. This system allows the manufacturer to fill a cylinder with liquid CO_2 up to 68% of the weight of water that a full cylinder could hold. The filling density of N_2O is 55%.

Cylinder pressures for gases stored in the liquid phase are much lower than those for gases stored in the gas phase. Because the liquid does not fill the entire volume of a cylinder, the space above the liquid surface contains gas in equilibrium with the liquid. The pressure in a liquid-filled cylinder equals the pressure of the vapor at any given temperature.

Pressure in a cylinder depends on the state of its contents. In a gas-filled cylinder, the pressure represents the force required to compress the gas into its smaller volume. In contrast, the pressure in a liquid-filled cylinder is the vapor pressure needed to keep the gas liquefied at the current temperature.

Measuring Cylinder Contents

Because of the previously described differences in the physical state of matter of compressed and liquid gases, different methods are needed to measure the contents of the cylinder.

Compressed gas cylinders. For gas-filled cylinders, the volume of gas in the cylinder is directly proportional to its pressure at a constant temperature. If a cylinder is full at 2200 psig, it will be half full when the pressure decreases to 1100 psig. To know how much gas is contained in a compressed gas cylinder, one needs only to measure its pressure.

Liquid gas cylinders. In a liquid gas cylinder or container, the measured pressure is the vapor pressure above the liquid. This pressure bears no relationship to the amount of liquid remaining. As long as some liquid remains (and the temperature remains constant), the vapor pressure and gauge pressure remain constant. When all the liquid is gone and the cylinder contains only gas, the pressure decreases in proportion to a reduction in volume. Weighing a liquid-filled cylinder is the only accurate method for determining the contents.

> **RULE OF THUMB** Monitoring the gauge pressure is useful in determining the contents of a gas-filled cylinder. Weighing a liquid-filled cylinder is the only accurate method for determining the remaining amount of gas, since gauge pressure will decrease only after all of the liquid has converted to a gas.

Fig. 41.6 compares the behavior of compressed-gas and liquid-gas cylinders during use. The vapor pressure of liquid gas cylinders varies with the temperature of the contents. The pressure in an N_2O cylinder at 21.1°C (70°F) is 745 psig; at 15.6°C (60°F), the pressure decreases to 660 psig. As the temperature increases toward the critical point, more liquid vaporizes, and the cylinder

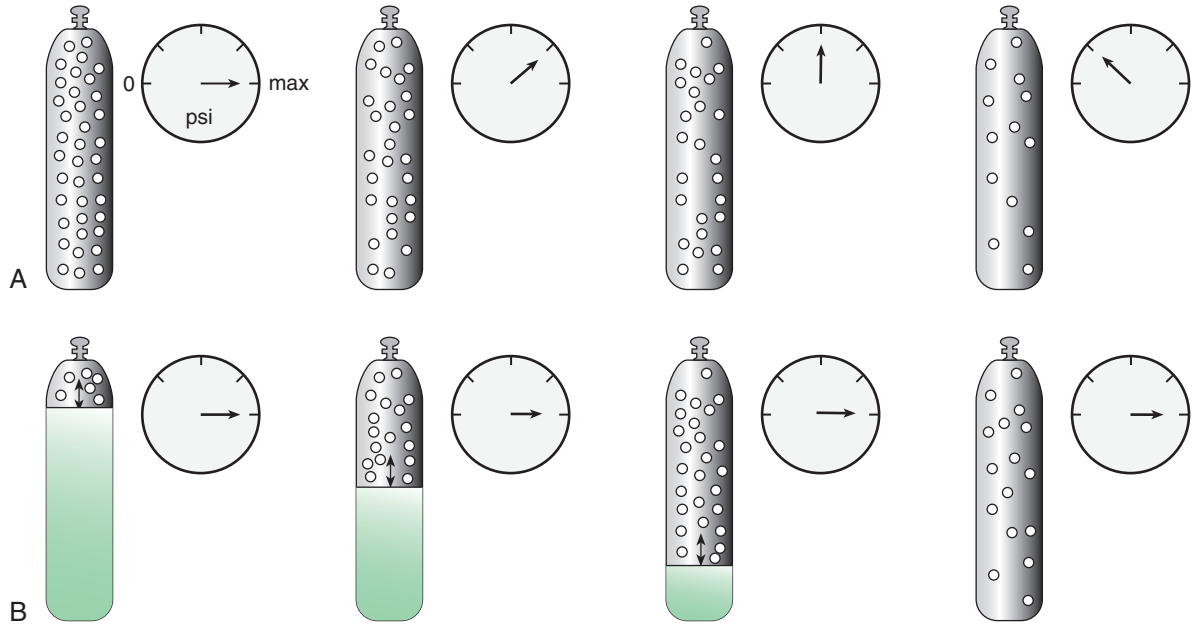

Fig. 41.6 The content of a gas-filled cylinder (A) is directly proportional to the gas pressure. A pressure decrease of 50% indicates a loss of 50% of the contained gas. In a liquid-gas cylinder (B), gauge pressure is a measure of only the vapor pressure of gas in equilibrium with the liquid phase. This value remains constant at a given temperature as long as liquid is present. Only when all the liquid has vaporized, as the cylinder nears depletion, does the gauge pressure decrease proportionately to the terminal volume of remaining gas.

pressure increases. If a cylinder of N_2O warms to 36.4°C (97.5°F) (its critical temperature), all the contents convert to gas. Only at this temperature and higher does the cylinder gauge pressure accurately reflect the cylinder's contents.

Estimating Duration of Cylinder Gas Flow

When a cylinder of therapeutic gas is used, it often is necessary to predict how long the contents will last at a given flow. The duration of flow of a cylinder can be estimated if the following are known: (1) the gas flow, (2) the cylinder's size, and (3) the cylinder's pressure at the start of therapy. For a given flow, the more gas a cylinder holds, the longer it lasts. The higher the gas flow, the quicker the cylinder empties. The duration of flow from a cylinder is directly proportional to the contents and inversely proportional to flow, as expressed in the following formula:

$$\text{Duration of flow} = \frac{\text{Contents}}{\text{Flow}}$$

Cylinder contents are generally specified in cubic feet or gallons, whereas gas flow is normally measured in liters. Table 41.3 provides the factors needed to convert these units. Rather than memorizing various cylinder contents and constantly converting metric and English units, the user can quickly calculate duration of flow by using *cylinder factors*, which are derived for each common gas and cylinder size with the following formula:

$$\text{Cylinder factor (L/psig)} = \frac{\text{Cubic feet (full cylinder)} \times 28.3}{\text{Pressure (full cylinder) in psig}}$$

TABLE 41.3 Gas Volume Conversion Factors

Liters	Cubic Feet	Gallons
28.316	1	7.481
1	0.03531	0.2642
3.785	0.1337	1

In the numerator of this equation, the English-metric conversion constant (28.3) is used to convert cubic feet to liters. Dividing the resulting volume by the pressure in a full cylinder yields the cylinder factor. The derived factor represents the volume of gas leaving a given cylinder for every 1-psig decrease in pressure. Table 41.4 provides cylinder factors for the therapeutic medical gases and common cylinder sizes.

When the factor for a given gas and cylinder is known, calculating the duration of flow is a simple matter of applying the following equation:

$$\text{Duration of flow (min)} = \frac{\text{Pressure (psig)} \times \text{Cylinder factor}}{\text{Flow (L/min)}}$$

A margin of safety must be allowed in estimation of cylinder duration of flow. Some clinicians return 30 to 40 minutes before the calculated time; others compute duration of flow to a level of 300 to 500 psig rather than 0 psig (empty). Assuming the calculations are correct and there is no change in flow, both methods ensure an uninterrupted supply. The accompanying rule of thumb presents a shortcut for estimating a cylinder's duration of flow.

TABLE 41.4 Factors for Calculation of Cylinder Duration of Flow (Minutes)

	CYLINDER SIZE			
Gas	**D**	**E**	**G**	**H and K**
O_2, O_2/N_2, air	0.16	0.28	2.41	3.14
O_2/CO_2	0.20	0.35	2.94	3.84
He/O_2	0.14	0.23	1.93	2.50

RULE OF THUMB A full E O_2 cylinder running at 10 L/min lasts approximately 60 min (1 h). A full H/K cylinder lasts at least 10 times longer (>10 h). Use these two simple rules to estimate flow duration. For example, a half-full E O_2 cylinder running at 10 L/min lasts approximately 30 min, whereas a full H cylinder running at 5 L/min lasts more than 20 h.

MINI CLINI

Computing a Cylinder's Duration of Flow

Problem

The RT needs to determine how long a G cylinder of O_2 with a gauge pressure of 800 psi set to deliver 8 L/min will last until empty.

Solution

Step 1: Determine the cylinder's factor for an O_2 G cylinder (see Table 41.4), which in this case is 2.41.

Step 2: Apply the duration of flow equation:

$$\text{Duration of flow (min)} = \frac{\text{Pressure (psig)} \times \text{Cylinder factor}}{\text{Flow (L/min)}}$$

$$\text{Duration of flow (min)} = \frac{800 \times 2.41}{8} = 241 \text{ minutes}$$

(approximately 4 hours)

Estimating Duration of Liquid Oxygen Cylinder Gas Flow

The only accurate method for determining the volume of gas in a liquid-filled cylinder is by weight. Because 1 L of liquid O_2 weighs 2.5 lb and produces 860 L of O_2 in its gaseous state, the amount of gas in a liquid O_2 cylinder can be calculated with the following formula:

$$\text{Amount of gas in cylinder} = \frac{\text{Liquid weight (lb)} \times 860}{2.5 \text{ lb/L}}$$

After the amount of O_2 remaining in the cylinder has been determined, the duration of the gas in minutes can be calculated with the following formula:

$$\text{Duration of gas (min)} = \frac{\text{Amount of gas in cylinder (L)}}{\text{Flow (L/min)}}$$

As with gaseous O_2 cylinders, a wide margin of safety is needed for estimation of cylinder duration. This margin of safety varies with the size of the portable O_2 unit or large storage container.

MINI CLINI

Computing the Duration of a Liquid Oxygen Container

Problem

The RT must estimate how long a portable liquid O_2 container will last if it contains 3 lb of liquid O_2 that supplies an O_2 delivery device running at 2 L/min.

Solution

Step 1: Determine the amount of O_2 in the cylinder.

$$\text{Amount of gas in cylinder} = \frac{\text{Liquid } O_2 \text{ weight (lb)} \times 860}{2.5 \text{ lb/L}}$$

$$= \frac{3 \times 860}{2.5}$$

$$= 1032 \text{ L}$$

Step 2: Calculate the duration of the gas in the container.

$$\text{Duration of gas} = \frac{\text{Amount of gas in the cylinder (L)}}{\text{Flow (L/min)}}$$

$$= \frac{1032 \text{ L}}{2} = \frac{516 \text{ minutes}}{60 \text{ (min/h)}}$$

$$= 8 \text{ hours } 36 \text{ minutes}$$

Gas Cylinder Safety

The following guidelines for cylinder safety are from the recommendations of the National Fire Protection Agency (NFPA)[2] and the Compressed Gas Association (CGA).[1,11] For ease of use, these safety guidelines are divided into cylinder storage, transport, and use.

Cylinder storage. The following guidelines apply to cylinder storage:

- Store gas cylinders in racks or chain cylinders to the wall to prevent them from falling or becoming damaged.
- Store cylinders away from any combustible material.
- Store gas cylinders away from sources of heat. Keep the cylinder temperature at less than 125°F (<52°C).
- Store flammable gases separately from gases that support combustion, such as air, O_2, and N_2O.
- If a cylinder is not in use, keep the protective cylinder cap in place.
- Do not store air compressors and gas cylinders together. A fire involving one or the other can damage both gas delivery systems.
- Contain and store cylinder supply systems in an enclosure that is well ventilated and drained constructed of a material with at least a 1-hour fire-resistive rating.
- Segregate full and empty cylinders; store them separately if possible.
- Place on each door or gate of the enclosure a sign indication the presence of an oxidizing gas suggesting caution in particular against smoking. This sign must be readable from a distance of at least 5 ft (1.5 m).
- Store liquid O_2 containers in a cool, well-ventilated area because of the venting of small amounts of O_2 from these low-pressure

containers. The venting of O_2 prevents these containers from overpressurizing because liquid O_2 is continuously converting to gaseous O_2.

Cylinder transport. The following guidelines apply to cylinder transport:

- Use cylinder carts with a securing mechanism for transportation of cylinders.
- Keep the protective cylinder caps in place during transportation of cylinders.
- Protect gas cylinders from striking other cylinders or objects to avoid damaging the safety devices, valve stems, or the cylinder itself.
- Avoid dropping, dragging, or rolling cylinders in transport.
- Do not transport cylinders for use that are not appropriately labeled.

Cylinder use. The following guidelines apply to cylinder use:

- Secure gas cylinders at the patient's bedside in a way that prevents them from falling. Secure cylinders to the wall with a chain, bind or chain them to a suitable cart, or support the cylinder with a stand.
- Do not use flammable materials, especially oil or grease, on regulators, cylinders, fittings, or valves. This restriction includes oily hands, rags, and gloves.
- Open the cylinder valve slightly to remove dust and dirt before attaching the regulator. When the valve is being slightly opened, make sure that no one is in front of it. "Crack" the cylinder before bringing it to the patient's bedside.
- Never use cylinder valves or regulators that need repair.
- Do not alter or deface cylinder markings or color.
- Never place cylinders near sources of heat.
- Never secure cylinders to movable objects unless the object has an apparatus that can contain the cylinder safely.
- Make sure that the connection between the regulator and the cylinder valve is an **American standard safety system** (ASSS) for H and G cylinders and a **pin-index safety system** (PISS) for E cylinders.
- When O_2 is in use, post a "No Smoking" sign unless signs at the entrances are posted that prohibit smoking in the facility.

Bulk Oxygen

Large acute care facilities use large volumes of O_2 every day. To meet these needs, a centralized bulk storage and delivery system is required. By definition, bulk O_2 storage systems hold at least 20,000 ft^3 of gas, including the onsite unconnected reserves.[2] Bulk O_2 may be stored in either gaseous or liquid form; liquid storage is most common. When needed, the O_2 flows from this central source throughout the facility by a piping system with conveniently located outlets.

A bulk O_2 system has several advantages over portable cylinders. Although initially expensive to construct, bulk O_2 systems are far less expensive over the long term. Bulk O_2 systems are less prone to interruption. These systems eliminate the inconvenience and hazard of transporting and storing numerous cylinders. Bulk O_2 systems regulate delivery pressures centrally, eliminating the need for separate pressure-reducing valves at each outlet. These systems also operate at low pressures, making them much safer than high-pressure cylinders.

Safety standards for bulk O_2 systems are set by the NFPA and are subject to further control by local fire and building codes.[2]

Gas Supply Systems

The three types of centrally located gas supply systems are an alternating supply system or cylinder **manifold** system, a cylinder supply system with reserve supply, and a bulk gas system with a reserve.[2] The *alternating supply* or *cylinder manifold system* consists of large (normally H or K size) cylinders of compressed O_2 banked together in series (Fig. 41.7). This alternating supply system has two sides: a primary bank and a reserve bank. When the pressure in the primary bank decreases to a set level, a control valve automatically switches over to the reserve bank. When this occurs, the primary bank is taken off line and the empty cylinders are replaced with full ones. The replenished primary

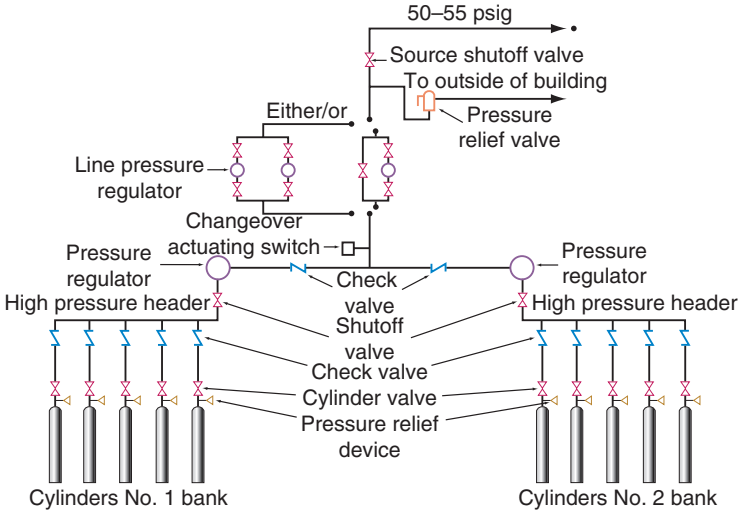

Fig. 41.7 Gas Cylinder Manifold System. The alternating supply system is composed of primary and reserve banks, which alternate to charge the piping system. (Modified from Standard for nonflammable medical gas systems, NFPA No. 56F. Copyright 1973, National Fire Protection Association, Boston, MA.)

Fig. 41.8 Alternating supply system of N_2O.

Fig. 41.9 Large stand tank and reserve tank of liquid O_2 represents a typical bulk gas system with a reserve.

bank becomes the reserve bank. These cylinder manifold systems have pressure-reducing valves for regulation of delivered pressure and normally have low-pressure alarms that sound when reserve switchover occurs; they also warn of impending depletion or malfunction. Cylinder manifolds or alternating supply systems are used to supply O_2 from a central location in small facilities or to supply specialty gases, such as N_2O, to operating rooms (Fig. 41.8).

A *cylinder supply system with a reserve* consists of a primary supply, a secondary supply, and a reserve supply. When the primary gas supply is depleted by the demand, it automatically switches to the secondary supply. Master signal panels indicate that the changeover has occurred. Such a supply system operates in a manner similar to the alternating system except that this system has a reserve supply if primary and secondary supplies become depleted. Liquid containers may be used as the primary and secondary gas sources, but the reserve supply is usually provided by high-pressure gas cylinders. Gas cylinders are used as the reserve supply because low-pressure liquid containers lose approximately 3% of their contents per day.[2]

For the sake of economy, safety, and convenience, most large health care facilities use a *liquid bulk O_2 system*. A small volume of liquid O_2 provides a very large amount of gaseous O_2 and minimizes space requirements. However, along with this advantage comes a major problem. O_2 has a critical temperature well below room temperature (−118.6°C [−181.4°F]).[1] Liquid O_2 must continually be stored below this temperature or it will revert to its gaseous state.

To stay in liquid form, O_2 is stored in large stand tanks (Fig. 41.9) at relatively low pressure (<250 psig). These tanks are similar to giant thermos bottles, consisting of inner and outer steel shells separated by an insulated vacuum chamber (Fig. 41.10). Because it eliminates heat conduction, the vacuum keeps the liquid O_2 below its critical temperature without refrigeration. When it flows through vaporizer coils exposed to ambient temperature, the liquid O_2 quickly converts back to a gas. With the O_2 in its gaseous form, the pressure is decreased to the standard working pressure of 50 psi by a pressure-reducing valve. A safety vent allows vaporized liquid O_2 to escape if warming causes cylinder pressure to increase above a set limit.

Smaller liquid cylinders are used for home O_2 supply. These cylinders come in several sizes and hold between ⅔ and 1½ ft^3 of liquid O_2. Small liquid O_2 cylinders are refilled onsite by means of transfer of liquid O_2 from a large cylinder. Chapter 57 describes the use of these small liquid O_2 cylinders in the home.

Bulk Oxygen Safety Precautions

The NFPA sets standards for the design, construction, placement, and use of bulk O_2 systems.[2] A key provision in these standards is the requirement for a reserve or backup gas supply to equal the average daily gas usage of the hospital. To meet this requirement, most large facilities have a second, smaller liquid tank. Smaller facilities may use a cylinder gas manifold as the backup.

Failure of bulk O_2 supply systems has been reported, with resultant major problems.[13–16] Failure of a bulk O_2 supply can be life-threatening to any patient receiving O_2 or gas-powered ventilatory support. For this reason, the RT team must be prepared. Adherence to an established protocol is a quick way to identify and prioritize all affected patients. When affected patients are identified, staff members move appropriate backup equipment to the bedside (e.g., portable cylinders, bag-valve-mask resuscitators). Trained personnel bypass the failed system and provide needed patient support while engineers determine the cause of the failure and correct it.

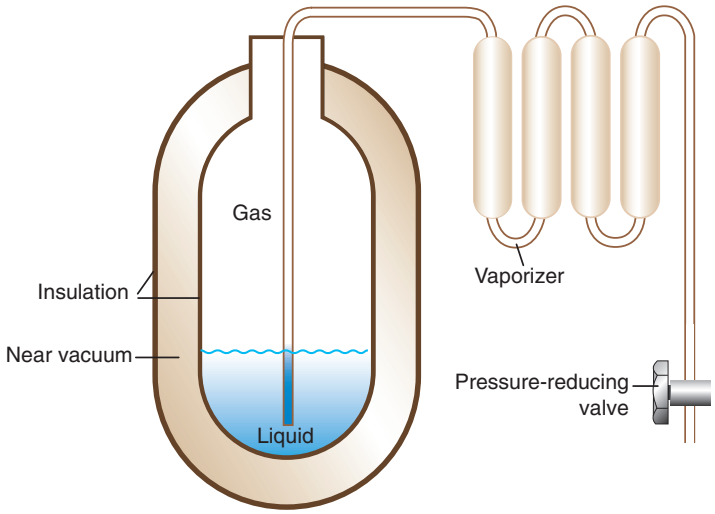

Fig. 41.10 Liquid O_2 stand tank (fixed station). (Modified from Cairo JM, Pilbeam SP: *Mosby's Respiratory Care Equipment*, ed 8, St Louis, 2010, Mosby.)

MINI CLINI

Failure of the Oxygen Supply

Problem

A delivery truck accidentally hit the hospital supply line, resulting in an O_2 leak. The O_2 supply to the hospital had to be turned off for approximately 12 h to repair the damaged pipe and allow associated testing.

Solution

Before the repair could occur, the RT team obtained H cylinders, reducing valves, O_2 hoses and quick connects and quickly moved these items to all areas of the hospital were patients required O_2. The reducing valve was connected to the H cylinder following the procedure described in this chapter and the O_2 supply line with the quick connect on one end was connected to the reducing valve. The reducing valve was set to deliver 50 psig. The zone valve was closed to the patient care area and the O_2 quick connect was connected to the O_2 outlet in an empty patient room. This setup back-feed all O_2 outlets in the patient care area. Having the zone vale closed prevents O_2 from traveling to other areas and allows the rupture gas supply line to be repaired. The RT team had to remain observant and change tanks as they neared empty. A backup tank, reducing valve, and O_2 supply line with a quick connect should always available when a patient care area is being back fed.

DISTRIBUTION AND REGULATION OF MEDICAL GASES

Before it can be administered to a patient, a medical gas must be delivered to the bedside and the pressure reduced to a workable level. This is the primary function of gas distribution and regulation systems. Modern hospital gas distribution systems deliver bulk O_2 and compressed air to patients' rooms and special care areas through an elaborate piping network. This network may include a vacuum source and, for surgical areas, N_2O. Patient transport still requires the use of portable cylinders. Whether delivery occurs by central bulk supply or cylinder, patient safety is always the primary aim. For this reason, RTs must be proficient in the use of both types of delivery systems.

Central Piping Systems

Structural standards for piping systems are established by the NFPA and are described in more detail elsewhere.[2] Fig. 41.11 shows a simple central piping gas system. The gas pressure in a central piping system is normally reduced to the standard working pressure of 50 psi at the bulk storage location. A main alarm warns of decreases in pressure or interruptions in flow from the source. **Zone valves** (Fig. 41.12) throughout the system can be closed for system maintenance or in case of fire. Wall or station outlets at the delivery sites allow for the connection of various types of equipment to the gas distribution system. Because most delivery outlets include O_2, air, vacuum, and possibly N_2O, special safety connectors are used to help prevent accidental misconnections.

Safety Indexed Connector Systems

One of the greatest risks in medical gas therapy is giving a patient the wrong gas. Carefully reading the cylinder or outlet labels is the best way to avoid these accidents. However, human error does occur. For this reason, industry has developed indexed safety systems for gas delivery. These safety systems make misconnection between pieces of equipment nearly impossible. Three basic indexed safety systems are used in the delivery and regulation of medical gases: (1) the American National Standard/Compressed Gas Association Standard for Compressed Gas Cylinder Valve Outlet and Inlet Connections, or the ASSS; (2) the **diameter-index safety system** (DISS); and (3) the PISS.[17,18]

American Standard Safety System

Adopted in the United States and Canada, the ASSS provides standards for threaded high-pressure connections between large compressed gas cylinders (sizes F through H/K) and their attachments.[17] Specifications exist for more than 60 gases and gas mixtures. Fig. 41.13 shows a typical ASSS connection between a threaded cylinder outlet and a pressure-reducing valve nipple. Use of the ASSS standards makes misconnections difficult because

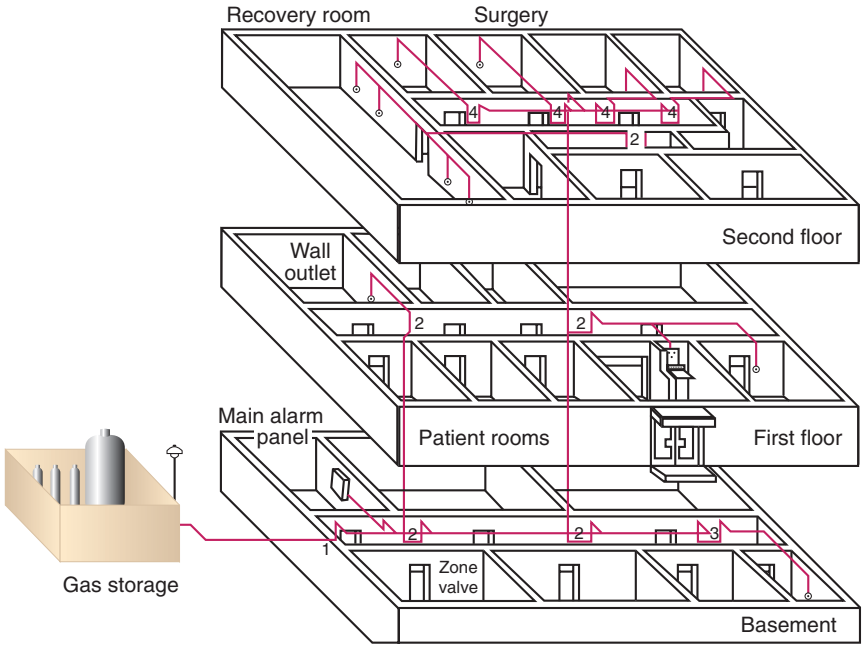

Fig. 41.11 A Hospital Piping System. Numbers indicate zone valves.

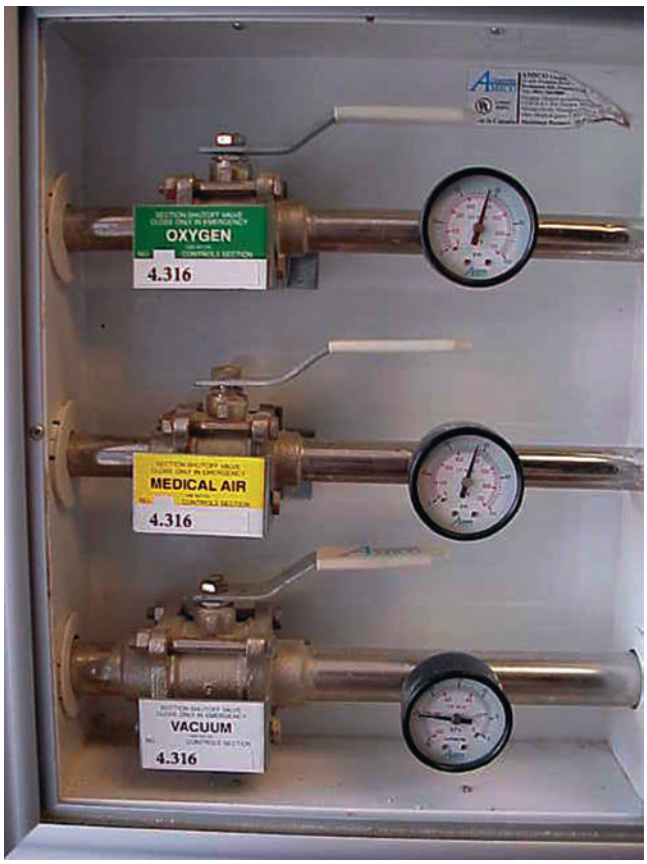

Fig. 41.12 O_2, air, and vacuum zone valves.

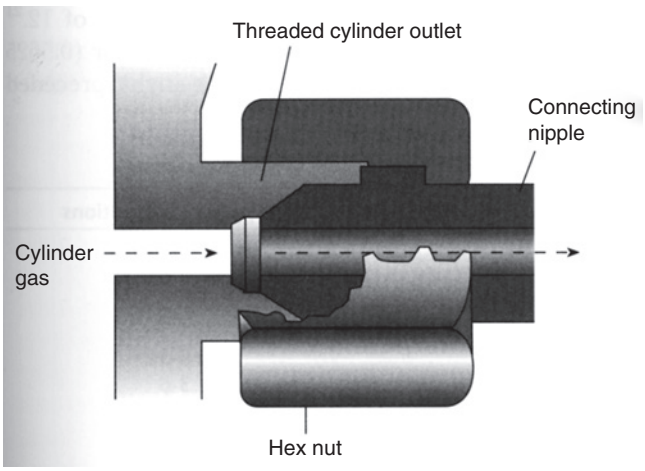

Fig. 41.13 Typical American standard supply system connection used to attach a reducing valve to a large high-pressure cylinder. A hexagonal nut is held on the nipple of the reducing valve by a circular collar. The connection is made by (1) aligning the reducing valve nipple with the conical cylinder valve outlet and (2) tightening the reducing valve hex nut onto the threaded cylinder outlet. Different threading and cylinder outlet sizes make accidental misconnections unlikely.

the size (bore) of the cylinder outlet and its threading differ based on the type of gas in the cylinder.

Because there are only 26 connections for the 62 listed gases and mixtures, each gas may not have a unique connection. Some gases have identical connections. Catalogues of cylinder equipment show the connection specifications for each type of cylinder and gas. A typical description for a large cylinder of O_2 is as follows: CGA-540 0.903-14NGO-RH-Ext. The connection for the threaded outlet of this cylinder is listed by the CGA as connection number 540. The outlet has a thread diameter (bore) of 0.903 in, there are 14 threads per inch, and the threads are right-handed (RH) and external (Ext). It is generally necessary to use only one or two outlet connections because most of the gases used by RTs are grouped within a few connector sizes. However, practitioners should be familiar with the classification scheme in general because expanding instrumentation and scope

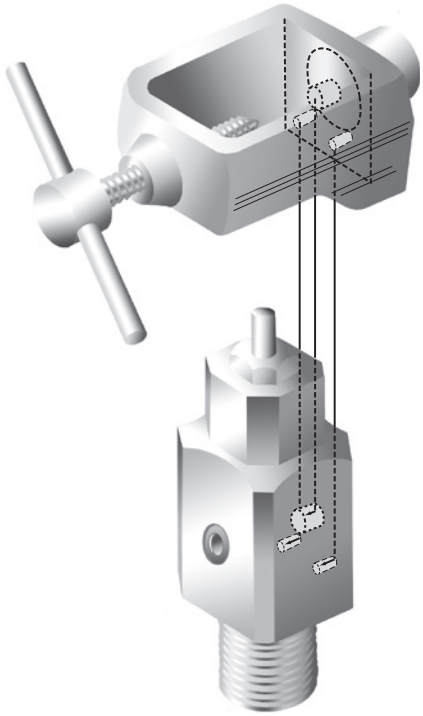

Fig. 41.14 Yoke connector showing regulator inlet and pin-indexed safety system (for cylinders size AA to E).

of services may bring RTs in contact with other gases and gas systems.

Pin-Index Safety System

Pin indexing is part of the ASSS but applies only to the valve outlets of small cylinders up to and including size E. These cylinders have a yoke type of connection. Fig. 41.14 illustrates the general structure of the pin-indexed yoke connection. The upper yoke fits over the lower valve stem. Two pins projecting from the inner surface of the yoke connector mate with two pinholes bored into the valve stem. Proper pin position aligns the small receiving nipple of the yoke with the recessed cylinder valve outlet. Tightening the hand screw on the yoke firmly seats the receiving nipple into the valve outlet. A nylon washer or bushing is typically used to ensure a leak-free connection.

Similar to the ASSS, the PISS helps prevent accidental misconnections between pieces of equipment. The exact positions of pins and pinholes vary for each gas. Unless the pins and holes align perfectly, the yoke nipple cannot seat in the recessed valve outlet. Six holes and pin positions constitute the total system. Because overlapping holes cannot be used, there are 10 possible pin combinations. Fig. 41.15 is a diagram of the location of all six possible holes and their index numbers. Table 41.5 lists the gases included in the PISS system, including their index positions.

Diameter-Index Safety System

The ASSS and the PISS provide standards for high-pressure connections between cylinders and equipment; the DISS was established to prevent accidental interchange of low-pressure (<200 psig) medical gas connectors.[18] RTs typically find DISS connections (1) at the outlets of pressure-reducing valves attached to

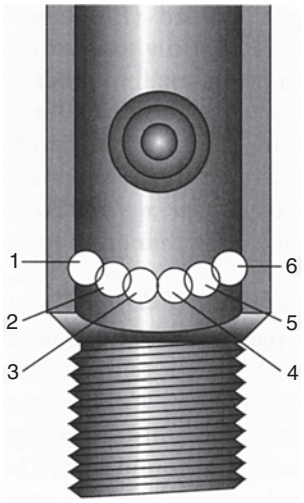

Fig. 41.15 Location of the pin-index holes in the cylinder valve face for different gases. See Table 41.5 for pin-index hole locations for various gases.

TABLE 41.5 Pin-Index Hole Positions

Gas	Pin Positions
O_2	2–5
O_2/CO_2 (CO_2 not >7%)	2–6
He/O_2 (He not >80%)	2–4
C_2H_4	1–3
N_2O	3–5
C_3H_6	3–6
He/O_2 (He > 80%)	4–6
O_2/CO_2 (CO_2 > 7%)	1–6
Air	1–5

cylinders; (2) at the station outlets of central piping systems; and (3) at the inlets of blenders, flow meters, ventilators, and other pneumatic equipment.

As shown in Fig. 41.16, the DISS connection consists of an externally threaded body and a mated nipple with a nut. As the two parts are joined, the shoulders of the nipple and the bores of the body mate, with the union held together by a hand-tightened hex nut. Indexing is achieved by varying the dimensions of the borings and shoulders. There are 11 indexed DISS connections and 1 connection for O_2 for a total of 12.[18] The standard threaded O_2 connector (0.5625 inch in diameter and 18 threads per inch) preceded adoption of this safety system. Nonetheless it has been assigned a DISS number of 1240.

Although O_2 and air are generally used from a central outlet, it may be necessary to administer other gases that have different DISS connections. To avoid stocking a large variety of pressure regulators, flow meters, and connectors for special gas use, adapters can be used to convert various DISS connections. The use of adapters to bypass a safety system carries an increased risk. For this reason, RTs should exercise extreme caution when adapting equipment connections. Misconnections can occur, with negative patient consequences.[13]

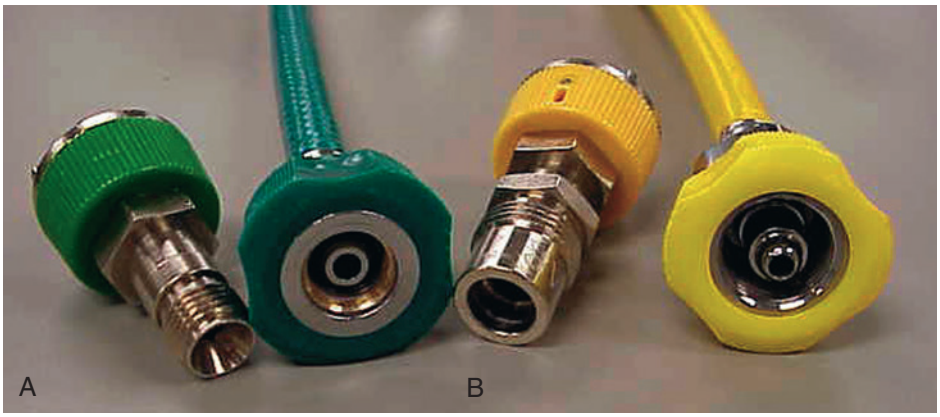

Fig. 41.16 O_2 (A) and air (B) diameter index safety system (DISS) connections. The two shoulders of the nipple allow the nipple to unite only with a body that has corresponding borings. If the match is incorrect, the nut does not engage the body threads. The difference in the shoulders and bore between the O_2 (A) and air (B) DISS connections is evident.

Quick-Connect Systems

Station outlets at the patient's bedside allow quick access to a bulk supply of O_2, air, or vacuum sources. Station outlets have DISS connections or quick-connect systems that are gas specific or vacuum specific. Manufacturers have designed specially shaped connectors for each gas (Fig. 41.17). Because each connector has a distinct shape, it does not fit into an outlet for another gas and each manufacturer has its own unique design. Therefore connectors from different manufacturers are not interchangeable. As long as a facility is standardized for a single quick-connect system, this incompatibility is seldom a problem.

A variety of safety systems help prevent inadvertent misconnections between medical delivery systems and equipment. Fig. 41.18 summarizes the use of and relationships between the ASSS, PISS, and DISS systems as applied to cylinder gases. Proficiency in the proper use of these systems is a basic skill of RTs.

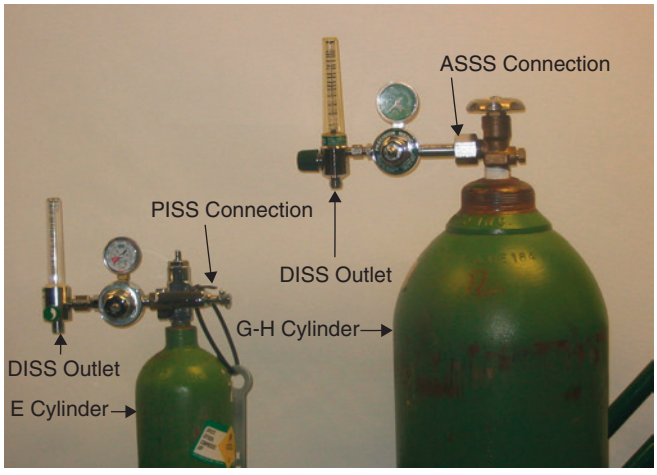

Fig. 41.18 Comparison of Safety Systems Used for Compressed Gases. The diameter-index safety system *(DISS)* connections are for low-pressure outlets (<200 psig). The American standard safety system *(ASSS)* provides for high-pressure connections with large cylinders. A variation of the ASSS entails a yoke-and-pin system *(PISS)* for connecting to small cylinders (AA through E).

Regulating Gas Pressure and Flow

Whatever the source of medical gas, the pressure and flow must be regulated or reduced to a safe level. If the goal is solely a reduction in gas pressure, a **reducing valve** is used. For control

of gas flow to a patient, a **flow meter** is used. If control of both pressure and flow is needed, a regulator is used.

Cylinder gases such as O_2 and air exert a pressure that is much too high for use with respiratory care equipment. These high pressures must be reduced to a lower "working" level. In the United States, this working pressure is 50 psig. For bulk delivery systems with individual station outlets, built-in reducing valves decrease the delivered pressure to 50 psig. This standard pressure can be directly applied to power devices such as ventilators (see Chapter 46). However, if the goal is to control gas delivery to a patient for O_2 therapy or nebulized medication (see Chapters 40 and 42), a flow meter must also be used.

High-Pressure Reducing Valves

The two basic types of high-pressure reducing valves are single stage and multiple stage. Reducing valves are available as preset or adjustable. Although all of these valves function on the same principle, the design, features, and use are different. This section differentiates preset reducing valves and adjustable reducing valves and discusses multiple-stage reducing valves.

Preset reducing valve. Fig. 41.19 shows the basic design of a high-pressure preset reducing valve. High-pressure gas (2200 psig for O_2) enters through the valve *(A)*, with the inlet pressure displayed on the pressure gauge *(B)*. The body of the valve is divided into a high-pressure chamber *(C)* and an ambient-pressure chamber *(D)* by a flexible diaphragm *(E)*. Attached to the diaphragm in the ambient-pressure chamber is a spring *(F)*, which is fixed to the other side of the chamber. Also attached to the diaphragm but in the high-pressure chamber is a valve stem *(G)* that sits on the high-pressure inlet *(H)*. Gas flows through the valve inlet *(H)* into the high-pressure chamber and on to the gas outlet *(I)*. The pressure chamber is supplied with a safety vent *(L)* preset to 200 psig to release pressure in the event of malfunction.

The spring tension is calibrated to give when the pressure on the diaphragm exceeds 50 psig. When this happens, the valve stem is pushed forward and closes the high-pressure inlet, preventing further entry of gas into the reducing valve. However, as long as gas is allowed to escape from the pressure chamber through the outlet *(I)*, the inlet valve remains open and allows gas flow. The regulator maintains a balance between outlet flow and inlet pressure. Automatic adjustment of the diaphragm–spring combination keeps the pressure in the high-pressure chamber at a near-constant 50 psig—hence the name *preset*. Preset reducing valves are normally used in conjunction with high-pressure gas cylinders to decrease the pressure to the standard 50 psig used with most respiratory care equipment.

Adjustable reducing valve. Although most respiratory care equipment works at the standard 50 psig, some devices need variable pressures. To provide variable outlet pressures from a high-pressure gas source, an adjustable reducing valve is needed. Fig. 41.20 shows the basic design of a high-pressure adjustable reducing valve. As with the preset design, the inlet valve *(H)* remains open until the gas pressure exceeds the spring tension, displacing the diaphragm and blocking further gas entry. However, whereas the preset reducing valve provides a fixed pressure, the adjustable reducing valve allows a change in outlet pressure. Outlet pressure can be changed with a threaded hand control *(K)* attached to the end of the diaphragm spring. Changing the tension on the valve spring varies pressure over a wide range, usually between 0 and 100 psig.

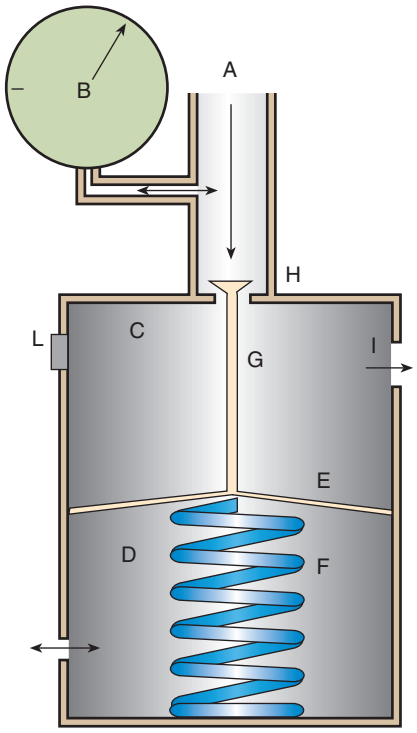

Fig. 41.19 Preset high-pressure reducing valve.

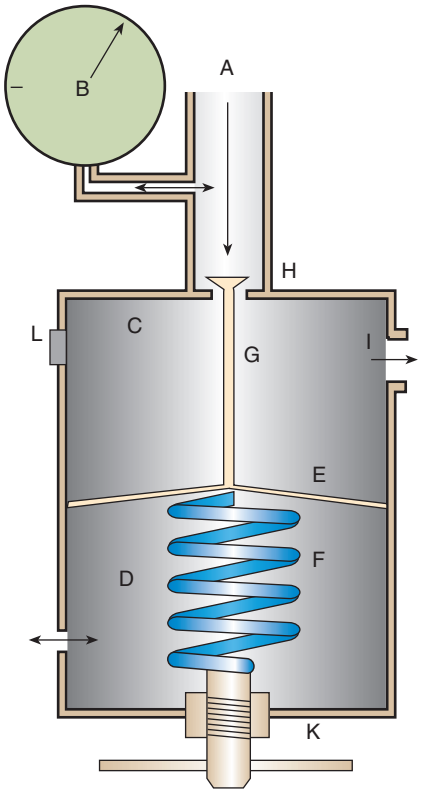

Fig. 41.20 Adjustable high-pressure reducing valve.

The adjustable reducing valve commonly is used in combination with a Bourdon-type flow gauge (discussed later). The combination of a flow meter with a reducing valve is called a **regulator**.

Multiple-stage reducing valve. As the name suggests, a *multiple-stage reducing valve* reduces pressure in two or more steps. Multiple-stage reducing valves can be either preset or adjustable and can be combined with a flow meter device as a true regulator. Two-stage reducing valves are used occasionally; three-stage units are rarely needed. A two-stage reducing valve functions as two single-stage reducing valves working in series. Gas enters the first stage, where the pressure is reduced to an intermediate level (usually 200 to 700 psig). Gas then enters the second stage, where the pressure is decreased to working level (usually 50 psig). Because each pressure chamber has one safety relief vent, the user can usually determine the number of stages in a reducing valve by noting the number of relief vents present. Because they reduce pressure in multiple steps, these valves provide more precise and smooth flow control. However, they are larger and more expensive than single-stage reducing valves. For this reason, a multiple-stage reducing valve should be considered only if minimal fluctuations in pressure or flow are critical factors, as in research activities. For routine hospital work, single-stage reducing valves are satisfactory.

Proper use of high-pressure reducing valves. When a cylinder attached to a high-pressure reducing valve is open, gas undergoes rapid decompression, followed by rapid recompression. These rapid pressure and temperature changes may cause failure of the reducing valve. Rapid temperature changes can ignite combustible materials; this risk is increased in the presence of 100% O_2. Box 41.1 provides guidelines for minimizing the risk associated with setting up O_2 cylinders with a high-pressure reducing valve or regulator.[1]

MINI CLINI

Leaky Connections

Problem

Following standard procedure, the RT attaches a pressure-reducing valve to an O_2 cylinder. When the RT opens the cylinder valve, she can hear gas leaking at or near the connection.

Solution

A leak usually indicates that the connection between the pressure-reducing valve and the cylinder outlet is not tight. If the cylinder outlet is a standard ASSS threaded connector, the connection is either cross-threaded or not properly seated and tightened. To solve this problem, the RT closes the cylinder valve and removes and reattaches the pressure-reducing valve, taking care to thread the connection properly and to tighten with a wrench. If the cylinder outlet is a pin-indexed connector, the RT closes the cylinder valve and removes the pressure-reducing valve. The RT checks to ensure that the nylon washer is present, in good condition, and properly fitted. She then reattaches the pressure-reducing valve, taking care to seat the connection properly and to tighten it by hand. If the leak continues after these corrective actions, it is likely that the pressure-reducing valve is malfunctioning and should be replaced.

BOX 41.1 Safe Procedure for Setup of an Oxygen Cylinder and Reducing Valve or Regulator

1. Secure the cylinder according to the CGA guidelines. Verify the contents from the label that matches the color code and valve indexing.
2. Remove the protective cap or wrap and inspect the cylinder valve to ensure that it is free of dirt, debris, and oil.
3. Warn any persons present that the cylinder valve is about to be "cracked" and that it will make some noise. Turn the cylinder valve away from persons present, stand to the side, and quickly open and close the valve. This removes any dust or small debris from the cylinder valve outlet.
4. Inspect the valve or regulator inlet for debris, dirt, and oil. Check the device label, and confirm that it is intended for high-pressure service and for use with the gas to be administered. O_2-reducing valves and regulators should have a label stating: *Oxygen: Use No Oil.*
5. After the valve or regulator inlet is confirmed to be free of contaminants, securely tighten (but do not force) the device onto the cylinder outlet. When connections to the cylinder are being made, use appropriate wrenches that are free of oil and grease. Never use pipe wrenches. Use only cylinder valve connections that conform to the ASSS and the PISS. Low-pressure connections must comply with the DISS or be noninterchangeable, low-pressure quick connects. Never connect fixed or adjustable orifices or metering devices directly to a cylinder without a pressure-reducing valve.
6. Confirm that the regulator or reducing valve is in the *off* or *closed* position and slowly open the cylinder valve to pressurize the attached reducing valve or regulator. After pressurization has occurred, open the cylinder valve completely and turn it back one-fourth to one-half turn (this maneuver prevents a condition known as "valve freeze," in which the valve cannot be turned).

Low-Pressure Gas Flow Meters

As with drugs, giving a medical gas to a patient requires knowledge of the dosage being delivered. Physicians often prescribe O_2 dosage as a flow in liters per minute. In addition, certain gas-mixing equipment requires accurate knowledge of input flows, sometimes involving two or more gases. Flow meters allow the rate of gas flow to a patient to be set and controlled. When the gas source is a high-pressure gas cylinder, a regulator (reducing valve plus flow meter) is required. However, when the source is a bulk central supply system, the pressure has already been reduced to 50 psig by the time it reaches the outlet stations and only a flow meter is required.

Three categories of flow meters are used in respiratory care: the flow restrictor, the **Bourdon gauge**, and the **Thorpe tube**. The Thorpe tube has two different designs: pressure compensated or not pressure compensated (uncompensated). Although uncompensated Thorpe tubes are rare, they may still be used at some institutions. For this reason, the principles underlying each of the four types of flow metering devices are compared and contrasted in the following text.

Flow restrictor. The flow restrictor is the simplest and least expensive flow meter device. As shown in Fig. 41.21, a flow restrictor consists solely of a fixed orifice calibrated to deliver a specific flow at a constant pressure (50 psig). The operation of

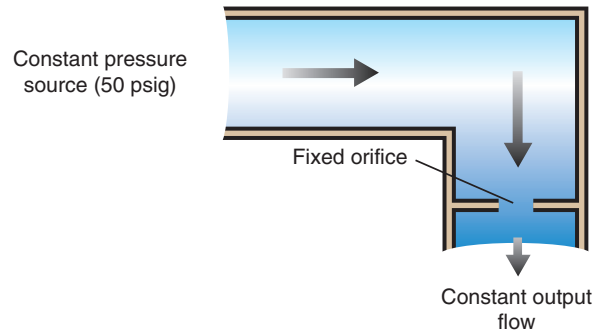

Fig. 41.21 Flow restrictor.

TABLE 41.6 Advantages and Disadvantages of Flow Restrictors

Advantages	Disadvantages
Low-cost, simple, reliable (no moving parts)	Different versions required for different flows
Cannot be set to incorrect flow	Accuracy varies with changes in source and downstream pressures
Can be used in any position (gravity-independent)	Cannot be used with high-resistance equipment

the flow restrictor is based on the principle of flow resistance. Specifically, the flow of gas through a tube can be quantified with the following equation:

$$R = \frac{P_1 - P_2}{V}$$

Rearranging the equation to solve for flow *(V)* yields the following:

$$V = \frac{P_1 - P_2}{R}$$

where V is the volumetric flow per unit time, P_1 is the pressure at the **upstream** point (point 1), P_2 is the pressure at the **downstream** point (point 2), and R is the total resistance to gas flow.

By design, a flow restrictor requires a source of constant pressure (usually 50 psig). As long as the source pressure remains fixed, $P_1 - P_2$ should stay constant. With a fixed-size orifice, the flow resistance *(R)* also remains constant. The rate of gas flow through a flow restrictor can be increased by increasing P_1 (upstream pressure) or by selecting a larger orifice size. Both fixed and adjustable orifice flow restrictors are used clinically. Commercially produced flow restrictors are calibrated at 50 psig. Table 41.6 summarizes the advantages and disadvantages of flow restrictors.

RULE OF THUMB A flow restrictor is typically used to deliver a nonadjustable flow of air or O_2 to a medication nebulizer. An adjustable flow restrictor combined with an E cylinder of O_2 is used to adjust flow to an O_2 delivery device, medication nebulizer, or resuscitation bag. It is important to remember that narrowing or pinching of the O_2 tubing going to these devices will reduce gas flow.

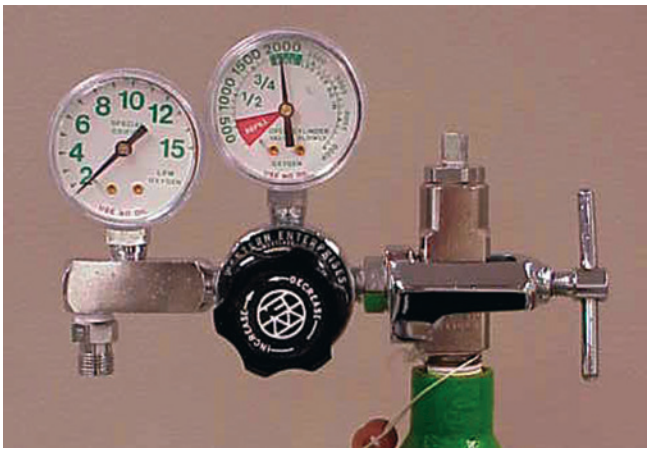

Fig. 41.22 Bourdon gauge regulator.

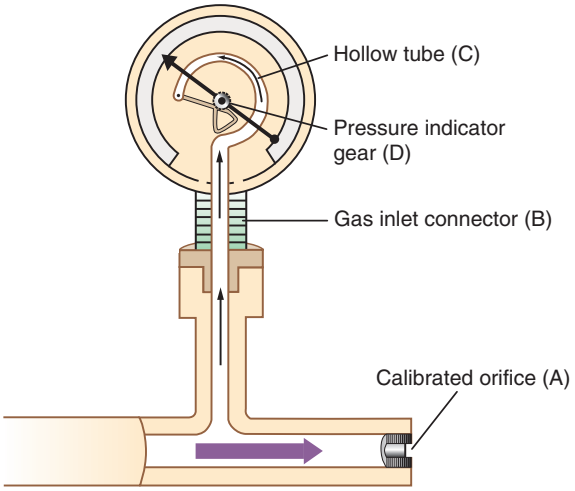

Fig. 41.23 Components of a Bourdon Pressure Gauge. See text for more information.

Bourdon gauge. A Bourdon gauge (Fig. 41.22) is a flow meter device that is always used in combination with an adjustable pressure-reducing valve. Similar to the flow restrictor, the Bourdon gauge uses a fixed orifice. In contrast to the flow restrictor, the Bourdon gauge operates under variable pressures as adjusted with the pressure-reducing valve. The Bourdon gauge is a fixed-orifice, variable-pressure flow meter, so increasing the upstream pressure increases gas flow out of the device unless downstream pressure also increases.

As shown in Fig. 41.23, a Bourdon gauge has a calibrated fixed orifice *(A)*, which creates outflow resistance. The gauge itself is attached with a connector *(B)* located proximal to the orifice. Inside the gauge is a curved hollow closed tube *(C)* that responds to pressure changes by changing shape. The force of gas pressure tends to straighten the tube, causing its distal end to move. This motion is transmitted to a gear assembly and indicator needle *(D)*. Although its reading changes based on pressure, the numbered scale is calibrated to read the needle movement in units of flow (liters per minute).

As with the flow restrictor with a fixed orifice, the output flow of the Bourdon gauge is proportional to the driving

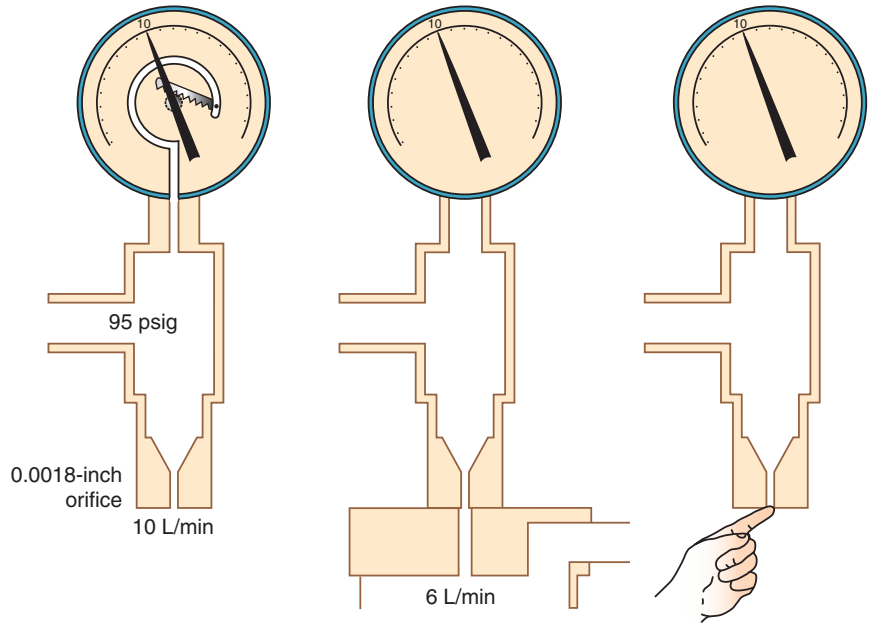

Fig. 41.24 Bourdon performance when downstream pressures increase as a result of high-resistance equipment or blockage. *Left,* Normal state with fixed orifice and no downstream resistance results in an accurate flow reading. *Center,* High-resistance nebulizer increases downstream pressure or back pressure. The result is a falsely high reading (10 L/min vs actual flow of 6 L/min). *Right,* Complete blockage (zero flow) results in flow reading on gauge.

pressure. However, the Bourdon gauge provides a continuous range of flow that the user adjusts by altering the driving pressure. Although the gauge actually measures pressure changes, it displays the corresponding flow.

As with a flow restrictor, gravity does not affect a Bourdon gauge. The Bourdon gauge is the best choice when a flow meter cannot be maintained in an upright position. This situation is common when a patient is being transported with a portable O_2 source. In these instances, keeping the E cylinder upright is seldom easy, and movement of both the O_2 supply and the patient is common. Combined with its continuous range of flows, this feature makes the Bourdon gauge the metering device of choice for patient transport.

The main disadvantage of the Bourdon gauge is its inaccuracy when pressure distal to the orifice (downstream pressure) changes. Specifically, if downstream pressure increases (as when high-resistance equipment is used), the pressure difference across the orifice and actual output flow decrease. However, the Bourdon gauge's flow reading depends on upstream pressure, which stays constant. In this situation, the gauge reading is falsely higher than the actual delivered flow. Because it measures upstream pressure, the gauge registers flow even when the outlet is completely blocked (Fig. 41.24). A user who needs accurate flow when using a device that creates high resistance should not select a Bourdon gauge. A compensated Thorpe tube should be used instead.

Integrated O_2 cylinders (Fig. 41.25), including the Grab 'n Go System (Praxair, Danbury, CT), have combined the O_2 cylinder with a pressure regulator and an adjustable flow restrictor to meter O_2 flow. These portable O_2 systems eliminate the need for separate O_2 tanks, Bourdon gauge regulators, and O_2 keys or wrenches (needed to turn on standard E-cylinders). These integrated systems virtually eliminate problems and delays associated with incorrectly mounted regulators. The practitioner simply selects the flow on the flow-adjusting knob and connects the O_2 tubing to the system connection and the patient.

Fig. 41.25 Grab 'n Go System (Praxair, Danbury, CT).

These integrated O_2 cylinders are available with a digital gauge (INTELLI-OX+TM, Airgas Healthcare) (Fig. 41.26) which displays the remaining gas volume and calculates cylinder duration. This system also incorporates visual and audible alerts. These alerts are activated when cylinder duration falls below 15 minutes or one fourth of the content is remaining. Besides the benefits stated above these systems may increase patient safety by alerting clinicians when the cylinder is nearing empty.

Fig. 41.26 INTELLI-OX+TM integrated O_2 cylinder. (Airgas Healthcare, Radnor, PA).

RULE OF THUMB The Bourdon gauge is the better choice when a flow meter cannot be maintained in an upright position, as in transporting a patient with an O_2 E cylinder. It is important to remember that narrowing or pinching of the O_2 tubing will reduce gas flow while the Bourdon gauge flow reading remains the same.

Thorpe tube. The Thorpe tube flow meter (Fig. 41.27) is always attached to a 50-psig source, either a preset pressure-reducing valve or a bedside station outlet. Compared with the flow restrictor and the Bourdon gauge, the Thorpe tube functions as a variable-orifice, constant-pressure flow meter; thus increasing the size of the orifice increases the flow of gas. Fig. 41.28 shows how a Thorpe tube works. The key component in this device is a tapered transparent tube that contains a float. The diameter of the tube increases from bottom to top. Gas flow suspends the float against the force of gravity. To read the flow, one simply compares the float position with an adjacent calibrated scale, normally calibrated in liters per minute.

Although the Bourdon gauge measures pressure, the Thorpe tube is used to measure true flow. Flow measurement involves the complex interaction of gravity and fluid dynamics. When gas begins to flow into a Thorpe tube, the initial pressure difference lifts the float. As the needle valve is opened, the float rises in the widening tube, the space available for flow around it increases, and resistance to flow decreases. The float ultimately stabilizes when the pressure difference across the float (an upward force) equals the opposing downward force of gravity.

Fig. 41.27 Thorpe tube flow meter.

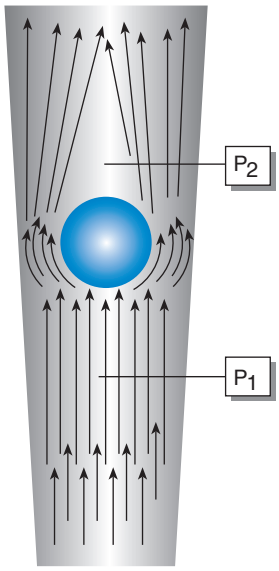

Fig. 41.28 The position of the float in a Thorpe tube flow meter is based on a balance between the force of gravity and the pressure difference ($P_2 - P_1$) across it as determined by the variable-sized orifice between the float and the tube wall.

As the needle valve of the flow meter is opened, the increase in flow initially disrupts this balance, causing an increase in the pressure difference across the float. With the upward pressure difference greater than the downward force of gravity, the float rises. However, as the float rises, the available "orifice" increases in diameter. Flow resistance around the float decreases, and the pressure difference again equilibrates with gravity. The float position stabilizes at a higher level, proportionate to the greater flow around it.

Thorpe tubes come in two basic designs: back pressure-compensated and back pressure-uncompensated. The term *pressure compensation* refers to a design that prevents changes in

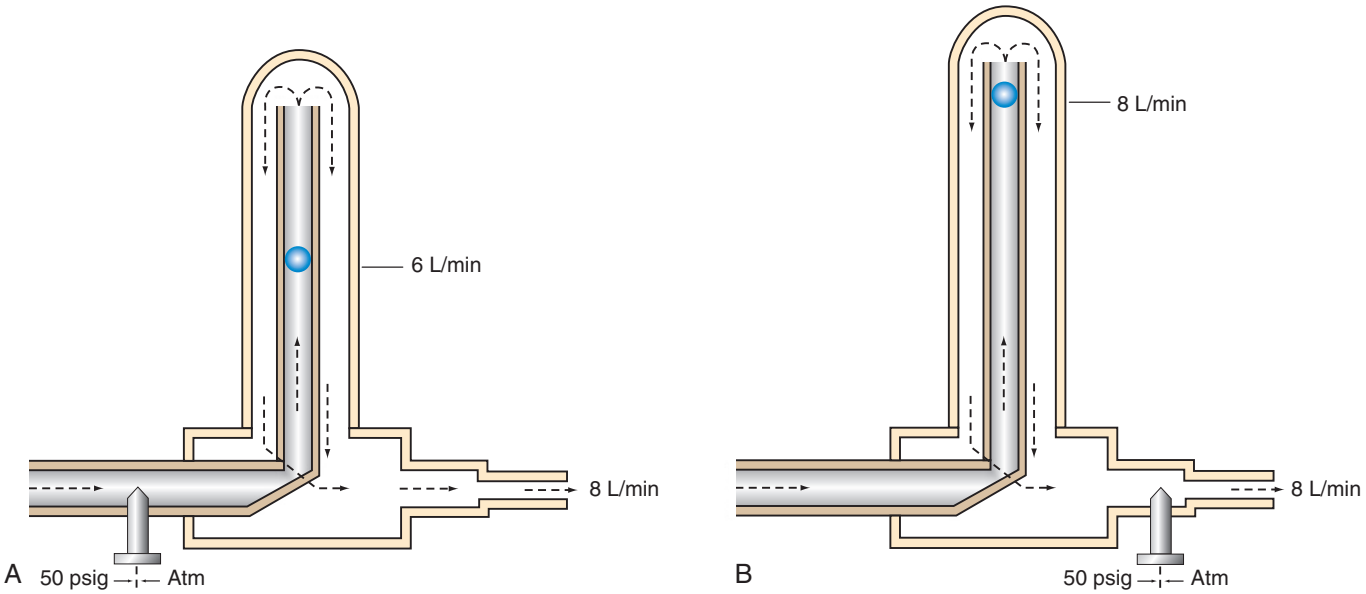

Fig. 41.29 Comparison of back pressure-uncompensated (A) and back pressure-compensated (B) Thorpe tube flow meters. In the pressure-uncompensated flow meter, the flow-control valve is proximal to the meter and the gauge records less than the actual output. In the pressure-compensated flow meter, location of the valve distal to the meter correlates the gauge reading with the output.

downstream resistance, or back pressure, from affecting meter accuracy. All manufacturers now supply only back pressure-compensated Thorpe tubes for the administration of medical gases. However, some ventilators and anesthesia machines still use back pressure-uncompensated Thorpe tubes. For this reason, clinicians using these devices must understand the effect of back pressure on their accuracy. Downstream resistance increases when the user connects a flow meter to certain types of equipment. Almost all therapy gas equipment produces some flow restriction. Devices such as jet nebulizers produce very high downstream resistance. Depending on their design, Thorpe tube flow meters respond to resistance in one of two ways.

The *uncompensated* Thorpe tube flow meter is calibrated in liters per minute but at atmospheric pressure (without restriction). Gas from a 50-psig source flows into the meter at a rate controlled by a needle valve located before the flow tube (Fig. 41.29A). When the user attaches flow-restricting equipment to the meter, downstream resistance increases, which increases pressure in the flow tube. As long as this pressure does not exceed 50 psig, gas continues to flow through the tube. However, the added downstream resistance increases the pressure in the flow tube above atmospheric pressure. At this higher pressure, a greater amount of gas flows through a given restriction than at atmospheric pressure so that the float at a given height on the scale indicates more gas flow through the tube than is actually occurring. Under these conditions, an *uncompensated Thorpe tube falsely shows a flow lower than that actually delivered to the patient.*[4]

In contrast, the scale of the compensated Thorpe tube flow meter is calibrated at 50 psig instead of at atmospheric pressure. Its flow-control needle valve is placed after (distal to) the flow tube (see Fig. 41.29B). The entire meter operates at constant 50-psig pressure. Knowing that the compensated Thorpe tube operates at 50 psig helps identify it. When a compensated Thorpe tube is connected to a 50-psig gas source with the needle valve closed, the float "jumps" and then returns to zero as the Thorpe tube is pressurized. Because the entire meter operates at constant pressure, an increase in downstream resistance increases pressure distal to the needle valve only. As long as the downstream pressure does not exceed 50 psig (in which case flow ceases), *the position of the float accurately reflects actual outlet flow*. For this reason, the pressure-compensated Thorpe tube is the preferred instrument in most clinical situations.

The only factor limiting the use of a pressure-compensated Thorpe tube is gravity. Because it is accurate only in an upright position, a Thorpe tube is not the ideal choice for patient transport. In these cases, the gravity-independent Bourdon gauge is a satisfactory alternative. Fig. 41.30 summarizes the effects of downstream resistance, or back pressure, on the Bourdon gauge and pressure-compensated and pressure-uncompensated Thorpe tube flow metering devices.

RULE OF THUMB When an accurate gas flow is needed with a device that creates a high resistance, a compensated Thorpe tube should be used instead of a Bourdon gauge. Thus a flow meter with a quick connect is attached to most O_2 and air outlets in patient care areas.

SUMMARY CHECKLIST

- All therapy gases must contain at least 20% O_2; all such gases support combustion.
- O_2 from a liquid source or cylinder is over 99% pure, whereas O_2 from a concentrator will be 90 to 96% pure. Changing from a cylinder to a concentrator may require an increase in liter flow to maintain the patient's arterial O_2 saturation.

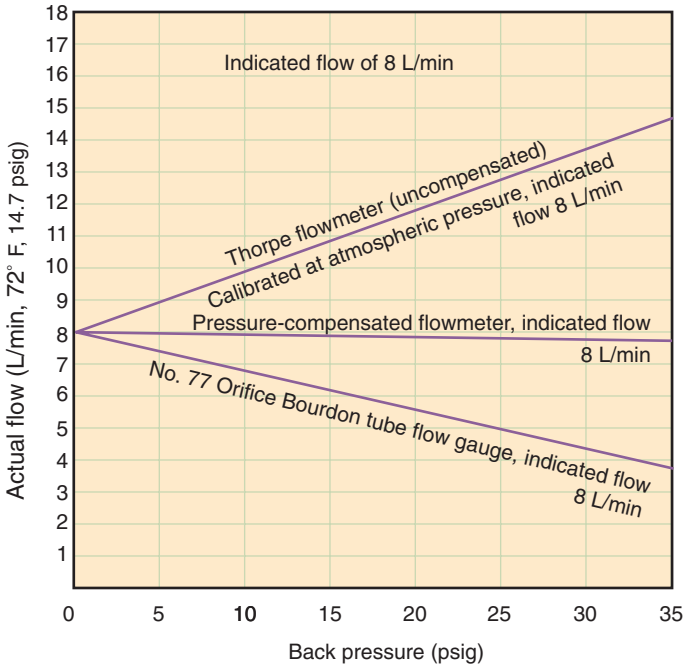

Fig. 41.30 Comparative accuracy of flow meter devices against increasing downstream pressure (back pressure). With the pressure-compensated Thorpe tube, indicated flow equals actual flow regardless of downstream pressure. With the uncompensated Thorpe tube, indicated flow is progressively lower than actual flow as downstream pressure increases. With the Bourdon gauge, indicated flow is progressively higher than actual flow as downstream pressure increases. MINI CLINI

Selection of Devices to Regulate Gas Pressure or Control Flow

Problem

Three staff RTs are given three separate requests to set up O_2. (1) Mark has an order to transport Ms. Patel to radiology with O_2. (2) Carmen needs to set up a pneumatically powered ventilator with O_2 in the ambulatory clinic (where there are no O_2 outlets). (3) Monica has to set up O_2 therapy with a jet nebulizer for a patient in the intensive care unit (ICU). What equipment should each RT select?

Solutions

1. Because he has to transport a patient using O_2, Mark should select an E cylinder with an adjustable regulator that includes a Bourdon gauge (unaffected by gravity) or an integrated O_2 cylinder that includes an adjustable flow restrictor.
2. Because pneumatically powered ventilators require 50 psig and no central outlets are available, Carmen needs a preset (50 psig) reducing valve and a large G or H size O_2 cylinder.
3. Because all modern ICUs have central wall outlets for O_2, Monica need only select a flow meter with the appropriate quick connect. A compensated Thorpe tube is required for metering flow through high-resistance equipment such as jet nebulizers.

- Inhaled NO is a pulmonary vasodilator; it is beneficial in treating term or near-term infants with severe hypoxia who do not have a diaphragmatic hernia.
- Inhaled NO has not been shown to be beneficial in improving pulmonary hypertension in adult patients; it is also costly.
- Medical gases are stored either in portable high-pressure cylinders or in large centralized bulk reservoirs.
- For positive identification of the contents of a medical gas cylinder, the label must be read carefully.
- The pressure in a gas-filled cylinder indicates its contents; the pressure in a liquid-filled cylinder does not.
- To compute duration of flow (minutes) of a medical gas cylinder, multiply the cylinder pressure (pounds per square inch) by the cylinder factor and divide the result by the set flow (liters per minute).
- Gas supply systems provide gas at 50 psig to outlets throughout a facility through a network of pipes. Such a system must include both zone valves for repairs or fire and alarms to warn of failure.
- Medical gas cylinders must be secured to the wall with a chain, bound or chained to a suitable cart, or placed in a specifically designed cylinder carrier.
- The protective cylinder caps must be kept in place during transportation or storage of cylinders.
- Cylinders for use that are not appropriately labeled should not be transported.
- Flammable materials, especially oil or grease, should not be used on regulators, cylinders, fittings, or valves.
- The cylinder valve should be opened slightly to remove dust and dirt before attaching the regulator.
- Cylinders should never be placed near sources of heat.
- When O_2 is in use, a "No Smoking" sign should be posted unless signs that prohibit smoking in the facility are posted in the entrances.
- Failure of a bulk gas supply system can threaten the lives of patients receiving O_2 therapy or being supported with pneumatically powered devices. A protocol must exist to deal with this emergency.
- Indexed safety systems help prevent misconnections between equipment. The ASSS provides high-pressure connections with large cylinders; the PISS does the same for small cylinders; and DISS connections are for low-pressure outlets, typically 50 psig.
- A reducing valve is used for reduction of gas pressure. A flow meter is used for control of gas flow. A regulator is used for control of both pressure and flow.
- A flow restrictor is used to provide fixed flows of O_2 or air to a medication nebulizer.
- An adjustable flow restrictor combined with an E cylinder of O_2 is used to adjust the flow to an O_2 delivery device, medication nebulizer, or resuscitation bag. It is important to remember narrowing or pinching of the O_2 tubing going to these devices will reduce this gas flow. The Bourdon gauge is the better choice when a flow meter cannot be maintained in an upright position during a patient transported with an O_2 E cylinder. Narrowing or pinching of the O_2 tubing will

reduce gas flow while the Bourdon gauge flow reading remains the same.

- When an accurate gas flow is needed with a device that creates high resistance, a compensated Thorpe tube should be used, especially with high-resistance equipment.

Medical Gas Therapy

Albert J. Heuer and Anne Marie Hilse

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe when oxygen (O_2) therapy is needed.
- Assess the need for O_2 therapy.
- Describe what precautions and complications are associated with O_2 therapy.
- Select an O_2 delivery system appropriate for the respiratory care plan.
- Describe how to administer O_2 to adults, children, and infants.
- Describe how to identify and correct malfunctions of O_2 delivery systems.
- Assess and monitor a patient's response to O_2 therapy.
- Describe how and when to modify or recommend modification of O_2 therapy.
- Describe how to implement protocol-based O_2 therapy.
- Identify the indications, complications, and hazards of hyperbaric O_2 therapy.
- Identify when and how to administer specialty therapeutic gases.

CHAPTER OUTLINE

KEY TERMS

atmospheric pressure absolute (ATA)
bronchopneumonia
bronchopulmonary dysplasia
croup
exudative
heliox therapy
high-flow system
high-flow nasal cannula (HFNC)
hyperbaric oxygen (HBO) therapy
hyperoxemia
hyperoxic acute lung injury
hypoxemia
low-flow system
neovascularization
nitric oxide (NO)
protocol-based oxygen therapy
rebound effect
reservoir system
retinopathy of prematurity (ROP)
retrolental fibroplasia

Gas therapy is the most common mode of respiratory care. Most medical gases are drugs. As with any drug, in consultation with the physician, respiratory therapists (RTs) recommend a dosage and delivery method for medical gases, initiate therapy, monitor the response, and alter therapy in relation to the patient care plan.

OXYGEN THERAPY

There is general agreement among clinicians about the proper use of O_2 therapy.[1-4] However, as the primary member of the healthcare team responsible for O_2 administration, the RT must be well versed in all aspects of its use in clinical practice.

General Goals and Clinical Objectives

The overall goal of O_2 therapy is to maintain adequate tissue oxygenation while minimizing cardiopulmonary work. Clinical objectives for O_2 therapy are the following:

- Correct documented or suspected acute hypoxemia
- Decrease symptoms associated with chronic hypoxemia
- Decrease the workload hypoxemia imposes on the cardiopulmonary system

Correcting Hypoxemia

O_2 therapy corrects **hypoxemia** by increasing alveolar and blood levels of O_2. Correction of hypoxemia is the most tangible objective of O_2 therapy and the easiest to measure and document.

Decreasing Symptoms of Hypoxemia

In addition to relieving hypoxemia, O_2 therapy can help relieve the symptoms associated with certain lung disorders, including dyspnea.[5] O_2 therapy also may improve mental function among patients with chronic hypoxemia.[6]

Minimizing Cardiopulmonary Workload

The cardiopulmonary system compensates for hypoxemia by increasing ventilation and cardiac output. In cases of acute hypoxemia, supplemental O_2 can decrease demands on both the heart and the lungs. Patients with hypoxemia breathing room air can achieve acceptable arterial oxygenation only by increasing ventilation. Increased ventilatory demand increases the work of breathing. In these cases, O_2 therapy can reduce both the high ventilatory demand and the work of breathing.

Patients with arterial hypoxemia can maintain acceptable tissue oxygenation only by increasing cardiac output or, if the hypoxemia is chronic, by increasing the red blood cell mass (i.e., polycythemia). Because O_2 therapy acutely increases blood O_2 content, the heart does not have to pump as much blood per minute to meet tissue demands. This reduced workload is particularly important when the heart is already stressed by disease or injury, as in myocardial infarction, sepsis, or trauma.

Hypoxemia causes pulmonary vasoconstriction and pulmonary hypertension. Pulmonary vasoconstriction and hypertension increase workload of the right side of the heart. For patients with chronic hypoxemia, this increased workload over the long term can lead to right ventricular failure (cor pulmonale). O_2 therapy can reverse pulmonary vasoconstriction and decrease right ventricular workload.[7]

Assessing the Need for Oxygen Therapy

There are three basic ways to determine whether a patient needs O_2 therapy. The first is the use of laboratory measures such as arterial blood gas testing to document hypoxemia. Second, a patient's need for O_2 therapy can be based on the specific clinical problem or condition. Third, hypoxemia may cause tachypnea, tachycardia, cyanosis, and distressed overall appearance, and therefore bedside assessment can help identify such a need.

Laboratory measures for documenting hypoxemia include hemoglobin saturation and partial pressure of oxygen (PaO_2), as determined by either invasive or noninvasive means (see Chapter 19). Threshold criteria defining hypoxemia with these measures vary depending on the source, but clinicians and studies predominantly agree that strategies must be balanced to prevent hypoxemia and the emerging dangers of **hyperoxemia**. However, commonly a used threshold for hypoxemia is a PaO_2 less than 55 to 60 mm Hg or O_2 saturation (SaO_2) less than 87% to 90% in subjects breathing room air.[2]

O_2 therapy is also needed for patients with disorders associated with hypoxemia. Examples are postoperative patients or patients with carbon monoxide or cyanide poisoning, shock, pulmonary embolus, trauma, and acute myocardial infarction or during cardiopulmonary resuscitation.[1,2,8]

TABLE 42.1 Clinical Signs of Hypoxia

Finding	Mild to Moderate	Severe
Respiratory	Tachypnea	Tachypnea
	Dyspnea	Dyspnea
	Paleness	Cyanosis
Cardiovascular	Tachycardia	Tachycardia, eventual bradycardia, arrhythmia
	Mild hypertension, peripheral vasoconstriction	Hypertension and eventual hypotension
Neurologic	Restlessness	Somnolence
	Disorientation	Confusion
	Headaches	Distressed appearance
	Lassitude	Blurred vision
		Tunnel vision
		Loss of coordination
		Impaired judgment
		Slow reaction time
		Manic-depressive activity
		Coma

Careful bedside physical assessment can help determine a patient's need for O_2 therapy. Table 42.1 summarizes the common respiratory, cardiovascular, and neurologic signs used in the detection of hypoxemia. This information can be combined with more quantitative measures such as arterial blood gas results to confirm the need for supplemental O_2.

RULE OF THUMB The three basic ways to determine the need for oxygen therapy include laboratory measurements such as arterial blood gas testing, the presence of a specific clinical problem such as during cardiopulmonary resuscitation, and a result of a clinical assessment which reveals the presence of tachypnea, cyanosis, or other physical manifestation.

Precautions and Hazards of Supplemental Oxygen

There is no doubt that oxygen saves lives. It is also a potent drug, carrying with it many precautions and potential hazards. The following are five such hazards which are common and potentially severe enough to warrant additional discussion.[2]

Oxygen Toxicity/Hyperoxic Acute Lung Injury

The condition formerly known as oxygen toxicity is currently termed **hyperoxic acute lung injury**. Hyperoxia has been defined by several studies as a PaO_2 greater than 300 mm Hg. These studies demonstrate hyperoxia induced vasoconstriction, decreased cardiac output, and decreased perfusion to the brain, heart, and skeletal muscles. The threshold appears clinically important at a PaO_2 of greater than 150 mm Hg.[9]

Two factors determine the extent of harmful effects of O_2: PaO_2 and exposure time (Fig. 42.1). The higher the PaO_2 and the longer the exposure, the greater the likelihood of damage. Historically, O_2 toxicity was thought to primarily affect the lungs and the central nervous system (CNS).[9-11] However, it appears

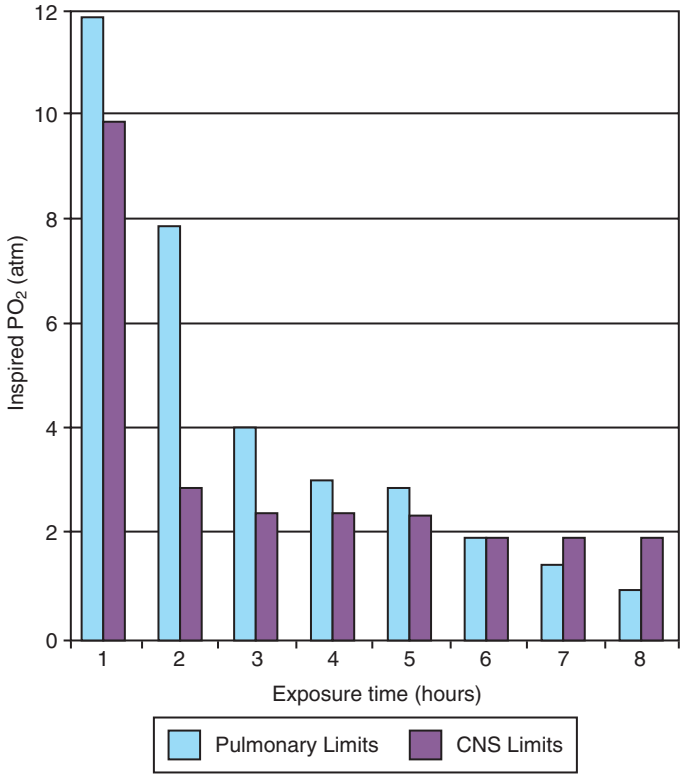

Fig. 42.1 Relationship between partial pressure of oxygen (PO_2) and exposure time causing O_2 toxicity. *CNS*, Central nervous system.

TABLE 42.2 Physiologic Responses of Healthy Individuals to Exposure to 100% Inspired Oxygen

Exposure Time (h)	Physiologic Response
0–12	Normal pulmonary function
	Tracheobronchitis
	Substernal chest pain
12–24	Decreasing vital capacity
25–30	Decreasing lung compliance
	Increasing $P(A\text{-}a)O_2$ (A-a Gradient)
	Decreasing exercise PO_2
30–72	Decreasing diffusing capacity

that CNS effects such as tremors, twitching, and convulsions occur mainly in patients breathing 100% O_2 at pressures greater than 1 atm (hyperbaric pressure). In addition, recent research suggests that high PaO_2 levels may be counterproductive in selected conditions involving ischemia and reperfusion, including myocardial infarction and stroke.[9]

Table 42.2 summarizes the physiologic response to breathing 100% O_2 at sea level. A patient exposed to a high PaO_2 for a prolonged period has signs similar to **bronchopneumonia**. Patchy infiltrates appear on chest x-rays and usually are most prominent in the lower lung fields.

Exposure to high PO_2 first damages the capillary endothelium. Interstitial edema follows and thickens the alveolar-capillary membrane. If the process continues, type I alveolar cells are destroyed, and type II cells proliferate. An **exudative** phase follows, characterized by alveolar fluid buildup, which leads to a low

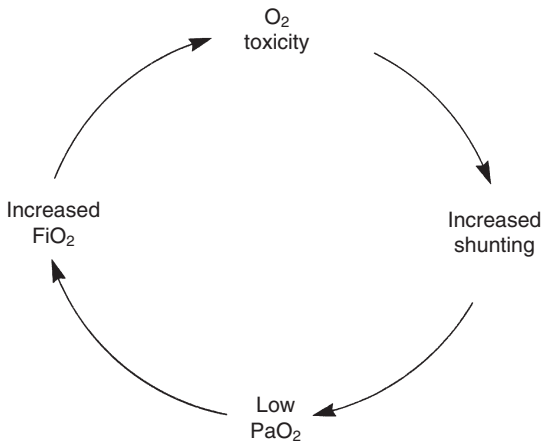

Fig. 42.2 The vicious circle that can occur in managing hypoxemia with high fractional inspired oxygen (FiO_2). High FiO_2 can be toxic to the lung parenchyma and cause further physiologic shunting. Increased shunting worsens the hypoxemia, necessitating higher FiO_2. *PaO_2*, Partial pressure of oxygen. (Modified from Flenley DC: Long-term oxygen therapy—state of the art, *Respir Care* 28:876, 1983.)

ventilation/perfusion ratio, physiologic shunting, and hypoxemia. In the end stages, hyaline membranes form in the alveolar region and pulmonary fibrosis and hypertension develop.

As the lung injury worsens, blood oxygenation deteriorates. If this progressive hypoxemia is managed with additional O_2, the toxic effects worsen (Fig. 42.2). However, if the patient can be kept alive while fractional inspired oxygen (FiO_2) is decreased, the pulmonary damage sometimes resolves.

The toxicity of O_2 is caused by overproduction of O_2 free radicals. O_2 free radicals are by-products of cellular metabolism. If unchecked, these radicals can severely damage or kill cells.[9,10]

In the presence of high PaO_2, free radicals can overwhelm the body's normal antioxidant system and cause cell damage. Cell damage provokes an immune response and causes tissue infiltration by neutrophils and macrophages. These scavenger cells release inflammatory mediators that worsen the initial injury. At the same time, local neutrophils and platelets may release more free radicals, which continue the process.

Exactly how much O_2 is safe is the subject of debate (see the following Rule of Thumb). Results of most studies indicate that adults can breathe up to 50% for extended periods without major lung damage.[11] In the past, a commonly used threshold for hypoxemia in patients breathing room air was a PaO_2 less than 55 to 60 mm Hg or SaO_2 less than 87% to 90%.[2] Rather than applying strict cutoffs, the goal always should be to use the lowest possible FiO_2 to achieve adequate tissue oxygenation. In addition, recent research indicates that excessively high SpO_2 levels in mechanically ventilated adult patients are associated with an increase in mortality. Currently, an oxygenation goal of a PaO_2 of 55 to 80 torr or an SpO_2 of 88% to 95% is recommended.[12]

RULE OF THUMB: Avoiding Oxygen Toxicity Limit patient exposure to 100% O_2 to less than 24 hours whenever possible. High FiO_2 is acceptable if the concentration can be decreased to 70% within 2 days and 50% or less in 5 days.

Because the growing lung may be more sensitive to O_2, extra caution is needed with infants. High PO_2 also is associated with **retinopathy of prematurity (ROP)** and **bronchopulmonary dysplasia** in infants.

Regardless of approach, supplemental O_2 never should be withheld from hypoxemic patients. Although the toxic effects of high O_2 concentrations can be serious, it is not FiO_2 but rather PO_2 that results in such harmful effects. If a patient needs a high FiO_2 to maintain adequate tissue oxygenation, the patient should receive it.

Depression of Ventilation

When breathing moderate to high O_2 concentrations, a very small percentage of patients with chronic obstructive pulmonary disease (COPD) and chronic hypercapnia may hypoventilate.[13,14] Decreases in ventilation of nearly 20% have been observed in these patients with accompanying elevations in arterial partial pressure of carbon dioxide ($PaCO_2$) of 20 to 23 mm Hg.[15] However, this hypoventilation is not typical of patients with COPD, and appropriate use of oxygen to avoid hypoxemia should **always** be the priority in clinical management.

One theory on why this small group of COPD patients hypoventilate is that O_2 administration and the resulting increase in arterial oxygen levels cause suppression of the hypoxic drive. In this subset of COPD patients, the normal response to increase ventilation in the presence of high partial pressure of carbon dioxide ($PaCO_2$) is blunted and the primary stimulus to breathe becomes lack of O_2 as sensed by the peripheral chemoreceptors. The increase in the blood O_2 level in these patients suppresses peripheral chemoreceptors, depresses ventilatory drive, and elevates the $PaCO_2$.[16,17] It is further suspected that high blood O_2 levels in such patients may also disrupt the normal ventilation/perfusion balance and cause an increase in dead space–to–tidal volume ratio (V_D/V_T) and in $PaCO_2$.[18]

Retinopathy of Prematurity

Retinopathy of prematurity (ROP), also called **retrolental fibroplasia**, is an abnormal eye condition that occurs in some premature or low-birth-weight infants who receive supplemental O_2. An excessive blood O_2 level causes retinal vasoconstriction, which leads to necrosis of the blood vessels. In response, new vessels form and increase in number. Hemorrhage of these delicate new vessels causes scarring behind the retina. Scarring often leads to retinal detachment and blindness.[19] ROP most often affects neonates up to approximately 1 month of age, by which time the retinal arteries have sufficiently matured. Excessive O_2 is not the only factor associated with ROP; other factors associated with ROP include hypercapnia, hypocapnia, intraventricular hemorrhage, infection, lactic acidosis, anemia, hypocalcemia, and hypothermia.

Because premature infants often need supplemental O_2, the risk of ROP poses a serious management problem. The American Academy of Pediatrics recommends keeping arterial PO_2 in an infant less than 80 mm Hg as the best way to minimize the risk of ROP.[8]

RULE OF THUMB The risk of ROP in infants can be minimized by keeping the PO_2 less than 80 mm Hg.

Absorption Atelectasis

FiO_2 values greater than 0.50 present a significant risk of absorption atelectasis.[20] Nitrogen normally is the most plentiful gas in both the alveoli and the blood. Breathing high levels of O_2 quickly depletes body nitrogen levels. As blood nitrogen levels decrease, the total pressure of venous gases rapidly decreases. Under these conditions, gases that exist at atmospheric pressure within any body cavity rapidly diffuse into the venous blood. This principle is used for removing trapped air from body cavities. Giving patients high levels of O_2 can help clear trapped air from the abdominal, cerebral, or pleural spaces.

This same phenomenon can cause lung collapse, especially if the alveolar region becomes obstructed (Fig. 42.3). Under these conditions, O_2 rapidly diffuses into the blood (see Fig. 42.3A). With no source for repletion, the total gas pressure in the alveolus progressively decreases until the alveolus collapses. Because collapsed alveoli are perfused but not ventilated, absorption atelectasis increases the physiologic shunt and worsens blood oxygenation.[20]

The likelihood of absorption atelectasis is greatest when present with other risk factors associated with low tidal volumes such as sedation, surgical pain, or CNS dysfunction. In these cases, poorly ventilated alveoli may become unstable when they lose O_2 faster than it can be replaced. The result is a more gradual shrinking of the alveoli that may lead to complete collapse, even when the patient is not breathing supplemental O_2 (see Fig. 42.3B).

Fire Hazard

Despite numerous preventive measures, fires involving enriched O_2 environments continue to occur in healthcare facilities. Fires seem to pose the greatest risk in operating rooms and in association with selected respiratory procedures. During surgery and procedures such as tracheotomies, electronic scalpels and similar devices are often used while the patient is receiving supplemental O_2. To complicate matters, even higher O_2 concentrations may exist under surgical drapes.[21] Other situations associated with increased fire risk involve home care patients smoking while receiving low-flow O_2 and the use of aluminum O_2 regulators. In addition, **hyperbaric oxygen (HBO) therapy** or therapy at increased atmospheric pressures (discussed later in this chapter) often involves the administration of supplemental O_2 and greatly increases fire risk.

Some simple strategies can be used to reduce the fire risk in healthcare facilities. Effectively managing the "fire triangle" of O_2, heat, and fuel is key. An essential component is always using the lowest effective FiO_2 for a given clinical situation. In addition, using scavenging systems to minimize O_2 buildup beneath sterile drapes during surgery or while performing tracheostomies can help reduce fire risk. Educating clinicians, patients, and caregivers about safe O_2 use is also important. In addition, fire prevention protocols for HBO therapy should be strictly followed.[21]

If a fire does occur in a healthcare facility, it is important to respond by following organizational protocol which includes applying the R.A.C.E. acronym. RACE stands for *Rescue* at-risk

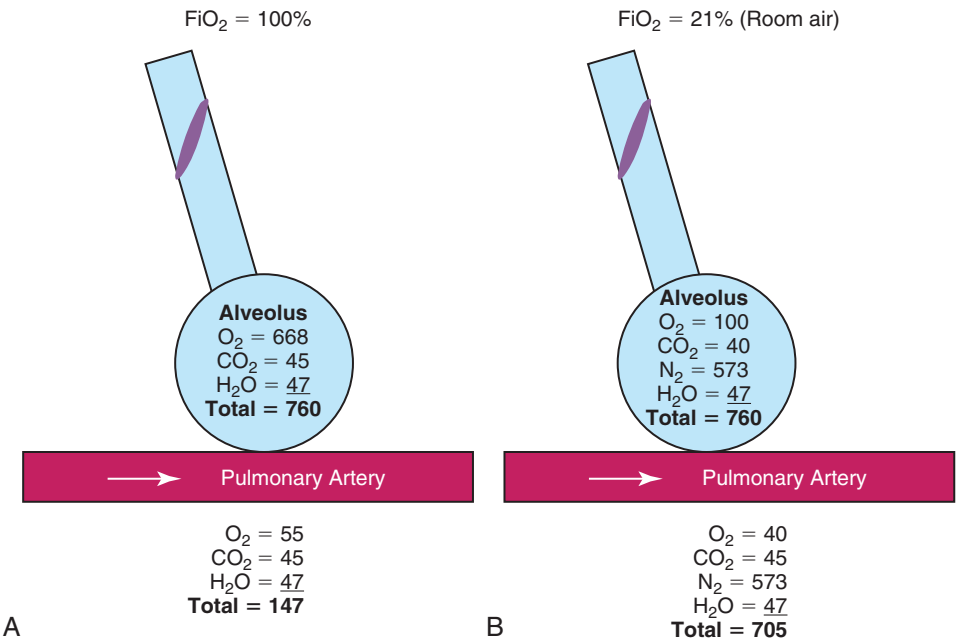

Fig. 42.3 The development of atelectasis beyond blocked airways when breathing of 100% O_2 (A) and room air (B). In each case, the sum of the gas pressures in mixed venous blood (pulmonary artery) is less than in the alveoli. The pressure gradient is much greater when breathing 100% O_2 (A), causing more rapid diffusion from the alveoli. *Note:* The gas pressures in the room air alveolus will change slightly over time, but the total will remain close to 760 mm Hg. *FiO_2*, Fractional inspired oxygen.

patients and personnel, initiate a fire *Alarm*; *Contain* to fire by closing doors, and *Extinguish* flames in a safe manner through the use of fire extinguishers. Another acronym, P.A.S.S., associated with a fire extinguisher which stands for *pull* the pin in the handle, *aim* the nozzle at the base of the fire, *squeeze* the handle, and *sweep* side to side while aiming at the base of the fire.[21]

RULE OF THUMB One of the best ways to maximize fire safety is to effectively manage the "fire triangle" by using the lowest effective O_2 concentration, eliminating potential sources of ignition and using noncombustible linens, medical supplies and equipment. However, if a fire occurs in a healthcare facility, the clinicians' response is guided by the RACE acronym. This stands for *Rescue* patients, initiate a fire *Alarm*, *Contain* the fire by closing doors and *Extinguish* the flames in a safe manner.

Oxygen Delivery Systems: Design and Performance

Proper device selection requires in-depth knowledge of both the general performance characteristics of these systems and the individual capabilities.[22] O_2 delivery devices are traditionally categorized by their design. Three basic designs exist: **low-flow systems**, **reservoir systems**, and **high-flow systems**. Enclosures are commonly identified as a fourth category. The design categories share functional characteristics, capabilities, and limitations.

The FiO_2 range of O_2 systems can be broadly divided into those designed to deliver a low (<35%), moderate (35% to 60%), or high (>60%) O_2 concentration. Some designs can deliver O_2 across the full range of concentrations (21% to 100%).

Although design plays an important role in the selection of these devices, clinical performance ultimately determines how the device is used. The user judges the performance of an O_2 delivery system by answering two key questions: (1) How much O_2 can the system deliver (FiO_2 or FiO_2 range)? (2) Does the delivered FiO_2 remain fixed or vary under changing patient demands?[22]

Regarding the FiO_2 range, O_2 systems can be broadly divided into systems designed to deliver a low (<35%), moderate (35% to 60%), or high (>60%) O_2 concentration. Some designs can deliver O_2 across the full range of concentrations (21% to 100%).

Whether a device delivers a **fixed** or **variable** FiO_2 depends on how much of the patient's inspired gas it supplies. If the system provides all of the patient's inspired gas, FiO_2 remains stable and **fixed**. If the device provides only some of the inspired gas and the patient must draw (or "entrain") the remainder from the surrounding air, it is classified as **variable**. In this case the more the patient breathes, the more air dilutes the delivered O_2, and the FiO_2 decreases. If the patient breathes less with this type of device, less air dilutes the O_2, and the FiO_2 increases. A system that supplies only a portion of the inspired gas always provides a variable FiO_2.[23] FiO_2 supplied with such systems can fluctuate widely from minute to minute and even from breath to breath.

Fig. 42.4 shows these concepts as applied to low-flow, reservoir, and high-flow systems. With the low-flow system (see Fig. 42.4A) the patient's inspiratory flow often exceeds the flow delivered by the device; the result is air dilution *(shaded areas)*. The greater the patient's inspiratory flow, the more air is breathed, and the FiO_2 varies. The high-flow system (see Fig. 42.4B) always exceeds the patient's flow and provides a fixed FiO_2. A fixed FiO_2 can be achieved with a reservoir system (see Fig. 42.4C), which stores a reserve volume (flow × time) that equals or exceeds the patient's tidal volume. For a reservoir system to provide a fixed FiO_2, the

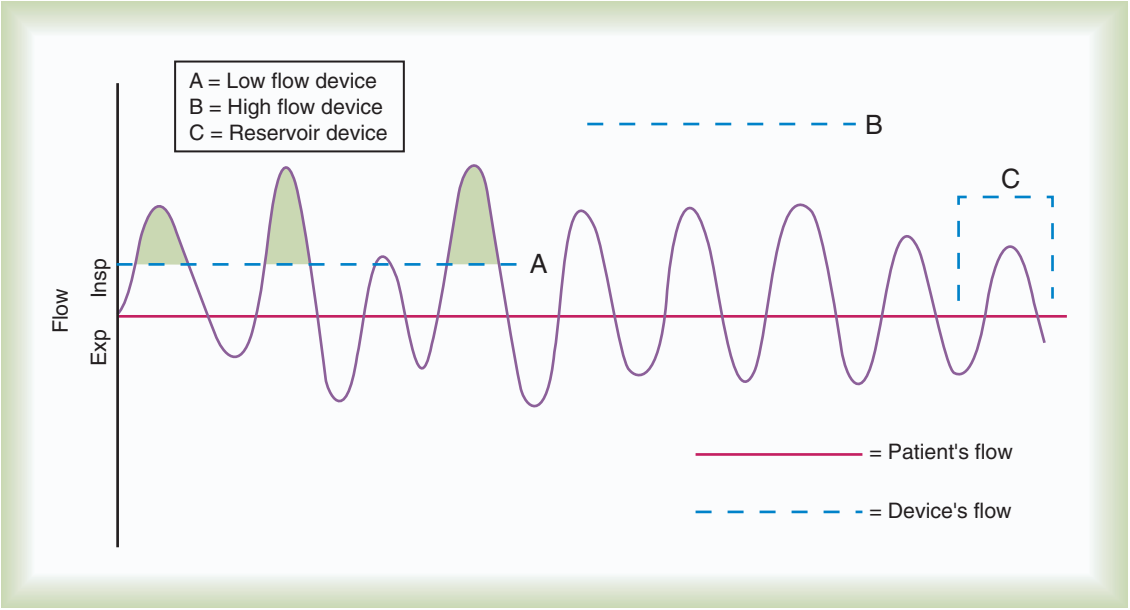

Fig. 42.4 Differences Between O_2 Delivery Systems. (A) Low-flow device. (B) High-flow device. (C) Reservoir device.

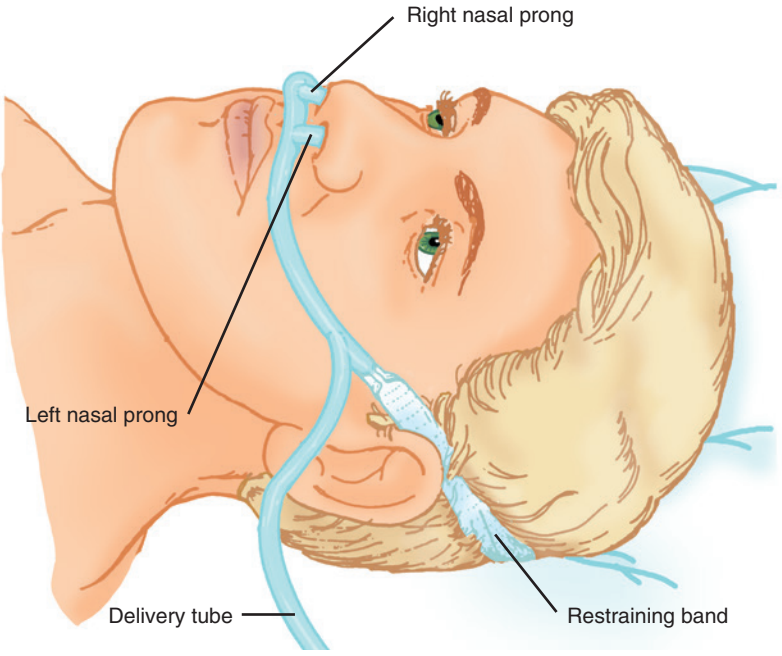

Fig. 42.5 Nasal cannula.

reservoir volume must always exceed the patient's tidal volume, and there cannot be any air leaks in the system. Table 42.3 outlines the general specifications for the common O_2 therapy systems in current use.

Low-Flow Systems

Typical low-flow systems provide supplemental O_2 directly to the airway at a flow of 8 L/min or less. Because the inspiratory flow of a healthy adult exceeds 8 L/min, the O_2 provided by a low-flow device is always diluted with air; the result is a low and variable FiO_2. Low-flow O_2 delivery systems include nasal cannula, nasal catheter, and transtracheal catheter.

Nasal cannula (low flow). A (low-flow) nasal cannula is by far the most commonly used oxygen delivery device. It consists of disposable plastic tips or prongs, approximately 1 cm long that are connected to several feet of small-bore O_2 supply tubing (Fig. 42.5). Prongs are inserted into the vestibule of the nose while supply tubing is attached directly to a flowmeter or bubble humidifier. In most cases a humidifier is used only when the input flow is greater than 4 L/min.[2] However, flows greater than

TABLE 42.3 Overview of Oxygen Therapy Systems

Category	Device	Flow	FiO_2 Range	FiO_2 Stability	Advantages	Disadvantages	Best Use
Low flow	Nasal cannula	¼–6 L/min (adults) ≤2 L/min (infants)	22%–40%	Variable	Use on adults, children, infants; easy to use; disposable; low cost; well tolerated	Unstable, easily dislodged; high flow uncomfortable; can cause dryness, bleeding; polyps; deviated septum and mouth breathing may reduce FiO_2	Patient in stable condition who needs low FiO_2; home care patient who needs long-term therapy, low to moderate FiO_2 while eating
	Nasal catheter	¼–5 L/min	22%–45%	Variable	Use on adults, children, infants; good stability; disposable; low cost	Difficult to insert; high flow increases back pressure; needs regular changing; polyps, deviated septum may block insertion; may provoke gagging, air swallowing, aspiration	Procedures in which cannula is difficult to use (bronchoscopy); long-term care of infants
	Transtracheal catheter	¼–4 L/min	22%–35%	Variable	Lower O_2 use and cost; eliminates nasal and skin irritation; improved compliance; increased exercise tolerance; increased mobility; enhanced image	High cost; surgical complications; infection; mucous plugging; lost tract	Home care or ambulatory patients who need increased mobility or do not accept nasal O_2
Resevior Systems	Reservoir cannula	¼–4 L/min	22%–35%	Variable	Lower O_2 use and cost; increased mobility; less discomfort because of lower flow	Unattractive, cumbersome; poor compliance; must be regularly replaced; breathing pattern affects performance	Home care or ambulatory patients who need increased mobility
	Simple mask	5–10 L/min	35%–50%	Variable	Use on adults, children, infants; quick, easy to apply; disposable; inexpensive	Uncomfortable; must be removed for eating; prevents radiant heat loss; blocks vomitus in unconscious patients	Emergencies; short-term therapy requiring moderate FiO_2; mouth breathing patients requiring moderate FiO_2
	Partial rebreathing mask	Minimum of 10 L/min (prevent bag collapse on inspiration)	40%–70%	Variable	Same as simple mask; moderate to high FiO_2	Same as simple mask; potential suffocation hazard	Emergencies; short-term therapy requiring moderate to high FiO_2
	Nonrebreathing mask	Minimum of 10 L/min (prevent bag collapse on inspiration)	60%–80%	Variable	Same as simple mask; high FiO_2	Same as simple mask; potential suffocation hazard	Emergencies; short-term therapy requiring high FiO_2

High flow	AEM	Varies; should provide output flow >60 L/min	24%–50%	Fixed	Easy to apply; disposable, inexpensive; stable, precise FiO_2	Limited to adult use; uncomfortable, noisy; must be removed for eating; FiO_2 >0.40 not ensured; FiO_2 varies with back pressure	Patients in unstable condition who need precise low FiO_2
	Air-entrainment nebulizer	10–15 L/min input; should provide output flow of at least 60 L/min	28%–100%	Fixed	Provides temperature control and extra humidification	FiO_2 <0.28 or >0.40 not ensured; FiO_2 varies with back pressure; high infection risk	Patients with artificial airways who need low to moderate FiO_2
	Blending system (open)	Should provide output flow of at least 60 L/min	21%–100%	Fixed	Full range of FiO_2	Requires 50 psi air/O_2; blender failure or inaccuracy common	Patients with high VE who need high FiO_2
	High-flow nasal cannula system	Up to 50 L/min, or more (depending on system)	35%–100%	Generally fixed, depending on system, input flow, and patient breathing pattern	Wide range of FiO_2 and relative/absolute humidity; use on adults, children, infants	FiO_2 is often ensured but depends on system, input flow, and patient breathing pattern; infection risk	Patients of all ages with high or variable VE who need supplemental O_2, positive pressure and humidity
Enclosure	Oxyhood	≥7 L/min	21%–100%	Fixed	Full range of FiO_2	Difficult to clean, disinfect	Infants who need supplemental O_2
	Isolette	8–15 L/min	40%–50%	Variable	Provides temperature control	Expensive, cumbersome, unstable FiO_2 (leaks); difficult to clean, disinfect; limits patient mobility; fire hazard	Infants who need supplemental O_2 and precise thermal regulation
	Tent	12–15 L/min	40%–50%	Variable	Provides concurrent aerosol therapy	Expensive, cumbersome, unstable FiO_2 (leaks); requires cooling; difficult to clean, disinfect; limits patient mobility; fire hazard	Toddlers or small children who need low to moderate FiO_2 and aerosol

AEM, Air-entrainment mask; *FiO_2,* fractional inspired oxygen; *VE,* minute volume.

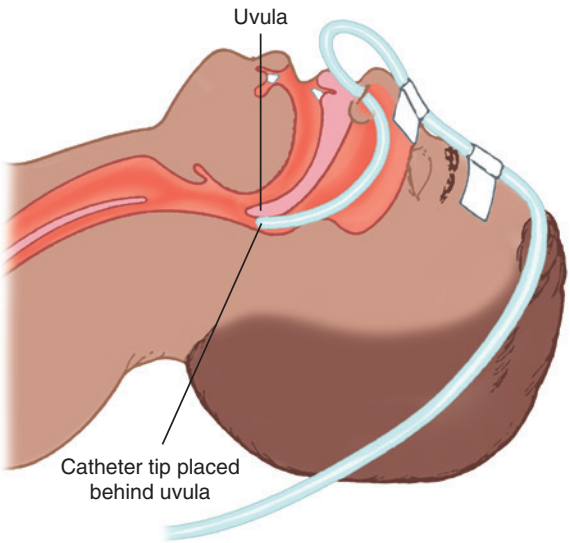

Fig. 42.6 Placement of nasal catheter in the nasopharynx.

6 to 8 L/min can cause patient discomfort.[22] Cannulas should not be used in newborns and infants if their nasal passages are obstructed, and flows generally should be limited to 2 L/min unless a specialized high-flow cannula system, discussed later in this chapter, is being used.[23] Table 42.3 lists the FiO_2 range, FiO_2 stability, advantages, disadvantages, and best use of a nasal cannula.

Nasal catheter. Nasal catheters are almost exclusively used for limited, short-term O_2 administration during specialized procedures such as a bronchoscopy. A nasal catheter is a soft plastic tube with several small holes at the tip that is inserted by gently advancing it along the floor of either nasal passage and visualizing it just behind and above the uvula (Fig. 42.6). Once in position, the catheter is taped to the bridge of the nose. If direct visualization is impossible, the catheter may be blindly inserted to a depth equal to the distance from the nose to the earlobe.

When placed too deep, the catheter can provoke gagging or swallowing of gas, which increases the likelihood of aspiration. In general, a nasal catheter should be replaced with a new one (placed in the opposite naris) at least every 8 hours. Nasal catheters are inappropriate for neonatal patients. As a result of these notable limitations, nasal catheters are rarely used currently.[4]

Transtracheal catheter. A transtracheal O_2 catheter is a thin polytetrafluoroethylene (Teflon) catheter inserted into the trachea between the second and third tracheal rings (Fig. 42.7), secured by a chain necklace. Standard tubing connected directly to a flowmeter provides the O_2 source flow.[24,25] Because flow is so low, no humidification is needed.

Because the transtracheal catheter resides directly in the trachea, O_2 builds up both there and in the upper airway during expiration. This process effectively expands the anatomic reservoir and increases the FiO_2 at any given flow. Compared with a nasal cannula, a transtracheal catheter needs approximately half of the O_2 flow to achieve a given PaO_2.[25] This reduced flow can be of great economic and practical benefit to patients needing continuous long-term O_2 therapy because it can greatly increase the duration of flow from portable O_2 systems. However, transtracheal

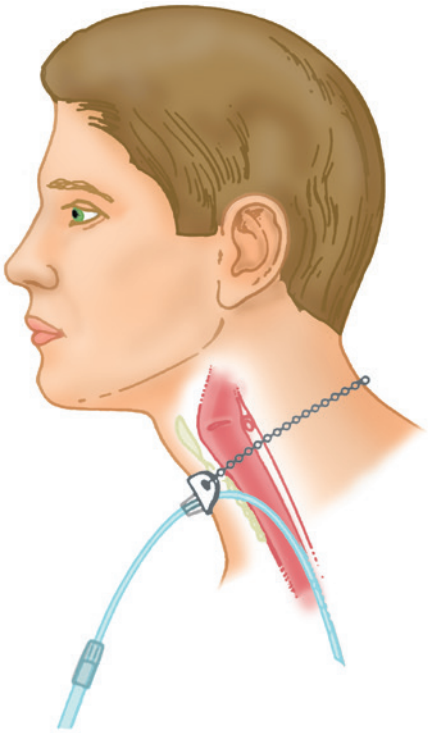

Fig. 42.7 Transtracheal O_2 catheter.

TABLE 42.4 Variables Affecting FiO_2 of Low-Flow Oxygen Systems

Increases FiO_2	Decreases FiO_2
Higher O_2 input	Lower O_2 input
Mouth-closed breathing[a]	Mouth-open breathing[a]
Low inspiratory flow	High inspiratory flow
Low tidal volume	High tidal volume
Slow rate of breathing	Fast rate of breathing
Small minute ventilation	Large minute ventilation
Long inspiratory time	Short inspiratory time
High I:E ratio	Low I:E ratio

[a]Cannula only.
FiO_2, Fractional inspired oxygen; *I:E,* inspiratory/expiratory.

O_2 therapy can pose serious problems and risks (e.g., collection of mucus which can obstruct the airway), and these devices are not currently in widespread use. Chapter 57 provides additional details on maintaining transtracheal O_2 setups. Table 42.3 lists the FiO_2 range, FiO_2 stability, advantages, disadvantages, and best use of a transtracheal catheter.

Performance Characteristics of Low-Flow Systems

Low-flow nasal systems provide O_2 concentrations ranging from 22% to 45%.[2,3,22] The range of 22%45% cited in Table 42.3 is based on 8 L/min as the upper limit of tolerable flow. These wide FiO_2 ranges occur because the O_2 concentration delivered by a low-flow system varies with the amount of air dilution. The amount of air dilution depends on several patient and equipment variables. Table 42.4 summarizes these key variables and how they affect FiO_2 provided by low-flow systems.

Simple formulas exist for estimating FiO_2 provided by low-flow systems (see the accompanying Rule of Thumb). However, given the large number of variables affecting FiO_2, the RT can never know precisely how much O_2 a patient is receiving with these systems. Without knowing the patient's exact FiO_2, the RT must rely on assessing the patient's response to O_2 therapy.

RULE OF THUMB: Estimating FiO_2 Provided by Low-Flow Systems For patients with a normal rate and depth of breathing, each 1 L/min of nasal O_2 increases FiO_2 approximately 4%. For example, a patient using a nasal cannula at 4 L/min has an estimated FiO_2 of approximately 37% (21 + 16).

Troubleshooting Low-Flow Systems

Common problems with low-flow O_2 delivery systems include inaccurate flow, system leaks and obstructions, device displacement, and skin irritation. Given the trend toward assessment of outcome of O_2 therapy (with either blood gases or pulse oximetry), ensuring the absolute accuracy of O_2 input flow generally is not essential. Nonetheless, similar to all respiratory care equipment, flowmeters should be subjected to regular preventive maintenance and testing for accuracy. Equipment that fails preventive maintenance standards should be removed from service and repaired or replaced. Table 42.5 provides guidance on troubleshooting the most common clinical problems with nasal cannulas.

Reservoir Systems

Reservoir systems incorporate a mechanism for gathering and storing O_2 between patient breaths. Patients draw on this reserve supply whenever inspiratory flow exceeds O_2 flow into the device. Because air dilution is reduced, reservoir devices generally provide higher FiO_2 than low-flow systems. Reservoir devices can decrease O_2 use by providing FiO_2 comparable with nonreservoir systems but at lower flow. Reservoir systems currently in use include reservoir cannulas, masks, and nonrebreathing circuits. In principle, enclosure systems, such as tents and hoods, operate as reservoirs surrounding the head or body.

TABLE 42.5 Troubleshooting Common Problems With a Nasal Oxygen Cannula

Problem or Clue	Cause	Solution
No gas flow can be felt coming from the cannula	Flowmeter not on	Adjust flowmeter
	System leak	Check connections
Humidifier pop-off is sounding	Obstruction distal to humidifier	Find and correct the obstruction
	Flow is set too high	Use alternative device
	Obstructed naris	Use alternative device
Patient reports soreness over lip or ears	Irritation or inflammation caused by appliance straps	Loosen straps
		Place cotton balls at pressure points
		Use a different device
Mouth breathing	Habitual mouth breathing, blocked nasal passages	Switch to simple mask or venturi mask

Reservoir cannula. Reservoir cannulas are designed to conserve O_2 and are an alternative to the pulse-dose or demand-flow O_2 systems described in Chapter 57. There are two types of reservoir cannula: nasal reservoir and pendant reservoir. Table 42.3 lists the FiO_2 range, FiO_2 stability, advantages, disadvantages, and best use of a reservoir cannula.

A nasal reservoir cannula operates by storing approximately 20 mL of O_2 in a small membrane reservoir during exhalation (Fig. 42.8). The patient draws on this stored O_2 during early inspiration. The amount of O_2 available increases with each breath and decreases the flow needed for a given FiO_2. Although the device is comfortable to wear, many patients object to its appearance and may not always comply with prescribed therapy.

The pendant reservoir system helps overcome esthetic concerns by hiding the reservoir under the patient's clothing on the anterior chest wall (Fig. 42.9). Although the device is less

Fig. 42.8 Reservoir cannula.

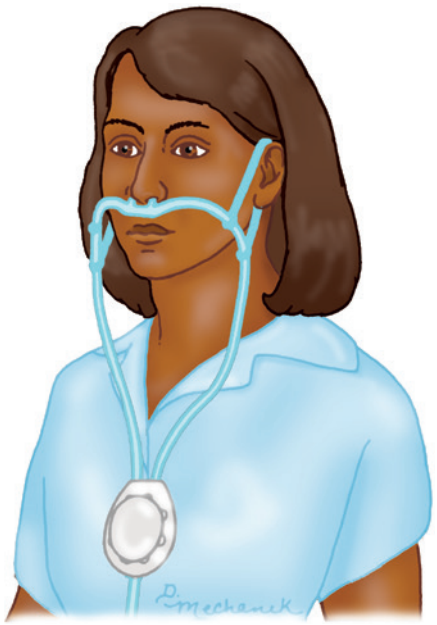

Fig. 42.9 Pendant reservoir cannula.

visible, the extra weight of the pendant can cause ear and facial discomfort.

At low flow, reservoir cannulas can reduce O_2 use 50% to 75%. A patient at rest who needs 2 L/min through a standard cannula to achieve an arterial SaO_2 greater than 90% may need only 0.5 L/min through a reservoir cannula to achieve the same blood oxygenation.[26] Although flow savings is predictable, factors such as nasal anatomy and breathing pattern can affect the performance of the device. For these devices to function properly at low flow, patients must exhale through the nose (this reopens or resets the reservoir membrane). In addition, exhalation through pursed lips may impair performance, especially during exercise. For these reasons, prescribed flow settings should be individually determined by clinical assessment, including SaO_2 monitoring.[26]

The low flow at which the reservoir cannula operates makes humidification unnecessary. Excess moisture can hinder proper action of the reservoir membrane.[26] Even regular use can cause membrane wear. For this reason, patients should replace the reservoir cannula approximately every 3 weeks.

Reservoir masks. Masks are the most commonly used reservoir systems. There are three types of reservoir masks: (1) simple mask, (2) partial rebreathing mask, and (3) nonrebreathing mask. Table 42.3 lists the FiO_2 range, FiO_2 stability, advantages, disadvantages, and best use of each of these devices.

A simple mask is a disposable plastic unit designed to cover both the mouth and the nose (Fig. 42.10). The body of the mask itself gathers and stores O_2 between patient breaths. The patient exhales directly through open holes or ports in the mask body. If O_2 input flow ceases, the patient can draw in air through these holes and around the mask edge.

The input flow range for an adult simple mask is 5 to 10 L/min. In general, if flow greater than 10 L/min is needed for satisfactory oxygenation, use of a device capable of a higher FiO_2 should be considered. At a flow less than 5 L/min in the adult population, the mask volume acts as dead space and causes carbon dioxide rebreathing.[27]

Because air dilution easily occurs during inspiration through its ports and around its body, a simple mask provides a variable FiO_2. How much FiO_2 varies depends on the O_2 input flow, the mask volume, the extent of air leakage, and the patient's breathing pattern.[28]

As shown in Fig. 42.11, a partial rebreathing mask and a nonrebreathing mask have a similar design. Each has a 1-L flexible reservoir bag attached to the O_2 inlet. Because the bag increases the reservoir volume, both masks provide higher FiO_2

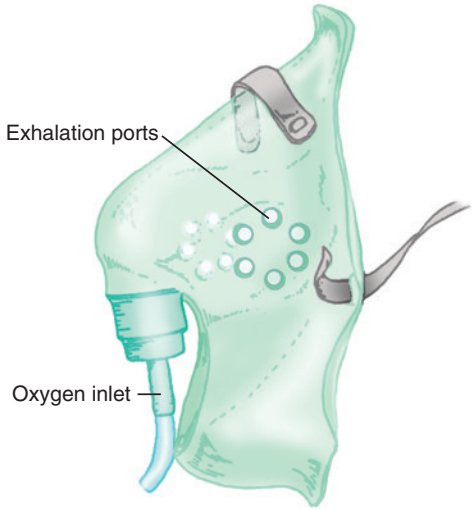

Fig. 42.10 Simple O_2 mask.

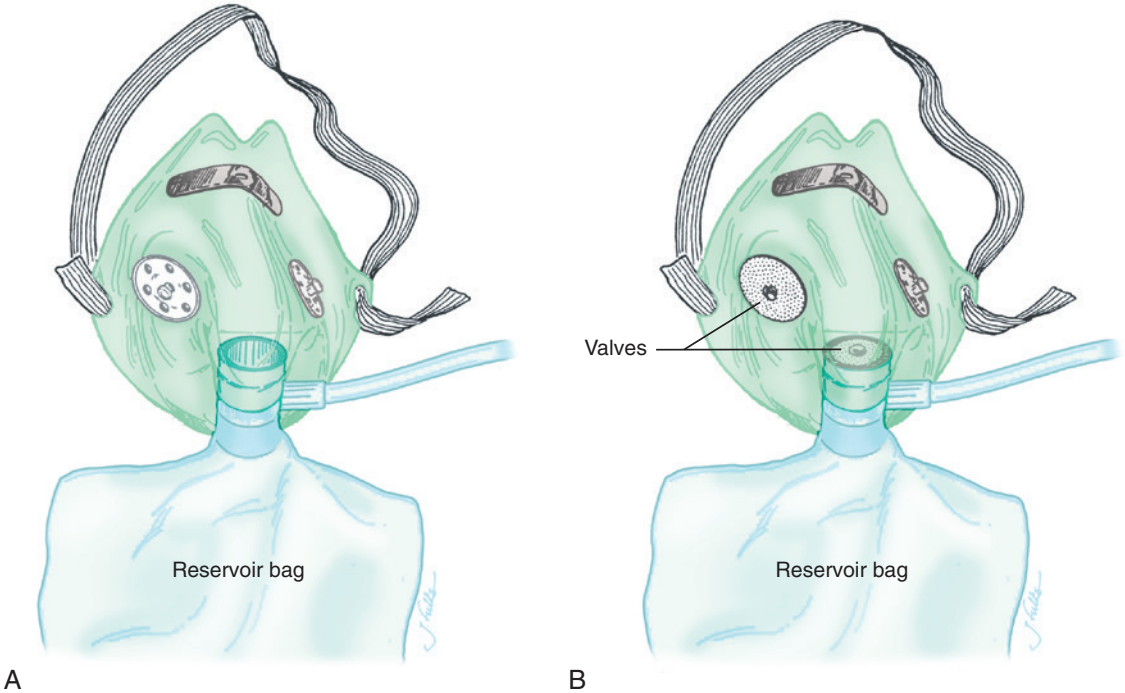

Fig. 42.11 (A) Partial rebreathing mask. (B) Nonrebreathing mask.

capabilities than a simple mask. The key difference between these designs is the use of valves. A partial rebreathing mask has no valves (see Fig. 42.11A). During inspiration, source O_2 flows into the mask and passes directly to the patient. During exhalation, source O_2 enters the bag. However, because no valves separate the mask and the bag, some of the patient's exhaled gas also enters the bag (approximately the first third). Because it comes from the anatomic dead space, the early portion of exhaled gas contains mostly O_2 and little CO_2. As the bag fills with both O_2 and dead space gas, the last two-thirds of exhalation (high in CO_2) escapes out the exhalation ports of the mask. As long as the O_2 input flow keeps the bag from collapsing more than approximately one-third during inhalation, CO_2 rebreathing is negligible.

Although it can provide a higher FiO_2 than a simple mask (see Table 42.3), a standard disposable partial rebreathing mask is subject to considerable air dilution. The result is delivery of a moderate but variable FiO_2 dependent on the same factors as with a simple mask.

A nonrebreathing mask, which is much more commonly used than a partial rebreathing mask, prevents rebreathing with one-way valves (see Fig. 42.11B). An inspiratory valve sits on top of the bag, and expiratory valves cover the exhalation ports on the mask body. During inspiration, slight negative mask pressure closes the expiratory valves, preventing air dilution. At the same time, the inspiratory valve on top of the bag opens, providing O_2 to the patient. During exhalation, valve action reverses the direction of flow. Slight positive pressure closes the inspiratory valve, which prevents exhaled gas from entering the bag. Concurrently, the one-way expiratory valves open and divert exhaled gas out to the atmosphere. Although nonrebreathing masks are often referred to as "100% oxygen devices," as indicated in Table 42.3, modern disposable nonrebreathing masks normally do not provide much more than approximately 70% O_2.[22] This is because large air leaks occur both around the mask body and through the open (nonvalved) exhalation port. This open exhalation port is a common safety feature designed to allow air breathing if the O_2 source fails but can result in air dilution (leakage) and a variable FiO_2 whenever inspiratory flow or volume are high.

Troubleshooting reservoir systems. Common problems with reservoir masks include device displacement, system leaks and obstructions, improper flow adjustment, and skin irritation. Table 42.6 provides guidance on troubleshooting the most common clinical problems with reservoir masks.

High-Flow Systems

High-flow systems use air-entrainment or gas blending, and supply a given O_2 concentration at a flow equaling or exceeding the patient's peak inspiratory flow. An air-entrainment or a blending system is used. As long as the delivered flow always exceeds the patient's demand, both systems can ensure a fixed FiO_2. The accompanying Rule of Thumb can help determine which devices truly qualify as high-flow systems.

RULE OF THUMB: High-Flow Devices To qualify as a high-flow device, a system should provide at least 60 L/min total flow. This flow criterion is based on the fact that the average adult peak inspiratory flow during tidal ventilation is approximately three times the minute volume. Because 20 L/min is close to the upper limit of sustainable minute volume for an ill person, a flow of 3 × 20, or 60 L/min, should suffice in most situations. In a few rare circumstances, flow must reach or exceed 100 L/min.

Principles of gas mixing. All high-flow systems mix air and O_2 to achieve a given FiO_2. These gases are mixed with air-entrainment devices or blending systems. Computations involving mixtures of air and O_2 are based on a modified form of the dilution equation for solutions:

$$V_F C_F = V_1 C_1 + V_2 C_2$$

In this equation, V_1 and V_2 are the volumes of the two gases being mixed; C_1 and C_2, the O_2 concentration in these two volumes; and V_F and C_F, the final volume and concentration of the resulting mixture.

Box 42.1 shows how to apply variations of this equation to compute: (1) the final concentration of a mixture of air and O_2, (2) the air-to-O_2 ratio needed to obtain a given FiO_2, (3) the total output flow from an air-entrainment device, and (4) the amount of O_2 that must be added to a volume of air to obtain a given FiO_2.

TABLE 42.6 Troubleshooting Common Problems With Reservoir Masks

Problem or Clue	Cause	Solution
Patient constantly removes mask	Claustrophobia	Use alternative device
	Confusion	Restrain patient
No gas flow can be detected	Flowmeter not on	Adjust flowmeter
	System leak	Check connections
Humidifier pop-off is sounding	Obstruction distal to humidifier	Find and correct obstruction
	High input flow	Omit humidifier if therapy is short term
	Jammed inspiratory valve	Fix or replace valve
Reservoir bag collapses when the patient inhales	Flow is inadequate	Increase flow
Reservoir bag remains inflated throughout inhalation	Large mask leak	Correct leak
	Inspiratory valve jammed or reversed	Repair or replace mask
Erythema develops over face or ears	Irritation or inflammation owing to appliance or straps	Reposition mask or straps
		Place cotton balls over ear pressure points
		Provide skin care

BOX 42.1 Equations for Computing Oxygen Percentage, Ratio, and Flow

To compute the O_2 percentage of a mixture of air and O_2:

$$\%O_2 = \frac{(\text{Airflow} \times 21) + (O_2\ \text{flow} \times 100)}{\text{Totalflow}} \quad \textbf{(Eq. 42.1)}$$

1. To compute the air-to-O_2 ratio needed to obtain a given O_2 percentage:

$$\frac{\text{Litersair}}{\text{Liters } O_2} = \frac{(100 - \%O_2)}{(\%O_2 - 21)} \quad \textbf{(Eq. 42.2)}$$

2. To compute the total output flow from an air-entrainment device (given the O_2 input):
   a. Compute the air-to-O_2 ratio (see Eq. 42.2).
   b. Add the air-to-O_2 ratio parts.
   c. Multiply the sum of the ratio parts by the O_2 input flow.
3. To compute the flow of O_2 and air needed to obtain a given O_2 percentage at a given total flow:
   a. Compute the O_2 flow:

$$O_2\ \text{flow} = \frac{\text{Totalflow} \times (O_2\% - 21)}{79} \quad \textbf{(Eq. 42.3)}$$

   b. Compute the airflow:

$$\text{Airflow} = \text{Totalflow} - O_2\ \text{flow}$$

MINI CLINI

Conflicting Assessment Information

Problem

A disoriented postoperative male patient breathing room air exhibits tachypnea, tachycardia, and mild cyanosis of the mucous membranes. Using a pulse oximeter, the respiratory therapist (RT) measures the patient's oxyhemoglobin saturation as 90%. What should the RT recommend to the patient's surgeon?

Discussion

This is a classic example of how monitoring data and results of bedside assessment can conflict. Both the patient's condition and the observed clinical signs indicate hypoxemia, but the pulse oximeter indicates adequate oxygenation. In situations such as this, it is always better to err on the side of the patient and recommend O_2 therapy—treat the patient, not the monitor. This concept is particularly important in the use of monitoring technologies known to have limited accuracy, such as pulse oximetry (see Chapter 19).

MINI CLINI

Determining FiO_2 of an Air-Oxygen Mixture

Problem

An air-entrainment device mixes at a fixed ratio of three volumes of air to each volume of O_2 (3:1 ratio). What is the resulting FiO_2?

Solution

Substituting air, O_2, and total (air + O_2) volumes into Eq. 42.1:

$$\%O_2 = \frac{(\text{Airflow} \times 21) + (O_2\ \text{flow} \times 100)}{\text{Total flow}}$$

$$\%O_2 = \frac{(3 \times 21) + (1 \times 100)}{3 + 1}$$

$$\%O_2 = 41$$

An air-entrainment device that mixes three volumes of air with one volume of O_2 provides a gas mixture with FiO_2 of approximately 0.40.

MINI CLINI

Computing Total Flow Output of an Air-Entrainment Device

Problem

A patient is receiving O_2 through an air-entrainment device set to deliver 50% O_2. The input O_2 flow is set to 15 L/min. What is the total output flow of this system?

Solution

Step 1: Compute the air-to-O_2 ratio by substituting 50 for the $\%O_2$ in Eq. 42.2:

$$\frac{\text{Liters air}}{\text{Liters } O_2} = \frac{(100 - \%O_2)}{(\%O_2 - 21)}$$

$$\frac{\text{Liters air}}{\text{Liters } O_2} = \frac{(100 - 50)}{(50 - 21)}$$

$$\frac{\text{Liters air}}{\text{Liters } O_2} = \frac{50}{29}$$

$$\frac{\text{Litersair}}{\text{Liters } O_2} = \frac{1.7}{1}$$

Step 2: Add the air-to-O_2 ratio parts:

$$1.7 + 1 = 2.7$$

Step 3: Multiply the sum of the ratio parts times the O_2 input flow:

$$2.7 \times 15\ \text{L/min} = 41\ \text{L/min}$$

An air-entrainment device set to deliver 50% O_2 that has an input flow of 15 L/min provides a total output flow of approximately 41 L/min.

Air-entrainment systems. Air-entrainment systems direct a high-pressure O_2 source through a small nozzle or jet surrounded by air-entrainment ports (Fig. 42.12). The amount of air entrained at these ports varies directly with the size of the port and the velocity of O_2 at the jet. The larger the intake ports and the higher the gas velocity at the jet, the more air is entrained.

Because they dilute source O_2 with air, entrainment devices always provide less than 100% O_2. More air entrainment increases total output flow, but lowers delivered FiO_2. For these reasons, air-entrainment devices function as true high-flow systems only at lower FiO_2. If the flow output from an air-entrainment device decreases to less than a patient's inspiratory flow, air dilution occurs, and FiO_2 becomes variable.

FiO_2 provided by air-entrainment devices depends on two key variables: the air-to-O_2 ratio and the amount of flow

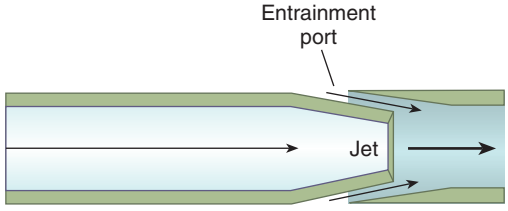

Fig. 42.12 Basic components of an air-entrainment system. Pressurized gas passes through a nozzle or jet, beyond which are air-entrainment ports. Shear forces at the jet orifice entrain air into the primary gas stream, diluting the O_2 and increasing the total flow output of the device.

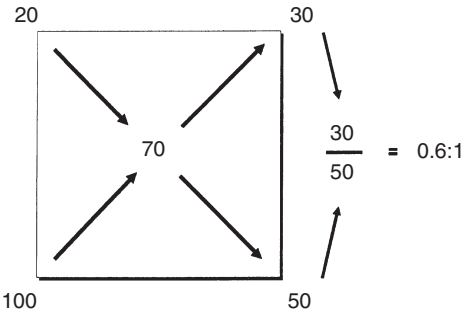

Fig. 42.13 The magic box used to estimate air-to-O_2 ratio.

resistance downstream from the mixing site. Changing the input flow of an air-entrainment device alters the total output flow but has little effect on delivered FiO_2. In general, FiO_2 remains within 1% to 2% of that specified by the manufacturer, regardless of input flow.[29]

The size of the jet and entrainment ports of a device determines the air-to-O_2 ratio and the delivered FiO_2. The accompanying Mini Clini entitled "Determining FiO_2 of an Air-Oxygen Mixture" shows how to compute the FiO_2 provided by an air-entrainment system if the air-to-O_2 ratio is known.

A more common clinical problem arises when the total output flow from an air-entrainment system must be determined. As described in the previous Rule of Thumb, the total flow output of a system determines whether it truly performs as a high-flow device. The accompanying Mini Clini entitled "Computing Total Flow Output of an Air-Entrainment Device" shows how to determine the total output flow of an air-entrainment system.

Rather than using Eq. 42.2 in Box 42.1 to compute air-to-O_2 ratio, many RTs derive quick estimates by using a simple mathematical aid called the *magic box* (Fig. 42.13). To use the magic box, one draws a square and places 20 in the top left corner and 100 in the bottom left corner. One places the desired O_2 percentage in the center of the box (as in the case illustrated in Fig. 42.13, 70%). One subtracts diagonally from lower left to the upper right (disregard the sign). One subtracts diagonally again from upper left to lower right (disregard the sign). The resulting numerator (30) is the value for air, and the denominator (50) is the value for O_2.

By convention, the air-to-O_2 ratio is expressed with the denominator (liters of O_2) set to 1. To reduce any ratio to a ratio of x:1, divide both the numerator and the denominator by the denominator. In the magic box example (also see Fig. 42.13):

$$\frac{30}{50} = \frac{30/50}{50/50} = \frac{0.61}{1}$$

The magic box can be used only for estimating the air-to-O_2 ratio. For absolute accuracy, Eq. 42.2 in Box 42.1 always should be used. Based on Eq. 42.2, Table 42.7 lists the approximate air-to-O_2 ratios for several common O_2 percentages.

The other major factor determining the O_2 concentration provided by an air-entrainment device is downstream flow resistance. In the presence of flow resistance distal to the jet, the volume of air entrained always decreases. With less air being entrained, total flow output decreases and the delivered O_2 concentration increases. More detail on this phenomenon is provided later in this chapter.[29]

TABLE 42.7 Approximate Air-to-Oxygen Ratios for Common Oxygen Concentrations

Percentage O_2	Approximate Air-to-O_2 Ratio	Total Ratio Parts
100	0:1	1
80	0.3:1	1.3
70	0.6:1	1.6
60	1:1	2
50	1.7:1	2.7
45	2:1	3
40	3:1	4
35	5:1	6
30	8:1	9
29	10:1	11
24	25:1	26

Total output flow (air + O_2) in L/min can be calculated by multiplying the total ratio parts by the O_2 input flow (L/min).

The two most common O_2 delivery systems in which air entrainment is used are the air-entrainment mask (AEM) and the air-entrainment nebulizer.

Air-entrainment (venturi) mask. The use of an O_2 mask with controlled FiO_2 by means of air entrainment was first reported in 1941 by Barach and Eckman.[30] The system provided relatively high FiO_2 (>40%) through the use of adjustable air-entrainment ports that controlled the amount of air mixed with O_2. Almost 20 years later, Campbell[31] developed an entrainment mask that provided controlled, low FiO_2 and called the device a *venturi mask* or *venti-mask*.

As the name *venti-mask* suggests, the operating principle behind these devices has often been attributed to the Venturi principle (see Chapter 6). This assumption is incorrect.[32] Rather than having an actual Venturi tube that entrains air, these devices have a simple restricted orifice or jet through which O_2 flows at high velocity. Air is entrained by shear forces at the boundary of jet flow, not by low lateral pressures. The smaller the orifice, the greater the velocity of O_2, and more air is entrained.

Fig. 42.14 depicts a typical AEM, designed to deliver a range of low to moderate FiO_2 (0.24 to 0.40). The mask consists of a jet orifice or nozzle around which is an air-entrainment port *(top drawing)*. The body of the mask has several large ports, which allow escape of both excess flow from the device and exhaled gas from the patient. In this design, FiO_2 is regulated by selection and changing of the jet adapter. The smallest jet provides the highest O_2 velocity, the most air entrainment, and the lowest FiO_2 (0.24). The largest jet provides the lowest O_2 velocity, the least air entrainment, and the highest FiO_2 (0.40). Other AEM designs may vary both jet and entrainment port size to provide an even broader range up to 50% FiO_2. The aerosol entrainment collar fits over the air-entrainment ports (see later).

For controlled FiO_2 at flow high enough to prevent air dilution, the total output flow of an AEM must exceed the patient's

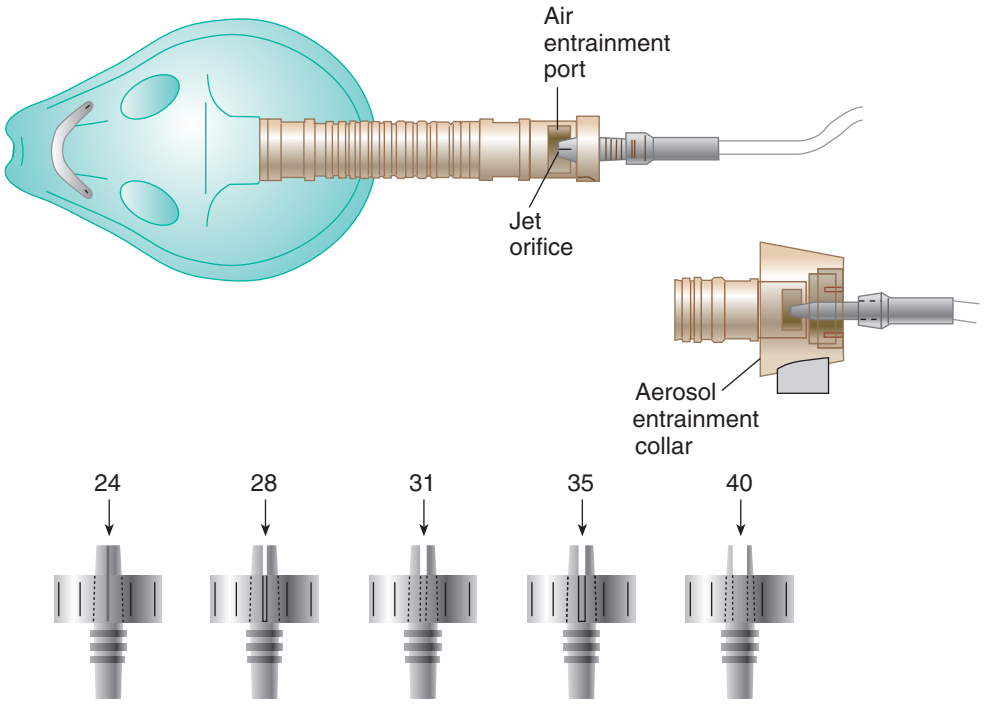

Fig. 42.14 Typical Air-Entrainment Mask. Fractional inspired oxygen (FiO_2) is regulated by changing a jet adapter. The aerosol collar allows high humidity or aerosol entrainment from an air source. (Modified from Kacmarek RM: In-hospital O_2 therapy. In Kacmarek RM, Stoller J, editors: *Current respiratory care*, Toronto, 1988, BC Decker.)

peak inspiratory flow.[29] With an entrainment ratio exceeding 5:1, an AEM set to deliver less than 35% O_2 has little trouble meeting or exceeding the 60 L/min high-flow criterion (see previous Rule of Thumb). At settings greater than 35%, total AEM flow decreases significantly, and FiO_2 becomes variable. For example, when set to deliver 50% O_2, some AEMs provide 0.39 FiO_2.[32-34]

Air-entrainment nebulizer. Pneumatically powered air-entrainment nebulizers have most of the features of air-entrainment nebulizers (AEMs) but have added capabilities, including additional humidification and temperature control. Humidification is achieved through production of aerosol at the nebulizer jet. Temperature control is provided by an optional heating element. In combination, these added features allow delivery of particulate water (in excess of needs for body temperature and pressure) to the airways. These devices are also widely known as *jet nebulizers* or *large volume nebulizers*.

Because of added humidification and heat control, air-entrainment nebulizers have been the traditional device of choice for delivering O_2 to patients with artificial tracheal airways. O_2 typically is delivered with a T tube or a tracheostomy mask. An alternative is to use an aerosol mask or a face tent to deliver an O_2 mixture to patients with intact upper airways (Fig. 42.15).[35]

AEMs can vary both jet and entrainment port size to obtain a given FiO_2; however, gas-powered nebulizers have a fixed orifice. Air-to-O_2 ratios can be altered only by varying entrainment port size. Disposable nebulizers usually have a continuous range of settings from 28% to 100%.[22]

Similar to AEMs, air-entrainment nebulizers perform as fixed-performance devices only when output flow meets or exceeds the patient's inspiratory demand. In contrast to AEMs, air-entrainment nebulizers do not allow easy increases in nebulizer output flow by means of an increase in O_2 input. With most nebulizer systems, the extremely small size of the jet needed for aerosol production limits the maximum O_2 input flow to 12 to 15 L/min at 50 psig. For example, the total output flow of an air-entrainment nebulizer set to deliver 40% O_2 ranges from 48 to 60 L/min. Although this amount may be adequate for most patients, it is insufficient for patients with very high inspiratory flow or minute volume,[35] and air entrainment nebulizers should be treated as fixed-performance devices only when set to deliver low O_2 concentration (≤35%).[33] The actual FiO_2 received by patients may be affected by the choice of airway appliance. For example, due to the open characteristics of a face tent, the FiO_2 delivered by this device is consistently less than the set FiO_2. Therefore such devices may not be appropriate for severely hypoxemic patients.[35]

There are two ways to assess whether the flow of an air-entrainment nebulizer meets the patient's needs. The first method is simple visual inspection. With this approach (generally used only with a T tube), the RT sets up the device to deliver the highest possible flow at the prescribed FiO_2 and observes the mist output at the expiratory side of the T tube. As long as mist can be seen escaping throughout inspiration, flow is adequate and the delivered FiO_2 is ensured.

The second way to assess the adequacy of nebulizer flow is to compare it with the patient's peak inspiratory flow. A patient's peak inspiratory flow during tidal breathing is at least three times minute volume. As long as the nebulizer flow exceeds this value, the delivered FiO_2 is ensured. If the patient's peak flow

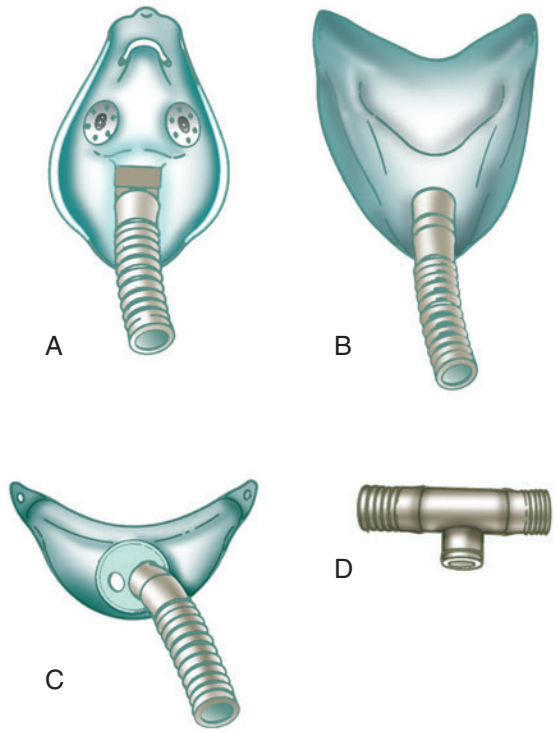

Fig. 42.15 Devices for Delivery of O_2 Mixtures With Aerosol. (A) Aerosol mask. (B) Face tent. (C) Tracheostomy collar. (D) T tube. (Modified from Kacmarek RM: In-hospital O_2 therapy. In Kacmarek RM, Stoller J, editors: *Current respiratory care*, Toronto, 1988, BC Decker.)

exceeds that provided by the nebulizer, the device functions as a low-flow system with variable FiO_2 (see the accompanying Mini Clini for an example).[35]

MINI CLINI

Computing Minimum Flow Needs

Problem

A physician orders 40% O_2 through an air-entrainment nebulizer to a patient with a tidal volume of 0.6 L and a respiratory rate of 33 breaths/min. If maximum nebulizer input flow is 12 L/min, will the patient receive 40% O_2? If not, what total flow is needed to meet this patient's needs?

Solution

1. Estimate the patient's inspiratory flow:

$$\text{Peak inspiratory flow} = VE \times 3 = (0.6 \times 33) \times 3 = 59.4 \text{ L/min}$$

2. Compute the total flow of the nebulizer:

$$\text{Sum of ratio parts}(3:1) \times \text{In put flow}(12 \text{ L/min}) = 48 \text{ L/min}$$

3. Compare value 1 with value 2 (patient with nebulizer):

$$59.4 \text{ L/min (patient)} > 48 \text{ L/min (nebulizer)}$$

Under these conditions, the patient does not receive 40% O_2. To deliver a stable 40% O_2 concentration, the total flow would have to be at least 59.4 L/min.

Troubleshooting air-entrainment systems. There are two major problems encountered with air-entrainment systems. The first is ensuring adequate flow at moderate to high FiO_2s. Another problem is that the performance of all air-entrainment devices is affected by downstream resistance, which can result in the delivery of inaccurate FiO_2s. These problems and their solutions are discussed as follows.

BOX 42.2 Increasing FiO_2 Capabilities of Air-Entrainment Nebulizers

- Add open reservoir to expiratory side of T tube
- Provide inspiratory reservoir with one-way expiratory valve
- Connect two or more nebulizers together in parallel
- Set nebulizer to low concentration; bleed-in O_2; analyze and adjust
- Use a commercial dual-flow system

FiO_2, fractional inspired oxygen.

Providing moderate to high FiO_2 at high flow. When set according to the manufacturer's specifications to provide much more than 45% to 50% O_2, AEMs simply do not generate enough flow to ensure the set FiO_2. The solution is to boost the total output flow. With AEMs, total output flow can be boosted with a simple increase in input flow. For a 35% AEM (5:1 ratio) with an input flow of 8 L/min, the total output flow is 48 L/min. This flow is insufficient to ensure 35% O_2 delivery to all patients. Simply increasing the input flow to 12 L/min boosts the output flow of the AEM by 50%, to 72 L/min. The new high flow ensures delivery of the set O_2 concentration to essentially all patients.

This solution is difficult with most air-entrainment nebulizers because the small jets in many of these devices limit O_2 flow to 12 to 15 L/min and input flow cannot be increased beyond these levels. A few nebulizer models, such as the Thera-Mist Barrel Nebulizer (Smiths Medical, London, England) and similar devices, can provide moderately high output flows of 54 L/min at FiO_2 80%. However, most air-entrainment nebulizers cannot because of the total flow-to-FiO_2 tradeoff. As a result, several alternatives for boosting the FiO_2 capabilities in these situations are presented in Box 42.2.

The simplest approach to achieving higher FiO_2 with these devices is to add a 50- to 150-mL aerosol tubing reservoir to the expiratory side of the T tube (Fig. 42.16). Given its simplicity, adding an open volume reservoir to the expiratory side of T tubes is standard procedure in most clinical settings. This approach can be used only in the treatment of intubated patients. Even then, the small reservoir size limits the ability of this system to ensure stable FiO_2, especially greater than 40%, and larger reservoirs can cause rebreathing.

Another approach to higher FiO_2 with air-entrainment nebulizers is to connect two or more devices together with a "wye" adapter (Fig. 42.17).[22] Although a single air-entrainment nebulizer set at 60% (1:1 ratio) with a maximum input flow of 15 L/min has a total output flow of only 30 L/min, connecting two of these devices together doubles the total output flow to 60 L/min (the minimum needed for a high-flow device). This approach works well only for delivery of a concentration of 60% or less to patients with a minute volume less than 20 L/min.[35]

An additional method for boosting FiO_2 provided by air-entrainment nebulizers is to set the device to a lower concentration than that prescribed (to generate high flow) while bleeding supplemental O_2 into the delivery tubing. This method increases

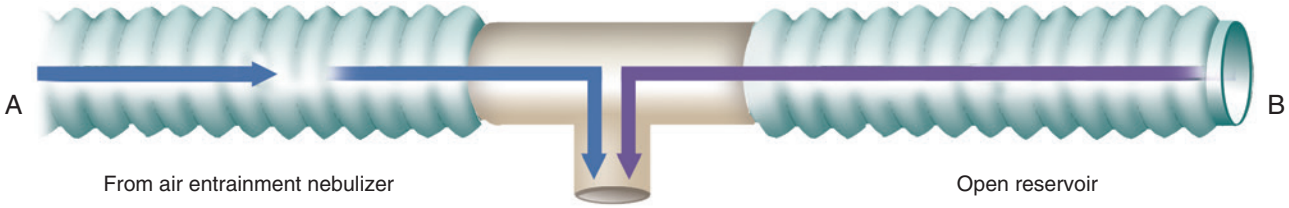

Fig. 42.16 Use of an open volume reservoir to enhance delivered O_2 concentration with a T tube. From 50 to 150 mL of aerosol tubing is connected to the expiratory side of the T tube. A, When the patient inhales, gas at the set fractional inspired oxygen (FiO_2) is drawn first through the inspiratory side of the circuit. B, If the patient's flow exceeds nebulizer flow, gas is drawn from the reservoir side. After the reservoir volume is fully tapped, room air is entrained, and FiO_2 decreases.

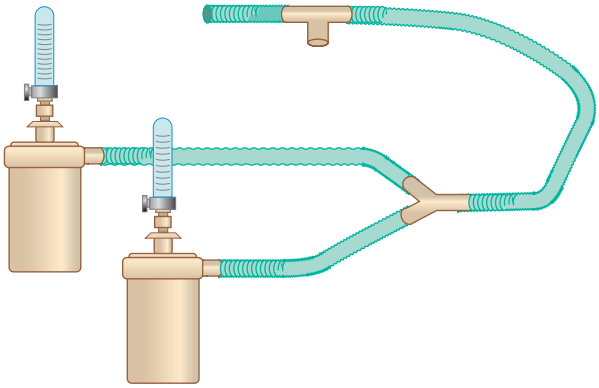

Fig. 42.17 Use of two nebulizers in parallel to provide high fractional inspired oxygen (FiO_2) at high flow.

both FiO_2 and total output flow. To achieve a specific FiO_2, the delivered concentration should be analyzed and the supplemental O_2 input flow adjusted until the desired concentration is achieved.

Commercial dual-flow systems entail a similar approach. One flow source powers the jet, while another flow source provides supplemental O_2. The Misty Ox (Vital Signs, Totowa, New Jersey) gas injection nebulizer is an example. This system is not an air-entrainment system because it does not depend on entrainment ports to increase total flow or O_2 concentration to the patient. Rather, it uses two flowmeters: one that operates the jet and one that feeds into the side of the jet manifold. The Misty Ox system can provide FiO_2 of 0.96 at a flow of 42 L/min and offers O_2 concentrations ranging from 0.21 to nearly 1.00.[35]

Problems with downstream flow resistance. Any increase in flow resistance downstream from (distal to) the point of air entrainment alters the performance of all air-entrainment systems. Increased downstream flow resistance causes back pressure. The back pressure decreases both the volume of entrained air and the total flow output of these devices. With less air entrained, the delivered O_2 concentration increases but, because total flow output also decreases, the effect on FiO_2 varies. High downstream flow resistance usually turns air-entrainment systems from high-flow (fixed) O_2 delivery systems into low-flow (variable) O_2 delivery systems incapable of delivering a precise and constant FiO_2.[29,36]

This problem explains why it is extremely difficult to deliver less than 28% to 30% O_2 with an air-entrainment nebulizer. The 5 to 6 ft (1.5 to 1.8 m) of aerosol tubing normally used with these devices produces enough flow resistance to decrease air entrainment and prevent a lower FiO_2.

A similar situation can occur when the entrainment ports of an air-entrainment device become obstructed (most common with AEMs). Delivered O_2 concentration increases, but total output flow decreases. The net effect usually is a variable FiO_2. The accompanying Mini Clini is an example of the effect of increased downstream flow resistance on the performance of an air-entrainment device.

MINI CLINI

Effect of Downstream Flow Resistance on Performance of an Air-Entrainment Device

Problem

A tracheostomy patient is receiving O_2 therapy through a T tube attached to an air-entrainment nebulizer set at 35% O_2 with an input flow of 10 L/min. Over the past 30 minutes, the patient's SpO_2 has decreased from 93% to 88%. When assessing the patient, the respiratory therapist (RT) finds that the large-bore delivery tubing of the nebulizer is partially obstructed with condensate and that aerosol mist at the T tube is not visible throughout inspiration. What is the likely problem, and what is the best solution?

Solution

The likely problem is a decrease in FiO_2 owing to the increased downstream resistance caused by the condensate. At 10 L/min input flow, the device was probably delivering approximately 60 L/min of 35% O_2 before the tubing became obstructed. Because aerosol mist is not visible at the T tube throughout inspiration, it is clear that the total output flow is no longer sufficient and that the patient is now diluting the delivered O_2 with room air. Draining the tubing solves this problem. Any other blockage of the large-bore tubing, such as tenacious secretions or being kinked in a bed rail, will cause a similar effect.

High-flow nasal cannula. A variation of the standard nasal cannula discussed earlier in this chapter is a **high-flow nasal cannula (HFNC)**. This form of oxygen delivery has been popular for pediatric and neonatal patients (see Chapter 35) with disorders including bronchiolitis and bronchopulmonary dysplasia. Currently, various systems have become available for adults, including the Vapotherm Precision Flow System (Vapotherm, Exeter, New Hampshire), which can deliver both FiO_2 and relative humidity greater than 90% by using heated, humidified O_2 flows up to 40 L/min. HFNC units offered by other manufacturers such as Fisher and Paykel's Optiflow (Irvine, California) featured

Fig. 42.18 High-flow nasal cannula setup (Courtesy Fisher & Paykel Healthcare, Inc., Irvine, California.)

in Fig. 42.18 have been shown to provide even higher flows of 60 L/min, as well as a maximum FiO_2 of more than 90%.

All HFNC systems require three components: (1) a patient interface, such as nasal prongs, (2) a gas delivery device that regulates FiO_2, and (3) a humidifier. The Vapotherm and Optiflow devices mentioned previously, feature a variety of proprietary designs that facilitate the separate control of flow and humidified supplemental oxygen. The ability to maintain a consistent FiO_2 under varying breathing patterns makes these devices suitable alternatives for early intervention in critically ill patients, as well as the preintubation and postextubation phases of care. These systems have been shown to successfully treat moderate hypoxemia through a combination of the four main features: (1) delivery of a high FiO_2, (2) meeting or exceeding the patient's minute ventilation and therefore acting as a fixed oxygen delivery device, (3) generating a distending, positive end-expiratory airway pressure (PEEP) of approximately 1 cm H_2O for each 10 L/min. of flow, and (4) washout of carbon dioxide from anatomic dead space.[37] Furthermore, the heated-humidity feature enables these systems to deliver highly humidified oxygen, thus preventing the drying effects that some high-flow devices have on the mucosa and enhancing mucociliary clearance. This advantage, along with the less confining design of these devices, makes them more comfortable and better tolerated by many patients than alternative oxygen delivery devices. As a result, such devices have become a popular substitute for both traditional high-flow oxygen devices and continuous positive airway pressure setups. Emerging research suggests additional benefits in reducing $PaCO_2$ for patients with acute hypercapneic respiratory failure.

Although definitive indications for HFNC are still evolving, patients with certain conditions seem to benefit from this modality. Table 42.8 summarizes the emerging indications for HFNC and the corresponding features which justify their use.

As a result of their features and advantages, HFNC devices are rapidly gaining popularity for being better tolerated than alternative therapies and enhancing clinical outcomes in selected patient populations. Despite the fact that some infection control concerns associated with older HFNC designs appear to have been largely overcome, several limitations persist. These include contraindications for use on patients with blocked nasal passages,

TABLE 42.8 Emerging Indications for HFNC and the Corresponding Features

Indication	HFNC Features
Hypoxemic respiratory failure *Example*: Pneumonia	High FiO_2, high-flow, PEEP, enhanced mucocilary clearance
Hypercapneic respiratory failure *Example*: COPD exacerbation	CO_2 washout, enhanced mucocilary clearance
Reduce reintubation risk. *Example:* Postextubation of a patient with significant comorbidities such as COPD.	High FiO_2, high-flow, PEEP, enhanced mucocilary clearance, CO_2 washout.
Do-not-intubate or hospice patient with respiratory failure. *Example:* End-stage lung cancer patient.	Multiple features which combat respiratory failure (see above) but more comfortable; less confining and drying than alternative therapies.
Inability to tolerate other oxygen delivery devices. *Example:* Claustrophobic COPD patient.	Multiple features which combat respiratory failure (see above) but more comfortable; less confining and drying than alternative therapies.

COPD, Chronic obstructive pulmonary disease; *HFNC*, high-flow nasal cannula; *PEEP*, positive end-expiratory airway pressure.

problems from the inability to precisely determine and monitor the level of positive pressure actually applied to the airway, and in rare instances, nasal skin erosions, mainly in neonates and infants, from an improperly fitting cannula.[38] In addition, care should also be taken not to delay escalation of treatment or emergent intubation if assessment reveals that the patient is not responding to, or simply not tolerating HFNC. Last, although HFNC may be part of the care plan for patients with a "Do Not Resuscitate" order, it should not substitute the need for formal transition to palliative care in terminally ill patients (see Chapter 58).

MINI CLINI

Indications for High-Flow Nasal Oxygen

Problem

A recently extubated patient experiencing moderate hypoxemia is having trouble tolerating a 50% venturi mask due to claustrophobia and airway dryness. When switched to a nasal cannula, his SpO_2 drops to 88%. The physician wants the patient SpO_2 to remain at 92% or higher and asks the respiratory therapist (RT) what options are available for delivering moderate oxygen concentrations to this patient while maximizing patient comfort.

Solution

A high-flow nasal oxygen setup is able to provide a moderate to high and consistent FiO_2 through varying patient breathing patterns. In addition, features including a less-confining design and delivery of a highly humidified gas tend to make them better tolerated than many other oxygen delivery systems. Hence in this instance, the RT should recommend a high-flow nasal oxygen setup.

Blending systems. When air-entrainment devices cannot provide a high enough O_2 concentration or flow, use of a gas blending system should be considered. With a blending system, separate pressurized air and O_2 sources are input, and the gases are mixed either manually or with a precision valve (blender).

This system allows precise control over both FiO_2 and total flow output. Most blending systems can provide flow much greater than 60 L/min, qualifying them as true fixed-performance delivery devices. For adults, gas is delivered from the blender either through an open system, such as an aerosol mask or T tube, or with a closed nonrebreathing system. For many patients requiring high FiO_2 and breathing spontaneously, this is the ideal setup, provided that the gas is humidified. The use of high-flow blended systems with heated humidity, as opposed to a heated aerosol, are very well tolerated by most patients, including patients with tracheostomies. In addition, because they do not produce an aerosol, they are better tolerated by tracheostomy patients than aerosol systems which can cause bronchospasm.

Mixing gases manually. When gases are mixed manually, separate air and O_2 flowmeters must be adjusted for the desired FiO_2 and flow (see the accompanying Mini Clini). For adults, this approach requires calibrated high-flow flowmeters (at least 60 L/min) and monitoring of delivered FiO_2.

MINI CLINI

Manually Mixing Air and Oxygen to Achieve Specified Concentration at a Given Flow

Problem

To mix air and O_2 manually to provide a patient with 50% O_2 at a total flow of 60 L/min, what O_2 and airflow would the respiratory therapist (RT) set?

Solution

1. Use Eq. 42.3 to compute the O_2 flow:

$$O_2 \text{ flow} = \frac{\text{Total flow} \times (O_2\% - 21)}{79}$$

$$O_2 \text{ flow} = \frac{60 \times (50 - 21)}{79}$$

$$O_2 \text{ flow} = 22 \text{ L/min}$$

2. Compute the airflow:

$$\text{Airflow} = \text{Total flow} - O_2 \text{ flow}$$

$$\text{Airflow} = 60 - 22$$

$$\text{Airflow} = 38 \text{ L/min}$$

To provide a patient with 50% O_2 at a total flow of 60 L/min, blend 22 L of O_2 with 38 L of air.

Oxygen blenders. Rather than manually mixing air and O_2, the RT more often uses an O_2 blender. Fig. 42.19 shows the major components of a typical O_2 blender. Air and O_2 enter the blender and pass through dual pressure regulators that exactly match the two pressures. Gas flows to a precision proportioning valve. Because the two gas pressures at this point are equal, varying the size of the air and O_2 inlets provides precise control over the relative concentration.

An alarm system gives an audible warning when either source gas fails or the pressure decreases below a specified value. The alarm system usually has a crossover or bypass feature whereby failure of one gas source causes the blender system to switch to the other. If the air source fails when delivering 60% O_2, the alarm sounds, and the blender switches over to delivery of 100% O_2.

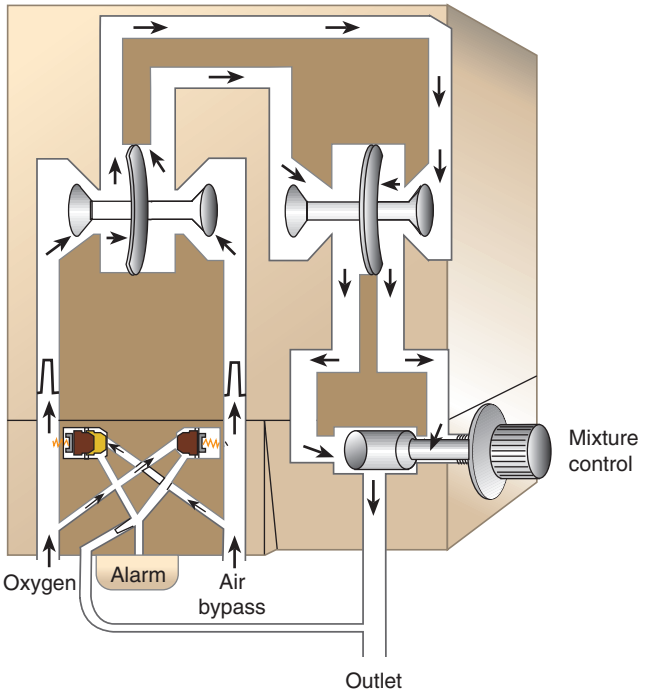

Fig. 42.19 O_2 blending device. (Modified from McPherson SP: *Respiratory therapy equipment*, ed 3, St. Louis, 1985, Mosby.)

BOX 42.3 Procedure for Confirming Operation of an Oxygen Blender

1. Confirm that inlet pressures of air and O_2 are within manufacturer's specifications.
2. Test low air and O_2 alarms by disconnecting each source; also confirm safety bypass or crossover system.
3. Analyze O_2 concentration at 100%, 21%, and specified FiO_2.

Although they allow ideal control over both FiO_2 and flow, blenders are especially prone to inaccuracy and failure.[36] Hence an operational check of any blender should be conducted before using it on a patient (Box 42.3). FiO_2 should be checked and confirmed with a calibrated O_2 analyzer at least once per shift. When a blender is used in the care of a neonate, an O_2 analyzer should be kept in-line at all times. In the use of a nonrebreathing or closed delivery system, (1) all breathing valves should be inspected and tested before application to a patient, and (2) a fail-safe inspiratory valve should be included in the delivery system.

Enclosures. The concept of enclosing a patient in a controlled-O_2 atmosphere is among the oldest approaches to O_2 therapy. Entire rooms once were used for this purpose. With current simpler airway devices, enclosures are generally used only in the care of infants and children. The primary types of O_2 enclosures used for infants and children are isolettes and hoods, both of which are discussed in Chapter 54 of this textbook.

BOX 42.4 Patient Factors in Selecting Oxygen Therapy Equipment

- Severity and cause of hypoxemia
- Patient age group (infant, child, adult)
- Degree of consciousness and alertness
- Presence or absence of tracheal airway
- Stability of minute ventilation
- Mouth breathing versus nose breathing patient

Other Oxygen Delivery Devices

Bag-mask devices. Bag-mask devices use a self-inflating bag and nonrebreathing valve features to provide up to 100% O_2. Bag-mask devices are often used in emergency life support and in critical care and are more completely discussed in Chapter 38.

Demand-flow and pulse-dose systems. Demand-flow or pulse-dose systems use a flow sensor and valve to synchronize gas delivery with inspiration. These devices can substantially extend duration of flow of a liquid or gaseous O_2 tank and are popular in alternative settings, as described in Chapter 57.

Selecting a Delivery Approach

The RT is often involved in the initial selection of an appropriate delivery system. This generally involves making recommendations based on sound patient assessment—to initiate, change, or discontinue the treatment regimen (see later section on **Protocol-Based Oxygen Therapy**).

The three *P*s—*purpose, patient,* and *performance*—are used in the initial selection or recommendation of a change in O_2 delivery system. The goal is to match the performance characteristics of the equipment to both the objectives of therapy (purpose) and the patient's special needs.

Purpose

The general purpose or objective of all O_2 therapy is to increase FiO_2 sufficiently to correct arterial hypoxemia. Other objectives, including decreasing hypoxic symptoms and minimizing increased cardiopulmonary work, follow from this primary purpose.

Patient

Key patient considerations in selecting O_2 therapy equipment for use in acute care are summarized in Box 42.4. Knowledge of these factors helps guide the RT in selecting the appropriate delivery device. For example, a simple mask at 5 to 6 L/min is probably more suitable than a nasal cannula at 4 L/min for a mouth breathing, mildly hypoxemic patient. An infant with moderate hypoxia and a normal airway usually needs an O_2 enclosure (hood or enclosed incubator).

Performance

O_2 systems vary according to actual FiO_2 delivered and stability of FiO_2 under changing patient demands. In general, the more critically ill the patient, the greater the need for a stable, high FiO_2. Less acutely ill patients generally need a lower, less exact FiO_2. Table 42.9 lists guidelines for selecting an O_2 delivery system based on the level and stability of the FiO_2 needed.

TABLE 42.9 Selection of an Oxygen Delivery System Based on Desired FiO_2 Level and Stability

Desired FiO_2 Level	DESIRED FIO_2 STABILITY	
	Fixed	**Variable**
Low (<35%)	AEM	Nasal cannula
	Air-entrainment nebulizer	Nasal catheter
	Blending system	Transtracheal catheter
	Isolette, incubator (infant)	
Moderate (35%–60%)	Air-entrainment nebulizer	Simple mask
	Blending system	Air-entrainment nebulizer
	Oxyhood (infant)	Tent (child)
High (>60%)	Blending system	Partial rebreather
	Oxyhood (infant)	Nonrebreather
	High-flow nasal cannula	

AEM, Air-entrainment mask; *FiO_2,* fractional inspired oxygen.

General Goals and Patient Categories

On the basis of overall consideration of the three *P*s, general goals can be set for several patient categories. In emergencies in which tissue hypoxia is suspected, patients should be given the highest FiO_2 possible—ideally 100%. This level can be achieved with a true high-flow or a closed reservoir system. The goal is the highest possible blood O_2 content. Clinical examples include respiratory or cardiac arrest, severe trauma, shock, carbon monoxide poisoning, and cyanide poisoning. Carbon monoxide and cyanide poisoning may necessitate HBO therapy (see later).

A critically ill adult patient with moderate to severe hypoxemia needs either a reservoir or a high-flow system capable of at least 60% O_2. Thereafter, changes in FiO_2 (and device) should be based on results of assessment of physiologic values. The goal is a PaO_2 greater than 60 mm Hg or oxyhemoglobin saturation greater than 90%.

In the care of adult patients in more stable condition but who are acutely ill with mild to moderate hypoxemia, a system capable of low to moderate O_2 concentration can be used. In these cases, stability of FiO_2 is not critical. Applicable devices include a nasal cannula at moderate flow or a simple mask. Common examples include patients in the immediate postoperative phase and patients recovering from acute myocardial infarction.

Adult patients with chronic lung disease and accompanying acute-on-chronic hypoxemia present a special case. In the care of these patients, the goal is to ensure adequate arterial oxygenation without depressing ventilation. Adequate oxygenation of these patients generally means an SaO_2 of 85% to 92% with PaO_2 of 50 to 70 mm Hg.[31,39,40] These values usually are achieved with either low-flow nasal O_2 or a low-concentration (24% to 28%) AEM. The less stable the patient's condition, the greater the need for a high-flow AEM.[22]

Because of size, discomfort, and appearance, AEMs are less well tolerated than nasal cannulas for long-term therapy. In

contrast to a cannula, an AEM must be removed for eating and drinking. Because even a short break in O_2 therapy can cause a rapid decrease in PaO_2 in some patients, these patients should be taught to switch to a nasal cannula whenever they must remove the mask.[22]

Lastly, it is sometimes necessary to modify O_2 delivery systems to facilitate patient transport. An example is a spontaneously breathing patient with a tracheostomy tube receiving a moderate FiO_2 via a blended system or an air-entrainment nebulizer connected to a tracheostomy mask. Given the impracticalities of transporting a patient on an air-entrainment nebulizer, it may be more suitable to connect a venturi adapter temporarily to provide the appropriate FiO_2 to the tracheostomy mask during the transport and then reconnect them back to the original aerosol setup immediately after the transport.

Protocol-Based Oxygen Therapy

O_2 therapy is ideally suited for protocol-based management. Bedside assessment of oxygenation by RTs and other clinicians has progressed to where it is more cost-effective and clinically appropriate to use a protocol rather than obtaining a new physician order for each change in FiO_2. An order for "O_2 therapy via protocol" permits O_2 therapy to be initiated, modified, or discontinued by the RT, provided an assessment reveals that the patient meets previously approved clinical criteria. A well-designed O_2 protocol ensures that the patient: (1) undergoes initial assessment, (2) is evaluated for protocol criteria, (3) receives a treatment plan that is modified to the need, and (4) stops receiving therapy as soon as it is no longer needed.

Fig. 42.20 shows the decision algorithm underlying an O_2 therapy titration protocol developed at the Cleveland Clinic Foundation. In the algorithm, a pulse oximetry saturation (SpO_2) of 92% is the point at which therapy is to be initiated. The patient is assessed each shift for the need of supplemental O_2, which is adjusted depending on need. When the SpO_2 is consistently 92% or greater on room air, therapy is discontinued.

HYPERBARIC OXYGEN THERAPY

HBO therapy is the therapeutic use of O_2 at pressures greater than 1 atm.[41-44] Pressures during HBO therapy usually are expressed in multiples of **atmospheric pressure absolute (ATA)**: 1 ATA equals 760 mm Hg (101.32 kPa). Most HBO therapy is conducted at pressures between 2 and 3 ATA, although other pressures may be used, often based on U.S. Navy diving treatment tables.[43-45]

Physiologic Effects

The known physiologic effects of HBO therapy are summarized in Box 42.5.[42] These effects are mainly due to either high pressure or high O_2 tension in body fluids and tissues. In conditions such as air embolism and decompression sickness, Boyle's law dictates that high pressure exerts a physical effect on air or nitrogen bubbles trapped in the blood or tissues, reducing their size, and minimizing potential harm. Because pressure is crucial in these cases, HBO treatments may be conducted at 6 ATA or more.[43,45]

BOX 42.5 Physiologic Effects of Hyperbaric Oxygen Therapy

- Bubble reduction (Boyle's law)
- Hyperoxygenation of blood and tissue (Henry's law)
- Vasoconstriction
- Enhanced host immune function
- Neovascularization

The second beneficial effect of HBO is hyperoxia. When a patient is breathing room air, only a small amount of O_2 dissolves in the plasma (approximately 0.3 mL/dl). At 3 ATA, plasma contains nearly 7 mL/dl dissolved O_2, a level exceeding average resting tissue uptake.[43]

O_2 supply to the tissues affects the immune system, wound healing, and vascular tone. A tissue PO_2 of at least 30 mm Hg is necessary for normal cellular function. Damaged and infected tissues often have a lower PO_2. Increasing O_2 supply to these tissues can help restore both white blood cell function and antimicrobial activity.

Hyperoxia affects the cardiovascular system. HBO therapy causes generalized vasoconstriction and a small decrease in cardiac output. Although these changes may decrease blood flow to a region, this effect is more than offset by the increase in O_2 content. In conditions such as burns, cerebral edema, and crush injuries, vasoconstriction may be helpful because it reduces edema and tissue swelling while maintaining tissue oxygenation.

Hyperoxia also helps form new capillary beds, a process called **neovascularization**. Although the exact mechanism is unknown, neovascularization is an essential component of tissue repair, especially in radiation-induced injuries.[43,44]

Study results suggest that HBO may be useful in many other conditions, including the management of stroke, wound healing, and treating stubborn soft tissue infections. Because HBO has emerged as a highly effective therapy for various conditions, its use in recent years has expanded.[46,47]

Methods of Administration

HBO is administered in either a multiplace or a monoplace chamber. A multiplace chamber is a large tank capable of holding a dozen or more people (Fig. 42.21A). Because patients are directly cared for by medical staff inside the tank, multiplace chambers have air locks that allow entry and exit without altering the pressure. The multiplace chamber is generally filled with air. If indicated, only the patient breathes supplemental O_2 (through a mask or another device). Because they can achieve pressures of 6 ATA or more, multiplace chambers are ideal for the management of decompression sickness and air embolism.[43-45]

A typical monoplace chamber consists of a transparent Plexiglas cylinder large enough only for a single patient (see Fig. 42.21B). During therapy, the cylinder O_2 concentration is kept at 100%. The patient need not wear a mask. Because of the high O_2 concentration, most electronic equipment cannot be used in a monoplace chamber. In addition, many ventilators do not function properly under the high atmospheric pressures. However, monitoring systems and ventilators can be adapted to allow

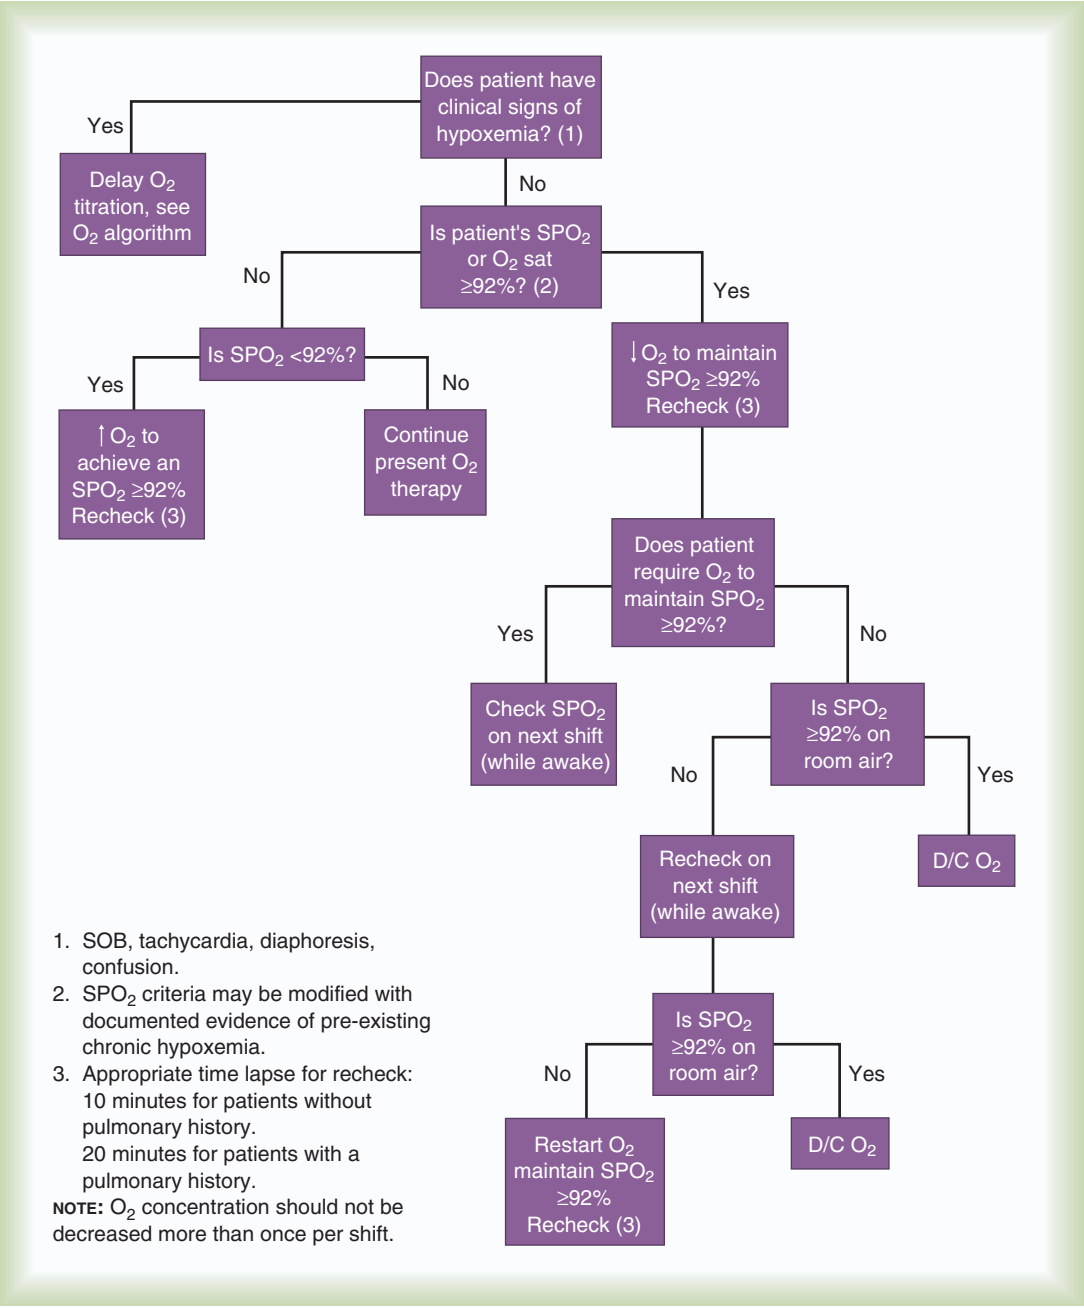

Fig. 42.20 Protocol for titration of O_2 therapy. (Courtesy the Respiratory Therapy Section, Cleveland Clinic Foundation, Cleveland, Ohio.)

treatment of a critically ill patient with hyperbaric pressure. In addition, artificial airways suited to function properly under hyperbaric conditions should be used.[42]

Indications

HBO has long been accepted as the primary treatment of divers with decompression sickness. Several other of the most common indications for HBO therapy are listed in Box 42.6. The two most common acute indications are air embolism and carbon monoxide poisoning.[42,45,47]

Air Embolism

Air embolism is a complication that can occur with certain cardiovascular procedures, lung biopsy, hemodialysis, and central line placement. HBO can decrease the size of air bubbles which may otherwise reach the cerebral or cardiac circulation and can cause symptoms or sudden death. Typical therapy for air embolism involves immediate pressurization in air to 6 ATA for 15 to 30 minutes. This step is followed by decompression to 2.8 ATA with prolonged O_2 treatment.[43-45]

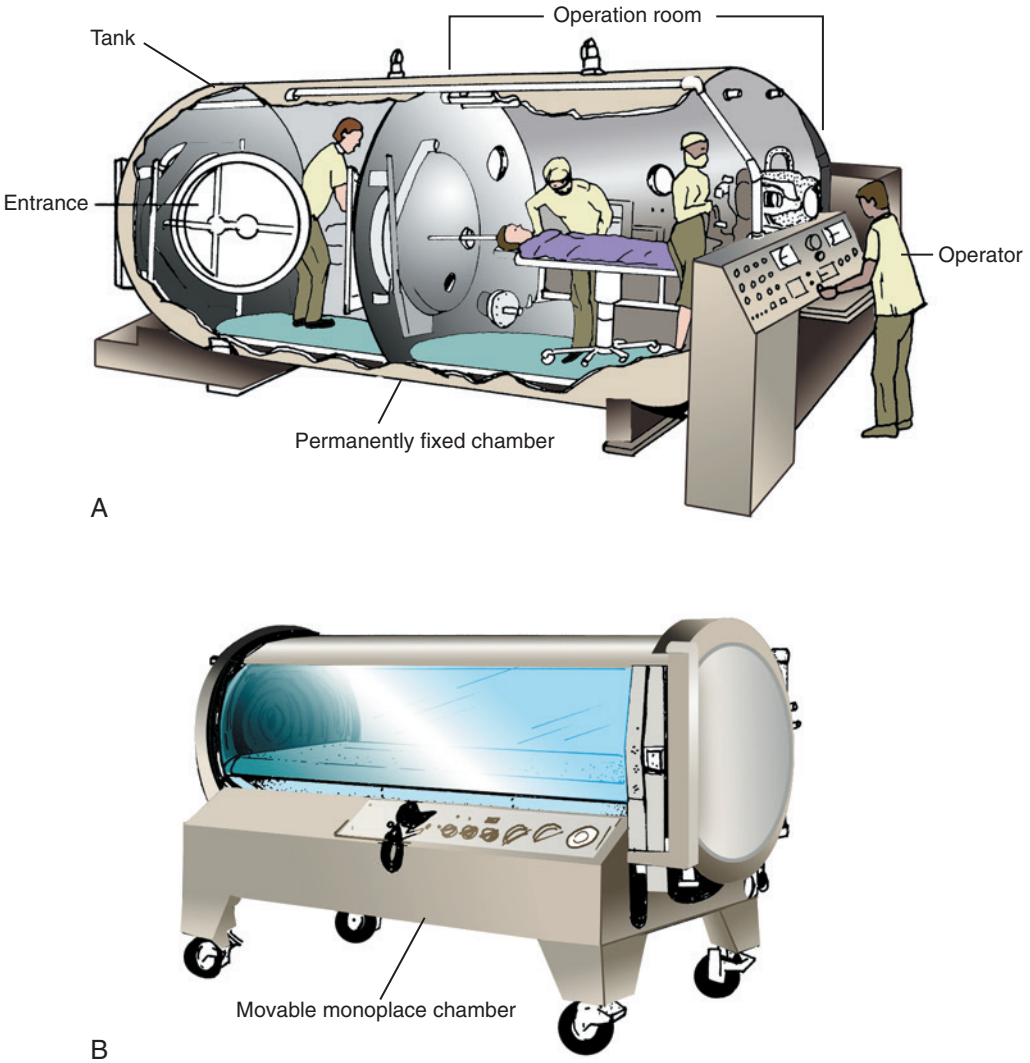

Fig. 42.21 (A) Fixed hyperbaric chamber. (B) Monoplace chamber.

BOX 42.6 Indications for Hyperbaric Oxygen Therapy

Acute Conditions

- Decompression sickness
- Air or gas embolism
- Carbon monoxide and cyanide poisoning
- Acute traumatic ischemia (compartment syndrome, crush injury)
- Acute peripheral arterial insufficiency
- Intracranial abscesses
- Crush injuries and suturing of severed limbs
- Clostridial gangrene
- Necrotizing soft tissue infection
- Ischemic skin graft or flap

Chronic Conditions

- Diabetic wounds of the lower extremities and other nonhealing wounds
- Refractory osteomyelitis
- Actinomycosis (chronic systemic abscesses)
- Radiation necrosis (hyperbaric oxygen as an adjunct to conventional treatment)

Carbon Monoxide Poisoning

Carbon monoxide poisoning accounts for approximately half of all poisoning deaths in the United States. The condition of a patient with carbon monoxide poisoning improves quickly with HBO treatment because this treatment is the fastest way to remove carbon monoxide from the blood.[47] If a patient breathes air, it takes more than 5 hours to remove only one-half of the carboxyhemoglobin in the blood. Breathing 100% O_2 reduces this "half-life" to 80 minutes. The half-life of carboxyhemoglobin under HBO at 3 ATA is only 23 minutes. Box 42.7 lists the major criteria for selecting patients with acute carbon monoxide poisoning for treatment with HBO.[47]

Complications and Hazards

Although the benefits of HBO are significant, this type of therapy also has significant risks. As a result, the benefits should be compared with the hazards before therapy is initiated. Common complications of HBO are listed in Box 42.8.[43] These complications are generally caused by high pressure, O_2 toxicity, fire, or

BOX 42.7 Criteria for Hyperbaric Oxygen Therapy for Acute Carbon Monoxide Poisoning

- History of unconsciousness
- Presence of neuropsychiatric abnormality
- Presence of cardiac instability or cardiac ischemia
- Carboxyhemoglobin level 25% (lower levels for children and pregnant women)

BOX 42.8 Major Complications of Hyperbaric Oxygen Therapy

Barotrauma
- Ear or sinus trauma
- Tympanic membrane rupture
- Alveolar overdistention and pneumothorax
- Gas embolism

Oxygen Toxicity
- Central nervous system toxic reaction
- Pulmonary toxic reaction

Other
- Fire
- Sudden decompression
- Reversible visual changes
- Claustrophobia
- Decreased cardiac output

worsening of certain existing conditions. The most frequent problems involve barotrauma to closed body cavities, such as the middle ear or sinuses. Pneumothorax and air embolism also are possible during HBO treatment but are rare in patients with normal lungs.

O_2 at high pressure can rarely be neurotoxic. Early signs of impending CNS toxicity include twitching, sweating, pallor, and restlessness and later seizures and convulsions.[44]

In terms of pulmonary O_2 toxicity, HBO treatments do not normally expose patients to high PO_2 long enough to cause damage. However, HBO may have an additive effect on critically ill patients who receive high FiO_2 between HBO treatments.[43,44]

Avoiding fire and sudden decompression are primary safety concerns. Only 100% cotton fabric should be used to avoid fire from a static electrical discharge. Other ignition sources such as matches or lighters should never be brought into HBO chambers, and alcohol- or petroleum-based products, including makeup or deodorant, should never be used. Other potential hazards of HBO involve the aggravation of existing conditions, including diabetes, epilepsy, and hypertension. These concerns can be addressed by an appropriate history and chart review, close patient monitoring, and appropriate adjustment of therapy.

There are numerous relative contraindications for HBO, many of which relate to the potential complications and hazards noted earlier. Relative contraindications include inner ear infections and seizure disorders. Absolute contradictions include an untreated pneumothorax and congenital heart defects resulting in dependency on a patent ductus arteriosus for survival.[44]

Troubleshooting

Although fire hazards restrict the use of certain electronic equipment, some state-of-the-art monitors and ventilators with solid-state circuitry can be used within the chamber. This equipment allows intensive care of critically ill patients.[42]

In regard to ventilator use, reductions in delivered tidal volume should be expected and corrected. In addition, tracheostomy or endotracheal tubes with foam or fluid-filled cuffs should generally be used to preserve cuff integrity under pressure. If not accounted for, reduced tidal volumes and leaks can lead to respiratory hypercapnia and acidosis. Hypercapnia can result in respiratory acidosis and can worsen CNS toxicity owing to cerebral vasodilation.[44] In general, pressure-regulating and flow-regulating equipment used in a hyperbaric chamber must be specifically designed for operation or equipment appropriately modified to function properly in such conditions.

OTHER MEDICAL GAS THERAPIES

O_2 is not the only medical gas administered by RTs. The potent pulmonary vasodilator **nitric oxide (NO)**, and helium-O_2 mixtures are also among other medical gases administered by RTs.

Nitric Oxide Therapy

Mode of Action

NO gas is a colorless, odorless, highly diffusible, and lipid-soluble free radical that oxidizes quickly to nitrogen dioxide (NO_2) in the presence of O_2. NO is normally produced in small amounts within the human body and activates guanylate cyclase, which catalyzes the production of cyclic guanosine 3′,5′-monophosphate (cGMP). The end result is increased cGMP levels that cause vascular smooth muscle relaxation.[48,49] The therapeutic benefit of inhaled NO (iNO) stems from improved blood flow to ventilated alveoli. The result is a reduction in intrapulmonary shunting, improvement in arterial oxygenation, and a decrease in pulmonary vascular resistance and pulmonary arterial pressure.

Indications

INOmax is indicated to improve oxygenation and reduce the need for extracorporeal membrane oxygenation in term and near-term (>34 weeks gestation) neonates with hypoxic respiratory failure associated with clinical or echocardiographic evidence of pulmonary hypertension in conjunction with ventilatory support and other appropriate agents (INOmax.com Product Information)

As approved by the U.S. Food and Drug Administration (FDA) in December 1999, INOmax (iNO) is a selective pulmonary vasodilator and is effective in term and near-term infants with hypoxemic respiratory failure (HRF) and persistent pulmonary hypertension of the newborn (PPHN).[50]

In adults, studies have shown that iNO has been effective in treating pulmonary hypertension associated with acute respiratory distress syndrome (ARDS). However, these benefits seem to be short-lived, and no significant improvement in clinical outcomes, including ventilator-days and mortality, have been shown to date. However, iNO is frequently used for the management

BOX 42.9 Potential Uses for Inhaled Nitric Oxide

- ARDS
- Persistent pulmonary hypertension of the newborn
- Primary pulmonary hypertension
- Pulmonary hypertension after cardiac surgery
- Cardiac transplantation
- Acute pulmonary embolism
- chronic obstructive pulmonary disease
- Congenital diaphragmatic hernia
- Sickle cell disease
- Testing pulmonary vascular responsiveness

of patients with acute or chronic pulmonary hypertension as a result of pulmonary or cardiac disease and as a diagnostic tool for assessing pulmonary vascular responsiveness prior to heart transplantation or other cardiac surgical procedures. But because of the high cost of NO, and the lower cost of alternative drug therapies, including inhaled epoprostenol sodium (Flolan) and similar medications (discussed in Chapter 36), most try to avoid the use of NO. iNO in adults has not been approved by the FDA. Irrespective, the potential indications for iNO are listed in Box 42.9.[50,51]

Dosing

For term and near-term neonates with hypoxic respiratory failure, the recommended dose of INOmax is 20 ppm. Treatment should be continued until underlying oxygenation desaturation has resolved. For many patients, dosages often can be reduced to less than 20 ppm at the end of 4 hours of initial treatment, as tolerated. At these levels, NO has minimal toxicity.[49-51]

Toxicity and Adverse Effects

Most of the toxic effects of NO are caused by its chemical by-products, especially NO_2. NO_2 is produced spontaneously whenever NO is exposed to O_2. NO_2 is more toxic than NO. Levels greater than 10 ppm can cause cell damage, hemorrhage, pulmonary edema, and death. The U.S. Occupational Safety and Health Administration has set the safety limit for NO_2 exposure at 5 ppm. Properly set up NO delivery systems safely and easily achieve this limit.[52]

Other harmful chemical by-products produced in reaction with NO include methemoglobin and peroxynitrite (produced when NO reacts with superoxide). Although it can occur with NO administration, methemoglobinemia is not common considering the doses commonly used and the required monitoring systems discussed later in this section. Peroxynitrite can cause severe cell damage; however, there is no hard evidence supporting its toxic effects during NO administration.

Potential adverse effects associated with NO therapy are listed in Box 42.10.[53] A poor or paradoxical response to NO has been observed in some patients. Of patients with ARDS, 40% do not have initial improvement in oxygenation with NO therapy, and some patients have experienced more severe hypoxemia (probably because of a worsening ventilation/perfusion imbalance when no shunt was present). NO inhibits platelet agglutination; however, no significant increase in bleeding time has been reported in NO trials with human subjects. Because it can quickly reduce right ventricular afterload, NO may increase left ventricular filling pressure in some patients. In the presence of congestive heart failure, this effect could cause or worsen pulmonary edema. Concerns involving increased left heart pressures also account for iNO being contraindicated for neonates with certain cardiac and vascular anomalies such as coarctation of the aorta.[50] In certain patients, the withdrawal of NO has resulted in development of hypoxemia and pulmonary hypertension, perhaps worse than they were before therapy was started. This phenomenon is known as a **rebound effect**. This rebound effect occurs because the administration of NO depresses the body's normal production of NO. When NO is finally discontinued, FiO_2 frequently needs to be initially increased then slowly reduced to baseline.[49]

Although NO has been used safely with other drugs and treatments such as dopamine, steroids, surfactant, and high-frequency ventilation, the interaction of NO with other medications is still being studied. One investigational area may involve the study of patients receiving both iNO and other NO-related compounds such as nitroglycerin and the possible development of methemoglobinemia or systemic hypotension.[51]

BOX 42.10 Adverse Effects Associated With Nitric Oxide Therapy

- Poor or paradoxical response
- Methemoglobinemia
- Increased left ventricular filling pressure
- Complications of certain cardiac anomalies (coarctation of the aorta)
- Rebound hypoxemia, pulmonary hypertension

BOX 42.11 Features of Ideal Nitric Oxide Delivery System

- Dependability and safety
- Delivery of a precise and stable dose of NO
- Limited production of nitrogen dioxide
- Accurate monitoring of NO and nitrogen dioxide levels
- Maintenance of adequate patient ventilation

NO, Nitric oxide.

Methods of Administration

NO is administered to mechanically ventilated patients through a system with the capability for operator-determined concentration of NO in the breathing gas, a constant concentration throughout the breathing cycle, and a concentration that does not cause generation of excessive iNO_2. Features of an ideal NO delivery system are listed in Box 42.11.

The INOmax DS_{IR} Plus (Delivery System-Infrared) (Mallinckrodt Pharmaceuticals, Bedminster, New Jersey) shown in Fig. 42.22 provides these features.[51,53] The INOmax DS_{IR} Plus delivers INOmax (NO) for inhalation into the inspiratory limb of the patient's breathing circuit in a manner that provides a constant dose of NO, as preset by the clinician, throughout inspiration.

Fig. 42.22 INOmax DS Plus (Delivery System-Plus) delivery system for administration of nitric oxide (NO) to mechanically ventilated patients. (Courtesy Mallinckrodt Pharmaceuticals, Bedminster, New Jersey)

This configuration tracks the ventilator flow waveforms and delivers a synchronized and proportional dose of NO through the injector module into the ventilator circuit. An integrated monitoring system continuously displays inspired FiO_2, NO_2, and NO. The INOmax DS_{IR} Plus uses several alarm systems to alert clinicians, including alarms for high and low NO and FiO_2 and high NO_2. Delivery alarms notify clinicians when the source gas (INOmax) pressure is low or if there is a monitoring failure. The device also informs clinicians when high calibrations for the monitoring system are due; low calibrations are performed automatically by the device without requiring user intervention.[53]

The delivery system requires the use of cylinder mixtures of NO containing 800 ppm of NO with the balance being nitrogen. This high concentration of NO is diluted by gases in the ventilator circuit before delivery to the patient. Because adding NO to the circuit decreases the FiO_2 (up to 10% at 80 ppm), O_2 concentration must be continuously monitored downstream from the titration site.

The INOmax DS_{IR} Plus is proven to be compatible with over seventy different ventilators including high-frequency oscillators, jet ventilators, anesthesia machines, and noninvasive breathing circuits. Other special considerations apply, and resources such as ventilator procedure manuals and department policy and procedures should be reviewed to help ensure proper setup and patient safety.[53]

The administration of iNO to spontaneously breathing patients is also possible. The INOmax DS_{IR} Plus has been interfaced with high- and low-flow nasal cannula systems and some nasal continuous positive airway pressure (CPAP) systems.[53]

Withdrawing Therapy

Care must be taken when NO therapy is withdrawn to prevent rebound effects. First, the NO level should be reduced to the lowest effective dose (ideally ≤5 ppm). Second, the patient's condition should be hemodynamically stable, and the patient should be able to maintain adequate oxygenation while breathing a moderate FiO_2 (≤0.4) on low levels of positive end expiratory pressure. Third, the patient should be hyperoxygenated (FiO_2 0.6 to 0.7) just before discontinuation of NO inhalation. Close monitoring of patients and use of these measures usually avoid an increase in pulmonary artery pressure and hypoxemia with withdrawal of NO.[50]

Helium-Oxygen Therapy

Indications

The value of helium as a therapeutic gas is based solely on its low density. As detailed in Chapter 6, when flow is turbulent, driving pressure varies with the square of the flow. Because flow in the large airways is mainly turbulent, breathing a low-density gas mixture can decrease the driving pressure needed to move gas in and out of this area. With less pressure needed to move gas through the large airways, the patient's work of breathing decreases. However, this effect is limited to large airway obstruction (flow in the small airways is not turbulent).

Helium-O_2 has been used for more than 70 years as an adjunct tool in the management of large airway obstruction.[54] **Heliox therapy** has been shown to be effective in treating acute obstructive disorders.[55,56] Either alone or combined with other therapies such as bronchodilators, helium-O_2 therapy has been shown to decrease the respiratory rate, the level of dyspnea, and the need for intubation and mechanical ventilation in patients with reversible obstructive disorders.[57] Specifically, heliox therapy has yielded promising results in the management of acute upper airway obstruction of varying origin, postextubation stridor in pediatric trauma patients, acute severe asthma, and **croup**.[57]

Guidelines for Use

Because it is inert and unable to support life, helium always must be mixed with at least 20% O_2. The most common combination is 80% helium and 20% O_2. From the standpoint of its ability to oxygenate, this mixture is comparable to air, but helium is used in place of nitrogen. Although air has a density of 1.293 g/L, the

density of an 80% helium mixture is 0.429 g/L. For a comparable flow through constricted large airways, this low-density mixture can dramatically decrease the work of breathing.

Most commonly, premixed, commercial heliox cylinders are used at the bedside. These premixed cylinders are commonly available in an 80:20 or a 70:30 combination. The 70% helium and 30% O_2 mixture has a density of 0.554 g/L and can provide additional O_2 for the management of the hypoxemia that can occur with large airway obstruction. Other combinations such as 60:40 mixtures show promising results.[57]

The low-density benefit of heliox is the same physical property that presents challenges in selecting a delivery device. Because helium is highly diffusible, administration through low-flow systems such as a nasal cannula tend not to deliver sufficient concentrations to treat obstructive disorders in adults. However, heliox administered via cannulas with an adequate seal at the nares has shown to be effective in some infants.[57] Nonetheless, heliox should generally be delivered to most spontaneously breathing patients via a tight-fitting nonrebreathing mask with a fully functional valved exhalation port. The delivery system should be high flow and sufficient to meet or exceed the patient's minute ventilation requirements. Closed systems with demand valves and reservoirs or the use of demand regulators has proven to be suitable for delivering heliox to patients with artificial airways. Ideally, an O_2 analyzer should be used to confirm the FiO_2 of the heliox mixture output flowing to the patient and all such patients should be closely monitored, including with a pulse oximetry.[57] Helium mixtures can be given through a cuffed tracheal airway with a positive pressure ventilator. However, the performance of ventilators in delivering heliox tends to vary significantly by model, and only some of them have received FDA clearance for such use. Consequently, RTs should ensure that an appropriate ventilator is being used to administer heliox, determine if a conversion factor is needed to adjust settings, and ensure that the patient is monitored closely while such an approach is being used.[57] Pressure measurements on mechanical ventilators are always accurate during the use of heliox but volume measurements can be grossly inaccurate if the ventilator is not calibrated to a heliox mixture.

Blenders have also been used to administer heliox. When a blender is used, the 80:20 heliox is generally attached to the air inlet, and an O_2 analyzer is placed downstream. However, because the accuracy of blenders tends to vary, the system's FiO_2 readings should first be tested, and the difference between the set and actual FiO_2 should be known.

Heliox has also been combined with bronchodilator therapy to treat acute obstructive disorders such as status asthmaticus. Heliox improves aerosol deposition mainly because of a reduction in turbulence and less impaction and medication loss. Because of the low density of heliox, when a nebulizer is driven by heliox, the liter flow must be increased from the customary 6 L/min to 10 to 12 L/min to achieve the same volume of aerosol generated per unit of time.

When heliox is given alone or as part of nebulization, the RT should realize that a typical hospital O_2 flowmeter is inaccurate because of the lower density of helium. Flowmeters calibrated for helium should be used to ensure accurate delivery. However, correction factors are available for O_2 flowmeters. The correction for an 80:20 helium-O_2 mixture is 1.8; this means that for every 10 L/min indicated flow, 10 × 1.8, or 18 L/min, of the 80:20 mixture actually leaves the flowmeter. For delivery of a specific flow from an 80:20 helium-O_2 source, the RT sets the flowmeter to the desired flow divided by 1.8. If a flow of 9 L/min of an 80:20 helium-O_2 mixture is needed, the RT sets the flowmeter to 9/1.8, or 5 L/min. Factors for any other mixture can be calculated if needed. The factor for a 70:30 helium-O_2 mixture is 1.6.

In addition to special flow considerations, the RT should use an O_2 analyzer to monitor heliox (actually O_2) concentrations continuously between the source of the mixture and the patient. The basis for this recommendation is that the gas is either helium or O_2, and if the FiO_2 is known, assuming there are no leaks, the remaining gas is helium. This monitoring helps ensure that the patient is receiving the therapeutic benefits of a less dense gas while maintaining the appropriate FiO_2.

MINI CLINI

Heliox for Severe Asthma

Problem

Bronchodilators and systemic steroids have just been initiated for a patient in the emergency room with a severe asthmatic attack. The physician would like your recommendation on reducing this patient's work-of-breathing until the asthma medications can take effect and possibly avoid the need for intubation and mechanical ventilation.

Solution

Breathing a low-density gas mixture such as heliox reduces the driving pressure needed to move gas in and out of the lungs. As a result, a heliox mixture of 80:20 or 70:30 should be recommended to reduce this patient's work-of-breathing until other elements of the care plan can address the underlying problems of airway obstruction due to bronchoconstriction and airway inflammation.

Troubleshooting and Hazards

The low density of helium mixtures makes them poor vehicles for aerosol transport. High-density bland water aerosols are difficult to deliver with helium mixtures. The low density of helium mixtures also makes coughing less effective. If the patient can develop an effective cough, this problem can be rectified by means of washing out the helium before coughing.

The most common side effect of helium is a benign one. When a patient is breathing a helium mixture, the spoken word is badly distorted at a pitch so high as to make it almost unintelligible. This effect is caused by the passage of a low-density gas through the vocal cords on exhalation.

A more serious problem is hypoxemia associated with breathing helium mixtures.[57] Although this problem may have been caused by using too low an O_2 concentration (20%), there is another possibility. Very rarely, some commercial helium-O_2 cylinders stored for long periods of time have been found to contain these gases in an unmixed, or separated, state. The only way to avoid this potential hazard is to analyze the O_2

concentration coming from the cylinder before administering the gas.

As clinical applications for heliox have expanded, other hazards have emerged. One potential problem is volume-induced lung injury when heliox is administered via a mechanical ventilator. This risk can be addressed by using only ventilators approved by the FDA for heliox administration. In addition, the lower density of helium-O_2 mixtures may result in greater variability in medication delivery to the airways. Careful patient monitoring during such therapy can help minimize this concern. Another rare but possible problem is hypothermia to infants receiving heliox via an oxyhood. This risk results from the high thermal conductivity of helium and can be avoided by warming and humidifying the heliox gas.[57]

Carbon Dioxide–Oxygen (Carbogen) Therapy

Although rarely used, CO_2-O_2 mixtures (carbogen) have been employed to treat hiccups, carbon monoxide poisoning, and some neonates with congenital cardiac anomalies and to prevent complete washout of CO_2 during cardiopulmonary bypass and extracorporeal gas exchange. More recently, it has been investigated as a treatment for hearing loss and seizures. However, the application of carbogen in clinical settings has been quite limited given the potential adverse effects of hypoxemia, premature ventricular contractions, hypertension, and muscle twitching.[58]

Carbogen is supplied in compressed gas cylinders as either 5%:95% or 7%:93% CO_2-O_2 mixtures. It can be administered to patients with a snug-fitting nonrebreathing mask, with a flow sufficient to prevent the reservoir from collapsing during inhalation. Because of the potential adverse effects, patients receiving carbogen should be monitored closely, especially at 7%:93% mixtures. If any significant adverse effects are noted, the therapy should be stopped.[58]

SUMMARY CHECKLIST

- O_2 therapy is used to: (1) correct acute hypoxemia, (2) decrease the symptoms of chronic hypoxemia, and (3) decrease cardiopulmonary workload.
- The need for supplemental O_2 can be assessed with laboratory measures, clinical history, and bedside patient evaluation.
- In the care of adults, children, and infants older than 28 days, O_2 therapy is indicated if PaO_2 is less than 60 mm Hg or SaO_2 is less than 90%.
- Exposure to 100% O_2 for more than 24 hours should be avoided whenever possible; high FiO_2 is acceptable if the concentration can be decreased to 0.70 within 2 days and to 0.50 or less in 5 days.
- Concern that O_2 therapy can cause hypoventilation should never preclude administration of O_2 to a patient in need. Prevention of hypoxia always is the first priority.
- The three components of the "fire triangle" are oxygen, heat, and fuel.
- If an O_2 delivery system provides all of a patient's inspired gas, FiO_2 remains stable. If the device provides only part of the inspired gas, air dilutes the O_2, and FiO_2 can vary.
- O_2 provided with low-flow devices such as a nasal cannula always is diluted with air; the result is a low and variable FiO_2.
- Reservoir devices can provide higher FiO_2 than low-flow systems or can be used to conserve O_2.
- To avoid rebreathing, a flow of at least 5 L/min should be used with O_2 masks; for reservoir masks with bags, the flow must be sufficient to prevent bag collapse.
- A nonrebreathing reservoir circuit can provide a full range of FiO_2 (21% to 100%) at any needed flow to both intubated and non-intubated patients.
- High-flow systems supply a given O_2 concentration at a flow of at least 60 L/min.
- Because entrainment devices dilute source O_2 with air, they always provide less than 100% O_2. The more air entrained, the higher the total flow, but the delivered FiO_2 is lower.
- Air-entrainment nebulizers should be treated as fixed-performance devices only when set to deliver low O_2 concentration (≤35%).
- One way to achieve high FiO_2 with air-entrainment nebulizers is to connect two or more devices together in parallel.
- Back pressure decreases both the volume of entrained air and the total flow output of air-entrainment devices.
- A HFNC can be useful in treating moderate hypoxemia, especially for patients who do not tolerate oxygen masks and need supplemental humidity.
- A blending system allows precise control over FiO_2 and total flow output; most blending systems qualify as true fixed-performance delivery devices.
- An operational check of an O_2 blender should always be conducted before the device is used.
- O_2 therapy enclosures are used mainly in the care of children and infants. Problems include limited and highly variable FiO_2 and temperature control.
- The three Ps—purpose, patient, and performance of the device—should be considered in the selection or recommendation of an O_2 delivery system.
- Protocol-based oxygen therapy ensures the patient: (1) undergoes initial assessment, (2) is evaluated for protocol criteria, (3) receives a treatment plan that is modified to the need, and (4) stops receiving therapy as soon as it is no longer needed.
- In HBO therapy, O_2 is administered at a pressure greater than 1 atm for management of conditions such as air embolism and carbon monoxide poisoning.
- iNO improves blood flow to ventilated alveoli, reduces intrapulmonary shunting, improves arterial oxygenation, and decreases pulmonary vascular resistance and pulmonary arterial pressure.
- Heliox mixtures are used to reduce the work of breathing in large airways obstruction. The low density of heliox makes standard O_2 flowmeters inaccurate and provides inaccurate volume and flow measurement on ventilators not calibrated for its use.
- Carbogen is used in the management of some neonates with congenital heart disease, to treat hiccups and to prevent complete washout of CO_2 during cardiopulmonary bypass or extracorporeal gas exchange.

Lung Expansion Therapy

Daniel F. Fisher

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Understand the causes of atelectasis
- Identify which patients are at the greatest risk for developing atelectasis and needing lung expansion therapy.
- Define the clinical findings seen in atelectasis.
- Describe how lung expansion therapy is able to reverse atelectasis.
- List the indications, hazards, and complications associated with the various modes of lung expansion therapy.
- Describe the primary responsibilities of the respiratory therapist in planning, implementing, and evaluating lung expansion therapy.

CHAPTER OUTLINE

KEY TERMS

atelectasis
compression atelectasis
continuous positive airway pressure (CPAP)
deep breathing/directed cough
egophony
gas absorption atelectasis
incentive spirometry (IS)
intermittent positive airway pressure breathing (IPPB)
lobar atelectasis
noninvasive ventilation (NIV)
high-flow nasal cannula (HFNC)
positive expiratory pressure (PEP)

Pulmonary complications are common serious problems seen in patients who have undergone thoracic or abdominal surgery.[1,2] Such complications include **atelectasis** (alveolar collapse), pneumonia, and acute respiratory failure. These respiratory problems can be minimized or avoided if proper respiratory care is implemented during the perioperative period. The most common form of therapy used in high-risk patients is lung expansion therapy.

Lung expansion therapy encompasses a variety of respiratory care procedures designed to prevent or correct atelectasis. The most common modalities include **early patient mobilization, deep breathing/directed cough, incentive spirometry (IS), continuous positive airway pressure (CPAP), positive expiratory pressure (PEP), intermittent positive airway pressure breathing (IPPB), and high-flow nasal cannula (HFNC)**. The common purpose that all of these techniques share is improving pulmonary function by maximizing alveolar recruitment and optimizing airway clearance.

Various lung expansion therapies can be effective in preventing or correcting atelectasis in selected patients.[1] There is no one specific method to apply in a given situation because no advantage of any one method has been established. In fact, evidence suggests that patient preference is as important as the chosen therapy.[3] The most efficient use of resources is a primary concern with any plan to apply lung expansion therapy.

All of the following therapies share a common goal, to increase functional residual capacity (FRC). In other words, all of these supplemental techniques are designed to simulate a deep breath or sigh. In consultation with the prescribing physician, the respiratory therapist (RT) should assist in identifying patients most likely to benefit from lung expansion therapy, recommend and

initiate the appropriate and most efficient therapeutic approach, monitor the patient's response, and alter the treatment regimen as needed.

CAUSES AND TYPES OF ATELECTASIS

Although atelectasis can occur from a large variety of problems, this chapter focuses on the two primary types associated with postoperative or bedridden patients who are breathing spontaneously without mechanical assistance: (1) gas absorption atelectasis and (2) compression atelectasis. **Gas absorption atelectasis** can occur either when there is a complete interruption of ventilation to a section of the lung or when there is a significant shift in ventilation/perfusion ($\dot{V}/\dot{Q}$). Gas distal to an obstruction is absorbed by blood passing through the pulmonary capillaries, which eventually causes partial collapse of the nonventilated alveoli. When ventilation is compromised in a larger airway or bronchus, **lobar atelectasis** can develop.

Compression atelectasis occurs when the transthoracic pressure (the pressure difference between the body surface and the alveoli) exceeds the transalveolar pressure (P_{AL}) (the pressure difference between the alveoli and pleural space).[2,4,5] Compression atelectasis is primarily caused by mechanisms that increase this pressure gradient. This situation is common with general anesthesia, with the use of sedatives and bed rest, when deep breathing is painful, as when broken ribs are present or surgery has been performed on the upper abdominal region, and in morbidly obese patients. Weakening or impairment of the diaphragm can also contribute to compression atelectasis. Compression atelectasis also results from fluid overload. It is a common cause of atelectasis in hospitalized patients. It may occur in combination with gas absorption atelectasis in a patient with excessive airway secretions who breathes with small tidal volumes for a prolonged period and in the presence of expiratory flow limitation.

Factors Associated With Causing Atelectasis

Patients who have difficulty taking deep breaths without assistance include those with significant obesity, patients with neuromuscular disorders, patients under heavy sedation, and patients who have undergone upper abdominal or thoracic surgery. Diaphragmatic position and function are major contributors to atelectasis. In an anesthetized patient, there is a cephalad (toward the head) shift of the diaphragm. For patients who are supine and breathing spontaneously, the lower, dependent portion of the diaphragm performs the most movement. The opposite occurs in patients who are paralyzed—the upper portion of the diaphragm is primarily involved in movement.[4,5] Patients undergoing lower abdominal surgery are at relatively less risk for developing atelectasis than patients undergoing upper abdominal or thoracic surgery. Neuromuscular injury patients are prone to respiratory complications, the most common of which is atelectasis. Atelectasis can occur in any patient who cannot or does not take deep breaths periodically and in patients who are restricted to bed rest for any reason.[6] Atelectasis is one of the leading causes of hypoxemia after abdominal surgery and may account for 24% of deaths within 6 days of surgery.[7] It is good clinical practice to consider atelectasis during assessment of postoperative patients.

Impairment of the function of pulmonary surfactant can also have an impact on the development of atelectasis. Surfactants decrease the surface tension of the walls of the alveoli. When there is deterioration of surfactant function or amount of this vital protein, the resulting increase in surface tension can cause alveoli to collapse.[5]

Most postoperative patients also have problems coughing effectively because of their reduced ability to take deep breaths. An ineffective cough impairs normal clearance mechanisms and increases the likelihood of retained secretions, which could lead to the development of absorption atelectasis and pneumonia in a patient with excessive mucus production. Patients with a history of lung disease that causes increased mucus production (e.g., chronic bronchitis) are most prone to develop complications in the postoperative period. Similarly, a significant history of cigarette smoking should alert the RT to the high risk for respiratory complications after surgery. Such patients must be identified in the preoperative period and considered strong candidates for airway clearance and lung expansion therapy. Elective surgery for these patients may need to be postponed in some cases until such therapies can be included in the treatment plan. Lung expansion therapy in the postoperative period may help to improve clearance of secretions by improving the effectiveness of coughing and secretion removal.

RULE OF THUMB

The closer the incision is to the diaphragm, the greater the risk for postoperative atelectasis. Patients with a history of inadequate nutritional intake, as shown by an albumin level less than 3.2 mg/dL, have an increased risk for pulmonary complications in the postoperative period. This increased risk is most likely due to inadequate strength of the inspiratory muscles to maintain a normal vital capacity (VC).

Laparoscopic surgery uses a scope inserted through small incisions to perform the procedure. Use of this technique has gained widespread acceptance in gastrointestinal procedures because of shortened recovery time, less pain for the patient, and smaller incisions. All of these factors also lessen the opportunities for developing postoperative pulmonary complications.[8,9]

MINI CLINI

Risk Factors for Atelectasis

Problem

The RT is called to evaluate a 47-year-old obese man admitted to the hospital for upper abdominal surgery. He has a 60 pack-year smoking history and is scheduled for surgery tomorrow morning. Examination reveals bilateral inspiratory and expiratory coarse crackles and expiratory wheezes. He is alert and oriented with normal vital signs. His past medical history is positive for diabetes and kidney stones. What factors are present that predispose this patient to postoperative atelectasis? What treatment plan should the RT recommend?

Discussion

Several important risk factors are present in this patient. The three most important are the patient's history of smoking, obesity, and the upper abdominal site of surgery. The findings of adventitious lung sounds and positive smoking history are very suggestive of a current pulmonary problem that would probably require bronchial hygiene and bronchodilators before surgery. Postoperatively, this high-risk patient would need careful monitoring for risks of atelectasis.

CLINICAL SIGNS OF ATELECTASIS

RTs must be able to recognize the clinical signs of atelectasis in patients so that appropriate therapy can be implemented in a timely fashion. The patient's medical history often provides the first clue in identifying atelectasis. Recent upper abdominal or thoracic surgery in any patient should suggest possible atelectasis. A history of chronic lung disease or cigarette smoking or both provides additional evidence that the patient is prone to respiratory complications after major surgery or prolonged bed rest.

MINI CLINI

Physical Signs of Atelectasis

Problem

How does a patient with atelectasis present during a physical assessment?

Discussion

Depending on the severity of atelectasis, the patient could be lying in bed and start to have a requirement for supplemental oxygen. On auscultation, the breath sounds can range from shallow and distant. When asking the patient to take a deep breath, you may hear faint crackles and see an improvement in oxygen saturation.

Moderate atelectasis can present itself with an increase in respiratory rate and a consistently lower SpO_2. Breath sounds may have definite crackles and you may also hear occasional bronchial breath sounds.

Severe atelectasis can present by having the patient complain of dyspnea, requiring an increasing amount of oxygen and absent breath sounds over the affected area with distinct bronchial breath sounds in the surrounding margins.

The physical signs of atelectasis may be absent or very subtle if the patient has minimal atelectasis. When the atelectasis involves a more significant portion of the lungs, the patient's respiratory rate increases proportionally. Fine, late-inspiratory crackles may be heard over the affected lung region. These crackles are produced by the sudden opening of distal airways with deep breathing. Bronchial-type breath sounds may be present as the lung becomes more consolidated with atelectasis. Diminished breath sounds are common when excessive secretions block the airways and prevent transmission of breath sounds. Another lung sound that may be present with consolidation is **egophony**. The consolidated tissue will decrease transmission of the higher-frequency lung sounds. Egophony has also been considered to be present if, when asked to say the letter "E," the patient sounds to the practitioner as if he or she were saying "Aaay." Tachycardia may be present if atelectasis leads to significant hypoxemia.

RULE OF THUMB

There is a direct relationship between the spontaneous respiratory rate and the degree of atelectasis present. Typically, as atelectasis progresses, respiratory rate increases proportionally.

The chest x-ray is often used to confirm the presence of atelectasis. The atelectatic region of the lung has increased opacity. Evidence of volume loss is present in patients with significant atelectasis. Direct signs of volume loss on the chest film include displacement of the interlobar fissures, crowding of the pulmonary vessels, and air bronchograms. Indirect signs include: elevation of the diaphragm; shift of the trachea, heart, or mediastinum; pulmonary opacification; narrowing of the space between the ribs; and compensatory hyperexpansion of the surrounding lung.

LUNG EXPANSION THERAPY

All modes of lung expansion therapy increase lung volume by increasing the P_{AL} gradient. As detailed elsewhere in this text (Chapters 47 and 52), P_{AL} gradient represents the difference between the alveolar pressure (P_{alv}) and the pleural pressure (P_{pl}):

$$P_{AL} = P_{alv} - P_{pl}$$

With all else being constant, the greater the P_{AL} gradient, the more the alveoli expand.

As depicted in Fig. 43.1, the P_{AL} gradient can be increased by either: (1) decreasing the surrounding P_{pl} (see Fig. 43.1A) or (2) increasing the P_{alv} (see Fig. 43.1B). A spontaneous deep inspiration increases the P_{AL} gradient by decreasing the P_{pl}. Applying positive pressure to the lungs increases the P_{AL} gradient by increasing the pressure inside the lung (P_{alv}).

All lung expansion therapies use one of these two approaches. IS enhances lung expansion through a spontaneous and sustained decrease in P_{pl}. Positive airway pressure techniques increase P_{alv} in an effort to expand the lung. Positive pressure lung expansion therapies may apply pressure during inspiration only, during expiration only (as in HFNC, PEP, and flutter valves), or during both inspiration and expiration (CPAP). IS and other patient-directed therapies require an alert, cooperative patient who is capable of taking a deep breath.

The goal of any lung expansion therapy should be to implement a plan that provides an effective strategy in the most efficient manner. Staff time and equipment are the two major issues related to efficiency. For a patient with minimal risk of postoperative atelectasis, deep breathing exercises, frequent repositioning, and early ambulation are usually effective and can be done with minimal coaching and time from clinicians and without equipment.[5] For a patient at high risk for atelectasis (e.g., a patient undergoing upper abdominal surgery), IS is usually instituted. The additional staff time and equipment are justified in this high-risk group. Positive pressure therapy requires significantly more staff time and equipment and is reserved for high-risk patients who cannot perform IS techniques.

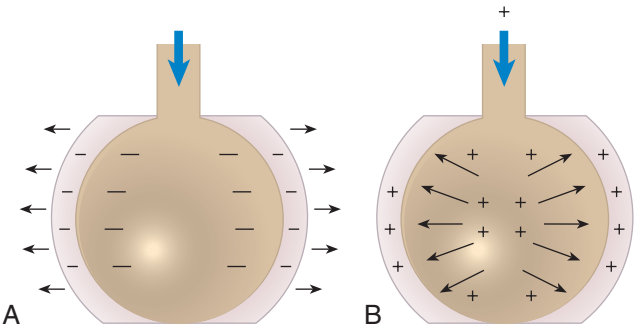

Fig. 43.1 Transalveolar pressure gradients with spontaneous inspiration (A) and positive pressure inspiration (B).

Baseline Assessment

Before beginning therapy, a baseline patient assessment should be conducted. This information helps to individualize the treatment and allows objective evaluation of the patient's subsequent response to therapy. Together with the patient's medical history, this baseline assessment also alerts the RT to possible problems or hazards associated with administering any therapy to the patient. The baseline assessment includes a general evaluation of the patient's clinical status and a specific assessment related to the chosen therapeutic goals. The general assessment, common to all patients for whom respiratory care is ordered, includes: (1) measuring vital signs, (2) assessing the patient's appearance and sensorium, (3) assessing the breathing pattern through chest auscultation, and (4) the patient's level of motivation and their ability to follow instructions.

Early Mobilization of the Patient

Intensive Care Unit Patient

Evidence supports that it is better for the overall recovery of patients to get them out of bed and provide early ambulation.[10-13] The complications of prolonged bed rest include cardiovascular, pulmonary, gastrointestinal, and skin integrity issues. Pulmonary complications of immobility include: development of atelectasis, pneumonia, and pulmonary emboli (PE).[11-13] Rates of early mobilization for intensive care unit (ICU) patients have been increasing in both Europe and the United States, along with an emphasis on decreasing morbidity in the ICU. Mobilization includes not only walking but also sitting, standing, and getting out of bed into a chair. As the patient changes body position, his or her breathing changes, as does the gas distribution within the lung. Improvements in ventilation results in less alveolar collapse.

Because of the beneficial pulmonary effects of early mobilization of the post–abdominal surgery patient, it has been suggested that mobilization should be considered as early as the day of surgery.[14] With the increasing knowledge of the benefits of early mobilization, the paradigm must change from thinking that a patient is too sick to get out of bed to one in which we must think that a patient is too sick to stay in bed.[13]

To move patients from the bed, it is important that they are not completely sedated. Along with early mobilization, there are other benefits of lighter sedation and even "sedation vacations" when all sedation for the patient is temporarily discontinued in order to reassess the need for sedation. Having a patient who is able to respond to the caregiver allows for better pain control with decreased risk of sedation-related complications.[15,16]

Non–Intensive Care Unit Patient

Having a non-ICU patient mobilize frequently may not have the technical roadblocks that are seen in the ICU such as multiple intravenous (IV) pumps, cardiovascular support devices (intra-aortic balloon pumps, ventricular assist devices, impella, or even extracorporeal membrane oxygenate [ECMO]),[17] but there is a personnel cost to moving the patient. The patient-nurse ratio is typically larger on the general medicine/surgery floors than in the ICU. The availability of support staff will also need to be coordinated.

Although early mobilization does not classify as a procedure, it does have distinct benefits in decreasing morbidity and mortality.[12,14,18,19] Early mobilization is a true multidisciplinary approach that requires the various members of the healthcare team (RT, nurse, physical therapist) to be present at the same time. Having the patient get out of bed and walk will improve ventilation and perfusion, which will prevent or lessen the occurrence of developing atelectasis, making the need for the following therapies less likely.

RULE OF THUMB—EARLY MOBILIZATION

Many of the techniques described in this chapter—IS, CPAP, IPPB, and PEP—simulate normal function if the patient were to be standing and walking. All are strong arguments for early mobilization. So get your patients out of bed and help them walk!

Incentive Spirometry

The purpose of IS is to coach the patient to take a sustained maximal inspiratory (SMI) effort resulting in a decrease in P_{AL} and maintaining the patency of airways at risk for closure. Because of its simplicity, IS has been the mainstay of lung expansion therapy for many years. IS devices are designed to mimic natural sighing by encouraging patients to take slow, deep breaths simulating a yawn or sigh. IS can be performed using devices that provide visual cues to patients when the desired inspiratory flow or volume has been achieved. IS was first described in 1972, which led to the development of a visual feedback device in 1973.[20]

The desired volume and number of repetitions to be performed are initially set by the RT or other qualified caregiver. The inspired volume goal is set on the basis of predicted values or observation of initial performance. The true benefit from IS is best achieved by repeated use and proper technique.[21]

Physiologic Basis

A sustained maximal inspiration is functionally equivalent to performing an FRC to inspiratory capacity (IC) maneuver, followed by a breath hold. Fig. 43.2 compares the alveolar and P_{pl} changes occurring during a normal spontaneous breath and an SMI during IS.

During the inspiratory phase of spontaneous breathing, the decrease in P_{pl} caused by expansion of the thorax is transmitted to the alveoli. With P_{alv} now negative, a pressure gradient is created between the airway opening and the alveoli. This transrespiratory pressure gradient causes gas to flow from the airway into the alveoli. Within certain limits, the greater the transrespiratory pressure gradient, the more lung expansion occurs.

RULE OF THUMB—INCENTIVE SPIROMETRY

IS was first developed as a simulated yawn. It was noted that as the patient yawns (sighs), oxygenation improves.

Indications

Indications for IS are listed in Box 43.1. The primary indication for IS is to treat existing atelectasis. IS may also be used as a

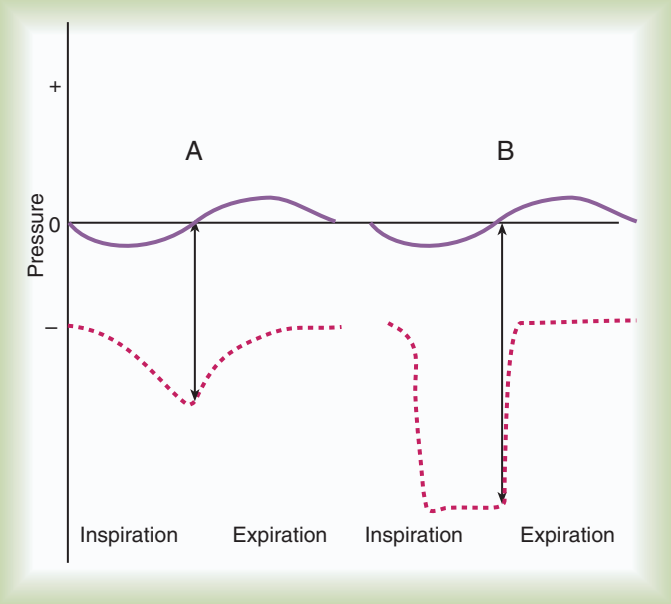

Fig. 43.2 Alveolar *(solid lines)* and pleural *(dotted lines)* pressure changes during spontaneous breathing *(A)* and sustained maximal inspiration *(B)*. Note the difference in transalveolar pressure (P_{AL}) gradients *(double arrows)*.

BOX 43.1 Indications for Incentive Spirometry

- Presence of pulmonary atelectasis
- Presence of conditions predisposing to atelectasis
  - Upper abdominal surgery
  - Thoracic surgery
  - Surgery in patients with COPD
- Presence of a restrictive lung defect associated with quadriplegia or dysfunctional diaphragm

COPD, Chronic obstructive pulmonary disease.

BOX 43.2 Contraindications to Incentive Spirometry

- Patient cannot be instructed or supervised to ensure appropriate use of device
- Patient cooperation is absent, or patient is unable to understand or demonstrate proper use of device
- Patient is unable to deep breathe effectively (VC < 10 mL/kg *or* IC < ⅓ of predicted)

IC, Inspiratory capacity.

preventive measure when conditions exist that make the development of atelectasis likely.[7]

Contraindications

IS is a simple and relatively safe modality. For this reason, contraindications are few (Box 43.2).

Hazards and Complications

Given its normal physiologic basis, IS presents few major hazards and complications; those that can occur are listed in Box 43.3.

BOX 43.3 Hazards and Complications of Incentive Spirometry

- Hyperventilation and respiratory alkalosis
- Discomfort secondary to inadequate pain control
- Pulmonary barotrauma
- Exacerbation of bronchospasm
- Fatigue

Acute respiratory alkalosis is the most common problem and occurs when the patient performs IS too rapidly or if the prescribed frequency of therapy is mismatched.[22] Dizziness and numbness around the mouth are the most frequently reported symptoms associated with respiratory alkalosis. This can be easily corrected with careful instruction and monitoring of the patient. Discomfort with deep inspiratory efforts due to pain is usually the result of inadequate pain control in a postoperative patient. Appropriate pain control before and during therapy is important.

Equipment

The original IS devices were electronic and provided the user with visual feedback even though the equipment needed for SMI is typically simple, portable, and inexpensive. Although advances in technology have produced more complex devices, there is no evidence that these devices produce any better outcomes than their lower-cost, disposable counterparts.

IS devices can generally be categorized as volume oriented or flow oriented. True volume-oriented devices measure and visually indicate the volume achieved during an SMI. The most popular true volume-oriented IS devices use a bellows that rises according to the inhaled volume. When the patient reaches a target inspiratory volume, a controlled leak in the device allows the patient to sustain the inspiratory effort for a short period (usually 5 to 10 seconds). Because the bellows types of IS devices are bulky and large, smaller devices that indirectly indicate volume based on flow through a fixed orifice have been developed. These devices sacrifice accurate measurement of the inhaled volume for portability and smaller size (Fig. 43.3).

Flow-oriented devices measure and visually indicate the degree of inspiratory flow (Fig. 43.4). This flow can be equated with volume by assessing the duration of inspiration or time (flow × time = volume). Both flow-oriented and volume-oriented devices attempt to encourage the same goal for the patient: an SMI effort to prevent or correct atelectasis. There is no benefit of one type of IS over the other.

Administration

The successful application of IS involves three phases: planning, implementation, and follow-up. Because many of the components of this process are similar to those previously described, we highlight only the key points and differences in approach.

Preliminary planning. During preliminary planning, the need for IS should be determined by careful patient assessment. Once the need is established, planning should focus on selecting specific therapeutic outcomes. Box 43.4 lists potential outcomes that can be considered for patients receiving IS.

Fig. 43.3 Volumetric Incentive Spirometer. (Courtesy DHE Healthcare, Canastoga, NY.)

Fig. 43.4 Flow-Oriented Incentive Spirometer. (From DeWit S: *Fundamental concepts and skills for nursing*, ed 2, St Louis, 2004, Saunders.)

BOX 43.4 Potential Outcomes of Incentive Spirometry

- Decrease or elimination of atelectasis
- Improved breath sounds
- Normal or improved chest x-ray
- Increased SpO_2
- Increased VC
- Improved inspiratory muscle performance and cough

SpO_2, Oxygen saturation.

Patients scheduled for upper abdominal or thoracic surgery should be screened before undergoing the surgical procedure. Assessment conducted at this point helps to identify patients at high risk for complications and allows determination of their baseline lung volumes and capacities. This approach provides an opportunity to orient high-risk patients to the procedure before undergoing surgery, increasing the likelihood of success when IS is provided after surgery.

Implementation. Successful IS requires effective patient teaching. The RT should set an initial goal that is attainable by the patient yet requires a moderate effort. Setting an initial goal that is too low for the patient results in little incentive and an ineffective maneuver, at least initially. The patient should be instructed to inspire slowly and deeply to maximize the distribution of ventilation.

The RT should watch the patient perform the initial inspiratory maneuvers and ensure the patient uses correct technique. Correct technique calls for diaphragmatic breathing at slow to moderate inspiratory flows. Demonstration is probably the most effective way to assist patient understanding and cooperation. Both the operation of the device and the proper breathing technique can be explained easily when the RT uses himself or herself as an example, and much trial and error can be avoided.

Many patients have difficulty with the slow inspiration followed by the breath hold. Nonetheless, patients should be encouraged to try not to breathe in too fast or slowly and to attempt a brief breath hold.

A normal exhalation should follow the breath hold, and the patient should be given the opportunity to rest as long as needed before the next SMI maneuver. Some patients in the early postoperative stage may need to rest for 30 seconds to 1 minute between maneuvers. This rest period helps to avoid a common tendency by some patients to repeat the maneuver at rapid rates, causing respiratory alkalosis. The goal is not rapid, partial lung inflation but intermittent, maximal inspiration.

The exact number of sustained maximal inspirations needed to reverse or prevent atelectasis is not known and probably varies according to the patient's clinical status. In fact, numerous studies have failed to report a standard frequency for either number of breaths per session or even how often to repeat the exercise during the day.[23] However, because healthy individuals average approximately six sighs per hour, an IS regimen should focus on ensuring a minimum of 5 to 10 SMI maneuvers each hour.[22]

Follow-up. Assessing the patient's performance is vital to ensuring achievement of goals. To do so, the RT should make return visits to monitor treatment sessions until the correct technique and appropriate effort are achieved. Suggested monitoring activities for IS are outlined in Box 43.5.

After the patient has demonstrated mastery of technique, IS may be performed with minimal supervision. For patients with a neuromuscular disease or spinal injury, the use of a mechanical cough device (insufflator-exsufflator) (see Chapter 44) may provide a similar therapeutic objective. There is a lack of supporting data that IS has an effect of preventing or reversing pulmonary complications in post-cardiac surgical patients or in those patients who have recently had upper abdominal surgery.[20,24]

BOX 43.5 Monitoring Patients Receiving Incentive Spirometry

Observe patient performance and use:

- Frequency of sessions
- Number of breaths per session
- Volume and flow goals achieved
- Breath hold maintained
- Effort and motivation
- Periodic observation of patient compliance, with additional instruction as needed
- Device within reach of patient and patient encouraged to perform independently
- Vital signs and breath sounds

BOX 43.6 Clinical Situations Contraindicating Intermittent Positive Airway Pressure Breathing Therapy

- Tension pneumothorax
- ICP >15 mm Hg
- Hemodynamic instability
- Active hemoptysis
- Tracheoesophageal fistula
- Recent esophageal surgery
- Radiographic evidence of blebs
- Recent facial, oral, or skull surgery
- Singultus (hiccups)
- Nausea

ICP, Intracranial pressure.

Noninvasive Ventilation

Noninvasive ventilation (NIV) provides breathing support to patients with inadequate ability to ventilate. NIV has been documented to have beneficial effects for patients who may need periodic, short-term support or patients who are experiencing exacerbations of pulmonary disease. NIV offers some benefits over traditional, invasive ventilation due to lower infection risk and reduced need for sedation because of the absence of an artificial airway. NIV is discussed in detail elsewhere (Chapter 50). In addition, variations of NIV, including IPPB, CPAP, HFNC, and PEP therapy, can be potentially valuable lung expansion tools and are discussed in the following sections.

Intermittent Positive Airway Pressure Breathing

Physiologic Basis

IPPB is a specialized form of NIV used for relatively short treatment periods (approximately 15 minutes per treatment). The intent of IPPB, unlike NIV, is not to provide full ventilatory support but to provide machine-assisted deep breaths assisting the patient to deep breathe and stimulate a cough. This section discusses the use of IPPB as a modality for the treatment of atelectasis.

IPPB has historically consisted of providing an aerosol under positive pressure, augmenting the patient's own inspiratory efforts and thus resulting in a larger tidal volume (V_T) than could be spontaneously generated. The effectiveness of IPPB as an enhancement for aerosol delivery has been shown to be incorrect. In fact, IPPB does not improve aerosol deposition at all.[3] The American Association for Respiratory Care (AARC) clinical practice guidelines (CPG) for IPPB even recommends a 10-fold increase in medication dosage when compared with other aerosol delivery methods.[14] Lung volumes are increased in IPPB because $P_{alv} > P_{pl}$. Depending on the mechanical properties of the lung, P_{pl} may exceed atmospheric pressure during a portion of inspiration. As with spontaneous breathing, the recoil force of the lung, stored as potential energy during the positive pressure breath, causes a passive exhalation. As gas flows from the alveoli out to the airway opening, P_{alv} decreases to atmospheric level, while P_{pl} is restored to its normal subatmospheric range (Fig. 43.5).

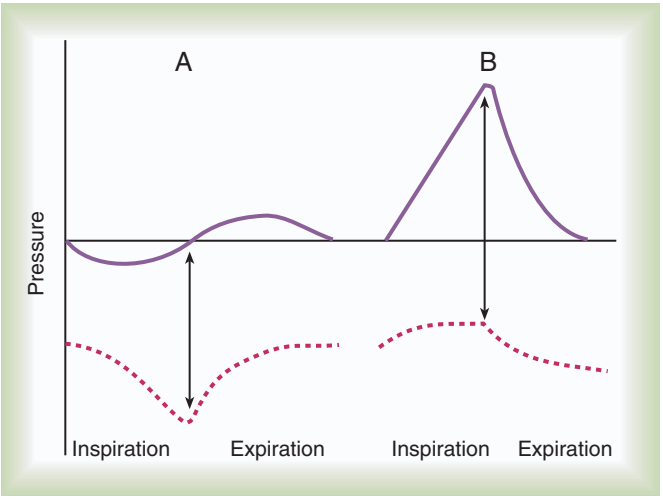

Fig. 43.5 Alveolar *(solid lines)* and pleural *(dotted lines)* pressure changes during spontaneous breathing *(A)* and intermittent positive airway pressure breathing *(B)*. Note the difference in transalveolar pressure (P_{AL}) gradients *(double arrows)*.

Indications

Although IPPB is not an effective aerosol delivery system, periodic sessions of positive pressure ventilation provided noninvasively can be useful in the treatment of pulmonary complications or exacerbations of lung disease.[12,15-17] IPPB should not be used as a single treatment modality for a patient with absorption atelectasis because of excessive airway secretions. Appropriate systemic hydration and airway clearance techniques should be used to assist in removal of excessive secretions.

In concept, IPPB treatment should provide the patient with augmented tidal volumes, achieved with minimal effort. *There are no data to support the use of IPPB as a method of preventing or expanding atelectasis.* The techniques listed later are more effective.

Contraindications

There are several clinical situations in which IPPB should not be used (Box 43.6). With the exception of untreated tension pneumothorax, most of these contraindications are relative. A patient with any of the conditions listed in Box 43.6 should be carefully evaluated before IPPB therapy is begun.

Hazards and Complications

As with any clinical intervention, certain hazards and complications are associated with IPPB. These potential problems should

BOX 43.7 Hazards and Complications of Intermittent Positive Airway Pressure Breathing

- Hyperventilation and respiratory alkalosis
- Discomfort secondary to inadequate pain control
- Pulmonary barotrauma
- Exacerbation of bronchospasm
- Fatigue

be addressed in the initial stages of planning for IPPB. The most common complication associated with IPPB is inducing respiratory alkalosis. This problem is easily avoided through proper coaching of the patient before and during treatment.

Another potential complication of IPPB is gastric distention; this occurs when gas from the IPPB device passes directly into the esophagus. Gastric distention is uncommon in an alert patient but is a significant risk for an obtunded patient. Normally, the esophagus does not open until a pressure of approximately 20 to 25 cm H_2O has been reached. Gastric distension represents the greatest risk in patients receiving IPPB at high pressures. The major hazards and complications of IPPB are listed in Box 43.7.

Administration

Effective IPPB requires careful preliminary planning, individualized patient assessment and implementation, and thoughtful follow-up.

Preliminary planning. During preliminary planning, the need for IPPB is determined and desired therapeutic outcomes are established. Box 43.8 lists potential accepted and desired outcomes of IPPB therapy. Not all the outcomes listed in Box 43.8 apply to every patient.

RULE OF THUMB

IPPB was once a mainstay therapy for respiratory care. Its nearest cousin, noninvasive ventilation, uses a mask. IPPB was generally given via a mouthpiece and nose clips.

MINI CLINI

Problem

While covering a surgical step-down floor, you are called to provide IPPB with a bland aerosol to help a patient with postoperative atelectasis.

Discussion

Because you are on the floor, you go to the patient's room, introduce yourself, and assess their pulmonary status. After you have completed your evaluation, you speak with the physician who ordered IPPB to find out what his therapeutic goals would be and you relay your evaluation of the patient. The physician states that the patient has severe atelectasis and he is concerned about developing pneumonia and wanted to try IPPB to help with lung recruitment and secretion clearance. You make the suggestion to try CPAP and give a flutter valve to the patient to use when not wearing the CPAP mask. The distending pressure from the CPAP will help to re-recruit the lung, while using PEP may aid secretion clearance by keeping the airways from collapsing on exhalation.

BOX 43.8 Potential Outcomes of Intermittent Positive Airway Pressure Breathing Therapy

- Decrease or elimination of atelectasis
- Improved breath sounds
- Normal or improved chest x-ray
- Increased SpO_2
- Increased VC
- Improved inspiratory muscle performance and cough

SpO_2, Oxygen saturation.

BOX 43.9 Monitoring Intermittent Positive Airway Pressure Breathing Therapy

Machine Performance

- Sensitivity
- Peak pressure
- Flow setting
- FiO_2

Patient Response[a]

- Breathing rate and expired volume
- Peak flow or FEV_1/FVC%
- Pulse rate and rhythm (from electrocardiogram if available)
- Sputum quantity, color, consistency, and odor
- Mental function
- Skin color
- Breath sounds
- Blood pressure
- SpO_2 (if hypoxemia is suspected)
- ICP (in patients for whom ICP is important)
- Chest x-ray (when appropriate)
- Subjective response to therapy

[a]Items should be chosen as appropriate for the specific patient.
FEV_1, Forced expiratory volume in 1 s; *FVC*, forced vital capacity; *ICP*, intracranial pressure; *SpO_2*, oxygen saturation.

Evaluating alternatives. Before starting IPPB, the RT and prescribing physician must determine therapeutic objectives for the treatment and whether simpler and less costly methods might be as effective in achieving the desired outcomes.

Discontinuation and Follow-Up

Depending on the goals of therapy and condition of the patient, IPPB treatments typically last 10 to 15 minutes. Follow-up activities include posttreatment assessment of the patient, recordkeeping, and equipment maintenance.

Posttreatment assessment. At the end of a treatment session, the patient assessment is repeated. As with the baseline assessment, this follow-up evaluation has two components. A follow-up evaluation should focus on determining any pertinent changes in vital signs, sensorium, and breath sounds, with emphasis on identifying possible untoward effects.

Treatment frequency should be determined by assessing patient response to therapy (Box 43.9). For acute care patients, orders should be reevaluated based on patient response to therapy at least every 72 hours or with any change of patient status.

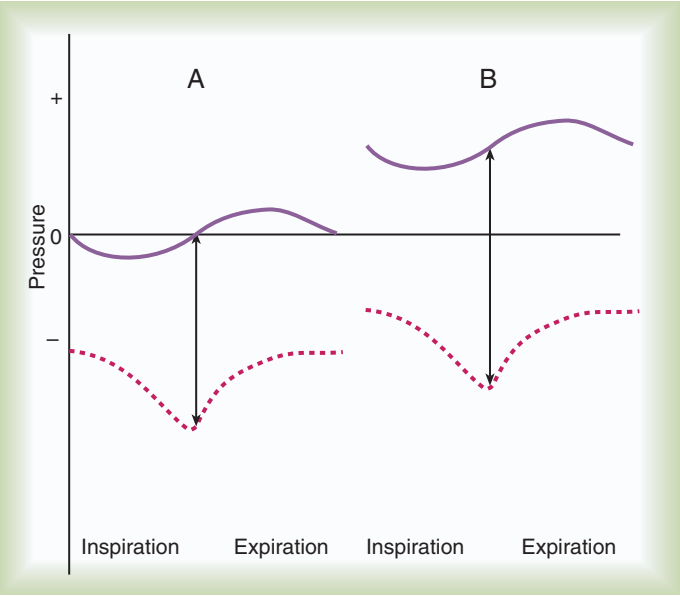

Fig. 43.6 Alveolar *(solid lines)* and pleural *(dotted lines)* pressures during spontaneous breathing (A) and continuous positive airway pressure (B). Note the difference in transalveolar pressure (P_{AL}) gradients *(double arrows)*.

BOX 43.10 Clinical Situations Contraindicating Continuous Positive Airway Pressure Therapy

- Tension pneumothorax/untreated pneumothorax
- ICP >15 mm Hg
- Hemodynamic instability
- Active hemoptysis
- Tracheoesophageal fistula
- Radiographic evidence of blebs
- Recent facial, oral, or skull surgery
- Nausea
- Hypoventilation

ICP, Intracranial pressure.

RULE OF THUMB

Many different types of interfaces can be used for CPAP therapy. They range from nasal prongs (common in neonates, Chapter 54), nasal masks, oronasal masks, and helmets. The ideal interface is that which is comfortable for the patient, does not produce excessive pressure on the face, and minimizes dead space (V_D).

Continuous Positive Airway Pressure

Physiologic Basis

Atelectasis causes a pulmonary shunt and contributes to impaired gas exchange. For areas with a low ventilation and perfusion ($\dot{V}/Q$) and an elevated FiO_2, the patient is at risk for developing gas absorption atelectasis, further complicating the situation.[25] CPAP provides a distending pressure to reinflate the collapsed airways thus improving $\dot{V}/Q$.

As can be seen in Fig. 43.6, CPAP elevates and maintains high alveolar and airway pressures throughout the full breathing cycle; this increases P_{AL} gradient throughout both inspiration and expiration. Typically, a patient on CPAP breathes through a pressurized circuit against a threshold resistor, with pressures maintained between 5 cm H_2O and 20 cm H_2O. To maintain system pressure throughout the breathing cycle, CPAP requires a source of pressurized gas.

Indications

Although evidence supports the use of CPAP therapy in the treating postoperative atelectasis, as with all mechanical techniques, the duration of beneficial effects appears limited. The corresponding increase in FRC may be lost within 10 minutes after the end of the treatment. For this reason, it has been suggested that CPAP should be used on a continuous basis until the patient recovers.

CPAP by mask also has been used to treat cardiogenic pulmonary edema. In such patients, CPAP reduces venous return and cardiac filling pressures, which is helpful in reducing pulmonary vascular congestion. Lung compliance is improved, and the work of breathing is decreased. The improvement in lung compliance and the removal of the edema from the alveoli will result in improved ventilation (decreased dead space V_D/V_T) and thus a decrease in hypercapnia.

Contraindications

Intermittent use of CPAP for correcting atelectasis is contraindicated when certain clinical situations exist. A patient who is hemodynamically unstable is unlikely to tolerate CPAP for even a short period. For those patients who are suspected to have hypoventilation, NIV is usually a better option than CPAP. CPAP is also inappropriate when the patient has nausea, facial trauma, untreated pneumothorax, or elevated intracranial pressure (ICP).

Hazards and Complications

Most hazards and complications associated with CPAP are caused by either the increased pressure or the apparatus (Box 43.10). The increased work of breathing caused by the apparatus can lead to hypoventilation and hypercapnia. An improperly fitted mask can also have detrimental effects on the success of CPAP. Too large a mask will increase the V_D.[26] A mask that is too small would require being tightly strapped onto the patient's face. This would increase their chances of developing a pressure-related wound. In addition, because CPAP does not augment spontaneous ventilation, patients with an accompanying ventilatory insufficiency may hypoventilate when CPAP is applied. Barotrauma is a potential hazard of CPAP and is more likely to occur in a patient with emphysema and blebs. Gastric distension may occur, especially if CPAP pressures greater than 25 cm H_2O are needed. This condition may lead to vomiting and aspiration in a patient with an inadequate gag reflex. A special case is the obese patient who may actually require high levels of CPAP to counteract the weight of their abdomen on the diaphragm.

Monitoring and Troubleshooting

CPAP poses a risk of hypoventilation. Experience with long-term CPAP shows that patients must be able to maintain adequate elimination of carbon dioxide on their own if the therapy is to

be successful. For these reasons, patients receiving CPAP must be closely and continuously monitored for untoward effects. In addition, it is vital that the CPAP device be equipped with a means to monitor the pressure delivered to the airways and alarms to indicate the loss of pressure owing to system disconnect or mechanical failure. There should also be a device allowing for excessive pressure to be released (pop-off). These are essential components of any CPAP device (Box 43.11).

The development of new CPAP units and improvement on the interface itself have addressed some of the comfort issues and correction of leakage associated with CPAP. The RT must also ensure that the flow is adequate to meet the patient's needs with the use of CPAP systems. Flow adjustments are made by carefully observing the airway pressure. Flow generally can be considered adequate when the system pressure decreases no more than 1 to 2 cm H_2O during inspiration.

BOX 43.11 Hazards and Complications of Continuous Positive Airway Pressure Therapy

- Barotrauma, pneumothorax
- Nosocomial infection
- Hypercarbia
- Hemoptysis
- Pressure ulcers from mask
- Gastric distension
- Impaction of secretions (associated with inadequately humidified gas mixture)
- Impedance of venous return
- Hypoventilation
- Increased V_D
- Vomiting and aspiration

V_D, Dead space.

Administration

Early administration of CPAP has been found to be beneficial for both reversing atelectasis and improving $\dot{V}/Q$.

Equipment. CPAP is most commonly delivered using either specialized CPAP machines (Fig. 43.7) or ventilators. These devices allow for a more consistent level of positive pressure and provide the benefit of some level of patient monitoring. In the case where ICU-level ventilators are used, this includes monitoring of respiratory rate, airway pressures, and alarms. In the event of a disconnect or if the patient becomes apneic, the ventilator alarms can provide a measure of safety not realized with a high-flow system and resistor valve.

Procedures. Whether used on an intermittent or continuous basis, CPAP is a complex and potentially hazardous approach to patient management. As with all therapies, the appropriate CPAP level for a patient must be determined on an individual basis. Initial application and monitoring require a broader range of knowledge and skill than is required for simpler modes of lung expansion therapy (Box 43.12).

Preliminary planning. As with all respiratory care, effective CPAP therapy requires careful planning, individualized patient

Fig. 43.7 Various continuous positive airway pressure systems. See text for description.

BOX 43.12 Potential Outcomes of Continuous Positive Airway Pressure Therapy

- Improved VC
- Increased FEV_1 or peak flow
- Enhanced cough and secretion clearance
- Improved chest x-ray
- Improved breath sounds
- Improved oxygenation
- Improved patient comfort

FEV_1, Forced expiratory volume in 1 s.

Device Performance

- Mask fit
- Set pressure
- Flow rate
- FiO_2

Patient Response[a]

- Breathing rate and expired volume
- Pulse rate and rhythm (from electrocardiogram if available)
- Mental function
- Skin color
- Breath sounds
- Blood pressure
- SpO_2 (if hypoxemia is suspected)
- Ventilation
- ICP (in patients for whom ICP is important)
- Chest x-ray (when appropriate)
- Subjective response to therapy

[a]Items should be chosen as appropriate for the specific patient.
ICP, Intracranial pressure; *SpO_2*, oxygen saturation.

assessment and implementation, and thoughtful follow-up (Box 43.13).

Evaluating alternatives. The use of CPAP, NIV, or HFNC has shown promise in decreasing the development of postoperative respiratory complications.[27]

Discontinuing and Follow-Up

Depending on the indications for CPAP (e.g., chronic heart failure [CHF]), once the underlying cause that indicated the need for CPAP has been addressed, it is possible to start to discontinue therapy. In the case of CHF, once the patient has been diuresed, they will most likely not need the positive pressure. Care for other patients may result in periods of time off therapy followed by periods back on until the patient shows signs of continued improvement.

Posttreatment assessment. Auscultation of breath sounds and monitoring oxygen saturation (SpO_2) in addition to patient assessment will help to guide the clinician.

High-flow nasal cannula. Providing supplemental oxygen via a nasal cannula has been a common practice in respiratory

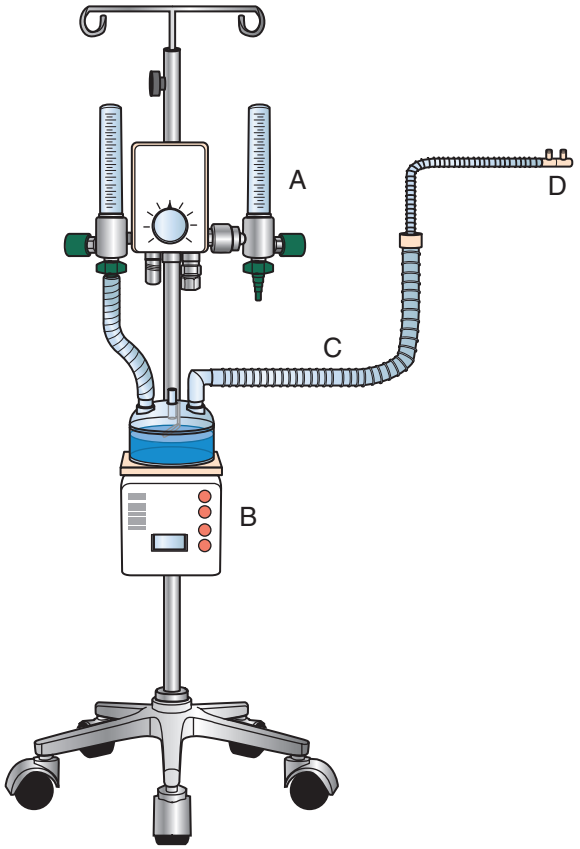

Fig. 43.8 Schematic of a high-flow nasal cannula system *(A)* air-oxygen blender, *(B)* humidifier, *(C)* circuit, *(D)* high-flow cannula.

BOX 43.14 Clinical Situations Contraindicating High-Flow Nasal Cannula Therapy

- Hypercarbic respiratory failure
- Inability to protect the airway
- Unable to tolerate high flow

care. The typical flow limit for these devices is approximately 6 L/min, which is a result of the upper airway to warm and humidify the inspired gas. Common patient complaints when standard nasal cannulas are used at high flows are headache, drying of nasal mucosa, and nosebleeds (Fig. 43.8).[26,28,29]

The small inner diameter of the standard nasal cannula also does not allow for higher flows. HFNC is specially designed with larger prongs allowing higher oxygen flow rates. In addition to the larger-bore cannula, the gas is also heated and humidified before being delivered to the patient providing a higher level of comfort. These two factors allow for the flow rate to be significantly higher, ranging from 40 to 50 L/min (Boxes 43.14 and 43.15).[28-30]

Physiologic Basis

HFNC at elevated inspiratory flows provides a more stable FiO_2. Another benefit from the enhanced flow is *washing out* the CO_2

BOX 43.15 Hazards and Complications of High-Flow Nasal Cannula Therapy

- Nosocomial infection
- Hypercarbia
- Headache
- Drying of mouth/upper airway
- Impaction of secretions (associated with inadequately humidified gas mixture)

BOX 43.16 Potential Outcomes of High-Flow Nasal Cannula Therapy

- Improved chest x-ray
- Improved breath sounds
- Improved oxygenation
- Improved patient comfort

from the anatomic dead space. This helps with ventilation because the CO_2 contained in the nasal pharynx has been eliminated and is not the first gas that enters the lowers respiratory tract with each breath. Essentially, gas flow in the upper airway is unidirectional, in through the nose and out through the mouth. This reduces anatomic dead space by approximately one-third, reducing PCO_2 by 3 to 5 mm Hg and decreasing the work of breathing.[30]

In addition to the washout, a small level of positive pressure is delivered as a result of resistance generated as with the patient breathing out against the high inspiratory flow. Most estimate that approximately 1 cm H_2O positive end-expiratory pressure (PEEP) is established for every 10 L/min flow through the HFNC. This low positive pressure will first help to recruit collapsed alveoli by increasing the P_{AL} and maintaining their inflation once reopened.[28,29] $\dot{V}/Q$ will improve as a result of the improved ventilation to previously perfused areas of the lung (Box 43.16).

Other Therapies

There are other therapies available to the RT with the aim of secretion clearance and possible treatment of postoperative pulmonary complications: intrapulmonary percussive ventilation (IPV) and high-frequency chest wall compression (HFCWC). There is a lack of supporting evidence for the effectiveness of either of these therapies, although each is similar to techniques previously discussed within this chapter. IPV is similar to IPPB with a high respiratory rate, and HFCWC is similar to chest physical therapy (CPT) using a pneumatic vest that the patient wears. These modalities are mentioned for completeness, although the evidence supporting them is low-level or anectdotal.[3,19]

Positive Airway Pressure

First introduced in Denmark during the 1970s as an airway clearance device, and similar to CPAP, PEP adjuncts use positive pressure to increase the P_{AL} gradient and enhance lung expansion.[31] In contrast to CPAP or HFNC, PAP therapy requires no complex machinery. Some methods do not even need a source of pressurized gas.

- Chest x-ray (when appropriate)
- Subjective response to therapy

[a]Items should be chosen as appropriate for the specific patient.
ICP, Intracranial pressure; *SpO_2*, oxygen saturation.

Physiologic Basis

There are three current approaches to PAP therapy: PEP, flutter, and CPAP. All three techniques are effective in treating atelectasis in most postsurgical patients.[32,33] Using either PEP or flutter as part of airway clearance is described in detail in Chapter 44. This chapter focuses on the uses of PAP for treating atelectasis.

PEP threshold, resistor, and flutter valves create expiratory positive pressure only without need for continuous flow or complex machinery,[28] whereas CPAP maintains a positive airway pressure throughout both inspiration and expiration. Fig. 43.6 compares the alveolar and P_{pl} changes occurring during a normal spontaneous breath (see Fig. 43.6A) and CPAP (see Fig. 43.6B).

The following factors involving PAP, flutter, and CPAP therapy contribute to the beneficial effects: (1) recruitment of collapsed alveoli through an increase in FRC, (2) decreased work of breathing due to increased compliance or elimination of intrinsic positive end-expiratory pressure ($PEEP_i$), (3) improved distribution of ventilation through collateral channels (e.g., pores of Kohn), and (4) increase in the efficiency of secretion removal (Box 43.17).

Indications

The evidence for PEP therapy suggests that patients with expiratory airflow limitation will best respond to this therapy.[31,34] PEP mimics the maneuver of pursed-lip breathing by presenting expiratory resistance either through a flow or threshold resistor, and an elongated expiratory phase. Those patients who are good candidates for PEP therapy are those who can follow instructions and repeat the demonstration back to the RT.

Similar to IS, there is no set duration for therapy nor a set number of repetitions during each session. Currently this therapy is given for patients who may either have atelectasis or have breathlessness.

Contraindications

Similar to the contraindications for the other lung expansion therapies, an untreated pneumothorax should be considered before starting therapy. A good baseline assessment of the patient is helpful to identify any predisposing issues.

Hazards and Complications

Regardless if it is flow limited, a threshold device, or oscillating PEP, care should be taken that the patient does not hyperventilate during therapy. Signs can include dizziness, tingling in the extremities, and light-headedness. In those cases, have the patient stop therapy until they feel better and then suggest a slower regimen of breaths.

Equipment

PEP valve and mouthpiece. The device is designed to fit into a pocket and taken apart for cleaning.

Procedures. Show the device to the patient and have them take a tidal, or slightly larger than tidal, breath. Have the patient exhale through the PEP device and set the resistor to the desired strength. Repeat the instructions if they are breathing out too quickly or slowly.[31,35]

Monitoring and Troubleshooting

Check the valve for obstructions if the patient cannot breathe out from the device. Some PEP devices include a 30-day diary that can be used to track progress.

MINI CLINI—PROBLEM WITH POSITIVE EXPIRATORY PRESSURE

Problem

During a follow-up visit with a patient that you instructed in the use of PEP therapy, it is observed that the patient is struggling on exhalation through the device and does not want to use it.

Discussion

Looking at the device, you see that the resistance is set to maximum. The patient had visitors who were looking at the device and may have moved the setting. You take the time to provide some education and reassurance to the patient and show how to set the resistance and enter it into the diary. With the correct settings, the patient is more willing to continue therapy.

INITIATION OF THERAPY

The best approach for achieving a given clinical goal is always the safest, simplest, and most effective method for an individual patient. Selecting an approach for lung expansion therapy requires in-depth knowledge of both the methods available and the specific condition and needs of the patient being considered for therapy.

Preliminary Planning

Patient education and motivation are key to the success for this therapy. The PEP devices are made to be portable and allow the patient to carry them while outside of the hospital or home. Many devices are now dishwasher safe for easier cleaning.

Evaluating Alternatives

If the patient cannot tolerate PEP, then alternative therapies could be either CPAP or HFNC. Both will aid in lung recruitment using a similar mechanism, with less patient coordination.

Discontinuing and Follow-Up

PEP therapy has been shown to have a positive effect on patient self-reported breathlessness for those patients who have non-cystic fibrosis bronchiectasis or severe chronic obstructive pulmonary disease (COPD).[35] PEP can be continued at home as part of a daily regimen for pulmonary hygiene and dyspnea.

Posttreatment Assessment

Auscultation of breath sounds and reviewing the patient diary for shortness of breath can help to guide the RT in determining if the therapy should be discontinued.

SELECTING AN APPROACH

Selecting an approach for lung expansion therapy requires in-depth knowledge of both the methods available and the specific condition and needs of the patient being considered for therapy.

Fig. 43.9 presents a sample protocol for selecting an approach to lung expansion therapy. As indicated in the algorithm, the patient first must meet the criteria for therapy by having one or more of the indications previously specified. For patients meeting the inclusion criteria, the RT first determines the degree of alertness. Because an obtunded patient cannot be expected to cooperate with IS or PEP or expiratory positive airway pressure (EPAP) therapy, HFNC or CPAP is initiated with appropriate monitoring.

For a patient having no difficulty with secretions, if the VC exceeds 15 mL/kg of lean body weight or the IC is greater than 33% of predicted, IS is given. If either the VC or the IC is less than these threshold levels, IPPB is initiated, with the pressure gradually manipulated from the initial setting to deliver at least 15 mL/kg. If excessive sputum production is a compounding factor, a trial of PEP therapy is substituted for IS. Based on patient response, bronchodilator therapy and bronchial hygiene measures may be added to this regimen. If monitoring fails to reveal improvement and atelectasis persists, a trial of CPAP should be considered. Because evidence of the effectiveness of CPAP is still contradictory, its use should be limited to treating atelectasis after alternative approaches have been tried without success.

Whether or not to keep critically ill patients on complete bed rest is being critically examined in the literature.[22-27,36,37] The complications of prolonged bed rest include cardiovascular, pulmonary, gastrointestinal, and skin integrity issues. Pulmonary complications of immobility include those that have been the focus of this chapter: development of atelectasis, pneumonia, and PE.[23-27,36] Rates of early mobilization for ICU patients have been increasing in both Europe and the United States, along

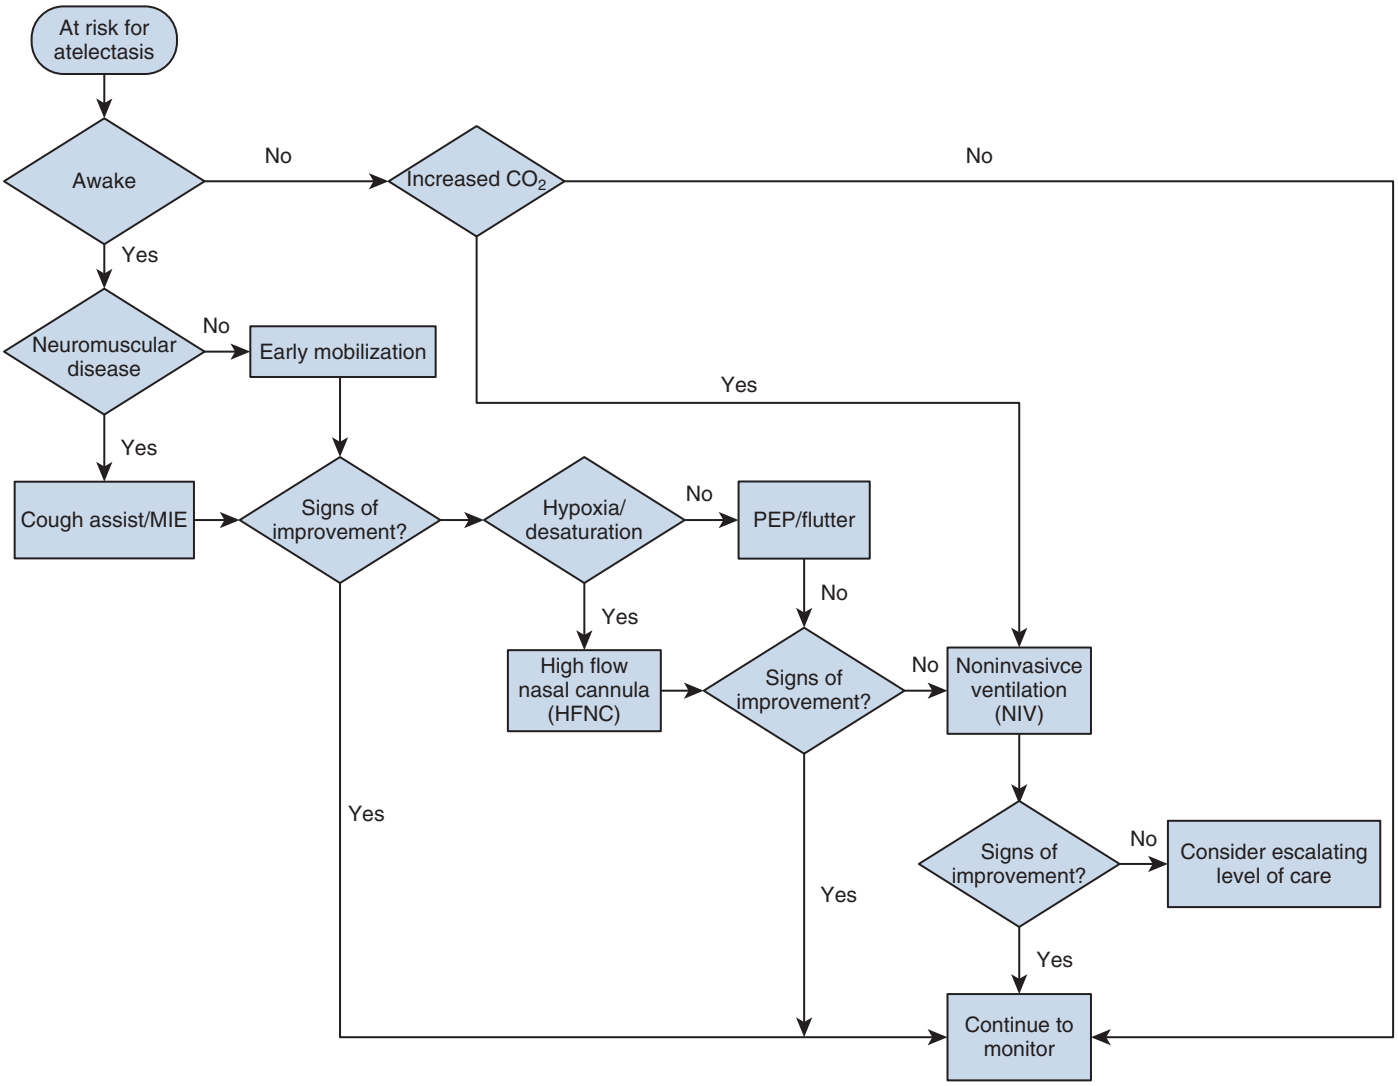

Fig. 43.9 Protocol for selecting an approach for lung expansion therapy. See text for details. *PEP*, Positive expiratory pressure. *MIE*, Mechanical insufflation exhalation.

with the an emphasis on decreasing morbidity in the ICU. Mobilization does not only include walking, but also sitting, standing, and getting out of bed into a chair. As the patient changes body position, his or her breathing changes, as does the gas distribution within the lung. Improvements in ventilation result in less alveolar collapse.

SUMMARY CHECKLIST

- Atelectasis is caused by persistent ventilation with small tidal volumes or by resorption of gas distal to obstructed airways.
- Patients who have undergone upper abdominal or thoracic surgery are at greatest risk for atelectasis.
- A history of lung disease or significant cigarette smoking increases the risk for atelectasis.
- Patients with atelectasis usually have rapid, shallow breathing; fine, late-inspiratory crackles; and abnormalities on chest radiograph.
- Lung expansion therapy corrects atelectasis by increasing the P_{AL} gradient; this can be accomplished by deep spontaneous breaths or by the application of positive pressure.
- The most common problem associated with lung expansion therapy is the onset of respiratory alkalosis, which occurs when the patient breathes too quickly.
- RTs are responsible for implementing, monitoring, and documenting results of lung expansion therapy.

Airway Clearance Therapy

David L. Vines and Donna D. Gardner

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Compare the normal airway clearance mechanisms to the factors that impair their function.
- Identify pulmonary diseases associated with abnormal secretion clearance.
- State the clinical indications for airway clearance therapy.
- Describe the proper technique that would result in potential benefits of each of the following:
  - Chest physical therapy
  - Directed coughing and related expulsion techniques
  - Vibratory positive expiratory pressure therapy
  - Mechanical insufflation-exsufflation (MIE)
  - High-frequency oscillation devices
    - Vibratory positive expiratory pressure
    - High-frequency airway pressure devices
    - High-frequency oscillation compression devices
  - Mobilization and exercise
- Evaluate a patient's response to airway clearance therapy to determine changes in the treatment plan.

CHAPTER OUTLINE

KEY TERMS

active cycle of breathing technique (ACBT)
autogenic drainage (AD)
bronchiectasis
chest physical therapy (CPT)
ciliary dyskinetic syndromes
forced expiratory technique (FET)
Hertz (Hz)
High-frequency chest wall compression (HFCWC)
huff coughing
inspissation
intrapulmonary percussive ventilation (IPV)
mechanical insufflation-exsufflation (MIE)
mucous plugging
oscillation
positive expiratory pressure (PEP)
splinting

Airway clearance therapy (ACT) uses noninvasive techniques designed to assist in mobilizing and removing secretions to improve gas exchange.[1] Historically, the term **chest physical therapy (CPT)** described the primary techniques used to assist with clearing secretions from the airways. Today, there are numerous options related to airway clearance including CPT, breathing retraining techniques, positive expiratory therapy (PEP), vibratory PEP, high-frequency oscillation devices, high-frequency chest wall compression (HFCWC) devices, **mechanical insufflation-exsufflation (MIE)**, and various exercise protocols.[1–3]

This chapter focuses on ACTs or techniques used to mobilize secretions and noninvasively assist in their removal. The primary *invasive* method for removing airway secretions is suctioning and is discussed in Chapter 37. Successful outcomes in airway clearance techniques require knowledge of normal and abnormal physiology, understanding of how clearance devices work, careful patient evaluation, rigorous application of evidence-based methods, and ongoing assessment targeted at achieving therapeutic goals.[1–4]

PHYSIOLOGY OF AIRWAY CLEARANCE THERAPIES

To apply ACTs properly, one must understand how normal airway clearance mechanisms work and what can impair their function.

Normal Clearance

Normal airway clearance requires patent airways, a functional mucociliary escalator, adequate hydration, and effective cough.[5] Mucociliary clearance normally occurs from the larynx down to the respiratory bronchioles. Mucus is produced by secretory (Clara, goblet, and serous) cells and submucosal glands.[5] Ciliated epithelial cells move this mucus via a coordinated wave of ciliary motion toward the trachea and larynx, where secretions can be swallowed or expectorated. Healthy individuals produce 10 to 100 mL of secretions in the airway on a daily basis that are cleared by this mucociliary escalator.[3,5]

The cough is one of the most important protective reflexes. Coughing clears the larger airways of excessive mucus and foreign matter, assists normal mucociliary clearance, and helps ensure airway patency. As shown in Fig. 44.1, there are four distinct phases to a normal cough: *irritation, inspiration, compression,* and *expulsion*. In the initial irritation phase, an abnormal stimulus provokes sensory fibers in the airways to send impulses to the medullary cough center in the brain. This stimulus normally is inflammatory, mechanical, chemical, or thermal. Infection is a good example of an *inflammatory* process that can stimulate a cough. Foreign bodies can provoke a cough through *mechanical* stimulation. Inhaling irritating gases (e.g., cigarette smoke) can result in coughing through *chemical* stimulation. Finally, cold air may cause *thermal* stimulation of sensory nerves, producing a cough. When these impulses are received, the cough center generates a reflex stimulation of the respiratory muscles to initiate a deep inspiration (the second phase). In normal adults, this inspiration averages 1 to 2 L.

During the third or compression phase, reflex nerve impulses cause glottic closure and a forceful contraction of the expiratory muscles. This compression phase is normally about 0.2 seconds and results in a rapid increase in pleural and alveolar pressures, often greater than 100 mm Hg. At this point, the glottis opens, initiating the expulsion phase. With the glottis open, a large pressure gradient between the lungs and the atmospheric pressure exists. Together with the continued contraction of the expiratory muscles, this pressure gradient causes a violent, expulsive high velocity of airflow from the lungs. This high-velocity gas flow, combined with dynamic airway compression, creates huge shear forces that displace mucus from the airway walls into the air stream. Mucus and foreign material are expelled from the lower airways to the upper airway, where they can be expectorated or swallowed.

Abnormal Clearance

Any abnormality that alters airway patency, mucociliary function, strength of the inspiratory or expiratory muscles, thickness of secretions, or effectiveness of the cough reflex can impair airway clearance leading to retention of secretions.[3,5] In addition, some therapeutic interventions, especially interventions used in critical care, such as an endotracheal tube, can result in abnormal clearance.

Retention of secretions can result in full or partial airway obstruction. Full obstruction, or **mucous plugging**, can result in atelectasis which causes hypoxemia due to shunting. A partial obstruction restricts airflow, increasing work of breathing and possibly leading to air trapping, lung overdistension, and ventilation/perfusion ($\dot{V}/\dot{Q}$) imbalances. In the presence of pathogenic organisms, retention of secretions can also lead to infections.

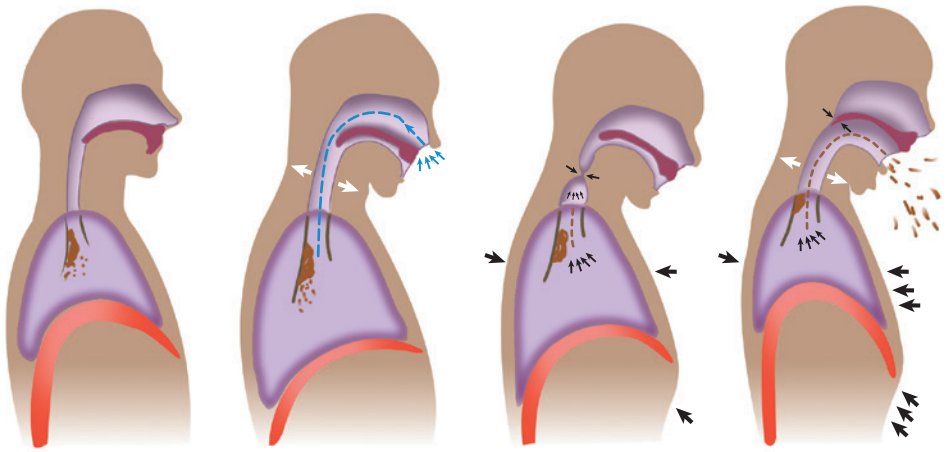

Fig. 44.1 The cough reflex. (Modified from Cherniack RM, Cherniack L. *Respiration in Health and Disease,* ed 3, Philadelphia, 1983, WB Saunders.)

TABLE 44.1 Mechanisms Impairing Cough Reflex

Phase	Examples of Impairments
Irritation	Anesthesia
	Central nervous system depression
	Narcotic analgesics
Inspiration	Pain
	Neuromuscular dysfunction
	Pulmonary restriction
	Abdominal restriction
Compression	Laryngeal nerve damage
	Artificial airway
	Abdominal muscle weakness
	Abdominal surgery
Expulsion	Airway compression
	Airway obstruction
	Abdominal muscle weakness
	Inadequate lung recoil (e.g., emphysema)

BOX 44.1 Causes of Impaired Mucociliary Clearance in Intubated Patients

- Endotracheal or tracheostomy tube
- Tracheobronchial suction
- Inadequate humidification
- High FiO_2 values
- Drugs
- General anesthetics
- Opiates
- Narcotics
- Underlying pulmonary disease

Infectious processes provoke an inflammatory response and the release of chemical mediators. These chemical mediators, including leukotrienes, proteases, and elastases, can damage the airway epithelium and increase mucus production, resulting in a vicious cycle of worsening airway clearance.[5]

In patients with retained secretions, interference with one of the four phases of cough can result in ineffective airway clearance. This occurs in patients following thoracic or upper abdominal surgery, in the intensive care unit, or with neuromuscular diseases (NMDs) such as amyotrophic lateral sclerosis (ALS), myasthenia gravis (MG), or cervical or thoracic spinal cord injuries. Table 44.1 provides examples of factors that can impair the normal cough reflex.

As indicated in Box 44.1, additional factors can impair airway clearance in critically ill patients with artificial airways, the most important of which is the airway itself.[6] The presence of an artificial airway in the trachea increases mucus secretion, and the cuff of the tube mechanically blocks the mucociliary escalator. In addition, movement of the tube tip and cuff can cause erosion of the tracheal mucosa, leading to further impairment of the mucociliary escalator. The endotracheal tube also impairs the compression phase of the cough reflex by preventing closure of the glottis (see Table 44.1). Although suctioning is used to aid secretion clearance, it too can cause damage to the airway mucosa and impair mucociliary transport. Inadequate humidification can cause thickening or **inspissation** of secretions, mucous plugging, and airway obstruction.[7] High fractional inspired oxygen (FiO_2) concentrations can impair ciliary function, resulting in retained secretions. Retained secretions can lead to acute tracheobronchitis. Several common drugs, including some general anesthetics and narcotic analgesics, may also depress mucociliary transport.[5]

RULE OF THUMB Several factors impair the mucociliary escalator resulting in increased mucus production: the presence of an artificial airway, suctioning beyond the end of an artificial airway, inadequate humidification, high concentrations of oxygen, and drugs (anesthetics and narcotic—analgesics).

Diseases Associated With Abnormal Clearance

Several diseases are associated with abnormal airway clearance, including diseases affecting airway patency, composition and production of mucus, ciliary structure and function, and normal cough reflex.[5] Internal obstruction or external compression of the airway lumen can impair airway clearance. Examples include foreign bodies, tumors, and congenital or acquired thoracic anomalies such as kyphoscoliosis. Internal obstruction also can occur with mucus hypersecretion, inflammatory changes, or bronchospasm that narrows the lumen. Examples include asthma, chronic bronchitis, and/or acute infections.

Diseases that alter normal mucociliary clearance also can cause retention of secretions. In cystic fibrosis (CF), the solute concentration of the mucus is altered because of abnormal sodium and chloride transport.[5] This alteration increases the viscosity of mucus and impairs its movement up the respiratory tract. Although less common, there are several conditions in which the respiratory tract cilia do not function properly.[5] The **ciliary dyskinetic syndromes** contribute to ineffective airway clearance. **Bronchiectasis** permanently damages and dilates airways that are prone to obstruction due to retained secretions.[5,8] Bronchiectasis is a common finding in CF and ciliary dyskinetic syndromes.[8–10]

Mucociliary function may be normal, but lack of an effective cough alters airway clearance leading to retained secretions, mucous plugs, obstructions, and atelectasis. The most common conditions affecting the cough reflex are musculoskeletal and NMD, including muscular dystrophy, ALS, spinal muscular atrophy, MG, poliomyelitis, and cerebral palsy (see Chapter 33).[11]

GENERAL GOALS AND INDICATIONS

The primary goal of ACT is to assist the patient to mobilize and remove retained secretions. Removal of these retained secretions may improve gas exchange, promote alveolar expansion, and reduce the work of breathing. Box 44.2 lists general indications for ACT.[1,3]

Airway Clearance Therapy for Acute Conditions

Patients with acute conditions in whom ACT may be indicated include: (1) acutely or chronically ill patients with copious

BOX 44.2 Indications for Airway Clearance Therapy

Acute Conditions
- Copious secretions
- Inability to mobilize secretions
- Ineffective cough

Chronic Conditions
- Cystic fibrosis
- Bronchiectasis
- Ciliary dyskinetic syndromes
- Chronic obstructive pulmonary disease patients with retained secretions.

secretions; (2) patients with retained secretions or ineffective cough (coarse crackles, worsening oxygenation and/or ventilation, volume loss on chest radiograph); (3) possibly patients with acute lobar atelectasis; or (4) patients with $\dot{V}/\dot{Q}$ abnormalities.[1] In treating *chronic* respiratory conditions, inhaled bronchodilator therapy before ACT may improve the overall effectiveness of the treatment both by opening the airways and by increasing the mucociliary activity.[12] For acute pulmonary infections and those with CF, inhaled antibiotics taken after ACT can lead to improved deposition of the antibiotic.[4] Acute conditions for which ACT is probably not indicated include: (1) routine care of chronic obstructive pulmonary disorder (COPD), (2) pneumonia without clinically significant sputum production, (3) routine postoperative care, and (4) uncomplicated asthma.[1,3]

RULE OF THUMB Bronchodilator therapy is not indicated in the acute care setting for airway clearance therapy unless the patient is wheezing due to a bronchospasm or has a chronic pulmonary condition with retained secretions.

Airway Clearance Therapy for Chronic Conditions

ACT has proved effective in secretion clearance and improving pulmonary function in chronic conditions associated with copious sputum production, including CF, bronchiectasis, and ciliary dyskinetic syndromes, and COPD patients with retained secretions.[1,3,4] Generally, sputum production must exceed 20 to 30 mL/day for ACT to improve secretion removal significantly.[3]

RULE OF THUMB Patients with copious secretions (20–30 mL/day) or inability to mobilize and expectorate secretions may benefit from airway clearance therapy.

Airway Clearance Therapy to Prevent Retention of Secretions

ACT has been used as preventive therapy in various disorders and current evidence is not supportive of this approach.[1,2] The best-documented preventive uses of ACT include: (1) body positioning and patient mobilization to prevent retained secretions in acutely ill patients, and (2) ACT combined with physical activity to maintain lung function in patients with CF.[1,2,4]

MINI CLINI

Assessing a Patient's Cough Clearance

Problem

The respiratory therapist (RT) is called by a nurse to determine a care plan to assist a patient who is having difficulty clearing secretions. The patient is an alert, obese, 45-year-old man who underwent general anesthesia and surgery for a cholestectomy 3 h earlier. Physical signs indicate retention of secretions, but there is no history of lung disease. Auscultation reveals coarse expiratory crackles. The patient is breathing spontaneously; however, his breathing is shallow and he has a very weak cough. Visual clues indicate the patient has severe pain in the epigastric area. The patient was given an injection of morphine to assist with the pain 1 h earlier.

Discussion

There is no surprise that this patient is having difficulty clearing secretions considering the recent anesthesia and receiving a narcotic analgesic, which may impair his cough. In addition, obesity (abdominal restriction), weakness, and pain are impairing the inspiration, compression, and expulsion phases of his cough effort.

The patient should immediately be started on ACT and hyperinflation or lung expansion therapies. Judicious use of pain medication, coinciding with therapies, should continue. Cough instruction including incisional splinting should be part of the plan. Early mobilization should be encouraged. Although the most common postoperative complication is atelectasis, pneumonia may also occur. The head of the patient's bed should be elevated at least to 30–45 degrees to minimize the risk of aspiration.

DETERMINING THE NEED FOR AIRWAY CLEARANCE THERAPY

Effective ACT requires proper initial and ongoing patient assessment (Chapter 16). Formulation of the respiratory care plan depends on review of the patient's medical history and interview for current symptoms, physical assessment, assessment of cough and sputum, laboratory testing (including pulmonary function tests), and radiologic evaluation. Box 44.3 lists the key factors that must be considered when assessing a patient's need for ACT.[1,3,4] Physical findings, such as a loose, ineffective cough; labored breathing pattern; decreased or bronchial breath sounds; coarse inspiratory and expiratory crackles; tachypnea; tachycardia; or fever may indicate a potential problem with retained secretions.

AIRWAY CLEARANCE METHODS

Five general approaches to ACT, which can be used alone or in combination, include: (1) CPT; (2) coughing and related expulsion techniques (including **mechanical insufflation-exsufflation [MIE]**); (3) positive airway pressure (PAP) adjuncts (**positive expiratory pressure [PEP]**, vibratory PEP, high-frequency PAP devices); (4) high-frequency oscillation devices; and (5) mobilization and physical activity. Table 44.2 provides a brief description and limitations associated with these ACTs. Appropriate use of these techniques requires an understanding of their underlying principles, relative usefulness, and methods of application.

BOX 44.3 Initial Assessment of Need for Airway Clearance Therapy

Medical Record

History of pulmonary problems causing increased secretions
Admission for upper abdominal or thoracic surgery; consider:
- Age (elderly)
- History of chronic obstructive pulmonary disease
- Obesity
- Nature of procedure
- Type of anesthesia
- Duration of procedure

Presence of artificial tracheal airway
Chest radiograph indicating atelectasis or infiltrates
Results of pulmonary function testing
Arterial blood gas values or O_2 saturation

Patient

Posture, muscle tone
Effectiveness of cough
Sputum production
Breathing pattern
General physical fitness
Breath sounds
Vital signs, heart rate and rhythm

Chest Physical Therapy Also Known as Postural Drainage and Percussion

CPT has long been considered a standard of care in patients with CF. Evidence suggests that these therapies benefit mucus transport and assist in the expectoration of secretions.[1,3,4] This therapy includes postural drainage (PD) and percussion or vibration.

CPT involves the use of positioning, gravity, and mechanical energy to help mobilize secretions. PD places the body in various positions that are intended to drain secretions from each of the patient's lung segments into the central airways, where they can be removed by cough or suctioning.[4] This drainage is accomplished by simply placing the segmental bronchus to be drained in a more vertical position, permitting gravity to assist in the process. Positions generally are held for 3 to 15 minutes (longer in special situations such as CF) and modified as the patient's condition and tolerance warrant. Specifically, with CF patients and all pediatric patients in general, head-down positioning should be avoided to prevent marked increases in intracranial pressure (ICP), especially during coughing.[2–4,13] Cough methods are used with CPT and are discussed separately.

The indications for CPT (and other ACTs) in a patient are the presence of copious secretions, the inability to mobilize and expectorate the secretions, and pulmonary disorders associated with retained secretions (CF, bronchiectasis, and ciliary dyskinetic syndromes).[1,3,4] This therapy does require a trained caregiver's assistance in order for it to be performed correctly. CPT may be most effective in conditions characterized by excessive sputum production (greater than 25 to 30 mL/day) that is not cleared by deep breathing and coughing. For maximum effect with PD, head-down positions should exceed 25 degrees below horizontal.[2–4,13] In patients with CF and pediatric patients in general head-down positioning should be avoided as discussed above.[2–4,13] If the patient cannot be placed in appropriate positions for the areas affected, another ACT should be considered. In spontaneously breathing patients, treatment frequency should be determined by assessing the patient's response to therapy. Critically ill patients, especially patients being mechanically ventilated, should be moved and rotated every 2 hours.[14]

RULE OF THUMB To achieve the maximum secretion drainage with postural drainage and percussion the head-down positions should exceed 25 degrees below horizontal. In patients with CF and pediatric patients in general head down positioning should be avoided because of increased ICP, especially of concern during coughing. If the patient cannot be placed in appropriate drainage positions for the areas affected, another ACT should be considered.

Technique

Based on a preliminary assessment of the patient and review of the physician's order, the RT should identify the appropriate lobes and segments for drainage. The RT may need to choose a different ACT method in patients with unstable cardiovascular status, hypertension, cerebrovascular disorders, or dyspnea. To avoid gastroesophageal reflux and the possibility of aspiration, treatment times should be scheduled before or at least 2 hours after meals or tube feedings to decrease the chance of vomiting or aspiration. If the patient assessment indicates that pain may hinder treatment implementation, the RT should consider coordinating the treatment regimen with prescribed pain medication. Contraindications for CPT are listed in Box 44.4.

Before positioning, the procedure (including adjunctive techniques) should be explained to the patient. The RT should inspect for incisions, monitoring leads, intravenous tubing, and oxygen (O_2) therapy equipment connected to the patient and, if necessary, make adjustments to ensure continued function during the procedure or choose a different ACT method. Before starting, during, and after the procedure, the RT should measure the patient's vital signs, auscultate the chest, and measure SpO_2 to assess the presence of hypoxemia. These simple assessments serve as baseline measurements for monitoring the patient's response during the ACT and can assist in determining outcomes. The following items also should be monitored before, during, and after CPT: subjective responses (pain, discomfort, dyspnea, response to therapy), arrhythmias, breathing pattern, sputum production (quantity, color, consistency, odor), skin color, and ICP if monitored.

Fig. 44.2 depicts the primary positions used to drain the various lung lobes and segments. Generally, to obtain the proper head-down position, the RT must lower the head of the bed by at least 16 to 18 inches to achieve the desired 25-degree angle. In the ambulatory care setting, a tilt table can be used in lieu of a hospital bed. A tilt table allows precise positioning at head-down angles up to 45 degrees. When angles this large are used, shoulder supports must be provided to prevent the patient from sliding off the tilt table.

After the patient is positioned, the RT confirms the patient's comfort and ensures proper support of all joints and bony areas with pillows or towels. The indicated position is maintained for

TABLE 44.2 Airway Clearance Therapies, Techniques, and Devices

ACT	Techniques and Devices	Limitations Associated With ACT
Chest physiotherapy (CPT) includes percussion and postural drainage	Manual percussion of the chest using cupped hands or mechanical device creates vibrations to loosen secretions and positioning uses gravity to draining secretions from the lung segments to the larger airways	• Patients who are short of breath may not tolerate being placed in Trendelenburg position. • The treatment is dependent of the patient being positioned appropriately. • Caregivers are required to perform the therapy
Active cycle of breathing	To mobilize secretions the breathing cycles includes alternating between relaxed breathing, deep breathing, and forced expiratory technique	• Patients who are unable to perform this therapy include those unable to take a deep breath or experiencing an exacerbation • This concept is difficult to perform in children less than 4 years old. • Repeated coaching may be needed in children up to the age of 10
Autogenic drainage	To loosen and move secretions into the larger airways and then expelled them, a patient can use a series of breathing patterns beginning with breaths at a low volume, then breaths at a normal tidal volume and ending with a high volume and high peak flow breath like a huff cough	• The patient's coordinated breathing is necessary making it difficult to perform when they are short of breath or unable to take a deep breath. • To perform correctly the patient needs to be an older than 10 years of age
Mechanical insufflator-exsufflator (MIE)	To expel secretions the device simulates an effective cough by using positive airway pressure on inspiration to increase tidal volume and then switching to a negative pressure to increase peak expiratory cough flows. The device may be used with a mask, mouthpiece or attached to an artificial airway. The device has an oscillatory mechanism to assist with mobilize the secretions	• In patients with bulbar ALS, the negative pressure expiratory phase may be limited by upper airway closure. • Patients with obstructive airway disorders may experience airway collapse with the negative pressure phase • Contraindicated in the presence or suspicion of untreated pneumothorax, unstable hemodynamic status, increased intracranial pressure, current maxillofacial surgery or trauma, active hemoptysis, or tympanic membrane rupture. • Caregiver is needed for this therapy
Positive expiratory pressure (PEP) or oscillatory or vibratory PEP (OPEP)	To mobilize secretions using PEP devices, an expiratory pressure of 10–20 cm H_2O is created by the patient actively exhaling against a fixed or variable orifice flow resistor. The OPEP creates flow oscillations by adding flow interruptions during the patient's active exhalation	• Patients must be able to take a deep breath and exhale with enough force to generate the PEP and oscillations. • Contraindicated in the presence or suspicion of untreated pneumothorax, unstable hemodynamic status, increased intracranial pressure, current maxillofacial surgery or trauma, active hemoptysis, or tympanic membrane rupture
High-frequency positive airway pressure devices	To loosen and move secretions into the larger airways the patient breathes in and actively exhales against short, rapid positive airway pressure pulses	• Younger patients will require a caregiver. • If the patient does not actively exhale, exhalation will depend on the patients' chest wall elastic recoil. • Contraindicated in the presence or suspicion of untreated pneumothorax, unstable hemodynamic status, increased intracranial pressure, current maxillofacial surgery or trauma, active hemoptysis, or tympanic membrane rupture
High-frequency chest wall compression	To mobilize the secretions in the larger airways the patient wears a vest that creates chest wall compression resulting in small pulses of volume at high frequencies	• Patients need to be at least 2 years of age begin using the device. • Avoid using the device in the presence of indwelling catheters or chest tubes
Mobilization and physical activity	Patients who participate in physical activity that results in increased tidal volume, heart rate, and cardiac output, and improved physical condition	• Patients may participate in physical exercise as long as their medical condition allows, or medical monitoring is available. • Caution is needed for patients at risk of developing bronchospasm in the presence of reactive airways

ACT, Airway clearance therapy; *ALS*, amyotrophic lateral sclerosis.

a minimum of 3 minutes if tolerated and longer if good sputum production results. Between positions, pauses for relaxation and breathing control are useful and can help prevent hypoxemia. Because postural drainage therapy can increase O_2 consumption, critically ill patients should be given supplemental O_2 during the procedure if SpO_2 decreases.

During the procedure, the patient is continually observed for any side effects or complications. Moderate changes in vital signs are expected during treatment. Table 44.3 lists complications and the recommended interventions. Significant problems may require immediate intervention.

Also, the RT should ensure that the patient uses appropriate coughing technique during and after positioning. When using the head-down position for non-CF and nonpediatric patients, the patient should avoid strenuous coughing because this markedly increases ICP.[1,2] Rather, the patient should use the forced expiration technique (described later in this chapter). Generally, total treatment time should not exceed 15 minutes for a routine

BOX 44.4 Contraindications to the Use of Chest Physical Therapy

The decision to use postural drainage requires assessment of potential benefits versus potential risks. Therapy should be provided for no longer than necessary to obtain the desired therapeutic results. Listed contraindications are relative unless marked as absolute *(A)*.

Positioning: All positions are contraindicated for:

- Head and neck injury until stabilized *(A)*
- Active hemorrhage with hemodynamic instability *(A)*
- Intracranial pressure (ICP) greater than 20 mm Hg
- Recent spinal surgery or acute spinal injury
- Active hemoptysis
- Empyema
- Bronchopleural fistula
- Pulmonary edema associated with congestive heart failure
- Aged, confused, or anxious patients who do not tolerate position changes
- Pulmonary embolism
- Rib fracture, with or without flail chest
- Surgical wound or healing tissue
- Large pleural effusions

Trendelenburg position contraindicated for:

- Recent gross hemoptysis related to recent lung carcinoma treated surgically or with radiation therapy
- ICP greater than 20 mm Hg
- Uncontrolled hypertension
- Distended abdomen
- Patients in whom increased ICP is to be avoided (e.g., neurosurgery, aneurysms, eye surgery)
- Uncontrolled airway at risk for aspiration (tube feeding or recent meal)
- Esophageal surgery
- External manipulation of the thorax contraindications (in addition to contraindications previously listed):
- Subcutaneous emphysema
- Recent epidural spinal infusion or spinal anesthesia
- Recently placed transvenous pacemaker or subcutaneous pacemaker
- Lung contusion
- Osteomyelitis of the ribs
- Coagulopathy
- Recent skin grafts, or flaps, on the thorax
- Burns, open wounds, and skin infections of the thorax
- Suspected pulmonary tuberculosis
- Bronchospasm
- Osteoporosis
- Complaint of chest wall pain

Excerpts from the American Association for Respiratory Care: Clinical practice guideline: postural drainage therapy. *Respir Care* 36:1418, 1991.

treatment and 30 minutes for extended treatment. Both the patient and the RT should understand that PD does not always result in the immediate production of secretions. More often, secretions are simply mobilized toward the trachea for easier removal by coughing. If the procedure causes vigorous coughing, have the patient sit up until the cough subsides.

After the procedure, the patient is repositioned to the pretreatment position, and the RT ensures the patient's stability and comfort. Immediate posttreatment assessment includes repeat vital signs, confirmation of satisfactory SpO_2, chest auscultation, and questioning the patient regarding his or her subjective response to the procedure. Because PD is coupled with other ACTs, the outcomes assessment and documentation are discussed later in the chapter.

MINI CLINI

Chest Physical Therapy (Postural Drainage, Percussion, and Vibration)

Problem

A physician's progress note indicates a potential bacterial pneumonia localized to a patient's right middle lobe. The patient has coarse breath sounds on the right midlung and a nonproductive cough. The physician orders CPT four times daily "until radiograph clears." What positions should the RT select for postural drainage, and where should the RT provide percussion?

Discussion

The correct position for draining the right middle lobe would be head down (foot of bed raised about 12 inches), with the patient rotated about 45 degrees left from supine (modified left side-lying position). Percussion should be performed on the right anterior chest wall, between the fourth and sixth ribs (see Chapter 16 for external anatomic landmarks).

RULE OF THUMB Generally, whenever you observe any patient adverse effects or complications during postural drainage, follow the "triple S rule": **stop** the therapy, return the patient to the original resting position, and **stay** with the patient until he or she is **stabilized**.

Percussion and Vibration

Percussion and vibration involve application of mechanical energy to the chest wall using either hands or various electrical or pneumatic devices. Both methods are designed to augment secretion clearance. In theory, percussion should help loosen secretions from the tracheobronchial tree, making them easier to remove by coughing or suctioning. The effectiveness of percussion as an adjunct to PD remains unclear. This controversy is due to variability in practice and the difficulty related to performing trials of percussion because percussion is only a part of the overall treatment regimen.[15]

Manual percussion. The RT performs manual percussion with his or her hands in a cupped position, with fingers and thumb closed and positioned parallel to the ribs (Fig. 44.3). This technique compresses air between the hand and chest wall. This technique should be applied against a thin layer of cloth, such as a hospital gown or bed sheet to help improve patient comfort. This technique involves the therapist's cupped hands rhythmically striking the chest wall, using both hands alternately in sequence with the elbows partially flexed and wrists loose (see Fig. 44.3). Slower, more relaxing rates are better tolerated by the patient and the therapist. This technique requires practice to determine the appropriate force and maintain a rhythmic pattern during this therapy (Fig. 44.4). Ideally, the RT should percuss back and forth in a circular pattern over the localized area for 3 to 5 minutes. Care should be taken to avoid tender areas or sites of trauma, surgery, or chest tubes, and one should never percuss directly over bony prominences, such as the clavicles, vertebrae or sternum.

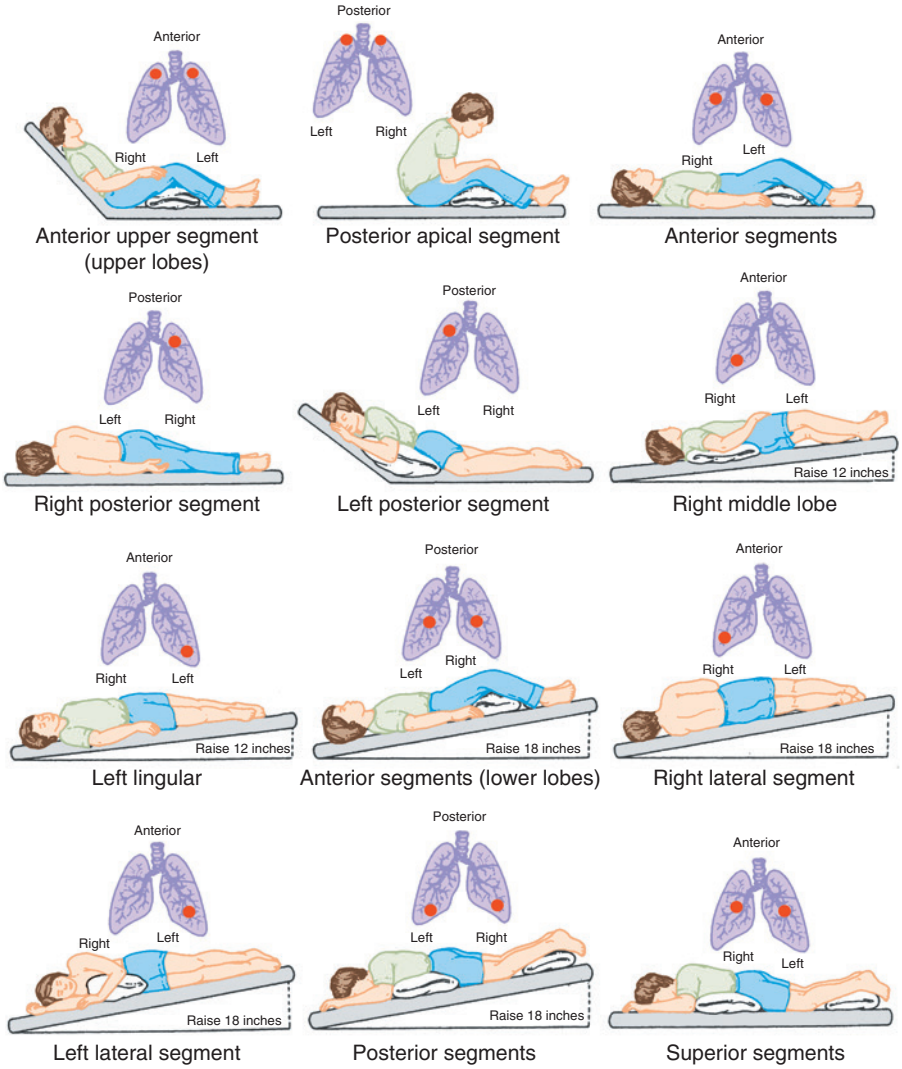

Fig. 44.2 Patient positions for postural drainage. (Modified from Potter PA, Perry AG: *Fundamentals of Nursing: Concepts, Process and Practice*, ed 4, St Louis, 1997, Mosby.)

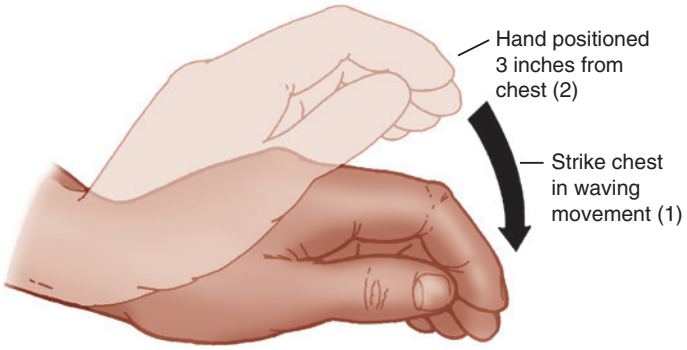

Fig. 44.3 Movement of cupped hand at wrist, to percuss chest.

Mechanical percussion and vibration. Mechanical vibration is used as an alternative to manual percussion in acutely ill patients with chest wall discomfort or injury. Various electrical and pneumatic devices have been developed to generate and apply the energy waves used during percussion and vibration. Typically, these devices have both a frequency and a percussion force control (Fig. 44.5). Most units provide frequencies between 20 and 50 cycles per second (20 to 50 **Hertz [Hz]**). Other sonic or acoustic devices may provide up to 120 Hz. Noise, excess force, and mechanical failure are all potential problems. Electrical devices also pose a potential electrical shock hazard. These devices have the advantage of reducing fatigue on the caregiver, decreasing treatment time, and delivering consistent rates, rhythms, and impact forces. These devices may improve hospitalized patients' compliance, especially when chest wall discomfort or injury is present. However, there is no firm evidence that such devices are more effective than manual techniques. For this reason, as with other ACT techniques, the selection of manual or mechanical methods should be based on individual patient factors such as age, condition, and tolerance.[2,4]

Coughing and Related Expulsion Techniques

Most ACTs only help move secretions into the central airways. Clearance of these secretions requires either coughing or suctioning. In this respect, an effective cough (or alternative expulsion measure) is an essential component of all ACT. These expulsion methods are also useful in obtaining sputum specimens for diagnostic analysis.

TABLE 44.3 Complications of Postural Drainage Therapy and Recommended Interventions

Complication	Action to Be Taken/Possible Intervention
Hypoxemia	Administer higher FiO_2 during procedure if potential for or observed hypoxemia exists. If patient becomes hypoxemic during treatment, administer 100% O_2, stop therapy immediately, return patient to original position, and consult physician
Increased intracranial pressure	Stop therapy, return patient to original resting position, and consult physician
Acute hypotension during procedure	Stop therapy, return patient to original resting position, and consult physician
Pulmonary hemorrhage	Stop therapy, return patient to original resting position, and call physician immediately. Administer O_2 and maintain an airway until physician responds
Pain or injury to muscles, ribs, or spine	Stop therapy that appears directly associated with pain or problem, exercise care in moving patient, and consult physician
Vomiting and aspiration	Stop therapy, clear airway and suction as needed, administer O_2, maintain airway, return patient to previous resting position, and contact physician immediately
Bronchospasm	Stop therapy, return patient to previous resting position, and administer or increase O_2 delivery while contacting physician. Administer physician-ordered bronchodilators
Arrhythmias	Stop therapy, return patient to previous resting position, and administer or increase O_2 delivery while contacting physician

Fig. 44.4 Hand placement for chest physical therapy. (From Harkreader H, Hogan M, Thobaben M: *Fundamentals of Nursing, Caring and Clinical Judgment*, ed 3, St Louis, 2007, Saunders.)

RULE OF THUMB Clinicians should coach the patient to create an effective cough with most airway clearance techniques to fully clear secretions.

Fig. 44.5 Example of an electrically powered mechanical percussor. (Courtesy General Physiotherapy, Inc. St Louis, MO.)

Directed Cough

Directed cough is a deliberate maneuver that is taught, supervised, and monitored. It aims to assist in creating a productive cough in patients unable to clear secretions with an effective spontaneous cough. In patients with copious secretions, directed coughing is an effective clearance method clearing secretions from the central—but not peripheral—airways. In addition to aiding in the removal of retained secretions from central airways, it should be a routine part of all ACT and may be helpful in obtaining sputum specimens for diagnostic analysis.

Box 44.5 lists the relative contraindications and potential complications associated with directed cough. These patients should be monitored for pain, discomfort, dyspnea, pulse rate, cardiac rhythm (if an electrocardiogram is available), breath sounds, pulse oximetry if desaturation is suspected, breathing pattern, skin color, sputum production, and ICP if elevated. To determine the effectiveness of directed cough techniques, therapists should evaluate the patient for any of the following outcome changes: increased sputum production, decreased pulse and respiratory rate, clearing of the breath sounds, improved O_2 saturation, and possibly clearing of infiltrates on the chest x-ray.

Standard technique. After the clinical need for directed coughing has been established, the RT should assess the patient for any factors that could limit the success of directed cough and relative contraindications. An effective directed cough is impossible with unresponsive, paralyzed, or uncooperative patients. In addition, some patients with severe COPD or severe restrictive disorders (including neurologic, muscular, or skeletal abnormalities) may be unable to generate an effective spontaneous cough. Pain, systemic dehydration, tenaciously thick secretions, artificial airways, or use of central nervous system depressants can also impact efforts to implement an effective directed cough. If any of these limitations exist, the RT should recommend an alternative to directed cough such as an assisted cough, which is discussed later in this chapter.

Patient education is a critical part of developing an effective directed cough. The three most important aspects in teaching a patient to have an effective cough are: (1) instruction on proper positioning, (2) instruction on breathing control, and (3) exercises to strengthen the expiratory muscles.[16] These activities are modified according to the patient's underlying clinical problem.

RULE OF THUMB Adequate expiratory muscle strength as well as proper instruction regarding patient positioning and breathing control are essential components to an effective directed cough.

BOX 44.5 Directed Cough

Contraindications

Directed cough is rarely contraindicated. The contraindications listed must be weighed against potential benefit in deciding to eliminate cough from the care of the patient. Listed contraindications are relative:

- Inability to control possible transmission of infection from patients suspected or known to have pathogens transmittable by droplet nuclei (e.g., *Mycobacterium tuberculosis*)
- Presence of elevated intracranial pressure or known intracranial aneurysm
- Presence of reduced coronary artery perfusion, such as in acute myocardial infarction
- Acute unstable head, neck, or spine injury
- Manually assisted directed cough with pressure to the epigastrium may be contraindicated in the presence of increased potential for regurgitation or aspiration, acute abdominal pathology, abdominal aortic aneurysm, hiatal hernia, pregnancy, bleeding diathesis, or untreated pneumothorax
- Manually assisted directed cough with pressure to the thoracic cage may be contraindicated in the presence of osteoporosis or flail chest

Hazards and Complications

- Reduced coronary artery perfusion
- Reduced cerebral perfusion
- Incontinence
- Fatigue
- Rib or costochondral fracture
- Headache
- Visual disturbances, including retinal hemorrhage
- Bronchospasm
- Muscular damage or discomfort
- Incisional pain, evisceration
- Anorexia, vomiting
- Gastroesophageal reflux
- Spontaneous pneumothorax
- Pneumomediastinum
- Subcutaneous emphysema
- Cough paroxysms
- Chest pain
- Central line displacement

Excerpts from the American Association for Respiratory Care: Clinical practice guideline: directed cough. *Respir Care* 38:495, 1993.

First, patients are taught to assume a sitting position with one shoulder rotated inward and the head and spine slightly flexed to aid exhalation and allow easy thoracic compression. It is difficult to generate an effective cough in the supine position. The patient's feet should be supported to provide abdominal and thoracic support for the patient. If the patient is unable to sit up, the RT should raise the head of the bed and ensure that the patient's knees are slightly flexed with the feet braced on the mattress.

Breathing control measures help ensure that the inspiration, compression, and expulsion phases of the cough are maximally effective and coordinated. For effective inspiration, the patient should be taught to inspire slowly and deeply through the nose, using the diaphragm. In patients with copious amounts of sputum, such breaths alone may stimulate coughing by loosening secretions in the larger airways.

After confirming that the patient can take a good, deep inspiration, the RT has the patient bear down against the glottis, in much the same manner as would occur with straining when lifting weights or during a bowel movement. For patients with pain or patients subject to bronchial collapse, it is probably best that they be shown how to "stage" their expiratory effort into two or three short bursts. For these patients, this method is generally less fatiguing and more effective in producing sputum than a single violent expulsion. Effective breathing control and effective coughing are best taught by demonstration. The RT demonstrates the various phases of the cough sequence while emphasizing the correct technique. The RT explains how to avoid common errors, such as simple throat clearing and weak cough efforts.

Proper positioning and breathing control alone may not result in an effective cough and clear secretions. This limitation is usually due to weak breathing muscles. Muscle weakness is common in patients with NMD, COPD, or those needing long-term ventilatory support. The breathing muscles may atrophy due to disease progression, lack of appropriate nutrition, or lack of use during mechanical ventilation. In these cases, either suctioning or using the mechanical insufflation-exsufflation (MIE) device may be effective in helping clear these secretions.

Modifications to directed cough technique. Modifying the normal directed cough to the needs of the individual patient may lead to a productive cough effort. Good clinical examples of the need to modify directed cough are seen in surgical patients, patients with COPD, and patients with neuromuscular disorders.

In surgical patients, preoperative training in deep breathing and directed cough can help prepare the patient for the postoperative regimen. This preparation can minimize the anxiety related to pain that commonly impairs an effective cough in these patients. In addition, coordinating the coughing sessions with prescribed pain medication and **splinting** the operative site can enhance the effectiveness of these sessions. The RT can use his or her hands with a pillow or blanket to support the area of incision during the expiratory phase of the cough. Eventually, the patient can learn to use a pillow or blanket roll to splint the incision site. The **forced expiratory technique (FET)** (discussed subsequently) may also be valuable in these patients.

In some patients with COPD, the high pleural pressures during a forced cough may compress the smaller airways and limit the effectiveness of the cough. FET maybe beneficial in these patients because the technique reduces transpulmonary pressures and decreases airway compression or closure.[15] In this situation, the patient is placed in the sitting position previously described. The patient is instructed to take in a moderately deep breath slowly through the nose. To help enhance expulsion, the patient should exhale with moderate force through pursed lips, while bending forward. This forward flexion of the thorax enhances expiratory flow by upward displacement of the abdominal contents. After three or four repetitions of this maneuver, the patient is encouraged to bend forward and initiate short staccato-like bursts of air. This technique relieves the strain of a prolonged hard cough, and the staccato rhythm at a relatively low velocity minimizes airway collapse. These staccato-like bursts of air against an open glottis are referred to as *huffing*. With this technique the patient is instructed to make the sound "huff, huff, huff" rapidly with the mouth and glottis open. **Huff coughing** is also referred to as FET.[15]

RULE OF THUMB Huff coughing or FET should be used to prevent small airway compression due to high pleural pressures during a forced cough in patients with COPD, CF, or bronchiectasis.

Forced Expiratory Technique

As stated above, FET consists of one or two forced expirations of middle to low lung volume without closure of the glottis, followed by a period of diaphragmatic breathing and relaxation.[16] The goal of this method is to help clear secretions with less change in pleural pressure and less likelihood of bronchiolar collapse. To help keep the glottis open during FET, the patient is taught to phonate or "huff" during expiration. The period of diaphragmatic breathing and relaxation following the forced expiration is essential in restoring lung volume and minimizing fatigue. Comparative clinical studies on the effectiveness of FET have shown favorable results. The technique is particularly useful in patients prone to airway collapse during normal coughing, such as patients with COPD, CF, or bronchiectasis.[17,18]

Manual Assisted Cough

Patients with neuromuscular conditions present a special challenge in cough management. These patients typically are unable to generate the forceful expulsion needed to move secretions toward the trachea.[11] If this problem results in retained secretions, there are only three options: (1) placement of an artificial airway and removal of secretions by suctioning (see Chapter 37), (2) manually assisted cough, and/or (3) MIE.

Manually assisted cough (quad—cough) is an external application of pressure to the thoracic cage or epigastric region, coordinated with a forced exhalation. In this technique, the patient takes as deep an inspiration as possible, assisted as needed by the application of positive pressure using a self-inflating manual resuscitation bag or ventilator. At the end of the patient's inspiration, the RT exerts pressure under the diaphragm (lateral costal margins or epigastrium) abruptly. This pressure increases the force of compression throughout expiration; this mimics the normal cough mechanism by generating an increase in the velocity of the expired air and may be helpful in moving secretions toward the trachea, where they can be removed by suctioning. Assisted cough with pressure to the lateral costal margins is contraindicated in patients with osteoporosis or flail chest. Assisted cough using epigastric pressure is contraindicated in unconscious patients with unprotected airways, in pregnant women, and in patients with acute abdominal pathology, an abdominal aortic aneurysm, or a hiatal hernia.

Active Cycle of Breathing Technique

To emphasize that FET should include breathing exercises, the originators of this technique modified the procedure and renamed it the **active cycle of breathing technique (ACBT)**. ACBT consists of repeated cycles of breathing control, thoracic expansion, and FET (Box 44.6). *Breathing control* involves gentle diaphragmatic breathing at normal tidal volumes for 5 to 10 seconds with relaxation of the upper chest and shoulders. This phase is intended to help prevent bronchospasm. The thoracic expansion exercises involve deep inhalation, approaching vital capacity, with relaxed exhalation, which may be accompanied by percussion, vibration, or compression. The *thoracic expansion* phase is designed to help loosen secretions, improve the distribution of ventilation, and provide the volume needed for FET. The subsequent FET moves secretions into the central airways. Postoperative patients may require splinting at the thoracic or abdominal incision site. Although ACBT can be performed in the sitting position, it is most beneficial when combined with PD. When ACBT is compared with similar methods of secretion clearance, studies indicate that ACBT can provide comparable results in terms of both sputum production and distribution of ventilation.[2,19] ACBT is not useful with young children (<2 years old) or critically ill patients. Caution should be taken in patients with reactive airways during ACBT.

BOX 44.6 Active Cycle of Breathing Technique Sequence

1. Relaxation and breathing control
2. Three or four thoracic expansion exercises
3. Relaxation and breathing control
4. Repeat three to four thoracic expansion exercises
5. Repeat relaxation and breathing control
6. Perform one or two forced expiratory techniques (huffs)
7. Repeat relaxation and breathing control

MINI CLINI

Modifications to Directed Cough

Problem

A patient who has been diagnosed with ALS who has been attending your multidisciplinary clinic for the last few years returns for a follow-up visit. The patient states that she has noticed that her cough is not as powerful as it has been and that she is "winded" when walking distances. The RT assesses the patient and finds: pulse rate of 80, respiratory rate of 24, and breath sounds of scattered wet crackles in both lungs. The patient performs spirometry and maximum inspiratory pressure (MIP) and maximum expiratory pressure (MEP) maneuvers. Her forced vital capacity (FVC) is 70% of predicted; MIP is negative 50 cm H_2O and MEP is 55 cm H_2O sitting; and MIP is negative 40 cm H_2O and MEP is 40 cm H_2O supine. The therapist reviews the values from the previous visit 3 months earlier and finds FVC was 75% of predicted and MIP was a negative 65 cm H_2O and the MEP was 70 cm H_2O both sitting and supine.

Discussion

Based on this assessment, the patient's lung volumes and muscle strength have declined. She also has retained secretions and would benefit from ACT and possibly MIE to assist with secretion removal. The patient began HFCWC to mobilize these secretions and MIE to assist in expectorating the secretions. This therapy should take place at least twice a day.

Autogenic Drainage

Autogenic drainage (AD) is another modification of directed coughing, designed as an airway clearance mechanism that can be performed independently by trained patients.[18] During AD, the patient uses diaphragmatic breathing to mobilize secretions by varying lung volumes and expiratory airflow in three distinct phases (Fig. 44.6). For maximum benefit, the patient should be in the sitting position. Patients are taught to control their expiratory flows to prevent airway collapse while trying to achieve a

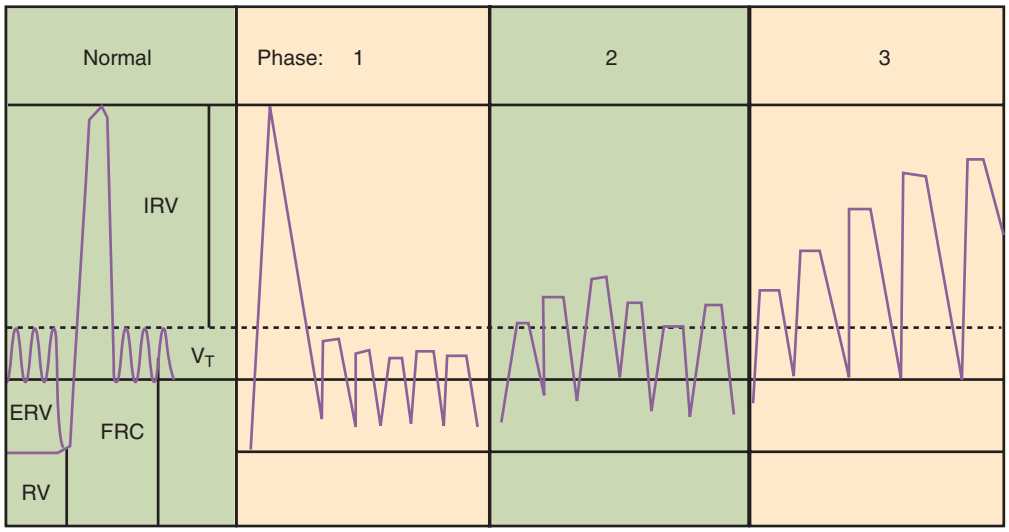

Fig. 44.6 Spirogram of lung volumes during three phases of autogenic drainage. Phase 1 involves a full inspiratory capacity maneuver, followed by breathing at low lung volumes. This phase is designed to "unstick" peripheral mucus. Phase 2 involves breathing at low-to-middle lung volumes to collect mucus in the middle airways. Phase 3 is the evacuation phase, in which mucus is readied for expulsion from the large airways. *IRV,* Inspiratory reserve volume; *ERV,* expiratory reserve volume; *FRC,* functional reserve volume; *RV,* residual volume. (Modified from Hardy KA, Anderson BD: Noninvasive clearance of airway secretions, *Respir Care Clin North Am* 2:323, 1996.)

mucous "rattle" rather than a wheeze. Coughing should be suppressed until all three breathing phases are completed.

In patients with CF, AD provides sputum clearance comparable to postural drainage percussion on a vibration (PDPV) but is less likely to produce O_2 desaturation. In addition, AD seems to be tolerated better by patients and has the advantage of being performed without assistance from a caregiver.[18]

Mechanical Insufflation-Exsufflation

The MIE device (also called *cough-assist device* or "coughlator") has gained popularity in its use to manage secretions in patients with certain neuromuscular disorders (Fig. 44.7).[11] The reason is growing evidence that MIE helps prevent respiratory complications in patients with NMD by helping them generate sufficient expiratory flow rates needed for effective secretion clearance.[1,11]

NMD patients who are not able to demonstrate a peak cough flow greater than 180 L/min or not able to generate an effective cough may benefit from MIE.[11,20] The American Association for Respiratory Care Clinical Practice Guideline for ACT recommends cough assist techniques when peak cough flows are less than 270 L/min in NMD patients.[1] The MIE devices have incorporated oscillation during inspiration or expiration to assist in mobilizing secretion The MIE delivers a positive pressure breath of 30 to 50 cm H_2O over a 1- to 3-second period via a face mask or artificial airway. The airway pressure is abruptly reversed to −30 to −50 cm H_2O and maintained for 2 to 3 seconds. Peak expiratory "cough" flows obtained with this device are in the normal range (mean 7.5 L/s); far better than can be achieved with manually assisted coughing. Expiratory flows remain high in the immediate post-exsufflation period, indicating that MIE does not promote airway collapse. Newer MIE devices have incorporated oscillation during inspiration or expiration to assist in mobilizing secretions.

Fig. 44.7 Mechanical insufflation-exsufflation device (mie, cough assist device).

A typical treatment session with the MIE consists of about five cycles (inspiration and expiration) followed by a period of normal spontaneous or assisted breathing (to avoid hyperventilation). This process is repeated five or more times until secretions are cleared from the airway and the patient is able to either suction or spit them out.

MIE delivered using an oronasal mask is effective, provided there is no fixed airway obstruction or glottic collapse during exsufflation that is present with bulbar ALS. For patients with severe restrictive disease and NMD who are not able to take deep breaths, insufflation pressures should be increased gradually based on the patient and their assessment to avoid chest wall muscle strains. Abdominal distension is infrequent and reduced by decreasing airway pressures during insufflation, not exsufflation.

Precautions should be observed using MIE with patients with known cardiac instability. It may be beneficial to monitor heart rate and O_2 saturation closely in these patients. MIE is contraindicated in patients with a history of bullous emphysema or previous barotrauma such as pneumothorax or pneumomediastinum.

Positive Airway Pressure Adjuncts

PAP adjuncts are used to help mobilize secretions and treat atelectasis. As adjuncts for airway clearance, these methods are usually paired with other airway clearance techniques such as directed cough. Indications for PAP adjuncts are like those listed early for all ACT. These devices elevate airway pressure and also may be beneficial in treating atelectasis. See Chapter 43 to review the use of these methods to treat atelectasis. Box 44.7 lists the contraindications and potential complications associated with PAP adjuncts. The following discussion will focus on the use of PAP devices for secretion clearance.

Positive Expiratory Pressure and Oscillating Positive Expiratory Pressure

PEP therapy involves active expiration against a fixed orifice flow resistor or variable orifice threshold resistor capable of developing pressures of 10 to 20 cm H_2O. Most fixed orifice devices allow adjustment of the orifice size to achieve a targeted PEP level. In theory, PEP therapy helps move secretions into the larger airways by providing a constant back-pressure that prevents airway collapse during expiration and the airway behind the mucus fills via collateral ventilation. A subsequent huff or FET maneuver may allow the patient to generate the flows needed to expel mucus from blocked airways.

PEP devices are available as PEP only or oscillating PEP (OPEP). OPEP devices (some refer to this as vibratory PEP) provide rapid fluctuations in airway pressure as the patient exhales. The frequency of the vibrations/oscillations has been reported to range from 10 to 30 Hz with amplitudes ranging from 20 to 100 torr at flows of 10 and 25 L/min.[21] Clinical studies of PEP and OPEP therapy showed that secretion clearance improved in hospitalized patients with CF,[2,22] and in COPD patients with secretion retention.[1] Generally, compared with other airway clearance methods (PDPV, AD, ACBT) in patients with CF, PEP therapy provides comparable mucociliary clearance, with the added advantages of being potentially self-administered and cost-effective.[1,15] Patients may prefer PEP over CPT.[15] PEP therapy

BOX 44.7 Positive Airway Pressure Adjuncts for Airway Clearance Therapy

Contraindications

Although no absolute contraindications to the use of positive airway pressure adjuncts have been reported, the following should be carefully evaluated before initiating therapy:

- Patients unable to tolerate increased work of breathing (acute asthma, chronic obstructive pulmonary disease)
- Intracranial pressure (ICP) greater than 20 mm Hg
- Hemodynamic instability
- Acute sinusitis
- Active hemoptysis
- Untreated pneumothorax
- Known or suspected tympanic membrane rupture or other middle ear pathology
- Recent facial, oral, or skull surgery or trauma
- Epistaxis
- Esophageal surgery
- Nausea

Hazards and Complications Include

- Pulmonary barotraumas
- Increased ICP
- Cardiovascular compromise (myocardial ischemia, decreased venous return)
- Skin breakdown and discomfort from mask
- Air swallowing, vomiting, and aspiration
- Claustrophobia
- Increased work of breathing that may lead to hypoventilation and hypercapnia

Excerpts from the American Association for Respiratory Care: Clinical practice guideline: use of PAP adjuncts to bronchial hygiene therapy. *Respir Care* 38:516, 1993.

cannot be used in young children (<3 years old). Patients also must be able to take a deep breath (>10 to 12 mL/kg) to generate adequate pressure, oscillations, and prolonged exhalations.

There are several available PEP and OPEP devices on the market, and manufacturer instructions on recommended application are included with each device (Fig. 44.8). Most of these are single-use commercial devices. A general clinical procedure for application of PEP therapy is presented in Box 44.8.[14] Regardless of the equipment used, it is important that actual intended PEP levels are reached, so monitoring and coaching of the patient for correct use is essential. There may be significant changes in the pressure amplitude and PEP with various devices as airway resistance increases, which warrants further clinical investigation regarding these findings clinical impact.[23]

RULE OF THUMB Patients must also be able to take a deep breath (>10–12 mL/kg predicted body weight [PBW]) to generate adequate pressure, oscillations, and prolonged exhalations during PEP therapy.

Common strategies for PEP therapy vary, with frequency determined by assessment of patient response. Studies provide conflicting results related to the amount of time and intervals of therapy sessions during acute exacerbations associated with CF and COPD. Two to four times daily are common frequencies used for PEP therapy. Aerosol drug therapy may be added to a PEP session using either an in-line handheld nebulizer or a metered dose inhaler attached to the one-way valve inlet of the

Fig. 44.8 Positive expiratory devices. (A) Flutter. (B) TheraPEP. (C) Acapella (Choice is used for a range of flows. Green is used for flows higher than 15 L/min. Blue is used for flows less than 15 L/min.). (D) Aerobika. (E) RC-Cornet.

BOX 44.8 Clinical Procedure for Positive Airway Pressure Therapy

1. Assess need for positive airway pressure (PAP) therapy and design a treatment program to accomplish treatment objectives.
   a. Bring equipment to bedside and provide initial therapy to patient, adjusting pressure settings to meet patient need.
   b. After initial patient treatment or training, communicate treatment plan to physician and nurse, and provide instruction to nursing staff if required.
2. Explain purpose of PAP therapy to patient; teach patient "huff" (directed cough procedure).
3. Instruct patient to:
   a. Sit comfortably.
   b. If using a mask, apply it tightly but comfortably over the nose and mouth. If mouthpiece is used, place lips firmly around it and breathe through mouth.
   c. Take in a breath that is larger than normal, but do not completely fill lungs.
   d. Exhale actively, but not forcefully, creating a PAP of 10–20 cm H_2O during exhalation (determined with manometer during initial therapy sessions). Length of inhalation should be approximately one-third of the total breathing cycle (inspiratory-to-expiratory ratio of 1 : 3 to 1 : 4).
   e. Perform 10–20 breaths.
   f. Remove the mask or mouthpiece and perform two or three "huff" coughs; rest as needed.
   g. Repeat above cycle four to eight times, not to exceed 20 min.
4. Evaluate patient for the ability to self-administer.
5. When appropriate, teach patient to self-administer. Observations on several occasions of proper technique, uncoached, should precede allowing the patient to self-administer without supervision.
6. When patients are also receiving bronchodilator aerosol, administer in conjunction with PAP therapy by placing a nebulizer in line with the PAP device.
7. When PAP device is visibly soiled, rinse it with sterile water and shake or air dry; leave within reach at patient's bedside in a clear plastic bag.
8. Send the PAP device (if single-patient use) home with the patient or discard it on discharge. If device is nondisposable, send in-house for high-level disinfection.
9. Document in the patient's medical record procedures performed (including device, settings used, pressure developed, number of breaths per treatment, and frequency), patient response to therapy, patient teaching provided, and patient ability to self-administer.

system. The combination of aerosol drug therapy with PEP seems to improve the efficacy of bronchodilator administration because of better distribution to the peripheral airways.[24] Some PEP devices can be modified to incorporate a mask for patients with ALS, toddlers, or stroke patients who are unable to use a mouthpiece.

High-frequency vibrations or **oscillations** refer to the rapid vibratory movement of small volumes of air back and forth in the respiratory tract. At frequencies of 12 to 25 Hz, these oscillations are thought to physically loosen secretions and move them toward the larger airways, which enhances airway clearance. There are two general approaches: airway application of oscillation methods such as OPEP discussed above or **high-frequency airway pressure devices (HFPAP) such as intrapulmonary percussive ventilation**, or external (chest wall) application referred to as **high-frequency chest wall compression (HFCWC)** devices.

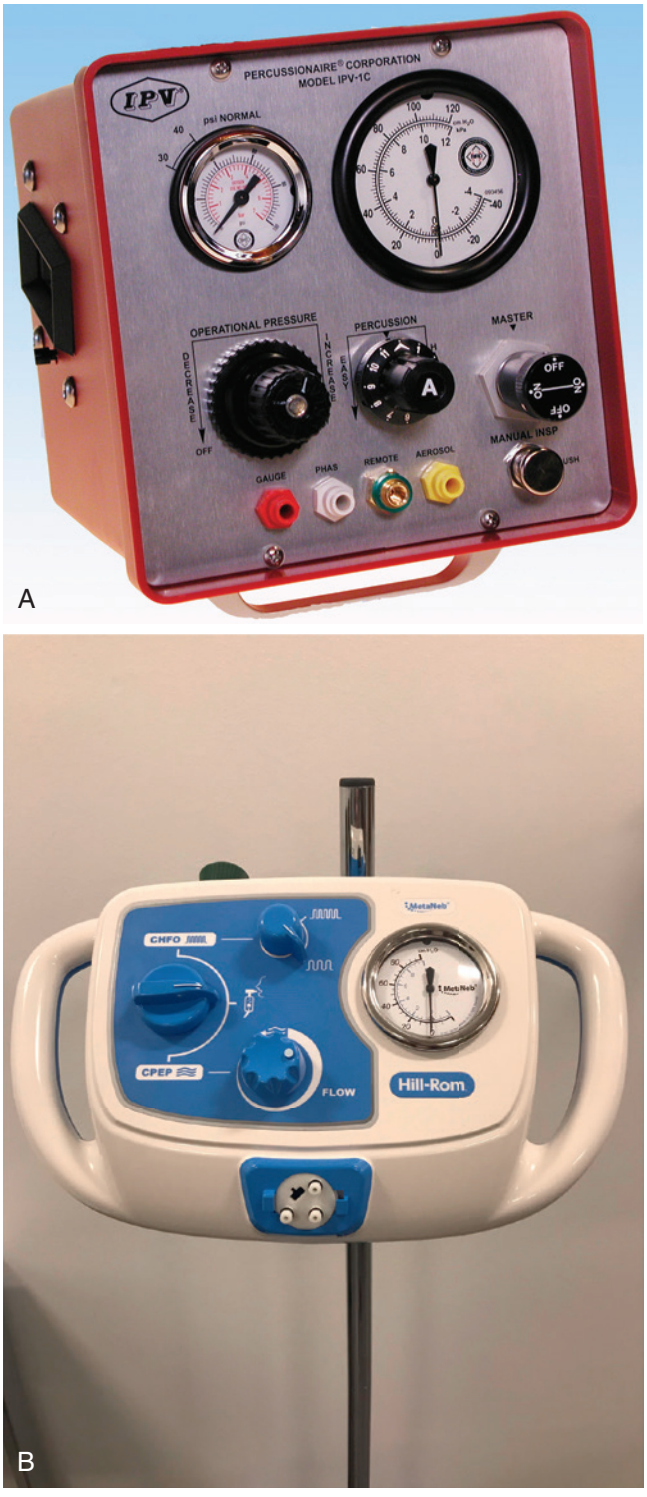

Fig. 44.9 (A) Intrapulmonary percussive ventilator, IPV. (Courtesy Percussionaire, SandPoint, Idaho.) B. MetaNeb. (Courtesy of HILL ROM.)

It is thought that the mucus moves because of the vibrations of the airways created when the oscillation frequency resembles the resonance frequency of the pulmonary system.[21,25]

High-Frequency Positive Airway Pressure Devices

HFPAP devices include the **intrapulmonary percussion ventilator (IPV)** and the **Metaneb** (Fig. 44.9). The IPV (Percussionaire

Corporation, Sandpoint, IN [some refer to this device as the Percussionator]) device (see Fig. 44.9A) was developed by Dr. Forest M. Bird in the late 1980s and it uses a pneumatic device to deliver a rapid series of pressurized gas minibursts at rates of 200 to 300 cycles per minute (1.7 to 5 Hz) to the airway.[26] During the percussive cycle, the patient can inhale and exhale through the device as this oscillating airway pressure is applied. This device also delivers aerosolized medication through its own nebulizer and relies on chest wall recoil or active patient exhalation. Previous research suggests that interpulmonary percussive ventilation is equivalent to other airway clearance strategies in enhancing sputum expectoration in patients with obstructive pulmonary diseases and pediatric patients with NMD.[4,27] The therapy is well tolerated by stable patients and may provide a more effective alternative for airway clearance in patients unable to take a deep inspiration. In a group of severe COPD patients receiving two treatments per day for 4 weeks, both IPV and HFCWC improved activities of daily living and pulmonary functions compared to the control group. IPV also significantly improved health status assessment and inflammatory cells in sputum compared to HFCWC.[28] Further studies are needed to determine the impact on healthcare utilization and hospital readmission.

Another HFPAP is the Metaneb device (Hill-Rom, Inc. Batesville, IN; Fig. 44.9B), which uses similar characteristics that provides a pneumatic form of chest physiotherapy. The Metaneb is able to deliver high-frequency rates, with oscillatory percussive breaths during inspiration and expiration, and resistance levels on exhalation. The Metaneb can deliver aerosol therapy during the lung expansion and secretion clearance cycles. The therapy lasts about 10 minutes alternating between the lung expansion and secretion clearance cycles depending on patient comfort. The percussion rate varies between 170 and 230 breaths/min.

Both Metaneb and IPV have venturi devices housed inside the device. The venturi devices create high-frequency percussions during inspiration and expiration, which result in a pressure gradient.[25] The pressure gradient creates an accelerated expiratory airflow and secretions move up into the larger airways for the patient to expel or are suctioned from an artificial airway.[25] In addition, hyperinflation occurs at the same time assisting the patient with a deeper breath, which improves cough effectiveness. These devices are used in the hospital setting. Clinical trials using both devices demonstrate they are effective at enhancing secretion removal.[1,2,22,25,27]

High-Frequency Chest Wall Compression

HFCWC devices are passive oscillatory devices. These devices use a two-part system: (1) a variable air-pulse generator, and (2) a nonstretch inflatable vest that wraps around the patient's entire torso. Examples of these devices are; Electromed—SmartVest; Hill Rom—The Vest; RespirTech—inCourage, and the AfflowVest (Fig. 44.10). Either one or two large-bore tubing(s) connect the vest to the air-pulse generator. Table 44.4 lists the devices, air-pulse waveforms, and hose configurations. The generator inflates and deflates the vest, creating pressure pulses against the thorax resulting in chest wall oscillations and moving secretions forward. The AfflowVest is battery operated, digitally programed and uses a technology that mimics hand CPT to mobilize secretions. HFCWC devices are used in hospital or home settings. The therapy is typically performed for a 30-minute session two to six times per day at oscillatory frequencies between 5 and 25 Hz. These therapy sessions depend on patient need and response. Clinical

MINI CLINI

Using High-Frequency Positive Airway Pressure Devices

Problem

A 60-year-old postoperative patient with a 20 pack-year smoking history admits to the surgical intensive care unit following a laparoscopic procedure. The patient is currently receiving 4 L/min nasal cannula with a pulse O_2 saturation of 92%. Their breath sounds are bilateral course rales that do not clear when the patient coughs. Their inspiratory vital capacity is only 550 mL which is 7.9 mL/kg of their predicted body weight. The critical care physician asks that you recommend an effective ACT.

Discussion

Based on this assessment, the patient's lung volumes are too low to effectively perform vibratory PEP therapy. IPV would assist in moving the secretions into the larger airway and increasing the patient's lung volume. This therapy should be every 4 h with the patient sitting up in the bed or chair. Fill the nebulizer with 15 mL of normal saline. Rotate the frequency knob to the easy position by turning this knob counterclockwise until it stops. Set the operating pressure at 20 psi to start. Have the patient breathe on the device through the mouthpiece. Push the button on the manual remote switch located on the nebulizer. Encourage the patient to slowly inhale and exhale through the device as it percusses. They also may need to splint their cheeks to avoid air and pressure loss. If the chest wall of the patient is not wiggling or visibly moving the operating pressure should be slowly increased to approximately 30 psi. Every few minutes the frequency can be increased or changed from easy to hard as tolerated by the patient. Provide breaks in this therapy to instruct the patient on a directed cough. Therapy should last approximately 15 min. The patient should be observed for signs of syncope or light headedness, changes in heart rate or breath sounds, and oxygen saturation.

trials with HFCWC have reported better or equivalent secretions clearance compared to other ACTs in CF patients.[17,18,22,29] Studies in other populations have shown some improvement, as measured by patient perception, increased compliance, or outcome.[1,11,15]

The Biphasic Cuirass Ventilation (BCV) device is an alternative to the vest devices. It may be used to provide noninvasive ventilation and/or cough assist. It uses a chest cuirass or shell that encompasses the anterior chest wall. The shell is connected to the generator that controls both phases of the respiratory cycle. The chest wall will expand when the negative pressure is applied. This device is capable of a frequency range between 1 and 999 oscillations per minute, I:E ratios of 1:6 and 6:1, and inspiratory and expiratory pressures of −70 to 70 cm H_2O. The recommended application is two sets of cycles that include a few minutes at a frequency between 600 and 700 at an I:E of 1:1, followed by a higher frequency at an inverse I:E ratio.[25]

Exercise, Mobilization, and Physical Activity

Immobility is a major factor contributing to complications in chronic disease and hospitalized patients. Early mobilization is recommended to reduce complications in hospitalized patients and is recommended as adjunctive therapy along with another ACT in CF to aid airway clearance and overall health benefits.[1,30] Physical activity may also improve lung function, exercise tolerance, quality of life, and adherence to therapy. For more on the use of exercise in ambulatory patients with severe lung disease see Chapter 56.

SELECTING AIRWAY CLEARANCE TECHNIQUES

Selection Factors

Box 44.9 specifies many factors that should be considered when selecting an airway clearance strategy. The correct application and patient motivation to perform the ACT are critical components regardless of the setting. No ACT is successful if it is abandoned by the patient. Likewise, no routine strategy is likely to be followed without results. In this regard, increased sputum production, less shortness of breath, and perhaps improved physical activity are a few outcomes that can be used to motivate patients and gain their ongoing cooperation. Age, disease process, available resources, and patient preference often affect the choice of ACT. Patient and caregiver goals for treatment should be discussed jointly, with the intent of choosing the method that best fits the patient's goals and lifestyle. The RT's skill and patience in teaching the ACT is also a factor in determining the success of the therapy. The patient's learning needs and barriers to learning also should be considered. Because patients reject methods that are fatiguing, this should be considered in method selection. In addition, the patient's disease either may suggest the best approach or may impose certain limitations that preclude using a particular method. Cost is a critical factor in selecting all treatment strategies. There are multiple inexpensive options that are effective. Patient or caregiver education also plays an important role in the effectiveness of the therapy (see Chapter 55).

BOX 44.9 Key Factors in Selecting an Airway Clearance Strategy

- Patient's motivation
- Patient's goals
- Patient's ability to comprehend—literacy and cognition levels
- Patient's physical limitations
- Physician/caregiver goals
- Effectiveness of technique
- Ease of learning and teaching
- Skill of therapists
- Patient fatigue associated, or work required to use device
- Need for assistance to use the equipment
- Limitations of technique based on disease type and severity
- Costs (direct and indirect)
- Desirability of combining methods

MINI CLINI

Recommending Airway Clearance Strategies

Problem

The RT is asked to evaluate and recommend an appropriate ACT regimen for a 7-year-old active girl with CF who is being cared for in her home by elderly grandparents.

Discussion

Generally, appropriate secretion clearance strategies for this patient include exercise, vibratory PEP, CPT, ACBT, high-frequency chest wall oscillation (HFCWO), and IPV. CPT would be difficult to implement in this patient's home setting (elderly caregivers), so emphasis should be placed on either vibratory PEP with ACBT or HFCWO and FET. An exercise plan should also be incorporated into the overall strategy. Dietary and medication considerations are also important.

Outcome Assessment

Specific outcome criteria indicating a positive response to ACT are listed in Box 44.10. Generally, achievement of one or more of these outcomes indicates that the therapy is meeting its objectives and should be continued. Not all criteria are required to justify continuing ACT. Because secretion clearance is affected by patient hydration, the RT may need to wait for at least 24 hours after optimal systemic hydration has been achieved to see any evidence of increased sputum production. In the interim, bland aerosol therapy may be useful for sputum induction and mobilizing secretions.

Breath sounds may seem to "worsen" after therapy by changing from diminished breath sounds before therapy to coarse crackles. This change is due to the loosening of secretions and their movement into the larger airways, an intended purpose of the therapy. These coarse crackles should clear after coughing

BOX 44.10 Assessment Outcomes After Airway Clearance Therapy

The following items represent individual criteria that indicate a positive response to therapy (and support continuation of therapy). Not all criteria are required to justify continuation of therapy (e.g., a ventilated patient may not have sputum production >30 mL/day but has improvement in breath sounds, chest radiograph, or increased compliance or decreased resistance).

- Change in sputum production
- Change in breath sounds of lung fields being drained
- Patient subjective response to therapy
- Change in vital signs
- Change in chest radiograph
- Change in arterial blood gas values or O_2 saturation
- Change in ventilator variables

Excerpts from the American Association for Respiratory Care: Clinical practice guideline: postural drainage therapy. *Respir Care* 36:1418, 1991.

or suctioning. In addition, the patient's chest x-ray may significantly improve after receiving a few ACTs.

In terms of the patient's subjective response to therapy, the patient should be encouraged to report any pain, discomfort, shortness of breath, dizziness, or nausea during or after therapy. Any of these adverse effects may be grounds for either modifying or stopping treatment. Patient reports of easier clearance or increased volume of secretions after therapy support continuing therapy.

Based on assessment results, ACT orders should be reevaluated for need at least every 2 to 3 days for hospitalized patients. Patients receiving home care should be reevaluated at least every 3 months or whenever their status changes.

Documentation and Follow-Up

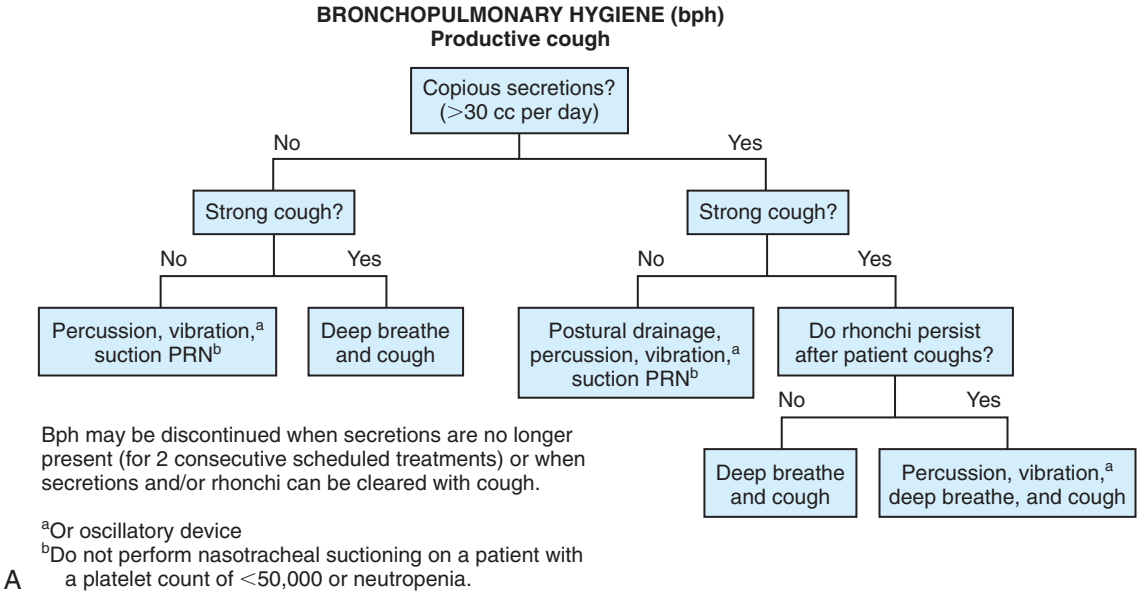
The chart entry for ACT should include the device, the therapy provided, the positions used, the time of treatment, patient tolerance, pre– and post–vital signs and breath sounds, subjective and objective indicators of treatment effectiveness (including amount, color, and consistency of sputum produced), and any adverse effects observed.

Protocol-Based Airway Clearance

Numerous RT-driven protocols have been published for ACT. All of these protocols involve rigorous assessment of the patient both to establish preliminary need and to determine continuation of or modification in therapy. Fig. 44.11 is an algorithm used in one such protocol. Changes in therapy occur throughout and are based on the patient's response and the RT's evaluation.

SUMMARY CHECKLIST

- Normal airway clearance requires a patent airway, a functional mucociliary escalator, and an effective cough.
- Patients with copious secretions (20 to 30 mL/day) or inability to mobilize and expectorate secretions may benefit from ACT.
- The primary goal of ACT is to help mobilize and remove retained secretions, improve gas exchange, and reduce the work of breathing.
- Retained secretions can increase the work of breathing, cause air trapping, worsen $\dot{V}/\dot{Q}$ imbalance, promote atelectasis and shunting, and increase the incidence of infection.
- Disorders associated with abnormal secretion clearance include foreign bodies, tumors, congenital or acquired thoracic anomalies, asthma, chronic bronchitis, CF, bronchiectasis, and acute infections.
- Musculoskeletal and neurologic disorders can impair coughing and lead to mucous plugging, airway obstruction, and atelectasis.
- Both mechanical and treatment factors impair mucociliary clearance in intubated patients.
- Clinical signs consistent with retained secretions include ineffective cough, absent or increased sputum production, a labored breathing pattern, abnormal or adventitious lung sounds (e.g., coarse crackles, decreased breath sounds), tachypnea, tachycardia, and fever.
- Turning promotes lung expansion, improves oxygenation, and prevents retention of secretions.
- Postural drainage involves placing the segmental bronchus to be drained in a vertical position relative to gravity and holding the position for 3 to 15 minutes.
- Cough methods must be modified in surgical patients, patients with COPD, and patients with neuromuscular disorders.
- FET, or huff cough, consists of one or two forced expirations of middle to low lung volume without closure of the glottis, followed by a period of diaphragmatic breathing and relaxation.
- ACBT consists of repeated cycles of breathing control, thoracic expansion, and FET.
- During AD, the patient uses diaphragmatic breathing to mobilize secretions by varying lung volumes and expiratory airflow in three distinct phases.
- MIE involves delivery of a positive pressure breath followed by the quick application of negative pressure; positive expiratory flows exceed flows developed by manually assisted coughing.
- PEP or vibratory therapy is a self-administered clearance technique involving active expiration against a variable-flow resistance, followed by FET; patients frequently prefer PEP over other methods.
- At high frequencies (12 to 25 Hz), airway oscillations enhance cough clearance of secretions.
- Airway oscillations can be created externally (HFCWC) or at the airway opening (flutter valve, Accapella, Aerobika, IPV, Metaneb).
- Adding physical activity to mobilization and coughing enhances mucus clearance, improves overall aeration and $\dot{V}/\dot{Q}$ matching, and improves pulmonary function.
- If performed correctly, no ACT has been proven better than another.
- Numerous factors must be considered in trying to select the best airway clearance strategy for a given patient.
- Outcomes of therapy should include subjective and objective measures.
- ACT protocols are beneficial to patient and practitioner.



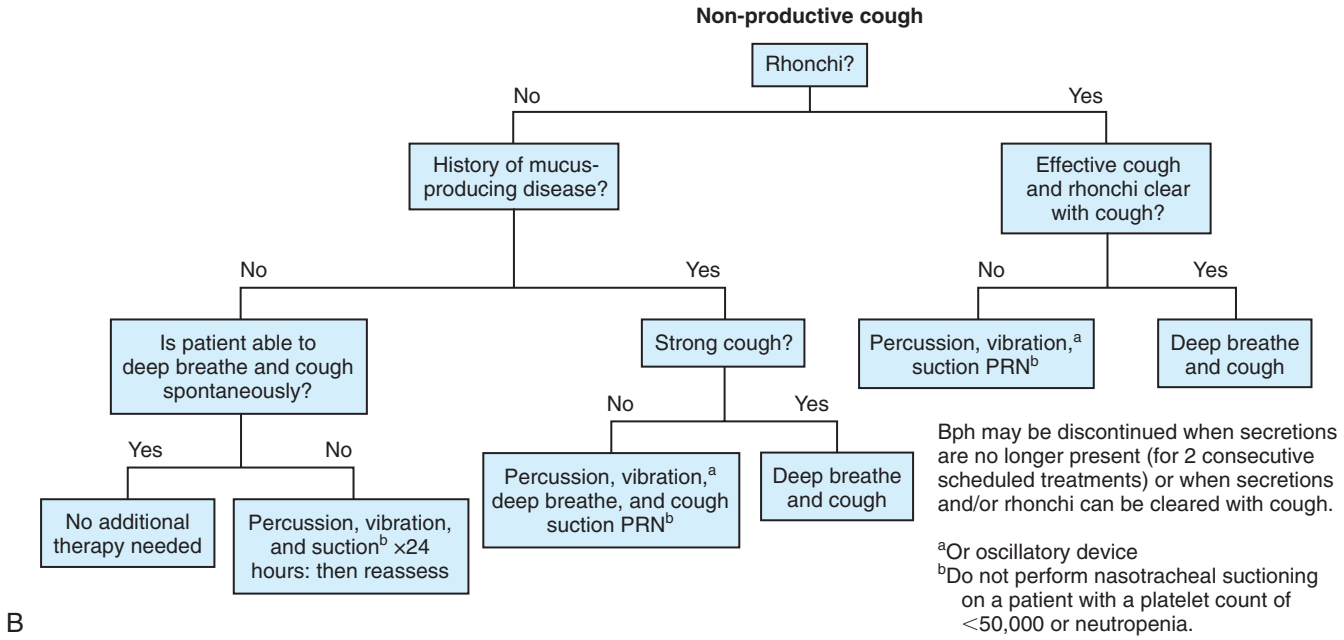


Fig. 44.11 Example of algorithm underlying an airway clearance protocol. (A) An algorithm used in patients with productive cough. (B) An algorithm used in patients with a nonproductive cough. Respiratory Failure and the Need for Ventilatory Support

Loutfi S. Aboussouan

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Define acute respiratory failure.
- Differentiate between hypoxemic respiratory failure (type I) and hypercapnic respiratory failure (type II).
- Discuss the causes of acute respiratory failure.
- Discuss the differences between chronic respiratory failure and acute-on-chronic respiratory failure.
- Identify the complications of respiratory failure.
- Discuss the indications for ventilatory support.
- Discuss general management principles of hypoxemic and hypercapnic respiratory failure.
- Discuss indications for noninvasive ventilation.

CHAPTER OUTLINE

KEY TERMS

auto-PEEP
barotrauma
dynamic hyperinflation
hypercapnic respiratory failure (type II)
hypoxemic respiratory failure (type I)
maximum expiratory pressure (MEP)
maximum inspiratory pressure (MIP)
maximum voluntary ventilation (MVV)
muscle fatigue
noninvasive ventilation (NIV)
orthodeoxia
platypnea
positive end-expiratory pressure (PEEP)
respiratory alternans
sniff nasal inspiratory pressure
pressure-time index
work of breathing

Respiratory failure is a clinical problem that all respiratory care practitioners must be skilled at identifying, assessing, and treating. The hospital mortality of patients requiring intensive care unit (ICU) admission with respiratory failure significantly decreased from 43.5% in 1993 to 32.2% in 2009.[1] The need for oxygen (O_2) delivery, mechanical ventilation, and other modalities in the management of such patients makes the respiratory therapist's (RT) role indispensable.

Respiratory failure is the "inability to maintain either the normal delivery of O_2 to the tissues or the normal removal of carbon dioxide (CO_2) from the tissues"[2] and often results from an imbalance between respiratory workload and ventilatory strength or endurance. Criteria based on arterial blood gases (ABGs) were established by Campbell who categorized respiratory failure into hypoxemia without hypercapnia, and hypoxemia with hypercapnia.[3] Generally, *failure* is defined as arterial partial pressure of oxygen (PaO_2) less than 60 mm Hg (also referred to as **hypoxemic** or **type I respiratory failure**), alveolar partial pressure of carbon dioxide ($PaCO_2$) 50 mm Hg or greater (**hypercapnic** or **type II respiratory failure**), or both, while breathing room air at sea level. Respiratory failure can be an acute or a chronic process. Hypercapnic respiratory failure is also known as *ventilatory failure* or "bellows" failure. Patients with baseline acid–base derangement (e.g., chronic obstructive pulmonary disease [COPD], neuromuscular disease, thoracic or parenchymal restrictive lung disease) may be chronically hypercapnic and in chronic ventilatory failure. Although ABG analysis is helpful in distinguishing hypoxemic (type I) and hypercapnic (type II) respiratory failure, many patients in acute respiratory failure develop both hypoxemia and hypercapnia.

HYPOXEMIC RESPIRATORY FAILURE (TYPE I)

The primary causes of hypoxemia are the following:

- Ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch
- Shunt
- Alveolar hypoventilation
- Diffusion impairment
- Perfusion/diffusion impairment
- Decreased inspired O_2
- Venous admixture or anatomic shunt

These entities are briefly discussed here and are discussed in more detail in Chapters 11 and 12.

Ventilation/Perfusion Mismatch

There are regions in healthy lungs where ventilation and perfusion are not evenly matched, so it seems logical that this is the most common cause of hypoxemia. West described a high $\dot{V}/\dot{Q}$ ratio at the apex of the lungs and a low ratio at the bases.[4] This concept can be oversimplified as there being more air than blood at the apices and more blood than air at the bases.

Pathologic $\dot{V}/\dot{Q}$ mismatch occurs when disease disrupts this balance, and hypoxemia results (Fig. 45.1A). Most commonly, areas of low $\dot{V}/\dot{Q}$ ratio are seen in which ventilation is decreased despite adequate blood flow. Obstructive lung diseases are frequent causes. The bronchospasm, mucous plugging, inflammation, and premature airway closure that signal asthmatic or emphysematous exacerbations worsen ventilation and create $\dot{V}/\dot{Q}$ mismatch. Infection, heart failure, and inhalation injury may lead to partially collapsed or fluid-filled alveoli, also resulting in decreased ventilation and reduced blood O_2 levels.

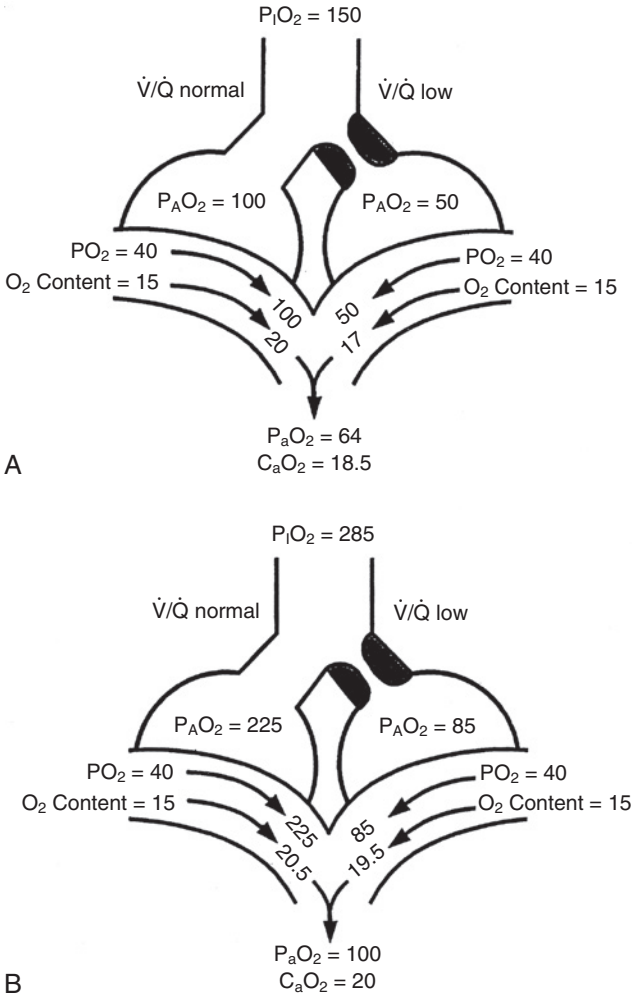

Fig. 45.1 Hypoxemia caused by $\dot{V}/\dot{Q}$ mismatch showing the effect of supplemental O_2. $\dot{V}/\dot{Q}$ is normal on the left side of each idealized lung unit and low on the right. Only O_2 exchange is shown, and P(A – a) O_2 is assumed to be zero. (A) With room air, not enough O_2 reaches the poorly ventilated alveolus to saturate its capillary blood fully. (B) With 40% O_2, PaO_2 in this alveolus is increased enough to make capillary PO_2 nearly normal. PaO_2 in the mixed blood from the two capillaries is determined by the average of the O_2 contents of the two streams of blood, not by the PaO_2 values. (Modified from Pierson DJ, Kacmarek RM: *Foundations of respiratory care*, New York, 1992, Churchill Livingstone.)

Clinical Presentation

Because patients present with hypoxemia, the initial goal is always to treat the low PaO_2 or SpO_2 (arterial O_2 saturation by pulse oximeter). $\dot{V}/\dot{Q}$ mismatch responds to supplemental O_2 (see Fig. 45.1B). Hypoxemia commonly causes dyspnea, tachycardia (rapid heart rate), and tachypnea (rapid breathing rate), but these are very nonspecific findings. However, patient observation is extremely valuable. The use of accessory muscles of respiration (scalene, pectoralis major, and sternomastoid) is an important

sign that normal diaphragmatic inspiration is inadequate. In an elderly, cachectic, or barrel-chested individual who is leaning forward on his or her arms, COPD is the likely diagnosis. Nasal flaring may be present. Lower extremity edema suggests cardiac failure as the cause of hypoxemia. Cyanosis may be peripheral and primarily due to decreased blood flow. Central cyanosis, seen most easily as a bluish tint around the lips, occurs when greater than 5 g/dL of unsaturated hemoglobin is present. This finding is more common in patients with polycythemia (an increase in red blood cells) but may be subject to wide observer variability. More severe hypoxemia can lead to significant central nervous system (CNS) dysfunction, ranging from irritability to confusion to coma.

Auscultation and percussion are very useful when added to patient observation. Bilateral wheezing, especially in a young patient in respiratory distress, often identifies the bronchospasm of asthma. Upper airway disease or fluid-filled airways may also result in wheezing. Breath sounds that are diminished bilaterally with increased resonance on percussion are common in emphysema. Unilateral abnormalities are significant. Wheezing in one lung may suggest an endobronchial lesion, whereas the absence of breath sounds and decreased resonance on one side of the chest may reflect collapse, infection, edema, or effusion as potential causes of $\dot{V}/\dot{Q}$ mismatch. Discordant exam findings with increased resonance on percussion and decreased breath sounds on the same side may suggest a pneumothorax. Unilateral crackles and decreased resonance on percussion generally indicate an alveolar filling process (mass, infection, fluid).

Radiographically, $\dot{V}/\dot{Q}$ mismatch can manifest as a "black" radiograph, with large or hyperinflated lungs as in the case of obstructive disease. A "white" chest radiograph is evident when alveoli are partially occluded. The "blackness" or "whiteness" of the lung fields on the plain chest radiograph has important diagnostic value in assessing a patient with acute respiratory failure.

Shunt

Shunt is an extreme version of $\dot{V}/\dot{Q}$ mismatch in which there is no ventilation to match perfusion ($\dot{V}/\dot{Q} = 0$). Two types of shunt can occur: anatomic and physiologic. About 2% to 3% of the blood supply is shunted via the bronchial and thebesian veins that feed the lungs and heart; this is normal anatomic shunt. Pathologic anatomic shunt occurs as a result of right-to-left blood flow through cardiac openings (e.g., atrial or ventricular septal defects) or in pulmonary arteriovenous malformations. Physiologic shunt accompanies $\dot{V}/\dot{Q}$ mismatch and leads to hypoxemia when alveoli collapse or are filled with fluid or exudate. Common etiologies of physiologic shunting include atelectasis, pulmonary edema, and pneumonia. Shunt does not respond to supplemental O_2 when the gas-exchange unit (the alveolus) is not open (Fig. 45.2A) or when the blood does not come into contact with ventilated areas of the lung (anatomic shunt).

Clinical Presentation

The clinical presentation and patient observations in shunting are very similar in many ways to the presentation of $\dot{V}/\dot{Q}$ mismatch. Bilateral or unilateral crackles are common owing to the alveolar filling process. Unilateral absence of breath sounds may indicate significant collapse, mass, or effusion; these conditions require treatment before oxygenation can improve. The parenchyma on chest radiograph may be "white" with physiologic causes of shunting as may occur in the acute respiratory distress syndrome (ARDS). Anatomic shunts may be harder to diagnose as the chest x-ray may appear normal, but can be diagnosed by using 100% O_2 breathing techniques, contrast-enhanced echocardiography, macroaggregated albumin scanning, or pulmonary angiography.[5] Shunt is differentiated from $\dot{V}/\dot{Q}$ mismatch by the lack of increase in PO_2 as fractional inspired oxygen (FiO_2) is increased (see Fig. 45.2B).

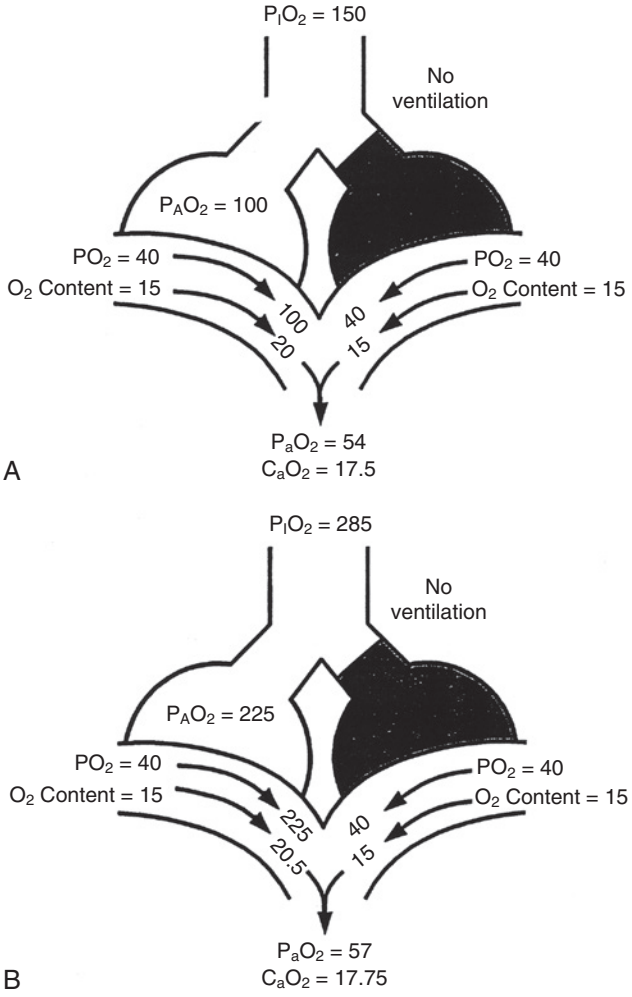

Fig. 45.2 Alveolar-capillary diagram of intrapulmonary (capillary) shunting showing why supplemental O_2 fails to correct hypoxemia. Only O_2 exchange is shown, and $P(A - a)O_2$ is assumed to be zero. (A) With room air, although blood leaving the normal alveolar-capillary unit is normally saturated, blood passing the capillary on the right "sees" no O_2 because its alveolus is unventilated, and it leaves the unit unsaturated. When the two streams of blood mix, the resulting PaO_2 is determined by the average of the O_2 contents, not by the PO_2 values. (B) Addition of 40% O_2 fails to correct the hypoxemia because O_2 content is not significantly increased in the normal unit, and capillary blood in the unventilated unit still "sees" no O_2. Even 100% O_2 could not completely reverse the oxygenation defect in this example; this is very different from the effect with low $\dot{V}/\dot{Q}$ as illustrated in Fig. 45.1. (Modified from Pierson DJ, Kacmarek RM: *Foundations of respiratory care*, New York, 1992, Churchill Livingstone.)

Alveolar Hypoventilation

Alveolar hypoventilation is discussed subsequently in the section on hypercapnic respiratory failure (type II).

Diffusion Impairment

Diffusion refers to movement of gas across the alveolar-capillary membrane along a pressure gradient. Although diffusion impairment is rarely a cause of significant hypoxemia at rest, its effects become more pronounced with exercise, which limits the time for gas exchange. Diffusion impairment in interstitial lung disease (e.g., pulmonary fibrosis, asbestosis, sarcoidosis), in which the thickening and scarring of the interstitium prevent normal gas exchange, may contribute 19% of the alveolar-arterial O_2 gradient at rest, and up to 40% during exercise).[6] Emphysema, with its alveolar destruction, also has decreased transfer of O_2 and CO_2 between the alveolus and the capillary. The reduced ventilation in both diseases implies that $\dot{V}/\dot{Q}$ mismatch also plays a role in the resulting hypoxemia.

Pulmonary vascular abnormalities also can lead to diffusion impairment. Anemia, pulmonary hypertension, and pulmonary embolus all may reduce capillary blood flow, resulting in diminished gas transfer.

Clinical Presentation

Signs and symptoms are related to the specific disease. Interstitial lung disease is a possible cause of a dyspneic patient with a dry cough and fine, basilar crackles on auscultation, and clubbing of the nail beds. Rheumatologic manifestations may be present if the underlying cause is a connective tissue disorder. Joint abnormalities, Raynaud disease, and *telangiectasia* (a vascular lesion formed by dilation of a group of small blood vessels) may be observed. The pallor of anemia can be a clue to poor gas exchange, although chronic hypoxemia may lead to polycythemia and possibly cyanosis. Pulmonary hypertension may cause signs of right-sided heart failure, such as edema, jugular venous distension, and a louder pulmonary component of the second heart sound.

Diffusion impairment can also manifest with multiple, varied radiographic forms. The hyperinflated, dark chest x-ray of emphysema was mentioned earlier. Interstitial disease may manifest with reduced lung volumes with interstitial markings. An enlarged right ventricle and pulmonary arteries may be evident in secondary pulmonary hypertension.

Perfusion/Diffusion Impairment

Perfusion/diffusion impairment is a cause of hypoxemia in individuals with liver disease complicated by the hepatopulmonary syndrome.[7] In this condition, right-to-left intracardiac shunt combines with dilated pulmonary capillaries, resulting in impaired gas exchange because the normal alveolar partial pressures of O_2 may be insufficient to drive the O_2 molecules to the center of the dilated pulmonary vasculature. Cirrhosis is the most common liver disease associated with the hepatopulmonary syndrome, and portal hypertension is usually present. Although shunt is a component of the syndrome, significant supplemental O_2 can overcome the hypoxemia, so this is commonly called a *perfusion/diffusion defect.*

Clinical Presentation

Obvious signs of liver disease (e.g., ascites, jaundice, and spider nevi) may or may not be present. Digital clubbing can occur in hepatopulmonary syndrome. ***Platypnea***, which is the sensation of dyspnea when moving to the upright position from the supine position, may be a patient complaint. **Orthodeoxia,** an actual decrease in the measured O_2 level when standing, may parallel this subjective sensation.

Decreased Inspired Oxygen

Also clinically uncommon, hypoxemia may develop when the inspired O_2 is less than usual. The most common situation in which this occurs is at high altitude, where hypoxemia occurs not because of a decrease in the fraction of O_2 in the ambient air (which remains 21%) but from barometric pressure decreases, which results in a decrease in the partial pressure of inspired O_2. Even with pressurized airplanes, air travelers with chronic hypoxemia may still need supplemental O_2 because the altitude equivalent inside a commercial airliner may be up to 8000 feet.[8] Similarly, mountain climbers sometimes require O_2 masks. Cases of patient-O_2 disconnects and delivery of an incorrect gas source are also included in this category.

Inspired O_2 less than 21% can also be used diagnostically and therapeutically. The Hypoxia Altitude Simulation Test replicates inspired partial pressure of O_2 (PiO_2) during air travel by asking the potential traveler to inhale a hypoxic mixture. Inhaling at FiO_2 of 15% replicates the PiO_2 found at an altitude of 8000 feet (108 mm Hg), and so is useful to assess whether the patient may require supplemental O_2 during commercial air travel. For a lower altitude of 5400 feet, an equivalent FiO_2 of 17% can be calculated.[8] Infants with certain cyanotic congenital heart defects (e.g., hypoplastic left ventricle) may benefit from FiO_2 below room air level. In the preoperative state, low FiO_2 helps prevent pulmonary dilation and the excessive pulmonary blood flow, which could flood the lungs.

Clinical Presentation

The signs and symptoms of hypoxemia may be present, with the cause related to the patient environment such as the altitude.

Venous Admixture

A decrease in mixed venous O_2 increases the gradient by which O_2 needs to be stepped up as it passes through the lungs and can contribute to the development of hypoxemia. Congestive heart failure with low cardiac output is the most common cause of low mixed venous O_2, owing to increased peripheral extraction of O_2. Other factors may contribute to hypoxemia, such as $\dot{V}/\dot{Q}$ mismatch and shunting.[9] Other causes include low hemoglobin concentration and increased O_2 consumption. A low mixed venous O_2 may have a significant effect on the final arterial O_2 tension when lung disease is present.

Clinical Presentation

Signs and symptoms of congestive heart failure (e.g., rales on chest auscultation, pedal edema, etc.) or underlying lung disease, or both, may be present.

Differentiating the Causes of Acute Hypoxemic Respiratory Failure

It is important to recognize the physiologic basis of each of the three main causes of hypoxemic respiratory failure (hypoventilation, $\dot{V}/\dot{Q}$ mismatch, and shunt). Hypoventilation differs from the other two causes in manifesting with a normal alveolar-to-arterial PO_2 difference [$P(A-a)O_2$] indicating normal lung parenchyma (Table 45.1). A clinical determination of this difference is made by subtracting PaO_2 from PAO_2 (partial pressure of alveolar O_2) derived from the alveolar air equation:

$$PAO_2 = FiO_2(P_B - P_{H_2O}) - PaCO_2/R$$

where P_B is barometric pressure, P_{H_2O} is water vapor tension, and R is the respiratory exchange ratio (0.8).

The $P(A-a)O_2$ ranges from 10 mm Hg in young patients to approximately 25 mm Hg in elderly patients while breathing room air (see the accompanying Rule of Thumb). In patients with hypoxemia caused by hypoventilation, treatment can be focused on improving ventilation because the hypoxemia is purely a result of alveolar displacement of O_2 by elevated CO_2.

RULE OF THUMB The mean alveolar-to-arterial difference [$P(A-a)O_2$] in PO_2 increases slightly with age and can be estimated with the following equation:

$$\text{Mean age–specific } P(A-a)O_2 = (\text{age}/4) + 4$$

Example: A 76-year-old person living at sea level:

$$P(A-a)O_2 = (76/4) + 4 = 19 + 4 = 23 \text{ mm Hg}$$

A $\dot{V}/\dot{Q}$ mismatch and shunt both result in elevated $P(A-a)O_2$ levels, indicating that the resultant hypoxemia is due to an abnormality of lung tissue, requiring treatment to address that abnormality. When the RT encounters an increased $P(A-a)O_2$, a $\dot{V}/\dot{Q}$ mismatch and anatomic shunt can be differentiated by means of O_2 administration (see Figs. 45.1 and 45.2). A significant response to applying even small amounts of O_2 identifies $\dot{V}/\dot{Q}$ mismatch as the cause of hypoxemia because altered $P(A-a)O_2$ has not been totally obliterated. True hypoxemia shows little or no improvement in oxygenation even with 100% FiO_2 (see Table 45.1). As a result, treatment of intrapulmonary shunt must be directed toward opening collapsed alveoli or clearing fluid or exudative material before O_2 can be beneficial at below toxic levels. Testing to rule out anatomic shunt should be done in the right clinical setting (e.g., clear or black parenchyma on the chest radiograph).

TABLE 45.1 Differentiating the Cause of Hypoxemia

Cause	$P(A-a)O_2$	Response to Increased FiO_2
Hypoventilation	Normal	Marked
Shunt	Increased	Minimal
$\dot{V}/\dot{Q}$ mismatch	Increased	Marked

FiO_2, Fractional inspired oxygen.

HYPERCAPNIC RESPIRATORY FAILURE (TYPE II)

Hypercapnic respiratory failure (type II), also known as *pump, bellows,* or *ventilatory failure,* is characterized by an elevated $PaCO_2$, creating an uncompensated respiratory acidosis (whether acute or acute-on-chronic). $PaCO_2$ and alveolar ventilation ($\dot{V}_A$) are inversely related, meaning that alveolar and arterial PCO_2 levels are doubled when alveolar ventilation is halved. This is illustrated by the metabolic hyperbola relationship:

$$PaCO_2 = (0.863\ \dot{V}CO_2)/\dot{V}_A$$

$$\dot{V}_A = MV\ (1 - V_D/V_T)$$

where $\dot{V}_A$ is alveolar ventilation (L/min), MV is minute ventilation (L/min), V_D/V_T is dead space–to–tidal volume ratio, and $\dot{V}CO_2$ is CO_2 production (mL/min).

This equation demonstrates a rectangular hyperbola relation between the $PaCO_2$ and ventilation (Fig. 45.3). Patients with chronic hypercapnia and low ventilation are on a steeper section of the metabolic hyperbola such that a minor drop in ventilation results in a significant increase in $PaCO_2$, making them more susceptible to developing a sudden further increase in $PaCO_2$ when even minor respiratory exacerbations occur. Also, with chronically elevated arterial $PaCO_2$, the ventilatory response to a further increase in $PaCO_2$ is more blunted.[10] This leads to an *acute ventilatory failure superimposed on chronic ventilatory failure.*

Similarly, this relationship shows that $PaCO_2$ may increase as dead space (V_D/V_T) rises or as CO_2 production ($\dot{V}CO_2$) increases. Additionally, a change in the $\dot{V}/\dot{Q}$ distribution of the lung toward lower ratios not only causes hypoxemia, as shown in Figs. 45.1 and 45.2, but also, to a lesser extent, can cause an elevation of $PaCO_2$ by reducing the CO_2 discharge from the pulmonary circulation to the alveoli. However, increased dead space, increased $\dot{V}CO_2$, and shifts in the $\dot{V}/\dot{Q}$ distribution toward lower ratios all are usually matched by a corrective increase in ventilation because respiratory control mechanisms tend to maintain the $PaCO_2$ constant. The following sections describe mechanisms of hypercarbia caused by an imbalance between

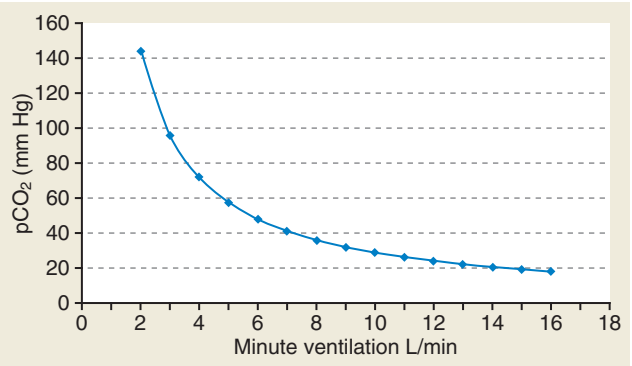

Fig. 45.3 The metabolic hyperbola. Due to the hyperbolic relationship between the pCO_2 and ventilation, a minor drop of ventilation occurring at an already low minute ventilation results in a significantly greater increase in the pCO_2 relative to an equivalent drop occurring at a higher minute ventilation.

MINI CLINI

Differentiating Causes of Hypoxemia

Problem

Two patients present with the following ABG values at sea level:

Patient A		Patient B	
pH	7.45	pH	7.21
$PaCO_2$	33 mm Hg	$PaCO_2$	72 mm Hg
PaO_2	40 mm Hg	PaO_2	53 mm Hg
HCO_3^-	22 mEq/L	HCO_3^-	28 mEq/L
SaO_2	70%	SaO_2	81%
FiO_2	0.21	FiO_2	0.21

1. Define the respiratory condition indicated by each ABG analysis.
2. What is the $P(A-a)O_2$ for each blood gas?
3. Identify the type of respiratory failure in each case.
4. In which case would administration of 100% FiO_2 help improve oxygenation?

Discussion:

1. Patient A exhibits uncompensated respiratory alkalosis with hypoxemia. Patient B exhibits partially compensated respiratory acidosis with hypoxemia.
2. Patient A:
   $PAO_2 = 0.21\ (760 - 47) - 33/0.8 = 108$ mm Hg
   $PaO_2 = 40$ mm Hg
   $P(A-a)O_2 = 108 - 40 = 68$ mm Hg on room air
   Patient B:
   $PAO_2 = 0.21\ (760 - 47) - 72/0.8 = 60$ mm Hg
   $PaO_2 = 53$ mm Hg
   $P(A-a)O_2 = 60 - 53 = 7$ mm Hg on room air
   The normal values for $P(A-a)O_2$ range from 10 mm Hg in young people to approximately 25 mm Hg in elderly people while breathing room air.
3. Patient A has hypoxemic respiratory failure (type I) as characterized by below-normal PaO_2 (40 mm Hg). $PaCO_2$ is also below normal (33 mm Hg), indicating hyperventilation is occurring in an effort to improve the oxygenation. Patient B has hypercapnic respiratory failure (type II) as characterized by an above-normal $PaCO_2$ (72 mm Hg), indicating that hypoventilation (ventilatory failure) is occurring. There is also an elevation of HCO_3^- (28 mEq/L), indicating that the acute ventilatory failure is superimposed on chronic ventilatory failure. This patient is also hypoxemic (53 mm Hg).
4. Patient A has hypoxemic respiratory failure with $P(A-a)O_2$ of 68 mm Hg, which is well above normal, indicating an oxygenation defect. The administration of 100% O_2 in this case would help to determine the cause of the defect. Specifically, a marked rise in PO_2 in response to 100% FiO_2 would point to $\dot{V}/\dot{Q}$ mismatch as the cause, whereas shunt would be implicated if PaO_2 did not respond to the increase in delivered O_2. In the latter condition, some form of positive end-expiratory pressure (PEEP) would be necessary to improve gas exchange by improving functional residual capacity. Patient B has hypercapnic respiratory failure (ventilatory failure) with hypoxemia, but with $P(A-a)O_2$ of 7 mm Hg, which is within the normal range. A pure ventilatory defect is the cause of hypoxemia, and administration of 100% FiO_2 would not raise the PO_2 value. Depending on the full patient scenario, this patient may require noninvasive mechanical ventilation or intubation and invasive mechanical ventilation to restore normal acid–base status.

CO_2 exposure (external or internal) and CO_2 clearance (central and respiratory effector mechanisms). Hypoxemia may often accompany pump failure simply because of the displacement of alveolar PO_2 (PAO_2) by the increased $PaCO_2$ from alveolar hypoventilation. This situation is identified on a room air ABG assessment by a normal $P(A-a)O_2$, as discussed previously. The presence of an increased $P(A-a)O_2$ indicates that accompanying hypoxemia is present, most likely as a result of $\dot{V}/\dot{Q}$ mismatch or shunt. The disorders that cause hypercapnic respiratory failure (ventilatory failure) are discussed next.

Unexpected Exposure to Breathing Carbon Dioxide

Although most cases of increased $PaCO_2$ are due to hypoventilation, an unexpected exposure to breathing CO_2 can occur in certain situations.

Clinical Presentation

These unexpected exposures follow unusual clinical situations including defective CO_2 scrubbers in anesthesia machines or life-support systems in scuba units, airtight chambers, spacecrafts, or submersible crafts. Occupational exposures also occur in spelunkers in caves (from groundwater seepage), individuals who work with dry ice (dry ice is a solid form of CO_2), miners, and firefighters.

Increased Carbon Dioxide Production

Fever, agitation, exertion, shivering, hypermetabolism, and excess caloric intake all can result in an increase in $\dot{V}CO_2$, with resulting hypercapnia in patients with additional impairment in respiratory control and CO_2 exhalation mechanisms.

Clinical Presentation

The most common clinical scenario involving increases in CO_2 production probably involves mechanically ventilated patients with already compromised lung function, in whom attempts to liberate from artificial ventilation are complicated by type II respiratory failure. Recognition and correction of fever, agitation, hypermetabolic states, and excess caloric intake, particularly due to carbohydrate-rich enteral solutions, may contribute to a favorable outcome.

Impairment in Respiratory Control

Both central (medullary) and peripheral (aortic and carotid bodies) chemoreceptors responding to CO_2 tension and O_2 tension stimulate the drive to breathe.[10] This ventilatory drive can be decreased by various factors, such as drugs (overdose or sedation), bilateral carotid endarterectomy with incidental resection of the carotid bodies, brainstem lesions, diseases of the CNS (multiple sclerosis, Parkinson disease, or elevated intracranial pressure [ICP]), hypothyroidism, morbid obesity (e.g., obesity-hypoventilation), and sleep apnea.[11] Patients at risk of having a decreased ventilatory drive usually can be identified by their clinical situation (e.g., CNS insult, overdose of sedative medications), and the clinician should be attentive to reversible causes.

Clinical Presentation

The key feature of decreased ventilatory drive is bradypnea (slow breathing) and perhaps ultimately apnea. A normal respiratory rate is usually no less than 12 breaths/min in adults. Drug overdose or a brain disorder can manifest with an altered level of consciousness, ranging from being merely lethargic to being obtunded and comatose, with decreased respirations. Evidence

of drug use by history or toxicity screen confirms the diagnosis of drug overdose. Evidence of head trauma and brain computed tomography (CT) scan abnormalities are important in the diagnosis of a brain disorder. Although hypothyroidism classically manifests with fatigue, weight gain, hyporeflexia, and constipation, it can also progress to significant hypoventilation and myxedema coma. Patients with obesity-hypoventilation may have a rapid, shallow breathing pattern, which results from decreased compliance and microatelectasis. Although these patients may also have nighttime sleep apnea, daytime $PaCO_2$ is also elevated because of a decrease in the drive to breathe and metabolic factors.[12] See Fig. 45.3 for the relationship between PCO_2 and minute volume.

Impairment in Exhaling Carbon Dioxide

Neurologic Diseases

The lungs inhale and exhale under the guidance of the CNS. In some patients, the CNS signal does not reach its goal, resulting in neuromuscular dysfunction. Examples include spinal trauma, motor neuron disease in which lesions of the anterior horn cells may gradually lead to progressive ventilatory failure (e.g., amyotrophic lateral sclerosis or poliomyelitis), motor nerve disorders (including Guillain-Barré syndrome and Charcot-Marie-Tooth disease), disorders of the neuromuscular junction (e.g., myasthenia gravis and botulism), and muscular diseases (including muscular dystrophy, myositis, critical care myopathy, and metabolic disorders).[13]

Clinical presentation. Although hypercapnia may be a common end point, these diseases have varied clinical presentations. Patient observation is a key skill. Drooling, slurred speech (dysarthria), and weak cough are common bulbar signs in amyotrophic lateral sclerosis and myasthenia gravis. In progressive neuromuscular disease, as muscle wasting and weakness become more severe, diaphragmatic insufficiency develops, and supine paradoxical breathing and orthopnea are common.[14] Guillain-Barré syndrome commonly causes lower extremity weakness progressing to respiratory failure in 20% to 30% of patients.[15] Weak cough and gag may be seen, which can threaten airway patency and lead to microatelectasis, hypoxemia, and uncompensated respiratory acidosis. Myasthenia gravis does not always cause respiratory failure.[16] These diseases are quite different in clinical course, but there is much overlap in their presentations, and they commonly result in respiratory **muscle fatigue** and failure and elevated $PaCO_2$.

Increased Work of Breathing

Despite normal respiratory drive, nerve transmission, and neuromuscular response, hypercapnic respiratory failure can still occur if the imposed workload cannot be overcome.[2] Most commonly, this situation occurs when increased dead space accompanies COPD, or when elevated airway resistance accompanies asthma. Both of these obstructive airway diseases may increase respiratory work requirements excessively due to the presence of intrinsic **positive end-expiratory pressure** (**auto-PEEP**). Increased workload can also result from thoracic abnormalities such as pneumothorax, rib fractures with a flail chest, pleural effusions, and other conditions creating a restrictive burden on the lungs. Finally, requirements for increased minute ventilation can arise when increased CO_2 production accompanies hypermetabolic states, such as in extensive burns.

Clinical presentation. The RT must be alert to the possibility of respiratory failure when a heavy load is imposed on the respiratory system. Patients with asthma or COPD should present with hyperventilation during an exacerbation, but if breathing becomes more rapid but shallow, it may indicate impending failure. This increased V_D/V_T ratio leads to hypercapnia because the significant airway obstruction does not resolve with treatment. Diminished breath sounds in a young patient with asthma likewise can be a concerning sign. Irritability, confusion, and ultimately coma are possible signs in worsening hypercapnia, as they are in hypoxemic respiratory failure. More subtle findings include muscle tremor owing to catecholamine release and papilledema resulting from cerebral vasodilation in states of elevated arterial PCO_2.[17]

In summary, hypercapnic (type II) respiratory failure, also known as *ventilatory failure*, develops when ventilation is impaired due to intrinsically or extrinsically increased CO_2 exposure; impairment in respiratory control; or impairment in exhalation mechanisms, including neurologic disease or pulmonary and chest wall disorders associated with increased work of breathing (Table 45.2).

CHRONIC RESPIRATORY FAILURE (TYPE I AND TYPE II)

For some patients with pulmonary disease and respiratory failure, the condition has developed over weeks to months to years and has become a chronic state, allowing compensatory adaptive mechanisms to develop. Most commonly, chronic hypercapnic respiratory failure accompanying COPD or obesity-hypoventilation syndrome prompts a renal response, and the kidneys retain bicarbonate to elevate the abnormally low blood pH. However, this compensatory metabolic alkalosis would not be expected to restore the pH all the way to normal. Chronic hypercapnic respiratory failure is also known as *chronic ventilatory failure*.

RULE OF THUMB Chronic and acute hypercapnic respiratory failure can be differentiated by the severity of change in pH.[18]

- Acute hypercapnic failure (acute ventilatory failure): pH decreases 0.08 for every 10 mm Hg increase in $PaCO_2$
- Chronic hypercapnic failure (chronic ventilatory failure): pH decreases 0.03 for every 10 mm Hg increase in $PaCO_2$.

Similarly, polycythemia may result from prolonged hypoxemic respiratory failure (e.g., sleep apnea) when O_2 delivery to the tissues is compromised, and erythropoietin levels increase to elicit erythrocytosis. Hemoglobin also releases O_2 more easily as the O_2 dissociation curve shifts to the right in the face of acidosis. Finally, O_2 delivery to the brain is enhanced when hypercapnia results in increased cerebral blood flow.[19]

Acute-on-Chronic Respiratory Failure

Chronic respiratory failure can be complicated by acute setbacks that create acute-on-chronic respiratory failure. Patients with

TABLE 45.2 Causes of Respiratory Failure

	TYPE II (HYPERCAPNIC)			
Type I (Hypoxemic)	**Increased Exposure**	**Impaired Respiratory Control**	**Neurologic Disease**	**Increased Work of Breathing**
ARDS	Extrinsic	Drug overdose	Spinal cord trauma	Obstructive lung disease
Pulmonary embolism	Defective CO_2 scrubbers (anesthesia or life-support systems)	Bilateral endarterectomy with carotid body resection	Motor neuron	COPD
Pulmonary edema	Occupational exposure (miners, spelunkers, dry-ice workers, firemen)	Central sleep apnea	Poliomyelitis	Asthma
Septic shock	Intrinsic	Hypocapnia	Amyotrophic lateral sclerosis	Upper airway obstruction
Pulmonary infection	Fever	Cheyne-Stokes	Motor nerve	Obesity-hypoventilation
Viral	Shivering	Acromegaly	Phrenic nerve	Pneumothorax
Bacterial	Hypermetabolism	Hypothyroid	Guillain-Barré	Severe burns
Fungal	Agitation	Brainstem lesions	Charcot-Marie-Tooth	Chest wall disorders
Inhalation	Excess caloric intake	Cerebrovascular accident	Neuromuscular junction	Kyphoscoliosis
Smoke		Encephalitis	Myasthenia gravis	Ankylosing spondylitis
Chemical		Multiple sclerosis	Botulism	
Water		Parkinson disease	Muscular	
Pleural effusion		Metabolic alkalosis	Muscular dystrophy	
Interstitial lung disease		Primary alveolar hypoventilation	Myositis	
Obstructive lung disease		(Ondine's curse)	Myopathy	
Aspiration		Congenital central hypoventilation	Acid maltase	
Primary pulmonary hypertension		Carotid body resection	Metabolic	
		Obesity-hypoventilation		

ARDS, Acute respiratory distress syndrome; *CO_2*, carbon dioxide; *COPD*, chronic obstructive pulmonary disorder.

chronic hypercapnic respiratory failure are at significant risk for this condition, as indicated by the fact that COPD is now the third leading cause of death in the United States.[20] Acute-on-chronic respiratory failure can also be the presenting manifestation of neuromuscular disease that is complicated by pulmonary infection.[21] Most common precipitating factors include bacterial or viral infections, congestive heart failure, pulmonary embolus, pneumothorax, chest wall dysfunction, and noncompliance with treatment. In these patients, the presence of respiratory failure cannot be judged by the normal ABG criteria but by a significant change from the baseline $PaCO_2$ to a level having the potential to cause morbidity and mortality.

Treatment goals include normalizing pH (avoiding mechanical ventilation if possible), elevating SaO_2 to 90% (if hypoxemia is also present), improving airflow, treating infection, monitoring and maintaining fluid status, and preventing or treating complications as necessary. Deaths are less due to respiratory failure, and are more associated with older age, the underlying illness, associated complications, and whether intubation was required.[22] Episodes of acute respiratory failure in these patients seem to have a significant long-term hazard, with mortality rates reaching 59% within the year after a critical illness requiring mechanical ventilation and tracheostomy.[23]

Patients with chronic **hypoxemic respiratory failure (type I)** are at similar risk for acute deterioration of hypoxemia. Infection and heart failure can result in worsening of the marginal oxygenation status of patients with interstitial pulmonary fibrosis or primary pulmonary hypertension.

Complications of Acute Respiratory Failure

Although respiratory failure is life-threatening by itself, complications frequently arise that can add significantly to morbidity and mortality. Especially in patients with ARDS, more deaths are due to complications (e.g., sepsis, multiorgan failure) than to the primary disease.[24] Modern ICUs with sophisticated mechanical ventilation can prolong but may not preserve life. Pulmonary complications such as emboli, **barotrauma**, and infection may be due to treatment strategies such as catheters, mechanical ventilation, and endotracheal tubes. A wide array of nonpulmonary complications may develop, including bacteremia, malnutrition, psychosis due to prolonged ICU stays, cardiac disorders (e.g., arrhythmias, hypotension), gastrointestinal ailments (e.g., hemorrhage, dysmotility), and renal disturbances (e.g., acute renal failure, positive fluid balance).

Clinical Presentation

Clinically, a patient with respiratory muscle fatigue shows an initially increased respiratory rate followed by *bradypnea* (slowed respiratory rate) and apnea as fatigue ensues. **Respiratory alternans,** which is a phasic alternation between rib cage and abdominal breathing, may also occur. Opinions vary on the sensitivity and specificity of abdominal motion paradox in patients with respiratory muscle weakness, but at least some investigators suggest that respiratory muscle paradox is an early sign (see Chapter 16). When ventilatory failure is full-blown, ABG results show hypercapnia with acidosis. As mentioned earlier, the

MINI CLINI

Acute or Chronic Hypercapnic Respiratory Failure

Problem:

A 55-year-old man presents to the emergency department complaining of increased shortness of breath and yellow-green sputum production for 1 week. He is alert and oriented. He has a 60 pack-year smoking history. Vital signs are blood pressure 165/90 mm Hg, pulse 120 beats/min, respirations 25 breaths/min, and temperature 100.5°F oral.

ABG values on room air are as follows:

pH	7.28
$PaCO_2$	70 mm Hg
PaO_2	35 mm Hg
HCO_3^-	36 mm Hg
SaO_2	66%

1. Define the respiratory condition indicated by the ABG results.
2. What is the $P(A-a)O_2$?
3. What type of respiratory failure is present?
4. What kind of therapy is indicated?

Discussion:

1. The ABG values indicate a partially compensated respiratory acidosis with hypoxemia.
2. $PAO_2 = 0.21\ (760 - 47) - 70/0.8 = 62$ mm Hg
   $PaO_2 = 35$ mm Hg
   $P(A-a)O_2 = 62 - 35 = 27$ mm Hg on room air
3. This is hypercapnic respiratory failure (type II), also known as *ventilatory failure*. However, in acute failure, the pH decreases 0.08 for every 10 mm Hg increase in $PaCO_2$. In this patient, $PaCO_2$ has increased 30 mm Hg (70 – 40), and the pH has decreased 0.12. The pH would be expected to decrease 0.24 (3×0.08) if this were acute ventilatory failure. This is a case of acute-on-chronic failure. The HCO_3^- of 36 mEq/L (normal 22 to 26 mEq/L) also indicates that renal compensation has occurred, which takes days to achieve. The $P(A-a)O_2$ is 27 mm Hg, which is above normal, indicating that hypoxemia cannot be explained fully by hypoventilation.
4. Because the patient is alert, conservative therapy to improve lung function is indicated. O_2 administration to achieve SaO_2 of at least 90% is required. If PaO_2 does not respond to O_2 administration, shunt is present, and positive airway pressure may be necessary. Antibiotics are indicated for the probable infection (fever, discolored sputum), and bronchopulmonary hygiene (bronchodilators, steroids, cough assist) is indicated to improve ventilation.

presence of hypercapnia with acidosis can also indicate that the respiratory center is not responding properly.[10]

Tachypnea is the cardinal sign of increased work of breathing. Tachypnea occurs when the respiratory center increases breathing frequency in an attempt to lessen respiratory excursion and reduce the amount of work performed by the respiratory muscles.[25] Overall workload is reflected in the minute volume needed to maintain normocapnia.

Indications for Ventilatory Support

For each type of oxygenation and ventilatory failure, the goal of mechanical ventilation is either to support the patient until the underlying problem resolves or to maintain support of the patient with chronic ventilatory problems. These goals may be achieved by improving alveolar ventilation and arterial oxygenation, increasing lung volume, or reducing work of breathing.[26]

TABLE 45.3 Physiologic Indicators for Ventilatory Support, Classified by Mechanism Underlying Respiratory Failure

Mechanism	Normal Values	Support Indicated
Inadequate Alveolar Ventilation		
$PaCO_2$ (mm Hg)	35–45	>55
pH	7.35–7.45	<7.20
Inadequate Lung Expansion		
Tidal volume (V_T) mL/kg	5–8	<5
Vital capacity (VC) mL/kg	65–75	<10
Respiratory rate	12–20	>35
Inadequate Muscle Strength		
Maximum inspiratory pressure (cm H_2O)	–80–100	–≤20
Vital capacity (VC, mL/kg)	65–75	<10
Maximum voluntary ventilation (MVV, L/min)	120–180	<2× VE
Increased Work of Breathing		
Minute ventilation ($\dot{V}_E$)	5–6	>10
V_D/V_T (%)	0.25–0.40	>0.6
Hypoxemia		
$P(A-a)O_2$ on 100% O_2 (mm Hg)	25–65	>350
PaO_2/FiO_2	350–450	<200

FiO_2, Fractional inspired oxygen; *$PaCO_2$,* partial pressure of carbon dioxide; *PaO_2,* partial pressure of oxygen; *VE,* minute ventilation.

This section discusses the indications for mechanical ventilation for hypoxemic (type I) and hypercapnic (type II) respiratory failure. Hypoxemic respiratory failure is divided into processes that require short-term and long-term ventilatory support. Hypercapnic respiratory failure is broken down into unstable ventilatory drive, muscle fatigue, excessive work of breathing, and alveolar hypoventilation.

Parameters Indicating Need for Ventilatory Support

Although various measurements have been proposed to help decide if a patient needs mechanical ventilation, the clinical status of the patient is the most important criterion. Table 45.3, and the discussion that follows, review common physiologic indicators for initiating support by the underlying cause of respiratory failure.

Hypoxemic respiratory failure. Severe, refractory hypoxemia is a common indication for intubation and ventilatory support. Table 45.3 lists different measures of hypoxemia that have been used to assess the need for ventilatory support. Most commonly, PaO_2 is compared with FiO_2 as with the PaO_2/FiO_2 ratio or the alveolar-arterial O_2 difference [$P(A-a)O_2$]. Indicators of profoundly impaired oxygenation suggesting the need for intubation, high inspired O_2 administration, and PEEP include $P(A-a)O_2$ value of 350 mm Hg on FiO_2 of 1.0 or a PaO_2/FiO_2 value of less than 200. These values are useful for all causes of hypoxemic respiratory failure (type I) but cannot help distinguish if the process is a readily reversible one, such as pulmonary edema or atelectasis, or a process that resolves more slowly, such as acute

lung injury. Frequently, patients have a combination of hypoxemic and hypercapnic respiratory failure.

Hypercapnic respiratory failure (ventilatory failure). As previously discussed, hypercapnic (type II) respiratory failure or ventilatory failure can be caused by increased ventilatory dead space, increased CO_2 production, or decreased alveolar ventilation. All of these processes cause an increase in $PaCO_2$.[9] Assessment of the pH allows a determination of whether the problem is acute or chronic. Chronic hypoventilation is compensated by the kidneys' retention of bicarbonate, although this response requires several days. The following example shows the importance of pH in interpreting the significance of elevated $PaCO_2$.

	Patient A	Patient B
$PaCO_2$	60 mm Hg	60 mm Hg
Serum HCO_3^-	25 mEq/L	36 mEq/L
pH	7.25	7.38

Although both patients in this example have the same level of hypercapnia, only patient A exhibits acute ventilatory failure with an elevated $PaCO_2$ but normal serum bicarbonate (25 mEq/L). Patient B has a compensated respiratory acidosis from chronic hypercapnic respiratory failure, as indicated by the normal pH and elevated serum bicarbonate (36 mEq/L). This condition is also known as *chronic ventilatory failure*. The distinction between acute and chronic ventilatory failure is very important in respiratory care and emphasizes the need to use both $PaCO_2$ and pH as indicators for ventilatory support. The trend in pH and $PaCO_2$ values is also useful in assessing the effects of therapies in correcting acute ventilatory failure.

Significance of elevated alveolar partial pressure of carbon dioxide. Because elevated $PaCO_2$ increases ventilatory drive in healthy subjects, the existence of hypoventilation suggests other problems with the respiratory apparatus. Specifically, the presence of acute respiratory acidosis indicates one of three major problems: (1) the respiratory center is not responding normally to elevated $PaCO_2$; (2) the respiratory center is responding normally, but the signal is not getting through to the respiratory muscles; or (3) despite normal neurologic response mechanisms, the lungs and chest bellows are incapable of providing adequate ventilation because of parenchymal lung disease or muscular weakness.[10]

ASSESSMENT OF RESPIRATORY FATIGUE, WEAKNESS, FAILURE, AND WORK OF BREATHING

Respiratory Muscle Weakness

Respiratory muscle weakness refers to the decreased capacity of a rested muscle to generate force and decreased endurance.[27] Respiratory muscle weakness occurs most commonly in patients with neuromuscular disease. Other conditions that lead to muscle weakness by increasing demand include COPD, kyphoscoliosis, and obesity.

The respiratory muscle strength is assessed by volitional tests, such as the **maximum inspiratory pressure (MIP)**, **maximum expiratory pressure (MEP)**, and **sniff nasal inspiratory pressure**; and non-volitional tests that involve stimulation of the phrenic nerve.[28] The **maximum voluntary ventilation (MVV)**, though previously thought to be a more specific test of respiratory muscle weakness, is generally proportionally reduced to the vital capacity (see Table 45.3).[28] A MIP of −30 cm H_2O or less (more negative) usually indicates adequate respiratory muscle strength to continue spontaneous breathing, but the overall trend needs to be considered. This consideration is especially important in patients with myasthenic crisis or Guillain-Barré syndrome, where values of MIP that are becoming less negative may be the only clue to impending respiratory failure.

Respiratory Muscle Fatigue

Fatigue is usually defined as a condition in which there is loss of the capacity to develop force or velocity of a muscle resulting from muscle activity under either a sustained or repetitive stimulation, which is reversible by rest.[29] It can be caused by both the specific demands placed on the muscle and the reduced supply of necessary nutrients. The demand on a muscle is raised by increased work of breathing, increased strength of muscle contraction, and decreased muscle efficiency. Hypoxemia, decreased inspiratory muscle blood flow, poor nutrition, and the inability of a muscle to extract energy from supplied nutrients can lead to fatigue as well.[27]

There are three types of respiratory **muscle fatigue**: Central fatigue, peripheral high-frequency fatigue, and peripheral low-frequency fatigue.[28] In central fatigue, the reduced respiratory muscle force is due to an impairment in central or motor-neuron drive with a preserved neuromuscular junction and muscular function. In this condition, the muscle's force response is preserved in response to direct electrical stimulation but impaired with maximal voluntary effort. One explanation is that stress-loaded breathing results in a central opioid expression that reduces the central neuronal output. In peripheral fatigue, the muscle's force response falls with direct electrical stimulation. A decline in muscle force with high frequencies of 50 to 100 Hz may be due to an impaired neuromuscular junction, reduced sarcolemmal membrane excitability, or a reduction in action potential propagation. In contrast, a decline in muscle force with low frequencies of 1 to 20 Hz may be due to a decrease in contractile protein activation despite an intact sarcolemmal action potential, and is likely due to a decrease in Ca2+ release. The recovery from low-frequency peripheral fatigue can be prolonged for hours or even days.[28]

Respiratory Failure

Respiratory failure is an unfavorable imbalance between a respiratory workload, on the one hand, and ventilatory muscle strength and endurance, on the other hand. The **pressure-time index** takes into account the fact that respiratory muscle endurance depends both on the magnitude of the respiratory load in relation to respiratory strength (P_{di}/P_{dimax}) and on the duration of the inspiratory effort in relation to total breath time (the duty cycle, or T_i/T_{tot}). This index $[(P_{di}/P_{dimax}) \times (T_i/T_{tot})]$ determines whether a respiratory load can be tolerated without development of respiratory muscle failure. Values of the pressure-time index

less than 0.15 are generally tolerated for over 1 hour without fatigue, whereas indices greater than 0.18 usually result in fatigue and respiratory failure within less than 40 minutes in a time frame that is inversely related to the index.[28] Comparing the spontaneous minute ventilation with MVV is also a helpful index because fatigue and failure are both likely to occur if the minute ventilation exceeds 60% to 80% of MVV.[28]

These closely related concepts of weakness, fatigue, and failure usually overlap and can result in acute or chronic respiratory failure. Respiratory muscle weakness can predispose to ventilatory muscle fatigue. Whether fatigue always leads to failure has been debated.[30] In one study, weaning failure was not accompanied by low-frequency fatigue of the diaphragm despite the presence of diaphragm weakness.[31]

Work of Breathing

Work of breathing (WOB) is the amount of pressure needed to move a given volume of air into the lung with a relaxed chest wall. Work of breathing is due to physiologic work and imposed work. Physiologic work involves overcoming the elastic forces of both the lung tissue and the chest wall during inspiration, and overcoming the resistance to the flow of air through the airways.[32] Normal WOB in Joules per liter of ventilation is 0.35 J/L, but it can also be expressed in power terms (Joules per minute of ventilation) with a normal value of 2.4 J/min.[32] Airway and pulmonary parenchymal abnormalities can cause auto-PEEP and active expiration, which increase the physiologic WOB. For example, auto-PEEP in a patient with COPD imposes a threshold load, as inspiratory muscles have to initiate a contraction equal to the auto-PEEP before the lung volume can increase.[32,33] Additionally, whereas expiration is normally passive and does not add to the WOB, it is more active in COPD due to the involvement of abdominal muscles to assist expiration, which adds to the WOB.[32] In intubated patients, sources of imposed work of breathing include the endotracheal tube ventilator circuit, and settings that may contribute further to **auto-PEEP.** Excessive WOB is the most common cause of respiratory muscle fatigue and can interfere with weaning. For example, 96% of patients with a physiologic work of breathing less than 0.8 J/L in one study were successfully liberated from ventilatory support and extubated.[34]

CHOOSING A VENTILATORY SUPPORT STRATEGY FOR DIFFERENT CAUSES OF RESPIRATORY FAILURE

The remainder of this chapter briefly discusses current ventilatory strategies for hypoxemic and hypercapnic respiratory failure. The clinical application of specific modes of mechanical ventilation is described in Chapters 46 and 49, and noninvasive ventilation (NIV) is reviewed in more detail in Chapter 50. When it has been determined that the patient needs ventilatory support, the initial decision is whether to intubate or to ventilate noninvasively. In the acute setting, this decision is sometimes based on the underlying process, the type of respiratory failure, and how rapidly the underlying process can be reversed.

Noninvasive Ventilation

Noninvasive ventilation (NIV) can be defined as any mode of ventilatory support that is provided without endotracheal intubation, including continuous positive airway pressure (CPAP) alone or in combination with any mode of pressure-limited or volume-limited ventilation.[35] NIV can improve hypoxemia and hypercarbia through several mechanisms including but not limited to: (1) compensating for the inspiratory threshold load imposed by intrinsic PEEP;[33] (2) supplementing a reduced tidal volume;[36] (3) partial or complete unloading of the respiratory muscles;[36] (4) reducing venous return and left ventricular afterload;[37] (5) alveolar recruitment;[38] (6) preventing intermittent narrowing and collapse in patients with obstructive sleep apnea/hypopnea syndrome by using pressure to splint the airway open during sleep;[39] and (7) improving lung function (particularly functional residual capacity) and daytime gas exchange in obstructive sleep apnea/hypopnea syndrome.[40] NIV is appropriate in both acute[41] and chronic[42] respiratory failure.

Noninvasive Ventilation in Acute Conditions

Exacerbations of Chronic Obstructive Pulmonary Disease

NIV is considered to be a standard of care in patients hospitalized with an exacerbation of COPD, hypercapnia with a $PaCO_2$ greater than 45 mm Hg and a pH less than 7.35.[43] For instance, NIV reduces mortality by 46% (the number needed to treat to avoid 1 death is 12), reduces the need to intubation by 65% (the number needed to treat to avoid 1 intubation is 5), reduces the hospital stay by 3.4 days, and reduces complications.[43]

Cardiogenic Pulmonary Edema

NIV is a recommended option in treating acute respiratory failure as part of cardiogenic pulmonary edema. Use of CPAP or NIV in these patients can significantly reduce the dyspnea score, heart rate, acidosis, and hypercapnia within the first hour after the start of treatment.[44,45] In the largest study of NIV for cardiogenic pulmonary edema, no improvement was seen in mortality, rates of intubation, rate of admission to the critical care unit, or mean length of hospital stay,[44] but smaller trials showed decreased intubation and mortality rates with NIV.[45] Selection and methodologic criteria may explain the difference (see Chapter 50).

Acute Asthma

NIV is used in about 40% of those who require some form of ventilatory support for an asthma exacerbation.[46] Less than 5% of those fail NIV, with a higher risk for failure in patients with a preceding hospitalization within the year, pneumonia, or diabetes. Those who fail end up staying in the hospital longer.[46] Otherwise, the group receiving NIV has a lower mortality and shorter length of stay.[46]

Acute Respiratory Distress Syndrome

A large international study (the LUNG-SAFE study) found that NIV was used in about 15% of patients with the ARDS, regardless of severity.[47] However, results have been generally disappointing, especially in more severe ARDS. For example, although NIV can prevent intubation in 78% of those with mild ARDS, that success rate drops to 50% to 60% in moderate and severe

ARDS.[47] More concerning, the mortality of those who fail NIV is high at 42.3%.[47] Of even greater concern, compared to invasive ventilation, NIV is associated with a worse mortality that is most apparent in those with a PaO_2/FiO_2 ratio less than 150 mm Hg.[47] Reasonable recommendations in the management of ARDS would be to start with high-flow nasal O_2 if O_2 needs exceed the 6 L per minute that can be delivered by nasal prongs. This approach does not decrease the intubation rates compared to standard O_2 therapy through a facial mask or to NIV, but it increases the ventilator-free days and reduces mortality.[48] If this fails, NIV can be tried in experienced centers, possibly with a helmet interface (shown to reduce intubation rates and mortality compared to a standard facial mask).[49] However, rapid reassessment of oxygenation is recommended, so that invasive ventilation is not unnecessarily delayed if those approaches fail.

Noninvasive Ventilation in Chronic Conditions

Obesity-Hypoventilation Syndrome

Obesity-hypoventilation syndrome refers to the presence of daytime hypercapnia ($PaCO_2$ >45 mm Hg) in obese individuals (body mass index >30 kg/m^2) when no other cause of hypoventilation is present. Factors associated with daytime hypercapnia include an increased body mass index, sleep apnea, a lower mean overnight O_2 saturation, and severity of restrictive pulmonary function.[50] In a randomized study comparing CPAP to NIV in the management of the obesity-hypoventilation syndrome, both interventions reduced the $PaCO_2$ and improved quality without a significant difference between the two interventions.[51]

Stable Chronic Obstructive Pulmonary Disease

NIV in the home setting for patients with severe COPD can prolong survival, improve quality of life, reduce hospitalization, and improve lung function, provided the patients and device setting are well chosen. For example, hypercapnic patients are most likely to benefit from NIV, and general recommendations for NIV use include those with a daytime PaCO2 ≥ 50 mm Hg or greater than 53 mm Hg more than 2 weeks after a hospital stay for an acute exacerbation.[52] The settings that have been found to be helpful include higher pressures and higher pressure support with inspiratory positive airway pressure (IPAP) of 22 to 24 cm H_2O while keeping the expiratory positive airway pressure (EPAP) low at 4 to 5 cm H_2O, and with a backup rate of 14 to 18 breaths per minutes.[52]

Neuromuscular Diseases and Thoracic Cage Abnormalities

Even in progressive neuromuscular disorders, NIV can prolong survival, improve quality of life, and reduce hospitalization rates.[53] Other NIV techniques using rocking beds, pneumobelts, and negative pressure ventilation are much less frequently used and are becoming less easily available.

Invasive Ventilatory Support

Patients with profound hypoxemia from a process that is expected to resolve slowly, such as acute lung injury, usually require intubation and mechanical ventilation. Other indications for intubation include conditions where NIV may be poorly tolerated or even possibly harmful, such as the presence of upper airway obstruction, inability to clear secretions or protect the airway, or inability to achieve a proper mask fit. Both hypoxemic and hypercapnic types of respiratory failure can be managed effectively by invasive mechanical ventilation.

Acute Respiratory Distress Syndrome

Profound hypoxemic respiratory failure is often due to severe pneumonia and ARDS. Patients with these conditions have very noncompliant lungs. Volume-cycled ventilation in patients with ARDS frequently leads to high peak airway and plateau pressures. Ventilating these patients with small tidal volumes (about 4 to 8 mL/kg) and aiming for a plateau pressure below 30 cm H_2O reduces complications associated with mechanical ventilation and improves survival.[54]

Increased Intracranial Pressure

Hyperventilation applied acutely and for short periods may be used to reduce ICP. The goal is to lower $PaCO_2$ to between 25 mm Hg and 30 mm Hg, which causes alkalosis. Alkalosis helps reduce cerebral blood flow until ICP can be controlled by other measures. Ongoing ventilatory support should maintain PCO_2 in the range of 30 to 40 mm Hg. By maintaining PCO_2 in this range, sudden increases in ICP can be quickly controlled by short-term hyperventilation. Although reducing blood flow can reduce brain swelling and ICP, cerebral ischemia can also result. Another concern in ventilating patients with elevated ICP is

MINI CLINI

Indications for Continuous Positive Airway Pressure Versus Continuous Mechanical Ventilation With Positive End-Expiratory Pressure

Problem:

A patient in the ICU is severely tachypneic and hypoxemic. The respiratory rate is 30 breaths/min. On approximately 50% O_2 by mask at sea level, PaO_2 is 50 mm Hg, $PaCO_2$ is 30 mm Hg, pH is 7.51, and HCO_3^- is 23 mEq/L. The patient is in distress but alert and able to cooperate and follow instructions.

1. What is this patient's $P(A-a)O_2$?
2. What type of respiratory failure is this?
3. What is the appropriate initial therapy?

Discussion:

This patient does not have hypercapnic respiratory failure, as is confirmed by the low $PaCO_2$ (30 mm Hg). The patient does have a serious oxygenation defect, as confirmed by the increased $P(A-a)O_2$.

$$PAO_2 = 0.50\,(713) - 30/0.8 = 318\ \text{mm Hg}$$

$$P(A-a)O_2 = 318 - 50 = 268\ \text{mm Hg}$$

The elevated $P(A-a)O_2$ is explained by the presence of severe intrapulmonary shunt. Shunts this severe can occur only when significant airway closure and atelectasis are present. The mode of therapy should be aimed at reinflating collapsed alveoli and keeping the alveoli open throughout the breathing cycle. In this patient, alveolar ventilation is not impaired ($PaCO_2$ = 30 mm Hg). CPAP alone may be effective in reducing shunt. (CPAP does not provide ventilation.) CPAP may be applied noninvasively via face mask, as would be indicated in this alert, cooperative patient. If hypercapnia and acidemia develop, mechanical ventilation with PEEP would be indicated.

MINI CLINI

Acute Hypercapnic Respiratory Failure

Problem:
A patient with COPD presents to the emergency department in moderate respiratory distress. He is alert and cooperative. The respiratory rate is 26 breaths/min. Lung examination shows poor air entry with expiratory wheezing. Room air ABGs show pH 7.24, $PaCO_2$ 60 mm Hg, and PaO_2 60 mm Hg.
1. What type of respiratory failure is this?
2. How should the patient be managed?

Discussion:
ABGs show an acute respiratory acidosis with normal $PAO_2 - PaO_2$ gradient.

$$PAO_2 = 0.21 * (713) - 60/0.8 = 74$$

$$P(A-a)O_2 = 74 - 60 = 14\ mm\ Hg$$

This patient has hypercapnic respiratory failure related to obstructive lung disease, also known as *ventilatory failure*. In addition to bronchodilators and corticosteroids, the RT should aim to improve ventilation to reverse the respiratory acidosis. In this patient, who is alert and cooperative, NIV using a face mask may be tried. Initial mask ventilation can start in the pressure support ventilation mode with a level of support of 10 cm H_2O and 5 cm H_2O PEEP. Tidal volume should be maintained at approximately 6 to 8 mL/kg. If this patient deteriorates despite therapy, he will need to be intubated and mechanically ventilated.

using PEEP to manage hypoxemia. There is a concern that increased intrathoracic pressure due to PEEP would cause decreased cerebral venous return leading to increased ICP. Also, there is concern that PEEP can decrease cerebral perfusion by limiting cardiac output. The use of PEEP in patients with elevated ICP may require invasive monitoring of ICP because the combination of decreased cerebral perfusion and elevated ICP can (but not always) narrow cerebral perfusion pressure.[55] Elevation of the head of the bed can offset the increased ICP associated with the application of PEEP.

Obstructive Lung Disease

Patients with obstructive lung disease have markedly increased airway resistance that leads to a decrease in the rate of expiratory flow with resulting hyperinflation. These patients frequently have problems with elevated airway pressure or **dynamic hyperinflation** (auto-PEEP), which can cause barotrauma and ineffective triggering of the ventilator.[56]

The goal in managing patients with obstructive lung disease and respiratory failure is to oxygenate and ventilate the patient successfully, while avoiding dyssynchrony and dynamic hyperinflation. In these patients, lower tidal volumes (6 to 8 mL/kg), moderate respiratory rates, and high sustained (square wave) inspiratory flow rates (70 to 100 L/min) are recommended to avoid dynamic hyperinflation.[57] These maneuvers reduce inspiratory time and prolong expiratory time, which allows a patient with obstructive lung disease to have a longer time to exhale.

Another consideration in patients with obstructive lung disease is the inspiratory threshold load imposed by auto-PEEP, resulting in increased patient inspiratory work.[33] In this case, applied (or extrinsic) PEEP can compensate for this threshold load and reduce the work of breathing for patient-triggered breaths in any assisted ventilatory mode.[33]

Ventilatory Support in Chronic Hypercapnic Respiratory Failure

The goal of therapy in hypercapnic respiratory failure (acute ventilatory failure) is to guarantee a set minute ventilation. In treating patients with chronic ventilatory failure, the goal is to normalize the pH but not the $PaCO_2$. Correction of $PaCO_2$ in a patient with chronic hypoventilation from diverse causes can lead to a posthypercapnic metabolic alkalosis, which can produce hypokalemia, seizures, and arrhythmias.

SUMMARY CHECKLIST

- Acute respiratory failure is identified by PaO_2 less than 60 mm Hg or $PaCO_2$ greater than 50 mm Hg, or both, in otherwise healthy individuals at sea level.
- Hypoxemic respiratory failure is most commonly due to $\dot{V}/\dot{Q}$ mismatch, shunt, or hypoventilation.
- Hypercapnic respiratory failure, also known as *ventilatory failure*, results from decreased ventilatory drive, neurologic disease, or increased work of breathing.
- Chronic respiratory failure may manifest with hypercapnia and evidence of a compensatory metabolic alkalosis (chronic ventilatory failure) or with polycythemia reflecting chronic hypoxemia.
- The clinical condition of the patient is the most important factor in determining the need for ventilatory support.
- Excessive work of breathing is the most common cause of respiratory muscle fatigue.
- Acute exacerbations of COPD and cardiogenic edema represent two acute conditions in which NIV has benefit.
- Increased FiO_2 and PEEP are the main treatments for severe hypoxemia.
- The goal of treating hypercapnic respiratory failure (acute ventilatory failure) is to normalize the pH.

Mechanical Ventilators

Robert L. Chatburn and Teresa A. Volsko

CHAPTER OBJECTIVES

After reading this chapter you will be able to

- Define a mechanical ventilator
- Describe the key design features of ventilator displays
- Discuss the importance of properly setting alarm thresholds
- Explain how the compliance of the patient circuit affects volume delivery
- Describe the 10 maxims used to develop a standardized ventilator taxonomy
- Demonstrate how to classify any mode of ventilation
- List the three main goals of mechanical ventilator support
- Discuss the differences between conventional and high-frequency ventilators

CHAPTER OUTLINE

KEY TERMS

adaptive targeting scheme
assisted breath
bio-variable targeting scheme
continuous mandatory ventilation (CMV)
continuous spontaneous ventilation (CSV)
control circuit
cycling
driving pressure
dual targeting scheme
elastance
intelligent targeting scheme
intermittent mandatory ventilation (IMV)
loaded breathing
machine cycled
machine triggered
mandatory
mode
pressure-control ventilation
resistance
servo targeting scheme
optimal targeting scheme
patient cycled
patient triggered
spontaneous breath
targeting scheme
tidal pressure
time constant
time-control
trigger
volume-control ventilation

To safely and effectively initiate and manage a mechanical ventilator, the respiratory therapist (RT) must have a basic understanding of (1) ventilator design principles related to patient-ventilator interaction; (2) appropriate clinical application of ventilatory modes (i.e., the proper matching of ventilator capability with physiologic need); and (3) the physiologic effects of mechanical ventilation, including gas exchange and pulmonary mechanics. This chapter focuses on the first of these. It explains classification terminology and outlines a framework for understanding current and future ventilatory support devices.[1]

HOW VENTILATORS WORK

Some basic knowledge of mechanics is helpful to understand how ventilators work. A ventilator is simply a machine that is designed to perform some portion of the work of breathing. These machines deliver a variety of medical gas mixtures, such as nitric oxide, helium, and oxygen. Sophisticated software and advanced monitoring systems make it possible to deliver a variety of breathing patterns to meet patient needs for safety, comfort, and, eventually, liberation (i.e., extubation).

Ventilators are used along the whole continuum of care, from intensive care units (ICUs) to patient transport to long-term and home care. They all require energy in the form of either electricity or compressed gas to function. The energy is transmitted or transformed (by the ventilator's drive mechanism) in a predetermined manner (by the **control circuit**) to augment or replace the patient's muscles in performing the work of breathing (the desired output).

RULE OF THUMB For patient transport, you must use either a pneumatically powered ventilator or one that can run solely on batteries. Always take along a manually powered bag-valve-mask resuscitator, and for long transports be sure to have backup power available (extra cylinders or batteries).

A basic schematic of an ICU ventilator is shown in Fig. 46.1. A simplified description of ventilator operation is as follows: High-pressure gas (air and oxygen, usually from a centrally located compressor and liquid oxygen source and piped into ICU rooms) enters the ventilator at 50 psi (in the United States). Inside the ventilator, the gas pressures of air and oxygen sources are usually reduced. The flow of gas to a reservoir is then controlled by two valves. The relative flows of air and oxygen to the reservoir controls the FiO_2. Output flow from the reservoir to the patient is managed by a high-flow proportional valve (i.e., flow is proportional to the voltage applied to the valve). The flow to the patient is coordinated with the exhalation valve that intermittently occludes the exhalation path. Thus, when the output flow valve is open and the exhalation valve is closed, gas flows into the lungs. When the output flow valve is closed and the exhalation valve is open, gas flows from the lungs, through the exhalation system, and to the atmosphere. Software controls the intricate interaction between the output valve and the exhalation valve to produce a variety of breathing patterns. These patterns can be dictated by the ventilator or entirely controlled by the patient's brain or ventilatory demand.

RULE OF THUMB Ventilators used near magnetic resonance imaging (MRI) equipment must be MRI compatible. Even when an MRI-compatible ventilator is used during imaging, it is important to maintain the ventilator within the designated safe distance from the MRI device.

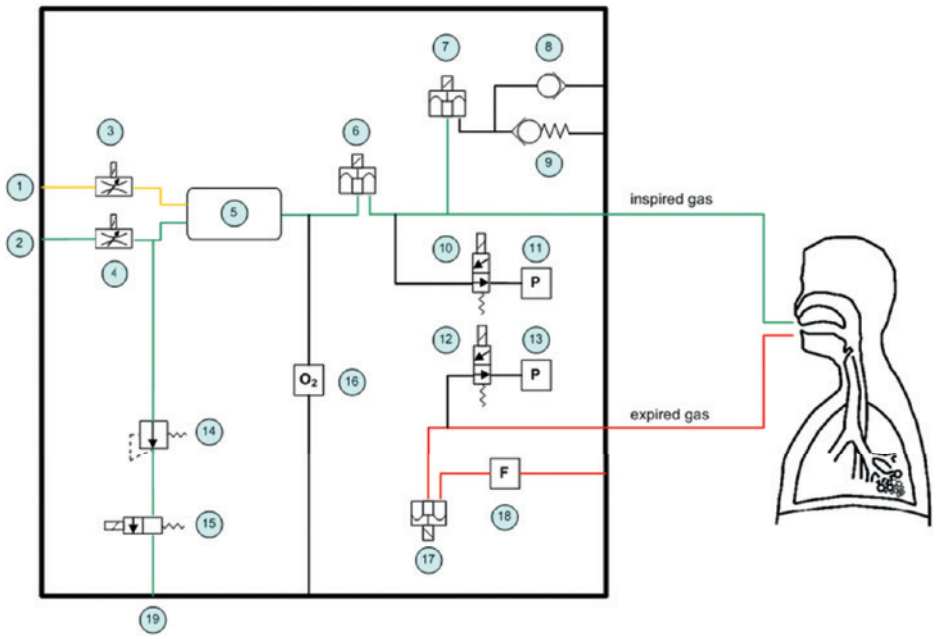

Fig. 46.1 Simplified Schematic of a Modern Intensive Care Ventilator. High-pressure gas enters the ventilator through the gas inlet connections for oxygen and air *(1,2)*. Mixing takes place in a reservoir *(5)* and is controlled by two valves *(3,4)*. Inspiratory flow from the reservoir is controlled by a separate proportional valve *(6)*. On the inspiratory circuit there is a safety valve *(7)* and two nonreturn valves *(8,9)*. In normal operation the safety valve is closed so that inspiratory flow is supplied to the patient's lungs. When the safety valve is open, spontaneous inspiration of atmospheric air is possible through the emergency breathing valve *(8)*. The emergency expiratory valve *(9)* provides a second channel for expiration when the expiratory valve *(17)* is blocked. Also on the inspiratory circuit are an inspiratory pressure (P) sensor *(11)* and a pressure sensor calibration valve *(10)*. The exhalation circuit consists of the expiratory valve *(17)*, expiratory pressure sensor *(13)* with its calibration valve *(12)*, and an expiratory flow *(F)* sensor *(18)*. The expiratory valve is a proportional valve and is used to adjust the pressure in the patient circuit. Conversion of mass flow to volume (barometric temperature and pressure saturated, BTPS) requires knowledge of ambient pressure, measured by another pressure sensor (not shown). Pressure in the patient circuit is measured with two independent pressure sensors *(11,13)*. Oxygen flow to the nebulizer port *(19)* is controlled by a pressure regulator *(14)* and a solenoid valve *(15)*. (Reproduced, with permission Mandu Press Ltd.)

The Operator Interface

The ventilator's operator interface (i.e., control panel) has evolved a lot over the last 45 years. Originally the displays on ventilators were very simple: operator inputs, or settings, were accomplished with hard-wired knobs, buttons, and dials. The ventilator outputs, such as alarm conditions and ventilating pressure, were displayed with bulbs, light-emitting diodes (LEDs), and meters. Some simple transport ventilators still use analog displays. The development of inexpensive microprocessors has led manufacturers to use digital displays almost exclusively on all types of ventilators. Today most ICU ventilators have computer touch screens for visual displays of ventilator data. They are usually designed as "virtual" instruments, meaning that knobs, buttons, dials, and meters are simulated on the screen, and may rely on only a single mechanical dial and perhaps a few buttons to set multiple parameters (Fig. 46.2).

Ventilator Displays

Ventilator displays serve three main functions: (1) to display the inputs—that is, the current state of the settings and allow changes to be made; (2) to show the outputs—meaning the measured values that characterize normal patient–ventilator interactions; and (3) to show alarm conditions. Additional functions include trends of past settings or measured values, performance of special monitoring or automated procedures such as the determination of optimal positive end-expiratory pressure (PEEP), and miscellaneous ventilator configuration settings and patient data.

Alphanumeric values. Measured or calculated data in the form of alphanumeric values are presented in numbers or text. Typically FiO_2, pressures (mean, baseline, peak, and plateau), volumes (inhaled/exhaled tidal volume, minute ventilation), peak inspiratory and expiratory flow, and frequency are represented as numeric values. A variety of calculated parameters including I:E ratio, percent leak, resistance, and compliance may also be displayed.

Trends. Trends provide clinicians with measured or calculated data related to ventilatory support over time. Gradual or sudden changes in the patient's ventilatory status can be identified by evaluating trends. Alarm logs can also be accessed and provide an additional layer of detail important for adjusting alarm limits to minimize nuisance alarms and enhance safety. Alarm logs can be invaluable in the event of a suspected ventilator failure and may be used as evidence in a legal investigation if significant patient harm has occurred.

Waveforms and loops. Graphic displays of pressure, volume, and flow convey a wealth of information. Not only is it possible to determine the mode of ventilation by examining these graphics, but the causes of patient–ventilator asynchrony can also be determined, including flow asynchrony, delayed or premature cycling, and missed triggers. Graphic representations of respiratory mechanics are helpful for identifying the ventilator parameters to be adjusted to improve the ventilator–patient interaction.[2] When pressure, volume, or flow is graphed on the vertical axis with time on the horizontal axis, a waveform or "scalar" display (Fig. 46.3) is the result. Loop displays plot one variable against another as *x-y* graphs (Fig. 46.4).

Pressure-volume (PV) loops can be used to set optimal PEEP and tidal volume levels (Fig. 46.5). PV loops are manually created by using a "super syringe" to inject discrete volumes of gas and then measuring static pressures (static pressure–volume curve). Alternatively, one can use the ventilator at very low constant inspiratory flows (<10 L/min) to minimize the pressure due to flow resistance and create what are called *quasi-static* loops. One

Fig. 46.2 Example of a modern intensive care unit ventilator display.

MINI CLINI

The Use of Trending Data to Optimize the Application of Mechanical Ventilation

Problem

A 43-year-old female in respiratory distress has a predicted body weight of 60 kg. She is intubated and receiving mechanical ventilation with the following settings:

Mode: PC-CMV
Set frequency: 20/min
Inspiratory pressure: 15 cm H_2O
PEEP: 8 cm H_2O
FiO_2: 0.60
Inspiratory time: 1 second

The following trends are available: Date	8/8	8/8	8/8	8/8	8/8	8/8
Time	0000	0200	0400	0600	0800	1000
V_T (mL)	420	415	390	385	373	362
Total frequency (breaths/min)	20	20	20	20	20	20
Minute ventilation (L/min)	5.04	4.98	4.68	4.62	4.48	4.34

V_T, tidal volume.

What value does the trend monitoring provide for the clinician? What additional data are needed for the clinician to optimize ventilation?

Answer

The data show that the patient has had no respiratory effort over the 10 recorded hours displayed on the data trend. This can be seen by comparing the set frequency with the total frequency. The trends also show that the tidal volume has decreased over time. This can be attributed to an increase in airway resistance or a reduction in lung compliance (or both) because the mode was a form of pressure ventilation. Accessing the trends for airways resistance will enable the clinician to differentiate between problems of airways resistance and lung compliance. If the airways resistance has remained relatively stable, the pulmonary compliance has decreased. Additional testing, such as chest x-ray and arterial blood gas monitoring, may be required to determine pathologic changes such as atelectasis as well as changes in acid-base balance.

very convenient approach is to automate the process using a slow-pressure ramp, which allows both identification of lung recruitability and determination of optimal PEEP.[3] The patient must be heavily sedated and/or paralyzed to avoid errors due to the patient's inspiratory efforts and to minimize patient anxiety and discomfort during the maneuver. For volume-control modes, pressure-volume loops are useful in displaying overdistention. Flow-volume loops are helpful for identifying the need to suction and/or response to bronchodilator therapy. Fig. 46.6 is an example of a composite display showing numeric values, waveforms, and loops.

RULE OF THUMB A pressure-volume curve will take the shape of a "bird's beak" when overdistention is present. This shape occurs because pressure continues to rise but there is no concomitant rise in volume during inspiration. Reducing the delivered tidal volume (by decreasing the set volume during volume-control ventilation or reducing the inspiratory pressure during pressure-control ventilation) will reduce overdistention.

Picture Graphics

An interesting development in ventilator displays involves the use of picture graphics to represent useful information about the patient–ventilator system (Fig. 46.7). Clinicians may also perceive lower subjective workloads when they are using picture graphics.

Alarm Settings

The purpose of ventilator alarms is to bring events to the attention of the clinician. Events are conditions or occurrences requiring clinician awareness or intervention. Ventilators typically announce the priority of alarms (i.e., low or high risk to patient) by means of different colors of lights and/or different sound tones and loudness. The actual setting of alarm thresholds is a complicated topic that has been studied but for which little information is available regarding mechanical ventilation. The basic goal is to maximize true alarms and minimize false alarms. A high rate of false alarms leads to what is called "alarm fatigue," meaning that clinicians get used to the warnings and eventually ignore them. False alarms can also lead to inappropriate responses. On average, ICU alarms occur six times per hour with only a small percentage (23%) indicating an actual urgent clinical situation and a high percentage (44%) being false-positive alarms.[4,5]

Although few studies have addressed mechanical ventilator alarms specifically,[6] it is not hard to imagine similar results for these devices. Ventilator alarms are usually set by the operator (or as default values by the ventilator) as either a set value or a set percentage of the current value. Examples would be low and peak airway pressure alarms set at the current value plus or minus 5 cm H_2O or low and high tidal volume ventilation per minute set at plus or minus 25% of the current value. The problem is that the parameters for which clinicians want to set alarms—and three in particular are highly variable—involve significant portions of readings at extreme values. Therefore limits set as absolute values or percentages may reduce safety for some extreme values while also increasing nuisance events for other values. Further research is needed to identify optimization algorithms (i.e., maximize safety and minimize nuisance), perhaps using artificial intelligence tools to adjust alarm thresholds automatically according to changing patient conditions.

RULE OF THUMB Setting alarms limits appropriately is an important to preventing harm. It is important to verify alarm settings when ventilator parameters are adjusted and with each patient–ventilator safety check.

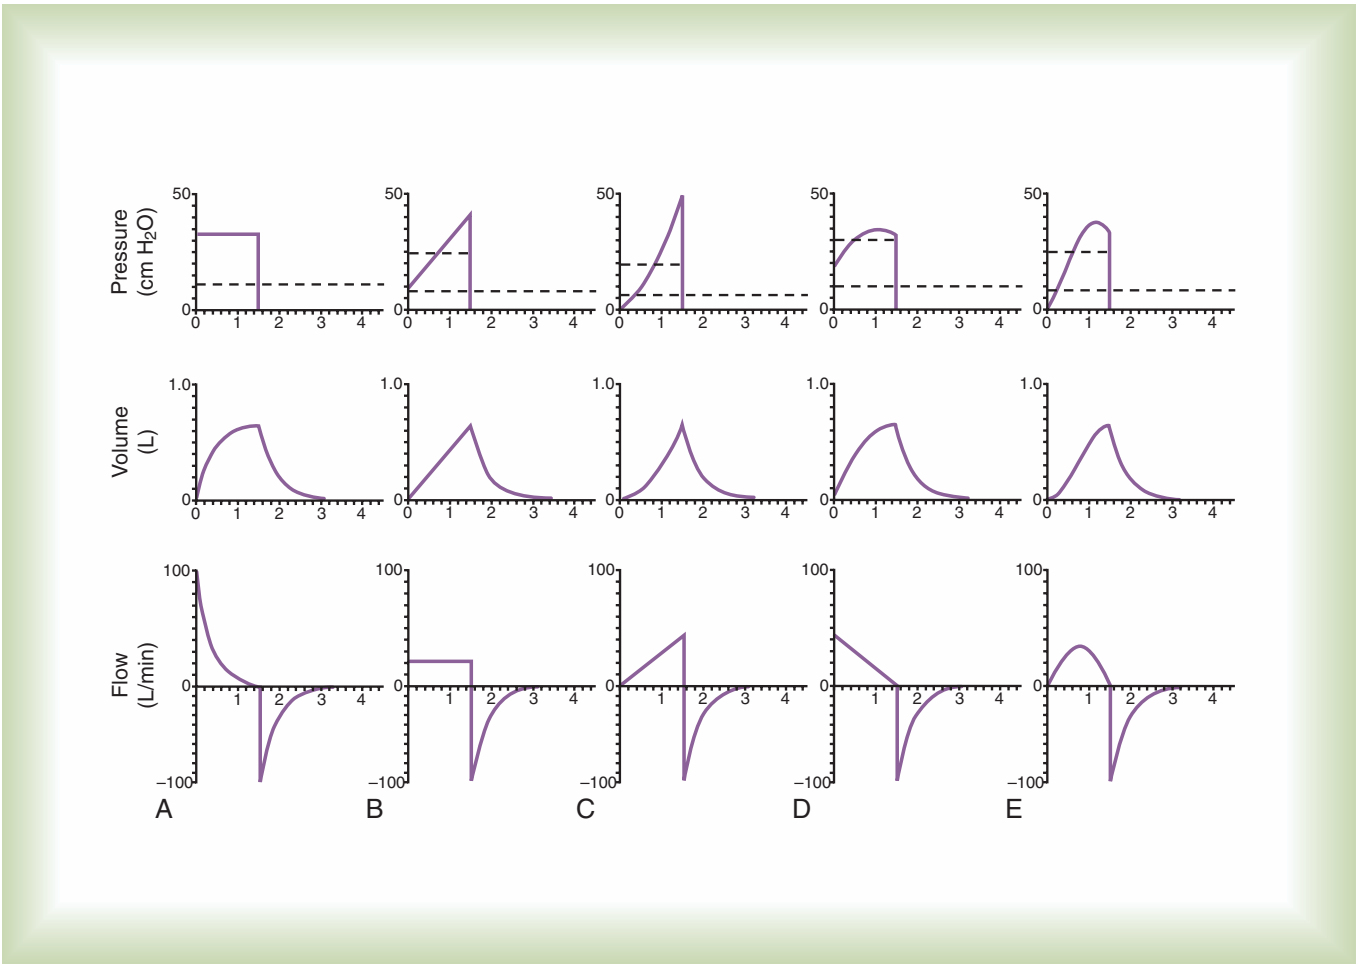

Fig. 46.3 Model Pressure, Volume, and Flow Waveforms Generated With a Computer Using the Equation of Motion. (A) Pressure-controlled inspiration with a rectangular pressure waveform (identical to flow-controlled inspiration with an exponential decay flow waveform). (B) Flow-controlled inspiration with a rectangular flow waveform (identical to volume-controlled inspiration with an ascending-ramp volume waveform). (C) Flow-controlled inspiration with an ascending ramp flow waveform. (D) Flow-controlled inspiration with a descending ramp flow waveform. (E) Flow-controlled inspiration with a sinusoidal flow waveform. The short dotted lines represent mean inspiratory pressure and the long dotted lines represent mean airway pressure (assuming zero positive end expiratory pressure). Note that for the rectangular pressure waveform in A, the mean inspiratory pressure is the same as the peak inspiratory pressure. For all waveforms, V_T = 644 mL, compliance = 20 mL/cm H_2O, and resistance = 20 cm H_2O/L per second.

The Patient Interface

The patient interface is the connection between the ventilator and the patient—typically a system of plastic hoses often called the *patient circuit*. From the perspective of understanding how ventilators work, the important thing to know about the patient circuit is that it contributes to discrepancies between the desired and actual ventilator output values. This is because the patient circuit has its own compliance and resistance. Thus, due to patient circuit resistance, the pressure measured on the inspiratory side of a ventilator will always be higher than the pressure at the airway opening. In addition, the volume and flow coming out of the ventilator will exceed that delivered to the patient because of the compliance of the patient circuit.

Using an analogy to electrical circuits, compliance of the delivery circuit can be shown to be connected in series with compliance of the respiratory system (that is, both elements sharing the same driving pressure). Consequently the total compliance of the ventilator–patient system is simply the sum of the two compliances. Similarly, the delivery circuit's resistance is connected in series with the respiratory system's resistance (that is, both elements sharing the same flow), so that the total resistance is the sum of the two. Based on these assumptions, the relationship between the volume input to the patient (at the point of connection to the patient's airway opening) and the volume output from the ventilator (at the point of connection to the patient circuit) can be described by the following equation:

$$\text{Volume input to patient} = \frac{\text{Volume output from ventilator}}{1 + C_{pc}/C_{rs}} \qquad \textbf{46.1}$$

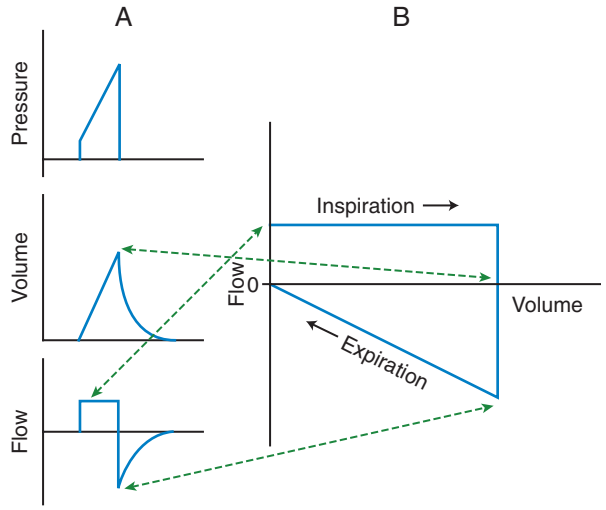

Fig. 46.4 Idealized waveforms (A) for volume-control ventilation with corresponding idealized dynamic (not static or quasi-static) pressure-volume loop (B). where C_{pc} is the compliance of the patient circuit and C_{rs} is the total compliance of the patient's respiratory system. The equation shows that the larger the patient circuit's compliance compared with the patient's respiratory system, the larger the denominator on the right-hand side of the equation. Therefore the delivered tidal volume is smaller than the volume coming from the ventilator's drive mechanism.

Assuming that the volume exiting the ventilator is the set tidal volume, the patient circuit's compliance (C_{pc}) is calculated as follows:

$$C_{pc} = \frac{\text{Set tidal volume}}{P_{plat} - \text{PEEP}} \quad \textbf{46.2}$$

where P_{plat} is the pressure measured during an inspiratory hold maneuver with the Y-piece of the patient circuit occluded (patient not connected) and PEEP is end-expiratory pressure (that is, baseline pressure). Most authors recommend the use of peak inspiratory pressure (PIP) for P_{plat} in this equation, which is acceptable but may lead to a slight underestimation of the patient circuit's compliance. P_{plat} is lower than PIP because of the flow-resistive pressure drop of the patient circuit if pressure is not measured at the Y-piece. This difference is greatest in small-bore corrugated patient circuit tubing but is probably insignificant.

The effects of patient circuit compliance are most troublesome during volume-controlled ventilation. For example, in neonatal ventilation, the patient circuit's compliance can be as much as three times that of the respiratory system even with small-bore tubing and a small-volume humidifier. Thus, in an attempt to deliver a preset tidal volume, the volume delivered to the patient may be as little as 25% of that exiting the ventilator whereas 75% is compressed in the patient circuit.

MINI CLINI

A respiratory therapist is preparing use a portable ventilator while transporting a 10-year-old child to the computed tomography (CT) suite. The child is intubated with a 5.0 cuffed endotracheal tube (ETT) and receiving volume control (VC)-CMV on the following settings:

V_T: 250 mL
Set rate: 14/min
PEEP: 5 cm H_2O
FiO_2: 0.40

Monitored parameters are as follows:

Total rate: 14
P_{plat}: 20 cm H_2O
PIP: 22 cm H_2O
Exhaled V_T: 244 mL

Calculate the tubing compliance.

Answer

$$C_{pc} = \frac{\text{Set tidal volume}}{P_{plat} - \text{PEEP}}$$

$$C_{pc} = \frac{250\,\text{mL}}{20\,\text{cm}\,H_2O - 5\,\text{cm}\,H_2O}$$

$$C_{pc} = \frac{250\,\text{mL}}{15\,\text{cm}\,H_2O}$$

$$C_{pc} = 16.7\,\text{mL/cm}\,H_2O$$

During pressure-control ventilation, the compliance of the patient circuit has the effect of rounding the leading edge of a rectangular pressure waveform, reducing the peak flow and possibly also reducing the volume delivered to the patient. This effect is prevented if the pressure limit is maintained for at least five time constants of the respiratory system.

For both pressure- and volume-control ventilation, the patient circuit's compliance and resistance—along with the resistance of the exhalation valve (in series with the patient circuit and respiratory system resistance)—increase the expiratory time constant. Thus a large circuit compliance coupled with a short expiratory time can lead to inadvertent PEEP (or auto-PEEP).

In summary, the set values for pressure, volume, and flow may be different from the output (from ventilator) values due to calibration errors and the effects of the patient circuit. These two general sources of error cause discrepancies between the desired and actual patient values.

IDENTIFYING MODES OF MECHANICAL VENTILATION

Ventilator manufacturers coin unique names for modes available on their respective devices, primarily as marketing tools. As a result, there have been no industry standards for naming modes of ventilation. This makes it difficult for clinicians to understand how the various modes of ventilation function. In some cases, ventilator modes function in the same way but have very different names. For example, pressure-control ventilation plus adaptive pressure ventilation on the Hamilton Galileo is the same as pressure-regulated volume control on the Siemens Servo 300. Volume control continuous mandatory ventilation (VC-CMV) on the Maquet SERVO-i ventilator and the PB 840 have identical names and function very differently.[7]

The 10 Maxims for Understanding Modes

There is a formal taxonomy for classifying modes of ventilation.[1] The purpose of the taxonomy is the same as the taxonomy for drugs (i.e., to allow the clinician to identify which modes are the same among over 300 unique names coined by manufacturers). The best way to understand the taxonomy is to review 10 fundamental concepts (or maxims) that explain the basic principles of ventilator design and patient–ventilator interaction.

A Breath Is One Cycle of Positive Flow (Inspiration) and Negative Flow (Expiration) Defined in Terms of the Flow-Time Curve

Breath delivery is one of the most basic functions a mechanical ventilator performs. A breath can simply be defined as one cycle of inspiratory flow followed by a matching expiratory flow (Fig. 46.8).

Inspiratory time and expiratory time are the two most basic definitions in reference to a breath. Inspiratory time is defined as the period from the start of inspiratory flow to the start of expiratory flow. Inspiratory time is equal to inspiratory flow time plus inspiratory hold time. Inspiratory flow time is the period from the start of inspiratory flow to the end of inspiratory flow. Inspiratory hold (or pause time) is the period from

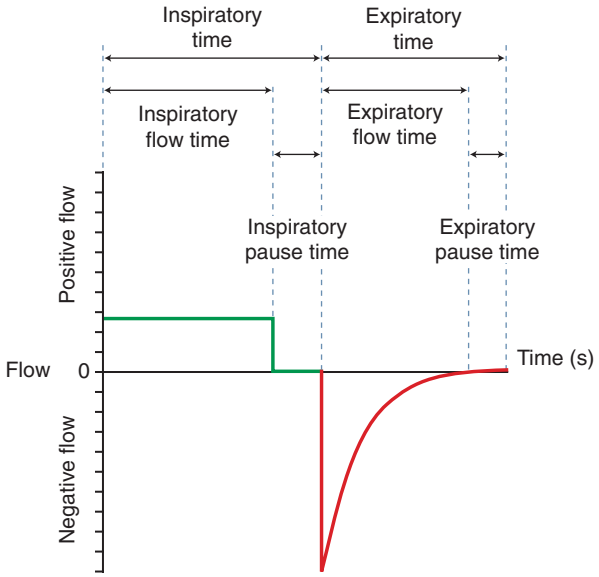

Fig. 46.8 A breath is defined in terms of the flow-time waveform. (Courtesy Mandu Press Ltd.)

the end of inspiratory flow to the start of expiratory flow. On some ventilators, the operator can set inspiratory hold time directly. On others, hold time is the difference between the preset inspiratory time and the inspiratory flow time due to the preset tidal volume at the preset inspiratory flow (i.e., inspiratory flow time = tidal volume/inspiratory flow). It may be used to create a static airway pressure also known as *plateau pressure*. During an inspiratory pause, the flow of gas to and from the patient ceases. Therefore the pressure displayed during the inspiratory pause, or plateau pressure, can be used to calculate respiratory system's resistance and compliance. The period from the start of expiratory flow to the start of inspiratory flow is known as *expiratory time*.

RULE OF THUMB A completely accurate plateau pressure cannot be obtained when the patient is actively breathing. When a patient has an active respiratory drive, sedation may be needed to temporarily suppress the drive while the plateau pressure is obtained.

A Breath Is Assisted If the Ventilator Provides Some or All of the Work of Breathing

Ventilators are designed to assist with the patient's work of breathing. *Work* is defined in terms of the pressure necessary to deliver the tidal volume to the respiratory system. In the simplest case (i.e., constant inspiratory pressure), work is the pressure change during inspiration times the volume change (i.e., tidal volume). An **assisted breath**, therefore, is one for which the ventilator does *some* work on the respiratory system whereas the patient does the rest.

On a ventilator graphic display, an assisted breath is identified as one in which airway pressure rises above baseline during inspiration (recall from maxim 1, inspiration is identified by flow above zero). A drop in airway pressure below baseline during inspiration indicates that the patient is doing work to initiate the breath and to move gas into his or her lungs. In this case, we say the breath is "loaded" rather than assisted. Some loading is unavoidable if the patient must signal to the ventilator when to start inspiratory flow by a drop in airway pressure, called *triggering* (see further on).[8] Optimization of ventilator settings minimizes **loaded breathing** by maximizing the synchrony between the ventilator output and the patient's demand.

A Ventilator Assists Breathing Using Either Pressure Control or Volume Control Based on the Equation of Motion for the Respiratory System

To understand how a ventilator assists breathing, we make use of a very important model of patient–ventilator interaction called the *equation of motion for the respiratory system*. This equation is a mathematical model describing a physical model composed of a single flow-conducting tube (representing the airways) and a single elastic compartment (representing the lungs and chest wall), as shown in Fig. 46.9. There are many versions of this equation, but the simplest version as it relates to ventilator mode classification is as follows:

$$P_{vent}(t) = EV(t) + R\dot{V}(t) \qquad \textbf{46.3}$$

where $P_{vent}(t)$ is inspiratory pressure generated by the ventilator as a function of time, E is the **elastance** of the respiratory system ($\Delta P/\Delta V$); $V(t)$ is volume as a function of time, R is respiratory-system **resistance** ($\Delta P/\Delta \dot{V}$); and $\dot{V}(t)$ is flow as a function of time. *Note that all these variables are measured relative to their end expiratory values.* Sometimes the equation is written with compliance ($C = \Delta V/\Delta P$) instead of elastance, in which case the term $EV(t)$ becomes $V(t)/C$. If the patient is spontaneously triggering the ventilator, the extra inspiratory force is accounted for by the variable representing muscle pressure, P_{mus}, and the left side of Eq. 46.3 becomes $P_{mus} + P_{vent}$, indicating that the work of breathing is shared in some way between the patient and the ventilator. However, if the patient is breathing independent of the ventilator, the left side of Eq. 46.3 is simply P_{mus} (normal spontaneous breathing).

A plot of $P_{vent}(t)$, $V(t)$, and $\dot{V}(t)$ versus time yields the waveforms seen on ventilator displays (Fig. 46.10). If the shape of the pressure waveform is determined by the ventilator settings, and is unaffected by changes in respiratory system mechanics, then the ventilator is providing *pressure control* (PC). In other words, the ventilator controls the left-hand side of Eq. 46.3, and the volume and flow waveforms will be dependent on E and R. In more practical terms, if the operator sets inspiratory pressure, or inspiratory pressure is controlled by the ventilator to be proportional to some measure of the patient's inspiratory effort, then by definition the mode of ventilation is a form of pressure control. One very confusing issue with **pressure-control ventilation** is that sometimes the operator sets the magnitude of the pressure waveform relative to atmospheric pressure (called *PIP*) and other times the magnitude is set relative to PEEP, in this case simply termed inspiratory *pressure*.[9]

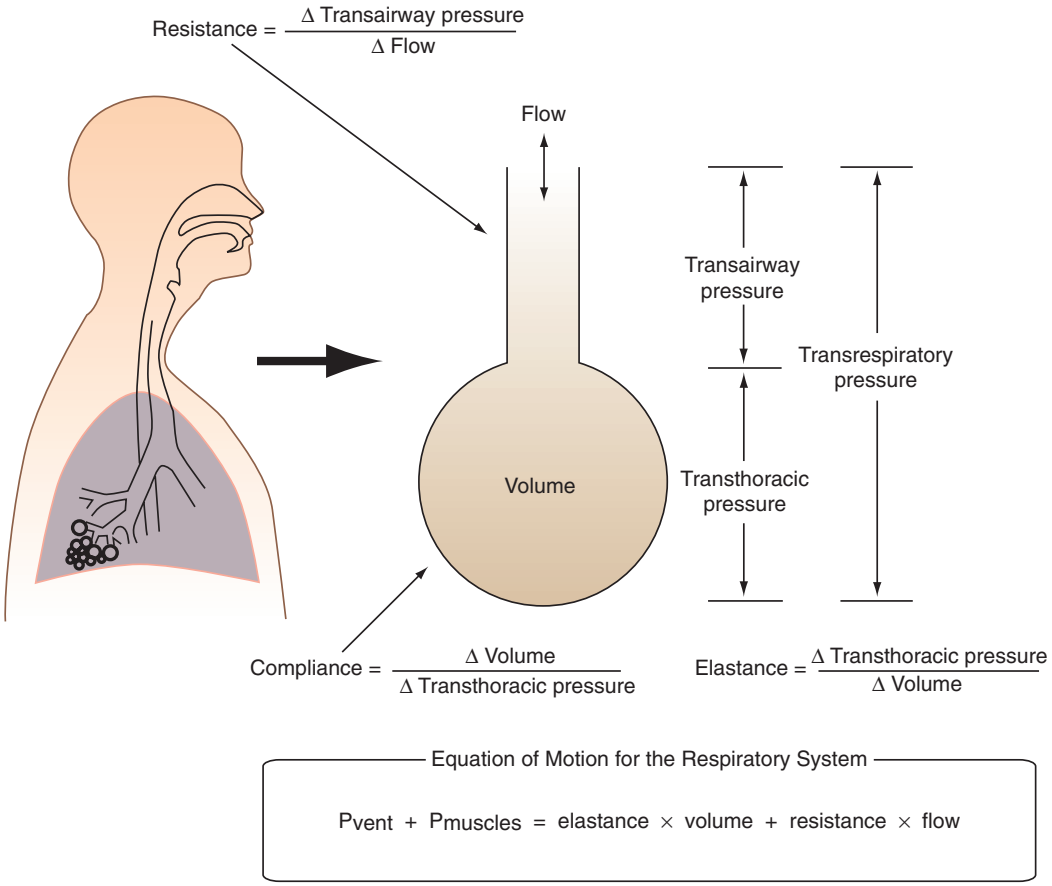

Fig. 46.9 The Respiratory System Can Be Modeled As a Single-Flow Conducting Tube Connected to a Single Elastic Compartment. This physical model can be described by a mathematical model called the *equation of motion* for the respiratory system. In this model, pressure, volume, and flow are variables (i.e., functions of time), whereas resistance and elastance (or compliance) are constants.

RULE OF THUMB In the equation of motion, the term EV (or V/C) is called **driving pressure**, ΔP. Perhaps a more accurate term is **tidal pressure**, P_T (because it is simply tidal volume scaled by elastance or compliance). If you do not know the value of E or C, ΔP can be calculated at the bedside as P_{plt} (PEEP + auto-PEEP). Note that in the literature, ΔP is sometimes defined as PIP minus PEEP during pressure-control modes. This kind of ΔP will overestimate tidal pressure if inspiratory flow has not returned to zero during the preset inspiratory time (i.e., tidal delivery is not complete). Hence we should distinguish between set and measured ΔP, or ΔP_{set} vs ΔP_{meas}, or better, simply use ΔP_{set} vs P_T.

Refer again to Fig. 46.10. If the shapes of the volume and flow waveforms are determined by the ventilator settings, and are unaffected by respiratory system mechanics, the ventilator is providing *volume control* (VC). In other words, the ventilator controls the right-hand side of Eq. 46.3, and the pressure waveform will be dependent on E and R. In more practical terms, if the tidal volume *and* inspiratory flow are preset, then by definition the mode of ventilation is volume control. The term *volume control* is used rather than *flow control* merely for historical reasons. Note that during **volume-control ventilation**, *both* volume and flow are preset prior to inspiration. We emphasize this because there are some *pressure-control modes* that allow the operator to set a target tidal volume but allow the ventilator to determine the flow. There are also pressure-control modes that allow the operator to set the maximum inspiratory flow but not the tidal volume. In this case, tidal volume delivery depends on the operator-set inspiratory pressure target and the mechanics of the patient's respiratory system.

In some rare cases of nonconventional ventilation, inspiratory flow, inspiratory volume, and inspiratory pressure are all dependent on respiratory system mechanics. As no parameters of the pressure, volume, or flow waveforms are preset, the only control of the breath is the timing (i.e., inspiratory and expiratory times). When this happens, the mode is called a form of time control. Examples of this are high-frequency oscillatory ventilation (3100 ventilator, CareFusion, San Diego, CA) and volumetric diffusive respiration (Percussionaire, Sagle, ID).

One way to compare volume- and pressure-control modes of ventilation is to first recognize that the aim is to control the patient's minute ventilation (because minute ventilation determines the $PaCO_2$ for a given rate of metabolic CO_2 production). Next, we can relate the operator-set variables that control minute ventilation for VC versus PC. A convenient way to do this is with influence diagrams, which are graphic illustrations that show how things are interrelated by using circles to represent (in this case) ventilator settings and lines to represent relationships.

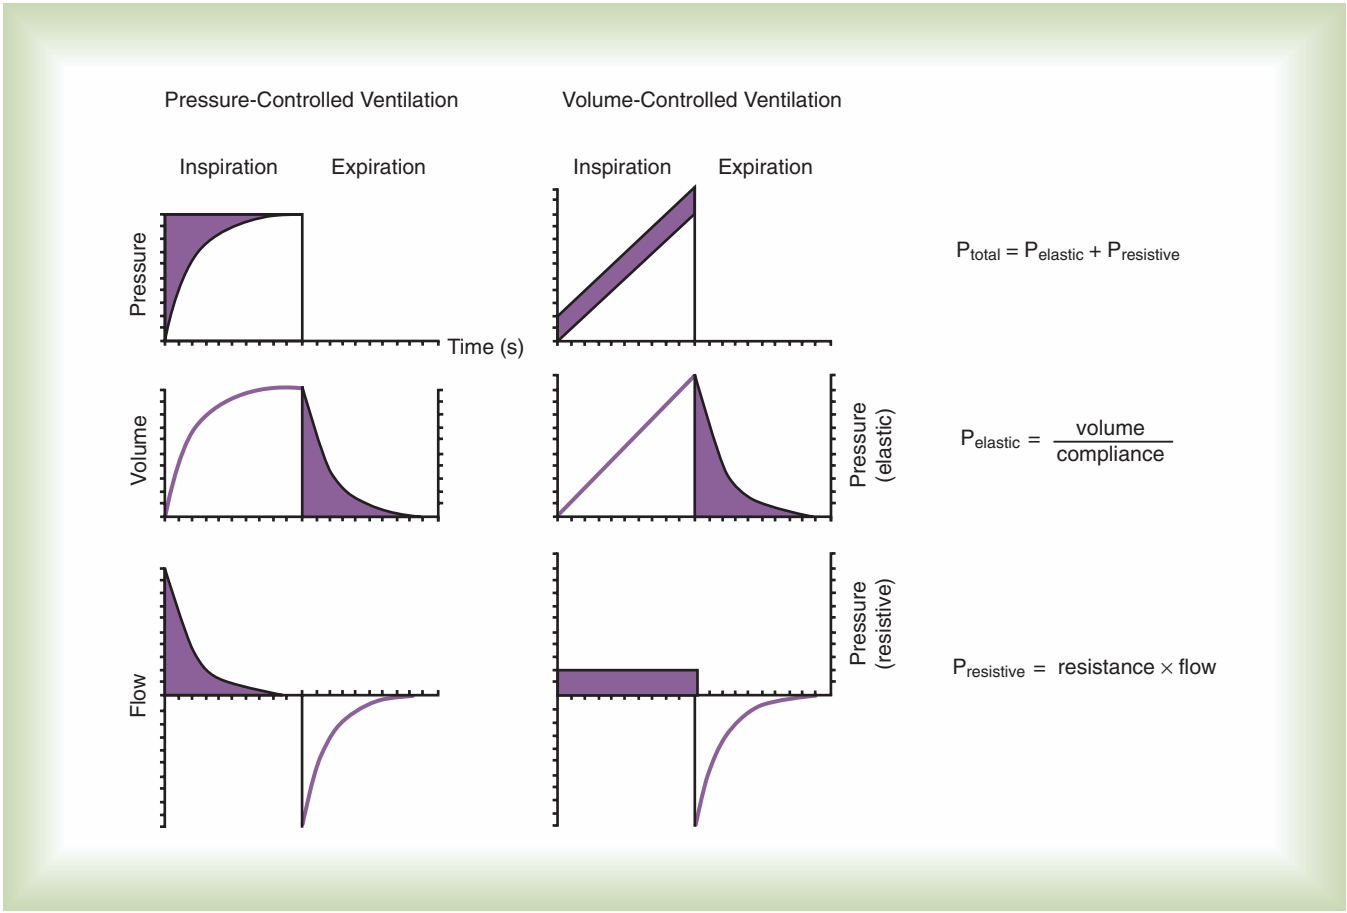

Fig. 46.10 Idealized Waveforms for Volume-Control and Pressure-Control Ventilation. Note that the volume waveform has the same shape as the transthoracic or lung pressure waveform (i.e., pressure due to elastic recoil). The flow waveform has the same shape as the pressure waveform due to airway resistance. The shaded areas represent pressures due to resistance; the open areas represent pressure due to elastic recoil. The dotted lines represent mean airway pressure. Note that the mean pressure at the airway is the same as that in the lung and that mean pressure for volume-control ventilation is less than that for pressure-control ventilation.

Fig. 46.11 shows the influence diagram for volume-control ventilation and Fig. 46.12 shows the influence diagram for pressure-control ventilation. The equations that relate the ventilator settings are given in Table 46.1.

In summary:

Volume control means that *both* volume and flow are preset prior to inspiration.

Pressure control means that inspiratory pressure is preset to some constant value or is proportional to inspiratory effort.

Time control means that pressure, volume, and flow are all dependent on changing respiratory system mechanics and nothing is predetermined except inspiratory and expiratory times.

RULE OF THUMB During volume-control modes, the operator-set flow will affect the inspiratory and expiratory times (if frequency is held constant). A flow-time waveform is helpful in evaluating whether the operator-set flow is sufficient for the patient. When flow does not return to baseline before the start of the next breath, a longer expiratory time is needed. Increasing the inspiratory flow will decrease inspiratory time and increase expiratory time, giving the patient more time to exhale.

Breaths Are Classified According to the Criteria That Trigger (Start) and Cycle (Stop) Inspiration

The definition of a breath (maxim 1) implies that the ventilator knows when to start (**trigger**) and when to stop (**cycle**) inspiratory flow. Several signals can be used to trigger inspiration, including time and changes in airway pressure, volume, or flow. An electrical signal from the diaphragm can also be used to trigger inspiration. Common cycle signals are the same as those for triggering. *Sensitivity* is a term used to describe the amount that the trigger or cycle signal must change before inspiration starts or stops. Fig. 46.13 shows an algorithm that can be used to identify trigger and cycle variables.

Trigger Variable and Cycle Events Can Be Initiated by Either the Patient or the Machine

There are instances when disease processes weaken the diaphragm or when medications, such as sedatives or paralytic agents, interfere with the patient's ability to generate trigger and cycle signals. Hence it is important to have a backup machine trigger system. However, when a patient's ability to generate trigger and cycle signals is intact, it is important to deliver inspiratory flow in

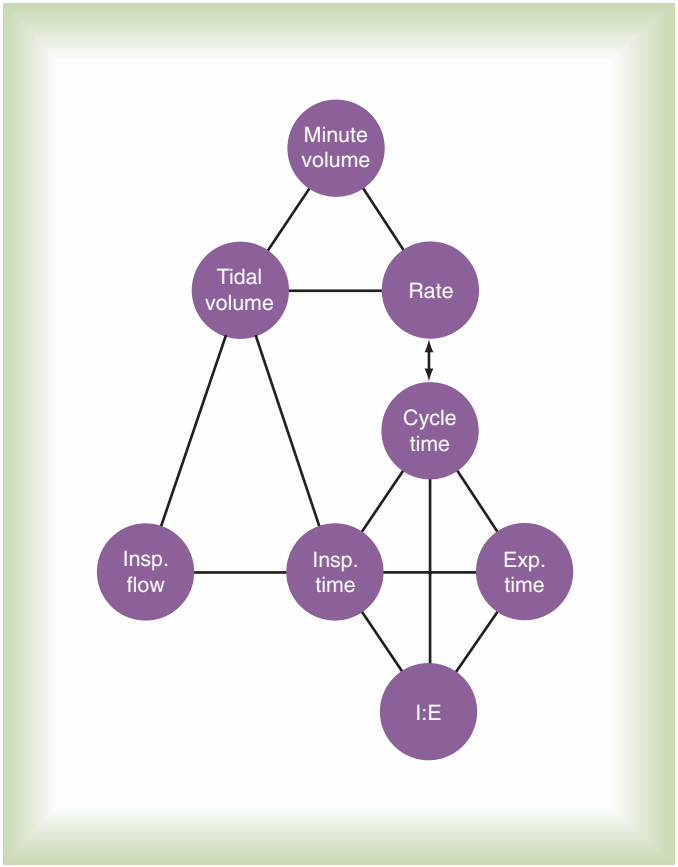

Fig. 46.11 Influence Diagram for Volume-Control Ventilation. Variables are connected by straight lines such that if any two are known, the third can be calculated (see Table 46.1).

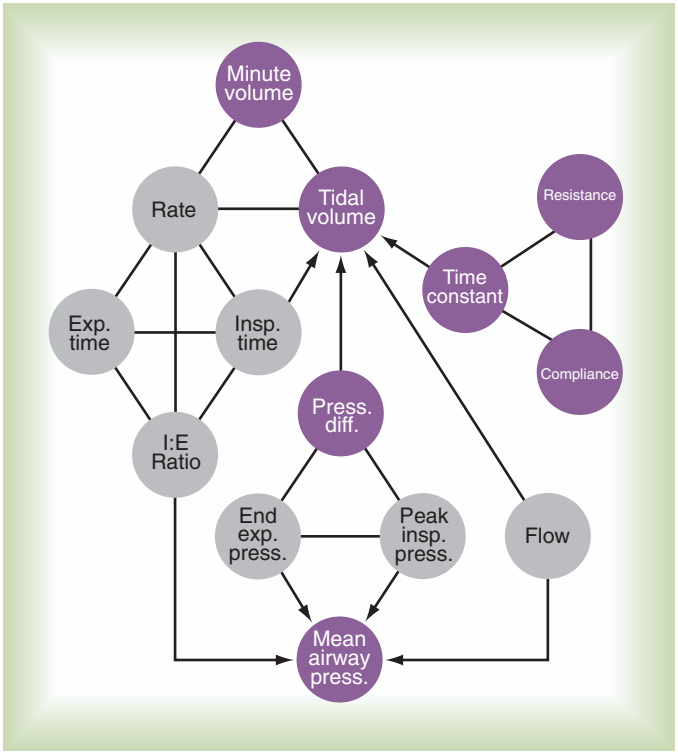

Fig. 46.12 Influence Diagram for Pressure-Control Ventilation. Variables are connected by *straight lines* such that if any two are known, the third can be calculated (see Table 46.1). *Arrows* represent relations that are more complex. *Purple circles* represent variables that are directly controlled by ventilator settings. *Gray circles* show indirectly controlled variables.

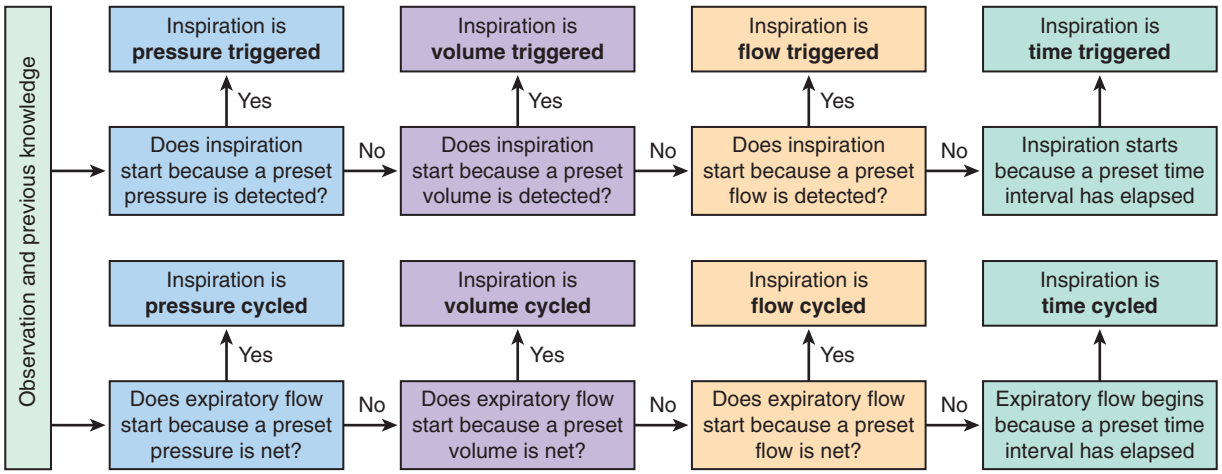

Fig. 46.13 Algorithm for determining the trigger and cycle variables during a breath on a mechanical ventilator.

synchrony with the patient's breathing efforts. Hence machine-initiated trigger and cycle capabilities are built into the mode of ventilation. The trigger variable can be either time, pressure, flow, or volume.

Machine triggering: Inspiration may be triggered by the machine after a preset time interval (e.g., because of a preset breathing frequency). In this instance, inspiration has started regardless of any inspiratory efforts made by the patient. During such a breath, therefore, we say that inspiration is machine-triggered. Minute ventilation threshold is another signal that a ventilator can use to machine-trigger inspiration. Minute ventilation is calculated by dividing the tidal volume by the time for one breath cycle (equivalent to multiplying tidal volume by frequency). Depending on the brand of ventilator used, the

TABLE 46.1 Equations Relating the Important Parameters for Volume-Controlled and Pressure-Controlled Ventilation

Mode	Parameter	Symbol	Equation
Volume-controlled	Tidal volume (L)	V_T	$V_T = \dot{V}_E \div f$ $V_T = \dot{V}_I \times T_I$
	Mean inspiratory flow (L/min)	$\bar{\dot{V}}_I$	$\bar{\dot{V}} = 60 \times V_T \div T_I$ $\bar{\dot{V}}_I = \frac{\dot{V}_E \times TCT}{T_I}$
Pressure-controlled	Tidal volume (L)	V_T	$V_T = \Delta P \times C \times (1 - e^{-t/\tau})$
	Instantaneous inspiratory flow (L/min)	$\dot{V}_I$	$\dot{V}_I = \left(\frac{\Delta P}{R}\right) e^{-t/\tau}$
	Pressure gradient (cm H_2O)	ΔP	$\Delta P = PIP - PEEP$
Both modes	Exhaled minute ventilation (L/min)	$\dot{V}_E$	$\dot{V}_E = V_T \times f$
	Total cycle time or ventilatory period (seconds)	TCT	$TCT = T_I + T_E = 60 \div f$
	I:E ratio	I:E	$I:E = T_I : T_E = \frac{T_I}{T_E}$
	Time constant (seconds)	τ	$\tau = R \times C$
	Resistance (cm H_2O/L/s)	R	$R = \frac{\Delta P}{\Delta \dot{V}}$
	Compliance (L/cm H_2O)	C	$C = \frac{\Delta V}{\Delta P}$
	Elastance	E	$E = \frac{1}{C}$
	Mean airway pressure (cm H_2O)	$\bar{P}_{aw}$	$\bar{P}_{aw} = \left(\frac{1}{TCT}\right) \int_{t=0}^{t=TCT} P_{aw} dt$
Primary variables	Pressure (cm H_2O)	P	
	Volume (L)	V	
	Flow (cm H_2O/L/s)	$\dot{V}$	
	Time (s)	τ	
	Inspiratory time (s)	T_I	
	Expiratory time (s)	T_E	
	Frequency (breaths/min)	f	
	Base of natural logarithm (≈2.72)	e	

PEEP, Positive end-expiratory pressure; *PIP*, peak inspiratory pressure.

clinician may be able to set a minimum threshold for minute ventilation. In this case, inspiration is triggered when minute ventilation drops below a preset threshold.

Machine cycling: A variety of signals may be used to implement machine-cycled inspiration. *Volume cycling* refers to inspiration that ends due to a preset tidal volume. Cycling due to a preset inspiratory time (or inspiratory pause time) is referred to as *time cycling*.

Patient triggering: This means that inspiration starts when the ventilator detects an inspiratory effort. When the patient makes an inspiratory effort, the ventilator commonly detects this by a change in airway pressure, volume, or flow. Inspiratory effort may also be detected by electrical signals derived from the movement of the diaphragm or expansion of the chest wall.

Patient cycling: This means that inspiration stops when the ventilator detects that inspiratory effort has ceased (or perhaps that the patient has made an expiratory effort). Patient cycling is most often based on the decrease in inspiratory flow in pressure-control modes. In fact, some ventilators allow the operator to set the expiratory cycle threshold in terms of a percentage of the peak inspiratory flow. For example, note in Fig. 46.11 (for pressure-control ventilation) during the inspiratory time, flow decays exponentially. Suppose that the peak inspiratory flow was 100 L/min. If the flow cycle threshold is set at 25% of peak flow, then inspiration would be cycled off when flow dropped below 25 L/min. Suppose further that this resulted in an inspiratory time of 1 second. Now, if the cycle threshold was raised to 50%, inspiration would end at 50 L/min and the inspiratory time would be shorter. This is an example of patient cycling that occurs with a mode of ventilation called *pressure support*, which delivers pressure-controlled breaths to spontaneously breathing patients.

Time Constant: In the previous example, the rate of the exponential fall in flow (for a passive breath) is determined by the resistance and compliance of the respiratory system. Indeed, exponential curves are important because they describe both volume and flow during inspiration and expiration, as shown in Fig. 46.10. The rate of the change of an exponential curve is important because it relates to ventilator settings. This rate of change is described in terms of the **time constant**. The time constant is the time required for an exponential curve to reach about 63% of its final (steady-state) value. Mathematically, the time constant for the respiratory system is calculated as the product of resistance and compliance. For example, if resistance is 10 cm H_2O/L per second and compliance is 0.040 L/cm H_2O,

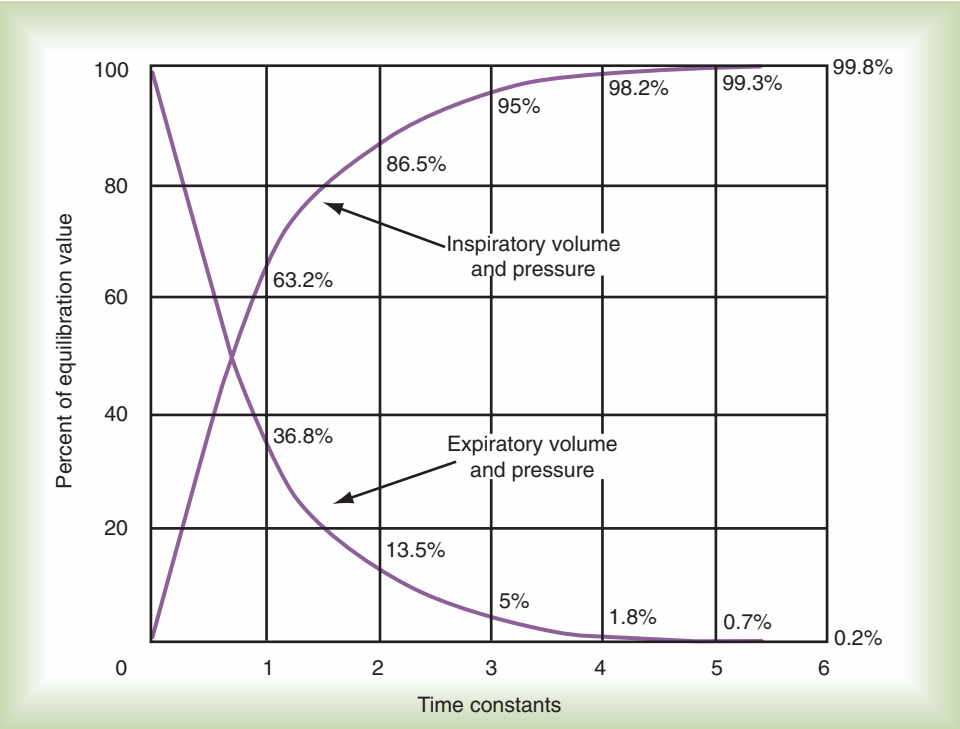

Fig. 46.14 The Time Constant Is a Measure of How Long the respiratory System Takes to Passively Inflate or Deflate in Response to a Sudden Change in Transrespiratory System Pressure. The time constant is calculated as the product of resistance times compliance and is expressed in units of time, usually seconds.

then the time constant is $10 \times 0.04 = 0.4$ seconds. It takes about five time constants for full inspiration (in pressure-control modes) or full expiration (in any mode, Fig. 46.14). Hence inspiratory time in pressure-control modes must be at least five time constants long to deliver the maximum tidal volume. For any mode, expiratory time must be at least five time constants long to prevent gas trapping (i.e., delivering the next breath while the patient is still exhaling). This is undesirable because gas trapping will decrease tidal volume delivery in pressure-control modes and cause lung overexpansion in volume-control modes.

The mechanics of the respiratory system plays a critical role in patient triggering and cycling. These factors are easiest to understand in the passive patient ($P_{mus} = 0$). Let us first consider the cycling of inspiration. If the ventilator delivers a constant inspiratory flow, then peak airway pressure is determined by the preset flow and the elastance and resistance of the patient's respiratory system. Suppose the ventilator is set to cycle inspiration off when a preset pressure threshold is met; for a given preset inspiratory flow, the elastance and resistance of the patient's respiratory system determines the time for this threshold. If these patient-determined factors change, inspiratory time will change. Cycling occurs independently of any preset machine-generated signal and inspiration is patient-cycled. Thus pressure cycling is a form of patient cycling. This can also be observed when a patient makes an expiratory effort, such as a cough, in response to airway irritation by the device's interface or by secretions. Pressure cycling most often occurs as an alarm condition (high-pressure alarm), but it is also a routine cycling mechanism used in automatic resuscitators.[10]

In summary:

Patient-triggering means starting inspiration based on a signal from the patient, which is independent of a machine-triggered signal.

Machine-triggering means starting inspiratory flow based on a signal (usually time) from the ventilator, which is independent of a patient-triggered signal.

Patient cycling means ending inspiratory time based on signals representing the patient-determined components of the equation of motion (i.e., elastance or resistance) and including effects due to inspiratory effort. Flow cycling is a form of patient cycling because the rate of flow decay to the cycle threshold, and hence the inspiratory time, is determined by patient mechanics.

Machine cycling means ending inspiratory time independent of signals representing the patient-determined components of the equation of motion.

Machine versus patient triggering and cycling variables can be identified using a simple algorithm (Fig. 46.15)

RULE OF THUMB When mechanical ventilatory support is being initiated, trigger sensitivity must be set appropriately for the patient's inspiratory efforts. Trigger thresholds set too high may cause a delay in flow delivery. In other words, the sensitivity is set too low, meaning not sensitive enough to detect the patient's inspiratory effort. On the other hand, trigger thresholds set too low may cause autotriggering. In other words, the sensitivity is set too high. Autotriggering means that inspiration is inadvertently triggered at a high rate and without trigger signals from the patient. Trigger thresholds set at either extreme (too high or too low) contribute to patient–ventilator synchrony problems, reduce patient comfort, and impair effective ventilation.

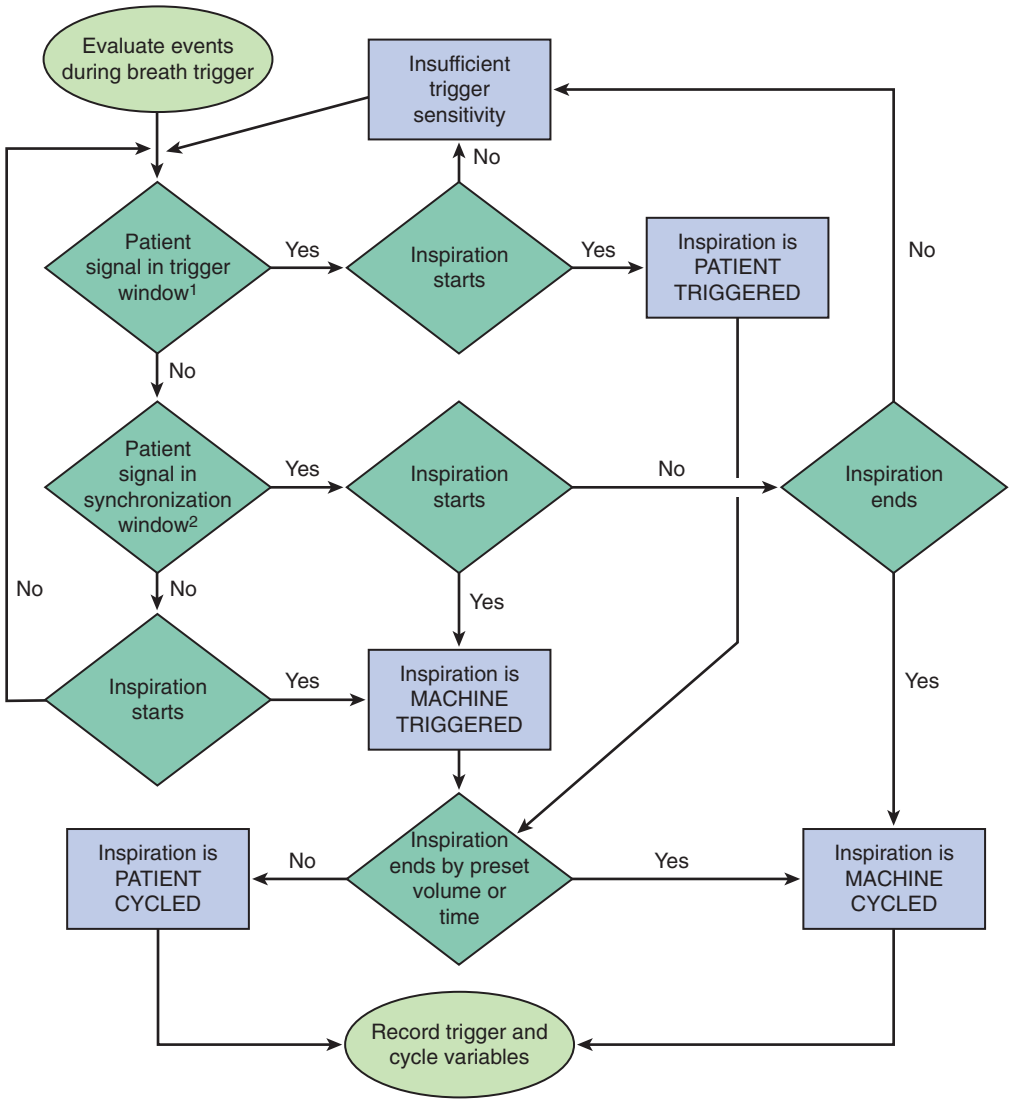

Fig. 46.15 An algorithm for distinguishing between machine versus patient events for triggering and cycling. (Courtesy Mandu Press Ltd.)

Breaths Are Classified as Spontaneous or Mandatory Based on Both the Trigger and Cycle Events

The terms *spontaneous* and ***mandatory*** describing types of breaths are fundamental concepts for the classification of modes. The dictionary definition of *spontaneous* is "without premeditation or external stimulus." If we apply this definition to breathing, it implies that the patient retains substantial control over timing. Therefore **spontaneous breaths** are those for which the patient determines the start and end of inspiration independent of any machine settings for inspiratory and expiratory times. In terms of the previous two maxims, then, a spontaneous breath is one for which inspiration is both triggered and cycled by the patient. A spontaneous breath may occur during a mandatory breath (e.g., airway pressure-release ventilation). The definition given here applies for assisted and unassisted breathing. For unassisted breathing, the brain provides the trigger and cycle signals. For assisted breathing, the signals may come from the brain or the ventilator.

A mandatory breath is a breath for which the patient has lost control over timing (i.e., frequency or inspiratory time). During a mandatory breath, the start and/or end of inspiration is determined by the ventilator, independent of the patient. Again, in terms of the previous two maxims, a mandatory breath is one for which the machine triggers or cycles inspiration (or both). A mandatory breath can occur during a spontaneous breath (e.g., high-frequency jet ventilation). A mandatory breath is, by definition, assisted.

In summary:

A *spontaneous breath* is one for which inspiration is both triggered and cycled by the patient.

A *mandatory breath* is anything else (machine triggered and patient cycled; patient triggered and machine cycled; machine triggered and machine cycled).

There Are Three Basic Breath Sequences: Continuous Mandatory Ventilation, Intermittent Mandatory Ventilation, and Continuous Spontaneous Ventilation

Spontaneous and mandatory breaths come out of a ventilator much as dots and dashes come out of a telegraph machine. Because there are only two types of breaths, it follows that there are only three possible breath sequences: all breaths are mandatory, called **continuous mandatory ventilation (CMV)**; there are both mandatory and spontaneous breaths, called **intermittent mandatory ventilation (IMV)**; and all breaths are spontaneous, called **continuous spontaneous ventilation (CSV)**.

More specifically, CMV is a breath sequence for which spontaneous breaths are not possible between mandatory breaths because every patient trigger signal in the trigger window produces a machine-cycled inspiration (i.e., a mandatory breath). CMV is commonly referred to as assist/control. Machine-triggered mandatory breaths may be delivered at a preset frequency with this breath sequence. The mandatory breath frequency for CMV is the set *minimum* value for the frequency. The total frequency may be higher than the set frequency but never below it. In some pressure-controlled modes on ventilators with an active exhalation valve, spontaneous breaths may occur during mandatory breaths, but the defining characteristic of CMV is that spontaneous breaths are not permitted between mandatory breaths.

IMV has three variations.

1. Mandatory breaths are always delivered at the set frequency (e.g., synchronized intermittent mandatory ventilation (SIMV) volume-control mode on the Servo U ventilator). When a synchronization window is used, the actual ventilatory period for a mandatory breath may be shorter than the set period. Some ventilators, such as the Dräger Evita V500, will add the difference to the next mandatory period to maintain the set mandatory breath frequency.
2. Mandatory breaths are delivered only when the spontaneous breath frequency falls below the set frequency. One example is the spontaneous/timed (S/T) mode on the Philips Bilevel positive airway pressure (BiPAP) noninvasive ventilator.
3. Mandatory breaths are delivered only when the measured minute ventilation (i.e., product of breath frequency and tidal volume) drops below a preset threshold. Examples of this variation include Dräger's mandatory minute volume ventilation mode and Hamilton's adaptive support ventilation mode.

In contrast to CMV, in IMV the mandatory breath frequency can never be higher than the set rate, but it may be lower (i.e., the set frequency is a *maximum* value).

Note that use of the definitions for mandatory and spontaneous breaths for determining the breath sequence (i.e., CMV, IMV, CSV) assumes normal ventilator operation. For example, coughing during VC-CMV may result in patient cycling for a patient-triggered breath due to the pressure alarm limit. Although inspiration for that breath is both patient triggered and patient cycled, this is not normal operation and the sequence does not turn into IMV.

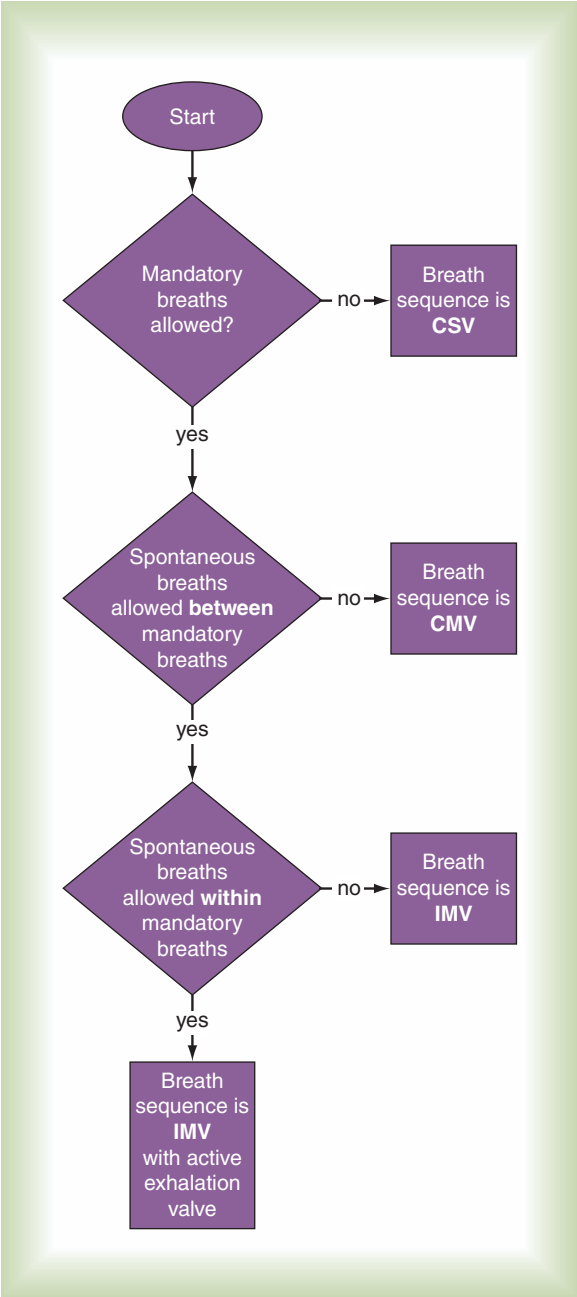

Fig. 46.16 Algorithm distinguishing between continuous spontaneous ventilation *(CSV)*, continuous mandatory ventilation *(CMV)*, and intermittent mandatory ventilation *(IMV)*.

CSV means that all breaths are spontaneous. Alternatively, you could think of it as the opposite of CMV, meaning that mandatory breaths are not permitted between spontaneous breaths.

Note that the definition of a breath sequence depends on the definition of spontaneous and mandatory breaths (maxim 6) and those definitions rely on the definitions of machine versus patient triggering and cycling (maxims 4 and 5). The distinctions between CMV, IMC, and CSV are illustrated in Fig. 46.16.

There Are Five Basic Ventilatory Patterns: VC-CMV, VC-IMV, PC-CMV, PC-IMV, and PC-CSV

A ventilatory pattern is a sequence of breaths (CMV, IMV, or CSV) with a designated control variable (volume or pressure)

for the mandatory breaths (or the spontaneous breaths for CSV). Thus, with two control variables and three breath sequences, there are five possible ventilatory patterns: VC-CMV, VC-IMV, PC-CMV, PC-IMV, and PC-CSV. The VC-CSV combination is not possible because volume control implies that inspiration ends when the preset tidal volume is delivered, which implies ventilator cycling, and ventilator cycling makes every breath mandatory, not spontaneous (maxim 6).

For completeness, we include the possibility of a time-control (TC) ventilatory pattern such as TC-IMV. Although this is uncommon and nonconventional, it is possible, as demonstrated by modes such as high-frequency oscillatory ventilation and intrapulmonary percussive ventilation. Because any mode of ventilation can be associated with one and only one ventilatory pattern, the ventilatory pattern serves as a simple mode classification system.

Ventilatory patterns are a simple mode classification system that offers practical advantages in clinical situations. We can use it to describe different modes a patient may experience without using the names for modes that vary depending on the ventilator manufacturer. For example, during surgery, there may be no need to worry about patient–ventilator synchrony; thus we might say VC-CMV was used (instead of saying volume assist/control or CMV, names that relate to specific ventilators).

RULE OF THUMB Tidal volume is an important ventilator parameter to set. During volume-control modes, the tidal volume is initially set at 4–6 mL/kg of predicted body weight. Setting the tidal volume too high can contribute to lung overdistention (volutrauma). When a tidal volume is set too low, hypoventilation can occur. Arterial blood gases and volumetric or end-tidal CO_2 monitoring can be used to evaluate the effectiveness of ventilation. Arterial blood gases and pulse oximetry can be used to evaluate the effectiveness of oxygenation.

Postoperatively, we could say we switched to PC-CMV to allow unrestricted inspiratory flow when the patient began to make some breathing effort (instead of saying pressure assist/control or pressure control; again, names of modes on specific ventilators). When the patient is evaluated for extubation, a "spontaneous breathing trial" may be attempted using PC-CSV (instead of saying pressure support or volume support). Referring to modes in terms of breathing patterns instead of specific names on particular ventilators simplifies both verbal communication and, perhaps more important, documentation in the patient's record.

RULE OF THUMB Tidal volume cannot be set directly during PCV. To prevent overdistention or hypoventilation, monitor the inhaled tidal volume during mandatory PCV breaths. Inhaled tidal volume should follow lung protective strategies. The inspiratory pressure should be set to deliver a tidal volume of 4–8 mL/kg predicted body weight. Arterial blood gases can be used to monitor the effectiveness of ventilation and oxygenation. Noninvasive monitors such as volumetric or end-tidal CO_2 monitoring may be used to evaluate ventilation and pulse oximetry to monitor oxygenation.

Ventilatory Patterns Vary According to Their Targeting Schemes (Set-Point, Dual, Bio-Variable, Servo, Adaptive, Optimal, and Intelligent)

Although the concept of ventilatory patterns may serve as a simple classification system in some cases, a more precise way to identify the differences among modes is necessary. To do this, we need a deeper understanding of the feedback control schemes used by engineers who design modes. We refer to these as **targeting schemes**.

Targeting schemes. Fig. 46.17 shows the schematic of a closed-loop or feedback control scheme. The operator sets a desired *input*—for example, inspiratory pressure. The software sends control signals to the flow-control and exhalation valves. The manipulated variable (typically flow) is delivered to the patient. The resulting inspiratory pressure (the *output*) is measured as a feedback signal and compared with the input setting. A variety of disturbances—such as patient circuit characteristics, leaks, patient ventilatory efforts, and respiratory system mechanics, to name a few—can affect the output. Any difference between the input and output generates an error signal. That signal is passed on to the control valves to bring the output closer to the input. This system is referred to as a *targeting scheme* in this chapter as it relates to modes of ventilation.

The targeting scheme is a key component of a mode description. A target is basically a predetermined goal of ventilator output. Pressure, volume, and flow waveforms are called *within-breath* targets. Inspiratory pressure, rise time, inspiratory flow, and tidal volume (set-point and dual targeting), and a constant proportionality between inspiratory pressure and patient effort (**servo targeting**) are examples of within-breath targets. Preset values within a breath that end inspiration—such as tidal volume, inspiratory time, or percent of peak flow—may also be considered cycle variables.

There may also be *between-breath targets*. These serve to modify the within-breath targets or the overall ventilatory pattern. Between-breath targets are used with more advanced targeting

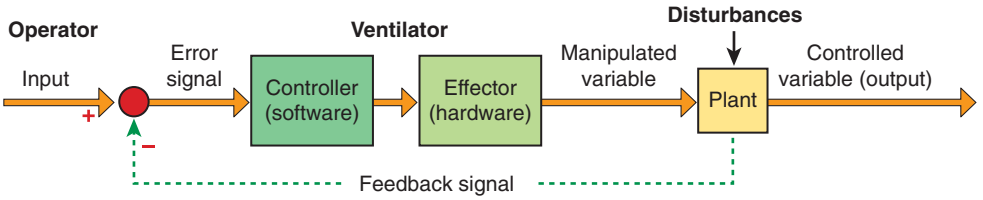

Fig. 46.17 Schematic of a closed-loop feedback-control scheme for a ventilator. (Courtesy Mandu Press Ltd.)

schemes, where targets act over multiple breaths. A simple example of a between-breath target is comparing actual exhaled volume to a preset between-breath tidal volume to automatically adjust the within-breath constant pressure or flow target for the next breath. Average tidal volume (for adaptive targeting), percent minute ventilation (for **optimal targeting**), combined PCO_2, volume, and frequency values describing a zone of comfort (for **intelligent targeting**) are examples of between-breath targets and targeting schemes.

At least seven targeting schemes are used on commercially available ventilators:[11]

1. *Set point:* This is the most common type and is found on all ventilators. The operator sets all parameters of the pressure waveform (pressure-control modes) or volume and flow waveforms (volume-control modes) and the ventilator makes no automatic adjustments to the targets. The advantage is simplicity. The disadvantage is that changing patient condition may make the settings inappropriate, so that frequent manual adjustments are necessary. Modes using set-point targeting include those named volume or pressure assist/control, volume or pressure SIMV, and pressure support.
2. *Dual:* The ventilator can automatically switch between volume-control and pressure-control during a single inspiration. The advantage is the ability to adjust to changing patient condition and assure either a preset tidal volume or PIP, whichever is deemed most important. The disadvantage is that some forms are complicated, difficult to set, and need constant readjustment. The original mode using **dual targeting** was called *volume assured pressure support*. In this mode, inspiration started off in pressure control but changed to volume control if flow decayed to the preset value before the tidal volume was delivered.[12] A much more common example of the opposite approach (switching from volume control to pressure control), is flow adaptive volume control on the Maquet SERVO-i ventilator. If the patient makes little or no inspiratory efforts, the mode looks like VC-CMV (e.g., assist/control). But if the patient makes strong enough efforts, the mode looks like PC-CSV (e.g., pressure support).[7] Many Servo I and Servo U ventilators are in use with this targeting scheme as the default (and perhaps only) option for volume control modes. The clinician must be aware of this because, with sufficient inspiratory effort, the patient can turn what was expected to be a mandatory volume-control breath into a spontaneous pressure-controlled breath (actually a pressure-support breath). Hence tidal volume can be much higher than set.
3. *Bio-variable:* This is an unusual targeting scheme. Studies have shown that varying tidal volume breath by breath to mimic normal breathing improves gas exchange.[13] Currently this **bio-variable targeting scheme** is available in only one mode, variable pressure support on the Dräger V500 ventilator. The operator sets a target inspiratory pressure and a percent variability from 0% to 100%. A setting of 0% means that the preset inspiratory pressure will be delivered for every breath. A 100% variability setting means that the actual inspiratory pressure will vary randomly from PEEP/CPAP level to double the preset pressure-support level.
4. *Servo:* The output of the ventilator (pressure/volume/flow) automatically follows a varying input. In current modes, this means that the inspiratory pressure is proportional to the patient's inspiratory effort; the more assistance the patient demands, the more the ventilator delivers. No other targeting scheme does this. The disadvantage is that it requires estimates of artificial airway and/or respiratory system mechanical properties or special equipment to monitor the respiratory effort signal. This targeting scheme is found on all ventilators that offer some form of automatic tube compensation (ATC).[14] Servo targeting makes possible the modes called proportional assist ventilation (PAV)[15] and neurally adjusted ventilatory assist (NAVA).[16]
5. *Adaptive:* The ventilator automatically sets targets between breaths in response to varying patient conditions. The advantage is that it can adjust to changing patient lung mechanics (including inspiratory effort). The disadvantage is that the automatic adjustment may be inappropriate if the algorithm assumptions are violated or they do not match the patient's actual physiology.[17] The first mode to use this was called *pressure regulated volume control*. This targeting scheme is now available on virtually all ICU ventilators and is given various names, including *volume guarantee, volume control plus, adaptive pressure ventilation,* and *autoflow.* In the literature, this is often called "volume targeting" or "volume-targeted pressure control."
6. *Optimal:* The ventilator automatically adjusts the targets of the ventilatory pattern to either minimize or maximize some overall performance characteristic. The advantage is that it can adjust to changing patient conditions. The disadvantage is that the automatic adjustment may be inappropriate if the algorithm assumptions are violated or they do not match the patient's actual physiology. The only mode currently using this is adaptive support ventilation (ASV) on Hamilton ventilators.[18]
7. *Intelligent:* This is a targeting scheme that uses artificial intelligence programs such as fuzzy logic, rule-based expert systems, and artificial neural networks. The advantage is that it can adjust to changing patient conditions. The disadvantage is that the automatic adjustment may be inappropriate if the algorithm assumptions are violated or they do not match the patient's actual physiology. The only modes currently using this scheme are Dräger's SmartCare/PS[19] and Hamilton's IntelliVent[20] (not available in the United States).

These targeting schemes, along with example modes that use them, are summarized in Table 46.2.

A Mode of Ventilation Is Classified According to Its Control Variable, Breath Sequence, and Targeting Schemes

In general terms, a mode of ventilation is a predefined pattern of interaction between the ventilator and the patient. Historically, modes have been referred to by the names coined by ventilator manufacturers, who use them as marketing devices. As a consequence, there are now so many different names that understanding and comparing all modes has become nearly impossible.

TABLE 46.2 Specifications for Some Modes Found on the Draeger Evita XL Ventilator

Name (Abbreviation)	Description	Advantage	Disadvantage	Example Mode Name	Ventilator (Manufacturer)
Set-point (s)	The operator sets all parameters of the pressure waveform (pressure-control modes) or volume and flow waveforms (volume-control modes).	Simplicity.	Changing patient conditions may make settings inappropriate.	Volume control CMV	Evita Infinity V500 (Drager)
Dual (d)	The ventilator can automatically switch between volume control and pressure control during a single inspiration.	It can adjust to changing patient conditions and ensure either a preset V_T or PIP, whichever is deemed most important.	It may be complicated to set correctly and may need constant readjustment if not automatically controlled by the ventilator.	Volume control	Servo-I (Maquet)
Servo (r)	The output of the ventilator (pressure/volume/flow) automatically follows a varying input.	Support by the ventilator is proportional to inspiratory effort.	It requires estimates of artificial airway and/or respiratory system mechanical properties.	Proportional assist ventilation	PB840 (Covidien)
Adaptive (a)	The ventilator automatically sets target(s) between breaths in response to varying patient conditions.	It can maintain stable V_T delivery with pressure control for changing lung mechanics or patient inspiratory effort.	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology.	Pressure-regulated volume control	Servo-I
Bio-variable (b)	The ventilator automatically adjusts the inspiratory pressure or V_T randomly.	It simulates the inspiratory time or V_T observed during normal breathing and may improve oxygenation or mechanics.	Manually set range of variability may be inappropriate to achieve goals.	Variable pressure support	Evita Infinity V500
Optimal (o)	The ventilator automatically adjusts the targets of the ventilator pattern to either minimize or maximize some overall performance characteristic (e.g., work or rate of breathing).	It can adjust to changing lung mechanics or patient inspiratory effort.	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology.	ASV	GS (Hamilton Medical)
Intelligent (i)	This is a targeting scheme that uses artificial intelligence programs such as fuzzy logic, rule-based expert systems, and artificial neural networks.	It can adjust to changing lung mechanics or patient inspiratory effort.	Automatic adjustment may be inappropriate if algorithm assumptions are violated or if they do not match physiology.	SmartCare/PS IrdelliVent-ASV	Evita Infinity V500 S1 (Hamilton Medical)

ASV, Adaptive support ventilation; *CMV*, continuous mandatory ventilation; *PIP*, peak inspiratory pressure; V_T, tidal volume.

The solution is to use a *taxonomy*. A taxonomy is a formal classification system.

Classification systems are important for organizing large amounts of information, as in biology (e.g., order, family, genus, species) and in large databases (e.g., Amazon.com) to facilitate searches. The use of a taxonomy for modes of ventilation makes it easier (1) to compare research reports and facilitate the development of evidence-based clinical practice; (2) for clinicians to select the most appropriate modes, making optimal ventilator management more likely; and (3) for manufacturers to communicate with clients, thus improving the effectiveness of both sales and training.

The taxonomy of modes is based on the concepts of the control variable, the breath sequence, and the targeting scheme, as described in the previous nine maxims.

A Taxonomy for Mechanical Ventilation

A taxonomy is a hierarchy (outline) of concepts starting with the most general and progressing to more specific with each successive level of the outline. The ventilator mode taxonomy has four hierarchical levels.[1]

1. Control variable (pressure, volume, or time)
   A. Breath sequence (CMV, IMV, or CSV)
      i. Primary breath targeting scheme (for CMV or CSV)
         a. Secondary breath targeting scheme (for IMV)

The "primary breath" is either the only breath there is (mandatory for CMV and spontaneous for CSV) or it is the mandatory breath in IMV. The targeting schemes can be represented by single lowercase letters: set-point = s, dual = d, servo = r, bio-variable = b, adaptive = a, optimal = o, intelligent = i. For example, on the Medtronic PB 980 ventilator there is a mode called A/C

volume control. This mode is classified as volume control continuous mandatory ventilation with set-point targeting, represented by VC-CMVs. A mode with the same functionality on the Dräger Evita V500 ventilator is called *CMV*. On that ventilator, you can alter the targeting scheme by activating a feature called *autoflow*. This changes the mode to pressure control continuous mandatory ventilation with adaptive targeting, or PC-CMVa.

Finally, some modes represent compound targeting schemes. For example, some ventilators offer tube compensation, a feature that increases inspiratory pressure in proportion to flow to support the resistive load of breathing through an artificial airway. This is a form of servo targeting. On the Dräger Evita V500, you can add tube compensation to CMV with autoflow to get a mode classified as PC-CMVar (*ar* represents the compound targeting scheme composed of servo added to set-point). A mode classified as pressure-control intermittent mandatory ventilation with set-point control for both primary (mandatory) and secondary (spontaneous) breaths would have a tag that looks like this: PC-IMVs,s. If you added tube compensation to the spontaneous breaths (e.g., Medtronic PB 980), the tag would change to PC-IMVs,sr. If you added it to both mandatory and spontaneous breaths (e.g., Dräger Evita V500), the tag would change to PC-IMVsr,sr.

The structure of this mode classification system is reminiscent of the taxonomy of biologic organisms comprising order (control variable), family (breath sequence), genus (primary targeting scheme), and species (secondary targeting scheme). Modes in the same "species" can be further differentiated by describing their "species variety" in terms of their phase variables (i.e., trigger and cycle variables plus the within- and between-breath targets and control algorithms). An example of the use of a "species variety" description is to distinguish between proportional assist ventilation and neurally adjusted ventilatory assist, both of which are forms of PC-CSVr. They can be distinguished simply by noting that PAV breaths are triggered and cycled with flow signals whereas NAVA is triggered and cycled with an electrical signal representing diaphragm activation. Of course there are a great many other distinguishing features (e.g., targeting algorithms), but these are better described in the operator's manuals than in a general classification table.

How to Classify Modes

Translating the name of a mode into a mode classification using the taxonomy we have described is a simple three-step procedure:

Step 1: Identify the control variable. Simply put, if you set inspiratory pressure, or if pressure is proportional to inspiratory effort, then the control variable is pressure. On the contrary, if you set tidal volume and inspiratory flow, then the control variable is volume. Fig. 46.18 shows the decision algorithm with a few refinements to accommodate dual targeting.

Step 2: Identify the breath sequence. Fig. 46.19 shows the decision rules.

Step 3: Identify the targeting schemes for the primary and (if applicable) secondary breaths (see Table 46.2).

Examples

To demonstrate these steps, we will classify some of the most commonly used modes in ICUs, starting with A/C volume control (Medtronic PB 980). For this mode, both inspiratory volume and flow are preset, so the control variable is volume. Every breath is volume cycled, which is a form of machine cycling. Any breath for which inspiration is machine cycled is classified as a mandatory breath. Hence the breath sequence is CMV. Finally, the operator sets all the parameters of the volume and flow waveforms, so the targeting scheme is set-point. Thus the mode is classified as volume-control continuous mandatory ventilation with set-point targeting (the tag or abbreviation is thus VC-CMVs).

Another common mode is volume control plus (Medtronic PB 980). For this mode, the operator sets a tidal-volume target but not the inspiratory flow. Because setting volume alone (like setting flow alone) is a necessary but not sufficient criterion for volume control, the control variable is pressure. Spontaneous breaths are allowed between mandatory breaths, which means that the breath sequence is IMV. The ventilator adjusts the inspiratory pressure of mandatory breaths to achieve an average preset tidal volume, making the primary targeting scheme adaptive. Spontaneous breaths between mandatory breaths are either CPAP or pressure support, so the targeting scheme is set point. The mode tag is thus PC-IMVa,s.

A very common mode for spontaneous breathing trials (or for assistance of spontaneous breaths in IMV modes) is pressure support. For this mode, the operator sets an inspiratory pressure, so the control variable is pressure. All breaths are patient triggered and patient cycled (note what was said about flow cycling earlier), so the breath sequence is CSV. Because the ventilator does not adjust any of the parameters of the breath, the targeting scheme is set point and the tag is PC-CSVs.

If carefully applied, the taxonomy has the power to clarify and unmask hidden complexity in a mode that has a cryptic name. Take, for example, the mode called CMV+ autoflow on the Dräger Evita V500 ventilator. Although CMV on this ventilator is the same as the "volume assist/control" described earlier, adding the "autoflow" feature changes it to a completely different mode. For CMV + autoflow, the operator sets a target tidal volume but not inspiratory flow. Indeed, inspiratory flow is highly variable because the ventilator actually sets the inspiratory pressure within a breath. Thus the control variable, according to the equation of motion, is pressure. Every inspiration is time cycled and hence every breath is mandatory and the breath sequence is CMV. The ventilator adjusts the inspiratory pressure between breaths to achieve an average tidal volume equal to the preset value using an **adaptive targeting scheme**. Thus the mode is classified as pressure control continuous mandatory ventilation with adaptive targeting (PC-CMVa).

On the other hand, the taxonomy can also unmask the complexity in an apparently simple mode. The mode called volume control (Getinge SERVO-U) allows setting of tidal volume and inspiratory time. Setting both volume and inspiratory time is equivalent to setting mean inspiratory flow (flow = volume/time), hence the control variable is volume. Every breath is normally time cycled and hence mandatory, so our initial thought is that the breath sequence is CMV. The tricky part is the targeting scheme. The operator's manual states that "if a pressure drop of 3 cm H_2O is detected during inspiration, the ventilator (switches) to pressure support with a resulting increase in

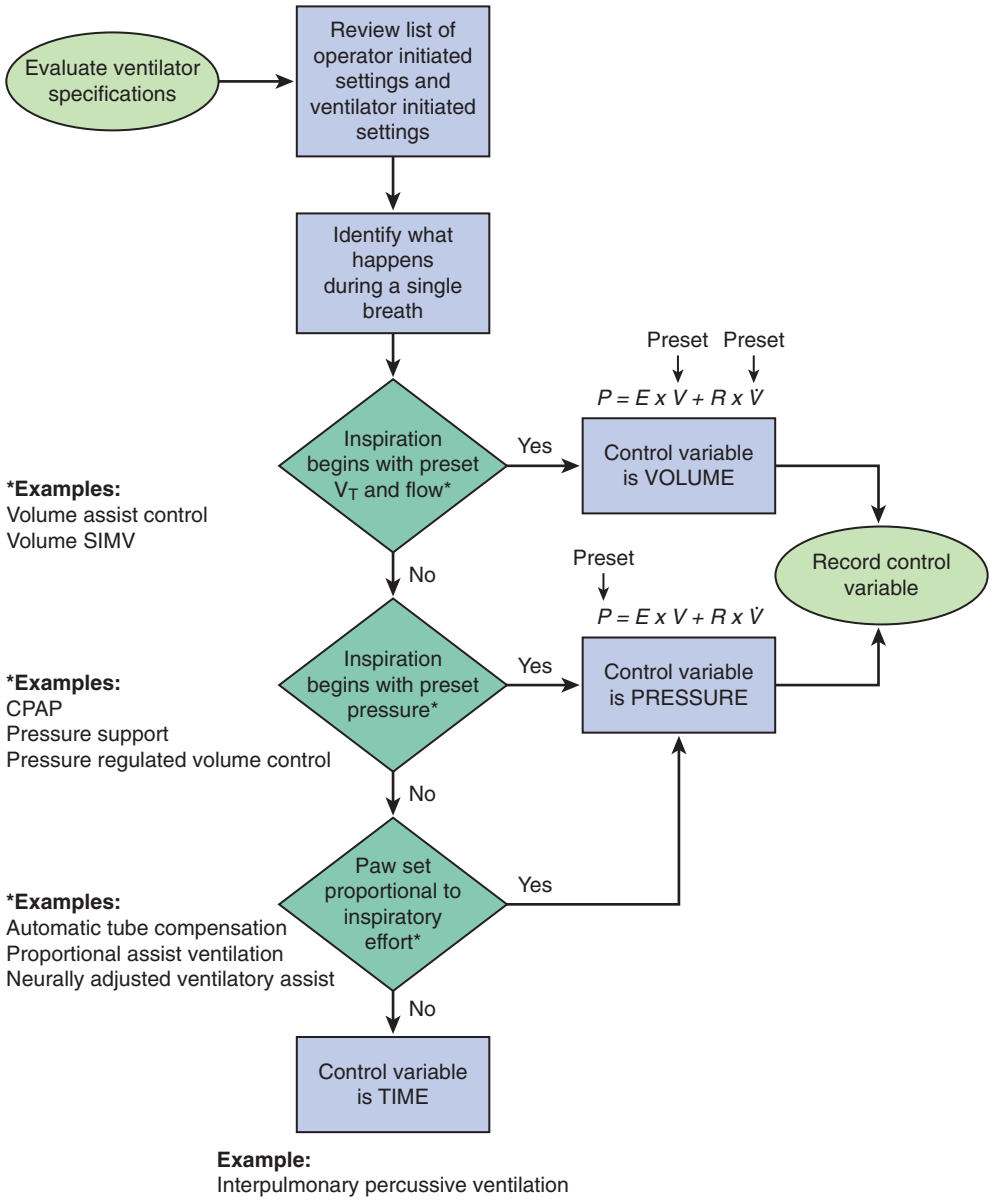

Fig. 46.18 Algorithm for determining the control variable of a mode. (Courtesy Mandu Press Ltd.)

inspiratory flow." This indicates dual targeting as described in maxim 9. Noting that the breath may switch to pressure support alerts us that the breath sequence is not what it first seemed to be. A breath may be patient triggered with a patient inspiratory effort, and if the effort is large enough and long enough, inspiration is flow cycled, not time cycled. Flow cycling (at a certain percentage of PIP) is a form of patient cycling because the time constant of the patient's respiratory system determines when the cycle threshold is met for passive exhalation. Alternatively, the patient may make an expiratory effort that cycles inspiration off. Either way, a patient-triggered and patient-cycled breath is a spontaneous breath. Thus spontaneous breaths may occur between mandatory breaths and the breath sequence is actually IMV. Finally, the tag for this mode is VC-IMVd,d. Note that with dual targeting modes, we need to identify which control variable is in effect at the start of inspiration (see Fig. 46.18) and in this case it is volume. In contrast, the mode called *pressure A/C with machine volume* (Vyaire Avea) incorporates dual targeting; it starts out in pressure control and may switch to volume control.

Finally, some modes are composed of compound targeting schemes. For example, some ventilators offer tube compensation, a feature that increases inspiratory pressure in proportion to flow to support the resistive load of breathing through an artificial airway. This is a form of servo targeting. On the Dräger Evita V500, tube compensation can be added to CMV with AutoFlow to get a mode classified as PC-CMVar (*ar* represents the compound targeting scheme composed of servo added to set-point, with no comma because there are only primary breaths). A mode classified as pressure control intermittent mandatory ventilation with set-point control for both primary (mandatory) and secondary (spontaneous) breaths would have a tag that looks

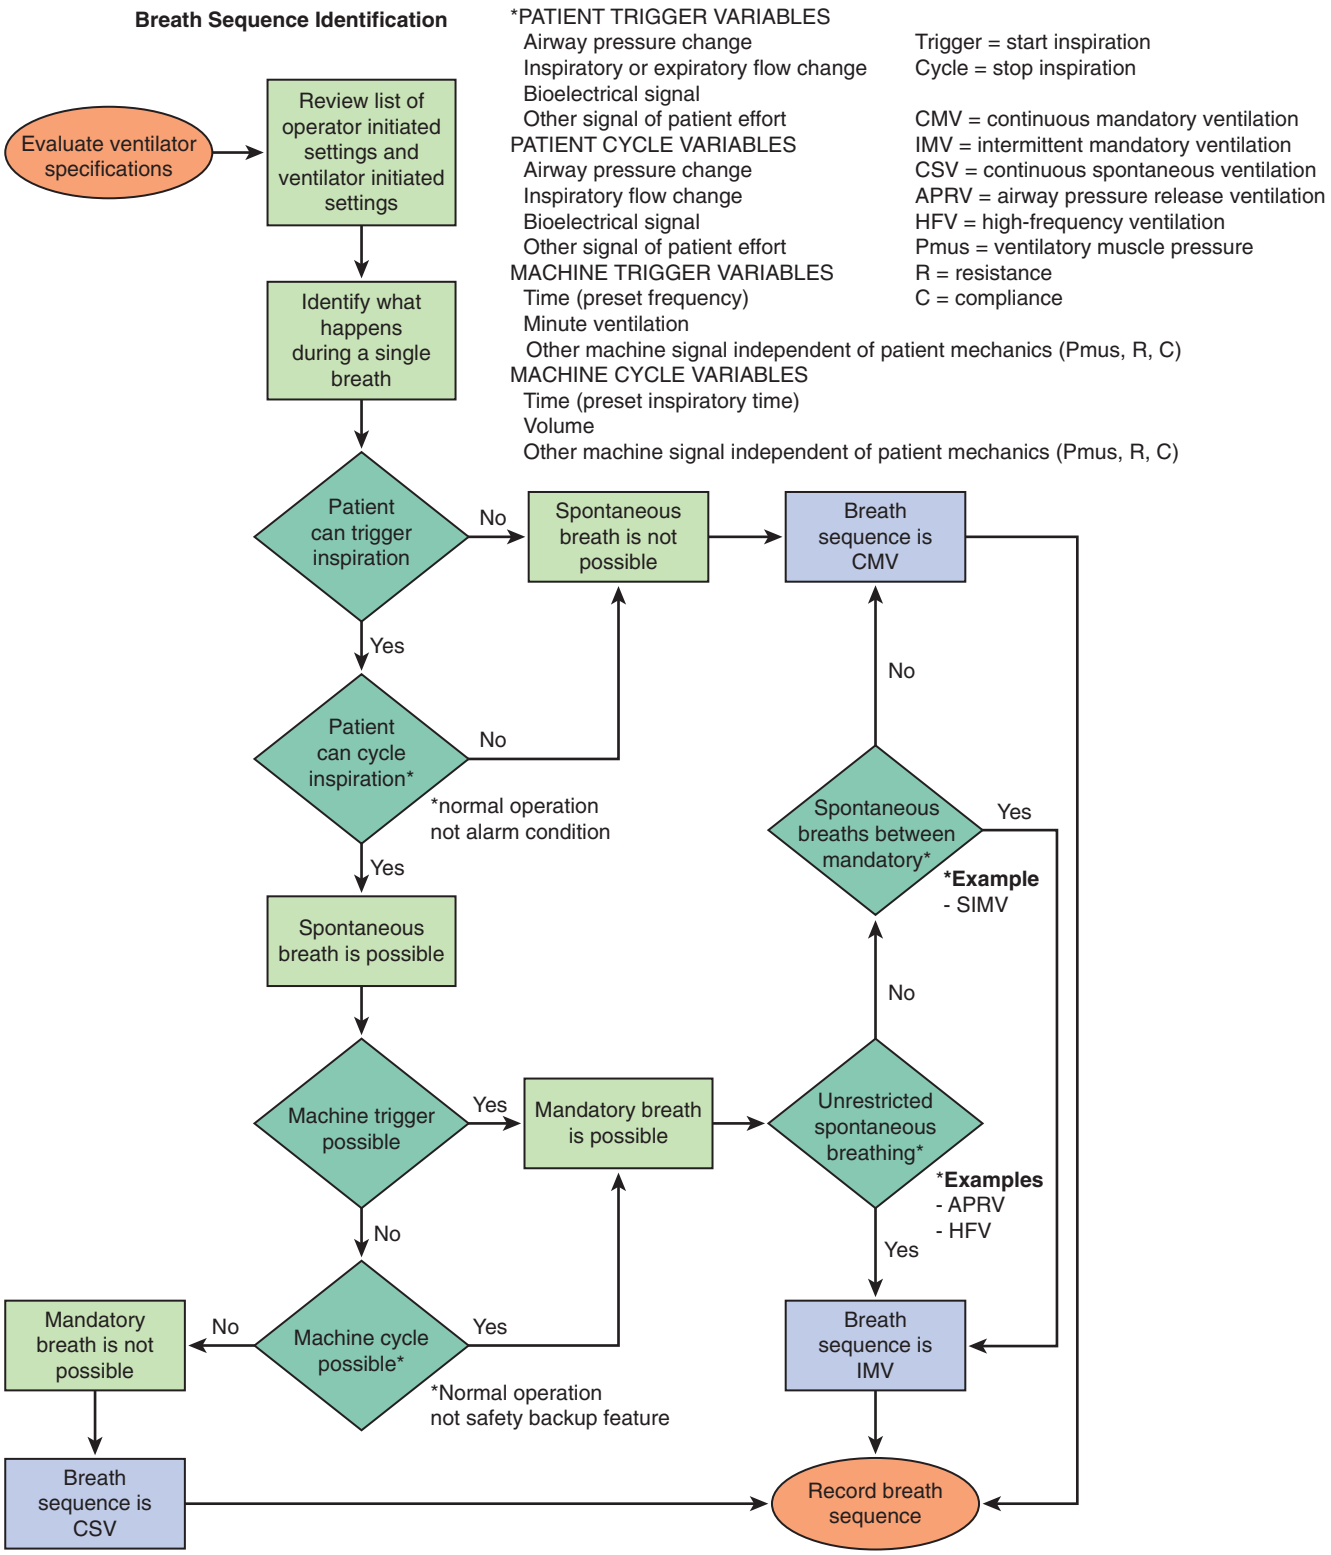

Fig. 46.19 Algorithm for determining the breath sequence of a mode. (Courtesy Mandu Press Ltd.)

like this: PC-IMVs,s (with a comma to denote primary and secondary breaths). If you added tube compensation to the spontaneous breaths (e.g., Medtronic PB 980), the tag would change to PC-IMVs,sr. If you added it to both mandatory and spontaneous breaths (e.g., Dräger Evita V500), the tag would change to PC-IMVsr,sr. Another example is IntelliVent mode (Hamilton G5 ventilator), which uses optimal targeting to minimize the work rate and intelligent targeting to establish lung protective limits and adjust PEEP and FiO_2. The tag for this mode is PC-CMVoi,oi.

TABLE 46.3 Example of Pocket Card Comparing Mode Names From Two Common ICU Ventilators

Covidien PB 840	Mode Tag
A/C volume control	VC-CMVs
SIMV volume control with pressure support	VC-IMVs, s
SIMV volume control with tube compensation	VC-IMVs, r
A/C pressure control	PC-CMVs
A/C volume control plus	PC-CMVa
SIMV pressure control with pressure support	PC-IMVs, s
SIMV pressure control with tube compensation	PC-IMVs, r
Bilevel with pressure support	PC-IMVs, s
Bilevel with tube compensation	PC-IMVs, r
SIMV volume control plus with pressure support	PC-IMVa, s
SIMV volume control plus with tube compensation	PC-IMVa, r
Spont pressure support	PC-CSVs
Spont tube compensation	PC-CSVr
Spont proportional assist	PC-CSVr
Spont volume support	PC-CSVa
Maquet Servo-1	**Mode Tag**
Volume control	VC-IMVd, d
SIMV (volume control)	VC-IMVd, d
Automode (volume control to volume support)	VC-IMVd, a
Pressure control	PC-CMVs
Pressure-regulated volume control	PC-CMVa
SIMV (pressure control)	PC-IMVs, s
Bi-Vent	PC-IMVs, s
Automode (pressure control to pressure support)	PC-IMVs, s
SIMV pressure-regulated volume control	PC-IMVa, s
Automode (pressure-regulated volume control to volume support)	PC-IMVa, a
Spontaneous/continuous positive airway pressure	PC-CSVs
Pressure support	PC-CSVs
Neurally adjusted ventilatory assist	PC-CSVr
Volume support	PC-CSVa

a, adaptive; *d,* dual; *PC-CMV,* pressure control continuous mandatory ventilation; PC-CSV, pressure control continuous spontaneous ventilation; PC-IMV, pressure control intermittent mandatory ventilation; *r,* servo; *s,* set-point; *VC-CMV,* volume control continuous mandatory ventilation; VC-IMV, volume control intermittent mandatory ventilation.

The utility of this taxonomy becomes evident when modes on different ventilators are being compared (e.g., for making a purchase decision). For example, suppose your hospital has standardized on two common ICU ventilators, the Medtronic PB 980 and the Getinge SERVO-U. An example of how modes can be compared across ventilators is shown in Table 46.3.

COMPARING MODES OF MECHANICAL VENTILATION

The use of the ventilator mode taxonomy allows clinicians to appropriately match the technology to the patients' needs. Clinicians must not only know what tool to use but also how to use it. Knowing how to use a mode involves understanding the technologic capabilities of the mode and how they serve the goals of mechanical ventilation. These goals are safety, comfort, and liberation. *Safety* means maintaining adequate gas exchange and hemodynamics while avoiding harm in the form of atelectrauma and volutrauma. *Comfort* means optimizing synchrony between the patient and the ventilator. *Liberation* means getting the patient off the ventilator in the shortest time with the fewest adverse events.

These goals can be further refined into specific objectives and clinical aims that may then be applied to individual patients. Goals, objectives, and aims are the product of a clinical assessment. After identifying the patient's need, the clinician simply matches those needs to the technological capabilities of the available modes of ventilation.[21]

MINI CLINI

Calculate the Expiratory Time Setting From the Frequency and Inspiratory Time

Problem

You are assigned to the neonatal intensive care unit (NICU) and have successfully intubated a newborn term infant diagnosed with respiratory distress syndrome. You are manually ventilating the infant with a flow-inflating bag at a frequency of 25 breaths/min. An inline manometer indicates the PIP is approximately 24 cm H_2O and the PEEP is 4 cm H_2O. The infant's vital signs (heart rate, respiratory rate, and blood pressure) are within normal limits and SpO_2 is 95%. The pressure and frequency you are using manually will serve as the initial ventilator settings on an infant ventilator. With this particular ventilator, however, setting the inspiratory and expiratory times determines the frequency. The attending physician has requested an inspiratory time (T_I) of 0.3 s. Calculate the expiratory time (T_E) necessary to give the desired frequency.

Discussion

Step 1: Compute the total cycle time (TCT) using the frequency (f):

$$TCT = \frac{1}{f} = T_I + T_E$$

$$f = \frac{25\ \text{breaths}}{\text{minute}} \times \frac{1\ \text{minute}}{60\ \text{seconds}} = \frac{25\ \text{breaths}}{60\ \text{seconds}}$$

$$TCT = \frac{1}{25\ \text{breaths}/60\ \text{seconds}} = \frac{60\ \text{seconds}}{25\ \text{breaths}} = \frac{2.4\ \text{seconds}}{\text{breath}}$$

Step 2: Compute the expiratory time:

$$T_E = TCT - T_I = 2.4 - 0.3 = 2.1\ \text{seconds}$$

Step 3: Check the digital display to verify the set frequency remains at 25/min.

TYPES OF VENTILATORS

Conventional Versus High-Frequency Ventilators

Ventilators may be divided into categories according to type and the setting in which the ventilator will be used. The two main categories are conventional and nonconventional. Conventional ventilators produce breathing patterns that are at or near physiologic normal values for the intended population (e.g., adult, pediatric, and infant). There are also manufacturing limits on

MINI CLINI

Calculate Inspiratory Hold Time Given Set Inspiratory Time, Tidal Volume, and Flow

Problem

You are performing a patient–ventilator assessment on an ICU patient with blunt chest trauma. The ventilator is set to deliver VC-IMV. The physician wants the minimum mean airway pressure for the given level of ventilation to preserve the patient's already low cardiac output. She asks you to make sure that the night shift therapist removed the inspiratory hold. Determine from the ventilator settings alone whether there is an inspiratory hold, and if so, make the appropriate changes to eliminate it.

Ventilator settings are as follows:

Tidal volume: 500 mL = 0.5 L

Inspiratory flow: 60 L/min = 1 L/s

Inspiratory time: 0.8 s

Frequency: 10 breaths/min

Discussion

Step 1: Calculate the inspiratory flow time (T_{IF}) using appropriate unit conversions:

$$T_{IF} = \frac{\text{tidal volume}}{\text{inspiratory flow}}$$

$$= \frac{500\,\text{mL}}{60\,\text{L/minute}} \times \frac{1\,\text{L}}{1{,}000\,\text{mL}} \times \frac{60\,\text{seconds}}{1\,\text{minute}} = 0.5\,\text{seconds}$$

Step 2: Compare the set inspiratory time (0.8 s) with the flow time resulting from the tidal volume and flow settings (0.5 s). Inspiratory time lasts longer than inspiratory flow. Because inspiration is time cycled, this means that there is an inspiratory hold of duration equal to 0.8 – 0.5 = 0.3 s.

Step 3: You could eliminate the inspiratory hold either by decreasing the inspiratory flow or decreasing the inspiratory time. Your goal is to minimize the mean inspiratory pressure. You choose to decrease inspiratory time for two reasons: (1) it decreases the I:E ratio and may allow more time for spontaneous breaths to occur, thus lowering mean intrathoracic pressure; (2) decreasing inspiratory flow may make tidal volume delivery slower than the patient demands, thus decreasing patient–ventilator synchrony.

the maximum breath rate a conventional ventilator may deliver. The US Food and Drug Administration places a maximum breath rate limit of 150 breaths/min for conventional ventilators. Tidal volumes that are either set by the operator or delivered to the patient as a result of a preset pressure through a conventional ventilator are sufficient or large enough to clear anatomic dead space. Conversely, high-frequency ventilators typically produce respiratory frequencies or breathing rates that are much higher than physiologically possible and tidal volumes that are less than anatomic dead space.

Conventional Ventilators

Conventional ventilators are called that mainly because they are designed to deliver ventilatory patterns (i.e., tidal volume and frequency) that are within the range of normal breathing. They may be used with a variety of interfaces in the critical care setting. Options are available on this type of ventilator for use with an artificial airway (endotracheal or tracheostomy tube) or noninvasively with a variety of interfaces (e.g., nasal, oronasal, or full face masks). The availability of the noninvasive option eliminates the need for a stand-alone noninvasive ventilator. However, stand-alone noninvasive ventilators do have applications and are also used in the critical care setting. Ventilators used in the critical care environment have the capability to assess and monitor complex ventilator–patient interactions.

High-Frequency Ventilators

High-frequency ventilators are called that because they are designed to deliver ventilatory tidal volumes well below normal while maintaining minute ventilation by using frequencies well above normal. The original idea behind the design of these machines was to minimize lung movement during open chest surgery and to minimize the risk of volutrauma when premature infants were being ventilated.

The availability of sophisticated devices such as jet ventilators and high-frequency oscillators facilitates the ventilatory management of infants, children, and adults in the PC-IMV mode who fail to maintain adequate oxygenation and acid-base balance with conventional ventilatory support. High-frequency jet ventilators, such as the Bunnell Life Pulse (Bunnell Inc., Salt Lake City, UT), deliver short bursts, or jet pulses, of mixed gas through a special adaptor for endotracheal tubes or a specially designed endotracheal tube. High-frequency jet ventilators require a high-pressure source (20 to 50 psig) to function. This type of ventilator consists of a system for regulating inlet pressure (psig), a cycling mechanism, and a device such as an air-oxygen blender for controlling FiO_2. The small volumes of gas are delivered at rapid rates (4 to 250 times the normal respiratory rate). The benefits of rescue and elective use of high-frequency jet ventilation (HFJV) as a treatment for acute lung disease and acute respiratory distress syndrome are unclear. However, the literature supports its effectiveness in maintaining alveolar ventilation and reducing morbidity during surgical repair of tracheal and airway anomalies.

High-frequency oscillation (HFO) also allows very small tidal volumes to be delivered at rapid frequencies (180 to 1200 cycles per second). High-frequency oscillators utilize a piston or diaphragm to produce the airflow oscillations. Tidal volume is dependent on the force and distance the piston moves from baseline. A special endotracheal tube is not required to implement this form of PC-IMV. The SensorMedics 3100A and 3100 B high-frequency oscillators (Vyaire, San Diego, CA) are approved and commercially available for use in neonatal/pediatric (<35 kg) and pediatric/adult populations (>35 kg), respectively.

However, the application of HFO to adults with the acute respiratory distress syndrome has been shown to be potentially deterimental.[22,23]

RULE OF THUMB High-frequency oscillators do not have an internal backup battery. In the event of a power failure, the ventilator will power down. Always plug the ventilator into a red outlet. The red outlet will provide backup generator power during an electrical outage. Portable external batteries may also be purchased. When a portable external battery is used, plug the high-frequency oscillator into the portable battery, then plug the external battery into a red power outlet.

Classification of Ventilators by Use

Ventilators may also be categorized by the setting in which they are used, specifically critical care, subacute care, home care, long-term care, and transport. Their designs match the needs of the population as well as the unique characteristics of the setting in which they are used. Ventilator manufacturers have paid particular attention to economic constraints that health care facilities are facing. Innovations in ventilator design have broadened their use across settings. An example of this is the use of ventilators for different patient ages. Although ventilators are not subcategorized as adult or pediatric in this chapter, is it crucial for the practitioner to be aware of factors such as minimal tidal volume limits, trigger sensitivity, response time, and availability of leak compensation a ventilator for use with the pediatric population is being selected.

Critical Care Ventilators

Critical care ventilators provide clinicians with sophisticated methods for breath delivery. This class of ventilators also provides advanced monitoring capabilities and tools that enable clinicians to readily assess the patient–ventilator interaction. Calculations of lung mechanics parameters including auto-PEEP, static and dynamic compliance, inspiratory/expiratory resistance, rapid shallow breathing index, time constant, and work of breathing are integrated into ventilators used in this environment. Integrated physiologic noninvasive and invasive assessment tools, such as esophageal pressure monitoring and end-tidal CO_2 monitoring, are also commercially available. The availability of these features equips bedside caregivers with the tools needed to assess patient–ventilator interaction and match ventilator capability with physiologic need.

Subacute Care Ventilators

Generally, mechanically ventilated patients in this setting have a stable cardiopulmonary status. Their condition is such that the care provided does not depend heavily on high-technology monitoring or complex diagnostic procedures. Rather, the focus is on coordinated services aimed at managing complex medical conditions, liberation from ventilatory support, and rehabilitation services. Ventilators used in this care venue have less sophisticated monitoring systems and mode options. Subacute care may be rendered in freestanding facilities or within a specialized unit within a hospital. As a result, the design of ventilators used in this environment bridge the gap between those designed specifically for critical care and those designed for home care and extended skilled care.

Home Care Ventilators

Patients with chronic respiratory failure from primary pulmonary disease, trauma, or neuromuscular disease may require ventilatory assistance to augment or replace spontaneous breathing and maintain life. Ventilators designed for use in the home or at long-term care institutions facilitate the transition of patients from the acute and subacute care environment to one focusing on enhancing the individual's quality of life and providing services to sustain or improve physical and physiologic function in a cost-efficient manner. Ventilators must be able to support the ventilatory needs of the patient and provide supplemental oxygen in a venue where compressed gas resources are limited, power supply interruptions may occur, and patient mobility needs must be met. The interface on this type of ventilator is much simpler than on ventilators used in critical or subacute care. The availability of a low-pressure input port is an essential feature that allows supplemental oxygen to be delivered by stationary and portable devices commonly used in the home, such as oxygen concentrators, small high-pressure tanks, and portable liquid oxygen reservoirs. Machine dimensions are also an important consideration, and this type of ventilator is generally compact in nature. The option to lock operator-set parameters minimizes the occurrence of inadvertent setting changes and concomitant alterations in alveolar ventilation and acid-base balance.

Ventilators used in home care and extended care facilities require not only an internal battery for brief power interruptions but also connections for an external battery when the power supply is interrupted for extended periods due to natural disasters, human-made occurrences, and participation in academic, employment, or recreational activities.

Transport Ventilators

Transport means moving a patient to different locations within the hospital (internal transport) or between a hospital and an external location (external transport). Transport ventilators share attributes common to ventilators used in the home and critical care environments. Indeed, sometimes home care ventilators and ICU ventilators are used for transport. But a dedicated transport ventilator must be lightweight, compact, durable, maintained on a reliable power supply, and consume relatively little compressed gas. The ventilator interface should be easy to navigate, allowing the clinician to set or change parameters prior to or during movement to and from a prescribed destination. Operator-set and monitored data should be visible under optimal conditions or conditions of low ambient light. These characteristics enhance patient safety and minimize the potential for complications or adverse effects to occur during air or ground transport. Monitoring is also an important consideration. Clinical practice guidelines recommend the level of monitoring during patient transport be analogous with that provided to the patient during stationary care. Modern transport ventilators provide the ability to display scalar waveforms and numerical data.

Noninvasive Ventilators

Noninvasive ventilation is used across the continuum of care—from critical care to home care—with individuals of any age. As previously mentioned, a noninvasive ventilation feature may be incorporated in critical care ventilators and home care ventilators. However, stand-alone noninvasive ventilators exist and are extensively used in a variety of settings from the hospital to home. In the acute and critical care setting, noninvasive ventilators have been used to reduce complications associated with diagnostic procedures, such as bronchoscopy, as well as in the treatment of acute respiratory insufficiency, respiratory failure, and the prevention of postextubation failure. This technology has also been associated with positive outcomes in the outpatient

setting. The literature reports the use of noninvasive ventilation to restore and maintain adequate alveolar ventilation with individuals compromised by neuromuscular disorders, congestive heart failure, chronic obstructive lung disease, and sleep-disordered breathing.

There are features common to home and hospital-grade units that enhance patient comfort and promote adherence to therapy. Ramp time allows the clinician to program a delay in the initiation of a delivered inspiratory pressure. Ramp time is usually adjustable (e.g., 0 to 45 minutes), during which the patient breathes at a preset or operator-set expiratory pressure (e.g., 4 cm H_2O). Likewise, rise time can be altered to reduce pressure overshoot and enhance breath delivery. The ability to detect and quantify interface leak, estimated tidal volume, and minute ventilation delivery are additional helpful tools. Hospital-grade units have the capability to display patient data in graphic and numeric form. Clinicians are able to view pressure, flow, and scalar waveforms. As with critical care ventilators, careful analysis of waveforms may assist clinicians in the identification and correction of patient–ventilator synchrony.

MINI CLINI

A respiratory therapist is preparing to noninvasively ventilate a 3-year-old patient with muscular dystrophy. The physician ordered the following settings:
PIP relative to atmospheric pressure: 12 cm H_2O
PEEP: 4 cm H_2O
Rate: 16/min
FiO_2: 0.35
Calculate the set driving pressure, ΔP_{set}:

$$\Delta P_{set} = PIP - PEEP = 12 - 4 = 8\ cm\ H_2O$$

If the child's ventilation is not sufficient on these settings, increasing the ΔP_{set} will improve ventilation. This can be accomplished by increasing the set inspiratory pressure. Note that we probably cannot calculate P_T because tidal volume measurement is uncertain during noninvasive ventilation (due to leaks) and hence we probably cannot even calculate compliance (or elastance).

SUMMARY CHECKLIST

- Ventilators can be described in terms of their input power requirements (e.g., electrical or pneumatic) and how the input power is transformed into desired outputs of pressure, volume, and flow.
- Ventilator displays serve three main functions: (1) to display the inputs, that is, the current state of the settings and allow changes to be made; (2) to show the outputs, meaning the measured values that characterize normal patient–ventilator interactions; and (3) to show alarm conditions.
- The patient interface is the connection between the ventilator and the patient—typically a system of plastic hoses often called the *patient circuit*.
- The important thing to know about the patient circuit is that it contributes to discrepancies between the desired and actual ventilator output values.
- A key feature of a ventilator is the variety of modes of ventilation that it offers.
- A mode of ventilation is a predetermined pattern of interaction with the patient. Modes are given many confusing names but they can be understood using a taxonomy or classification system.
- A breath is one cycle of positive flow (inspiration) and negative flow (expiration) defined in terms of the flow-time curve.
- A breath is "assisted" if the ventilator provides some or all of the work of breathing.
- A ventilator assists with the work of breathing by using either pressure control or volume control according to the equation of motion for the respiratory system. This equation relates pressure, volume, and flow as variables of time.
- Two key parameters of respiratory system mechanics are elastance (Δpressure/Δvolume) and resistance (Δpressure/Δflow). Sometimes compliance (Δvolume/Δpressure) is substituted for elastance.
- Pressure control means that pressure is preset or is proportional to patient effort. Inspiratory flow and volume are dependent on respiratory system mechanics (including inspiratory effort).
- Volume control means that inspiratory flow and volume delivery are preset. Inspiratory pressure is dependent on respiratory system mechanics (including inspiratory effort).
- Breaths are classified according to how inspiration is triggered (started) and stopped (cycled).
- Either the machine (ventilator) or the patient may initiate the trigger and cycle events.
- A spontaneous breath is one for which inspiration is **patient triggered** and **patient cycled**. A mandatory breath is one for which inspiration is **machine triggered** and/or **machine cycled**.
- Spontaneous breaths may be assisted (meaning that the ventilator provides some portion of the work of breathing) or unassisted. Mandatory breaths are generally assisted.
- The breath sequence of a mode is the pattern of mandatory versus spontaneous breaths. CSV means that all breaths delivered by the ventilator are spontaneous. IMV means that spontaneous breaths can occur between mandatory breaths. CMV means that spontaneous breaths cannot occur between mandatory breaths.
- The targeting scheme is a description of the relation between operator settings and ventilator outputs for a mode. Currently all modes can be classified as having one of six targeting schemes (set-point, dual, servo, adaptive, optimal, and intelligent).
- Mode classification is based on identifying three main components: the primary control variable, the breath sequence, and the targeting schemes used for mandatory and spontaneous breaths.
- Ventilators can themselves be classified by the environments in which they are used. Examples include: critical care, subacute care, home care, transport, and noninvasive ventilators.

Physiology of Ventilatory Support

Robert M. Kacmarek

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the pressures and pressure gradients that affect gas delivery during spontaneous breathing, negative pressure ventilation (NPV), and positive pressure ventilation (PPV).
- Identify the effects of mechanical ventilation on oxygenation, ventilation, and lung mechanics.
- Describe the currently available modes of mechanical ventilation.
- Discuss the indications and physiologic effect of positive end-expiratory pressure (PEEP).
- Describe the cardiovascular effects of PPV and NPV.
- Describe the effects of PPV on intracranial pressure, renal function, liver and splanchnic perfusion, gastrointestinal function, and central nervous system.
- Identify and list the complications and hazards of providing mechanical ventilatory support.
- Discuss how to minimize adverse effects of mechanical ventilation.

CHAPTER OUTLINE

KEY TERMS

aerophagia
atelectrauma
autoregulation
barotrauma
biotrauma
driving pressure
mean airway pressure
passive
patient–ventilator asynchrony
plateau pressure
time constant
transairway pressure
transalveolar pressure
trans–chest wall pressure
transdiaphragmatic pressure
transpulmonary pressure
transrespiratory pressure
transthoracic pressure
volutrauma

Mechanical ventilation can be beneficial or detrimental depending on how it is applied and modified as the patient's condition changes. Respiratory therapists (RTs) must be able to anticipate the physiologic effects of mechanical ventilation and respond appropriately when complications arise. This chapter familiarizes the reader with (1) the physiologic effects of mechanical ventilation on lung and cardiovascular function and other body systems, (2) the basic approaches to providing mechanical ventilation, and (3) the complications and hazards of mechanical ventilation. A solid understanding of the normal physiology of breathing is essential for all RTs, especially when working with patients receiving mechanical ventilation. RTs must understand intrathoracic pressure changes associated with spontaneous, negative pressure, and positive pressure breathing. Intrathoracic pressure changes are necessary for ventilation to occur; however, large changes in these pressures may also induce physiologic changes in other systems.

PRESSURE AND PRESSURE GRADIENTS

For gas to flow through the airway, a pressure gradient must exist. The airway begins at the mouth and end at the alveoli, so mouth pressure (*pressure at the airway opening* [P_{awo}]) and *alveolar pressure* (P_{alv}) are important in describing gas flow, as are *intrapleural pressure* (P_{pl}) and *body surface pressure* or atmospheric pressure (P_{bs}). In addition, *intra-abdominal pressure* (P_{ab}) affects the impact of P_{pl} change on diaphragm movement. P_{pl} is the pressure in the pleural space, the virtual space between the visceral and parietal pleurae, and is usually negative in relation to P_{alv}. Fig. 47.1 shows a graphic model of the respiratory system with these pressures identified as points in space. The respiratory system is everything that exists between the airway opening and the body surface. The associated pressure difference is **transrespiratory pressure** (P_{TR}), defined as $P_{awo} - P_{bs}$. The components of P_{TR} correspond to the components of the graphic model. The airways are represented by **transairway pressure** (P_{TA}), defined as $P_{awo} - P_{alv}$. The lungs are represented by the **transalveolar pressure**: ($P_L = P_{alv} - P_{pl}$). However, clinically what can be measured is **transpulmonary pressure**: ($P_{TP} = P_{awo} - P_{pl}$). The chest wall is represented by **trans–chest wall pressure**: ($P_{TCW} = P_{pl} - P_{bs}$). If the lungs and chest wall are lumped together, they can be represented by **transthoracic pressure**: ($P_{TT} = P_{alv} - P_{bs}$).

Another pressure gradient not defined in Fig. 47.1 that also affects gas movement is the **transdiaphragmatic pressure** (P_{di}). This pressure gradient is the difference between P_{ab} and pleural pressure and affects diaphragmatic movement: ($P_{pl} - P_{ab}$).

Airway, Alveolar, and Intrathoracic Pressure, Volume, and Flow During Spontaneous Ventilation

Spontaneous breathing is normally an autonomic phenomenon. In other words, we do not think about breathing; it is controlled by the autonomic nervous system. Not until our breathing is stressed, do we consider the effort to breathe or the energy expended. At end-exhalation, P_{pl} is slightly negative. Alveolar, mouth, and body surface pressures are zero. The diaphragm contracts in response to stimulation of the phrenic nerve via

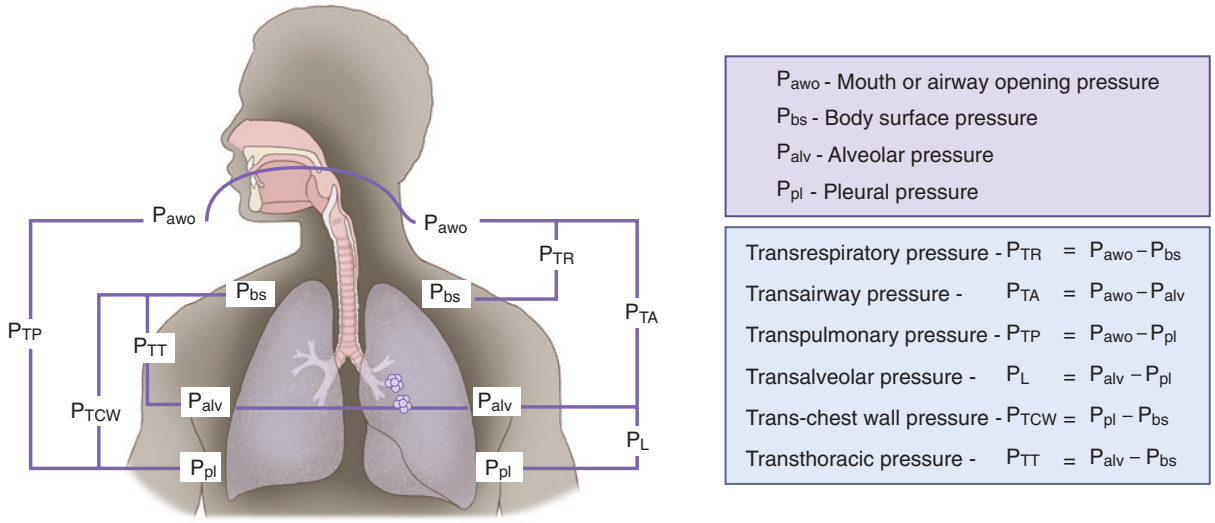

Fig. 47.1 Pressures and Pressure Gradients in the Lung. Airflow is a function of the transairway pressure *(P_{TA})*, which is the pressure gradient between the airway *(P_{awo})* and the alveoli *(P_{alv})*. Transalveolar pressure *(P_L)* maintains alveolar inflation, and transpulmonary pressure *(P_{TP})* is the pressure needed to expand the lungs and chest wall.

TABLE 47.1 Changes in Airway Pressure Gradients During Spontaneous, Negative, and Positive Pressure Ventilation

Pressure (cm H_2O) Ventilation Type	Transpulmonary Pressure	Transthoracic Pressure	Transairway Pressure	Transrespiratory Pressure
Spontaneous				
Inspiration	Small increase (+)	Increase (+)	Increase (+)	Constant (–)
Expiration	Small increase (–)	Increase (–)	Increase (–)	Constant (+)
Negative (NPV)				
Inspiration	Small increase (+)	Increase (+)	Increase (+)	Constant (–)
Expiration	Small increase (–)	Increase (–)	Increase (–)	Constant (+)
Positive (PPV)				
Inspiration	Small increase (+)	Increase (+)	Increase (+)	Increase (+)
Expiration	Decrease (–)	Decrease (–)	Decrease (–)	Decrease (–)

NPV, Negative pressure ventilation; *PPV*, positive pressure ventilation.

the respiratory center in the medulla of the brain. When the diaphragm contracts, it descends into the abdominal cavity, decreasing P_{pl}. When P_{pl} becomes more negative, P_{alv} becomes negative as well. The effects of spontaneous breathing on the pressure gradients are shown in Table 47.1. Under normal circumstances, a decrease in P_{pl} results in decreased P_{alv}, increased P_{TA}, and inspiration of a tidal volume (V_T) (Fig. 47.2).

At end-inspiration, P_{alv} returns to zero when the muscles of inspiration stop contracting. Lung recoil causes a sudden increase in P_{alv} in relation to pressure at the mouth, reversing the P_{TA} gradient, and air flows out of the lungs. However, at end-expiration the P_{TP} and P_L return to a positive value. If there were to stay negative, alveoli would collapse. Normally, there is a short end-expiratory pause before the next inspiration.

V_T and flow during spontaneous ventilation may be described by the equation of motion.[1,2] The equation of motion describes the relationship between muscle pressure (analogous to pleural pressure in spontaneous breathing), compliance, resistance, flow, and volume as follows:

$$P_{musc} = \text{Volume/Compliance} + (\text{Resistance} \times \text{Flow})$$

where P_{musc} is muscle pressure (P_{tp}), volume is V_T, compliance is lung-thorax compliance, resistance is airway resistance (R_{aw}), and flow is gas flow through the airway. When the equation is rearranged, volume inhaled during spontaneous ventilation is proportional to muscle pressure and lung-thorax compliance and inversely related to the product of R_{aw} and flow:

$$\text{Volume} = [P_{musc}/(\text{Resistance} \times \text{Flow})] + \text{Compliance}$$

Ventilation (owing to P_{TP}) is the sum of the pressure needed to move gas through the airways (P_{TA}) and the pressure needed to inflate the alveoli (P_L):

$$\text{Transpulmonary pressure} = P_{TA} + P_L$$

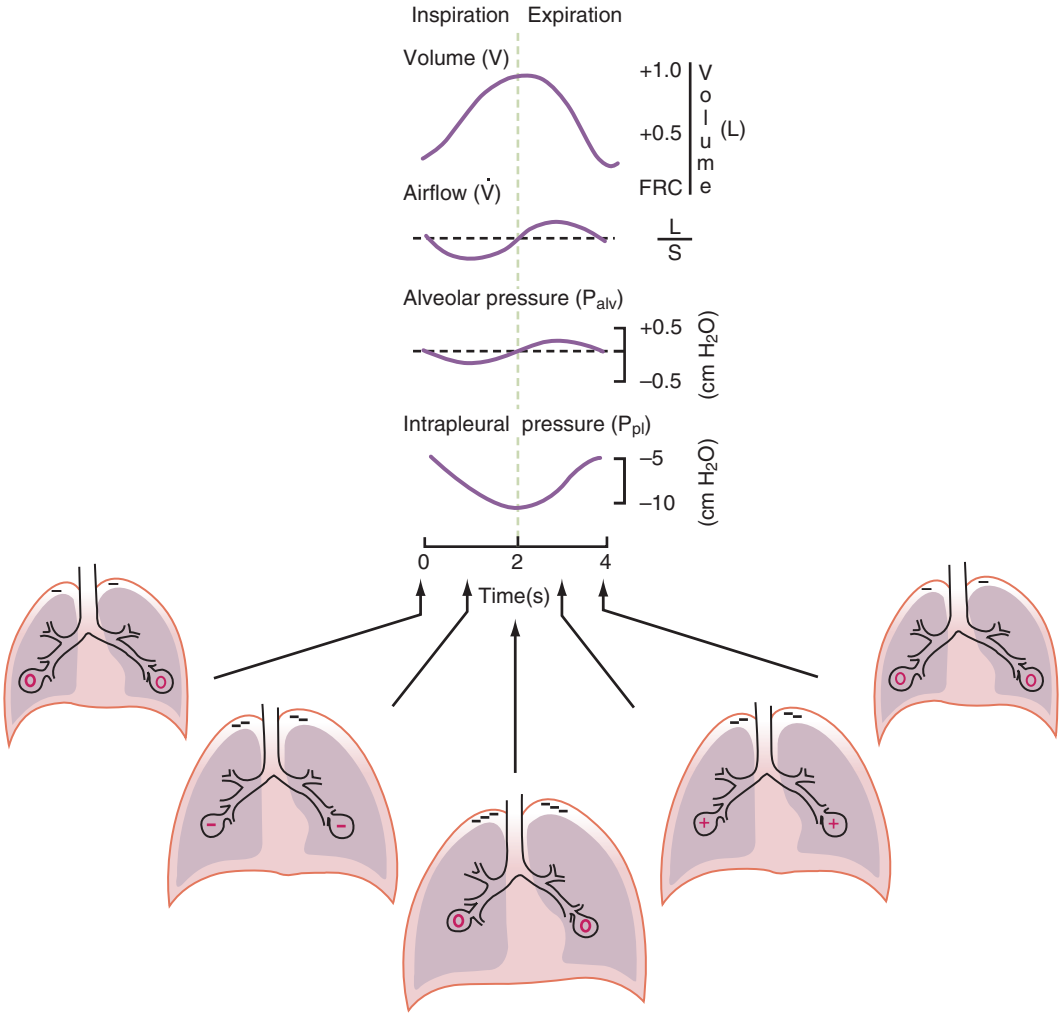

Fig. 47.2 Changes in pressure, volume, and flow during a single spontaneous breath. *FRC*, Functional residual capacity. P_{rs}, Transrespiration system pressure. (Modified from Martin L: *Pulmonary physiology in clinical practice: the essentials for patient care and evaluation*, St. Louis, 1987, Mosby.)

Airway, Alveolar, and Intrathoracic Pressure, Volume, and Flow During Negative Pressure Mechanical Ventilation

Mechanical negative pressure ventilation (NPV) is similar to spontaneous breathing. NPV decreases pleural pressure (P_{pl}) during inspiration by exposing the chest to subatmospheric pressure. Negative pressure at the body surface (P_{bs}) is transmitted first to the pleural space and then to the alveoli (P_{alv}). Because the airway opening remains exposed to atmospheric pressure during NPV, a P_{TA} gradient is created. Gas flows from the relatively high P_{awo} (zero) to the relatively low pressure in the alveoli (negative). As with spontaneous breathing, alveolar expansion during NPV is determined by the magnitude of the P_{TP} gradient. During expiration in both spontaneous breathing and NPV, the lungs and chest wall passively recoil to their resting end-expiratory levels. As this recoil occurs, pleural pressure becomes less negative, and P_{alv} increases above atmospheric pressure (Fig. 47.3). This increase in P_{alv} reverses the P_{TA} gradient. As P_{alv} becomes greater than P_{awo}, gas flows from the alveoli to the airway opening. The effects of NPV on the pressure gradients are shown in Table 47.1.

Volume and flow during NPV also are described by the equation of motion except P_{TA} developed by the ventilator fully or partially replaces the patient's respiratory muscle pressure as follows:

$$P_{musc} + P_{vent} = \text{Volume/Compliance} + (\text{Resistance} \times \text{Flow})$$

In this equation, P_{vent} is the pressure the ventilator develops to overcome the patient's lung-thorax compliance and R_{aw} to deliver the V_T. In this case, P_{vent} is negative but is the driving force behind decreasing the P_{pl} and increasing the transairway and transpulmonary pressures.

Physiologic complications associated with NPV are uncommon because NPV simulates normal spontaneous breathing. The most common problems with NPV are related to interference with caring for the patient caused by the device surrounding the chest (the iron lung or chest cuirass). Supplemental oxygen

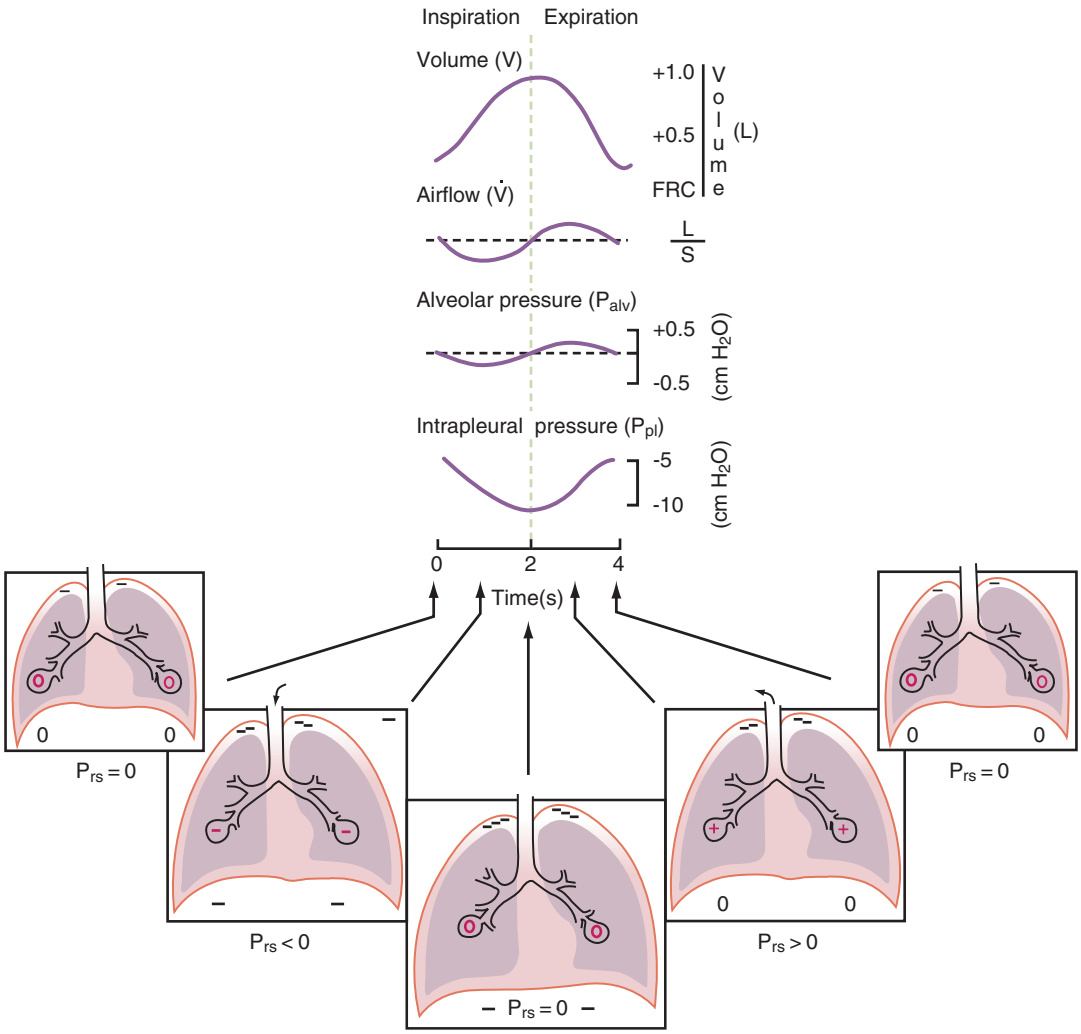

Fig. 47.3 Changes in Pressure, Volume, and Flow During a Single Mechanical Negative Pressure Breath. The box surrounding the lungs represents the enclosure formed by the negative pressure ventilator. *FRC*, Functional residual capacity. (Modified from Martin L: *Pulmonary physiology in clinical practice: the essentials for patient care and evaluation*, St. Louis, 1987, Mosby.)

(O_2) cannot be provided to the patient through the negative-pressure ventilator. Depending on patient need, low-flow or high-flow O_2 delivery devices must be used to provide O_2 therapy. Immediate access to patients requiring routine or emergent medical care may be difficult in systems that enclose the entire thorax and lower body, such as the iron lung and Porta-Lung (Respironics Inc., Murrysville, PA) (see Chapter 50). These systems may impede venous return by creating a negative pressure in the abdomen and lower half of the body, which may lead to hypotension, a phenomenon known as "tank shock." The risk of glottis closure and the development of obstructive sleep apnea have been reported in association with NPV of patients with chronic obstructive pulmonary disease (COPD) and neuromuscular dysfunction.

RULE OF THUMB A negative end-expiratory transpulmonary pressure results in collapse of alveoli, atelectasis. During mechanical ventilation PEEP is applied to maintain a positive end-expiratory transpulmonary pressure.

Airway, Alveolar, and Intrathoracic Pressure, Volume, and Flow During Positive Pressure Mechanical Ventilation

Pressure mechanical ventilation (positive pressure ventilation [PPV]) causes air to flow into the lungs because of an increase in airway pressure, not a decrease in pleural pressure as occurs during spontaneous breathing and NPV (Fig. 47.4). However, similar to spontaneous breathing and NPV, PPV causes an increase in P_{TP}, which allows gas to flow into the lungs. Gas flows into the lungs because P_{awo} is positive, and P_{alv} is initially zero or less positive. P_{alv} rapidly increases during the inspiratory phase of PPV. The increased P_{alv} expands the airways and alveoli. Because P_{alv} is greater than pleural pressure (P_{pl}) during PPV, positive pressure is transmitted from the alveoli to the pleural space, causing pleural pressure to increase during inspiration. Depending on the compliance and resistance of the lungs, pleural pressure may markedly exceed atmospheric pressure during a portion of inspiration. These changes in pleural pressure during PPV

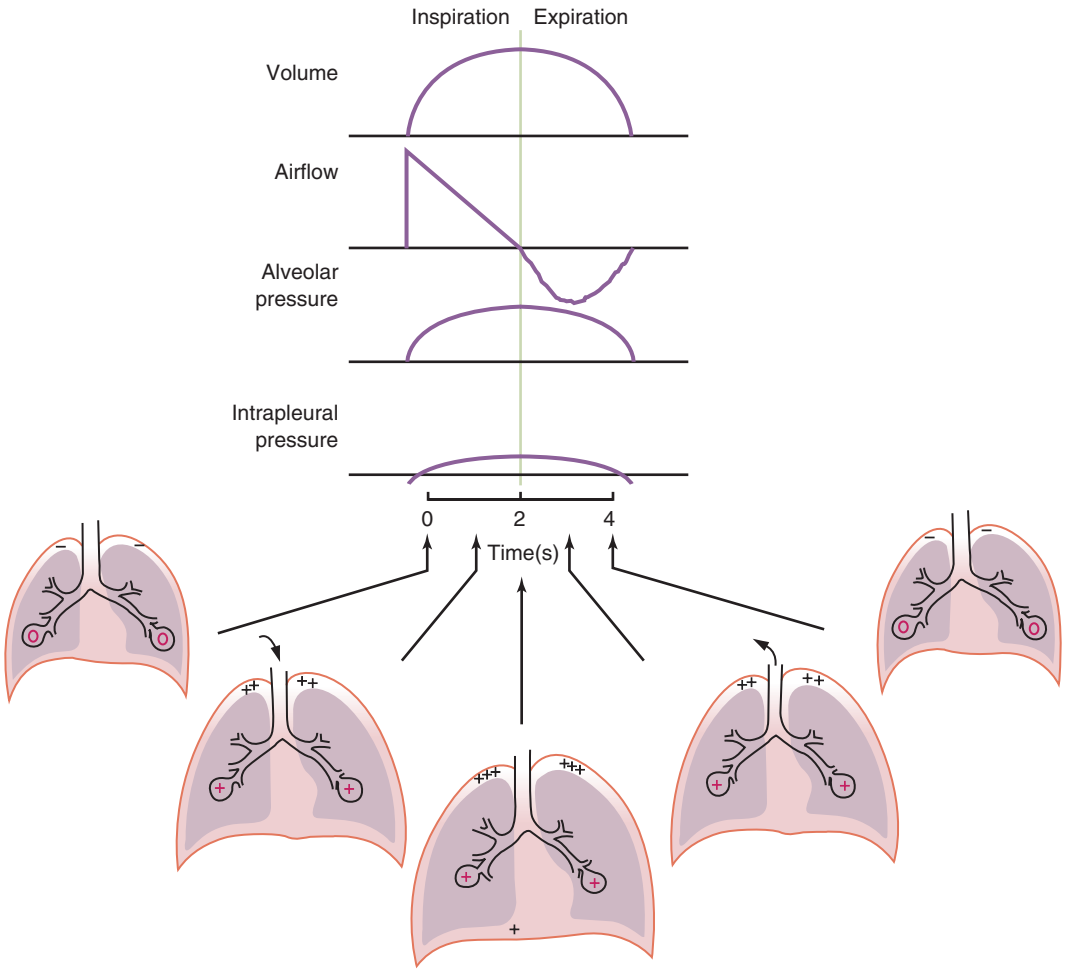

Fig. 47.4 Changes in Pressure, Volume, and Flow During a Single Decelerating Flow, Positive Pressure Breath. *Arrows* into and out of the trachea represent airflow. (Modified from Martin L: *Pulmonary physiology in clinical practice: the essentials for patient care and evaluation*, St. Louis, 1987, Mosby.)

can lead to significant physiologic changes (see later sections). Pressure gradients during PPV are similar to pressure gradients during spontaneous breathing and NPV except that they are created by a positive P_{awo} instead of a negative pressure in the pleural space (see Table 47.1). All pressure gradients change in the same direction as during NPV and spontaneous breathing except the P_{TR}, which changes in the opposite direction and becomes more positive instead of negative.

Similar to spontaneous breathing, the recoil force of the lungs and chest wall, stored as potential energy during the positive pressure breath, causes passive exhalation. As gas flows from the alveoli to the airway opening, P_{alv} decreases to atmospheric level, while pleural pressure is restored to its normal subatmospheric level (see Fig. 47.4).

Volume and flow during PPV are also described by the equation of motion. The magnitude of P_{vent} depends not only on the patient's lung mechanics but also on the P_{musc} of the patient. If the patient makes no effort, P_{vent} is responsible for all volume and flow. During volume-controlled ventilation, as muscle effort increases, P_{vent} decreases and V_T remains constant. During pressure-controlled ventilation, as P_{musc} increases, V_T increases and P_{vent} remains unchanged.

RULE OF THUMB Ideally, the transpulmonary pressure should be as low as possible during mechanical ventilation. A transpulmonary pressure less than approximately 28 cm H_2O minimizes the development of ventilator-induced lung injury. If the plateau pressure is kept less than 28 cm H_2O, the transalveolar pressure can never exceed this level during controlled ventilation.

EFFECTS OF MECHANICAL VENTILATION ON VENTILATION

Minute Ventilation

The primary indication for mechanical ventilation is *hypercapnic respiratory failure,* also known as *ventilatory failure*. For patients with acute ventilatory failure, the goal of mechanical ventilation is improving alveolar ventilation to compensate for the patient's inability to maintain a normal $PaCO_2$. $PaCO_2$ is inversely related to alveolar ventilation, which is related to minute ventilation. Minute ventilation ($\dot{V}_E$) is the product of V_T and ventilatory rate (f):

$$\dot{V} = V_T \times f$$

Use of a mechanical ventilator usually implies a change in V_T, ventilatory rate, or both from preintubation values. A normal

spontaneous V_T is approximately 5 to 7 mL/kg. The currently accepted V_T for all patients acutely requiring mechanical ventilation is 4 to 8 mL/kg predicted body weight (PBW). These volumes are always based on PBW regardless of the size of the patient. The mechanical ventilator rate depends on the patient's status. For postoperative ventilation, a rate of 12 to 20 breaths/min may be adequate. Conditions that necessitate a higher initial rate include acute respiratory distress syndrome (ARDS), pulmonary fibrosis, acutely increased intracranial pressure (ICP) (with caution; see later), and metabolic acidosis. Conditions that may necessitate a lower rate include acute asthma exacerbation, to allow an increased expiratory time to minimize air trapping. When an appropriate V_T is established, the set rate is adjusted to achieve desired $PaCO_2$. Mechanical ventilation increases minute ventilation by increasing V_T, ventilator rate, or both.

MINI CLINI

Alveolar, Transpulmonary, and Transalveolar Pressures

Problem

Mr. Jones is 58 years old, 5 feet 8 inches tall, and weighs 410 lb and is being ventilated because of ARDS. His current ventilator settings are pressure control mode, peak pressure 37 cm H_2O, PEEP 20 cm H_2O, FiO_2 0.50, respiratory rate 26 breaths/min, and V_T 400 mL. At the end of expiration gas flow returns to zero approximately 100 ms before the end of the breath. What are the end-inspiratory and end-expiratory alveolar, transpulmonary, and transalveolar pressures for Mr. Jones?

Solution

Because there is a short end-inspiratory pause, it is reasonable to assume that the peak airway pressure in pressure control is equal to the average peak P_{alv}. The term average is used here because alveolar units have different time constants and as a result different peak pressures, but when there is an end-inspiratory equilibration of pressure, the resulting value is the average pressure across all lung units. To be more confident of this value, an additional end-inspiratory pause can be added for a single breath to determine better the end-inspiratory pause pressure or plateau pressure. End-expiratory transpulmonary is determined by an end-expiratory pause. As with the end-inspiratory pause, this ensures that the pressure reading reflects the average pressure across all alveoli at end-exhalation.

To determine the end-inspiratory and end-expiratory P_{TP} ($P_{awo} - P_{pl}$) and P_L ($P_{alv} - P_{pl}$), an estimate of pleural pressure must be made. The ideal method is to measure the esophageal pressure. Although not exactly equal to the pleural pressure, it accurately reflects changes in pleural pressure. Some authors have also recommended evaluation of bladder pressure, which changes in the same manner as esophageal pressure. The reading from the esophageal catheter at the time an end-expiratory pause was applied was 23 cm H_2O. The end-expiratory P_{TP} and P_L are the same: 25 to 23 cm H_2O or 2 cm H_2O. The reading at end-inspiration is 28 cm H_2O. The end-inspiratory P_{TP} and P_L are the same: 37 to 28 cm H_2O or 9 cm H_2O. This is because Mr. Jones was ventilated in pressure control, and there was a short end-inspiratory pause, so both peak and **plateau pressures** were equal. However, if he was ventilated in volume ventilation and the peak airway pressure might be 45 cm H_2O, while the plateau pressure (P_{plat}) remained 37 cm H_2O when an end-inspiratory pause was added, the transalveolar pressure and P_{TP} would still be the same: 37 – 28 cm H_2O or 9 cm H_2O.

Mr. Jones is receiving lung protective ventilation because his transalveolar pressure is only 9 cm H_2O at end-inspiration. The high airway pressures are needed because of his large body mass, which minimizes the transmission of pressure across the lung, reducing lung stretch.

Increased Alveolar Ventilation

Alveolar ventilation ($\dot{V}_A$) is inversely related to $PaCO_2$ as defined by the following relationship:

$$\dot{V}_A = (\dot{V}CO_2 \times 0.863)/PaCO_2$$

where $\dot{V}CO_2$ is carbon dioxide (CO_2) production.[2]

As alveolar ventilation decreases, $PaCO_2$ increases. As CO_2 production increases, alveolar ventilation must increase to maintain the same $PaCO_2$. Mechanical ventilation may be needed in either case. It is more useful to look at this equation solved for $PaCO_2$ because changes in $PaCO_2$ usually correlate with the need for mechanical ventilation:

$$PaCO_2 = (\dot{V}CO_2 \times 0.863)/\dot{V}_A$$

If $\dot{V}_A$ decreases or $\dot{V}CO_2$ increases, $PaCO_2$ increases, and hypercapnic respiratory failure follows; mechanical ventilation may be indicated in this setting. Because mechanical ventilation increases ventilation, $PaCO_2$ can be decreased to the desired level depending on the total ventilatory rate.

Ventilation/Perfusion Ratio

Spontaneous ventilation results in gas distribution mainly to the dependent and peripheral zones of the lungs. Controlled PPV tends to reverse this normal pattern of gas distribution, and most of the delivered volume is directed to nondependent lung zones (Fig. 47.5). This phenomenon is caused partly by the inactivity of the diaphragm and chest wall during controlled PPV. Although these structures actively facilitate gas movement during spontaneous breathing, inactivity of these structures during controlled PPV impedes ventilation to dependent lung zones. An increase in ventilation to the nondependent zones of the lung, where there is less perfusion, increases the ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio, effectively increasing physiologic dead space. The increase in $P(A - a)O_2$ often observed with PPV is caused by areas of low $\dot{V}/\dot{Q}$ ratio.

PPV decreases the $\dot{V}/\dot{Q}$ ratio in the bases and dependent lung zones mainly as a result of ventilation being primarily distributed to nondependent lung zones. The $\dot{V}/\dot{Q}$ ratio may also increase in nondependent lung zones because of the effect of PPV on perfusion. PPV can compress the pulmonary capillaries. This compression increases pulmonary vascular resistance and decreases perfusion. Minimal blood flow perfuses the areas with the greatest V_T and contributes to a further increase in dead space. Conversely, blood intended for these areas is diverted to regions with lower vascular resistance—generally more dependent lung regions. Pulmonary blood flow during PPV tends to perfuse

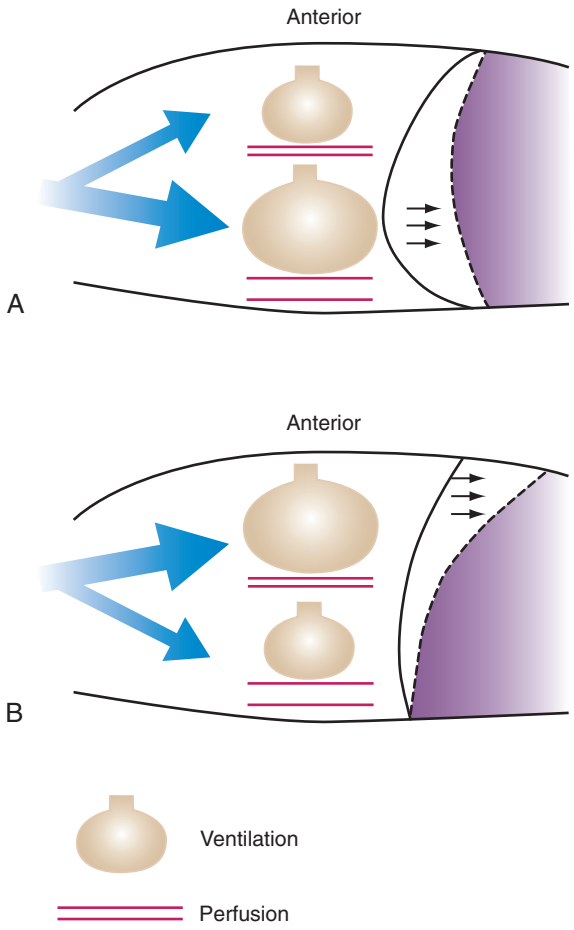

Fig. 47.5 Effect of Spontaneous Ventilation and Positive Pressure Ventilation (PPV) on Gas Distribution in a Supine Subject. (A) During spontaneous ventilation, diaphragmatic action distributes most ventilation to the dependent zones of the lungs, where perfusion is greatest. The result is a nearly normal $\dot{V}/\dot{Q}$ ratio. (B) Partly because of diaphragmatic inactivity, PPV reverses this normal pattern of gas distribution, and most delivered volume is directed to the upper lung zones. An increase in ventilation to the upper lung zones, where there is less perfusion, increases the $\dot{V}/\dot{Q}$ ratio, effectively increasing physiologic dead space. At the same time, higher alveolar pressure in the better ventilated upper lung zones diverts blood flow away from these areas to the areas receiving the least ventilation. The result is areas of low $\dot{V}/\dot{Q}$ ratio and impaired oxygenation. (Modified from Kirby RR: *Clinical application of ventilatory support*, New York, 1990, Churchill Livingstone.)

the least well-ventilated lung regions. This perfusion decreases the $\dot{V}/\dot{Q}$ ratio in those areas and increases the $P(A-a)O_2$.

Alveolar and Arterial Carbon Dioxide

Normal alveolar carbon dioxide tension ($PACO_2$) is 40 mm Hg, whereas mixed venous blood typically has a $P\bar{v}CO_2$ of 45 mm Hg. Under normal circumstances, CO_2 moves out of the blood at the pulmonary capillary interface; the result is a $PaCO_2$ of 40 mm Hg. In the event of a decrease in alveolar ventilation or an increase in CO_2 production, $PaCO_2$ increases. Mechanical ventilation can increase minute volume and alveolar ventilation and reduce $PACO_2$ and $PaCO_2$. With an increase in V_D/V_T, $PaCO_2$ increases if there is no change in minute volume; this may occur when alveolar blood flow is decreased by acute pulmonary embolism, an excessive level of positive end-expiratory pressure (PEEP), or advanced dead space–producing disease such as emphysema or pulmonary embolism.

When inappropriate PEEP is used and blood flow is diverted from ventilated alveoli to hypoventilated alveoli; the result is an increased $\dot{V}/\dot{Q}$ ratio. In emphysema, formation of bullae is coincident with the destruction of pulmonary capillaries; the result is large areas of poorly perfused but ventilated alveoli. Pulmonary emboli may completely occlude pulmonary vessels; the result is lack of perfusion to alveoli distal to the blockage.

Acid–Base Balance

Respiratory acidosis, occurs when minute ventilation and alveolar ventilation per minute ($\dot{V}_A$) are inadequate to meet the needs of the body. Volume delivery also decreases if high airway pressures develop secondary to volume loss as a result of ventilator circuit tubing compliance (compressible volume loss). Ventilator circuits may have compliance of 1 to 3 mL/cm H_2O, which effectively reduces V_T:

$$\text{Volume lost} = \text{Tubing compliance} \times (\text{Peak pressure} - \text{PEEP})$$

Tubing compliance was a concern with older ventilators; however, most intensive care unit (ICU) ventilators in use at the present time allow the user to compensate for compressible volume loss as a result of tubing compliance. When activated, the volume set is the volume delivered to the patient. This issue is discussed in more detail later in the chapter.

An increase in V_D/V_T ratio can cause a reduction in alveolar ventilation, even though minute ventilation may be normal or increased. These problems emphasize the importance of proper selection of V_T and mandatory rate. When respiratory acidosis exists, the patient may become restless and anxious, resulting in **patient–ventilator asynchrony** (see Chapter 48). A communicative patient may complain of dyspnea. If these symptoms are observed, especially when $PaCO_2$ is increased, minute ventilation generally should be increased.

Respiratory alkalosis occurs if the minute ventilation is too high. A patient who is dyspneic, anxious, or in pain may develop this condition; the usual manifestations are an increased ventilatory rate or patient–ventilator asynchrony or both. The ventilator can cause respiratory alkalosis secondary to an inappropriately high V_T or rate. Regardless, the result is excessive minute and alveolar ventilation. This condition requires that the RT adjust the ventilator appropriately and address the patient's pain or anxiety to avoid the systemic effects of a prolonged alkalosis.

With metabolic acidosis, the patient tries to compensate by increasing minute ventilation to blow off CO_2 in an effort to increase the pH. The resulting increase in work of breathing (WOB) may lead to ventilatory muscle fatigue and continued respiratory failure. The best therapy for metabolic acidosis is to manage the underlying cause while supporting the patient's ventilation as needed. Many patients cannot be liberated from mechanical ventilation until the underlying acidosis is controlled.

With metabolic alkalosis, in an effort to compensate for the increased pH, the patient tries to decrease minute ventilation. If weaning is attempted when the patient has a metabolic alkalosis, the patient may continue to hypoventilate and weaning

may fail. As with metabolic acidosis, the underlying cause should be determined and managed. Common causes of metabolic alkalosis include hypochloremia or hypokalemia secondary to gastrointestinal loss, diuretics, or steroid administration. See Chapter 14 for details on acid–base balance.

EFFECTS OF MECHANICAL VENTILATION ON OXYGENATION

Inspired Oxygen

Mechanical ventilators usually deliver an increased fractional inspired oxygen (FiO_2) ranging from room air (0.21) to 100% O_2 (1.0). As a result, the alveolar partial pressure of oxygen (PAO_2) and arterial partial pressure of oxygen (PaO_2) may be restored to normal with appropriate management. The effectiveness of increased FiO_2 in the management of hypoxemia depends on the cause of hypoxemia. Hypoxemia caused by a decrease in the $\dot{V}/\dot{Q}$ ratio or hypoventilation is more responsive to increased FiO_2 than hypoxemia caused by a diffusion defect or shunt. Hypoxemia caused by hypoventilation responds well to an increase in FiO_2, but alveolar ventilation can be restored only by improved ventilation. Hypoxemia caused by diffusion defect and shunt generally respond better to an increase in PEEP than to an increase in FiO_2. If the patient is receiving mechanical ventilation and has adequate alveolar ventilation, failure of the PaO_2 to respond to increased FiO_2 likely means that hypoxemia is due to a diffusion defect or shunt.

It should be remembered that FiO_2 in an acutely ill patients should not be applied excessively.[3] Sufficient current data indicate that hyperoxia increases mortality of critically ill patients. As a result, the FiO_2 should be adjusted to ensure that the PaO_2 is 55 to 80 mm Hg and/or the SpO_2 is 88% to 95%.

Alveolar Oxygen and Alveolar Air Equation

Increasing FiO_2 increases PAO_2, according to the alveolar air equation (see Chapter 11).[2]

When FiO_2 is increased, PAO_2 increases as well, if there is no change in $PaCO_2$ or the respiratory exchange ratio. $PaCO_2$ may change with a change in alveolar ventilation or metabolic rate. O_2 consumption and CO_2 production increase with an increase in metabolic rate, such as with fever or overfeeding. If metabolic rate and alveolar ventilation are constant, an increase in FiO_2 results in a proportional increase in PAO_2.

RULE OF THUMB It should be remembered that FiO_2 in an acutely ill patients should not be applied excessively. Sufficient current data indicate that hyperoxia increases mortality of critically ill patients. As a result, the FiO_2 should be adjusted to ensure that the PaO_2 is 55–80 mm Hg and/or the SpO_2 is 88%–95%.

Arterial Oxygenation and Oxygen Content

Mechanical ventilation at FiO_2 of 0.21 may restore arterial oxygenation if the only cause of hypoxemia was hypoventilation. Hypoventilation may be the sole cause with central nervous system depression, apnea, and neuromuscular disease. With other causes of hypoxemia, an increase in FiO_2 is needed to increase arterial O_2 content.

O_2 content (see Chapter 12) is directly related to arterial oxygenation and hemoglobin concentration. Under circumstances of normal diffusion, FiO_2, and hemoglobin concentration, the arterial content is normal at approximately 19.8 mL O_2/100 mL blood. As defined by this equation, CaO_2 decreases if hemoglobin concentration, arterial saturation, or PaO_2 decreases.

Decreased Shunt

Mechanical ventilation alone does not decrease shunt. Otherwise, it would be much easier to restore PaO_2 in patients with ARDS. Administration of PEEP with mechanical ventilation or to a spontaneously breathing patient in the form of continuous positive airway pressure (CPAP) helps to maintain open alveoli and stabilize small, collapsed, or fluid-filled alveoli. The results are an increase in alveolar surface area for diffusion and improvement in $\dot{V}/\dot{Q}$ matching and arterial oxygenation.

PEEP or CPAP should be used judiciously (see later in this chapter and Chapter 49). High pressure can overdistend alveoli and redistribute pulmonary blood flow to capillaries surrounding poorly ventilated alveoli, resulting in increased shunt.

Increased Tissue Oxygen Delivery

When a mechanical ventilator is used to improve arterial oxygenation by increasing FiO_2 or PEEP, CaO_2 increases. However, the increase in CaO_2 represents only part of tissue O_2 delivery because O_2 delivery is defined by CaO_2 and cardiac output, as follows[2]:

$$DO_2\ (\text{tissue oxygen delivery in ml/min}) = CaO_2\ (\text{ml } O_2/100\ \text{ml blood}) \times \text{Cardiac output (L/min)} \times 10$$

where 10 is a constant for converting deciliters to milliliters.

Normal tissue O_2 delivery is approximately 990 mL/min because the normal CaO_2 is approximately 20 vol%, and the normal cardiac output is approximately 5 L/min. When PaO_2, CaO_2, and cardiac output are adequate, so is tissue O_2 delivery. When PEEP is needed to improve PaO_2, it must be used cautiously because PEEP increases intrathoracic pressure. When intrathoracic pressure is increased, pleural pressure around the heart also increases, and the increase can affect the mechanical activity of the heart and impede venous return and decrease cardiac output. As discussed in Chapter 49, careful titration of PEEP must include monitoring the cardiovascular status of the patient. *Optimal PEEP* provides adequate arterial oxygenation and tissue O_2 delivery.

EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION ON LUNG MECHANICS

Time Constants

The time necessary for **passive** inflation and deflation of the lung or each alveolus is determined by the product of compliance and resistance. This product is the **time constant** of the lung or alveolar unit. The compliance of a "normal" lung is approximately 0.1 L/cm H_2O, and resistance of a normal lung

MINI CLINI

Oxygen Delivery

Problem

Oxygen delivery (DO_2) depends on PaO_2, hemoglobin concentration, and cardiac output. The formula for DO_2 is:

$$DO_2 = CaO_2 \times \text{Cardiac output (L/min)} \times 10$$

where CaO_2 is the arterial oxygen content, and 10 is the conversion factor between deciliters and milliliters. Normal DO_2 is 990 mL/min. DO_2 is normal when the hemoglobin concentration is 15 g/dL, cardiac output is 5.0 L/min, and PaO_2 is 100 mm Hg:

$$DO_2 = [15\,g\,Hb \times 1.34\,ml\,O_2/g\,Hb \times 0.97\,(SaO_2)] + 0.003 \times 100\,mm\,Hg] \times (5.0\,L/min) \times 10$$
$$= 19.8\,(CaO_2) \times 5\,(L/min) \times 10 = 990\,ml/min$$

When the practitioner calculates DO_2 and determines it to be low, the component of the formula that is low denotes the problem and the therapeutic target. If CaO_2 is low because of a low hemoglobin concentration, increasing the hemoglobin concentration with blood transfusion is indicated. If CaO_2 is low because of low PaO_2 or SaO_2, increasing PaO_2 and SaO_2 with O_2 or PEEP is indicated. If cardiac output is low, the cause (decreased preload, increased afterload, decreased contractility, or bradycardia) is determined, and appropriate therapy is initiated. Frequently, a decrease in CaO_2 results in an increase in the cardiac output to compensate for decreased DO_2.

Example:

Given PaO_2 of 65 mm Hg, hemoglobin concentration of 10 g/dL, SaO_2 of 91%, and cardiac output of 4.8 L/min, what increase in cardiac output is necessary to maintain DO_2 of 900 mL/min?

DO_2 at given values is $[(1.34 \times 10 \times 0.97) + (0.003 \times 65)] \times 4.8 \times 10 = 633\,ml/min$

An increase in cardiac output to 6.8 L/min results in DO_2 that is close to normal: $[(1.34 \times 10 \times 0.97) + (0.003 \times 65)] \times 6.8 \times 10 = 897$ mL/min. However, an increase in cardiac output to 6.8 L/min increases myocardial work. Because the cause of decreased DO_2 in this patient is hypoxemia and anemia, the goal of therapy should be to increase PaO_2. This strategy allows cardiac output and work to return to normal while adequate DO_2 is maintained. Increasing the hemoglobin concentration is normally not performed by transfusion unless the hemoglobin concentration is less than 8–10 g/dL because of the adverse effects associated with transfusions.

is approximately 2.5 cm H_2O/L/s. The time constant for a normal lung is 0.25 second (1.0 L/cm H_2O × 0.25 cm H_2O/L/s). For patients with normal lungs, 95% of the alveoli are inflated within three time constants (i.e., within 0.75 second). In four time constants (1.0 second), 98% of alveoli are inflated, and in five time constants (1.25 second), 99.3% of alveoli are inflated. The same numbers apply for exhalation.

The two major factors that affect alveolar time constants are changes in compliance and changes in resistance. If compliance or resistance decreases, the time constant for a given lung unit decreases, and the lung fills and empties faster. If compliance or resistance increases, the time constant increases, and it takes more time to fill and empty the lung.

There are clinical implications for patients with disorders consistent with abnormal time constants. A longer inspiratory time may be needed for patients with asthma because R_{aw} is increased. Attempting to ventilate these patients with a normal inspiratory time may result in inadequate volume to affected lung units because the airways are obstructed, and volume is likely to travel to airways with the lowest resistance. Inspiratory time in severe asthma needs to be set between approximately 1.0 to 1.5 seconds to ensure adequate gas delivery. The primary limiting factor is that the airways are also obstructed during exhalation. The expiratory time must also be longer to allow as complete an exhalation as possible.

Asthma is very different from COPD, in which the inspiratory time constant is normal, but the expiratory time constant is long. In general, asthma requires very slow respiratory rates with longer than normal inspiratory and expiratory times to account for the altered time constants during both inspiration and expiration. Patients with COPD generally tolerate a more rapid rate because only the expiratory time constant is lengthened. In both of these situations, air trapping is very common because of the long expiratory time constants. In patients with COPD, inspiratory times are generally short (approximately 0.7 to 0.9 second). In patients with ARDS or acute lung injury (ALI), time constants are very short, and as a result inspiratory times can also be very short. Most patients with ARDS require an inspiratory time of only 0.5 to 0.8 second. Expiratory time constants are also short—hence the ability to ventilate these patients rapidly with small V_T. Respiratory rates greater than 30 breaths/min are frequently well tolerated by patients with ARDS. The major concern with patients with ARDS and their short time constants is that any disruption of the airway rapidly results in a loss of lung volume. Atelectasis occurs with disconnections from the ventilator in 1 seconds. As a result, *all* patients with ARDS should be suctioned *only* with inline suction catheters, and any circuit disconnection should be avoided. Ventilator management in the care of patients with COPD, asthma, and ARDS is described in detail in Chapter 49.

Increased Pressure

Peak inspiratory pressure (PIP) is the highest pressure produced during the inspiratory phase. It is the sum of the pressures necessary to overcome R_{aw} and lung and chest wall compliance. PIP is also known as *peak pressure* or *peak airway pressure*.

P_{plat} is the pressure observed during a period of inflation hold or end-inspiratory pause. To obtain a P_{plat}, the RT initiates an inspiratory pause time of 0.5 to 2.0 seconds. During inspiration, the peak pressure is reached and then immediately followed by the inspiratory pause. During the pause, pressure decreases to a pressure plateau. When a valid P_{plat} is obtained, the inspiratory pause time is returned to zero. P_{plat} represents the average peak P_{alv}. In volume-controlled ventilation, P_{plat} is always lower than peak pressure because the peak pressure is the sum of the P_{alv} and the pressure needed to overcome R_{aw}. When flow is delivered by a square waveform, the difference between P_{plat} and peak pressure is the pressure necessary to overcome R_{aw}. If the V_T is divided by the difference between the P_{plat} and total PEEP (applied plus auto-PEEP), the quotient is the quasistatic lung-thorax compliance[4]: The reason for this is that the baseline pressure prior to the start of inspiration is the total PEEP, not the applied PEEP.[4]

$$C_{static} = V_T/(P_{plat} - PEEP)$$

This value is referred to as the lung-thorax compliance because the compliance of the lungs and the compliance of the rib cage are being calculated as a unit. The lung compliance cannot be determined without the use of an esophageal balloon.[4] Ideally, the volume lost owing to tubing compliance should be subtracted from the V_T if the ventilator does not compensate for it, making the equation[4]:

$$C_{static} = \text{Adjusted } V_T / (P_{plat} - \text{total PEEP})$$

It may be more useful to follow trends in lung compliance, rather than making judgments on only one calculation. A downward trend in compliance means that the lungs or chest wall is stiffer, as in ARDS.

R_{aw} during volume ventilation is estimated by the difference between PIP and P_{plat} divided by the inspiratory flow ($\dot{V}_I$) in L/s, provided that the flow is constant (square waveform)[4]:

$$R_{aw} = (PIP - P_{plat}) / \dot{V}_I$$

During mechanical ventilation, the P_{plat} should be less than 28 cm H_2O.[5,6] At levels greater than 28 cm H_2O, alveolar damage from overdistention is likely. This form of *ventilator-induced lung injury (VILI)* is referred to as **volutrauma** (see later). This trauma can result in air leakage from alveoli, the release of inflammatory mediators, and multisystem organ failure (MSOF). When the P_{plat} approaches 28 cm H_2O during either volume or pressure ventilation, the pressure limit or the V_T should be decreased. This approach to ventilation is referred to as *lung protective ventilation*.[4–6] In addition the **driving pressure**, P_{plat} minus PEEP should be less than 15 cm H_2O.[7] Driving pressure greater than 15 cm H_2O increases mortality and driving pressures less than 15 cm H_2O decreases mortality. Many consider the driving pressure the most important variable in relation to ventilator induced lung injury.[7]

RULE OF THUMB When measuring lung mechanics, R_{aw} and compliance always use the same ventilator settings to make comparisons from one point in time to another much easier. In adults, typical settings are volume ventilation, V_T 500 mL, square wave flow, and peak flow set at 60 L/min.

Mean Airway Pressure

Mean airway pressure is the average pressure across the total cycle time (TCT). The mean airway pressure ($P_{\overline{AW}}$) can be calculated manually if the flow is constant, as follows[4]:

$$P_{\overline{AW}} = \tfrac{1}{2}(PIP - PEEP) \times (\text{Inspiratory time}/TCT) + PEEP$$

Mean airway pressure is computed by the ventilator as the integral of the pressure signal over the TCT (as a rolling average), so the RT can record the ventilator computed value rather than manually calculating it. Because expiratory (baseline) pressure is lower than inspiratory pressure, the mean pressure is between peak and end-expiratory pressure. The variables affecting mean pleural and mean airway pressure are summarized in Box 47.1. For a given minute volume, partial ventilatory support modes such as synchronized intermittent mandatory ventilation (SIMV) result in lower mean airway and pleural pressures than continuous mandatory ventilation (CMV) modes. For a specific mandatory breath, as peak pressure increases, so does mean pressure. Likewise, long inspiratory times increase mean pressure. Prolonging expiratory time has the opposite effect on mean airway pressure. In general, the harmful cardiovascular effects of PPV are more likely to occur when $P_{\overline{AW}}$ or inspiratory-to-expiratory (I:E) ratio increases (e.g., >1:1).

BOX 47.1 Factors That Increase Mean Airway Pressure

- Absence of spontaneous ventilation
- Increasing positive pressure
- Increasing duration of inspiration
- Decreasing duration of expiration
- Nature of inspiratory waveform
- Increasing level of positive end-expiratory pressure
- Decreasing compliance, increasing airways resistance

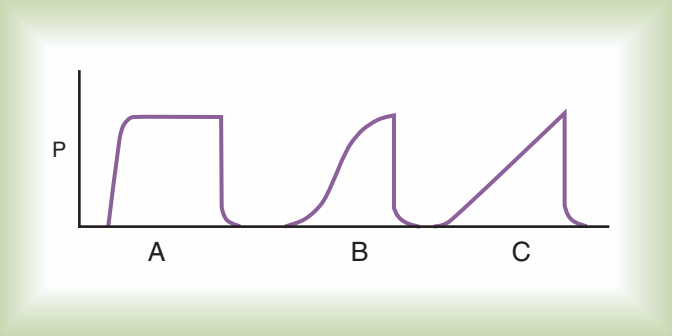

Fig. 47.6 Pressure patterns resulting from a descending ramp flow waveform *(A)*, a sine wave flow waveform *(B)*, and a constant flow waveform *(C)*. Because waveform *A* has the highest pressure for the longest inspiratory time, it also has the greatest mean airway pressure.

The pressure waveform of a mandatory breath affects mean pressure. In Fig. 47.6, for a given inspiratory time, the constant pressure pattern (curve *A*) results in the greatest area under the airway pressure curve and the highest mean airway pressure. A constant pressure pattern is normally produced by a pressure targeted breath that provides decreasing (descending ramp) flow. The effect of PEEP on mean airway pressure is simple: Every 1 cm H_2O of applied PEEP increases the mean airway pressure 1 cm H_2O.

Effect of Peak Airway Pressure on Lung Recruitment

As peak airway pressure increases, previously collapsed, small, or partially fluid-filled alveoli are recruited (i.e., reopened).[8] This reopening of alveoli increases alveolar surface area and restores functional residual capacity (FRC). At the alveolar level, the surface area available for diffusion is increased. As a result, PaO_2 increases, consistent with Fick's law. The use of extrinsic PEEP maintains the airways and recruited open alveoli. Extrinsic PEEP is controlled directly by the PEEP control on the ventilator, and the RT always knows how much extrinsic PEEP is present. Several factors, including inverse ratio ventilation (IRV), may add intrinsic

PEEP or auto-PEEP by starting the next breath before the previous exhalation has ended. The amount of intrinsic PEEP added by IRV can be estimated by an end-expiratory pause, which stops the next breath from being delivered. During this end-expiratory pause, alveolar and mouth pressures equilibrate, and the total PEEP is now presented by the ventilator. The amount of auto-PEEP present is the difference between the total PEEP and the extrinsic PEEP:

$$\text{Intrinsic PEEP (auto-PEEP)} = \text{Total PEEP} - \text{Extrinsic PEEP}$$

Increased Lung Volume: Tidal Volume

The volume delivered during pressure-controlled modes varies with changes in set pressure, patient effort, and lung mechanics. For all pressure-targeted modes, the volume delivered at a given pressure decreases as compliance decreases. An increase in resistance, active exhalation, or muscle tensing by the patient during inspiration also decreases delivered volume in pressure ventilation.

If pressure serves as the limit variable instead of the cycle variable, changes in R_{aw} during pressure-limited ventilation may or may not affect delivered volume. In this case, the key factor is the time available for pressure equilibration. Volume can remain constant even if R_{aw} increases, as long as there is sufficient time for alveolar and airway pressures to equilibrate. However, if insufficient time is available for pressure equilibration, delivered volume decreases as R_{aw} increases. The length of time needed for pressure equilibration is usually at least three times greater than the time constant for the respiratory system. In pressure modes, ventilator-delivered flow varies with patient effort and lung mechanics; this tends to avoid patient–ventilator asynchrony.[9]

Increased Functional Residual Capacity

FRC is not known to change significantly with the application of PPV alone because passive exhalation allows the end-expiratory pressure to return to atmospheric pressure with each breath. If an increase in FRC is to be achieved, PEEP or CPAP must be applied. PEEP or CPAP does not recruit collapsed lung units but prevents lung units that have been opened from collapsing at end-expiration. Peak airway pressure recruits lung volume. The magnitude of the increase in FRC sustained by PEEP or CPAP is proportional to the lung-thorax compliance. With acute restriction, as PEEP is increased, lung compliance improves. Initially, the FRC gain as PEEP is added is small. There is no practical way of measuring FRC in all patients, so other methods of determining an increase in FRC are used, such as improving PaO_2 at a constant FiO_2, increasing PaO_2/FiO_2 ratio, decreasing shunt fraction, or decreasing FiO_2 while maintaining PaO_2. The management of PEEP is described in more detail in Chapter 49.

Pressure-Volume Curve and Lung Recruitment in Acute Respiratory Distress Syndrome

Fig. 47.7 depicts the pressure-volume (P-V) relationship of the lung-thorax in an idealized patient with ARDS.[8] On the inflation P-V curve, there are two points of inflection: the lower inflection point referred to as P_{flex} or *lower corner pressure,* and an upper inflection point, also referred to as *upper corner pressure*. These

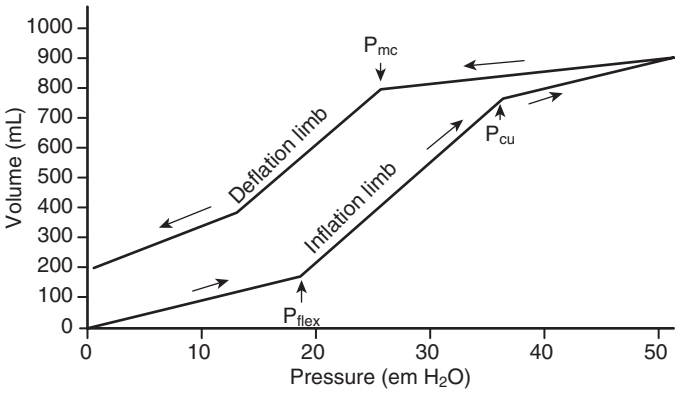

Fig. 47.7 Pressure-Volume (P-V) Curve of the Lung-Thorax Indicating the Inflation and Deflation Limbs. *Arrows* indicate direction of flow. P_{CL}, Lower corner pressure or P_{flex} or lower inflection point; P_{CU}, upper corner pressure or upper inflection point; P_{MC}, point of maximum compliance change. (Modified from Godon S, Fujino Y, Hromi JM, et al: Optimal mean airway pressure during high frequency oscillation, *Anesthesiology* 94:862–868, 2001.)

two points represent defined changes in compliance. The lower inflection point represents an abrupt increase in lung-thorax compliance as collapsed or atelectatic lung begins to be recruited.[10] The upper deflection point represents the point where the rate of lung recruitment decreases and over inflation begins.[10] It is most important to realize from this graph that the lung is recruited by pressure and that the higher the peak airway pressure, the greater the potential for lung to be recruited. The maximum pressure needed to recruit a given patient's lung is unknown; however, pressures up to 50 cm H_2O most likely are safe with most patients when applied for short (1 to 3 minutes) periods.[11–13] If these pressures were applied for longer periods, lung injury would most likely result.

The deflation limb of the P-V curve is similar in shape to the inflation limb but is separated from the inflation limb. This hysteresis (separation) is a result of surfactant and surface tension interactions. Basically, less pressure is required to keep the lung open on the deflation limb of the P-V curve than on the inflation limb; this is obvious on examination of the volume maintained in the lung at P_{flex}, or 20 cm H_2O. On the inflation limb, lung volume increases approximately 200 mL at 20 cm H_2O, but on the deflation limb, lung volume increases approximately 550 mL. The goal of an open lung approach to ventilation that has been proposed by many authors is to open the lung and then to ventilate the patient on the deflation limb of the P-V curve at the least PEEP maintaining the lung open.[11–13]

Fig. 47.7 is an idealized P-V curve; actual patient P-V curves in ARDS are not as well defined. In approximately 20% of patients with ARDS, P_{flex} cannot be identified on the inflation P-V curve. As a result, despite two positive randomized controlled trials using P_{flex} to set PEEP,[14,15] the use of P-V curves clinically has not become common practice; a second reason for this is the difficulty of measuring the P-V curve. However, many newer ICU ventilators are including algorithms that allow P-V curves to be performed by the ventilator with the ventilator identifying P_{flex}.

The approach to setting PEEP that ensures ventilation on the deflation limb of the P-V curve and the minimal PEEP to sustain the benefit of lung recruitment is a decremental PEEP trial immediately after a lung recruitment maneuver (RM).[13,14,16] Many different approaches to performing lung RMs have been published, but the approach that is considered the safest and most efficacious is the use of pressure-controlled continuous mandatory ventilation (PC-CMV).[13,14,16] To perform a lung RM with PC-CMV, high enough PEEP must be set to avoid derecruitment after each inspiration. Essentially, a minimum of 20 cm H_2O PEEP is required during the RM. Peak pressure is usually stopped at 40 cm H_2O, but if the patient tolerates the pressure hemodynamically, it may be increased to 50 cm H_2O (PEEP 35 cm H_2O), ensuring a driving pressure of no more than 15 cm H_2O (Box 47.2). Inspiratory time is increased to approximately 2.0 to 3.0 seconds, and respiratory rate is decreased to approximately 10 to 15 breaths/min. The maneuver is applied for 1 to 3 minutes. During the RM, the patient must be sedated to apnea to avoid fighting the ventilator.

Before any RM, the patient must be hemodynamically stable. RMs should not be performed in patients with existing **barotrauma** or with a high likelihood of developing barotrauma (blebs or bullae) or in patients who are hemodynamically unstable. In addition, RMs are most effective and result in the least adverse reaction if performed early during ARDS. During and after the RM, the patient must be carefully monitored for hemodynamic and oxygenation instability and the development of barotrauma.

After an RM, the best way to identify the minimum effective PEEP level that maintains the lung open is to perform a decremental PEEP trial.[13,14,16] This trial is performed by changing the mode from PC-CMV to volume-controlled continuous mandatory ventilation (VC-CMV), V_T 4 to 6 mL/kg, inspiratory time 1.0 second or less, PEEP 20 to 25 cm H_2O, and rate set at the maximum that does not cause auto-PEEP.[17] After stabilization (3 to 5 minutes), dynamic compliance is measured.[17] PEEP is then decreased 2 cm H_2O, the patient allowed to stabilize (30 to 45 seconds), and measurement of dynamic compliance is repeated; this is continued until the PEEP level at which the compliance decreases is identified. In general, compliance at 20 to 25 cm H_2O PEEP is low and increases as PEEP is decreased; compliance then decreases as PEEP is decreased further. Open lung PEEP is the PEEP associated with the highest compliance. Set PEEP is open lung PEEP plus 2 cm H_2O.

After open lung PEEP is identified, the lung is again recruited because during the decremental PEEP trial derecruitment occurred. After recruitment, PEEP is set at the identified level, ventilation is adjusted using a lung protective V_T (4 to 8 mL/kg), and rate is adjusted to normalize PCO_2. After all is set, FiO_2 is decreased to the level that maintains PaO_2 in the range of 55 to 70 mm Hg. Repeat RMs may be needed if the patient did not respond to the initial RM or if the patient is disconnected from the ventilator and derecruitment occurs. A successful RM is one that allows the FiO_2 to be reduced to less than 0.5.

The use of RM has been documented in many case series; however, no data have been published indicating that outcome is improved as a result of RMs and decremental PEEP settings. Research is ongoing.

BOX 47.2 Effects of Positive Pressure Ventilation on System Other Than the Lungs

Increased intracranial pressure
Decreased cerebral perfusion pressure
Decreased renal blood flow
Decreased urinary output
Decreased sodium and potassium excretion
Increased plasma renin activity
Increased plasma aldosterone level
Increased vasopressin level
Decreased atrial natriuretic hormone level
Decreased liver and splanchnic perfusion
Increased serum bilirubin level
Decreased gastrointestinal function
Gastric mucosal ischemia
Development of stress ulcers
Gastric distention

RULE OF THUMB A lung RM is most likely to be successful if it is performed early in the course of ARDS. Ideally a lung RM should be performed once the patient is fully stabilized after intubation and initiation of mechanical ventilation. The longer the patient is mechanically ventilated, the less likely it is that the RM would be successful.

Increased Dead Space

The dead space fraction is increased with the institution of mechanical ventilation owing to inspiratory mechanical bronchodilation and the preferential ventilation of more nondependent alveoli, the reduction of blood flow away from ventilated alveoli, and the continued perfusion of basilar or dependent alveoli (see Fig. 47.5). This increase is concurrent with a decrease in $\dot{V}/\dot{Q}$ ratio.

Decreased Work of Breathing

Although improper ventilator management can increase WOB (poor patient–ventilator interaction, see Chapter 48 for details), one of the primary objectives of mechanical ventilation is to decrease WOB. PPV can significantly reduce WOB in patients with actual or impending respiratory muscle fatigue. RTs frequently see patients relax as the ventilator assumes a major portion of their WOB. To lessen WOB, ventilation must be sufficient to meet the patient's needs. Otherwise, a spontaneously breathing patient tends to resist the ventilator, and an asynchronous breathing pattern develops. Inappropriately applied PPV can result in alveolar hypoventilation and consequently a considerable increase in the patient's WOB.

Mode, trigger setting, and inspiratory flow have an effect on WOB. WOB consists of two components: (1) ventilator work (WOB_{vent}) occurring as the ventilator forces gas into the lungs and (2) patient work (WOB_{pt}) as the inspiratory muscles draw gas into the lungs. The magnitude of WOB_{pt} depends on compliance, resistance, and ventilatory drive and on ventilator variables,

such as trigger sensitivity, peak flow, cycling coordination, and V_T.[18,19]

Regardless whether flow or pressure triggering is selected, either should always be set as sensitive as possible without causing autotriggering. The less sensitive the setting, the greater the patient effort. In older generation ventilators, flow triggering was shown to require less effort than pressure triggering.[20] However, with the newest generation of ICU ventilators, both are equally effective.[21]

As described in Chapter 46, a mode of ventilation is a ventilatory pattern that can be described by identifying the control variable, breath sequence, and targeting scheme. The breath sequence may be thought of as being on a continuum from assuming very little to assuming all WOB. As the breath sequence is changed from continuous spontaneous ventilation (CSV) to CMV, the ventilator assumes more WOB. An example of this transition would be from CPAP to pressure support to CMV. In CPAP, a continuous spontaneous mode of ventilation, the patient assumes all WOB. The ventilator merely provides constant positive pressure throughout the patient's breathing cycle. The ventilator assumes more WOB during CMV. Pressure support is also an example of CSV. During pressure support ventilation (PSV), the patient determines breath timing (length of inspiration and expiration) and frequency. Depending on the set inspiratory pressure, the clinician may program the ventilator to provide a minimal to a maximal amount of WOB. In instances where the patient has no spontaneous efforts, all breaths during CMV are time triggered and all work performed is WOB_{vent}. Although it may be advantageous for the ventilator to assume all WOB for a while, extended periods of passive ventilation may cause diaphragmatic atrophy, which may unnecessarily prolong the need for mechanical ventilation and delay weaning. At initiation of patient-triggered pressure or volume modes, WOB_{pt} resumes.

During assisted ventilation, pressure-targeted modes are generally more capable of meeting patient ventilatory demands and minimizing WOB_{pt}.[22] As pressure level is increased, ventilatory muscles are unloaded, V_T increases for a given amount of patient effort, and WOB_{pt} decreases. Most clinicians increase pressure level until the breathing pattern approaches normal—that is, until the spontaneous ventilatory rate is 15 to 25 breaths/min and the spontaneous V_T is normal (5 to 8 mL/kg).

Measuring WOB is technically difficult. It is often accomplished by esophageal balloon monitoring, in which a balloon is placed in the distal third of the esophagus, and a pneumotachometer is attached to the airway (see Chapter 52). WOB is the integral of the esophageal pressure and V_T. Normal WOB is 0.6 to 0.9 J/L.[23]

MINIMIZING ADVERSE PULMONARY EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION

Decreasing Pressure

The main objective of mechanical ventilation is to provide a minute ventilation appropriate to achieve adequate alveolar ventilation and supplemental O_2 and PEEP to provide adequate arterial oxygenation.

MINI CLINI

Overcoming an Increase in the Work of Breathing

Problem

A patient's WOB is minimal during mechanical ventilation with an appropriate V_T and rate. As the ventilator support is gradually discontinued and the patient is expected to take over more of WOB, R_{aw} associated with breathing through an endotracheal tube may become clinically important. The RT must be able to recognize this problem readily and know how to correct it.

A patient has received mechanical ventilation in volume-controlled continuous mandatory ventilation mode for the past week. The patient's condition is now clinically stable, and ventilation is provided by PSV. As the PSV pressure level is reduced to 8 cm H_2O, the patient begins using accessory muscles to breathe, the spontaneous respiratory rate increases to 30 breaths/min, and the patient reports shortness of breath. Blood gas values are acceptable, and no abnormal lung sounds are present. What is the problem, and what should the RT do?

Solution

The patient may be experiencing excessive WOB because of R_{aw} associated with the endotracheal tube; a small sized tube or partial obstruction of the tube with secretions may be the problem. Other possibilities that should be considered include deterioration in the patient's cardiopulmonary status, but the normal blood gas values and lung sounds suggest the problem is not the lungs. Passing a suction catheter through the tube may help to identify the problem. If the catheter does not pass easily, the tube may be partially obstructed. Two options exist: change the tube or extubate the patient. Because the tube would need to be removed regardless of the choice, a trial extubation should be considered. Because this patient is at risk immediately after extubation, noninvasive ventilation should be started. If the patient cannot tolerate extubation, an appropriate-sized endotracheal tube can be reinserted.

Peak pressure is the result of the pressure required to overcome system resistance and compliance. Although there is no absolute maximum pressure, most practitioners try to avoid peak pressures greater than 40 cm H_2O. As the peak pressure approaches 40 cm H_2O, it is important to consider the causes. Factors that increase R_{aw} include airway edema, bronchospasm, and secretions and ETT obstruction. The RT can manage or avoid these problems by ensuring adequate humidity, bronchial hygiene (suctioning, airway care), and administration of bronchodilators and antiinflammatory drugs. Factors that increase the pressure needed to inflate the lung and overcome compliance include alveolar and interstitial edema, atelectasis, fibrosis, and chest wall restriction.

P_{plat} reflects mean maximum P_{alv}. P_{plat} of 28 cm H_2O or greater has an increased likelihood of causing lung injury.[4–6] If P_{plat} approaches 28 cm H_2O during volume ventilation, the V_T should be decreased so that the P_{plat} is less than 28 cm H_2O, or with pressure ventilation, target pressure should be set less than 28 cm H_2O.[5,24] The patient population where this guideline is most likely violated is the markedly obese patient who may require more than 20 cm H_2O PEEP. (See Chapter 30.)

Driving pressure is the difference between P_{plat} and total PEEP and should not exceed 15 cm H_2O.[7] As described earlier, the lower the driving pressure the lower the risk of mortality. Even in the markedly obese patient, if the V_T and PEEP are set properly the driving pressure can be kept below 15 cm H_2O, even when the P_{plat} exceeds 28 cm H_2O.

Mean airway pressure is decreased by decreasing inspiratory time, V_T, respiratory rate, PEEP, or PIP. Increased mean airway pressure reduces venous return and may reduce cardiac output.

RULE OF THUMB Driving pressure (plateau pressure minus PEEP) should be less than 15 cm H_2O. Driving pressure greater than 15 cm H_2O increase mortality and driving pressures less than 15 cm H_2O decrease mortality. Many consider the driving pressure the most important variable in relation to ventilator induced lung injury.

Positive End-Expiratory Pressure or Continuous Positive Airway Pressure

PEEP is the application of positive pressure at end-exhalation. PEEP is used primarily to improve oxygenation in patients with refractory hypoxemia. As a rule, refractory hypoxemia exists when PaO_2 cannot be maintained at greater than 50 to 60 mm Hg with FiO_2 0.50 or greater. PEEP improves oxygenation in these patients by maintaining alveoli open, restoring FRC, and decreasing physiologic shunting. The improved alveolar volume provided by PEEP allows a lower FiO_2. Other values such as lung compliance, shunt fraction, and PaO_2/FiO_2 ratio also may improve when PEEP is appropriately applied. PEEP may be indicated in the care of patients with COPD who have dynamic hyperinflation (auto-PEEP).[25,26] (See discussion later in this chapter.)

Beneficial and harmful effects are associated with the use of PEEP (Table 47.2). Detrimental effects of inappropriately high levels of PEEP include decreased cardiac output, increased pulmonary vascular resistance, and increased dead space. When one or more of these problems occur, PEEP is decreased to the previous level or to a value between the current level and the previous level. If cardiac output decreases and an increase in PEEP is necessary to maintain oxygenation, intravenous fluid, inotropic cardiac drugs, or both are administered to restore cardiac output.

PEEP is contraindicated in the presence of a tension pneumothorax. PEEP should be applied cautiously in patients with severe unilateral lung disease because PEEP would overinflate the lung with higher compliance. The result is lung overdistention and compression of adjacent pulmonary capillaries. Independent lung ventilation can be used to apply separate inspiratory and baseline pressures to the right and the left lung when severe unilateral lung disease is present.[27] PEEP is not contraindicated in the care of patients with increased ICP, caution must be used to prevent the application of PEEP from increasing ICP further. In general, if the head of the bed can be elevated to a height equal to the amount of PEEP applied, the hydrostatic pressure increase caused by the PEEP can by offset by the elevation of the head of the bed.

TABLE 47.2 Physiologic Effects of Positive End-Expiratory Pressure

Beneficial Effects of Appropriate PEEP	Detrimental Effects of Inappropriate PEEP
Restored functional residual capacity, avoids derecruitment	Increased pulmonary vascular resistance
Decreased shunt fraction	Potential decrease in venous return and cardiac output
Increased lung compliance	Decreased renal and portal blood flow
Decreased work of breathing	Increased intracranial pressure
Increased PaO_2 for a given FiO_2	Increased dead space

PEEP, Positive end-expiratory pressure.

RULE OF THUMB Refractory hypoxemia exists when PaO_2 cannot be maintained at greater than 50–60 mm Hg with FiO_2 0.50 or greater. This situation is an indication for PPV with PEEP or CPAP because an increased end-expiratory pressure with either of these modalities improves oxygenation by stabilizing lung open decreasing physiologic shunting.

Effects of Ventilatory Pattern

The most commonly used inspiratory flow patterns are constant or square and descending ramp during volume-controlled ventilation and exponential decay during pressure-controlled ventilation. In mechanical and computer models, a descending ramp (volume-controlled ventilation and pressure control ventilation) flow pattern improves gas distribution to lung units with long-time constants. The literature often refers to the descending ramp as a decelerating flow pattern. Similar findings in humans have been reported. Compared with a square flow waveform, a descending ramp has been shown to reduce peak pressure, inspiratory work, V_D/V_T, and $P(A-a)O_2$ without affecting hemodynamic values.[28] In addition, compared with volume-controlled ventilation with a square flow waveform, pressure-controlled ventilation with an exponential decay flow waveform may result in a higher PaO_2, lower $PaCO_2$, and lower PIPs. However, mean airway pressure is higher with pressure-controlled ventilation compared with volume-controlled ventilation because pressure rapidly increases to the set inspiratory pressure and remains constant throughout inspiration. During pressure-controlled ventilation, flow is responsive to patient demand. The ventilator delivers flow to the patient in proportion to patient demand. Flow is also greater at the onset of inspiration, resulting in V_T delivery at a time when the lungs are most compliant, the beginning of the breath. As a breath ends, flow is least, and the volume delivered is small. The result is a lower peak airway pressure for any given V_T.

In most spontaneously breathing persons, lower inspiratory flows improve gas distribution. However, during PPV, low inspiratory flow may lead to lengthy inspiratory times and air trapping if expiratory time is too short. High ventilator inspiratory flow allows more time for exhalation and reduces the incidence of air trapping. Avoidance of air trapping improves gas exchange and reduces WOB in patients with high ventilatory demands.[19,29]

An inflation hold also affects gas exchange. By momentarily maintaining lung volume under conditions of no flow, an inflation hold allows additional time for gas redistribution between lung units with different time constants. In both animal and human studies, increasing the length of an inflation hold decreases the V_D/V_T, $PaCO_2$, and inert gas washout time. Adding an inflation hold effectively increases total inspiratory time, shortening the time available for exhalation and predisposes patients with airway obstruction to auto-PEEP. In practice, an inflation hold

should be used only to obtain P_{plat} values. Because the technique prevents the onset of exhalation, asynchrony occurs if the patient is actively breathing.

Trigger Site and Work of Breathing

Studies have examined the effects of sensing a patient's inspiratory effort at the tip of the endotracheal tube rather than in the ventilator circuit, as is done with all ventilators. Triggering and managing gas delivery by measurement of pressure at the tip of the endotracheal tube decreases patient effort and improves synchrony; however, no practical system has been designed.[30] In addition, the efficiency of ventilator flow and pressure triggering seems to improve with each new generation of mechanical ventilator.

PHYSIOLOGIC EFFECTS OF VENTILATORY MODES

Volume-Controlled Ventilation Versus Pressure-Controlled Ventilation

Fig. 46.5 illustrates the important variables for volume ventilation modes. The figure shows that the primary variable to be controlled is the patient's minute ventilation. A particular ventilator may allow the operator to set minute ventilation directly. More frequently, minute ventilation is adjusted by means of a set V_T and frequency. V_T is a function of the set inspiratory flow and the set inspiratory time. Inspiratory time may be affected by the set frequency and, if the I:E ratio is set. The mathematical relationships among all these variables are shown in Table 47.3.

With pressure-controlled ventilation, the goal is also to maintain adequate minute ventilation. However (as the equation of motion shows), when pressure is controlled, V_T and minute ventilation are determined not only by the ventilator's pressure settings but also by the elastance and resistance of the patient's respiratory system. Minute ventilation and hence gas exchange are less stable in pressure-controlled modes than in volume-controlled modes. Fig. 46.6 shows the important variables for pressure-controlled ventilation. V_T is not operator set. It is the result of the patient inspiratory effort, the set inspiratory pressure, the patient's lung mechanics, and the inspiratory time. On most ventilators, the speed with which inspiratory pressure is achieved (i.e., the pressure rise time) is adjustable. That adjustment affects the shape of the pressure waveform and the mean airway pressure.

TABLE 47.3 Equations Relating the Important Parameters for Volume-Controlled and Pressure-Controlled Ventilation

Mode	Parameter	Symbol	Equation
Volume-controlled	Tidal volume (L)	V_T	$V_T = \dot{V}_E \div f$ $V_T = \dot{V}_I \div T_I$
	Mean inspiratory flow (L/min)	$\bar{\dot{V}}_I$	$\bar{\dot{V}}_I = 60 \times V_T \div T_I$ $\bar{\dot{v}}_I = \frac{\dot{v}_E \times TCT}{T_I}$
Pressure-controlled	Tidal volume (L)	V_T	$V_T = \Delta P \times C \times (1 - e^{-t/\tau})$
	Instantaneous inspiratory flow (L/min)	$\dot{v}_I$	$\dot{v}_I = \left(\frac{\Delta P}{R}\right) e^{-t/\tau}$
	Pressure gradient (cm H_2O)	ΔP	$\Delta P = PIP - PEEP$
Both modes	Exhaled minute ventilation (L/min)	$\dot{V}_E$	$\dot{V}_E = V_T \times f$
	Total cycle time or ventilatory period (s)	TCT	$TCT = T_I + T_E = 60 \div f$
	I:E ratio	I:E	$I{:}E = T_I : T_E = \frac{T_I}{T_E}$
	Time constant (s)	τ	$\tau = R \times C$
	Resistance (cm H_2O/L/s)	R	$R = \frac{\Delta P}{\Delta \dot{V}}$
	Compliance (L/cm H_2O)	C	$C = \frac{\Delta V}{\Delta P}$
	Elastance	E	$E = \frac{1}{C}$
	Mean airway pressure (cm H_2O)	$\bar{P}_{aw}$	$\bar{P}_{aw} = \left(\frac{1}{TCT}\right) \int_{t=0}^{t=TCT} P_{aw} dt$
Primary variables	Pressure (cm H_2O)	P	
	Volume (L)	V	
	Flow (cm H_2O/L/s)	$\dot{V}$	
	Time (s)	τ	
	Inspiratory time (s)	T_I	
	Expiratory time (s)	T_E	
	Frequency (breaths/min)	f	
	Base of natural logarithm (≈2.72)	e	

Continuous Mandatory Ventilation

CMV (also referred to as *assist/control*) is a mode of ventilation in which total ventilatory support is provided by the mechanical ventilator. All breaths are mandatory and delivered by the ventilator at a preset volume or pressure, breath rate, and inspiratory time. If the patient has spontaneous respiratory efforts, the ventilator delivers a patient-triggered breath. If patient efforts are absent, the ventilator delivers time-triggered breaths. The clinician needs to set an appropriate trigger level and flow rate for the patient in this mode of ventilation. There is a potential for the ventilator to autotrigger when the trigger level is set too sensitive. As a result, hyperventilation, air trapping, and patient anxiety often ensue. However, if the trigger level is not sensitive enough, the ventilator does not respond to the patient's inspiratory efforts, which results in increased WOB.

Occasionally, all attempts to optimize patient comfort, reduce WOB, and achieve the goals of this mode of ventilation are futile. In cases in which this mode is poorly tolerated and spontaneous triggering is counterproductive to the goals set for a particular patient, sedation or paralysis or both may be required. These agents may be used to minimize patient effort and normalize WOB.

Volume-Controlled Continuous Mandatory Ventilation

VC-CMV is indicated when a precise minute ventilation or blood gas parameter, such as $PaCO_2$, is therapeutically essential to the care of patients.[29] Theoretically, volume control (with a constant inspiratory flow) (Fig. 47.8) results in a more even distribution of ventilation (compared with pressure control) among lung units with different time constants where the units have equal resistances but unequal compliances (e.g., ARDS).[30]

During VC-CMV, volume is guaranteed, but airway pressure varies depending on changes in the patient's lung mechanics. A reduction in lung compliance or an increase in resistance causes higher peak airway pressures. Care should also be taken when setting the inspiratory flow. Avoid setting a flow that fails to match patient needs or exceeds patient demand. An insufficient flow rate would result in an imposed increase in the patient's WOB and a concomitant increase in O_2 consumption. The inspiratory phase may be prematurely shortened if the set inspiratory flow exceeds patient demands. Meticulous patient monitoring and use of VC-CMV allow the clinician to achieve precise and predictable physiologic results. VC-CMV results in gas exchange and hemodynamic stability at the same level as PC-CMV, and either can be used effectively during controlled ventilation; the patients are passively ventilated. However, when the patient is actively triggering the ventilator, better patient ventilator synchrony and less WOB are achieved during PC-CMV than VC-CMV.

Pressure-Controlled Continuous Mandatory Ventilation

Similar to VC-CMV, PC-CMV can be used as a basic mode of ventilatory support. The primary difference between volume-controlled and pressure-controlled ventilation is the control variable with which the clinician is most concerned.[31,32] Theoretically, pressure control (with a constant inspiratory pressure) (Fig. 47.9) results in a more even distribution of ventilation (compared with volume control) among lung units with different time constants when units have equal compliances but unequal resistances.[30] The instability of V_T caused by airway leaks can be minimized by using pressure-controlled rather than volume-controlled ventilation. Increased V_T stability may lead to better gas exchange and lower risk of pulmonary volutrauma.[33]

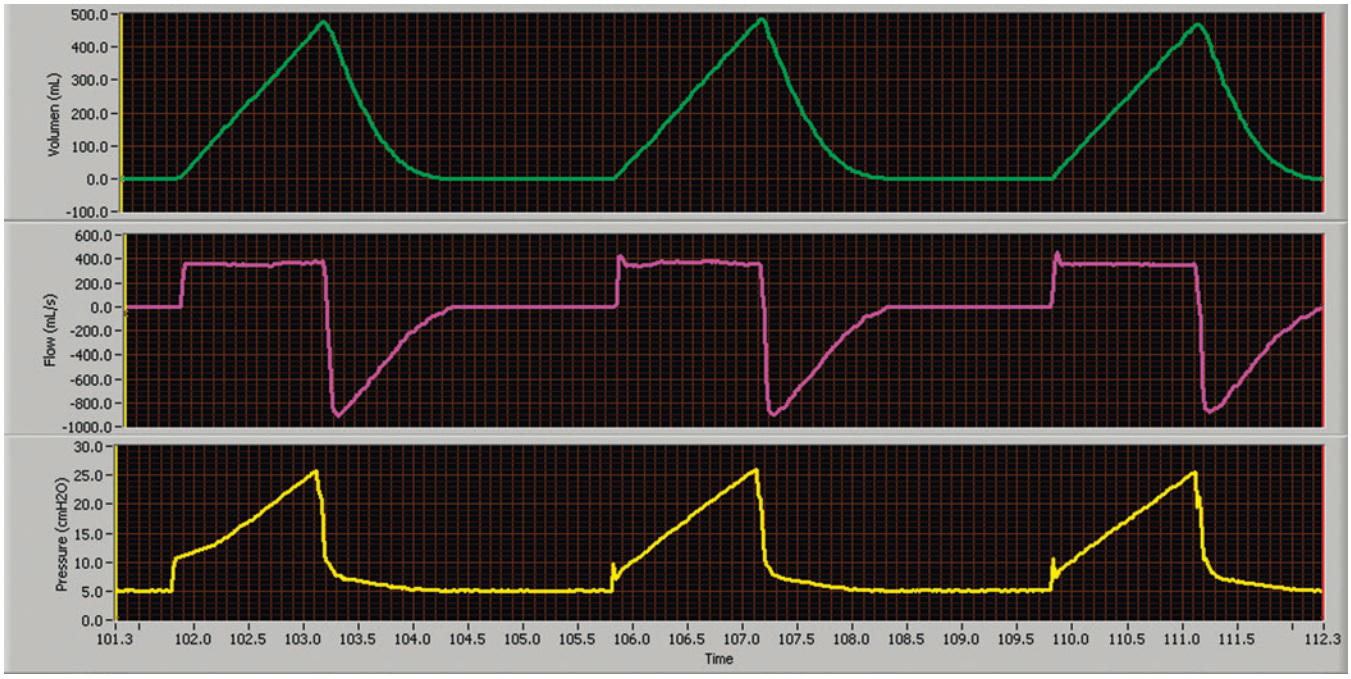

Fig. 47.8 Volume-Controlled Continuous Mandatory Ventilation. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform. V_T, Tidal volume.

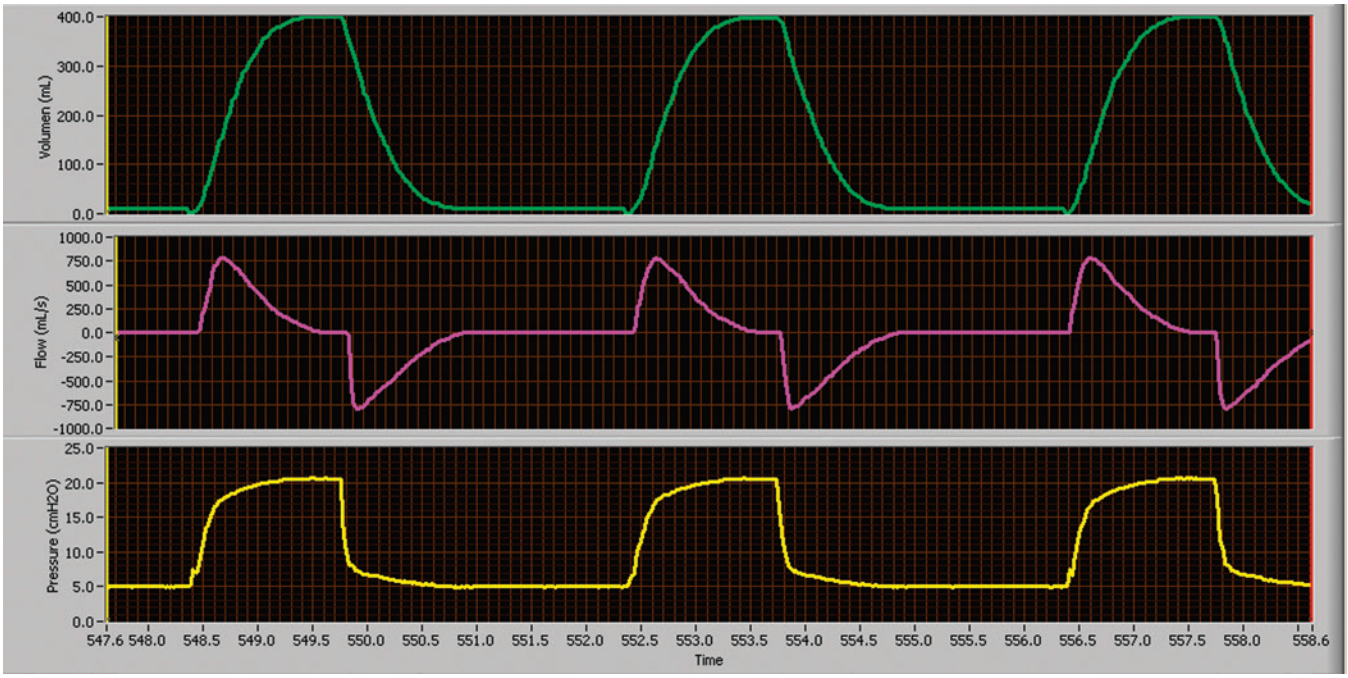

Fig. 47.9 Pressure-Controlled Continuous Mandatory Ventilation. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform. *V_T,* Tidal volume.

Use of a rectangular pressure waveform opens alveoli earlier in the inspiratory phase during PC-CMV and results in a higher mean airway pressure than VC-CMV with a rectangular flow waveform, allowing more time for oxygenation to occur.[34] However, in PC-CMV, inspiratory flow is not a parameter set by the clinician. It is variable and dependent on patient effort and lung mechanics, improving patient comfort and patient-ventilator synchrony. However, as lung mechanics or patient effort or both change, volume delivery (V_T and minute ventilation) changes.

Because V_T is not directly controlled, the driving pressure (P_{plat} – PEEP) is the primary parameter used to alter the breath size and CO_2 tensions. Typically, PIP is adjusted to provide the patient with a V_T within the desired range.[35] As with VC-CMV, the mandatory breath rate set by the clinician depends on the presence of ventilatory muscle activity and the severity of lung disease. When higher mandatory breath rates are needed (>30 breaths/min), it is essential for the clinician to provide a sufficient expiratory time and prevent air trapping.

As long as lung mechanics and patient effort remain constant, the volume and peak flow delivered to the patient remain unchanged.[36] When patient effort decreases, or compliance decreases, or resistance increases, less volume is delivered for the preset pressure for each breath. Conversely, improvements in patient effort and mechanics can dramatically increase the volume delivery to the patient in this mode. Close V_T monitoring is required to avoid ventilator-induced hyperventilation or hypoventilation and ventilator-induced lung injury.

The patient's cardiac index and O_2 consumption should be closely monitored as well. Higher mean airway pressures may impair cardiac output. In addition, PC-CMV with IRV can lead to the development of auto-PEEP, which can impair venous return, compromise O_2 delivery to the tissues, and result in marked air trapping.[37]

Pressure-Controlled Inverse Ratio Ventilation

PC-CMV may be used to accomplish pressure-controlled inverse ratio ventilation (PC-IRV), by increasing the inspiratory time directly or by increasing the I:E ratio to the desired value. PC-IRV is defined as pressure-controlled ventilation with an I:E ratio greater than 1:1 (Fig. 47.10). Although some studies have shown improvement in oxygenation with PC-IRV versus CMV with PEEP, others have shown concurrent decreases in cardiac output.[31,38] In general, if applied PEEP in normal ratio ventilation is equal to total PEEP (applied and intrinsic PEEP) in PC-IRV, the oxygenation benefits are equivalent without the marked depression in cardiac output.

Intermittent Mandatory Ventilation

As a partial support mode, IMV allows or requires the patient to sustain significant WOB. The level of mechanical support needed depends on the specific physiologic process causing the need for mechanical ventilation, presence or degree of ventilatory muscle weakness, and presence and severity of lung disease. In this mode, mandatory breaths are delivered at a set rate. Between the mandatory breaths, the patient can breathe spontaneously at his or her own V_T and rate (Fig. 47.11). Breaths can occur separately (e.g., IMV); breaths can be superimposed on each other (e.g., spontaneous breaths superimposed on mandatory breaths, as in bilevel positive airway pressure [bilevel PAP] or airway pressure release ventilation [APRV]); or mandatory breaths can be superimposed on spontaneous breaths, as in

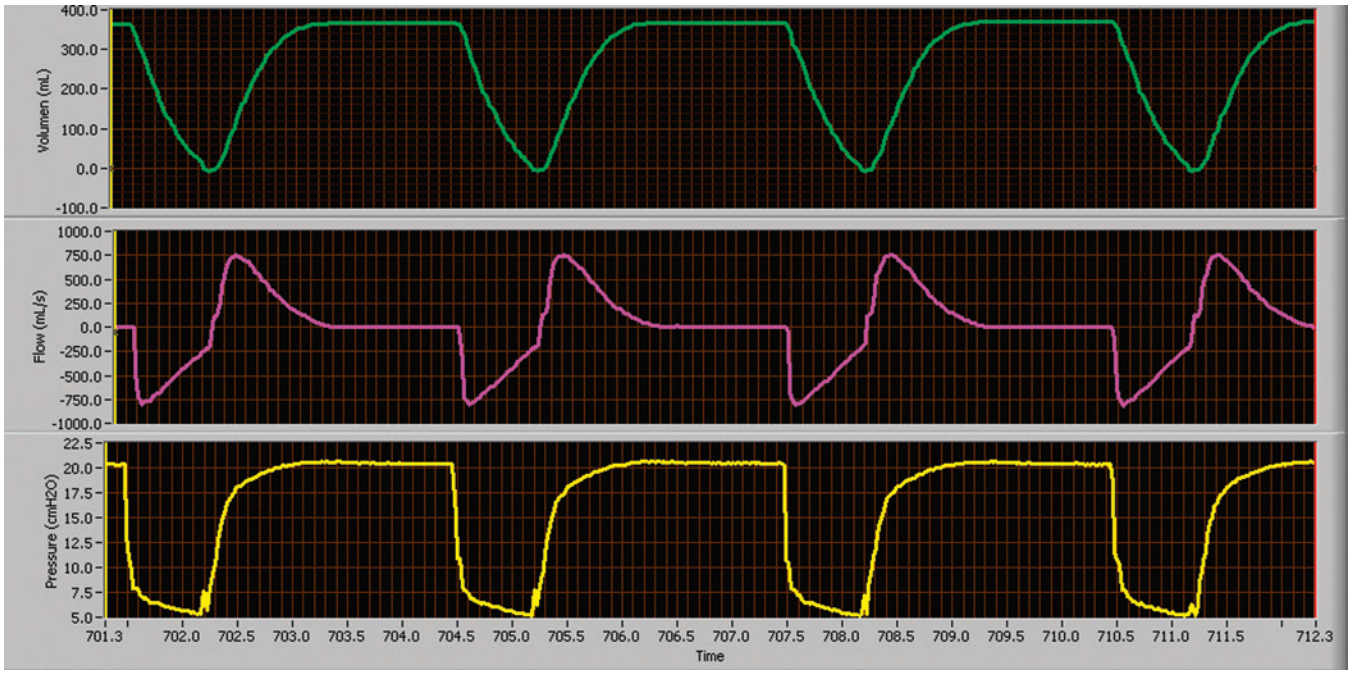

Fig. 47.10 Pressure-Controlled Inverse Ratio Ventilation. The flow waveform for any breath does not return to baseline before the next breath, resulting in auto–positive end-expiratory pressure and an increase in mean airway pressure. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform. *V_T,* Tidal volume.

MINI CLINI

Using Pressure-Controlled Ventilation

Problem

The RT is caring for a 20-year-old patient with ARDS. The patient has no respiratory effort. Current ventilator settings are as follows:
Mode: VC-CMV
V_T: 400 mL
Frequency: 25 breaths/min
PEEP: 14 cm H_2O
FiO_2: 1
PIPs monitored on the ventilator: 35–40 cm H_2O
Mean airway pressure: 20–22 cm H_2O
Plateau pressure: 27 cm H_2O

An arterial blood gas is obtained, which reveals pH 7.28, PCO_2 41 mm Hg, and PO_2 50 mm Hg. The physician would like to employ pressure-controlled ventilation. What are the appropriate initial settings in PC-CMV mode to maintain the current minute ventilation?

Solution

Initial ventilator setting would be as follows:
Ventilator frequency, PEEP, and FiO_2: the same
Frequency: 25 breaths/min
PEEP: 14 cm H_2O
FiO_2: 1

To keep the minute ventilation constant, the RT needs to set the PIP high enough to deliver the same V_T as in volume control (400 mL).

1. Calculate the patient's respiratory system compliance:

$$\begin{aligned}\text{Compliance} &= V_T/P_{plat} - \text{total PEEP}\\ &= 400\,\text{mL}/27\,\text{cm}\,H_2O - 14\,\text{cm}\,H_2O\\ &= 31\,\text{mL/cm}\,H_2O\end{aligned}$$

2. Calculate the pressure limit in PC-CMV mode to achieve the target V_T. Because the pressure limit is measured relative to PEEP on this ventilator, the equation is:

$$\begin{aligned}\text{Ventilating pressure} &= V_T/\text{Compliance}\\ &= 400\,\text{mL}/31\,\text{mL/cm}\,H_2O\\ &= 13\,\text{cm}\,H_2O\\ \text{PIP in PC} &= \text{ventilating pressure} + \text{PEEP}\\ &\text{PC set } 13\,\text{cm}\,H_2O + \text{peep } 14\,\text{cm}\,H_2O\\ &\text{or } 27\,\text{cm}\,H_2O\end{aligned}$$

A shortcut is to realize that the required pressure limit is the P_{plat} on VC-CMV. The PIP (relative to atmospheric pressure) is 27 cm H_2O.

high-frequency ventilation administered during spontaneous breathing. Spontaneous breaths may be assisted (e.g., PSV) (Fig. 47.12) or unassisted.

When the mandatory breath is patient-triggered, modern day ventilators deliver the mandatory breath in synchrony with the patient's inspiratory effort. If no spontaneous efforts occur, the ventilator delivers a time-triggered breath. Because spontaneous breaths decrease pleural pressure, ventilatory support with IMV usually results in a lower mean intrathoracic pressure than CMV, which can result in a higher cardiac output.[39]

When used to wean a patient from mechanical ventilation, the intent of IMV is to provide respiratory muscle rest during the mandatory breaths and exercise during spontaneous breaths. However, studies have shown that IMV increases the WOB,

MINI CLINI

Determining Appropriate Ventilator Rate

Problem

A 36-year-old woman with traumatic brain injury was intubated in the emergency department with a 7-mm endotracheal tube and transferred to the RT in the neurointensive care unit. She is paralyzed and sedated. Her current ventilator settings are as follows:

Mode: VC-CMV

V_T: 405 mL

Frequency: 15 breaths/min

FiO_2: 0.5

The pulse oximeter displays 97%, and end-tidal CO_2 monitor is reading 49. The patient's weight is estimated at 45 kg. End-tidal CO_2 is stable and 4 mm Hg higher than $PaCO_2$. The clinical goal is to minimize ICP. Because intracranial blood flow is inversely proportional to $PaCO_2$, ventilation should be increased to maintain $PaCO_2$ at approximately 35–40 mm Hg. The RT needs to make appropriate ventilator changes to achieve the target $PaCO_2$.

Discussion

The current V_T is already large at 8 mL/kg. The increase in ventilation must be achieved by increasing frequency. Because the patient is paralyzed, the ventilation level is controlled by the set frequency, and $PaCO_2$ is predictable. The new frequency required is calculated using the following equation:

$$\text{Required frequency} = \text{Current frequency} \times \text{Current } PaCO_2 / \text{Desired } PaCO_2$$

$$\text{Required frequency} = 15 \text{ breaths/min} \times 49 \text{ mm Hg}/35 \text{ mm Hg} = 21 \text{ breaths/min}$$

asynchrony and weaning prolongs the duration of mechanical ventilation compared with PSV and spontaneous breathing trials.[40,41] In general at this stage in the development of ventilatory support we would recommend against the routine use of SIMV.

Volume-Controlled Intermittent Mandatory Ventilation

Volume-controlled intermittent mandatory ventilation (VC-IMV) has been advocated for patients with relatively normal lung function recovering from sedation or rapidly reversing respiratory failure.[42,43] However, the use of IMV has greatly decreased over the years in favor of VC-CMV, PC-CMV, and PSV, and there are no specific situations in adults where IMV would be the optimal mode.

Pressure-Controlled Intermittent Mandatory Ventilation

PC-IMV has been traditionally associated with mechanical ventilation of infants not only because of their oxygenation problems but also because traditionally it had been difficult to control V_T at such small values.[44,45]

Liberation from this mode involves the gradual reduction of the PIP and the mandatory breath rate. As lung compliance improves, adjustments in PIP are necessary to prevent overdistention of the lung. Adjustments in PIP and set mandatory breath rate are critical to prevent hyperventilation.

Airway Pressure Release Ventilation

A mode related to both PC-IRV and PC-IMV is APRV, in which the patient breathes spontaneously throughout periods of high and low applied CPAP (Fig. 47.13).[46] APRV intermittently

decreases or "releases" the airway pressure from an upper pressure (P_{high}) or CPAP level to a lower pressure (P_{low}) or CPAP level. The pressure release usually lasts approximately 0.2 to 1.5 seconds depending on whether or not air trapping is desired. In Fig. 47.13, inspiratory time is longer than expiratory time, and spontaneous breaths are superimposed on this mandatory pattern of pressurization and release. Spontaneous breaths may be supplemented by PSV. This is a feature of APRV available on some ventilators, where APRV is referred to as *bilevel ventilation.* In APRV, the I:E ratio is usually greater than 1 : 1, which is similar to PC-IRV, but APRV allows spontaneous breathing throughout inspiratory and expiration.[47]

APRV also provides ventilation and oxygenation without adversely affecting hemodynamic values because of the periodic reductions in intrathoracic pressure during the spontaneous breaths. In addition, peak airway pressure during APRV may be less than with VC-IRV for comparable oxygenation and ventilation.[48] APRV compared with conventional volume-controlled or pressure-controlled SIMV showed that with APRV there was a decrease in peak airway pressures, improved hemodynamics, and a decreased need for vasopressor and inotropic support.[49] However, the cost of these potential benefits is patient effort; WOB is markedly increased and P_{TP} is excessive, potentially inducing lung injury during APRV.[47] There are no data to indicate a better outcome with APRV than with other approaches to ventilatory support when a similar approach to managing oxygenation is used. Specific indications for APRV are unclear. Recent data imply that APRV results in greater mortality in pediatric patients than conventional ventilatory modes of ventilation,

Continuous Spontaneous Ventilation

Spontaneous breath modes include modes in which all breaths are initiated and ended by the patient. The level of support these modes of ventilation provide determines the amount of WOB the patient ultimately assumes. CPAP, PSV,[50] automatic tube compensation (ATC), proportional assist ventilation (PAV), and neurally adjusted ventilatory assist (NAVA) are continuous spontaneous breath modes.[51]

Continuous Positive Airway Pressure

CPAP is spontaneous breathing at an elevated baseline pressure (Fig. 47.14). Breaths are patient-triggered and cycled.[52,53] V_T depends on patient effort and lung mechanics. CPAP increases P_{alv} and maintains alveoli open. In contrast to NPV and PPV, airway pressure with CPAP is theoretically constant (baseline pressure ±2 cm H_2O) throughout the respiratory cycle. Because airway pressure does not change, CPAP does not provide ventilation. For gas to move into the lungs during CPAP, the patient must create a spontaneous P_{TA} gradient. Although NPV and PPV produce the pressure gradients needed for gas flow into the lungs, CPAP maintains alveoli at greater inflation volume, restoring FRC. An important physiologic feature of CPAP is that as alveoli are maintained open, FiO_2 needed to maintain adequate PaO_2 may decrease. Oxygenation becomes more efficient at any given FiO_2, as measured by PaO_2/FiO_2 ratio and shunt fraction. The potential side effects associated with PPV also exist for CPAP but usually to a lesser degree.

Pressure Support Ventilation

PSV is a form of PC-CSV that assists the patient's inspiratory efforts (Fig. 47.15). At very low levels of support, this mode unloads WOB the ventilator circuitry imposes on the respiratory muscles.[54] If the level of support is maximized, the ventilator may assume all WOB.[55] The result of high levels of support is a reduction in the respiratory rate, reduction in respiratory muscle activity, reduction in O_2 consumption, and improvement or stabilization of spontaneous V_T.[56,57] However, the positive attributes of this mode of ventilation can be negated if ventilator parameters are not properly set. The ventilator must be able to detect spontaneous patient effort. It is critical for the clinician to adjust the trigger sensitivity correctly. Of equal importance is the clinician-set rise time, the time required for the ventilator to reach the inspiratory pressure limit, and termination criteria, the minimal flow resulting in cycling to exhalation (see Chapter 48). Ventilator graphics are often helpful when adjusting these parameters and optimizing patient–ventilator synchrony.

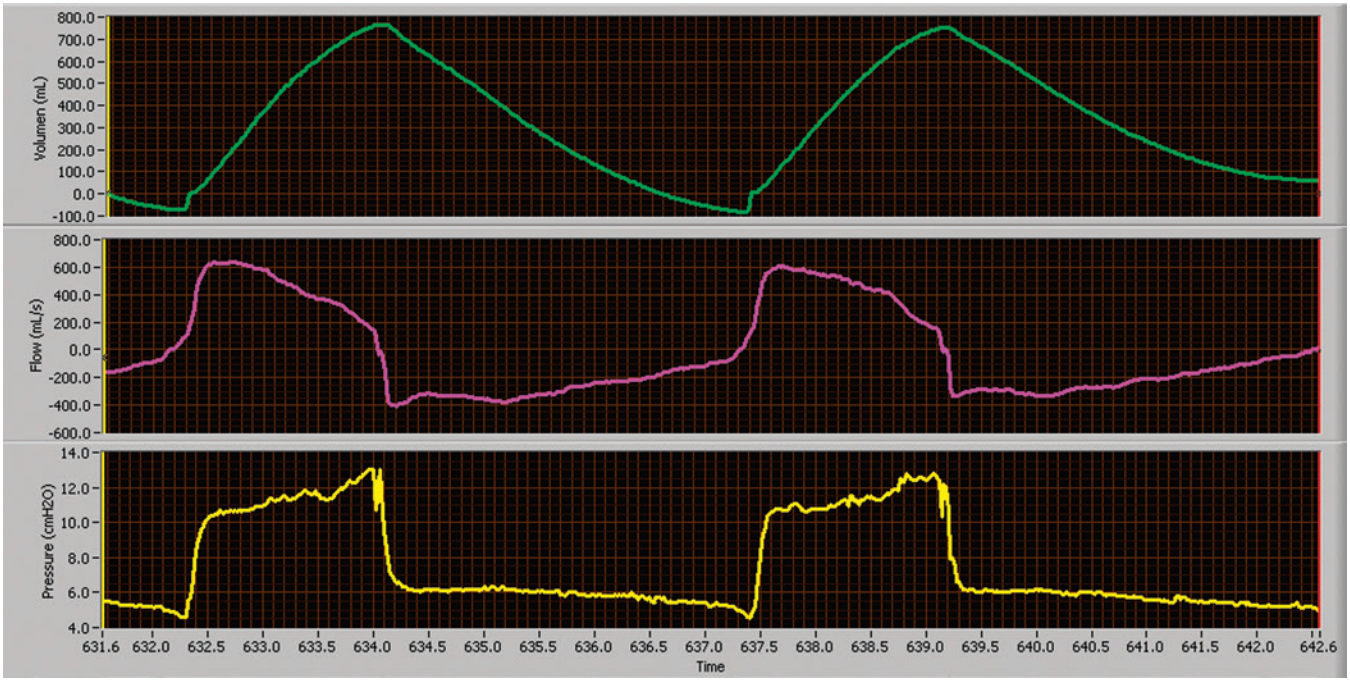

Fig. 47.15 Pressure Support Ventilation. *Top,* V_T; *middle,* flow; *bottom,* airway pressure waveform. V_T, Tidal volume.

Regardless of the level of support provided, the patient has primary control over the breath rate and inspiratory time and flow rate delivered during this mode of assisted ventilation. The V_T resulting from a PSV breath depends on the preset pressure level, patient effort, and mechanical forces opposing ventilation (lung–chest wall compliance and R_{aw}). Of all of the classic modes of ventilation, PSV exerts the least control over the patient's ventilatory pattern and as a result should improve patient-ventilator synchrony. Since the first description of PSV in 1982, it has been used either to overcome the imposed resistance associated with the artificial airway or to provide ventilatory support with minimal control.[58] PSV is useful in any patient with an intact ventilatory drive and a stable ventilatory demand.

Bilevel PAP (BiPAP; Respironics, Inc., Murrysville, PA) is simply PSV with PEEP applied noninvasively.[59] With bilevel PAP, inspiratory positive airway pressure (or PSV) and PEEP are set. The duration of inspiratory positive airway pressure and expiratory positive airway pressure can be independently adjusted to set the I:E ratio. Although it was originally developed to enhance the capabilities of home CPAP systems used for management of obstructive sleep apnea, bilevel PAP has been successfully used in the home and the hospital for noninvasive ventilatory support of patients with acute and chronic respiratory failure.[60] (See Chapter 50 for details.)

Example. An example of the use of PC-CSV is noninvasive PSV and PEEP in the management of a patient with COPD in an acute exacerbation. As described in detail in Chapter 50, noninvasive ventilation has been shown in this setting to decrease the frequency of intubation, length of mechanical ventilation, development of ventilator-associated pneumonia, and patient mortality.

Proportional Assist Ventilation

PAV is based on both the mechanics of the total respiratory system and the resistive properties of the artificial airway; that is, the ventilator delivers a pressure assist in proportion to the patient's desired V_T (volume assist) and to the patient's instantaneous inspired flow (flow assist). The response of these two aspects of ventilatory assistance is automatically adjusted to meet changes in the patient's ongoing ventilatory demand. This algorithm is based on the law of motion as it applies to the respiratory system:

$$P_{musc} + P_{appl} = (Volume \times E) + (Flow \times R)$$

where P_{musc} is pressure generated by the respiratory muscles, P_{appl} is pressure applied by the ventilator, and E and R are elastic and resistance properties of the respiratory system. Assuming that E and R are linear during inspiration, the instantaneous flow and volume to be delivered are proportional to the resistive and elastic WOB. The ventilator continuously measures the instantaneous flow and volume and periodically measures the E and R. Using this information, the ventilator software adjusts gas delivery by estimating P_{musc} and assisting P_{musc} in a proportional manner, the percentage of support set by the clinician. The patient is the determinant of the ventilatory pattern. Patients are given the freedom to select a ventilatory pattern that is rapid and shallow or slow and deep. If the patient desires a small V_T, a low level of pressure is applied, and if a large V_T is desired, a high pressure is applied. The ventilator does not force any control variable except the unloading of E and R in a proportional manner. See Chapter 46 for details on operation of PAV.

Numerous studies have evaluated the effect of PAV during noninvasive PPV.[61–65] Most of these comparisons were between

PAV and PSV,[61,65] and in almost all of these comparisons the patients evaluated had chronic respiratory failure and were in an acute exacerbation. Patients managed with PAV had a lower refusal rate, had a more rapid reduction in respiratory rate, and developed fewer complications.[63,64] In these studies, gas exchange and respiratory pattern did not differ between PSV and PAV, but the patients ventilated with PAV were more comfortable. PAV has also been shown to be essentially equivalent to PSV in stable patients with chronic ventilatory failure[62] and in patients with acute cardiogenic pulmonary edema.[65]

PAV has been most widely studied during invasive mechanical ventilation.[66–68] As with the evaluation of PAV in other settings, most of the comparisons focused on the physiologic response observed when PSV is changed to PAV. In general, during invasive ventilation, the change from PSV to PAV results in lower V_T, more rapid respiratory rate, lower peak airway pressure, and lower mean airway pressure without significant changes in gas exchange or hemodynamics.[69–71] In a randomized comparison of PAV versus PSV each for a 48-hour period in a series of critically ill patients,[68] the percentage of patients' failing the transition to PAV or PSV differed, 11% failing PAV versus 22% failing PSV. In addition, the proportion of patients developing asynchrony was greater with PSV versus PAV. The current data on PAV indicate it can sustain the same patients as PSV—patients who can breathe spontaneously and manage their ventilator drive normally.

Neurally Adjusted Ventilatory Assist

From a conceptual perspective, NAVA is essentially the same as PAV except that PAV responds to changes in airway pressure and flow, whereas NAVA responds to changes in diaphragmatic electromyograph (EMG) activity. However, for NAVA to function properly, a specially designed nasogastric catheter with a 10-cm length of EMG electrodes must be in place. Both PAV and NAVA respond to patient effort providing ventilatory support in a proportional manner. The clinician does not set pressure, volume, flow, or time in either mode. The only parameter set is the proportion of effort unloaded by the ventilator; in NAVA, this is set as the number of cm H_2O pressure applied per microvolt of inspiratory diaphragmatic EMG activity.

NAVA responds similarly to PAV; when compared with pressure support, NAVA results in low airway pressures, smaller tidal volumes, more rapid rates, and increased patient–ventilator synchrony.[72,73] PEEP titration also affects baseline diaphragmatic EMG activity. As PEEP is increased, EMG activity decreases. Minimal EMG activity seems to correspond to optimal PEEP level.[74]

NAVA application in neonates results in similar outcomes as observed in adults.[75,76] After the change to NAVA, V_T tends to decrease, respiratory rate to increase, and peak diaphragmatic EMG activity to decrease. In addition, despite the open ventilating system (uncuffed artificial airway), triggering and cycling are still primarily neurally activated.[75,76]

The most important advantage of PAV and NAVA over traditional modes of ventilation is improved synchrony. The specific indications for PAV and NAVA are not fully established; however, both can be reasonably used in any patient with an intact ventilatory drive. The primary indication would be a patient with a significant level of asynchrony.

Automatic Tube Compensation

ATC is similar to the flow assist aspect of PAV but considers only the resistance of the endotracheal tube.[77] ATC is an adjunct that automatically adjusts the airway pressure to compensate for endotracheal tube resistance to gas flow by maintaining tracheal pressure constant at the baseline level.[77] The goal is to eliminate WOB imposed by the endotracheal tube. In ATC, the RT inputs into the ventilator the type and size of artificial airway (endotracheal tube or tracheostomy tube) and the percentage compensation desired (10%–100%). The ventilator continuously measures flow and calculates the amount of pressure needed to overcome the resistance of the airway (pressure = resistance × flow). As a result, the greater the inspiratory demand, the greater the pressure applied. Pressure varies throughout the breath.

ATC may be applied during inspiration (positive airway pressure) or during both inspiration and expiration (negative airway pressure). However, expiratory ATC may result in early airway closure and increased air trapping. ATC has been referred to as *electronic extubation,* meaning that if the airway pressure is low during inspiration (5 to 7 cm H_2O), it is simply overcoming the resistance of the endotracheal tube with a normal inspiratory effort.[78] Consequently, many clinicians consider this an indication that spontaneous ventilation can be maintained without ventilatory support and the patient should be considered for extubation. Although in theory the use of ATC to wean patients appears ideal, no data to date have indicated that ATC weans patients faster than spontaneous breathing trials.

Adaptive Modes and Dual Control

The first adaptive control/dual control mode was described by Amato and colleagues.[79] Their major finding was that the ventilatory workload imposed on the inspiratory muscles during volume-assured PSV was significantly reduced using dual control. In this mode, pressure support is combined with volume control. However, this benefit was due to the fact that inspiration started out in pressure support and stayed there unless the V_T target was not met. The improvement was mostly a result of the improved synchrony between the patient and the machine. These investigators did not show a specific benefit of the actual dual nature of the mode (i.e., switching from pressure support to volume control), and no evidence has been published in the literature since then supporting this mode. Anecdotal reports indicate that it is difficult to adjust pressure, volume, and flow settings to make the mode work properly, in particular, if the mechanical properties of the patient's respiratory system are changing rapidly.

Pressure-regulated volume control (PRVC), or PC-CMV, and *volume support (VS)*, or PC-CSV, are examples of adaptive control/dual control modes. PRVC is based on pressure-controlled ventilation, and VS is based on PSV. In both modes, the ventilator attempts to maintain a target V_T by adjusting the pressure level based on the previous breath. When a clinician places a patient in PRVC, a target V_T, minimal breath rate, and maximum (i.e., alarm) pressure limit are clinician set, whereas for a patient placed

in VS, a target V_T and maximum (i.e., alarm) pressure limit are clinician set. In both modes, once the patient is connected to the ventilator, the patient–ventilator interaction that occurs in the first few breaths is critical. Initially, the ventilator calculates total system compliance. On the succeeding three or four breaths, the ventilator monitors the peak airway pressures and expiratory V_T. The ventilator determines the pressure level necessary to deliver the clinician-set "target" V_T, for the given total system compliance.

The patient–ventilator interaction is monitored on a breath-by-breath basis. If the patient's lung compliance improves (or patient effort increases), the ventilator delivers subsequent breaths at a lower pressure level to maintain the target V_T. This adjustment by the ventilator reduces the risk of alveolar overdistention and volutrauma. Conversely, the ventilator responds to worsening pulmonary compliance (or decreasing patient effort) by increasing the pressure limit until the V_T is achieved. The ventilator makes pressure level changes in small increments, 1 to 3 cm H_2O per breath, and does not exceed the maximum pressure limit set by the clinician. These automatic ventilator responses to changes in a patient's lung mechanics minimize the risk of ventilator-induced hyperventilation or hypoventilation. The desired outcome is a stable or consistent minute ventilation and enhanced patient comfort. However, the major problem with these modes is that the ventilator cannot distinguish between the patient improving and heightened levels of ventilator demand. If patient demand results in a larger V_T, the ventilator ventilates less.[80]

In most ventilators, pressure can be decreased all the way to the PEEP level. This situation can lead to ventilatory failure.[80] Both RPVC and VS should be used very cautiously in all patients with a normal or increased ventilatory demand. Randomized comparison between these modes and other, more traditional, modes failed to show any outcome benefit.[81,82]

Example. PRVC or VS has been used in infants with respiratory distress syndrome.[83] Rapidly changing pulmonary mechanics from surfactant administration are associated with complications such as pulmonary air leaks, intraventricular hemorrhage, and bronchopulmonary dysplasia. These adaptive modes respond to changes in a patient's lung mechanics and may reduce the incidence of these common complications.

Adaptive support ventilation (ASV), or PC-IMV, is an example of optimal control in adaptive ventilation. ASV is a pressure-targeted mode that optimizes the relationship between V_T and respiratory frequency based on lung mechanics as predicted by Otis.[84] ASV uses a pressure ventilation format establishing a ventilatory pattern that minimizes WOB and auto-PEEP, while limiting peak airway pressure. In this regard, ASV is similar to PC-CMV and PRVC in its gas delivery format. It differs from PC-CMV and PRVC by its additional algorithmic control of the ventilatory pattern.[85] ASV automatically determines the V_T and respiratory rate that best maintains the peak pressure below the target level.[86] The clinician inputs the patient's ideal body weight, high pressure limit, PEEP, FiO_2, inspiratory rise time, flow cycle percentage, and percentage of predicted minute volume desired. The ventilator periodically measures dynamic compliance and the respiratory time constant and determines the desired mandatory rate. Ideal body weight is used by the ventilator to calculate the minute volume, which is divided by the rate for determination of V_T.[87] The newest adaption to ASV is referred to as Intellivent. With this adaption the ventilator operates the same as with ASV but in addition has the ARDSnet PEEP/FIO_2 tables programed into the ventilator algorithm. Thus, as the patient's SpO_2 changes, PEEP and FIO_2 are adjusted as dictated by the ARDSnet protocols.

When ASV is compared with VC-IMV, ASV decreases inspiratory load and improves patient–ventilator synchrony.[88] Others have shown that ASV resulted in a shorter duration of intubation than VC-IMV in postoperative cardiac patients with no complications.[89] More recently, Belliato and colleagues[90] comparing PC-IMV (optimal) to ASV showed that the ventilator was able to differentiate between patient types and select appropriate settings.[91] Using a lung model, Sulemanji and coworkers[92] determined that ASV could provide better lung protection than a fixed V_T of 6 mL/kg ideal body weight. ASV control has been adapted to respond to end-tidal CO_2 levels.[92] This new adaptation allows specific algorithms to be selected based on patient diagnosis: ARDS, COPD, brain injury, or healthy lung. This mode is the most sophisticated of the closed loop control modes available on ICU ventilators at the present time. However, additional study is needed to determine fully the type of patient in whom ASV is most useful. Current data would indicate ASV works very well in patients under controlled approaches to ventilatory support, but additional data in spontaneously ventilated patients are needed before it can be recommended in these patients.

RULE OF THUMB Most patients requiring ventilatory support can be effectively ventilated with volume assist/control, pressure assist/control, and PSV modes.

Patient Positioning to Optimize Oxygenation and Ventilation

Patients receiving mechanical ventilation are turned frequently, usually at least every 2 hours, unless turning is contraindicated. Kinetic beds continually rotate patients and are designed to help prevent atelectasis, hypoxemia, secretion retention, and pressure ulcers. When patients are kept immobile, pooling of secretions in dependent lung zones can promote nosocomial pneumonia, and shrinking of dependent alveoli leads to decreases in ventilation and hypoxemia. However, the use of rotating kinetic beds is controversial in the prevention of nosocomial pneumonia.[93] No data are available to indicate that these very expensive beds improve patient outcome.

Patients with unilateral lung disease benefit from being placed in positions that promote matching of ventilation and perfusion. In unilateral lung disease, only one lung is affected by atelectasis, consolidation, or pneumonia. If the affected lung is placed in the dependent position, blood flow follows. The resultant poor $\dot{V}/\dot{Q}$ ratio in the affected lung contributes to venous admixture and hypoxemia. However, if the patient is rotated so that the good lung is in the dependent position, these relationships are reversed. With the good lung down, blood flows to well-ventilated

alveoli, and $\dot{V}/\dot{Q}$ matching and arterial blood gas values improve. An added benefit of this maneuver is that the affected lung is placed in a postural drainage position, which promotes gravity drainage of retained secretions so that they can be removed.

Prone Positioning

A similar phenomenon has been described in ARDS. In a supine patient with ARDS, alveoli in the bases and posterior segments become atelectatic. Shunt increases, and the patient requires a high FiO_2 and PEEP for adequate oxygenation. If the patient is rotated into the prone position, several mechanisms have been proposed to improve oxygenation.[94] Blood flow is redistributed to areas that are better ventilated. This redistribution improves $\dot{V}/\dot{Q}$ relationships. Prone positioning removes the weight of the heart from its position over the lungs while the patient is supine. Pleural pressure in the now nondependent collapsed lung becomes more negative, improving alveolar recruitment. In addition, the stomach no longer lies over the dependent basilar posterior segments of the lower lobes.

A number of studies have demonstrated some benefit of prone positioning.[95–98] However, several persons are needed to "flip" the patient while ensuring monitoring lines and catheters are not disrupted and the patient is not inadvertently extubated. Wound dehiscence, facial or upper chest wall necrosis despite extensive padding, cardiac arrest immediately after movement to the prone position, dependent edema of the face, and corneal abrasion have been reported.[96] A recent meta-analysis of existing randomized controlled trials indicated no outcome benefit from prone positioning in patients with ARDS.[97] However, this meta-analysis also found that patients with PaO_2/FiO_2 less than 100 mm Hg were the group most likely to benefit from prone positioning. A subsequent randomized controlled trial showed the same results.[98] Considering the complications associated with prone positioning, only patients with very severe hypoxemia (PaO_2/FiO_2 <100 mm Hg) should be placed prone.

RULE OF THUMB Patients who have unilateral or dependent consolidation or atelectasis and severe hypoxemia may benefit from positioning with the affected lung or segments in the nondependent position to promote improvement in $\dot{V}/\dot{Q}$ relationships. Prone positioning is indicated only if the PaO_2/FiO_2 is less than 100 mm Hg. When positioning the patient, great care should be taken to avoid the hazards associated with prone positioning.

CARDIOVASCULAR EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION

Thoracic Pump and Venous Return During Spontaneous and Mechanical Ventilation

The lungs and heart have a close functional relationship, and impaired performance of one affects the other. For this reason, the RT must fully understand what happens to cardiovascular function when a patient receives ventilatory support.

Early studies of the effect of PPV on the cardiovascular system showed an early, small, and transient increase in cardiac output that was followed almost immediately by a marked reduction in left ventricular outflow. In general, the reduced cardiac output in these cases was directly related to the amount of pressure applied. More specifically, the decrease in left ventricular output corresponded to the increase in pleural pressure that occurred with PPV. Fig. 47.16 compares the effects of spontaneous inspiration with the effect observed during PPV. Negative pleural pressure during spontaneous inspiration normally enhances venous return, increases right atrial filling, and improves pulmonary blood flow (see Fig. 47.16A). In combination, these factors increase left atrial and left ventricular filling and left ventricular stroke volume.

However, during PPV, pleural pressure becomes positive (see Fig. 47.16B). Positive pleural pressure compresses the intrathoracic veins and increases central venous and right atrial filling

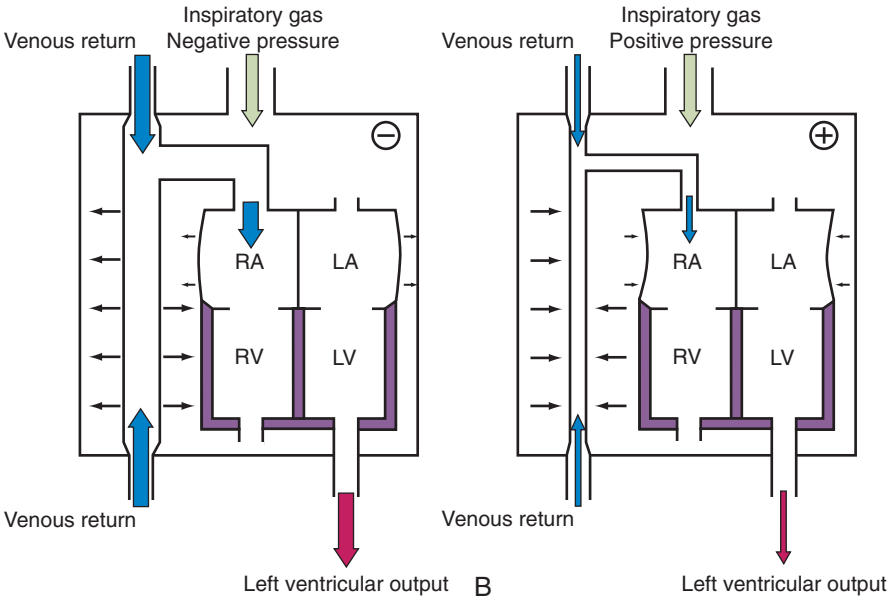

Fig. 47.16 Relationship between pleural pressure and cardiac output in spontaneous (A) and positive pressure (B) breathing. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

pressures. As these pressures increase, venous return to the heart is impeded, and right ventricular preload and stroke volume decrease, as does pulmonary blood flow. Blood already in the pulmonary circulation is initially displaced into the left side of the heart and causes a transient increase in filling pressure and output. This initial effect lasts for only a few heartbeats. If positive pressure is continued, flow both to and from the left side of the heart decreases.

The high impedance encountered by blood returning to the right heart causes venous pooling, mainly in the capacitance vessels of the abdominal viscera. This process effectively removes a large volume of blood from the circulation, which can further impair left ventricular output. These interactions are magnified when pleural pressure is increased further or circulating blood volume is low.[99] The venous impedance caused by PPV is not limited to blood flow coming from the abdomen. An increase in central venous pressure can restrict return flow from the brain. Impedance to venous return from the brain can increase ICP and reduce cerebral perfusion pressure (CPP). In combination with a decrease in left ventricular output, an increase in ICP during PPV can significantly impair cerebral perfusion and possibly result in cerebral ischemia and cerebral hypoxia.

In healthy individuals, the effects of PPV on cerebral blood flow (CBF) are minimized by autoregulatory mechanisms that maintain cranial perfusion pressures within a narrow range. However, patients with preexisting cerebrovascular problems and patients who already have an elevation in ICP may be at risk of decreased cerebral perfusion with PPV. Examples include neurosurgical patients and patients with head injuries, intracranial tumors, or cerebral edema from any cause. ICP monitoring may be necessary in the care of these patients.

Compensation in Healthy Persons

A decrease in cardiac output or blood pressure is rare among individuals with a normal cardiopulmonary system who are receiving mechanical ventilation. Compensatory mechanisms used to counter the decrease in stroke volume include increased heart rate, increase in systemic vascular and peripheral venous resistance, and shunting of blood away from the kidneys and lower extremities, which results in a consistent blood pressure. Because these compensatory mechanisms function by reflexes, the reflexes must be intact. Factors that block or blunt these vascular reflexes include sympathetic blockade, spinal anesthesia, spinal cord transection, and polyneuritis.

Pulmonary Vascular Pressure, Blood Flow, and Pulmonary Vascular Resistance

In patients with a normal cardiopulmonary system who are receiving mechanical ventilation, there is no significant increase in pulmonary vascular pressure or pulmonary vascular resistance and no decrease in pulmonary blood flow. However, when alveoli are distended by increased V_T or high PEEP, pulmonary blood flow is impeded because of the alveoli pressure against the pulmonary capillaries. The pressure increases right ventricular afterload and volume and decreases right ventricular output. The ventricular septum may be shifted to the left, but this effect is more consistent with a high PEEP. This condition decreases left ventricular filling and output. The magnitude of these changes is proportional to lung compliance. As lung compliance decreases, the stiffer lungs can retain the increased pressure imposed by PEEP. In other words, the increased pressure in the lung is not transmitted to the vasculature to impede right ventricular output. An increase in P_{pl} secondary to an increase in lung pressure impedes venous return and decreases cardiac output further. In general, at an optimal PEEP that sustains lung open, the increase in pulmonary vascular resistance is minimized. A decrease in lung volume and an increase in lung volume over normal FRC levels both adversely affect pulmonary vascular resistance. This maintaining lung volume by appropriate PEEP minimizes cardiovascular impairment associated with mechanical ventilation.

Right and Left Ventricular Function

Under conditions of a normal cardiovascular system with normal ventilation values, there are no significant changes in right or left ventricular function. Otherwise, mechanical ventilation would be difficult to manage, and the mortality and morbidity among patients receiving ventilation would be much higher. Right or left ventricular dysfunction appears to occur if the patient is hypovolemic, is receiving an excessive V_T, or is receiving more or less than optimum PEEP. The common factor is excessive P_{alv}, enough to overcome or impede pulmonary blood flow or venous return.

Effect on Left Ventricular Dysfunction

PPV can improve cardiac output in some patients. In patients with left ventricular failure, application of PPV can increase both the left ventricular ejection fraction and the cardiac output. These improvements occur because PPV decreases left ventricular afterload in these patients. Afterload is an important factor in determining cardiac output, as is the resistance of the systemic vasculature. When afterload increases, cardiac output decreases (heart failure). When afterload is decreased by PPV or pharmacologic therapy, cardiac output may increase. This phenomenon explains why the cardiovascular status of some patients deteriorates when PPV is discontinued or treatment is changed from full to partial ventilatory support.

Endocardial Blood Flow

Blood flow in the coronary arteries depends on the gradient between the systemic diastolic pressure and the left ventricular end-diastolic pressure (represented by the pulmonary capillary wedge pressure). Any factor that decreases systemic diastolic pressure or increases wedge pressure decreases endocardial perfusion pressure. The factors of PPV that may decrease the systemic diastolic pressure are high mean airway pressure owing to a high PEEP, large V_T, or long inspiratory time. Factors that may increase the wedge pressure include excessive PEEP and left ventricular failure.

Cardiac Output, Cardiac Index, and Systemic Blood Pressure

When the cardiovascular system is normal with normal ventilation values, there are no significant changes in cardiac output, cardiac index, or systemic blood pressure. Cardiac output can

be affected by a decrease in stroke volume with PPV, but this decrease is compensated by an increase in heart rate. Because the cardiac index is the quotient of cardiac output and body surface area (cardiac index = cardiac output in liters per minute/body surface area in square meters), a change in cardiac output would be reflected in the cardiac index. Systemic arterial pressure remains stable because of reflex compensation, which increases systemic vascular resistance. Cardiac output, cardiac index, and arterial pressure decrease only when mean airway pressure is high and P_{pl} increases precipitously. Hypotension owing to PPV alone is rare because clinicians do all that is necessary to prevent it, including adequate fluid administration, proper management of mean airway pressure and PEEP, and use of vasoconstricting drugs. Most cases of hypotension during mechanical ventilation are caused by sepsis and the accompanying vascular collapse.

RULE OF THUMB Patients most likely to experience hemodynamic effects of mechanical ventilation are patients with a normal or increased lung compliance associated with decreased chest wall compliance. In this setting, there is little lung stretch but maximum transmission of ventilating pressure to the intrathoracic space.

MINIMIZING CARDIOVASCULAR EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION

The effect of PPV on the circulatory system depends primarily on two major factors: mean pleural pressure and cardiovascular status.

Mean Pleural Pressure

Pleural pressure is the pressure in the virtual pleural space. At the bedside, pleural pressure usually is measured indirectly as the esophageal pressure through an esophageal balloon connected to a pressure transducer. Because the esophagus is close to the pleurae, separated by only the flexible esophageal wall, change in esophageal pressure reflects change in pleural pressure but may not equal actual pleural pressure. An alternative to measuring pleural pressure is measuring mean airway pressure. Mean airway pressure is linearly related to mean pleural pressure and can be used clinically for monitoring of pressure changes.[100]

The effect of PEEP on pleural pressure is complex and depends on the patient's lungs and thoracic mechanics. Some of the pressure generated by a ventilator reaches the alveoli, where it is transmitted across the alveolar walls to the pleural space. How much of this P_{alv} is transmitted to the pleural space depends on lung and thoracic mechanics.

In general, for a given P_{alv}, the more compliant the lung, the greater is the increase in pleural pressure. A patient with a disease causing a loss of elastic tissue, such as emphysema, is more subject to the cardiovascular effects of positive pressure than a person with normal lungs. In contrast, a lung with low compliance transmits less pressure to the pleural space; this explains, in part, why high levels of PEEP often are used with minimal cardiovascular effects on patients with low lung compliance (e.g., ARDS).

When the compliance of the chest wall is reduced, expansion of the thorax is limited, and more P_{alv} is transmitted to the pleural space. Patients who have normal lungs but have thoracic restriction, as caused by kyphoscoliosis and spondylitis, are more subject to the cardiovascular effects of positive pressure than individuals with normal chest wall compliance. A similar effect can occur in patients with normal thoracic compliance who actively oppose a mandatory breath by contracting the expiratory muscles (as might occur in patient–ventilator asynchrony). Contraction of the expiratory muscles effectively decreases thoracic compliance and causes more P_{alv} to be transmitted to the pleural space.

If resistance to airflow is high, less of the pressure generated at the airway reaches the alveoli. The high peak airway pressure common in patients with obstructive disorders is not reflected in high pleural pressure.

The effects of moderate increases in pleural pressure on cardiac output in healthy persons are minimal. In healthy persons, as left ventricular stroke volume decreases, compensatory responses increase both the cardiac rate and the tone of the venous capacitance vessels. These normal responses ensure adequate blood flow and perfusion pressure. However, if the patient already is hypovolemic or has lost peripheral venomotor tone, cardiovascular compensation may be impossible. In these cases, even a small increase in pleural pressure may result in a marked decrease in cardiac output.

Decreasing Mean Airway Pressure

Mean airway pressure is affected by respiratory rate, V_T, inspiratory time, inspiratory pause, expiratory time, I:E ratio, peak pressure, baseline pressure (PEEP or CPAP), and inspiratory flow waveform. If a decrease in mean airway pressure is necessary, altering any factor that contributes to mean airway pressure has an effect. If the PaO_2 is high, one of the most effective changes is a decrease in PEEP because it has a 1:1 relationship with mean airway pressure. If a decrease in PEEP is indicated, the RT must ensure that desaturation does not occur when the decrease has been accomplished. If the patient is being hyperventilated, a decrease in mandatory rate or V_T also decreases mean airway pressure.

The best way to determine the magnitude of the change is to use the mean airway pressure monitor on the ventilator. The peak pressure usually decreases with a decrease in V_T. In pressure-controlled modes, the peak pressure may be decreased directly. The P_{plat} is a reflection of mean peak P_{alv}. In volume-controlled ventilation, a decrease in V_T decreases P_{plat}. In pressure-controlled ventilation, the pressure setting may be reduced to limit P_{plat}. Efforts that increase lung compliance, such as PEEP or administration of diuretics to decrease interstitial edema, also may affect P_{plat}. Inspiratory time, expiratory time, and I:E ratio affect mean airway pressure. As inspiratory time lengthens or expiratory time decreases, mean airway pressure increases.

Fluid Management and Cardiac Output

The relationship between cardiac output and preload (end-diastolic volume) is described by the Frank-Starling phenomenon, which states, "in the normal heart, the diastolic volume (preload) is the principal force that governs the strength of ventricular

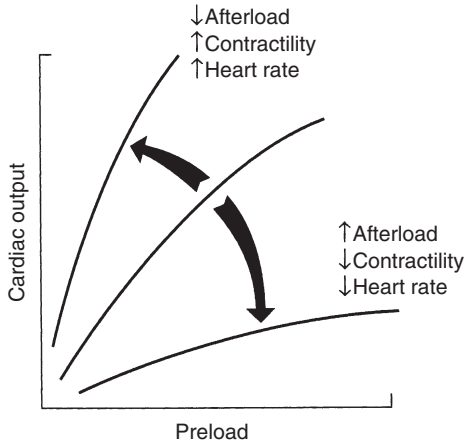

Fig. 47.17 Effects of preload, afterload, contractility, and heart rate on cardiac output function curve. (Modified from Green JF: *Fundamental cardiovascular and pulmonary physiology*, ed 2, Philadelphia, 1987, Lea & Febiger.)

contraction."[101] As preload (stretch) increases, so does force and presumably stroke volume. Stroke volume continues to increase with preload until the heart is distended by excess preload, after which stroke volume decreases. Another cause of a decrease in stroke volume is the decrease in ventricular contractility that occurs when afterload increases as the result of hypertension. With hypertension comes dilation and distention of the ventricles, which make the heart structurally abnormal. In an abnormal heart, it takes much less preload to put the heart into failure. Failure in this case is defined as decreased stroke volume despite increased preload (Fig. 47.17).

When a patient receives PPV, there is risk of a decrease in venous return (preload) because of the increase in P_{pl}. Stroke volume may decrease, but the decrease is compensated for by a reflex increase in heart rate and vasomotor tone. Because of these compensatory mechanisms, most patients with a normal cardiopulmonary status who receive mechanical ventilation do not need additional fluid to maintain cardiac output. However, certain conditions can increase the risk of relative or actual hypovolemia, and the increase can decrease stroke volume, even if normal reflex compensation is present. These conditions include hypovolemic shock (owing to trauma and blood loss), sepsis (in which the normal reflex compensation is not present), and high PEEP and high mean airway pressure. In these conditions, fluid or blood administration may be necessary to maintain cardiac output and end-organ perfusion. In some patients who receive PPV with PEEP, an increase in PEEP can decrease cardiac output as discussed earlier. In this case, the outcome of PEEP in terms of improved tissue oxygenation (oxygen delivery [DO_2] = CaO_2 × cardiac output) should be determined. If tissue O_2 delivery decreases because of a decrease in cardiac output, but CaO_2 increases, fluid administration may be indicated to restore cardiac output by increasing preload.

Pharmacologic Maintenance of Cardiac Output and Blood Pressure

First-line therapy for decreased cardiac output and blood pressure is fluid administration, unless the patient has congestive heart failure. In heart failure, inotropic therapy is indicated for decreased myocardial contractility, and vasodilators and diuretics are used to control hypertension, which decreases afterload. Diuretics are used to control fluid overload and to decrease preload to the distended heart. These factors in combination may return the heart to a more optimal portion of the Frank-Starling curve and improve stroke volume.

EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION ON OTHER BODY SYSTEMS (Box 47.2)

Increased Intracranial Pressure

Perfusion of the brain is quantified by the CPP. The CPP is the difference between mean arterial pressure (MAP) and ICP. CPP may decrease in any case in which MAP decreases or ICP increases. If CPP decreases, CBF decreases. The result is cerebral ischemia and a decrease in cerebral O_2 metabolism. The cerebral circulation has the ability to maintain CBF even when CPP changes, a process called *cerebral autoregulation*. Cerebral **autoregulation** is a function of cerebral vascular resistance. If CPP decreases, cerebral vascular resistance decreases to maintain CPP. Cerebral autoregulation functions as long as CPP is in the range of 60 to 150 mm Hg and is limited by the ability of the cerebral arterioles to constrict and dilate. Under normal conditions, cerebral O_2 delivery and CPP exceed the metabolic needs of the brain for O_2 and glucose.

Normal MAP is 93 mm Hg if arterial pressure is 120/80 mm Hg. Normal ICP is less than 10 mm Hg, so normal CPP is approximately 80 to 85 mm Hg. CPP decreases when MAP decreases or ICP increases. Conditions leading to a decrease in MAP are shock, high PEEP, and high mean airway pressure. Increases in ICP are caused by traumatic brain injury (TBI), cerebral hemorrhage, cerebrovascular accident (stroke), and tumors. A CPP greater than 60 mm Hg maintains CBF and cerebral O_2 metabolism.

CO_2 is a potent cerebral vasodilator and an important regulator of the cerebral arteriolar diameter. As $PaCO_2$ decreases from 40 mm Hg, systemic pH increases. CO_2 concurrently diffuses across the blood-brain barrier. The result is an increased cerebrospinal fluid (CSF) pH. Although $PaCO_2$ is monitored in patients with TBI, the CSF pH modulates cerebral vascular resistance in an effort to decrease the ICP. When mechanical hyperventilation is used, cerebral vascular resistance increases, and the result is decreased ICP; this is why hyperventilation has been used in the management of TBI and acute increased ICP. However, in the presence of an already decreased CPP, CBF may decrease to the point at which cerebral ischemia is likely; this is the problem with immediate hyperventilation of a patient with TBI. In addition, prolonged hyperventilation allows renal excretion of bicarbonate, which allows the CSF pH to return to normal and negates any positive effect of hyperventilation on ICP. The effect of hyperventilation on the reduction of ICP lasts 1 hour. If hyperventilation is withdrawn and arterial pH and $PaCO_2$ return to normal values, the CSF pH decreases. Subsequent CSF acidosis leads to cerebral vasodilation and a rebound increase in CBF and ICP that exceeds the values before hyperventilation. For

these reasons, hyperventilation must be used cautiously in the treatment of patients with TBI.[102] Normally patients with TBI are managed with a $PaCO_2$ that is relatively normal, 35 to 40 cm H_2O.

Treatment of a Patient With a Closed Head Injury

Guidelines for the management of severe TBI were developed by neurosurgeons in the Joint Section on Neurotrauma and Critical Care.[103] The recommendation is as follows: "The use of prophylactic hyperventilation ($PaCO_2$ <35 mm Hg) during the first 24 hours after TBI should be avoided because it can compromise cerebral perfusion during a time when CBF is reduced. Hyperventilation therapy may be necessary for brief periods when there is acute neurologic deterioration or for longer periods if there is intracranial hypertension refractory to sedation, paralysis, CSF drainage, and osmotic diuretics." The Joint Section further noted that "in the absence of increased ICP, chronic, prolonged hyperventilation therapy ($PaCO_2$ <35 mm Hg) should be avoided after TBI." These findings have resulted in several recommendations regarding the care of patients with TBI, as follows:

1. Patients with TBI may have transient, short periods of increased ICP, called *plateau waves*. Plateau waves may be caused by suctioning, repositioning, or other noxious stimuli. During a plateau wave, acute hyperventilation can control ICP until the pressure returns to baseline, at which time ventilation is resumed at the previous rate.
2. Hyperventilation should be avoided after TBI; other methods can be used to decrease elevated ICP. These methods include ventriculostomy for drainage of CSF, craniotomy for removal of mass lesions, osmotic diuretics, sedation, placing the patient in the semi-Fowler position, and paralysis. CPP should be maintained at greater than 70 mm Hg.
3. Intubation should be attempted only after the patient has been sedated, to prevent the associated increase in ICP. Exhaled partial pressure of end-tidal carbon dioxide ($PETCO_2$) should be monitored to maintain a constant $PaCO_2$ after arterial blood gas values are determined to find the correlation between $PaCO_2$ and $PETCO_2$.
4. ICP should be maintained at less than 20 mm Hg.[103]

Effect on Renal Function

Some patients receiving long-term PPV retain salt and water. In critically ill patients, water retention usually is evident when rapid weight gain occurs. In addition, such patients may have a reduced hematocrit, which is also consistent with hypervolemia secondary to water retention. These early observations are attributed to the direct and indirect effects of PPV on renal function.

In terms of direct effect, PPV can reduce urinary output 30% to 50%. This reduced urinary output during PPV is associated with a simultaneous reduction in renal blood flow, glomerular filtration rate, and sodium and potassium excretion.

Decreases in MAP to less than 75 mm Hg reduce renal blood flow, glomerular filtration rate, and urinary output. However, MAP this low seldom is caused by PPV alone, and kidney autoregulatory mechanisms generally can keep renal perfusion pressure within normal limits over a wide range of arterial pressures. Because restoring cardiac output to normal does not entirely restore urinary output compromised by PPV, other mechanisms must be involved. Impaired renal function during PPV is better associated with a decrease in intravascular volume.

The indirect effect of PPV on renal function may be most important. PPV has a marked effect on the water-retaining and sodium-retaining hormonal systems. Specifically, long-term PPV increases plasma renin activity, plasma aldosterone level, and level of vasopressin (urinary antidiuretic hormone). In addition, PPV decreases atrial natriuretic hormone levels (Fig. 47.18).

Decreased right atrial transmural pressure is primarily responsible for the decrease in atrial natriuretic hormone, which leads to sodium retention. Similarly, vasopressin secretion may be enhanced by stimulation of the left atrial stretch receptors, which innervate the posterior pituitary gland. Increased secretion of vasopressin (antidiuretic hormone) and activation of the renin-angiotensin-aldosterone system lead to a decrease in urine output.

Decreased Liver and Splanchnic Perfusion

The effects of PPV on the liver and intestine are related to its effects on the cardiovascular system. Hepatic dysfunction with PPV can occur in patients with otherwise normal livers and manifests as an increase in serum bilirubin level. These effects appear to be directly related to the reduction in hepatic blood flow that occurs with PPV. Regardless of cause, these effects are aggravated by PEEP but can be reversed when cardiac output is returned to pre-PEEP levels with intravascular volume infusions.

Decreased Gastrointestinal Function

An increase in splanchnic resistance can contribute to gastric mucosal ischemia and helps explain the high incidence of gastrointestinal bleeding and stress ulceration in patients receiving long-term PPV. Stress ulcers (erosions of the gastric mucosa) are common among patients with life-threatening illness. Impaired blood flow inhibits the ability of the gastric mucosa to replace itself normally every 2 or 3 days. Stress ulcers are caused by impaired blood flow, not gastric acidity. Gastroduodenal motility also is severely impaired in mechanically ventilated patients.[104] These factors may result in translocation of bacteria from the intestine to the blood and nosocomial septicemia. Mechanical ventilation for more than 48 hours and most other conditions necessitating ICU admission are considered indications for stress ulcer prophylaxis. Optimal prophylaxis for stress ulcers is restoration of mesenteric blood flow. Pharmacologic approaches include administration of a cytoprotective agent (sucralfate) and an acid suppression agent (cimetidine or ranitidine).[101]

Gastric distention can be caused by **aerophagia** secondary to an artificial airway cuff leak or by the use of mask ventilation (pressure >20 to 25 cm H_2O). The RT can prevent this complication by taking great care to ensure that the cuff is properly inflated. If patients being ventilated noninvasively are swallowing air, an artificial airway may be considered. In the case of aerophagia and gastric distention, a nasogastric tube may be inserted to evacuate the air.

Bleeding from erosion through the surface vessels of the gastric mucosa is one consequence of stress ulceration. The incidence of bleeding from stress ulcers is almost 100%, but only

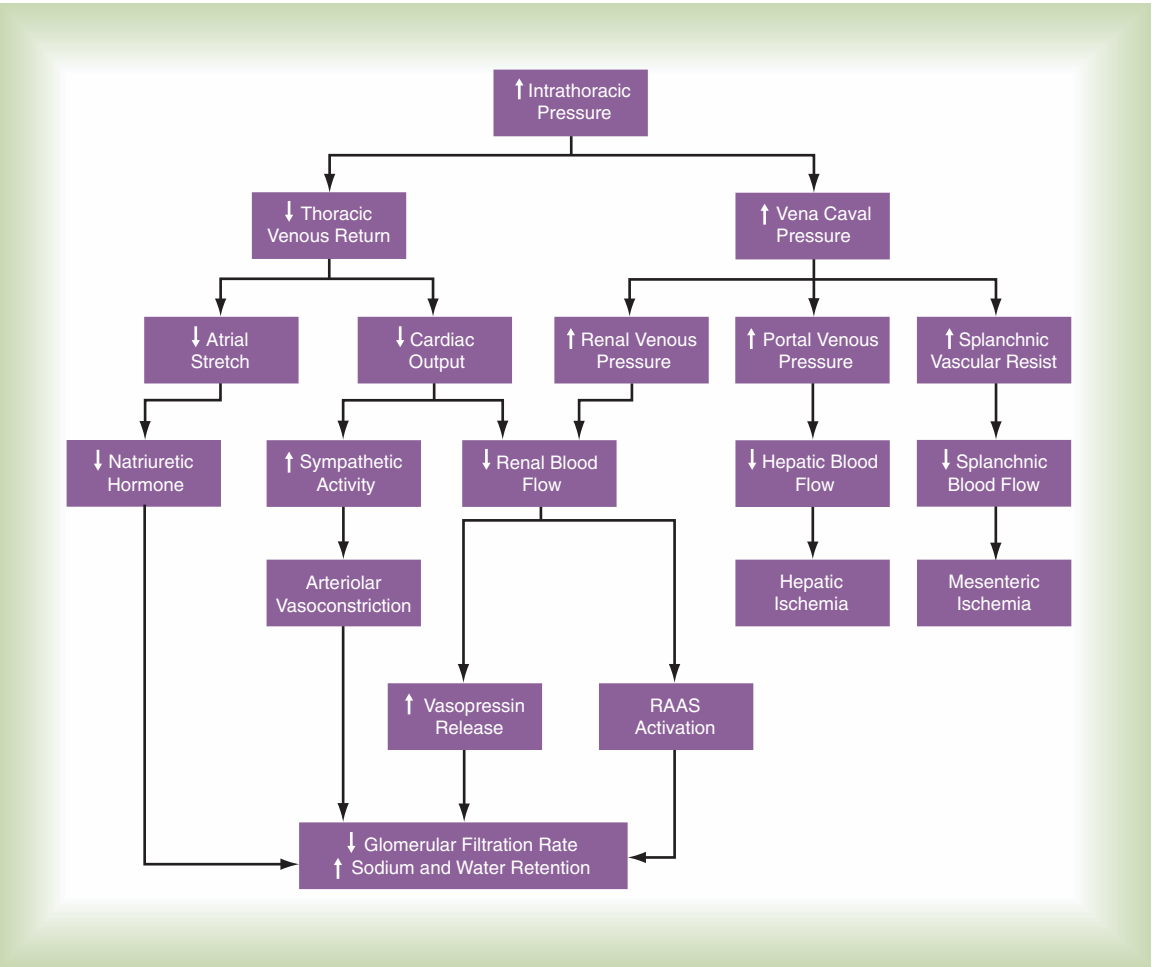

Fig. 47.18 Cardiac, renal, hepatic, and splanchnic effects associated with increased intrathoracic pressure caused by positive pressure ventilation. *RAAS,* Renin-angiotensin-aldosterone system; ↑, increased; ↓, decreased. (Modified from Florete OG, Gammage GW: Complications of ventilatory support. In Kirby RR, Banner MI, Downs JB, editors: *Clinical applications of ventilatory support*, New York, 1990, Churchill Livingstone.)

approximately 5% of bleeding is clinically apparent hemorrhage, and less than 1% to 2% necessitates blood transfusion.

Because patients receiving mechanical ventilation often have an artificial airway or are obtunded, a nutritional deficit may exist. Even in a normal metabolic state, intravenous solutions of saline and dextrose provide only a fraction of the required calories and micronutrients. Patients in the ICU often are hypermetabolic and need two to three times the normal calories. See Chapter 23 for details on nutritional support.

Effect on Central Nervous System

Patients in the ICU are placed into an artificial environment over which they have little control. From the start, the patient loses autonomy. When mechanical ventilation is introduced, the patient is sedated and possibly paralyzed and may not return to a normal, awake level of consciousness until discharged from the ICU. Instead, the patient is kept somnolent (easily aroused and aware) or is stuporous (arousable with difficulty and impaired awareness) or comatose (arousable but unaware).[101] The presence of an artificial airway makes communication difficult. Caregivers should make a paper tablet and pen, communication board, or communication cards available to patients who are aware enough to write or use them.

Sedatives, Hypnotics, and Neuromuscular Blocking Agents

Sedation is necessary but should always be the minimal level required for the management of the nearly inevitable agitation, fear, and anxiety associated with the ICU environment, pain, invasive and noninvasive procedures, and loss of normal sleep pattern. The Society of Critical Care Medicine has published guidelines for sedation and analgesia in the care of critically ill patients.[105]

The level of sedation is monitored with the Modified Ramsay Sedation Scale (Box 47.3). Sedation is titrated to achieve a level of 2 to 3 on the Ramsay scale. This way the patient is responsive yet not restless or agitated and not paralyzed or comatose.

According to the Society of Critical Care Medicine, facilitation of mechanical ventilation in severe ARDS is the most common reason for prolonged neuromuscular blockade. Neuromuscular

BOX 47.3 Modified Ramsay Sedation Scale

1. Agitated, anxious, restless
2. Calm, cooperative, oriented, tranquil
3. Responds to verbal commands
4. Brisk response to light touch
5. Unable to be assessed (paralyzed)

blocking agents are used with mechanical ventilation to improve gas exchange, to avoid ICP spikes, to avoid hemodynamic instability, and to prevent bodily injury. Because they paralyze but do not sedate, neuromuscular blocking agents always are used in conjunction with appropriate sedative or analgesic agents (see earlier). In the absence of a sedative, a patient under the influence of a neuromuscular blocking agent is paralyzed and fully aware of the surroundings. During neuromuscular blockade, patients should be assessed for the degree of blockade that is being sustained.[105] The patient is observed for ventilatory effort, and train-of-four stimulation is performed. Neuromuscular blockade should be allowed to dissipate daily so that clinical evaluation, assessment of concomitant sedation and analgesia, and evaluation of the need for continued paralysis can be conducted.

Opioids

Pain is a major issue in any patient in the ICU. An ETT is very painful, and all of the procedures performed in the ICU tend to be painful. As a result, careful attention to the of pain medication is indicated. Much of the anxiety and discomfort treated with sedatives should be treated with pain medication. Appropriate management of pain and sedation reduces the likelihood delirium developing.

COMPLICATIONS OF MECHANICAL VENTILATION

Negative Pressure Ventilation

Pulmonary

Hypoventilation during NPV can be caused by a decrease in the P_{TA} owing to inadequate negative pressure or leaks in the ventilator or patient–ventilator interface. Iron lung negative pressure ventilators rely on a tight seal at the patient's neck and at all access ports in the tank. Chest cuirass ventilators rely on a tight seal between the cuirass and thorax. Poncho-type ventilators must remain free of leaks or tears. When there is a leak at any of these points, P_{TA} decreases, and the result is a decrease in minute ventilation.

Hyperventilation can occur if the pressure is more negative than is necessary. The results are increased P_{TA}, increased V_T, and increased minute ventilation.

Cardiovascular

Abdominal blood pooling can occur in patients receiving NPV in an iron lung. The negative pressure exerted on the thorax also is exerted on the more compliant abdominal wall. When the pressure in the iron lung becomes negative, the abdominal wall is pulled outward and with it the viscera and associated blood supply. Venous return to the heart, cardiac output, and systemic blood pressure decrease; the result is a condition called "tank shock."

Positive Pressure Ventilation: Artificial Airway Complications

Chapter 37 describes complications related to artificial airways.

Complications Related to Pressure

Ventilator-associated lung injury is the term used to define lung injury in humans owing to mechanical ventilation. These are complications resulting from high pressure, infection, and patient-ventilator asynchrony. High ventilation pressure has long been associated with barotrauma. Barotrauma is categorized as pneumothorax, pneumomediastinum, pneumopericardium, and subcutaneous emphysema (Fig. 47.19). All of these complications are descriptions of extra-alveolar air. High ventilatory pressure can cause gas to escape through ruptured alveoli. The eventual location of the escaping gas defines the type of barotrauma. If gas escapes through ruptured alveoli into the pleural space, pneumothorax occurs. Gas escaping along perivascular sheaths to the mediastinum produces pneumomediastinum. Further dissection from the mediastinum to tissue planes in the neck and chest wall results in subcutaneous emphysema and potentially pneumomediastinum and pneumoperitoneum.

Pneumothorax is identified by observation of a decrease in chest movement, hyperresonance on percussion, possible deviation of the trachea away from the affected side, and decreased or absent breath sounds over the affected side. In nonintubated patients, there may also be a decrease in vocal fremitus over the affected side. A line separating lung tissue from air is observed on the chest radiograph, although the line sometimes is difficult to see in a small (<20%) pneumothorax (see Chapter 21). Respiratory distress increases with increasing pneumothorax, as does hypoxemia. Normally, in spontaneously breathing patients, intrapulmonary and pleural pressures are equal in pneumothorax. PPV can cause P_{pl} to increase (tension pneumothorax).

Tension pneumothorax is life threatening because it tends to develop very rapidly in patients who are mechanically ventilated and shifts the mediastinum, heart, and great vessels; the results are a decrease in cardiac output and hypotension. Tension pneumothorax is a medical emergency; it is relieved by insertion of a large-bore needle into the pleural space through the anterior second or third interspace above the rib. This maneuver is followed by chest tube insertion. While waiting for needle decompression, the patient may be ventilated with 100% O_2 at a low V_T and airway pressure. Pneumomediastinum and pneumoperitoneum are identified on a chest radiograph by the presence of air in these locations.

Complications Related to Volume

VILI has been defined as the application of pressure, positive or negative, to the lungs causing damage. The damage has been described as an increase in permeability of the alveolar-capillary membrane, pulmonary edema, cell wounding and necrosis, and diffuse alveolar damage as the result of using an inappropriate

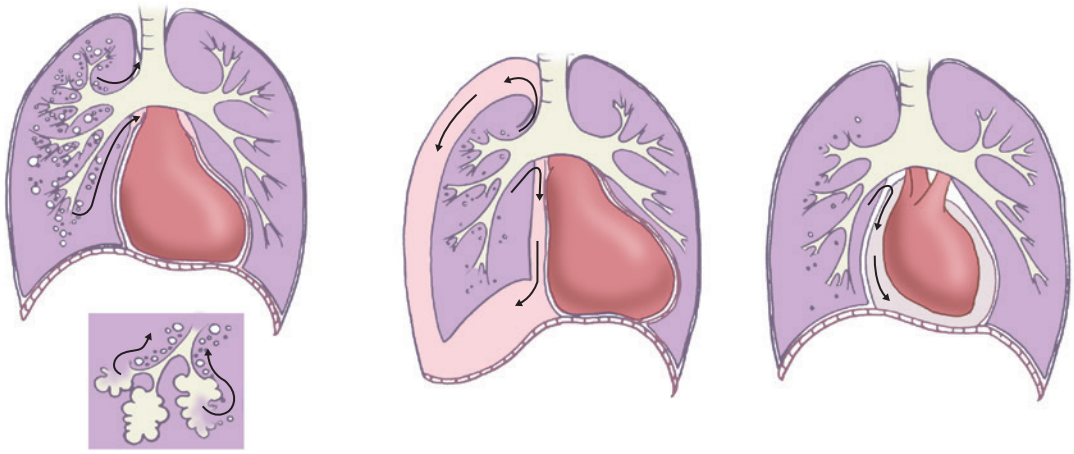

Fig. 47.19 Pulmonary Barotrauma. (A) Ruptured alveoli are indicated in framed alveoli at bottom. Air dissects from alveoli along vascular sheaths to the hilum and then to the pleural space. (B) Pneumothorax. Origin of air in lung tissue and its pathway to inflate the pleural space are indicated. The heart shifts to the left because of high pressure in the right side of the chest. (C) Course of air from the lung to pericardial space. The distended pericardial space causes cardiac tamponade. (Modified from Korones SB: *High-risk newborn infants*, ed 4, St Louis, 1986, Mosby.)

ventilation strategy. Several more recent reviews summarize the mechanisms, effects, and means to prevent VILI.[106–108]

It has been shown that overdistention, as opposed to volume or pressure per se, is an important determinant of lung damage. Animals ventilated with large V_T (>30 mL/kg) develop severe injury—hence the term **volutrauma**. The degree of alveolar distention is determined by the P_{TP} (P_{plat} minus the pleural pressure), which must be approximated by the esophageal pressure. As P_{plat} increases, so does P_{TP}, increasing the likelihood of lung damage. Lung damage may also occur when ventilating at low V_T, if alveoli are allowed to deflate and reinflate repeatedly with each breath. This injury is called **atelectrauma**. These two factors have led to the recommendation that lungs should be opened ("recruited") and kept open by an appropriate PEEP level and ventilated to a P_{plat} of no more than 28 cm H_2O by decreasing V_T and a driving pressure of no more than 15 cm H_2O. This technique is called the *open lung technique* and is described in detail in Chapter 49.

Factors that predispose a patient to VILI include underlying lung disease (injured lungs are more susceptible to VILI), systemic inflammation, surfactant dysfunction, aspiration, pulmonary edema, extremes of age, and heterogeneous lung ventilation. An important factor is the uneven distribution of ventilation, especially in ARDS. Because ARDS is a heterogeneous disorder, there are areas of both low and normal compliance. A given pressure in an area of low compliance may allow lung units to open and close with each breath, causing atelectrauma. The same pressure in an area of normal compliance may cause overdistention and stretch injury. Pulmonary edema is a prominent feature of VILI, owing to an increase in alveolar-capillary membrane permeability. Microvascular damage is characterized by separation of capillary endothelial cells, disruption of alveolar epithelium, and destruction of alveolar type I cells.

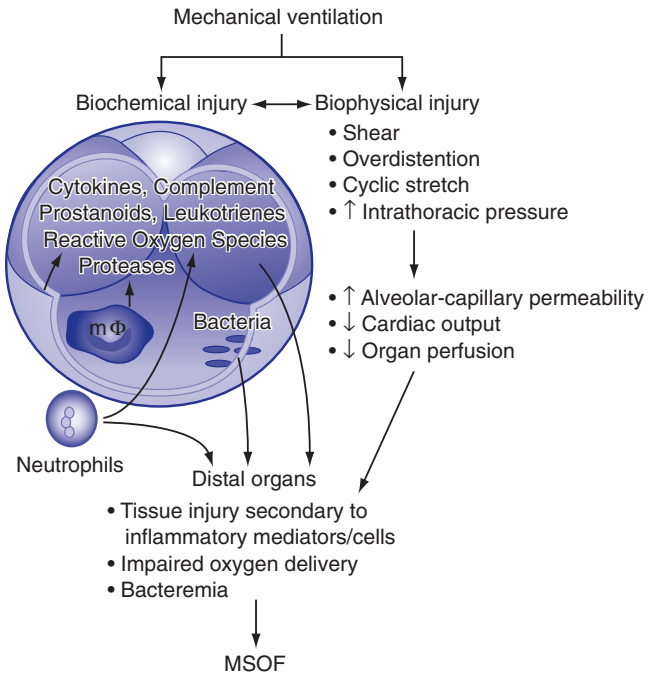

Fig. 47.20 Mechanisms by which mechanical ventilation might contribute to multisystem organ failure (MSOF). (From Mason RJ, Broaddus VC, Murray JF, et al: *Murray and Nadel's textbook of respiratory medicine*, ed 4, Philadelphia, 2005, Saunders.)

VILI occurs via two mechanisms, as shown in Fig. 47.20.[109] One mechanism is the physical disruption of tissues and cells *(biophysical injury)*. Physical disruption of the tissues occurs as air ruptures across the alveolar epithelial surface and tracks along the bronchovascular sheath. Air tracks into the interstitium causing pulmonary interstitial emphysema, into the pleural space

causing pneumothorax, and into the pericardium causing pneumopericardium. The pulmonary capillary epithelium also fails in response to high-volume ventilation, resulting in hemorrhage and edema. Another factor in biophysical injury is the interdependence of adjacent alveoli and terminal bronchi. When the lung is unevenly expanded, alveolar collapse increases the traction forces between alveoli. This recruitment-derecruitment develops pressures up to 140 cm H_2O across lung units, resulting in air-filled cavities and pseudocysts. Finally, injurious ventilation causes surfactant to become dysfunctional or deficient or both.

The second mechanism is the release of inflammatory mediators *(biochemical injury)*. When the lungs are abnormally stretched, this is detected by cells and converted into biochemical signals, a process called *mechanotransduction*. These biochemical signals cause the release of cytokines, complement, prostanoids, leukotrienes, reactive O_2 species, and proteases. The release of these substances has been called **biotrauma**. These mediators go on to the terminal organs and cause tissue inflammation, impairment of O_2 delivery, and bacteremia (see Chapter 29), leading to MSOF. As mentioned earlier in the chapter, hyperinflation during mechanical ventilation causes bacteria to "spill over" from the gut into the bloodstream, a process called *translocation*. In this manner, translocation contributes to MSOF, as bacteria migrate into the blood and then to terminal organs. Other factors contributing to MSOF are an increase in circulating cell death (apoptotic) factors, suppression of the peripheral immune response, and individual genetic variability.

Alveolar distention occurs when the lungs are stiff and the chest wall is normal or when one or both lungs are ventilated with a high P_{plat}. P_{plat} ideally should be maintained at less than 28 cm H_2O in all patients. However, in patients with a stiff chest wall (marked obesity, fluid overload, increased abdominal pressure), higher P_{plat} can be tolerated without injury because of the reduction in P_{TP} caused by the stiff chest wall. In this setting driving pressure can normally be maintained less than 15 cm H_2O.

Human studies have compared high and low V_T ventilation, using ICU mortality, ventilator-free days, and overall mortality as outcome variables. The consensus is that a low V_T strategy, with PEEP adequate to keep lungs open to avoid atelectrauma, results in a significantly better outcome. In studies in which inflammatory mediators were also measured, high V_T groups had a higher level of inflammatory mediators.[110,111] VILI is related to both mechanical and chemical factors. On one hand, overstretch directly injures the alveolar epithelium and capillary endothelium. On the other hand, through mechanotransduction, cells release many inflammatory mediators into the blood, leading to MSOF.

Auto–Positive End-Expiratory Pressure

Air trapping occurs with incomplete emptying of lung units. Lung units prone to air trapping are units with long-time constants (i.e., with high resistance or high compliance). Air trapping during PPV is often referred to as *dynamic hyperinflation, auto-PEEP, occult PEEP,* or *intrinsic PEEP*. This problem associated with air trapping cannot be determined by simple observation of airway pressure. Auto-PEEP often goes unrecognized. Refer to Chapter 48 for details on the management of auto-PEEP.

Oxygen Toxicity

O_2 toxicity causes lung tissue damage and an increase in the permeability of the alveolar-capillary membrane. As suggested in Chapter 42, factors associated with the development of O_2 toxicity include elevated FiO_2, long duration of exposure, and patient susceptibility. FiO_2 of 0.6 or more for longer than 24 to 48 hours is associated with the development of O_2 toxicity. In the presence of a high concentration of O_2, O_2 free radicals are produced. These radicals are the hydroxyl (OH^-), perhydroxyl (HO_2), and superoxide (O_2^-) radicals. Free radicals normally are rapidly detoxified by the enzyme superoxide dismutase, which is produced by alveolar type II cells. With higher FiO_2, the presence of free radicals is greater, and type II cells are less likely to produce superoxide dismutase. The presence of free radicals increases the permeability of the alveolar-capillary membrane. The combination of direct injury by free radicals and decreased surfactant production leads to exudation of fluid into the alveoli and a subsequent decrease in compliance. Every effort should be made to decrease FiO_2 whenever it exceeds 0.6. The decrease usually is accomplished with application of PEEP or CPAP. However, the evidence supporting the development of O_2 toxicity in critically ill patients is poor, and appropriate oxygenation should never be sacrificed for the purpose of avoiding O_2 toxicity.

Current recommendations are that FiO_2 should be adjusted to maintain the PaO_2 55 to 80 mm Hg or the SpO_2 88% to 95% to decrease mortality risk. It has been clearly demonstrated that maintaining hyperoxia increases the risk of death in ICU patients.

Ventilator-Associated (Nosocomial) Pneumonia

Pneumonia is the second most common nosocomial infection, primarily affecting infants and young children, adults older than 65 years, patients with severe underlying disease, immunosuppressed patients, patients who have depressed sensorium, patients with cardiopulmonary disease, and patients who have had thoracoabdominal surgery. RTs should be prepared to prevent this threat to respiratory patients, who are 6 to 21 times more susceptible to the development of nosocomial pneumonia than the general population. A review by Craven[112] stated that healthcare costs related to each case of nosocomial pneumonia are approximately $40,000. Most of these cases of pneumonia are caused by aspiration of bacteria that have colonized the upper gastrointestinal tract or oropharynx. Intubation greatly increases the risk of nosocomial pneumonia because the lower airway is left exposed, and normal protective mechanisms are bypassed. This type of pneumonia has been known for years as *ventilator-associated pneumonia*. This name has been challenged because it is not the ventilator but rather the microaspiration of microorganisms in oral or gastrointestinal secretions that causes the infection. Secretions that sit on the top of the endotracheal or tracheostomy tube cuff are aspirated via the small folds in the cuff. Most cases of pneumonia are polymicrobial, consisting of gram-negative organisms. However, methicillin-resistant *Staphylococcus aureus* has been common in the past 10 years. The endotracheal or tracheostomy tube is a site of bacterial growth, and these bacteria become encased in what is referred to as a

biofilm. The use of a silver-coated endotracheal tube,[113] use of endotracheal tubes with alternative cuff designs,[114] use of subglottic suction airways,[115] proper cuff care,[116] the use of devices to remove biofilm from the inside of the ETT,[117] and avoidance of lavaging when suctioning all reduce the risk of aspiration. See Chapter 37 for details.

Prevention of Ventilator-Associated Pneumonia

In addition to standard precautions, specific infection control procedures apply to the use of endotracheal tubes and ventilators. These ventilator bundles for prevention of ventilator-associated pneumonia include the following[116]:

- Perform appropriate hand hygiene. Hands should be disinfected with a sanitizer (e.g., Cal-Stat hand sanitizer) before entering any patient's room regardless of the reason and when leaving the patient's room regardless of the activities that occurred in the room.
- Perform gentle suctioning (to help prevent coughing, aspiration, and sloughing of biofilm).
- Place the patient in a semirecumbent position (30- to 45-degree head elevation).
- Do not routinely change ventilator circuits.
- Drain and discard inspiratory tube condensate away from the patient, or prevent its formation by using heated wire circuits or heat and moisture exchangers.
- Use a metered dose inhaler rather than a nebulizer for medication administration. If a small volume nebulizer is used, it should be replaced after each treatment (i.e., one nebulizer = one treatment). However, the new vibrating disc nebulizers are as protective as meter dose inhalers.
- Interrupt sedatives daily to evaluate patient readiness to wean from the ventilator—this is effective in decreasing the length of intubation and mechanical ventilation.
- Assess daily the ability of the patient to perform a spontaneous breathing trial.
- Use noninvasive ventilation whenever possible to avoid intubation.
- Perform regular oral hygiene at least every 4 hours.

Early tracheostomy has been evaluated as a possible preventive measure, but several studies and meta-analyses showed no advantage of tracheostomy in preventing ventilator-associated pneumonia.[112] Other measures that may decrease the likelihood of nosocomial infection include the use of closed suction systems; use of disposable resuscitation bags; and high-level disinfection of ventilators, O_2 analyzers, and other equipment between patients.

Ventilator Malfunction

Ventilator malfunction can be categorized as a failure in the patient circuit or a failure in the ventilator. Failures in the patient circuit include failures related to the endotracheal tube: cuff rupture, main stem intubation, laryngeal intubation, esophageal intubation, soft tissue erosion because the cuff pressure is too high, and disconnection from the circuit. Failures in the tubing circuit include leaks anywhere there is a tubing connection; a leak at the site of a nebulizer or metered dose inhaler (Fig. 47.21); humidifier malfunctions that include failure to fill the reservoir, overheating, or mechanical failure; and exhalation valve failure.

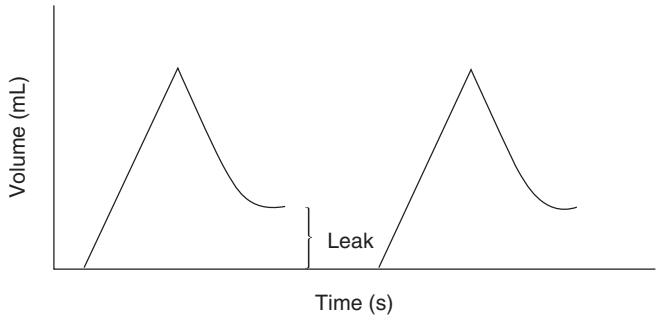

Fig. 47.21 Volume-Time Waveform Illustrating a Leak in the Ventilator Circuit. Note the abrupt end of expiration before the tracing reaches the baseline.

These failures are recognized by the ventilator as changes in respiratory rate, airway pressure, or V_T outside the limits set on the alarms.

Airway and ventilator malfunctions can be avoided with proper care of the endotracheal tube (taping the tube snugly), ensuring equal breath sounds, checking to ensure the tubing is patent and free of leaks, and ensuring that all connections are firmly made. If patient activity is the cause of ventilator disconnection, patient teaching to refrain from attempting to disconnect the ventilator or pulling on or biting the tube or sedation or restraint may be necessary. Failures related to the ventilator include electrical failure, microprocessor failure, exhalation valve failure, internal volume leakage, gas supply failure, and any failure that could result in an increase or decrease in minute ventilation or FiO_2. Ventilators have alarms that alert the RT to these dysfunctions.

Patient safety is always the primary concern when a malfunction is detected. For this reason, a manual resuscitator always should be placed near the bedside. If the reason for the patient's distress is clear, such as disconnection at the endotracheal tube, the connection is reestablished, and patient comfort and ventilation are ensured. If the reason is not obvious, the patient is ventilated with a manual ventilator while the cause of the malfunction is investigated. The steps for managing sudden distress in a patient receiving ventilatory support are listed in Table 47.4.

RULE OF THUMB Always have a manual ventilator (bag-valve-mask device [Ambu bag]) at the bedside of a patient receiving mechanical ventilation. Ensure that the manual ventilator is connected to an O_2 source. If the patient is receiving PEEP, ensure that the manual ventilator is equipped with a PEEP valve that provides PEEP equivalent of that being administered to the patient with the ventilator. Keep the patient connection of the manual ventilator clean and covered and the valve free of secretions.

Operator Error

The provision of mechanical ventilation is highly complex, the equipment used is very sophisticated, and the potential options to be applied to a given patient increase each year. As a result, clinician error is an ongoing concern. To minimize the possibility of error, a clinician should never make an adjustment to a

TABLE 47.4 Causes of Sudden Respiratory Distress and Remedies in a Patient Receiving Ventilatory Support

Cause	Remedy
Patient Related	
Artificial airway problems	Assessment of cuff, airway position (see Chapter 37)
Pneumothorax	Chest tube insertion
Bronchospasm	Bronchodilator therapy
Secretions	Suctioning, tracheobronchial hygiene
Pulmonary edema	Therapy directed at cause of pulmonary edema
Auto-PEEP	Decreased minute volume, tracheobronchial hygiene, decrease in I:E
Abnormal respiratory drive	Therapy directed at cause, possible sedation or paralysis
Alteration in body posture	Repositioning of patient
Abdominal distention	Therapy directed at cause, insertion of nasogastric tube
Anxiety	Reassurance, anxiolytics, assessment of minute ventilation
Patient–ventilator asynchrony	Assessment of flow and sensitivity, auto-PEEP, change of mode to accommodate patient's pattern of ventilation
Ventilator Related	
System leak	Assessment of connections in the ventilator circuit
Circuit malfunction	Assessment of circuit with test lung, replace if necessary
Inadequate FiO_2	Assessment of SpO_2, assessment of FiO_2 with analyzer, increase in FiO_2, or replacement of blender or ventilator if malfunction is found
Inadequate ventilatory support	Review of therapeutic strategy for the patient (see Chapter 49)
Improper flow-trigger setting	Adjust trigger and flow to patient demand

PEEP, Positive end-expiratory pressure.

mechanical ventilator unless he or she has been properly trained to operate the ventilator and the clinician's skills at using the machine have been assessed by an independent evaluator. It is essential for the operator to document ventilator settings in a consistent manner and to understand the terminology used when documenting the ventilator–patient interaction charted in medical record. Appropriate operation of the mechanical ventilator should be assessed on a regular basis based on the severity and criticality of the patient's clinical presentation. To minimize errors, any adjustment should be checked to ensure that the appropriate change was actually made and that the patient responded as expected. A clinician should never leave the bedside of a patient until the clinician is assured that the patient is being ventilated as ordered and that the ventilator is responding as expected. Patient safety should always be the primary concern of all RTs.

SUMMARY CHECKLIST

- Response to an increase in FiO_2 helps to determine the cause of hypoxemia.
- Hypoxemia responsive to an increase in FiO_2 is likely caused by a low $\dot{V}/\dot{Q}$ ratio.
- Hypoxemia unresponsive to increased FiO_2 is likely caused by a diffusion defect or shunt.
- Alveolar ventilation and CO_2 production determine $PaCO_2$.
- Mechanical ventilation should increase alveolar ventilation and may decrease CO_2 production when WOB is relieved. These factors decrease $PaCO_2$.
- Mechanical ventilation with positive pressure increases dead space and increases $\dot{V}/\dot{Q}$ ratio.
- Inspiratory or expiratory time can be manipulated to improve oxygenation and alveolar emptying in disorders that affect alveolar time constants.
- Physiologic benefits of PPV include improved oxygenation and ventilation, alveolar expansion, decreased WOB and cardiac work, and improved O_2 delivery.
- No outcome differences have been identified among the various modes of ventilation except that SIMV prolongs the weaning process. However, modes of ventilation that allow the patient control over the process of gas delivery have been shown to improve patient–ventilator synchrony.
- No single flow pattern has been shown to be the most physiologically beneficial. However, research results indicate better oxygenation, ventilation, and patient–ventilator synchrony with the decelerating flow compared with the square wave flow pattern.
- A decelerating flow waveform tends to have a lower peak and a higher mean airway pressure, whereas a square wave tends to have a higher peak and a lower mean airway pressure.
- Flow triggering appears to decrease WOB compared with pressure triggering on older generation ventilators.
- PEEP is used to restore FRC in acute restrictive disease and to splint the airways in obstructive disease.
- WOB is decreased by the appropriate application of mode, trigger variable, and flow.
- PPV is detrimental to the $\dot{V}/\dot{Q}$ ratio primarily by shifting ventilation to areas that are less perfused. PPV can cause hyperventilation, tissue damage, and barotraumas if not carefully managed.
- PPV can decrease venous return and cardiac output, especially when it increases intrapleural and mean airway pressures.

- PPV can cause renal, hepatic, and gastrointestinal malfunction primarily owing to decreased perfusion of the capillary tissue beds.
- Elevation of the head, osmotic diuretics, and CSF drainage are effective means of decreasing ICP in TBI. Acute hyperventilation should be used only temporarily until other, more effective means can be used.
- Ventilator bundles should always be adhered to during mechanical ventilation to minimize the development of ventilator-associated pneumonia.
- Patient safety and error-free patient care are the first priority when caring for any patient.

Patient–Ventilator Interactions

Robert M. Kacmarek

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the reasons why appropriate patient–ventilator interactions are critical to ensuring safe and effective mechanical ventilation
- Discuss those clinical issues that can result in poor patient–ventilator interaction
- Discuss and define the different types of asynchronies commonly observed during mechanical ventilation
- Discuss the control variables that affect appropriate patient–ventilator interaction and identify the modes of ventilation that are most likely to result in asynchrony
- Discuss the steps that should be taken to determine the cause and correction of asynchrony before sedation is considered
- Discuss what should be done to modify or eliminate flow asynchrony
- Discuss the setting of rise time during pressure-targeted ventilation
- Discuss what should be done to modify double triggering/reverse triggering
- Discuss what should be done to modify missed triggering
- Discuss what should be done to modify delayed triggering
- Discuss what should done to modify autotriggering
- Discuss the setting of expiratory cycling criteria during pressure support ventilation
- Discuss the reasons why proportional assist ventilation and neurally adjusted ventilatory assist modes are most likely to result in the least asynchrony
- Discuss the measurement of P_{100} during the patient–ventilator assessment to identify excessive ventilatory drive and modify approaches to ventilatory support

CHAPTER OUTLINE

KEY TERMS

atrophy
autotriggering
cycle asynchrony
diaphragmatic dysfunction
double triggering
fatigue
endobronchial intubation
expiratory cycling criteria
innominate artery rupture
missed triggering
mode asynchrony
neurally adjusted ventilatory assist (NAVA)
P_{100} or $P_{0.1}$
patient–ventilator asynchrony
proportional assist ventilation (PAV)
reverse triggering
rise time
tension pneumothorax
tracheal malasia
tracheal stenosis
tracheoesophageal fistula
trigger asynchrony
trigger delay

In general it is relatively easy to set and adjust the ventilator during controlled mechanical ventilation because the patient does not actively interact with the mechanical ventilator. Though rarely used, controlled mechanical ventilation is provided entirely as a result of the adjustments made by the managing clinician. This is not true during assisted patient-triggered ventilation or partial ventilatory support. In this setting the patient and the ventilator must interact intimately, the ventilator must be set to meet the patient's ventilatory demand, and the patient must be capable of adjusting to the settings of the ventilator. In many modes of mechanical ventilation the patient must follow the lead of the ventilator—that is, adjust to the way the ventilator is set and breathe with a ventilatory pattern that is consistent with the parameters defined by the mode of ventilation applied and the specific settings.[1,2] When this interaction is not good, **patient–ventilator asynchrony** occurs or the patient is characterized as "fighting the ventilator."[3] However, it must be noted that there are many other clinical/technical issues that can result in poor patient–ventilator interaction. In this chapter all aspects of patient–ventilator interaction are discussed with a focus on what should be done to improve the interaction. It is important to remember that sedation of the patient is **ALWAYS** the last intervention to be considered to improve patient–ventilator interaction. When sedation is used, it should be administered sparingly. The patient, airway, and ventilator should all be carefully assessed and necessary adjustments made before deciding whether sedation will be needed to improve patient–ventilator interaction.[3]

RULE OF THUMB Appropriate patient–ventilator interaction during patient-triggered assisted ventilation requires intimate coordination between the demands of the patient's respiratory center and the settings of the mechanical ventilator.

Patient–ventilator interaction refers to patient comfort, work of breathing (WOB), and synchrony during patient-triggered breaths. Generally, ventilatory support should be initially adjusted to minimize the WOB and to allow the ventilatory muscles to rest.[3,4] **Diaphragmatic dysfunction** often accompanies ventilatory failure, and a sustained increase in workload can lead to structural injury to the ventilatory muscles.[5] When the ventilatory muscles become fatigued, at least 24 hours is required for recovery.[6] At the other extreme, complete rest of the diaphragm, as in controlled ventilation, may lead to diaphragmatic deconditioning, weakness, and atrophy in 48 hours.[6] In the presence of spontaneous breathing, inappropriate ventilator settings may further increase patient work and **fatigue**.[2] However, careful selection of ventilator settings can reduce the workload to a normal range without resulting in deconditioning and **atrophy** of the respiratory muscles.[2]

EFFECTS OF POOR PATIENT–VENTILATOR INTERACTION ON OUTCOME

Regardless of the cause of the poor patient–ventilator interaction, the result is negative for the patient. At a minimum, hemodynamics, ventilatory pattern, and gas exchange are adversely affected. Patients may become hypotensive, hypertensive, tachycardic, or bradycardic. Their ventilatory pattern may markedly change to a rapid shallow pattern or they may attempt to inhale large tidal volumes (V_T) at a slow rate when their ventilatory drive is affected by pharmacologic agents. Normally, poor patient–ventilator interaction results in hypoxemia due to poor matching of ventilation and perfusion or increased true shunt. Both hypercarbia and hypocarbia may result, based on the stimulus. Those who experience hypoxemia will frequently respond with hyperventilation. However, if hemodynamic compromise is present, hypercarbia is normally the result.[3] The reason for this is an alteration in dead space. Any decrease in cardiac output will result in an increase in dead space, which promotes hypercarbia unless the patient has the ability to increase the minute ventilation.

Most causes of poor patient–ventilator interaction are of rather short duration because the continuation of the cause frequently has significant negative short-term effects. For example, a tension pneumothorax during mechanical ventilation must be corrected quickly or it will lead to cardiac arrest. Obstruction of the airway, even if only partial, normally results in marked changes in airway pressure or V_T, which should rapidly alert clinicians to the problem. Bronchospasm or pulmonary edema are usually rapidly recognized by the changes in clinical presentation and alterations in patient response to the ventilator. Patient–ventilator asynchrony is a more subtle problem that can be difficult to identify and can persist for the entire time that the patient is mechanically ventilated. Identification of asynchrony calls for a careful assessment of patient and ventilator waveforms and sometimes also a lengthy observation of waveforms. Although asynchrony is more subtle than other causes of poor patient–ventilator interaction, its effects in the long term can be very serious. Recent data indicate that asynchrony occurs in all patients receiving assisted patient-triggered ventilation, is most significant during the morning when clinician–patient interaction is greatest, is present even during periods of sedation, and varies from mild to very severe.[7] It is most important to remember that asynchrony has been associated with increased length of mechanical ventilation, length of stay in the intensive care unit (ICU), and length of hospitalization. The need for tracheostomy and ICU and hospital mortality are also increased.[7-10] At this time it cannot be said that asynchrony causes an increase in mortality, but patients who have high levels of asynchrony have greater ICU and hospital mortality than those who have lower levels of asynchrony. Therefore, a careful review of ventilator waveforms and ventilator settings should occur during every patient–ventilator assessment, and adjustments should be made to minimize the level of asynchrony every time the clinician assess a patient.

RULE OF THUMB Asynchrony has been associated with increased length of mechanical ventilation, ICU and hospital length of stay, the need for tracheostomy, and ICU and hospital mortality.

CAUSES OF POOR PATIENT–VENTILATOR INTERACTIONS

The primary causes of poor patient–ventilator interaction are listed in Table 48.1. It is important to note that most of these

TABLE 48.1 Causes of Poor Patient–Ventilator Interaction

Patient-Related Causes
Abnormal respiratory drive
Abdominal distension
Alteration in body posture
Artificial airway problems
Agitation
Bronchospasm
Drug-induced problems
Dynamic hyperinflation
Fever
Hemodynamic compromise
Hypoxemia
Pneumothorax
Pulmonary edema
Pulmonary embolism
Secretions
Ventilator-Related Causes
Circuit malfunction
Inadequate F_iO_2
Inadequate ventilator support
System leak
Patient–ventilator asynchrony

issues also result in sudden respiratory distress. Except for some forms of asynchrony, the causes listed in Table 48.1 can arise in patients under both controlled and assisted ventilated.

Change in Clinical Status

One of the primary causes of poor patient interaction with the mechanical ventilator is a change in the patient's clinical status.[3] Excessive secretions, bronchospasm, and agitation are the most common and regularly seen causes of poor patient-ventilator interaction, and these issues should be assessed at every patient–ventilator assessment. In addition, fever, hypoxemia, and hemodynamic compromise are also regular causes of poor patient–ventilator interaction (see Table 48.1). When these issues are present, the cause should be identified and rapidly corrected. In addition, artificial airway problems, pneumothorax, pulmonary edema, pulmonary embolism, dynamic hyperinflation, alterations of body position, drug administration, and abdominal distention can all cause poor patient–ventilator interaction.[3]

Artificial Airways

Artificial airway problems are a common cause of sudden respiratory distress. As outlined in Chapter 37, a number of problems can suddenly occur with artificial airways. Of primary concern is the development of biofilm on the internal surface of the endotracheal tube, as illustrated in Fig. 48.1. Biofilm develops on all endotracheal tubes. Extensive biofilm development on the inner surface of the endotracheal tube can markedly alter a patient's clinical presentation and also place him or her at higher risk for pulmonary infection.[11] Patients who are aspirating oral secretions around the endotracheal tube or who produce excessive secretions in the lower airway can easily develop obstructions

Fig. 48.1 An endotracheal tube with biofilm/secretions partially occluding greater than half of the airway. (From Mietto C, Foley K, Salerno L, et al: Removal of endotracheal tube obstruction with a secretion clearance device, *Respir Care* 59:e122–e126, 2014.)

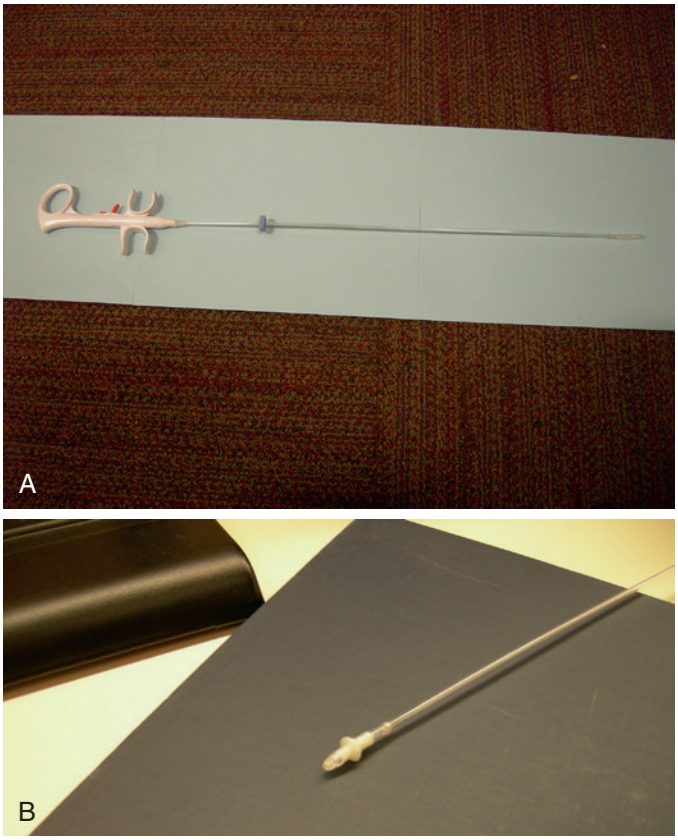

Fig. 48.2 (A) Picture of a mucus shaver device. This device is designed to remove biofilm/secretions from the inside of an artificial airway. (B) The dilated tip of the mucus shaver inflated to remove secretions.

that occupy more than 50% of the lumen of the endotracheal tube. This can rapidly progress to complete occlusion if proper humidification is not provided.[12] If the lumen of the endotracheal tube is almost totally obstructed, airway resistance markedly increases, resulting in an increase in peak airway pressure during volume ventilation and a decrease in V_T in pressure ventilation. This is an airway emergency requiring immediate action. Either the endotracheal tube must be changed or the secretions must be removed. A number of devices designed to remove secretions from the lumen of the artificial airway are currently on the market (Fig. 48.2). These "mucus shavers" can help to avoid the need to change the airway and can also dramatically improve ventilation.[13,14]

Another common problem with endotracheal tubes is movement of the airway into the oral pharynx or movement into the right mainstem bronchus. Thus it is important to determine the location of the endotracheal tube at each patient–ventilator assessment. Depending the patient's height, the tube should be positioned about 22 to 25 cm from the teeth (incisors) in men and about 19 to 23 cm from the teeth in women (see Chapter 37). In addition, following intubation, the location of the tip of the tube in relation to the carina must be evaluated. In adults, the tip of the tube should be 3 to 5 cm above the carina; its length at the teeth should also be noted and regularly reassessed to ensure proper placement.

A right mainstem intubation presents with sudden increases in airway pressure and absent breath sound on the left side of the chest. Depending on the patient's status, hypoxemia, hypercarbia, and hemodynamic compromise may be present. Careful movement of the tube to the proper position at the teeth corrects this problem. Following adjustment, however, a chest x-ray should always be taken to ensure proper positioning. Flexion and extension of the head and neck always results in movement of the tip of the endotracheal tube. Extension of the head and neck moves the tip closer to the carina and flexion moves the tip closer to the pharynx. This movement on average is 1 to 3 cm in either direction and can be as much as 7 cm.

Kinking of the endotracheal tube is also a potential problem. This usually occurs in a patient with a well-secured endotracheal tube that the patient is actively trying to move out of the airway by biting and "tonguing" the tube. This causes the tube to move toward the oral pharynx, but because it is well secured, it kinks. The result is increased airway resistance. Inability to pass a suction catheter more than a short distance into the airway and visualization of the tube in the mouth and pharynx identifies this problem. Repositioning of the tube is indicated. Differentiation of tube kinking from tube obstruction can be difficult, but biofilm and secretion obstruction usually occurs in the lower third of the airway and kinking the middle to the first third of the airway.

Long-term artificial airway placement can also result in the development of **tracheal stenosis**, **tracheal malasia**, **tracheoesophageal fistula**, and **innominate artery rupture**. Of these, innominate artery rupture is the most devastating. It requires surgical intervention and can be fatal. It is difficult to identify the problem until the rupture actually occurs. However, in some patients the tracheostomy tube will start to pulsate with eroding of the tracheal wall toward the innominate artery, allowing the pulse to be counted from the pulsation.

Pneumothorax

Another life-threatening situation during mechanical ventilation is the development of a pneumothorax, which in most circumstances is a tension pneumothorax. That is, with every positive-pressure breath, more gas moves into the pleural space but is unable to exit it. As a result, the pressure in the pleural space continues to increase, causing lung collapse and eventually complete cardiovascular collapse and cardiac arrest. Treatment is decompression of the pleural space and the placement of a chest tube, as described earlier.

A tension pneumothorax typically develops very rapidly. Airway pressure increases with each breath in volume ventilation, whereas V_T decreases with each breath in pressure ventilation. The change is more dramatic in volume ventilation than in pressure ventilation because, in pressure ventilation, the pressure in the pleural space can increase only to the peak pressure set by the clinician, whereas in volume ventilation pressure can increase to the pressure limit setting, which may be very high. As pressure increases, the affected side's lung collapses and begins to compress the unaffected side. In severe cases, the mediastinum and trachea are shifted away from the side with the pneumothorax. Patients rapidly become hemodynamically unstable. Breath sounds are absent on the side of the pneumothorax, the percussion note is hyperresonnant on the affected side, and palpation of the chest generally shows a rise and fall only of the side of the chest opposite the pneumothorax.

RULE OF THUMB A tension pneumothorax causes increasing airway pressure with each breath in volume ventilation and decreasing V_T with each breath in pressure ventilation. As pressure in the pleural space increases, lung collapse occurs.

Airway Emergencies

A rapid deterioration in the patient's clinical status associated with increased airway pressure and decreased V_T associated with progressive hemodynamic compromise and deteriorating gas exchange should always alert clinicians to the possibility of three problems: tension pneumothorax, airway obstruction, and right mainstem intubation. Box 48.1 lists the steps that should be taken to identify the cause of the problem. Removing the patient from the ventilator and manually ventilating (using an AMBU bag) with rapid shallow breaths will eliminate the ventilator as the cause of the concern. Rapid suctioning of the airway will determine if airway obstruction is the problem. If obstruction is not the problem, then **endobronchial intubation** or a **tension pneumothorax** is the cause. If assessment of the patient is consistent with a tension pneumothorax and the tube is at the correct length at the teeth, the problem is almost always a tension pneumothorax. Severe hemodynamic compromise and continued increasing of airway pressure are not normally seen in a right mainstem intubation.

BOX 48.1 Management of Sudden Respiratory Distress

1. Remove the patient from the ventilator.
2. Initiate manual ventilation using a self-inflating bag delivering 100% oxygen. If unable to ventilate, remove airway and bag-mask ventilate.
3. Perform a rapid physical examination and assess monitored indices.
4. Check patency of the airway (pass a suction catheter). If airway is completely obstructed, remove airway and bag-mask ventilate.
5. If death is imminent, consider and treat the most likely causes (e.g., pneumothorax, airway obstruction).
6. After the patient is stabilized, undertake more detailed assessment and management.

MINI CLINI

Management of Emergency Airway Issues

Problem

Mr. Smith is a 36-year-old victim of a motor vehicle accident presenting with massive head and chest trauma. He is immediately intubated in the emergency department and mechanically ventilated in the volume control mode. He has received sedation and paralysis and is ventilated with the following settings: V_T 500 mL (6 mL/kg predicted body weight [PBW]), rate 22/min, peak flow 40 L/min, inspiratory time 0.66 seconds, 10 cm H_2O positive end-expiratory pressure (PEEP), and an F_iO_2 of 60%. At these settings his SpO_2 is 95%, pulse is 78/min, and arterial blood pressure is 110/70. His peak airway pressure is 24 cm H_2O, and his plateau pressure is 18 cm H_2O. He has received a total of 4 L of fluid.

The respiratory therapist (RT) standing at the bedside observes a breath-by-breath increase in the patient's peak airway pressure, and the high-pressure alarm sounds at 50 cm H_2O. His SpO_2 has decreased to 88% and appears to be decreasing breath by breath. His pulse is 140/min and blood pressure is 80/50. The RT observes that the patient's trachea is deviated to the left, and on auscultation there are no breath sounds on the left. The percussion note is hyperresonant on the left side and on palpitation the RT notes a rise only of the right chest. What should be done?

Solution

Clearly some dramatic change in the ability to ventilate the patient has rapidly occurred. This presentation is most likely the result of an airway obstruction, a mainstem intubation, or a tension pneumothorax. Therefore the patient should immediately be disconnected from the ventilator and the endotracheal tube suctioned. This will eliminate obstruction of the airway and the ventilator as the problem. It is most likely not a mainstem intubation because most such intubations are into the right mainstem bronchus and the fact that breath sounds are absent on the right eliminates this. In addition, the patient's presentation is more consistent with a tension pneumothorax; rapid deterioration, hyperresonant on the affected side, deviated trachea way from the affected side, and an increase in peak airway pressure with each breath (see Chapter 16).

Immediate decompression of the chest with a 19-gauge needle is indicated, followed by insertion of a chest tube. Decompression is done by sliding the needle over the third rib at the mid-nipple line. Blood vessels and nerves run along the lower border of the ribs, not the upper border. During these procedures, very gentle ventilation with a manual ventilator should occur with 100% oxygen and a rapid shallow pattern minimizing pressure to avoid extending the pneumothorax.

The Mechanical Ventilator

A potential but infrequent cause of poor patient–ventilator interaction is malfunction of the mechanical ventilator. Poor responsiveness and ventilator circuit issues can be a problem, but with the newest generation of mechanical ventilators these technical malfunctions are rarely the cause of poor patient–ventilator interaction. However, the ventilator settings should be checked to ensure that an appropriate V_T, respiratory rate, and F_iO_2 are being delivered.

RULE OF THUMB The percentage of breaths on average that are asynchronous is about 3%, but at some periods of time in some patients over 50% of the breaths may be asynchronous![7]

VARIABLES CONTROLLED DURING MECHANICAL VENTILATION

During spontaneous ventilation the individual has complete control over the process of gas movement into and out of the lungs. In health, normal breathing is a process that generally goes unnoticed; we breathe without conscious thought of breathing and without any effort. As we know from the equation of motion (discussed in detail in Chapter 47), all of the WOB is provided by the individual during spontaneous breathing. During controlled ventilation the patient has absolutely no control over the process of ventilation. The ventilator moves gas into and out of the lungs based on how the clinician decides to set the mechanical ventilator. Thus, from the patient's perspective, no active work is performed and no concern exists for coordination between what the respiratory center desires versus how the clinician sets the ventilator. Of course, to achieve controlled ventilation, the patient must be pharmacologically medicated to apnea. Assisted mechanical ventilation is very different from either spontaneous breathing or controlled ventilation. In this case the patient and the ventilator must intimately interact. Ideally the ventilator is set to meet the neurologic output from the respiratory center and there is no competition between the respiratory center and the ventilator. However, this is rarely achieved in critically ill patients. The percentage of breaths on average that are asynchronous is about 3%, but during select time periods in some patients over 50% of the breaths are asynchronous.[7]

TABLE 48.2 Variables Controlled During Different Modes of Mechanical Ventilation Possible Variables Controlled: Pressure, Flow, Volume, and Time

Volume A/C	Volume
	Flow
	Time
Pressure A/C	Pressure
	Time
Pressure support	Pressure
PAV and NAVA	None

A/C, Assist/control; *NAVA*, neurally adjusted ventilatory assist; *PAV*, proportional assist ventilation.

Generally, the more control exerted by the ventilator, the greater the likelihood that the patient will be asynchronous.[15-17] With the classic modes of ventilation, the ventilator leads and the patient must follow. Specifically, if the clinician sets the inspiratory time at 1.0 second or the V_T at 400 mL, this is what the patient must accommodate to. This accommodation is difficult, and as a result, asynchrony occurs. Depending on the mode of ventilation, the ventilator can control one or more of the following gas delivery variables: pressure, flow, volume, or time (Table 48.2). The more variables controlled, the greater the likelihood of asynchrony. Volume ventilation is the most controlling mode of ventilation because the ventilator in some way controls volume, flow, and time. The only variable the patient can control is pressure. As a result, the likelihood of asynchrony is greater with volume assist/control (A/C) than with any other mode of ventilation. With pressure A/C, the ventilator controls only pressure and time; less control means less likelihood of asynchrony. In pressure support, only the pressure is controlled; thus, of all the classic modes of ventilation, the mode that is least likely (if set properly) to cause asynchrony is pressure support. However,

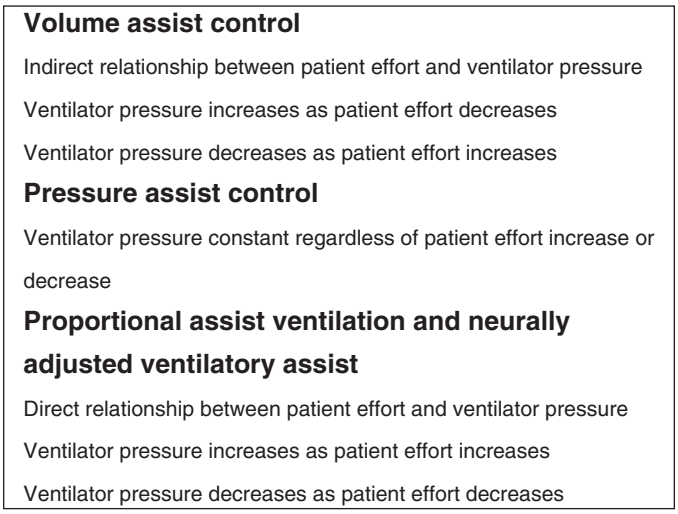

Fig. 48.3 Ventilator Modes: Relationship Between Ventilator Pressure and Patient Effort During Various Forms of Ventilatory Support. Proportional assist ventilation and neurally adjusted ventilatory assist present the ideal relationship between patient effort and ventilator pressure. As patient effort increases, ventilator pressure increase, and as patient effort decreases, ventilator pressure decreases. With pressure ventilation, ventilator pressure is constant regardless of change in patient effort. Volume ventilation establishes an inverse relationship between patient effort and ventilator pressure. As patient effort increases, ventilator pressure decreases, and as patient effort decreases, ventilator pressure increases.

as is well documented in the literature,[18-23] **proportional assist ventilation (PAV)** and **neurally adjusted ventilatory assist (NAVA)** are the modes of ventilation that are least likely to cause asynchrony because they do not exert any control over the patient. These modes do not control pressure, flow, volume or time. What they do is provide a proportional assist based on patient demand (see Chapters 46 and 47). They do not require the patient to conform to the settings of the clinician, but instead they require the ventilator to follow the output of the respiratory center, and as a result the patient's respiratory center controls the ventilatory pattern—thus, less asynchrony.[18-23]

Fig. 48.3 discusses the response of different modes of ventilation to patient demand.[24] As noted, when patient demand (effort) increases in volume ventilation, the ventilator provides less support; that is, an inverse relationship between patient effort and ventilator pressure is established. In pressure ventilation, when patient demand increases, the ventilator support remains unchanged. However, in PAV and NAVA, as patient effort increases, ventilatory support increases, and as patient effort decreases, ventilatory support decreases.[22,24] Control is by the patient's respiratory center, creating greater synchrony than any other approaches to ventilatory support.

RULE OF THUMB The ventilator can control one or more of the following gas delivery variables: pressure, flow, volume, or time. The more of these variables controlled by the ventilator, the greater the likelihood of asynchrony.

TYPES OF ASYNCHRONY

Table 48.3 lists the types of asynchrony. **Flow asynchrony** occurs when the flow from the ventilator does not match the flow demand of the patient.[25-29] This can occur in any mode of ventilation but most commonly occurs in volume ventilation because the clinician sets the V_T, peak flow, flow waveform, and inspiratory time. Thus, the patient's respiratory center must demand exactly the same gas delivery each and every breath that equals that set on the ventilator, or there will be flow asynchrony.

TABLE 48.3 Types of Asynchrony

Flow asynchrony	Inadequate flow at onset and during inspiration to meet patient demand, can induce lung injury if not corrected.	
Trigger asynchrony	Poor coordination of patient's initiation of inspiration and ventilator response. Double triggering can induce lung injury.	Trigger delay Double trigger Missed trigger Autotrigger Reverse triggering
Cycling asynchrony	Poor coordination of patient's desire to exhale and ventilator response.	Inappropriately short inspiratory time, Inappropriately long inspiratory time
Mode asynchrony	Inappropriate mode	

There are several forms of **trigger asynchrony**, and each can occur in any mode of ventilation. The most common form of trigger asynchrony is **trigger delay**, in which the length of time between the beginning of neuro-inspiration and activation of the ventilator is excessive.[29] Under normal circumstances, trigger delay should not exceed 100 ms to avoid patient perception of the delay and an increase in ventilatory drive.[29-31] Another common form of trigger asynchrony is **missed triggering**, in which the patient is unable to trigger the ventilator with each inspiratory effort. Frequently a pattern of missed triggering and triggering is established.[32-34] That is, for every two or three inspiratory efforts, the ventilator is triggered only once.[31-34] **Double triggering** is usually a result of the patient's ventilatory center desiring a larger breath or a longer inspiratory time than is set on the ventilator.[35] This causes the patient to continue inspiration when the ventilator transitions into the expiratory phase, resulting in the ventilator triggering a second time. The biggest problem with double triggering is that there may be no exhalation after the first breath, so that the actual delivered V_T may be up to double what is set on the ventilator. Double triggering is most common with volume A/C because of the precise setting of the V_T. **Autotriggering** is a much less frequent form of trigger asynchrony. It is the seemingly automatic triggering of the ventilator without any patient inspiratory effort.[36]

The most recently described from of trigger asynchrony is **reverse triggering**. With reverse triggering a controlled mechanical breath results in stimulation of the respiratory center, which then triggers the subsequent breath.[37,38] This form of asynchrony occurs only during controlled ventilation. Most of the other forms of asynchrony occur only during assisted ventilation.

Cycle asynchrony occurs when the ventilator ends the breath at a time different from when the patient's respiratory center wants to end the breath.[39-42] It is more common in pressure-targeted than in volume-targeted ventilation, but it can occur

TABLE 48.4 Causes of Asynchrony

Inappropriately Set Sensitivity	
Inappropriately set PEEP	If inadequate, atelectasis inducing greater patient effort
Auto-PEEP	Causes missed triggering
Volume A/C	Inadequate peak flow
	Inappropriate inspiratory time
	Inadequate or excessive V_T
Pressure A/C or pressure support	Inappropriate rise time
	Inappropriate inspiratory time or inappropriate inspiratory termination criterion
	Inadequate or excessive driving pressure
Inappropriate mode of ventilation	Patient unable to tolerate mode of ventilation without excessive ventilation asynchrony

A/C, Assist/control; PEEP, positive end-expiratory pressure; V_T, tidal volume.

in all modes of ventilation. Cycle asynchrony is described in two forms: asynchrony that results in an inappropriately long inspiratory time, and asynchrony that results in an inappropriately short inspiratory time.

Mode asynchrony is the selection of a mode of ventilation that is highly unlikely to meet a patient's inspiratory demand. As should be obvious from Table 48.2, during assisted ventilation it is most likely that mode asynchrony will occur with volume A/C, followed by pressure A/C, and then pressure support. It is least likely to occur with PAV and NAVA.[18-22,43]

CAUSES OF ASYNCHRONY

Table 48.4 summarizes the major causes of asynchrony. Across all modes of ventilation, inappropriately set sensitivity, inappropriate selection of PEEP, and the presence of auto-PEEP result in asynchrony. The one exception to this is NAVA; because NAVA is controlled by the diaphragmatic electromyographic (EMG) signal, the presence of auto-PEEP does not affect the function of this mode.[34] All other modes are triggered by airway pressure, flow, or volume and are dramatically affected by auto-PEEP. In volume ventilation, poor matching of the ventilator settings to the patient's ventilatory drive results in asynchrony. Specifically, inadequate peak flow and inadequate or excessive inspiratory time result in asynchrony. In pressure A/C or pressure support ventilation, asynchrony is caused by inappropriately set rise time, inappropriately set inspiratory time (pressure A/C) or termination criteria (pressure support), and inadequate or excessive V_T. Finally, selection of an inappropriate mode can cause asynchrony (see Chapters 47 and 49).

RULE OF THUMB Asynchrony is a result of inappropriate matching of the ventilator's settings and the patient's ventilatory demand or the presence of auto-PEEP.

FLOW ASYNCHRONY

Volume Ventilation

Flow asynchrony can occur in any mode of ventilation but is more common in volume A/C because a precise flow pattern

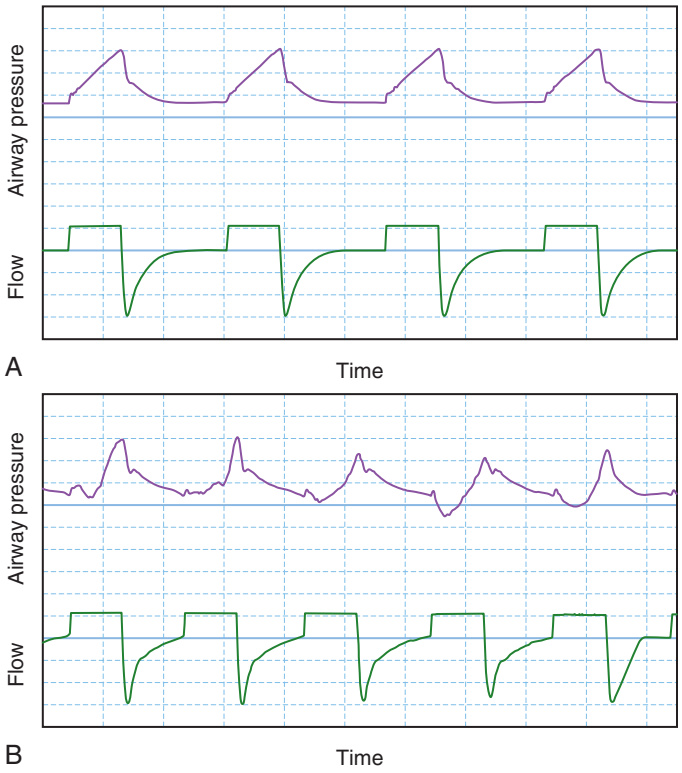

Fig. 48.4 Flow Asynchrony During Volume Assist/Control. (A) Airway pressure and flow waveforms during controlled volume ventilation. Note the linear increase in airway pressure over time. (B) Same patient with severe flow asynchrony during patient-triggered ventilation. The ventilator is not able to meet patient demand, resulting in a markedly altered airway pressure waveform. The difference between the area under the airway pressure-versus-time waveforms (A and B) is equal to the work of breathing preformed by the patient during patient-triggered ventilation.

and peak flow is set, resulting in the selected V_T being delivered in a precise inspiratory time. This is not physiologic; with normal spontaneous breathing, there is a large variability in the ventilatory pattern from breath to breath.

If a patient is spontaneously triggering the ventilator, peak flow delivery during volume ventilation should match the patient's inspiratory flow demand.[25,26] Most adult patients with moderate to strong ventilatory demands require a peak flow of 60 L/min or greater. As shown by Marini and colleagues,[25,26] if the peak flow does not meet the patient's inspiratory demand, the WOB performed by the patient increases (Fig. 48.4). In this setting, the efficiency of the work may be greater than during spontaneous breathing, but the overall patient work may be similar.[25,26] In volume ventilation, there is always an indirect relationship between the work provided by the ventilator and the patient's WOB (see Fig. 48.3). The more work the patient does, the less work the ventilator performs for the patient. If the patient is triggering the positive pressure breaths, the WOB is shared between the patient and the ventilator. For this reason, patients initially receiving assisted ventilation show altered gas delivery patterns after they are sedated to apnea. With the transition to controlled ventilation, the peak airway pressure usually increases during volume ventilation.[44] Because the patient no longer performs a portion of the WOB, the work performed by the ventilator

Fig. 48.5 Airway pressure *(P_{aw})*, flow, volume, raw *(R_{aw})* electromyographic activity of the diaphragm *(E_{di})*, integrated E_{di}, and muscular work of the diaphragm *(P_{mus})* in volume ventilation during varying inspiratory flow and inspiratory time settings (columns *A, B, C, D, E*). As peak flow is increased and inspiratory time is decreased (left to right), indices of patient effort and work are decreased. Ideal settings of flow and inspiratory time generally can be identified by observing the airway pressure curve during volume ventilation. The closer the airway pressure curve is to the ideal curve (*D* and *E*), the less the patient's work. (From Fernandez R, Mendez M, Younes M: Effect of ventilator flow rate on respiratory timing in normal humans, *Am J Respir Crit Care Med* 159:710–719, 1999.)

must increase. The opposite is also true in volume ventilation when the patient's ventilatory demand is high—the patient can be doing a disproportionate amount of work if the ventilator is not set to meet the patient's inspiratory demand.

Most ventilators during volume A/C can deliver gas flow in a decelerating or square-wave flow pattern. If the patient is triggering inspiration, we recommend a decelerating flow pattern, especially when a small V_T is being delivered.[44,45] A decelerating flow pattern allows a high peak flow to be delivered but also ensures that the inspiratory time can be adequately set. In patients who are sedated and who are not triggering the ventilator, the choice of flow waveform is unimportant, and the setting of peak flow depends on the inspiratory time and V_T desired by the clinician.

If a patient is triggering every breath, the set inspiratory time should equal the patient's neuro-inspiratory time.[46] As illustrated in Fig. 48.5, when the ventilator's inspiratory time is decreased to equal the patient's desired inspiratory time and peak flow is increased to match the patient's demand, the patient's WOB and effort correspondingly decrease (Box 48.2). This improvement in asynchrony can be performed without changing the V_T, as illustrated in Fig. 48.5. A patient with a moderate to high ventilatory demand rarely desires an inspiratory time greater than 1 second.[44] Many adults with moderate or high ventilatory demands desire an inspiratory time between 0.6 and 0.9 second.[45] Carefully matching the ventilator's inspiratory time with the patient's inspiratory time generally markedly improves patient–ventilator synchrony.

BOX 48.2 Flow Asynchrony: Volume Ventilation

To correct flow asynchrony:

- Change to decelerating flow
- Increase peak flow (>60 L/min)
- Match ventilator's inspiratory time to patient's inspiratory time
- Ensure that the airway pressure waveform is as similar as possible to the ideal airway pressure waveform during controlled volume ventilation
- Change to a pressure-targeted mode of ventilation

In general, the airway pressure waveform during volume A/C ventilation should be similar to the airway pressure waveform during controlled ventilation except for a slight dip in pressure at the start of the breath indicating patient triggering (see Fig. 48.4). The more the actual waveform differs from the ideal, the greater the patient WOB and the greater the asynchrony.[25,26] If the ventilator cannot be set to meet patient demand and all other potential causes of asynchrony have been ruled out, the patient will require sedation or a change in the mode of ventilation. In general, the mode should be changed before the patient is sedated.

RULE OF THUMB Flow asynchrony can occur in any mode of ventilation but is more common in volume A/C; since a precise flow pattern and peak flow are set, the selected V_T are delivered in a precise inspiratory time.

Pressure Ventilation

Flow asynchrony occurs in pressure ventilation but it is less likely than in volume ventilation if the ventilator is set properly. All newer-generation critical care ventilators include an inspiratory pressure **rise time** or pressure slope control. This control functions only with pressure-limited breaths (pressure support ventilation [PSV], pressure control ventilation [PCV], pressure regulated volume control [PRVC], volume support, airway pressure release ventilation, pressure synchronized intermittent mandatory ventilation [SIMV]). The purpose of this control is to adjust the rate at which flow increases from baseline to peak (Fig. 48.6).[46-48] Generally, rise time should be set at a value that ensures adequate inspiratory gas flow (meeting or exceeding patient demand) without an excessive "overshoot" of the pressure at the beginning of inspiration. A slow or low rise time increases the patient's WOB (Fig. 48.7).[46-48] If the rise time is inadequate to meet the patient's demand, a concavity during the initial part of inspiration is noted, similar to what occurs in volume A/C with inadequate flow.[49] As in volume ventilation, the rise time should be set to ensure that the actual airway pressure waveform matches the ideal airway pressure waveform (Box 48.3).

RULE OF THUMB Flow asynchrony can be greatly improved in volume ventilation by increasing peak flow and decreasing inspiratory time. In pressure ventilation, flow asynchrony can be corrected by adjusting rise time.

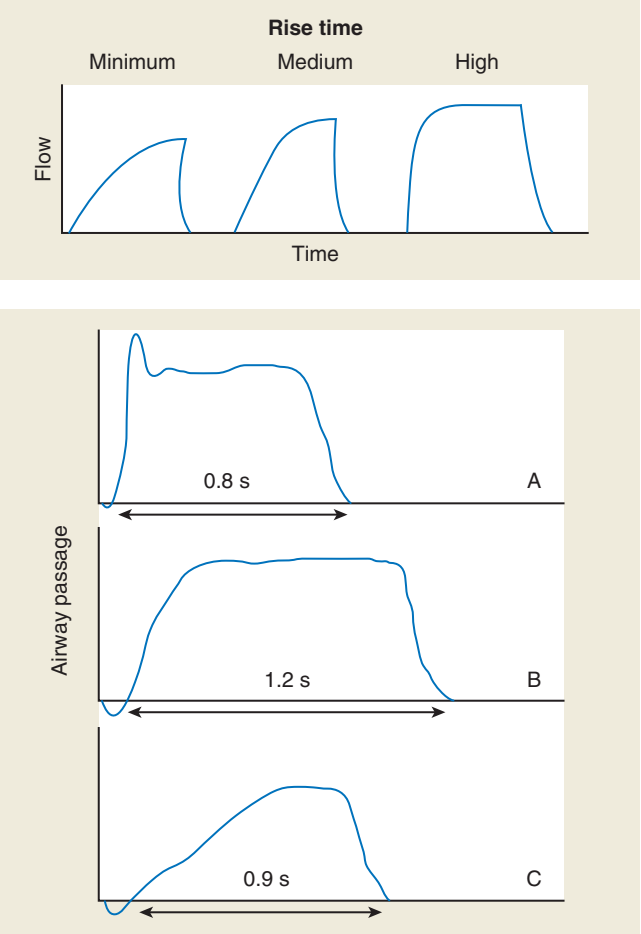

Fig. 48.6 The Effect of Different Rise Time Settings. When rise time is adjusted, the slope of the flow acceleration from zero to peak flow is altered. A slow rise time indicates that peak flow will not be achieved until some time after the midpoint of the breath. A high rise time indicates that peak flow will be obtained early in the breath. A medium rise time is somewhere in between. The actual setting variation depends on the ventilator's manufacturer.

BOX 48.3 Flow Asynchrony: Pressure Ventilation

To correct flow asynchrony:

- Adjust rise time until the initial airway pressure rises rapidly without any concavity but does not exceed the set pressure at the beginning of inspiration.
- If inadequate flow: initial concavity in airway pressure, increase rise time.
- If excessive flow: initial airway pressure exceeds the set level, decrease rise time.

TRIGGER ASYNCHRONY

As noted in Table 48.3, there are numerous types of trigger asynchrony; of these, missed triggering is a common cause of asynchrony. However, the single most important variable affecting trigger asynchrony is the presence of auto-PEEP.

Auto–Positive End-Expiratory Pressure/Missed Triggering

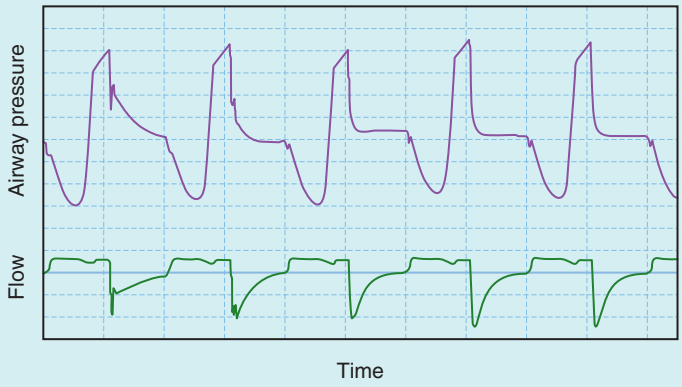
As illustrated in Fig. 48.8, auto-PEEP is a result of air trapped in the lung at the end of exhalation.[50] It can be measured in most ventilators by performing an expiratory pause. Auto-PEEP is most commonly caused by dynamic airway obstruction,[51] but it is also caused by an expiratory time that is too short (and inspiratory time that is too long) or the delivery of excessive minute ventilation/V_T.[52] In dynamic airway obstruction, because of airway disease, the structural integrity of the airways is compromised. A loss of smooth muscle causes the airway diameter to change from inspiration to expiration. During expiration the elastic recoil of the lung and thorax causes these damaged airways to at least partially collapse and in some cases totally collapse, trapping gas behind the obstruction or limiting flow to the point that at end-exhalation there is gas in the lung periphery under pressure or the presence of auto-PEEP.[50,51] The presence of auto-PEEP is not uniform. In some lung units no auto-PEEP is present, and in

MINI CLINI

Assist/Control Volume Ventilation, Square Wave

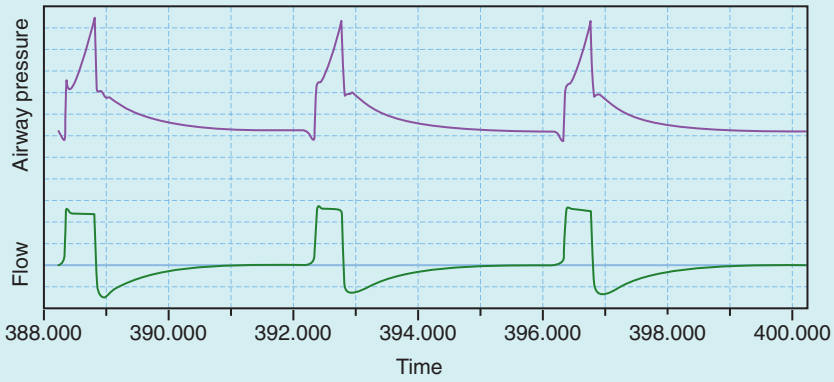
Problem

Mrs. Jones, who is 68 years old, has chronic obstructive pulmonary disease (COPD). She presented in the emergency department with an acute exacerbation and was initially managed with noninvasive pressure support at 8 cm H_2O PEEP. However, after 24 hours she was intubated and mechanically ventilated in volume A/C. She was started at a V_T of 300 mL (5 mL/kg PBW) with an inspiratory time of about 1.0 s and a peak square-wave flow of 20 L/min. Her PEEP level is set at 8 cm H_2O and F_iO_2 at 50%. Her SpO_2 is 90%, pulse 120/min, blood pressure 150/100, and respiratory rate 30/min. You study her airway pressure and flow waveforms and observe the following:



Solution

The shape of the airway pressure-versus-time curve would indicate that there is marked flow asynchrony. The airway pressure during triggering is below baseline for a considerable period of time and the rise in the airway pressure curve is concave and does not reach peak pressure until more than halfway through the inspiratory time. To try to correct this, peak flow should be increased to 50 L/min and the inspiratory time decreased to 0.6 s. When this is done, the following airway pressure and flow waveforms are obtained. These much more closely resemble the ideal waveforms during controlled ventilation.



others there are varying levels of auto-PEEP. When auto-PEEP is measured, the average level of auto-PEEP is determined.

Auto-PEEP can develop in any patient who is mechanically ventilated if the minute ventilation/V_T is excessive and cannot be passively exhaled in the expiratory time defined by the respiratory center.[52] Auto-PEEP essentially has the same effect as applied PEEP but only in the lung units where auto-PEEP develops. In reference to asynchrony, auto-PEEP is the primary reason why missed triggering occurs. Essentially the patient cannot decompress the auto-PEEP with every inspiratory effort, and missed triggering occurs. In patients with COPD, auto-PEEP can be greater than 15 cm H_2O and frequently shows a pattern of one triggered breath to one, two, or three missed triggered breaths (Fig. 48.9).[53]

RULE OF THUMB The primary cause of missed triggering is auto-PEEP. This is normally corrected by decreasing minute ventilation and/or increasing expiratory time. But in the patient with chronic airway obstruction, PEEP is applied to minimize the effort needed to trigger the ventilator.

Applied PEEP has been advocated in the presence of auto-PEEP when the cause of the auto-PEEP is dynamic airway obstruction.[51] In this setting, applied PEEP in the presence of auto-PEEP is indicated only if the patient has difficulty triggering the ventilator. Because the patient is breathing spontaneously, the measurement of auto-PEEP (end-expiratory pause) is very difficult; the patient frequently forces exhalation, negating the measurement. The presence of auto-PEEP is generally indicated by the

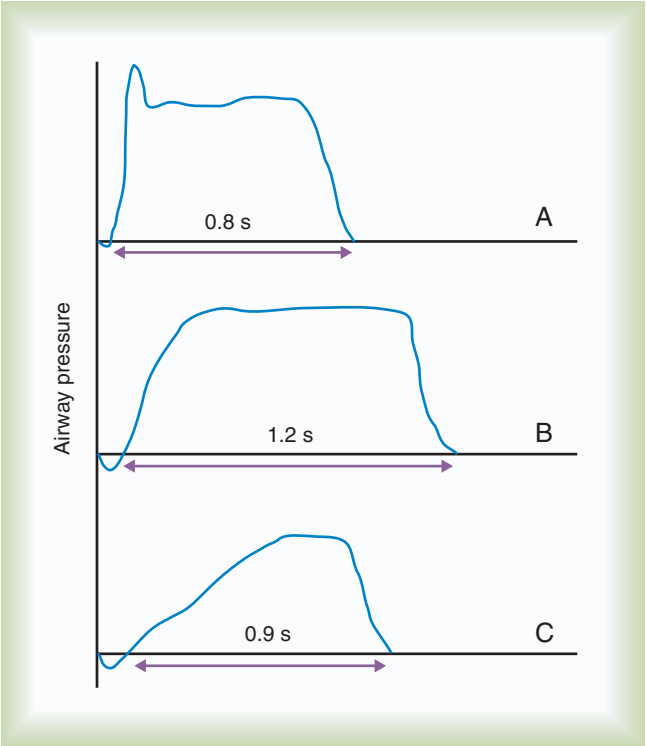


Fig. 48.7 Effect of Changing Rise Time During Pressure-Targeted Breaths for a Patient Who Prefers a Moderate Flow. (A) Flow exceeds patient demand; a pressure spike and short inspiratory time result. (B) As flow decreases, inspiratory time lengthens and the pressure spike disappears. Machine output matches patient demand. (C) When flow is reduced further, patient demand exceeds machine flow; the result is deformation of the pressure waveform and a decrease in inspiratory time. (Modified from Branson RD, Campbell RS, Davis K, et al: Altering flow rate during maximum pressure support ventilation [PSV_{max}]: effect on cardiorespiratory function, *Respir Care* 35:1056–1069, 1990.)

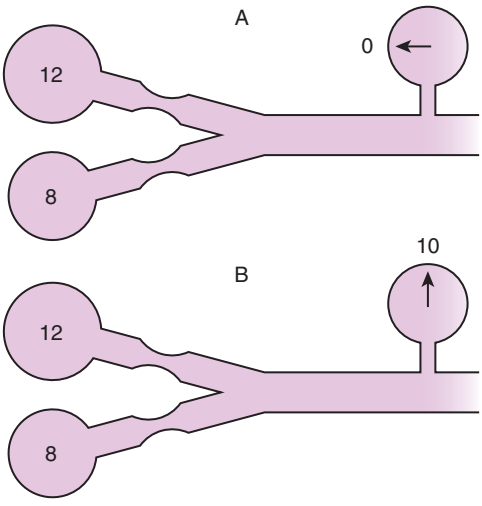

Fig. 48.8 (A) Two alveoli with different auto-PEEP levels and no end-expiratory pause. (B) The same alveoli with an end-expiratory pause. Note that in (A) the end-expiratory pressure is zero, since the system is open at end exhalation, whereas in B the average auto-PEEP level (10 cm H_2O) is indicated on the manometer because of the end-expiratory pause.

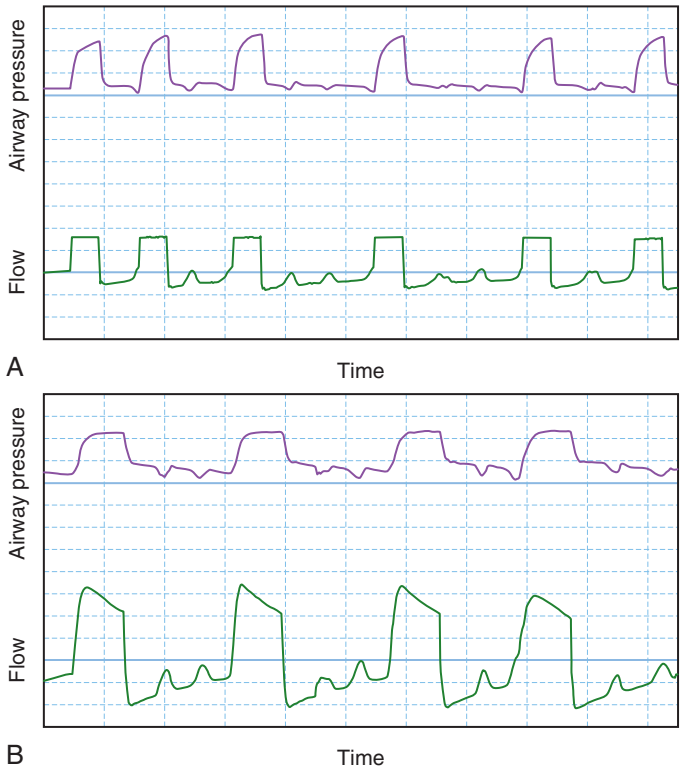

Fig. 48.9 Missed triggering during volume assist/control (A) and pressure-support ventilation (B). Arrows indicate missed triggered breaths.

expiratory flow waveform (Fig. 48.10) and the fact that there are missed triggered breaths. That is, the patient inspires but is unable to trigger the ventilator. In this case, PEEP is slowly applied in increments of 1 to 2 cm H_2O, rechecking the patient and ventilator response with each adjustment. When the patient is able to trigger the ventilator with each inspiratory effort, the PEEP level is set properly.[51] The exact auto-PEEP level may never be known in these patients; however, this is unimportant. What is important is that each patient effort triggers the ventilator. Research indicates that if the amount of PEEP applied does not exceed approximately 80% of the measured auto-PEEP, the patient's lung mechanics are not affected by the application of PEEP.[53,54] Airway pressures and V_T should be monitored during the application of PEEP to ensure that intrinsic PEEP does not increase as PEEP is applied. With the application of PEEP, airway pressure (volume ventilation) should not increase and V_T (pressure ventilation) should not decrease unless intrinsic PEEP is increased. Box 48.4 summarizes methods for minimizing the effects of auto-PEEP. An absolute contraindication to applied PEEP is an uncontrolled tension pneumothorax. However, PEEP should be cautiously applied in any patient with severe intrinsic lung disease, hypotension, and/or elevated intracranial pressure. During controlled ventilation, increasing PEEP simply because of the presence of auto-PEEP is not indicated.

RULE OF THUMB In the presence of dynamic airway obstruction, the application of PEEP offsets the effect of auto-PEEP on missed triggering.

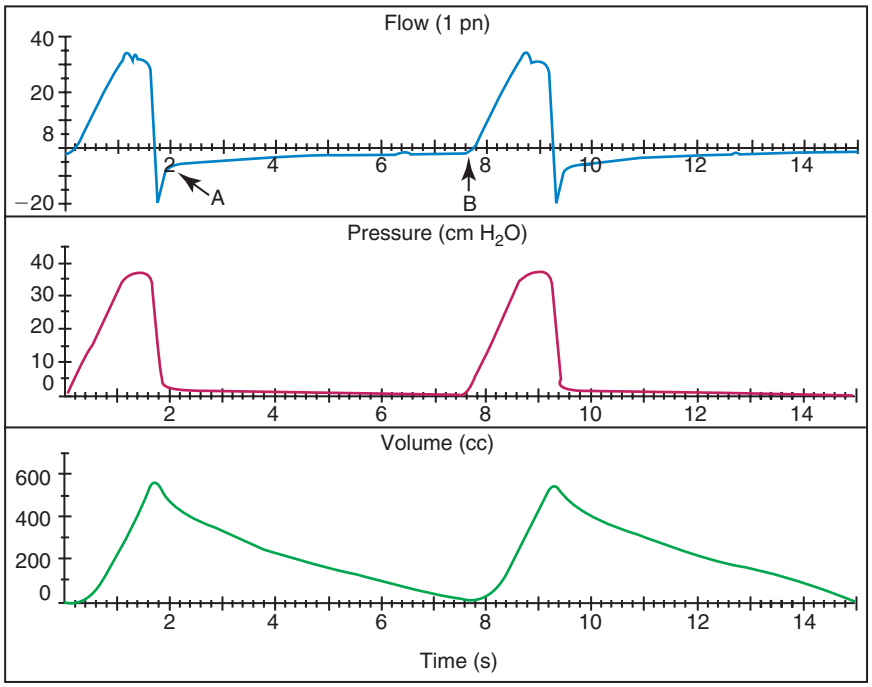

Fig. 48.10 Airway flow, pressure, and volume in a patient with severe airflow obstruction and auto-positive end-expiratory pressure (PEEP). There is a rapid decrease in expiratory flow at the onset of exhalation because of the obstruction *(arrow A)*, and there is a lack of return of flow to baseline at the end of the breath *(arrow B)*. This type of expiratory flow pattern, regardless of the expiratory time, indicates auto-PEEP. The amount of auto-PEEP cannot be determined from this example, but whenever end expiratory flow is greater than zero, auto-PEEP is present.

BOX 48.4 Techniques for Minimizing Effects of Auto-Positive End-Expiratory Pressure

- Decrease airflow obstruction
- Manage secretions
- Implement aggressive bronchodilation
- Use larger endotracheal tubes
- Modify ventilatory pattern, decrease minute ventilation/V_T /respiratory rate, and increase expiratory time
- Decrease inspiratory time
- Increase inspiratory flow (on ventilators with inspiratory peak flow control)
- Decrease percentage inspiratory time (on ventilators with % inspiratory time [T_i control)
- Decrease V_T
- Increase expiratory time
- Decrease rate
- Use low-compressible volume circuit
- Apply PEEP or CPAP to balance auto-PEEP in patients actively triggering ventilation

CPAP, Continuous positive airway pressure; *PEEP*, positive end-expiratory pressure; *V_T*, tidal volume.

In patients without intrinsic lung disease who develop auto-PEEP, dynamic airway obstruction is not present. Auto-PEEP is a result of excessive minute ventilation/V_T. Usually returning the V_T to the recommended 4 to 8 mL/kg PBW level eliminates the auto-PEEP and as a result the missed triggering.[52]

Outside of auto-PEEP the only other factor that can result in missed triggering is inappropriately set sensitivity. In general, sensitivity should be set as sensitive as possible without causing autotriggering. Should flow or pressure sensitivity be used? With older-generation ICU ventilators, pressure sensitivity was less effective than flow sensitivity.[55,56] But in today's generation of ICU ventilators, both function equivalently.[30] When both are set appropriately, neither should be the cause of missed triggering.

RULE OF THUMB Excessive minute ventilation/V_T in patients without dynamic airways obstruction results in auto-PEEP. Decreasing V_T to the range of 4 to 6 mL/kg PBW generally eliminates the auto-PEEP.

Trigger Delay

Trigger delay is caused by an inappropriately set sensitivity or when auto-PEEP is insufficient to cause mistriggering.[30,47] Normally the trigger delay should be minimal, less than 100 ms. When it exceeds 150 ms, the cause should be determined. Adjusting the sensitivity, setting the V_T appropriately, and/or applying PEEP should correct delayed triggering unless there is a true ventilator malfunction (Box 48.5).

Autotriggering

Setting the sensitivity control to be overly sensitive will cause autotriggering. In addition, autotriggering can be caused by the movement of water accumulated in the ventilator circuit. The back-and-forth movement of fluid in the circuit can cause triggering of the ventilator. Leaks in the ventilator circuit are the most likely cause of autotriggering. The most easily missed cause of autotriggering is in the patient who has undergone cardiac surgery and is in a hyperdynamic state.[36] Forceful contraction

MINI CLINI

Assist/Control Volume-Targeted Ventilation and Auto–Positive End-Expiratory Pressure

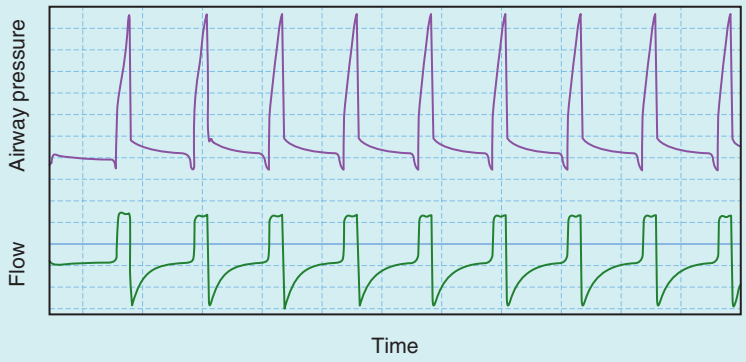
Problem

Mr. Garcia, 72 years old, has severe COPD. He has been intubated and mechanically ventilated for the last 3 days. The ventilator is set with a PEEP of 5 cm H_2O, F_iO_2 of 0.4 and an A/C V_T of 480 mL (6.5 mL/kg PBW). The ventilator's respiratory rate is 18/min. The patient's pulse is 105/min, blood pressure 130/90, and SpO_2 92%. When you look at the ventilator you notice the following airway pressure and flow waveforms:

In addition, when you palpate Mr. Garcia's diaphragm, you note that it is contracting at a rate of 36/min with the ventilator responding at a rate of only 18/min.

Solution

The expiratory flow does not return to baseline before the patient attempts to inspire. As a result, Mr. Garcia has auto-PEEP. To correct this, either Mr. Garcia's V_T should be decreased or applied PEEP should be increased. Since his V_T is at 6.5 mL/kg PBW it is unlikely that a further change will affect the level of auto-PEEP. Because he has dynamic airway obstruction from his severe COPD, adding PEEP to balance the auto-PEEP across the dynamic airway obstruction should decrease the pressure gradient to trigger the ventilator. PEEP should be increased in 1 to 2 cm H_2O steps until Mr. Garcia can trigger the ventilator with every inspiratory effort. At an applied PEEP level of 12 cm H_2O the mistriggering disappeared.



BOX 48.5 Correcting Trigger Delay

Trigger delay is caused by
- Auto-PEEP
- Poor sensitivity setting
- Ventilator malfunction

Corrected by
- Minimizing auto-PEEP
- Apply PEEP
- Decrease minute volume/V_T
- Appropriately set sensitivity
- Replace ventilator

PEEP, positive end-expiratory pressure; *V_T*, tidal volume.

of the heart can trigger the ventilator. Careful assessment of diaphragmatic contraction and readjustment of the sensitivity setting are indicated (Box 48.6).

Double Triggering

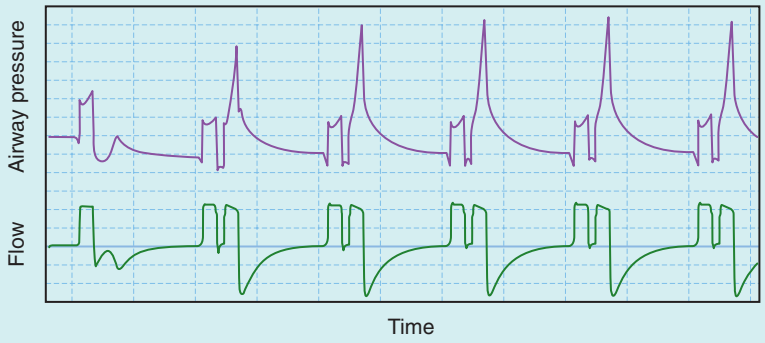
Double triggering most commonly occurs in volume A/C when the V_T delivered is less than the patient demands or the inspiratory time set on the ventilator is less than the neuro-inspiratory time.[37] Double triggering is a problem because, as demonstrated in Fig. 48.11, in most cases of double triggering there is no exhalation between the two breaths. Thus, the V_T during the double-triggered breath is twice the set V_T. A patient with a lung-protective V_T of 6 mL/kg PBW would periodically be receiving a V_T of 12 mL/kg PBW, which is clearly not a lung-protective V_T.[57,58] Double triggering can usually be corrected by increasing the V_T (but not greater than 8 mL/kg PBW), increasing the

MINI CLINI

Volume Targeted Assist/Control Ventilation

Problem

Mr. King, 54 years old, has acute pancreatitis as well as acute respiratory distress syndrome (ARDS). He is currently being ventilated in volume A/C mode with a V_T of 6 mL/kg PBW (400 mL). His respiratory rate is 26/min and his inspiratory time is 0.5 s. Gas is being delivered in a square-wave flow pattern with a peak flow of 48 L/min. Mr. King is tachycardic, with a pulse rate of 118/min, blood pressure 138/98, and SpO_2 92%. Visual assessment of the his ventilatory pattern indicates that he is using his accessory muscles with every breath. You observe the following waveform on the ventilator:



Solution

Assessment of the pressure and flow waveforms indicates that there is frequent double triggering. You have a number of choices on how to eliminate the double triggering: increasing the V_T to 8 mL/kg PBW, increasing the inspiratory time while changing the waveform to decelerating flow, changing to pressure support, or performing a number of these changes.[57,58] Only after these approaches have failed should the patient be sedated. Changing to pressure support at a pressure level that maintains the V_T below 8 mL/kg PBW may be the best option if Mr. King can maintain his ventilatory pattern. This would allow him to determine his V_T needs on a breath-by-breath basis. The V_T can simply be increased; this may work in some patients, but in others the constant V_T may still be a problem. Inspiratory time can be increased with the waveform changed to decelerating flow and the V_T increased to 8 mL/kg PBW. This may also be a viable option. Sedation is always the last choice and may not eliminate the double triggering until the patient has been sedated to total apnea.

BOX 48.6 Autotriggering

Caused by
- Circuit leaks
- Water in circuit
- Inappropriately set sensitivity
- Hyperdynamic cardiac contractions

Corrected by
- New ventilator circuit
- Removal of water from the circuit
- Appropriate setting of sensitivity

BOX 48.7 Double Triggering

Caused by
- Inadequate peak flow
- Inadequate V_T
- Short inspiratory time
- Inappropriate mode of ventilation

Corrected by
- Increased V_T (≤8 mL/kg PBW)
- Increased peak flow to match patient demand
- Increased inspiratory time to match patient's inspiratory time
- Mode changed to pressure support

V_T, Tidal volume.

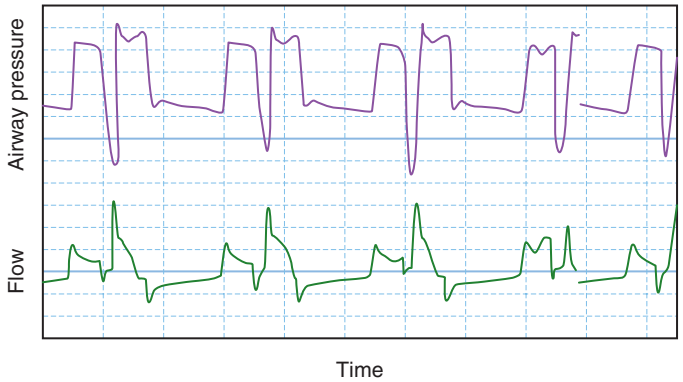


Fig. 48.11 Double Triggering (Breath Stacking). With each inspiratory effort, the patients' inspiratory time exceeds the ventilator's inspiratory time. As a result, the patient triggers a second breath without exhaling. Both tidal volume and airway pressures can be markedly increased.

inspiratory time, or changing from volume A/C to pressure A/C or pressure support.[57,58] If none of these changes eliminates the double triggering, sedation is indicated (Box 48.7).

RULE OF THUMB Double triggering is most commonly observed in volume ventilation when the set V_T and inspiratory time are less than the patient's demand. Increasing V_T or inspiratory time or changing to pressure-targeted ventilation can correct double triggering.

Reverse Triggering

Reverse triggering is a form of double triggering that occurs during controlled ventilation. It has primarily been described in patients with ARDS in whom a controlled mechanical breath

stimulates the respiratory center via stretch receptors to attempt a spontaneous breath.[38,39] The reverse trigger can occur in any mode of ventilation and can occur within the controlled breath or during the subsequent expiratory phase (Fig. 48.12). Little is known about why reverse triggering develops or its effects on the patient except that it can cause double triggering and the periodic delivery of excessive V_T. If reverse triggering occurs, alteration of V_T or inspiratory time should be attempted. Since the patient is already sedated, sedation is not the solution. More research is needed to determine the potential harm of reverse triggering, its causes, and its treatment.

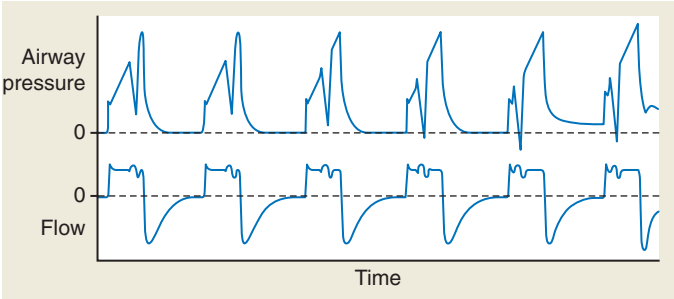

Fig. 48.12 These Waveforms Illustrate Reverse Triggering. Note that the volume-targeted breaths are all machine triggered, with no patient effort. However, within each machine breath there is a patient inspiratory effort. Reverse triggering is the stimulation of a patient effort following a machine-controlled breath.

CYCLE ASYNCHRONY

Cycle asynchrony is a result of a difference between the patient's inspiratory time and that of the ventilator.[41] Thus cycle asynchrony can result in excessively long inspiratory times (Fig. 48.13) or excessively short ones (Fig. 48.14). Theoretically, cycle asynchrony can occur in any mode of ventilation but is by far most commonly seen in pressure ventilation.[40] If the ventilator's inspiratory time is excessive compared with the patient's inspiratory time, a spike in pressure above the set level is commonly observed at the end of the pressure-targeted breath (see Fig. 48.13). If the ventilator inspiratory time is too short, a double trigger will occur with every breath (see Fig. 48.14).

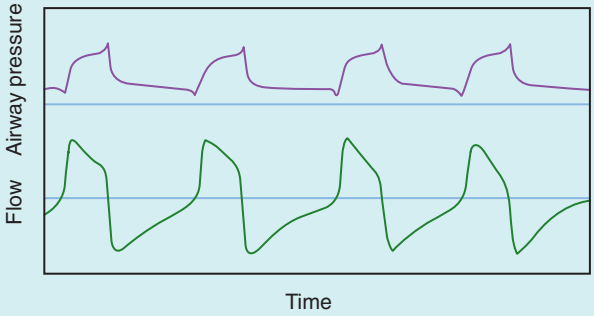
During pressure support, cycle asynchrony can be corrected by adjusting the variable that terminates inspiration or the **expiratory cycling criteria**.[44,45] Normally, pressure support is terminated when the peak flow decreases to a predetermined level. Historically, this level was 25% of peak flow.[47] However, not all patients choose to terminate inspiration at this 25% setting (Fig. 48.15). Patients with marked respiratory distress and those with chronic pulmonary disease choose to end inspiration at high terminal flows.[40] In our experience, these patients require a termination criterion set around 50%. If the termination criterion is set too low, patients will contract their abdominal muscles during the latter part of mechanical inspiration in an effort to force exhalation to occur. The clinician can identify that this is happening by an increase in the set pressure at the end of inspiration. This increase indicates that the breath is terminated by the pressure support secondary termination criterion or an

MINI CLINI

Pressure Support Ventilation

Problem

Mrs. Gonzalez, 68 years old, presents with an acute exacerbation of COPD. She has failed noninvasive ventilation and has been intubated and invasively ventilated in the pressure support mode. Her pressure support level is 12 cm H_2O with 8 cm H_2O PEEP delivering an average V_T of 6.5 mL/kg PBW (350 mL). F_iO_2 is 0.5 and respiratory rate is 28/min. She appears to be working hard to interact with the ventilator; she is using her accessory muscles to breathe. Her SpO_2 is 90% and her blood gases are PO_2 59 mm Hg, PCO_2 55 mm Hg, with a pH of 7.34. You note the following pressure and flow waveforms on the ventilator.



Solution

Mrs. Gonzalez and the ventilator are not ending inspiration at the same time. She is choosing to begin exhalation during the pressure support breath. This is shown on the airway pressure waveform as an increase in the airway pressure at the end of the pressure support breath. In addition, upon palpation of the diaphragm, you note that Mrs. Gonzalez is contracting her abdominal muscles during the inspiratory phase of the ventilator, trying to force exhalation. To correct this, the expiratory cycling criterion must be properly set. It is currently set at 25% of peak flow but should be set at a much higher percentage. You should slowly increase the expiratory cycling criterion until the airway pressure waveform does not show a spike in airway pressure at the end of the breath. To do this, slowly increase the expiratory cycling criterion in 5% increments, observing the effect on the airway pressure curve. The lowest percentage that eliminates the pressure spike is the correct setting. When this is set properly, Mrs. Gonzalez's respiratory rate should decrease and contraction of her abdominal muscles during inspiration should end.

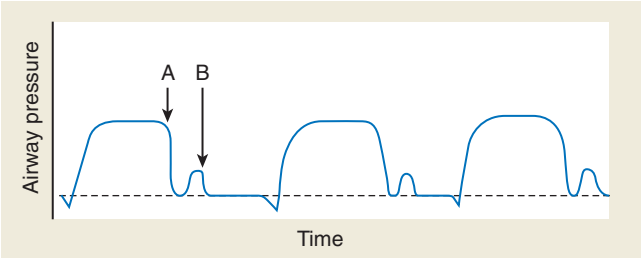


Fig. 48.13 Cycling Asynchrony in Pressure Ventilation. In this figure the patient's inspiratory time is longer than the ventilator's inspiratory time. *A* indicates the end of the ventilator's inspiratory time, and *B* indicates the end of the patient's inspiratory time. To correct this, the ventilator's inspiratory time must be increased to equal the patient's inspiratory time. In pressure support this is done by decreasing the percent cycle sensitivity and in pressure control breath by directly increasing the set inspiratory time.

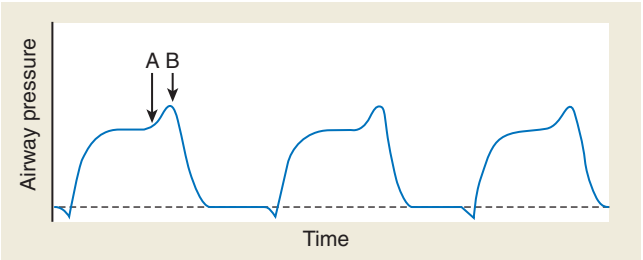

Fig. 48.14 Cycling Asynchrony in Pressure Ventilation. In this figure the patient's inspiratory time is shorter than the ventilator's inspiratory time. *A* indicates the end of the patient's inspiratory time, and *B* indicates the end of the ventilator's inspiratory time. To correct this, the ventilator's inspiratory time must be decreased to equal the patient's inspiratory time. In pressure support this is done by increasing the percent cycle sensitivity, and in pressure control breath by directly decreasing the set inspiratory time.

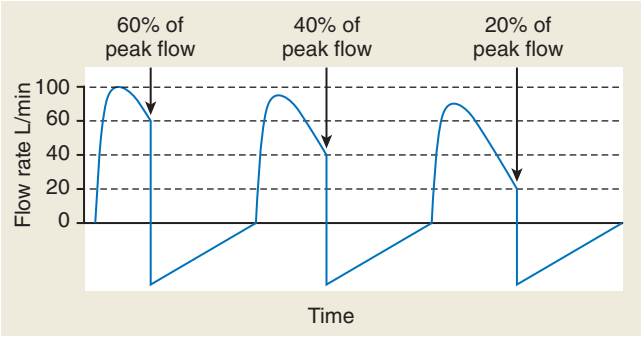

Fig. 48.15 Function of Cycling (Termination) Sensitivity (Criterion). In all three breaths the peak flow is 100 L/min. However, the first breath has the shortest inspiratory time, cycling criterion 60% (60% of peak flow). The middle breath has a longer inspiratory time, cycling criterion 40% (40% of peak flow). The last breath has the longest inspiratory time, cycling criterion 20% (20% of peak flow).

increase in airway pressure above the set level. This level is ventilator specific.[47] If the breath is ended by a spike in pressure, the termination criterion must be increased slowly until there is a smooth decrease in pressure. If the ventilator cannot adjust the termination criterion, the problem can be corrected by switching to PA/C. PA/C essentially operates during assisted breaths the same as PSV except that inspiration terminates at a set time.[40]

BOX 48.8 Cycle Asynchrony

Caused by
- Pressure assist/control or SIMV
  - Ventilator inspiratory time to short
  - Ventilator inspiratory time to long
- Pressure support
  - Expiratory cycling criteria percentage too high
  - Expiratory time criteria percentage too low
- If ventilator inspiratory time too long, corrected by
  - Decreasing ventilator inspiratory time in pressure assist/control or SIMV to eliminate the pressure spike at the end of the breath
  - Increasing expiratory cycling criteria percentage so that the breath ends sooner, eliminating the pressure spike at the end of the breath
- If ventilator inspiratory time is too short, corrected by
  - Increasing ventilator inspiratory time in pressure A/C or SIMV to eliminate the double trigger at the end of the breath
  - Decreasing expiratory cycling criteria percentage so that the breath ends sooner, eliminating the double trigger at the end of the breath

SIMV, Synchronized intermittent mandatory ventilation

If there is a spike in pressure at the end of a PA/C breath, the inspiratory time setting must be decreased until the spike disappears. In all other pressure modes, inspiratory time or termination criteria can be adjusted; make sure that the patient and ventilator end the breath at the same time.

If the termination criterion is set too high in patients with relatively healthy lungs or inspiratory time too short, double triggering can occur with every breath.[59,60] These are primarily postoperative patients or overdose patients (see Fig. 48.14). In such patients the termination criterion is decreased until the double trigger is eliminated. As opposed to the patient with high ventilatory demand who requires a termination criterion of more than 50%, these patients frequently require the termination criterion be set at only 10% to 15%. In this setting, the termination criterion is slowly decreased, followed by careful assessment until the double triggering is gone. In pressure A/C and pressure SIMV where inspiratory time is set, inspiratory time is slowly increased until the double triggering is eliminated (Box 48.8).

RULE OF THUMB Cycle asynchrony occurs most commonly in pressure ventilation when the patient's neuro-inspiratory time and the ventilator's inspiratory time are not equal.

MODE ASYNCHRONY

Mode asynchrony implies that an inappropriate mode of ventilation has been selected for a given patient. There are many biases regarding mode of ventilation and few data to support any relationship between mode and patient outcome. See Chapters 46, 47, and 49 for a detailed discussion regarding modes of ventilation. However, it is increasingly clear that asynchrony is highest in volume ventilation because of its control over the variables associated with ventilation. Of all the classic modes of ventilation, pressure support is the least confining and should result in little asynchrony. PAV and NAVA, however, can be expected to result in the least asynchrony because those modes do not control any gas delivery variable and follow the patient's desires

rather than dictating the required ventilatory pattern to the patient.[18-20,43] However, for clinicians to accept these modes of ventilation, they must be willing to accept the resultant ventilatory pattern. Most patients will breathe in a rapid, shallow manner when they are experiencing respiratory distress/failure—that is, when V_T are in the range of 4 to 6 mL/kg PBW and the respiratory rate exceeds 25/min. In spite of this pattern, both PAV and NAVA have been shown to reduce asynchrony.[18-20,43]

The mode of ventilation that can be the most problematic is SIMV. This is because of the variation in ventilatory load between mechanical and spontaneous breaths (see Chapters 47 and 49 for details). As the percentage of the total spontaneous breaths increases, the WOB also increases, not only in the spontaneous breaths but also in the mechanical breaths.[61,62] Essentially, the respiratory center cannot distinguish between mechanical and spontaneous breaths once some 50% of the breaths are spontaneous, resulting in the same level of patient work exerted during both spontaneous and mechanical breaths.[61,62] This is a major reason why SIMV has been shown to be the least effective mode in weaning patients from ventilatory support.[62,63]

PATIENT–VENTILATOR ASSESSMENT

Periodic assessment of the patient–ventilator system should occur on a regular basis. The frequency of the assessment varies from every hour to every 4 hours depending on the severity of the patient's illness. For highly unstable patients, such assessments may be done at bedside on a minute-to-minute basis. In such situations a complete assessment of both the patient and the ventilator should occur; assessing the patients' cardiopulmonary status and the function and settings of the mechanical ventilator. Depending on the patient's overall status, all of the following should be measured and documented: plateau pressure, driving pressure, and P_{100}. In addition, a prolonged review of the patient's airway pressure and flow waveforms should occur. Asynchronies are not easy to identify, and a lengthy review of waveforms may be necessary to identify their presence. Based on the finding of this assessment, adjustments to gas delivery should occur. Adjustment of V_T, peak flow, flow waveform, and inspiratory time may be necessary in volume ventilation. In pressure ventilation, rise time, inspiratory termination criteria, pressure setting, and inspiratory time may have to be adjusted. In most patients a minor adjustment of ventilator settings is necessary with each patient-ventilator assessment.

P_{100} or $P_{0.1}$ should be measured and assessed during every patient–ventilator assessment if the patient is triggering the ventilator! The P_{100} is an assessment of ventilatory drive or the level of ventilatory distress. A normal P_{100} is about −0.5 to −1.5 cm H_2O (Box 48.9).[64] The more negative the P_{100}, the greater the drive or ventilatory distress. In mechanically ventilated patients, a P100 of −0.5 to −5 cm H_2O is considered acceptable. A P_{100} of −5.1 to −10 cm H_2O generally requires significant adjustment of the way ventilation is provided and may require sedation if ventilator adjustment does not normalize the P_{100}. A P_{100} more negative than a −10 H_2O generally requires controlled ventilation.[65] Since ventilatory patterns vary from breath to breath, it is important to measure the P_{100} three or four times and establish an average value that reflects the patient's condition.[66] The P_{100}, though not a precise assessment of a patient's ventilatory distress, does provide a reasonable guide to assessment of the adequacy of ventilator setting and the need for more or less ventilatory support.

BOX 48.9 P_{100} or $P_{0.1}$

The P_{100} is an assessment of ventilatory drive or ventilatory distress.
Normal P_{100} is −0.5 to −1.5 cm H_2O
Acceptable during patient-triggered ventilation: −0.5 to −5.0 cm H_2O
Need for ventilator adjustment and possibly sedation: −5.1 to −10 cm H_2O
Requires controlled ventilation more negative than −10 cm H_2O

SUMMARY CHECKLIST

- Patient–ventilator interaction is not a problem during controlled ventilation because the patient is not interacting with the ventilator, but it is always a major issue during patient-triggered ventilation.
- Poor patient–ventilator interaction has been associated with increased length of mechanical ventilation, length of ICU stay, need for a tracheotomy, and mortality.
- A change in patient status is commonly the reason for the development of poor patient–ventilator interaction.
- Artificial airway issues can cause marked changes in patient–ventilator interaction.
- The development of a pneumothorax or tension pneumothorax is a major cause of markedly deteriorating patient–ventilator interaction.
- Whenever there is an acute severe change in the ability to provide ventilatory support, the three most probable causes are tension pneumothorax, airway obstruction, and right mainstem bronchus intubation.
- Malfunction of the mechanical ventilator can be a cause of poor patient–ventilator interaction but it is a highly unlikely cause with today's mechanical ventilators.
- The four variables that can be controlled during classic modes of mechanical ventilation are pressure, flow, volume, and time.
- The less control that is exerted by the mechanical ventilator on the patient's ventilatory pattern, the less likely it is that the patient will develop patient–ventilator asynchrony.
- The general types of asynchrony are flow asynchrony, trigger asynchrony, cycle asynchrony, and mode asynchrony.
- Asynchrony can be caused by inappropriately set sensitivity, PEEP, flow, V_T, and inspiratory time.
- Flow asynchrony is a result of the flow provided by the ventilator being inadequate to match the patient's inspiratory demand.
- Trigger asynchrony can manifest as missed triggering, delayed triggering, autotriggering, double triggering, and reverse triggering.
- Missed triggering and delayed triggering are normally a result of auto-PEEP.
- Autotriggering is normally a result of circuit leaks or fluid moving back and forth in the ventilator circuit, but can also be caused by hyperdynamic contractions of the myocardium.

- Flow asynchrony is a result of the ventilator providing less flow then the patient's respiratory center requires.
- Mode asynchrony occurs when the selected mode of ventilation does not match the patient's ventilatory demands.
- Volume ventilation can be expected to cause the most asynchrony because it controls volume, flow, and time.
- Pressure support should result in the least asynchrony of the commonly used modes of ventilation.
- PAV and NAVA cause the least asynchrony because they do not force a ventilatory pattern but follow the ventilatory pattern selected by the patient.
- Patient–ventilator assessment should include careful evaluation of airway pressure and flow waveforms and adjustment of the ventilator if asynchrony identified.
- P100 should be assessed during ALL patient-triggered patient-ventilator assessments.

Initiating and Adjusting Invasive Ventilatory Support

Robert M. Kacmarek

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the goals of ventilatory support.
- Describe how to choose an appropriate ventilator to begin ventilatory support.
- Explain how to select an appropriate mode of ventilation given a patient's specific condition and ventilatory requirements.
- Choose appropriate initial ventilator settings, based on patient assessment.
- Describe how to assess a patient after initiation of ventilation.
- Discuss how to adjust ventilatory support based on oxygenation and ventilation status.
- Discuss how to ventilate using the concept of lung protective ventilation.
- Explain how to adjust the ventilator on the basis of the patient's oxygenation response.
- Explain how to adjust the ventilator on the basis of the patient's ventilation response.

CHAPTER OUTLINE

KEY TERMS

controlled ventilation
full ventilatory support
high-frequency oscillatory ventilation (HFOV)
lung protective ventilatory strategy
neurally adjusted ventilatory assist (NAVA)
partial ventilatory support
plateau pressure (P_{plat})
pressure-controlled ventilation (PCV)
pressure-regulated volume control (PRVC)
pressure support ventilation (PSV)
proportional assist ventilation (PAV)
synchronized intermittent mandatory ventilation (SIMV)
transpulmonary pressure
volume-controlled ventilation
volume support

Mechanical ventilation uses sophisticated life-support technology to maintain adequate tissue oxygenation and remove carbon dioxide (CO_2). At its most basic level, mechanical ventilation supports or replaces the normal ventilatory pump, moving air into and out of the lungs. The primary function of a mechanical ventilator is to ventilate. The main indication for mechanical ventilation is inadequate or absent spontaneous breathing.

Mechanical ventilation is not without risk, and the complications and hazards can be life-threatening. The decision to initiate mechanical ventilatory support is a serious one that requires sound clinical judgment and a clear understanding of the various approaches to ventilatory support. This chapter reviews and describes the initial set-up of the ventilator and the adjustments made in ventilatory support based on the patient's response. Techniques for patient stabilization; methods for optimizing oxygenation, ventilation, and acid–base balance; and methods for minimizing harmful side effects are described.

GOALS OF MECHANICAL VENTILATION

The goals of mechanical ventilatory support are to maintain adequate alveolar ventilation and oxygen (O_2) delivery, restore acid–base balance, and reduce the work of breathing (WOB) with minimum harmful side effects and complications.[1] Mechanical ventilation may also reduce increased myocardial work secondary to hypoxemia and an increased WOB.[1] Other physiologic objectives of mechanical ventilatory support include increasing or maintaining lung volume with positive end-expiratory pressure (PEEP) for promotion, improvement, or maintenance of lung recruitment.[1]

Lung Protective Ventilatory Strategies

Lung protective ventilatory strategies entail an approach to mechanical ventilation that includes the use of small tidal volume (V_T), low plateau pressures and driving pressures, appropriate fractional inspired oxygen (FiO_2), and appropriate levels of PEEP.[2] This approach was first described in patients with acute respiratory distress syndrome (ARDS); however, the concept of lung protection today should be applied to all patients requiring ventilatory support for acute respiratory failure. Ventilator-induced lung injury is primarily caused by an elevated transpulmonary pressure during positive pressure ventilation.[3] **Transpulmonary pressure** is the difference between alveolar pressure and pleural pressure. A safe transpulmonary pressure during mechanical ventilation is not firmly established, but most clinicians would agree that the lower the transpulmonary pressure, the less likely the development of ventilator-induced lung injury.[4] At the bedside we measure plateau pressure and driving pressure (plateau pressure – PEEP) and use these variables to assess the safety of our ventilator settings. Analysis of stress and strain applied to the lungs during ventilatory support identified 27 cm H_2O as the maximum plateau pressure without increasing the risk of significant lung injury.[4] Therefore most recommend that plateau pressure should be maintained ≤28 cm H_2O. Amato et al.[5] identified a driving pressure greater than 15 cm H_2O, increasing the risk of mortality during ventilatory support. Table 49.1 lists all of the components of a lung-protective approach to ventilatory support, which will be discussed later in the chapter. See Chapter 52 for a discussion of esophageal and transpulmonary pressure measurements. High transpulmonary pressures are associated with alveolar overdistention and lung injury.[3]

TABLE 49.1 Components of a Lung Protective Approach to Ventilatory Support

- V_T 4–8 mL/kg PBW greater P_{plat} lower V_T
- Plateau Pressure <28 cm H_2O
- Driving pressure <15 cm H_2O
- PEEP appropriate for the patient presentation
- Avoid asynchrony
- Avoid autoPEEP and air trapping
- Appropriate FiO_2 maintain PaO_2 55–80 and SpO_2 88%–95%

FiO_2, Fractional inspired oxygen; *PEEP,* positive end-expiratory pressure.

RULE OF THUMB The goals of mechanical ventilatory support are to maintain adequate alveolar ventilation and oxygen (O_2) delivery, restore acid-base balance, and reduce the WOB) with minimum harmful side effects and complications.

Plateau pressure (P_{plat}), the end inspiratory equilibration pressure, measures the mean peak alveolar pressure and is the best bedside clinical reflection of transpulmonary pressure.[2,4,6] Although P_{plat} is not an accurate measurement of transpulmonary pressure, the transpulmonary pressure during controlled ventilation never exceeds the P_{plat}.[4] P_{plat} provides an excellent bedside assessment of the level of potentially dangerous ventilating pressure. Limiting P_{plat} reduces the likelihood of ventilator-induced lung injury. Generally, the lower the P_{plat} the better the patient outcome.[2,6] Ideally, P_{plat} should be less than 28 cm H_2O;[4] however, a P_{plat} greater than 28 cm H_2O may need to be applied in patients with a morbid obesity requiring high PEEP (>20 cm H_2O) levels and in patients with decreased thoracic compliance without resulting in overdistention;[6] this is because a decrease in chest-wall compliance (massive fluid resuscitation, abdominal distention, elevated bladder pressure) increases the pleural pressure, decreasing the transpulmonary pressure. Generally, the lowest possible P_{plat} is maintained by selecting a V_T of 4 to 8 mL/kg of ideal body weight (IBW). The higher the P_{plat}, the smaller the V_T should be. Generally, a V_T greater than 10 mL/kg IBW is never indicated in critically ill patients.

Lung injury can also be caused by repetitive opening and closing of unstable lung units.[7] The application of an appropriate level of PEEP ensures that unstable lung units are maintained in the open position, reducing the likelihood of additional lung injury.

RULE OF THUMB Driving pressure has recently been linked to mortality and it has recently been demonstrated that driving pressures greater than 15 cm H_2O increase mortality.

The general trajectory of pH, PCO_2, and PO_2 during the progression of acute respiratory failure is depicted in Fig. 49.1. Table 49.2 lists the most common causes of acute respiratory failure

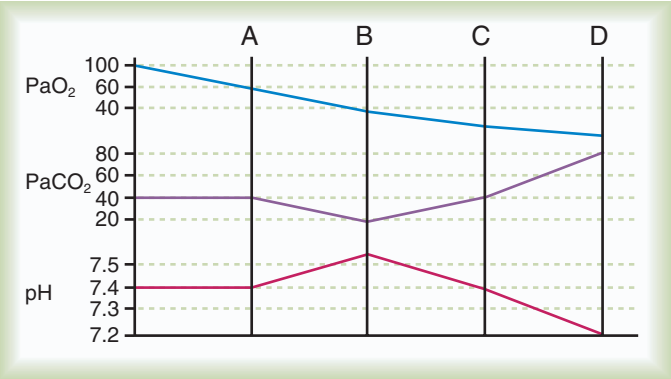

Fig. 49.1 Typical progression of acute respiratory failure. Initially, there is a decline in arterial O_2 tension and saturation. When PaO_2 decreases to approximately 60 mm Hg *(A)*, the patient begins to breathe more, $PaCO_2$ decreases, and pH increases. Early in the progression, arterial blood gas results show acute alveolar hyperventilation (uncompensated respiratory alkalosis) secondary to hypoxemia. As the patient's condition worsens, increases in ventilatory workload typically lead to the adoption of a rapid, shallow breathing pattern; although minute ventilation may remain high, effective ventilation decreases, $PaCO_2$ begins to increase, and pH begins to decrease *(B)*. At point *C*, arterial blood gas results may show normal $PaCO_2$ and pH with moderate to severe hypoxemia. If mechanical ventilation is not initiated, the patient's condition may progress to acute ventilatory failure, severe hypoxemia, and corresponding severe respiratory acidosis *(D)*.

TABLE 49.2 Most Common Causes of Acute Respiratory Failure Requiring Mechanical Ventilation in the United States and Canada

Condition	Rank	Percentage
Postoperative respiratory failure	1	17
Sepsis	1	17
Other	2	16
Heart failure	3	13
Pneumonia	3	13
Trauma	3	13
ARDS	4	9
Aspiration	5	3

ARDS, Acute respiratory distress syndrome.
Modified from Esteban A, Anzueto A, Alia I, et al: How is mechanical ventilation employed in the intensive care unit? An international utilization review. *Am J Respir Crit Care Med* 161:1450, 2000.

leading to ventilatory support in the United States and Canada. Hazards of mechanical ventilation include decreased venous return and cardiac output, patient–ventilator asynchrony (see Chapter 48), and ventilatory muscle dysfunction owing to inappropriate ventilator settings, ventilator-associated pneumonia, and ventilator-induced lung injury.[1] Box 49.1 lists the goals of ventilatory support, and Box 49.2 lists specific objectives of mechanical ventilation.

RULE OF THUMB A **lung protective ventilatory strategy** is an approach to mechanical ventilation that includes the use of small tidal volume (V_T), low plateau pressures and driving pressures, appropriate FiO_2 and appropriate levels of PEEP.

BOX 49.1 Physiologic Goals of Ventilatory Support

- Support or manipulate gas exchange.
- Maintain alveolar ventilation ($PaCO_2$ and pH).
- Maintain arterial oxygenation (PaO_2, SaO_2, SpO_2, CaO_2, and DO_2).
- Increase end-expiratory lung volume, functional residual capacity (FRC).
- Reduce or manipulate work of breathing.
- Minimize cardiovascular impairment.
- Ensure patient–ventilatory synchrony.
- Avoid ventilator-induced lung injury.

BOX 49.2 Specific Clinical Objectives of Ventilatory Support

- To reverse hypoxemia.
- To reverse acute respiratory acidosis.
- To prevent or reverse atelectasis.
- To reverse ventilatory muscle dysfunction.
- To decrease systemic or myocardial O_2 consumption.
- To maintain or improve cardiac output.
- To reduce intracranial pressure.
- To stabilize the chest.

VENTILATOR INITIATION

When the decision to begin mechanical ventilatory support is made, one must choose the mode of ventilation, select an appropriate device, and establish the initial ventilator settings. The goals of mechanical ventilation are achieved by choosing an appropriate mode of ventilation, PEEP level, FiO_2, V_T or pressure level, rate, peak flow and flow waveform, and inspiratory time. Appropriate trigger sensitivity, pressure limit, alarms, backup ventilation, and humidification must be selected. After initial ventilator setup, adjustments must be made based on the patient's response and the patient-specific clinical objectives of ventilatory support. Most patients who need mechanical ventilatory support receive invasive positive pressure ventilation; however, an increasing number of patients are being ventilated noninvasively (see Chapter 50). Next, the clinician must choose the mode of ventilation (e.g., volume assist/control [VA/C], pressure assist/control [PA/C], pressure support ventilation [PSV], **pressure-regulated volume control [PRVC]**, **volume support**, adaptive support ventilation, **proportional assist ventilation [PAV]**, or **neurally adjusted ventilatory assist [NAVA]**) and initial ventilator settings (e.g., rate, V_T or pressure level, FiO_2, PEEP). Finally, the clinician must choose appropriate alarm and apnea settings. Box 49.3 summarizes key decisions that must be made as part of the initial ventilator setup.

RULE OF THUMB Generally, a V_T greater than 10 mL/kg IBW is never indicated in critically ill patients.

Establishment of the Airway

Conventional mechanical ventilatory support requires the establishment of an artificial airway. Initially, nearly 100% of patients

BOX 49.3 Initial Ventilator Setup

Initial ventilator setup includes the following key decisions:
- Noninvasive versus invasive ventilation.
- Type and method of establishment of an airway.
- Partial versus full ventilatory support.
- Choice of ventilator.
- Mode of ventilation.
- Assist/control ventilation (volume vs. pressure) vs. pressure support.
- Other newer modes and adjuncts to ventilation.

Next, the clinician must consider key ventilatory values:
- Trigger method (pressure or flow trigger) and sensitivity.
- V_T (volume ventilation) or pressure level (pressure support and PA/C).
- Rate
- Inspiratory flow, inspiratory time, expiratory time, or I:E ratio.
- Inspiratory flow waveform.
- FiO_2
- PEEP

Last, the clinician must choose appropriate alarm and backup values:
- Low-pressure, low PEEP alarms.
- High-pressure limit and alarm.
- Volume alarms (low V_T/high V_T, high and low minute ventilation).
- High rate and low rate alarms.
- Apnea alarm and apnea ventilation values.
- High/low O_2 alarm.
- High/low temperature alarm.
- I:E ratio limit and alarm.

FiO_2, Fractional inspired oxygen; *I:E,* inspiratory-to-expiratory; *PA/C,* pressure assist/control; *PEEP,* positive end-expiratory pressure.

receiving positive pressure ventilation are intubated and, of these, 99% have oral endotracheal tubes and only approximately 1% are intubated nasally.[8,9] Approximately 5% to 10% of patients receiving mechanical ventilation have a tracheotomy performed at some point.[8,9] Airway management is described in detail in Chapter 37.

RULE OF THUMB Initial setup of ventilation parameters should include a limitation of tidal volume (4–8 mL/kg predicted body weight [PBW]), plateau (<28 cm H_2O), and driving (<15 cm H_2O) pressure in ALL patients acutely requiring mechanical ventilation.

Pressure-Controlled Versus Volume-Controlled Ventilation

The next decision to be made regarding initiation of mechanical ventilation is whether to use a pressure-targeted or volume-targeted mode of ventilation. Volume-targeted ventilation essentially includes VA/C and synchronized intermittent mandatory ventilation (SIMV). Pressure ventilation includes PA/C, SIMV, PRVC, volume support, and airway pressure release ventilation (APRV). In addition, the clinician can select the patient-controlled modes PAV or NAVA; however, most patients are initially ventilated with pressure or volume forms of ventilation. The operational capabilities of these modes are described in detail in Chapter 46, and the indications, benefits, and concerns regarding these modes are discussed in Chapter 47.

Full Ventilatory Support Versus Partial Ventilatory Support

Full ventilatory support can be defined as the application of mechanical support such that all or most of the energy necessary for effective alveolar ventilation is provided by the ventilator.[9] When a ventilator is set to deliver full ventilatory support, the patient is either passive or simply triggers the breath to initiate inspiration, allowing the ventilator to perform most of the WOB; however, it is very difficult to set the ventilator to assume all of the WOB without significantly sedating the patient. In most patient-triggered approaches to ventilatory support, patient-ventilatory synchrony is a major issue, and very careful titration of the ventilator settings is necessary to ensure synchrony and minimize patient WOB. See Chapter 48 for details on patient-ventilatory synchrony.

Partial ventilatory support implies that only a percentage of the WOB is provided by the ventilator.[9] Normally, when partial ventilatory support is indicated, SIMV, pressure support ventilation (PSV), volume support, PAV, and NAVA are the modes of choice; however, as with full ventilatory support, care in setting the ventilator is critical to ensure that patient–ventilator synchrony is maximized. Partial ventilatory support strategies minimize the loss of ventilatory muscle function, require less sedation, assist in recruiting and stabilizing alveolar units, and generally move patients closer to ventilator discontinuance than full ventilatory support approaches.

Choice of a Ventilator

After the decision is made to initiate mechanical ventilatory support, the clinician must select an appropriate ventilator. This decision should be guided by considering the features, modes available, pressure and flow capabilities, alarms and monitoring systems, and reliability, in relation to the patient needs; however, the most important feature is the clinician's familiarity with the equipment. Only a ventilator that the clinician is totally familiar with should ever be used.

INITIAL VENTILATOR SETTINGS

Initial ventilator settings are chosen based on the patient's clinical presentation and the need to provide full or partial ventilator support.

Choice of Mode

Most modern critical care ventilators include VA/C, PA/C, SIMV, and PSV and many of the newer modes of ventilation; however, some modes of ventilation are found only on a specific type of ventilator, such as PAV PB 840 and PB 980 (Medtronic, Boulder, Colorado), adaptive support ventilation and Intellivent Hamilton ventilators (Hamilton Medical, Bonaduz, Switzerland), NAVA Servo-U and Servo-i ventilators (Maquet, Inc, Wayne, New Jersey), and SmartCare Draeger ventilators (Draeger Medical, Inc, Telford, Pennsylvania).

Assist/Control Ventilation (Patient-Triggered or Time-Triggered Continuous Mandatory Ventilation)

A/C ventilation involves the patient receiving a pre-set number of machine breaths per minute at a pre-set V_T; however, the

MINI CLINI

Selecting Initial Ventilator Settings

Problem

A 52-year-old man, 5 ft 10 in (178 cm) tall and weighing 200 lb (91 kg) is being returned from the operating room after coronary artery bypass surgery. He is being manually (bag-valve-mask) ventilated with supplemental O_2 by the anesthesiologist en route to the intensive care unit (ICU). He is apneic at this time. The patient has no history of lung disease and has never smoked cigarettes. Heart rate and blood pressure are stable, and SpO_2 during manual ventilation is 99%. What initial mode, V_T, rate, and FiO_2 should the respiratory therapist (RT) select when starting ventilatory support for this patient?

Solution

The patient is apneic at this time but is likely to resume spontaneous breathing as the anesthetic wears off and sedation is reduced. The patient is expected to resume breathing spontaneously, so volume ventilation or pressure ventilation in assist/control (A/C) is appropriate.

Initial V_T and rate should be selected to provide full ventilatory support. Generally, initial V_T of approximately 6–8 mL/kg IBW or pressure control setting to establish this V_T with a rate of 12–20 breaths/min provides an adequate starting minute ventilation for most adult patients. The formulas for estimating IBW are:

$$\text{IBW in kg (men)} = [106 + 6(H - 60)]/2.2$$
$$\text{IBW in kg (women)} = [105 + 5(H - 60)]/2.2$$

where H is height in inches.

For this patient:

$$\text{IBW} = [106 + 6(70 - 60)]/2.2 = 75.5 \text{ kg}$$

On the basis of IBW of 75.5 kg, initial V_T can be set at about 450 mL, 6 mL/kg IBW. Initial inspiratory flow should be set at 60 L/min with a decreasing ramp flow waveform to achieve an inspiratory time of approximately 0.8 s in VA/C. In PA/C, the pressure control level is set to maintain a V_T of 450 mL with an inspiratory time of 0.8 s. Initially, the rate can be set at 12/min. Owing to the fact that the patient has a normal respiratory system and that it is usual to return from the operating room with a below-normal body temperature, a low initial control rate is indicated. Trigger sensitivity (A/C) should be set so that minimal patient effort triggers the ventilator without autocycling.

Initial FiO_2 should be set at 1.0 but because of the patient's history and the presence of normal lung function, it is expected that it will be reduced rapidly as the patient recovers. Initial PEEP is set at 5 cm H_2O. In summary, appropriate initial ventilator settings for this patient are:

Mode: A/C (volume or pressure)

V_T: 6 mL/kg, 450 mL

f_{mach}: 12 breaths/min

FiO_2: 1.0 followed by immediate assessment and SpO_2 observation with titration downward as indicated to maintain an SpO_2 between 88% and 95%.

Inspiratory flow and time: 60 L/min, decreasing ramp, inspiratory time approximately 0.8 s in VA/C, pressure control set to achieve V_T 450 mL and inspiratory time 0.8 s.

Pressure limit: Adjust to 10 to 15 cm H_2O above peak inspiratory pressure (PIP) after patient connection.

Humidification: Heated humidifier to achieve temperature >35°C at the airway or an appropriate heat and moisture exchanger (HME).

BOX 49.4 Typical Values for Ventilator Initiation for Adults Receiving Volume or Pressure Assist/Control Ventilation

- Trigger sensitivity: –0.5 to –1.5 cm H_2O or 1–2 L/min set to minimize trigger work without autocycling.
- V_T: Volume ventilation 6–8 mL/kg IBW; pressure ventilation, pressure level to achieve 6–8 mL/kg IBW.
- Rate: Backup rate of ≥12–14 breaths/min if providing assisted ventilation.
- Inspiratory flow: Volume ventilation 60–80 L/min to achieve inspiratory time of approximately 0.6–1.0 s and I:E ratio of ≤1 : 2; inspiratory flow ≥80 L/min may be required to meet or exceed the patient's spontaneous inspiratory flow demand.
- Flow waveform volume ventilation: Decreasing ramp.
- Inspiratory time pressure ventilation:0.6–1.0 s.
- PEEP: 5 cm H_2O.
- Pressure limit: Start at 30–40 cm H_2O depending on approach (volume 40 cm H_2O-) and adjust after patient connection to 10–15 cm H_2O above PIP.
- Humidification: Begin with heated humidifier to provide temperature of 35°C at the airway connection or appropriate HME.

HME, heat and moisture exchanger; *IBW,* ideal body weight; *PEEP,* positive end expiratory pressure; *PIP,* peak inspiratory pressure.

patient can initiate additional machine breaths, which will be given at the pre-set V_T. AC can be delivered in either pressure-targeted or volume-targeted ventilation. Suggested initial settings for **volume ventilation** in the care of adults are listed in Box 49.4. Advantages of AC volume ventilation include the assurance that a minimum safe level of ventilation is achieved, yet the patient can still set his or her own breathing rate. In the event of sedation or apnea, a minimum safe level of ventilation is guaranteed by the selection of an appropriate backup rate, usually approximately 4 to 6 breaths/min less than the patient's assist rate but not less than the rate necessary to provide a minimum safe level of ventilation (e.g., a backup rate of at least 12 to 14 breaths/min).[9]

Owing to the fact that AC ventilation usually provides full ventilatory support, it may result in less WOB than partial support modes; however, less WOB should not be assumed just because the patient is in AC ventilation. Trigger work may be significant if inappropriate sensitivity settings are selected. In addition, when a breath is triggered, inspiratory muscle activity persists.[10,11] If the inspiratory flow rate during volume ventilation does not meet or exceed the patient's inspiratory demand, or inspiratory time is too lengthy, the patient's WOB may be greater or equaling the work of a spontaneous unassisted breath.[10,11] In pressure ventilation, lengthy inspiratory times, inadequate rise time, and improperly set pressure levels can also cause asynchrony (see Chapter 48).

If properly applied and tolerated by the patient, AC ventilation may provide ventilatory muscle rest that allows the ventilatory muscles to recover. Disadvantages of AC mode include an increase in WOB if not applied properly.[9,12] AC may also be poorly tolerated by awake, nonsedated patients because the patient may fight the ventilator or asynchronous patient-to-ventilator breathing patterns may develop. Because flow is based on patient

BOX 49.5 Advantages and Disadvantages of Pressure-Controlled Ventilation

Advantages

- Variable flow results in square pressure waveform and improves gas distribution.
- Ensures that P_{plat} cannot exceed set pressure control level.
- All alveoli are placed under the same sustained inspiratory pressure, which decreases hyperinflation of more compliant alveoli compared with volume ventilation square wave flow.
- Sustained inspiratory pressure may result in more alveolar recruitment.
- Improved gas distribution allows for lower V_T.
- Lower PIP is achieved compared with that achieved with volume ventilation with a square flow waveform.

Disadvantages

- Higher mean airway pressure can decrease venous return and decrease cardiac output if preload is inadequate.
- V_T varies depending on lung compliance, resistance, and patient effort.
- If V_T or minute ventilation alarms are not set properly, alveolar hypoventilation and acidosis may not be rapidly detected.

PIP, Peak inspiratory pressure.

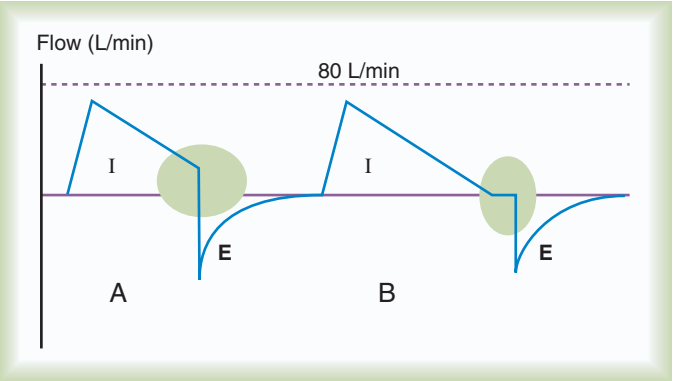

Fig. 49.2 Flow versus time waveform during pressure-controlled ventilation (PCV). *Curve A* shows a flow pattern during controlled ventilation in which inspiratory time is inadequate to ensure maximum V_T has been delivered. During inspiration, flow does not decrease to zero before exhalation occurs, so the preset pressure has not equilibrated to that in the lung. *Curve B* shows an increase in inspiratory time from *curve A.* Inspiratory flow reaches zero, maximizing V_T delivery and allowing the preset pressure to equilibrate in the lungs. Exhaled V_T is greater for *curve B* than for *curve A* despite the pressure setting not changing.

demand in pressure-targeted ventilation, synchrony is generally better achieved during PA/C than with VA/C ventilation. Advantages and disadvantages of **pressure-controlled ventilation (PCV)** are described in Box 49.5.

AC volume ventilation is the most common ventilator mode used throughout the world for the primary initial mode of ventilatory support.[7,13] Regardless of the indication for ventilatory support or the underlying disease, this mode can provide adequate ventilatory support for all indications for ventilatory support when properly adjusted and the patient is properly managed.[6,13]

Controlled Ventilation (Time-Triggered Continuous Mandatory Ventilation)

Controlled ventilation, pressure or volume, is characterized by the patient's inability to trigger breaths above the number of breaths set. Controlled ventilation is achieved using the AC mode when the patient is apneic owing to a medical condition, anesthesia, or use of sedative drugs and paralytic agents. Ventilators in use today do not prevent a patient with sufficient effort from triggering additional breaths. Controlled ventilation can only be achieved with pharmacologic agents. Advantages of controlled ventilation include eliminating WOB and complete control over the patient's ventilatory pattern. In cases where WOB is high, controlled ventilation may allow for ventilatory muscle rest, reduce O_2 consumption of the ventilatory muscles, and "free up" O_2 for delivery to the tissues.[9]

Controlled ventilation is a common initial approach in situations of severe acute respiratory failure, especially if the primary problem is hypoxemia. Fig. 49.2 depicts the effects of inspiratory time on V_T during PA/C. Disadvantages of controlled ventilation include the need for sedatives and, perhaps, paralytic drugs. All patients given paralytic drugs must be sedated adequately because paralysis does not alter the patients' perception of their surroundings. All patients' senses are active: none are affected by paralysis; only voluntary muscles are paralyzed. In addition, in the care of apneic patients, ventilator malfunction or disconnection can lead to death.

RULE OF THUMB All modes of ventilation are equally as effective and equally well tolerated in patients requiring controlled ventilation: that is when the patient is NOT triggering any breaths; however, with assisted ventilation patient-triggered breaths, volume ventilation is more likely to cause asynchronies than pressure ventilation, specifically, the development of flow asynchrony.

Synchronized Intermittent Mandatory Ventilation

SIMV is characterized by the patient receiving a pre-set number of machine breaths per minute at a pre-set V_T; however, the patient can initiate additional breaths at the PEEP level set generally without any inspiratory support, and not the pre-set volume as with AC mode. SIMV may be used as a means of providing partial or full ventilatory support.[9] With SIMV, the machine breath may be volume or pressure targeted; in adults, it is typically a volume-targeted breath. SIMV is often combined with pressure support to overcome the imposed WOB (WOB_I) during spontaneous breathing owing to the artificial airway. SIMV allows the clinician to vary the amount of support provided from minimal to full ventilatory support. Disadvantages of SIMV include possible development of respiratory muscle dysfunction, especially in patients with rapid, shallow spontaneous breathing patterns; acute hypoventilation with use of low rates if patients do not continue to do their share of breathing; and an increase in WOB secondary to lack of ventilatory support during spontaneous breaths unless pressure support is applied.[9] SIMV also delays weaning compared with spontaneous breathing trials or pressure support and, as a result, is not a recommended mode of ventilation in adults.[14,15] The advantages and disadvantages of SIMV modes are summarized in Table 49.3. Outside of the United States, SIMV is an infrequently used mode of ventilation because of the above-mentioned problems.

TABLE 49.3 Advantages and Disadvantages of Synchronized Intermittent Mandatory Ventilation

Advantages	Disadvantages
Lower mean airway pressure may result than is achieved with assist/control ventilation	SIMV with PSV may increase mean airway pressure
Ventilatory muscle activity, strength, and coordination are maintained	Ventilatory muscle fatigue may occur
Level of support to maintain adequate levels of alveolar ventilation is easy to titrate	Acute hypoventilation may occur, especially with lower machine rates (<8 to 10 breaths/min)
Weaning protocols are easy to apply	Weaning is prolonged
Spontaneous breathing, which is physiologic, is incorporated	Addition of pressure support is often required to overcome WOB_I during spontaneous breathing
Patients tend not to hyperventilate and may not fight the ventilator, as they may do with assist mode	Patients may have difficulty adjusting to the ventilator; breath stacking is common with intermittent mandatory ventilation
Sedation or paralysis is not required, as it is in control mode	Patients may experience or continue a rapid, shallow breathing pattern or continue to make spontaneous breathing efforts during delivery of a "machine breath"
Full or partial ventilatory support and level of support can be titrated according to patient's need	Patient's workload increases considerably when SIMV rate decreases to approximately 50% of full ventilatory support value

PSV, Pressure support ventilation; *SIMV,* synchronized intermittent mandatory ventilation; *WOB_I,* imposed work of breathing.

Pressure Support Ventilation

PSV is characterized by spontaneous triggering of the ventilatory at a patients totally determined rate. PSV assumes minimal control over the patient's ventilatory pattern. Specifically, only the level of pressure applied is controlled by the ventilator, with all other aspects of gas delivery controlled by the patient; however, PSV is very similar to PA/C. The primary difference is that in PSV, flow terminates the breath, whereas in PA/C, time terminates the breath. Other than this, PA/C has a backup rate, and with pressure support an apnea mode of ventilation is set.[16] PSV can reduce WOB and may improve patient–ventilator synchrony by placing more control with the patient.[17] Many clinicians use PSV simply to overcome WOB imposed by the artificial airway.[17] The PSV level required to overcome WOB_I may be estimated as follows:

$$PSV = \frac{(PIP - P_{plat}) \times \dot{V}_I \text{ spontaneous}}{\dot{V} \text{ ventilator}}$$

where PSV is the pressure support level needed to overcome WOB_I, PIP is the peak inspiratory pressure during a volume-control machine breath, P_{plat} is the plateau pressure after an inspiratory pause (usually >1 second), $\dot{V}_I$ is the patient's spontaneous peak inspiratory flow (L/s), and $\dot{V}$ ventilator is the ventilator peak inspiratory flow rate (L/s) with a square wave inspiratory flow waveform. An example of the calculations for PSV needed to overcome WOB_I is presented in Box 49.6.

BOX 49.6 Calculation of Pressure Support Ventilation Level Needed to Overcome Imposed Work of Breathing and During Synchronized Intermittent Mandatory Ventilation

- Machine delivered V_T during VA/C: 450 mL
- Machine inspiratory flow rate: 50 L/min (1 L/s)
- Flow pattern: Square wave
- PIP: 25 cm H_2O
- P_{plat}: 23 cm H_2O
- Patient's spontaneous inspiratory flow rate: 30 L/min (0.5 L/s)

$$PSV = \frac{(PIP - P_{plat}) \times \dot{V}_I \text{ spontaneous}}{\text{Ventilator inspiratory flow}}$$
$$= \frac{(40 - 30 \text{ cm } H_2O) \times 0.5 \text{ L/s}}{1 \text{ L/s}}$$
$$= \frac{10 \text{ cm } H_2O \times 0.5 \text{ L/s}}{\text{L/s}} = 5 \text{ cm } H_2O$$

PIP, Peak inspiratory pressure; *VA/C,* volume assist/control.

PSV can be, and is being, increasingly used as a primary mode of ventilation. PSV is essentially the only mode of ventilation used during noninvasive ventilation and is equal to the difference between inspiratory positive airway pressure (I-PAP) and expiratory positive airway pressure (E-PAP). It is also an acceptable mode of ventilation for any patients capable of triggering ventilatory support who have an intact ventilatory drive. Many clinicians use this mode in the initial phases of ventilatory support and following the most acute phase of ventilatory failure. The actual PSV level required is based on the desired V_T. PSV is adjusted to ensure the desired V_T (4 to 8 mL/kg, IBW) is delivered, and the rise time and termination criteria are set to avoid asynchrony. Few clinicians attempt to calculate a PSV level based on the previously listed formula.

RULE OF THUMB The use of SIMV to wean patients from ventilatory support lengthens the time mechanical ventilation is required. Patients are liberated most rapidly from ventilatory support by the use of spontaneous breathing trials.

Airway Pressure Release Ventilation

APRV is a mode of ventilation designed to allow patients to breath spontaneously without assistance at high CPAP levels that are supplemented by a change in pressure from a high level (High continuous positive airway pressure [CPAP]) to a low level (Low CPAP). The original discussions of APRV referred to it as varying pressure between 2 CPAP levels. In addition to setting the High and Low CPAP levels, the time allocated to High and Low CPAP must be set. Essentially this mode is the same as pressure control inverse ratio ventilation with the addition of patients being able to breathe spontaneously at both the High and Low CPAP levels.

APRV has been indicated in the management of trauma patients and trauma/surgical patients with ARDS, but there is currently no data indicating that APRV is better than a lung protective approach to ventilatory support using classic modes of ventilation. In fact, there is data to indicate that the outcome may be worse with APRV.

High continuous positive airway pressure. The High CPAP level is set based on the combined need to establish a high mean airway pressure to improve oxygenation and to establish a pressure gradient to facilitate CO_2 removal during the transition from High to Low CPAP. The High CPAP is usually set between 20 and 30 cm H_2O but may be set higher depending on the pathophysiology of the specific patient.

Low continuous positive airway pressure. In the classic application of APRV, the Low CPAP level is set at 0 to 5 cm H_2O. This is done because the application of PEEP during the Low CPAP periods is accomplished by creating autoPEEP. Generally, spontaneous breathing does not occur at the Low CPAP level because of short Low CPAP times; however, the Low CPAP time can be set to any level. Usually, the longer the Low CPAP time the higher the Low CPAP level owing to an inverse relationship between the Low CPAP time and the development of autoPEEP.

High continuous positive airway pressure time. Generally, the High CPAP time is set at 3 to 5 seconds to establish a rate of change to Low CPAP (mechanical respiratory rate) of about 10 to 15 /min. The lengthy High CPAP time is set to maintain a high mean airway pressure to manage oxygenation.

Low continuous positive airway pressure time. The most common method to set the Low CPAP time is to ensure that autoPEEP is established with the short time. What is currently recommended is that the Low CPAP time is determined by expiratory flow; that is, expiratory time is limited to the time needed to allow expiratory flow to decrease to 70% to 75% of peak expiratory flow. This setting insures that autoPEEP is established during the Low CPAP time period.

Concerns with airway pressure release ventilation. A number of concerns are inherent in the typical application of APRV. First, the tidal volume delivered during the change from High to Low CPAP is large, frequently above the recommended 4 to 8 mL/kg PBW and commonly above 10 mL/kg, causing lung injury. Second, PEEP is established during Low CPAP by autoPEEP. AutoPEEP is established in lung units with long time constants, not short time constants, and thus it is likely that the lung units with short time constants will collapse and reopen with reestablishment of High CPAP, causing lung injury. Third, breathing spontaneously at High CPAP requires a large change in intrathoracic pressure, potentially creating an excessive transpulmonary pressure and inducing lung injury.

High-Frequency Oscillatory Ventilation

High-frequency oscillatory ventilation (HFOV) is the primary approach to high-frequency ventilation used in adults. Respiratory rates range from approximately 3 Hz (180/min) to approximately 8 Hz (480/min), and very small V_T, often approaching anatomic dead space, is delivered.[18] Gas transport during HFOV is caused by conventional bulk flow and a number of gas-moving and mixing effects associated with the rapid frequency (see Derdak et al.[18] for details regarding gas delivery in HFOV). Although high-frequency ventilation has been shown to be safe and effective in maintaining oxygenation and ventilation in various patients,[18-20] HFOV has not been shown to be superior to conventional ventilation. In fact, two recent randomized controlled trials indicate that HFOV in adults may negatively affect outcome.[21,22] In one of these trials, those ventilated with HFOV had a higher mortality than patients managed with conventional ventilation.[21] The primary setting where HFOV has been used is in the treatment of ARDS. Recently, however, some well-conducted research has suggested that HFOV is not associated with favorable outcomes such as length of stay, ventilator days and mortality; hence HFOV is rarely used in adult ARDS patients today.

RULE OF THUMB PSV can and is increasingly being used as a primary mode of ventilation. PSV is essentially the only mode of ventilation used during noninvasive ventilation and is equal to the difference between I-PAP and E-PAP.

Initial Choice of Mode

Most patients who need mechanical ventilation in the acute care setting initially are managed with volume or pressure ventilation.[7,13] SIMV may also be used, but it has no advantage over these modes, and it has considerable disadvantages; however, there is no evidence suggesting any of the modes are more beneficial in terms of patient outcomes except that asynchrony is increased and weaning delayed with SIMV.[14,15] Consequently, the choice of initial ventilator mode is primarily one of clinician preference and patient tolerance. Once the patient is stabilized on a ventilator mode, decisions can be made regarding the use of other, newer modes of ventilation such as PRVC, volume support, adaptive support ventilation, PAV, or NAVA.

RULE OF THUMB For most patients, begin with mechanical ventilatory support with VA/C, PA/C, or PSV. When the patient is stabilized, other modes of ventilation can be considered.

Tidal Volume and Rate

V_T and machine rate should be chosen concurrently because these are the two major determinants of minute ventilation. Normal spontaneous V_T for unstressed adults is, on average, 6.3 mL/kg IBW (approximately 5 to 7 mL/kg IBW) with a respiratory rate of 12 to 18 breaths/min, establishing a minute ventilation of approximately 100 mL/kg IBW per minute.[23] Acceptable V_T for mechanical ventilation usually ranges from 4 to 8 mL/kg IBW.[1,5] V_T larger than 8 mL/kg IBW is harmful in patients with ARDS[2,24,25] and is mostly harmful to any patient in acute respiratory failure regardless of the cause of the failure.

Generally, regardless of mode, an initial V_T of 6 to 8 mL/kg IBW with a rate of 12 to 16 breaths/min is suggested for patients without acute restrictive disease.[5,26] After initiation of ventilation, the P_{plat} can be assessed, and V_T can be adjusted downward, as needed, for maintenance of a P_{plat} less than 28 cm H_2O and driving pressure less than 15 cm H_2O. A smaller initial V_T (4 to

6 mL/kg IBW) is appropriate for patients with ARDS[2,23,24] and a high P_{plat} and is usually necessary in patients with severe acute asthma. Table 49.4 lists V_T values for men and women according to calculated IBW.

RULE OF THUMB When starting ventilatory support for most adult patients, use an initial V_T of 6–8 mL/kg (IBW) and a respiratory rate of 12–16 breaths/min.

V_T times rate (f) determines minute ventilation ($\dot{V}_E$). As a rule, for adult patients, the resultant minute ventilation should be approximately 100 mL/kg IBW per minute.[9] A 70-kg adult (IBW) would have a minute ventilation of approximately 7000 mL/min. Patients with elevated CO_2 production ($\dot{V}CO_2$) or increased physiologic dead space (V_{Dphys}) need a larger minute ventilation to maintain acceptable $PaCO_2$. Minute volume should be increased by increasing the rate not the V_T.

In SIMV, the total minute ventilation is composed of spontaneous tidal volume (V_{Tsp}), spontaneous rate (f_{sp}), machine tidal volume (V_{Tmach}), and machine rate (f_{mach}). For SIMV, total minute ventilation ($\dot{V}_{ETOT}$) is described as follows:

$$\dot{V}_{ETOT} = \dot{V}_E \text{ machine} + \dot{V}_E \text{ spontaneous}$$

and

$$\dot{V}_E = (V_{Tmach} \times f_{mach}) + (V_{Tsp-average} \times f_{sp})$$

For PA/C or PSV, the delivered V_T depends on the pressure limit, the inspiratory time, and the patient's lung mechanics.

TABLE 49.4 Tidal Volume Based on Ideal Body Weight[a]

Height (in)	Height	Weight (lb)	Weight (kg)	6 mL/kg	8 mL/kg	10 mL/kg	12 mL/kg

[a]Ideal body weight (lb): Men, 106 + [6(H – 60)]; women, 105 + [5(H – 60)], where H is height in inches.

TABLE 49.5 Suggested Initial Tidal Volume and Frequency for Mechanical Ventilation Based on Disease State or Condition

Patient Type	Tidal Volume (mL/kg)[a]	Frequency (breaths/min)
Adults		
Normal lungs	6–8	12–16
Neuromuscular disease, postoperative period, or with normal pulmonary mechanics in which maintaining lung volume is a concern	6–8	12–16
Acute restrictive disease, ALI/ARDS	4–8	20–35
Obstructive lung disease (COPD)	6–8	10–12[b]
Acute severe asthma exacerbation	4–6	8–12
Children		
Age 8–16 years	6–8	20–30
Age 0–8 years	6–8	25–35

[a]In all patients, maintain P_{plat} at <28 cm H_2O and driving pressure <15 cm H_2O.
[b]For patients with obstructive disease, ensure a short inspiratory time and long expiratory time to avoid air trapping and minimize auto-PEEP. Lower V_T and rate may be necessary in acute asthma to avoid further lung overinflation.
ALI, Acute lung injury; *ARDS,* acute respiratory distress syndrome; *COPD,* chronic obstructive pulmonary disease

Generally, the pressure limit is increased or decreased to achieve a target V_T while a P_{plat} of less than 28 cm H_2O and a driving pressure less than 15 cm H_2O is maintained. A good initial pressure setting is to start at 10 cm H_2O (above PEEP) and observe the resulting V_T. Pressure is increased or decreased to achieve the desired volume. As with VA/C, minute ventilation with PA/C is simply rate multiplied by tidal volume V_T($\dot{V}_E = f \times V_T$). Recommended initial V_T and frequency for various patient types are described in Table 49.5.

Patients with ARDS may need lower V_T to avoid further lung injury and a higher rate to maintain effective alveolar ventilation, while P_{plat} is maintained less than 28 cm H_2O and driving pressure less than 15 cm H_2O. Results of multicenter studies suggest V_T of 4 to 8 mL/kg IBW for patients with ARDS.[2,23,24] Set respiratory rates of 25 to 35 breaths/min may be needed in patients with ARDS to maintain adequate minute ventilation. Box 49.7 summarizes the ARDS Clinical Network guidelines for initial ventilator setup.[2]

Trigger Sensitivity

Trigger sensitivity should be set at the most sensitive level avoiding autotriggering to minimize trigger work and missed triggering. With flow triggering, the trigger should be set at 1 to 2 L/min, and with pressure triggering, the range is generally −0.5 to −1.5 cm H_2O; however, because of pin holes in disposable ventilator circuits, the sensitivity may need to be adjusted to 3 or 4 L/min or −2 cm H_2O to avoid autotriggering. The increased use of ventilator graphics packages has led to the recognition that patients' inspiratory efforts are often insufficient to trigger the ventilator.[9] Factors that can prolong ventilator response time include large V_T, low trigger sensitivity, auto-PEEP, high bias circuit flow, and abdominal paradox (Box 49.8) (see Chapter 48).

Many ventilators offer the option of a pressure or a flow trigger. With older generation intensive care unit (ICU) ventilators, flow triggering offered slightly lower trigger work than pressure triggering,[27-29] although the gain in terms of the patient's total WOB was slight. Newer ventilators with fast pressure-triggering capabilities are as sensitive as flow-triggered devices;[30,31] however, no triggering mechanism can reduce the WOB caused by auto-PEEP, which must be addressed by other means (see Chapter 48). Flow-trigger settings vary by ventilator. Generally, for flow triggering, the trigger flow should be set 1 to 2 L/min below baseline or bias flow.

BOX 49.7 Initial Ventilator Setup and Management of Oxygenation, Plateau Pressure, and pH

1. Calculate predicted (ideal) body weight as follows:
   - Men: Weight in kilograms = 50 + 2.3 (height in inches − 60)
   - Women: Weight in kilograms = 45.5 + 2.3 (height in inches − 60)
2. Select assist/control mode.
3. Set V_T to 6–8 mL/kg of predicted body weight.
4. Set initial rate to achieve baseline minute ventilation ($\dot{V}_E$). Rate only limited by the development of auto-PEEP.
5. Adjust V_T and rate to achieve pH of 7.30–7.45 while maintaining P_{plat} of ≤28 cm H_2O.
6. Set inspiratory flow rate above patient demand (may be >80 L/min).
7. For oxygenation to achieve PaO_2 of 55–80 mm Hg or SpO_2 88%–95%, set FiO_2 after establishing PEEP to the level resulting in acceptable oxygenation. Over time adjust FiO_2 to maintain oxygenation level. When FiO_2 is ≤0.5, decrease PEEP slowly 2 cm H_2O every 8 hours. If patient desaturates during PEEP decrease, reestablish PEEP.

FiO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
Low PEEP	5	5	8	8	10	10	10	12
High PEEP	12–14	14	16.0	16.0	18–20	20	20	20
FiO_2	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
Low PEEP	14	14	14	16	18	20	22	24
High PEEP	20	20–22	22	22	22	22	22	24

8. Check P_{plat}, SpO_2, respiratory rate, V_T, and pH (if available) at least every 4 hours and after each change in PEEP or V_T:
   - If P_{plat} is >28 cm H_2O, decrease V_T by 1-mL/kg steps (minimum 4 mL/kg).
   - If P_{plat} is <25 cm H_2O and V_T is <6 mL/kg, V_T may by increased in 1-mL/kg steps until P_{plat} is >25 cm H_2O or V_T is 6 mL/kg.
   - If P_{plat} is <20 and breath stacking occurs, V_T may be increased in 1-mL/kg increments (maximum 8 mL/kg).
9. The pH goal is 7.30–7.45.
   For acidosis management (pH < 7.30):
   - If pH is 7.15–7.30, increase the rate until pH is >7.30.
   - If metabolic acidosis is present, address the cause of the acidosis maintaining $PaCO_2$ > 25 mm Hg.
   For alkalosis management (pH > 7.45), decrease ventilator rate, if possible.

FiO_2, Fractional inspired oxygen; *PEEP,* positive end-expiratory pressure.
Adapted from National Institutes of Health (NIH) National Heart Lung and Blood Institute (NHLBI) ARDS Clinical Network Mechanical Ventilation Protocol Summary (Mechanical Ventilation Protocol Summary, revised 25 January 2005).

BOX 49.8 Factors That Can Prolong Ventilator Response Time

- Low trigger sensitivity
- Large V_T (causing air trapping)
- Abdomen–rib cage paradox
- Auto-PEEP (dynamic hyperinflation)
- High tubing compliance
- High circuit dead space
- High bias flow in the circuit
- Mechanical malfunction

PEEP, Positive end-expiratory pressure.

Inspiratory Flow, Time, and Inspiratory-to-Expiratory Ratio for Volume Ventilation

Most modern critical care ventilators allow the clinician to select peak flow, V_T, and rate *or* inspiratory time (or percentage inspiratory time, V_T, and rate). For most adults, an initial inspiratory time of approximately 0.8 second (range 0.6 to 1.0 second) with a resultant inspiratory-to-expiratory (I:E) ratio of 1:2 or lower is a good starting point. This value corresponds to an initial peak flow setting of approximately 60 L/min (range 40 to 80 L/min) and a down ramp (decelerating) or square flow waveform. Higher flow (≤100 L/min) may improve gas exchange in patients with chronic obstructive pulmonary disease (COPD), which may be a result of a longer expiratory time resulting in less air trapping.[10] (See Chapter 48.)

Inspiratory flow rate should be adjusted to ensure that the flow provided meets or exceeds the patient's spontaneous inspiratory flow[1] (see Chapter 48). A less sensitive trigger level and lower ventilator inspiratory flow tend to increase the patient's WOB. Common ventilator configurations and related controls that determine inspiratory flow, time, and I:E ratio are described in Fig. 49.3.

For ventilators with V_T, peak flow, and rate controls, inspiratory time is determined by V_T, peak flow, and flow pattern. To decrease inspiratory time, one may increase peak flow, decrease V_T, or change from a down ramp to a square wave flow pattern. Expiratory time and I:E ratio are determined by inspiratory time and rate. To increase expiratory time (and decrease I:E ratio), one may decrease the inspiratory time as described earlier or increase the expiratory time by decreasing the rate.[1]

For ventilators with V_T (or minute ventilation), percentage inspiratory time, and rate controls, the inspiratory time and V_T determine the inspiratory flow rate. On these ventilators, one can directly increase or decrease the percentage inspiratory time. At the same rate, as inspiratory time (or percentage inspiratory time) decreases, expiratory time and inspiratory flow rate increase, and I:E ratio decreases. An increase in V_T at the same percentage inspiratory time and rate also increases inspiratory flow rate with no change in I:E ratio. Box 49.9 shows the calculation of inspiratory flow rate based on percentage inspiratory time settings. To alter I:E ratio on these ventilators, one simply adjusts inspiratory percent time. Decreasing rate at the same inspiratory percent time setting does not affect I:E ratio, and both inspiratory time and expiratory time increase owing to a longer respiratory cycle. Changing the inspiratory flow waveform on these ventilators has no effect on inspiratory time, expiratory time, or I:E ratio; however, flow waveform changes affect peak and mean airway pressure.

BOX 49.9 Calculation of Inspiratory Flow Rate From Percentage Inspiratory Time

The effect of percentage inspiratory time on inspiratory flow rate can be estimated as follows:

$$\text{Inspiratory flow rate} = \frac{\text{Set minute ventilation}}{\text{Percentage inspiratory time} \times 0.01}$$

For example, a patient being treated with a Servo ventilator may have the following ventilator settings:

- Set minute ventilation = 12 L/min
- Set CMV rate = 20 breaths/min
- Resulting V_T = 12 L/20 breaths/min = 0.6 L or 600 mL
- Set time inspiratory percentage = 25%
- Set pause time percentage = 0%

$$\text{Inspiratory flow rate} = \frac{12\,\text{L/min}}{25\% \times 0.01} = \frac{12\,\text{L/min}}{0.25} = 48\,\text{L/min}$$

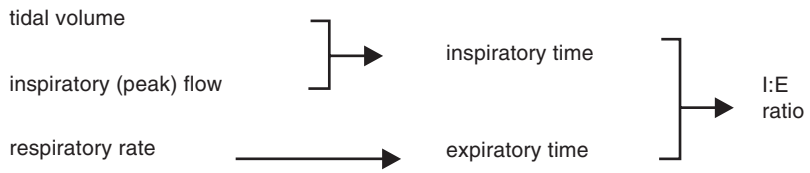
CMV, Continuous mechanical ventilation.

Flow Waveform

Flow waveform options on mechanical ventilators vary from a preset square wave to seven adjustable waveforms on older ventilators. Common choices available on current generation ventilators for waveform are square or down ramp (decreasing or "decelerating" waveform). Pressure support and pressure-controlled modes also deliver decreasing flow waveforms, but the decrease is patient-specific and not programmed into the gas delivery. The literature on clinical application of specific waveforms is mixed;[32] however, as one moves from an increasing ("accelerating") flow waveform to a square wave to a decreasing flow waveform, while holding inspiratory time constant, there tends to be a predictable decrease in peak airway pressure and a corresponding increase in mean airway pressure.[32] Increases in mean airway pressure may improve oxygenation, but may also impede venous return to the heart.[32] We suggest a decreasing, or down ramp, flow waveform when the goal is optimization of the distribution of inspired air and improvement in oxygenation. A square waveform may be useful in reducing mean airway pressure in patients with severe hypotension or cardiovascular instability. Fig. 49.4 compares the effect of ventilator flow waveforms on peak and mean airway pressure. Box 49.10 describes guidelines for selecting flow waveform during volume ventilation.

During PCV or PSV, a decreasing flow waveform is delivered. The initial peak flow is typically reached rapidly. Flow decreases throughout inspiration until the breath is terminated. With PSV, inspiration ends when the flow decreases to a preset value, typically adjustable from 5% to 85% of the peak flow in some newer ventilators. With PCV, flow continues to decrease until the inspiratory time has elapsed. In the PCV mode, increasing inspiratory time tends to increase V_T until zero flow is reached at end inspiration. Further increases in inspiratory time do not increase V_T, although distribution of inspired air may improve and mean airway pressure does increase.

A. Tidal volume, peak flow, and rate determine inpiratory time, expiratory time, and I:E ratio.



↑ tidal volume → ↑ inspiratory time → ↓ expiratory time→ ↑ I:E ratio

↓ tidal volume → ↓ inspiratory time → ↑ expiratory time → ↓ I:E ratio

↑ peak flow → ↓ inspiratory time → ↑ expiratory time → ↓ I:E ratio

↓ peak flow → ↑ inspiratory time → ↓ expiratory time → ↑ I:E ratio

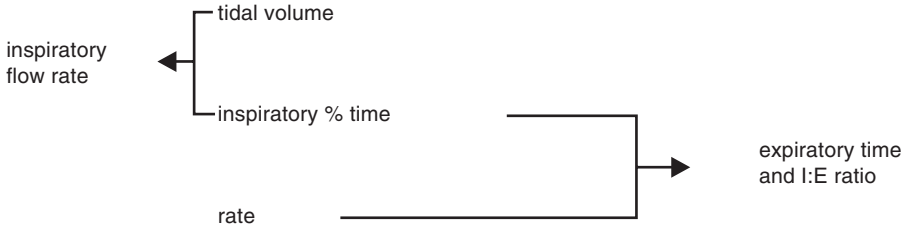
↑ rate → ↓ expiratory time → ↑ I:E ratio

↓ rate → ↑ expiratory time → ↓ I:E ratio

 to or → ↑ inspiratory time → ↓ expiratory time → ↑ I:E ratio

 or  to  → ↓ inspiratory time → ↑ expiratory time → ↓ I:E ratio

B. Tidal volume, % inspiratory time, and rate determine inspiratory flow rate, expiratory time, and I:E ratio.



↑ tidal volume → ↑ inspiratory flow rate → no change in inspiratory time, expiratory time, or I:E ratio

↓ tidal volume → ↓ inspiratory flow rate → no change in inspiratory time, expiratory time, or I:E ratio

↑ rate → ↓ expiratory time → I:E ratio constant or ↑*

↓ rate → ↑ expiratory time → I:E ratio constant or ↓*

↑ inspiratory % time → ↓ expiratory time

↓ inspiratory % time → ↑ expiratory time

*In the VC-CMV mode, ventilators with a percent inspiratory time control will maintain a constant I:E ratio with changes in rate. For the Servo 900C, 300, 300A, and Hamilton Veolar, changes in SIMV rate will alter I:E ratio in the SIMV mode, as described.

Fig. 49.3 Relationship between V_T, inspiratory flow, inspiratory time, expiratory time, and I:E ratio in various ventilator systems. (A) Effects of V_T, flow, and respiratory rate on inspiratory time, expiratory time, and inspiratory-to-expiratory (I:E) ratio. Some ventilators provide V_T, inspiratory flow, and rate control in volume control (VC) and synchronized intermittent mandatory ventilation (SIMV) modes. (B) Effects of volume, inspiratory time, and rate on inspiratory flow, expiratory time, and I:E ratio. Other ventilators provide controls for inspiratory time (or percentage inspiratory time), V_T (or minute ventilation), and rate control in the VC and SIMV modes. In the VC mode (controlled ventilation), ventilators with a percentage inspiratory time control maintain a constant I:E ratio with changes in respiratory rate. In the SIMV mode, changes in SIMV rate alter I:E ratio on these machines.

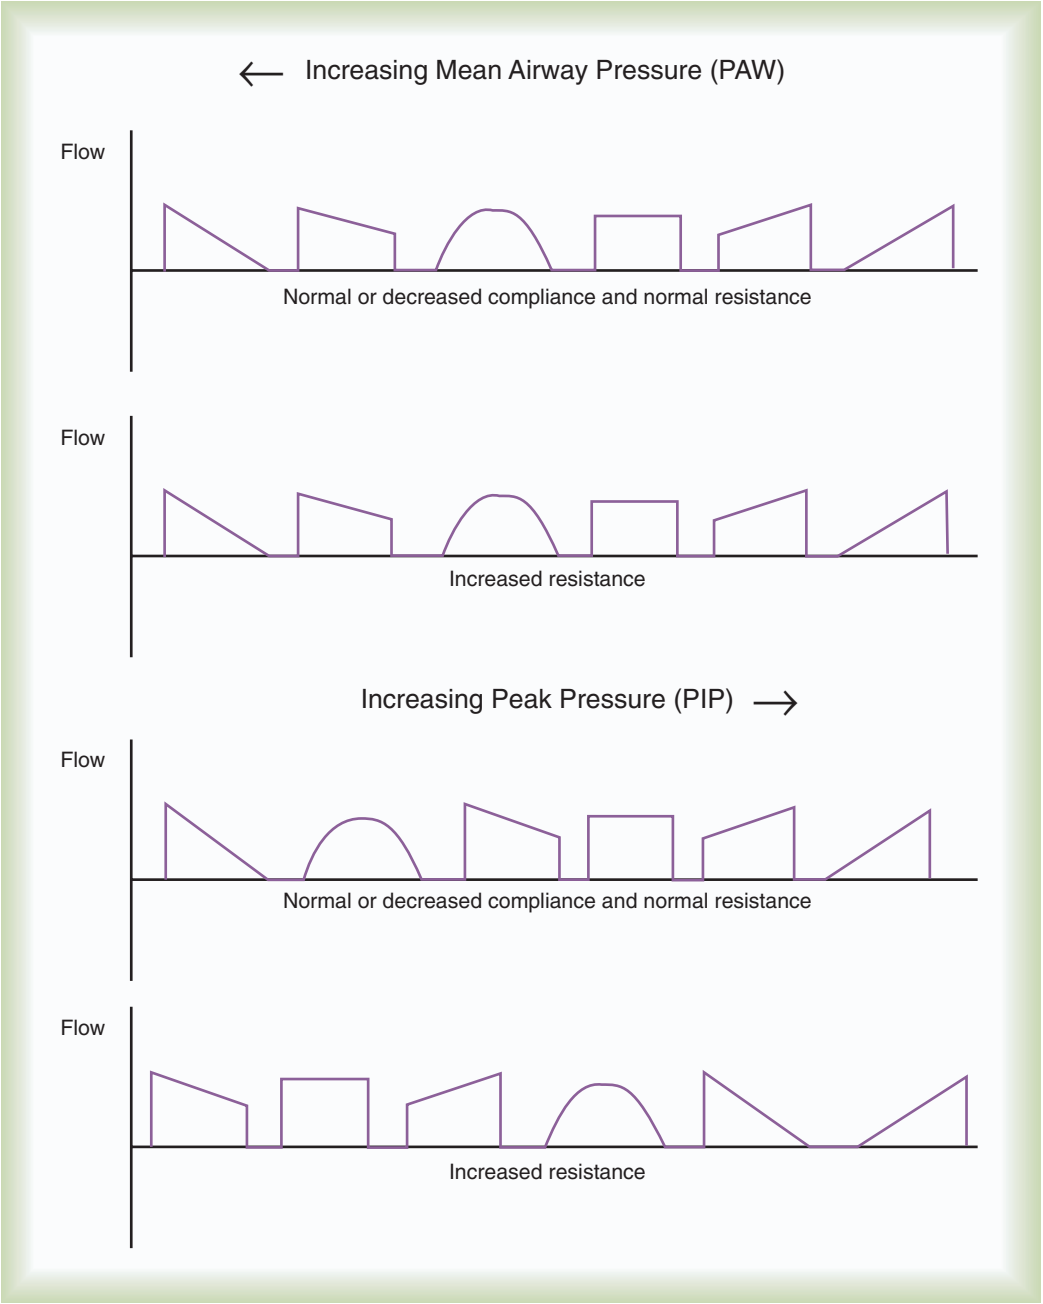


Fig. 49.4 Effect of ventilator flow waveform on peak and mean airway pressure with changing lung mechanics. Generally, flow waveforms that tend to increase mean airway pressure also decrease peak pressure *(PIP)* and vice versa. Consequently, if increasing mean airway pressure is the goal, decelerating *(down ramp)* flow waveforms may be helpful; however, in the care of patients with cardiovascular compromise, in whom reducing mean airway pressure may be helpful, a square wave may be valuable. Accelerating flow waveforms are no longer available on newer critical care ventilators. (Modified from Rau JL, Shelledy DC: The effect of varying inspiratory flow waveforms on peak and mean airway pressures with a time-cycled volume ventilator: a bench study. *Respir Care* 36:347, 1991.)

Inspiratory Pause

An inspiratory pause is rarely used for therapeutic purposes; it is normally used for estimating the plateau pressure. In addition to inspiratory time or flow, most ventilators have an option for setting an inspiratory pause or hold in the volume-control mode. From an assessment standpoint, an inspiratory pause may be used; however, from the therapeutic perspective, a brief inspiratory pause (up to 10%) has been recommended in the past for improving the distribution of the inspired air and PaO_2.[33] Use of an inspiratory pause has been suggested for administration of bronchodilators to improve medication delivery; however, in COPD patients, an inspiratory pause did not result in significant improvement in bronchodilator effectiveness.[9] If a brief inspiratory pause is used, I:E ratio and mean airway pressure

BOX 49.10 Guidelines for Selecting Inspiratory Flow Waveforms During Volume Ventilation

Constant Flow Waveform

- Alternative terms: Square wave, rectangular wave, constant flow generator.
- Advantages: High flow provided with a reduced inspiratory time and improved I:E ratio; may decrease mean airway pressure, which may be helpful in terms of venous return and cardiac output in compromised patients.
- Disadvantages: Increased PIP may lead to excessive pressure; lower mean airway pressure may affect oxygenation; inadequate peak flow may cause flow asynchrony.

Decreasing Flow Waveform

- Alternative terms: Down ramp, decelerating flow, descending ramp.
- Advantages: Lower PIP and higher mean airway pressure; this flow waveform may improve gas distribution, oxygenation, and patient–ventilator synchrony.
- Disadvantages: Increased mean airway pressure may impede venous return and cardiac output in compromised patients; in ventilators that have a peak flow control, the down ramp increases inspiratory time and I:E ratio and decreases expiratory time.

I:E, Inspiratory-to-expiratory; *PIP,* peak inspiratory pressure.

increase. An inspiratory pause of 0.5 to 2 seconds applied for a single breath is used for measurement of P_{plat} and in estimation of airway resistance (Raw):

$$\text{Raw} = \text{PIP} - P_{plat}/\text{Inspiratory flow (L/sec)}$$

where PIP is peak inspiratory pressure. An inspiratory pause should never be set in a spontaneously breathing patient except for a single breath in attempts to measure P_{plat} because it increases the level of asynchrony, causing the patient to fight the pause and to try to exhale during the pause.

An inspiratory pause can also be used for diagnostic or assessment purposes to either determine plateau pressure or ensure a full inspiration before a chest radiograph is obtained.[34] Irrespective as to whether it is used for therapeutic or diagnostic purposes, the use of an extended inspiratory pause should be limited because of the resultant increase in mean airway pressure and risk of impeding venous return and cardiac output. This is especially true in patients who are hypovolemic or hypotensive or whose condition is hemodynamically unstable.

RULE OF THUMB An end inspiratory pause should only be used to estimate the end inspiratory P_{plat}. It should never be applied continuously to a patient actively triggering the ventilator.

Oxygen Percentage (Fractional Inspired Oxygen)

FiO_2 selected on initiation of mechanical ventilation varies with the patient's condition. If little is known about the patient or if the patient's condition appears to be grave, 100% O_2 is the preferred starting point. Examples of disease states or conditions that typically warrant initial FiO_2 of 1 include acute pulmonary edema, ARDS, near drowning, cardiac arrest, severe trauma, suspected aspiration, severe pneumonia, carbon monoxide poisoning, and any disease state or condition resulting in a large right-to-left shunt. After initiation of mechanical ventilation with FiO_2 of 1, the FiO_2 should be reduced as soon as is practical to avoid O_2 toxicity and absorption atelectasis. In most patients, FiO_2 should always be adjusted to ensure PaO_2 of 55 to 80 mm Hg or SpO_2 of 88% to 95%. Recent data indicates that patients maintained on high FiO_2 resulting in $PaO_2 > 100$ mm Hg or $SpO_2 > 95\%$ have greater mortality than those maintained at an FiO_2 that maintains PaO_2 of 55 to 80 mm Hg or SpO_2 of 88% to 95%.[35,36]

Patients who have undergone previous blood gas measurement or oximetry who are doing well clinically, and patients with disease states or conditions that normally respond to low to moderate concentrations of O_2, may begin ventilation with a lower O_2 concentration (50%). These typically are patients with normal ventilation/perfusion ($\dot{V}/\dot{Q}$) or a $\dot{V}/\dot{Q}$ imbalance without shunt ($\dot{V}/\dot{Q}$ <1 but >0). Patients who often do well with low-to-moderate concentrations of O_2 include patients with acute exacerbation of COPD, emphysema, chronic bronchitis, drug overdose without aspiration, or neuromuscular disease and postoperative patients with normal lungs. For example, a patient with an acute exacerbation of COPD who needs mechanical ventilatory support may have had PaO_2 of 50 mm Hg with a nasal cannula at 4 L/min before intubation and mechanical ventilation. This patient would probably do well with FiO_2 of approximately 0.50 when adequate ventilation is restored. The patient can begin with 50% O_2 and be immediately assessed for assurance of adequate SpO_2. FiO_2 can be adjusted according to the patient's response. Many ICU patients are now managed with an FiO_2 of 21% because that is all that is needed to maintain appropriate oxygenation.

Positive End-Expiratory Pressure and Continuous Positive Airway Pressure

PEEP and CPAP are effective techniques for improving and maintaining lung volume and improving oxygenation for patients with acute restrictive disease such as pneumonia, pulmonary edema, and ARDS.[1,9] PEEP and CPAP should be cautiously applied in the treatment of patients with an already elevated functional residual capacity (FRC), such as patients with COPD or acute asthma, except at levels that are applied to offset auto-PEEP and air trapping.[9] Generally, the indication for PEEP or CPAP is inadequate arterial O_2 with moderate-to-high concentrations of O_2 caused by unstable lung units that are collapsed. PaO_2 less than 50 to 60 mm Hg with FiO_2 greater than 0.40 is a good general starting place for considering use of PEEP or CPAP.

In terms of ventilator initiation, initial PEEP or CPAP levels are usually 5 to 8 cm H_2O, even in the absence of unstable lung units or auto-PEEP. Most experts advocate for the use of 5 cm H_2O PEEP for all patients who have an artificial airway in place. Intubation results in small reductions in FRC,[1,9] which can be balanced with the application of PEEP or CPAP.

PEEP has been advocated in the presence of auto-PEEP, in particular in the care of patients with obstructive lung disease.[37] Applied PEEP in the presence of auto-PEEP is indicated only if the patient has difficulty triggering the ventilator. During controlled ventilation, increasing PEEP in the presence of auto-PEEP is usually not indicated (see Chapter 48 for auto-PEEP details). An absolute contraindication to PEEP is an uncontrolled tension

pneumothorax; however, PEEP should be cautiously applied in any patient with severe intrinsic lung disease, hypotension, and elevated intracranial pressure.

Open Lung Strategy, Recruitment Maneuvers, and Positive End-Expiratory Pressure

In the care of patients with ARDS, it is usually necessary to initiate PEEP at 10 to 15 cm H_2O;[24,25,38,39] however, many clinicians use the ARDS Clinical Network PEEP/FiO_2 tables to set PEEP initially during the establishment of ventilatory support (see Box 49.7). When patients are stabilized, the use of an open lung ventilation strategy in early-stage ARDS has been recommended.[1,5] Such a strategy incorporates V_T of 4 to 8 mL/kg IBW with either pressure-targeted or volume-targeted ventilation and a PEEP level set after a lung recruitment maneuver using a decremental PEEP trial.[1,5,40,41] The lung recruitment maneuver is intended to open collapsed lung units, and the setting of PEEP using a decremental PEEP trial is intended to apply PEEP based on the patient's lung mechanics to keep the recruited lung units open.

Although all patients with ARDS require PEEP, not all patients with ARDS respond to low-level PEEP, and patients with pulmonary (vs. nonpulmonary) causes of ARDS, such as pneumonia, may be less likely to respond to low to moderate levels of PEEP.[12] Nonpulmonary causes of ARDS (e.g., extrathoracic trauma, intraabdominal sepsis) seem to respond well to PEEP.[12] In practice, some authors have suggested that higher levels of PEEP (>15 cm H_2O) be reserved for patients with a high percentage of recruitable lung.[4] High levels of PEEP have been shown to improve outcomes in ARDS in patients with the most severe forms of ARDS (PaO_2/FiO_2 < 150 mm Hg).[42,43] (See later section on the performance of recruitment maneuvers and the setting of PEEP by decremental trial.)

Pressure Rise Time or Slope

Most newer, critical care ventilators include an inspiratory pressure rise time or pressure slope. This control functions only with pressure-limited breaths (PSV, PCV, PRVC, volume support, APRV, pressure SIMV). The purpose of this control is to adjust the rate at which flow increases from baseline to peak (see Chapter 48 for details).[44-46]

Limits and Alarms

Ventilator alarms and limits warn of ventilator malfunction and changes in patient status. Ventilator malfunction alarms include power or gas supply loss and electronic or pneumatic malfunction. These alarms are usually preset by the manufacturer.

Patient status alarms are usually set by the RT. These include maximum inspiratory pressure, low-pressure and low-PEEP alarms, high-volume, low-volume and rate alarms, O_2 and humidification alarms, and apnea alarms. After initiation of ventilation, alarms and limits are readjusted as needed. Alarms are usually set so that they warn the clinician of important changes or problems. Without proper setting, these alarms can become a nuisance by falsely signaling problems that are not real.[9]

In volume ventilation, a pressure limit should be set. Generally, before the patient is connected to the ventilator, the limit should be set at 40 cm H_2O to avoid over pressuring the system when the patient is connected. After the patient is connected to the ventilator, the peak and plateau pressures should be assessed. If P_{plat} is greater than 28 cm H_2O, consideration should be given to decreasing the set V_T. If P_{plat} is less than 28 cm H_2O, the high-pressure limit can be adjusted to 10 to 15 cm H_2O above PIP. One can decrease peak pressure by decreasing the peak flow rate, increasing the inspiratory time, changing the inspiratory flow waveform from a square to a down ramp, or decreasing the delivered V_T. For spontaneously breathing patients, inspiratory flow and time must meet or exceed the patient's inspiratory demand to ensure one does not increase the patient's WOB further (see Chapter 48 for details). Preset or adjustable alarms common to most ventilators include pressure (high-low), volume (high-low V_T, minute ventilation), apnea, O_2 percentage, and temperature. Suggested initial settings for these alarms and backup ventilator settings are presented in Table 49.6.

TABLE 49.6 Alarm and Backup Ventilation Setting of Initial Ventilatory Setup (Adults)

Low pressure	5–10 cm H_2O below PIP
Low PEEP/CPAP	3–5 cm H_2O below PEEP
High pressure limit	Max 50 cm H_2O, adjusted to 10–15 cm H_2O above PIP
Low exhaled V_T	100 mL or 50% below set V_T
Low exhaled minute ventilation	2–5 L/min or 50% below minimum SIMV or assist/control backup minute ventilation
High minute ventilation	50% above baseline minute ventilation
O_2 percentage (FiO_2)	5% above and below set O_2 percentage
Temperature	2°C above and below set temperature, do not exceed 37°C
Apnea delay	20 s
Apnea values	V_T and rate set to achieve full ventilatory support (V_T 8–10 mL/kg; rate 10–12 breaths/min) with 100% O_2

CPAP, Continuous positive airway pressure; *FiO_2,* fractional inspired oxygen; *PEEP,* positive end-expiratory pressure; *PIP,* peak inspiratory pressure.

Humidification

Humidification is required during both invasive and noninvasive mechanical ventilation. A heated humidifier or a HME should provide a minimum of 30 mg/l of water with a temperature of 30°C or greater.[47] Use of HMEs should be avoided in the care of patients with thick and or retained secretion and patients with low body temperature (<32°C), high spontaneous minute ventilation (>10 L/min), or air leaks in which exhaled V_T is less than 70% of delivered V_T.[47] Heated humidifiers may be used to deliver saturated gas at 100% relative humidity at body temperature (see Chapter 39). Current clinical practice guidelines suggest an inspired gas temperature of 35 ± 2°C.[48] The optimal humidity approach uses a heated humidifier to deliver gas in the range of 35 to 37°C at the airway and at a temperature consistent with patient comfort during noninvasive ventilation; however, in patients without primary pulmonary dysfunction and short-term ventilation, HMEs are very useful. Generally, these are postoperative patients after elective surgery, patients in the emergency department, and patients recovering from an overdose.

Periodic Sighs

Constant, monotonous tidal ventilation at a small volume (<7 mL/kg) may result in progressive atelectasis.[9,49] Periodic deep breaths or sighs delivered every 6 to 10 minutes reverse this trend.[9,49] During the 1960s and 1970s, it was common to ventilate patients with a smaller V_T (5 to 7 mL/kg) and no PEEP. As a result, an intermittent sigh function was incorporated into most volume ventilators. Sighs were programmed at 1½ to 2 times the set V_T at an interval of every 6 to 10 minutes. Sometimes, multiple sighs were included at a preset interval of up to 10 times per hour; however, because of the use of PEEP, sighs are no longer routinely included. Appropriate PEEP helps prevents the formation of atelectasis with constant small V_T. This is the primary reason why 5 to 8 cm H_2O of PEEP is routinely used on patients, including patients with healthy lungs. General guidelines for the initial ventilator settings for most adult patients are described in Box 49.11.

BOX 49.11 General Guidelines for Initial Ventilator Settings for Adult Patients

Mode
- Assist/control volume or pressure targeted
- Pressure support

Tidal Volume
- 4–8 mL/kg IBW
- Avoid overdistention
- Maintain P_{plat} <28 cm H_2O
- For COPD, V_T 6–8 mL/kg IBW in assist/control or pressure support mode with adequate expiratory time for reducing air trapping is suggested
- For ARDS, begin at 6–8 mL/kg IBW; adjust as indicated to maintain P_{plat} <28 cm H_2O
- For acute asthma, V_T 4–6 mL/kg IBW is indicated to maintain P_{plat} <28 cm H_2O

Rate
- 18 (asthma)–40 breaths/min
- Minimize auto-PEEP
- Set initial rate and V_T to maintain baseline minute ventilation (approximately 100 mL/kg IBW for most healthy adults)

PEEP
- 5 cm H_2O in most patients ventilated without acute lung injury
- 10 cm H_2O in patients with mild ARDS
- 15–20 cm H_2O in most patients with moderate to severe ARDS
- 5 cm H_2O in patients with COPD, adjust as indicated to offset effect of auto-PEEP on ventilator triggering
  0–5 cm H_2O with asthma, must evaluate the effect of applied PEEP on total PEEP. In most asthmatic patients, applying PEEP increases total PEEP.
- Trigger sensitivity –0.5 to –1.5 cm H_2O or flow trigger 1–2 L/min; minimize trigger work without autocycle
- Inspiratory flow and time 60–100 L/min
- Inspiratory time 0.6–1.0 s; inspiratory flow must meet or exceed patient's spontaneous inspiratory flow demand
- Resultant I:E ratio should be ≤1 : 2

ARDS, Acute respiratory distress syndrome; *COPD,* chronic obstructive pulmonary disease; *IBW,* ideal body weight; I:E, inspiratory-to-expiratory; *PEEP,* positive end-expiratory pressure.

ADJUSTING VENTILATORY SUPPORT

After ventilator initiation, the patient should be carefully assessed and the ventilator adjusted so that patient–ventilator synchrony is ensured; WOB is minimized; and oxygenation, ventilation, and acid–base balance are optimized while harmful cardiovascular effects are minimized. Initial patient evaluation should include physical assessment, assessment of ventilator settings, cardiovascular assessment, oximetry, and measurement of arterial blood gases (Box 49.12).

MINI CLINI

Humidification of the Airways During Mechanical Ventilation

Problem

A mechanically ventilated patient is in the medical ICU recovering from acute respiratory failure secondary to aspiration pneumonia. The patient currently needs airway suctioning every 30–60 min according to the RT and staff nurse caring for the patient. Both caregivers note that the secretions are thick and copious. Current ventilator settings are as follows:
Mode: A/C volume ventilation
V_T: 500 mL (6.8 mL/kg IBW)
Preset rate: 16 breaths/min
Total rate: 26 breaths/min
FiO_2: 0.50
PIP: 31 cm H_2O
V_E: 13 L/min

The RT is asked to place an HME on the ventilator circuit at the "wye." Is this an appropriate action?

Solution

Humidification can be provided with either a heated humidifier or an HME. Although useful in some instances, placement of an HME would be contraindicated in this case for several reasons. Adequate humidification for a patient with an artificial airway is critical in preventing inspissation of airway secretions, injury to and destruction of the airway epithelium, and atelectasis.

The patient information in this clinical scenario points to several potential problems with use of an HME, the most obvious one being copious, thick airway secretions. The HME may not provide sufficient water vapor and heat output, and secretions could be retained. The airway secretions could be coughed into the HME, causing increased resistance to flow and possible obstruction. Because the patient has high ventilatory requirements, as evidenced by an elevated exhaled minute ventilation, it is important that the humidification system can maintain adequate heat and moisture output when demands dictate.

Other situations in which an HME should not be used are administration of aerosol treatments through the ventilator tubing circuit, high-minute ventilation (>10 L/min), and body temperature less than 32°C.

BOX 49.12 Initial Assessment of Ventilatory Support

- Inspection, palpation, and auscultation.
- Assessment of position of artificial airway and cuff inflation.
- Assessment of pulse, blood pressure, oximetry, and electrocardiogram.
- Inspection of patient–ventilator system breathing circuit, humidifier, ventilator settings, and findings.
- Analysis of arterial blood gas values.
- Inspection of chest radiograph.

Physical assessment should include general appearance, level of consciousness, signs of anxiety or dyspnea, color, extremities (temperature, edema, capillary refill, cyanosis), heart rate and blood pressure, respiratory rate and pattern, inspection of the neck for jugular venous distention, and chest examination. Use of accessory muscles, tachypnea, retractions, or paradoxical abdomen movement may indicate increased WOB. Unilateral or unequal lung expansion is associated with bronchial intubation, pneumothorax, and other unilateral disorders.

Breath sounds should be assessed for good aeration, and absent, diminished, or abnormal breath sounds should be documented. Palpation should be performed as appropriate for tracheal position, chest wall motion, and presence of subcutaneous air. Percussion of the chest should be performed for assessment of resonance, dullness, or hyperresonance. Key findings at initial assessment of a patient undergoing ventilation are described in Table 49.7.

Ventilator settings that should be assessed after initiation of mechanical ventilation include peak, plateau, and mean airway pressures; exhaled volumes (spontaneous and machine V_T, minute ventilation); respiratory rate (spontaneous and machine rate); baseline pressures (PEEP, CPAP, auto-PEEP); trigger effort; O_2 concentration; inspiratory time; flow; I:E ratio; humidification; airway temperature; and airway cuff pressure. In addition, patient-ventilator interaction should be assessed to ensure that a spontaneously breathing patient is able to trigger a breath easily and that inspiratory flow and time are such that WOB is minimized. When using pressure ventilation, the patient should also be evaluated to ensure ease of cycling to expiration. Factors that may affect patient–ventilator interaction are discussed in detail in Chapter 48.

The artificial airway should be assessed for proper placement, patency, and cuff inflation. Size, position, and depth of the endotracheal tube and cuff pressure, including volume used to inflate the cuff, should be recorded. A clean, functioning manual resuscitator with O_2 supply and suction equipment including an appropriate supply of suction catheters, sterile water or saline solution, and sterile gloves must also be placed near the bedside. Patients requiring high levels of PEEP (>5 cm H_2O) should have PEEP valves attached to the manual ventilator.

Cardiovascular assessment should include observation of heart rate, blood pressure, and electrocardiogram for the presence of arrhythmias. Tachycardia, ST segment elevation, and frequent premature ventricular contractions may indicate myocardial ischemia. If the patient has a central venous line or pulmonary arterial catheter, hemodynamic variables may be assessed, including central venous pressure, pulmonary arterial pressure, wedge pressure, and cardiac output.

Continuous monitoring with pulse oximetry is recommended for patients receiving mechanical ventilatory support in the ICU, and arterial blood gases should be measured 30 to 60 minutes after initiation of mechanical ventilation. A chest radiograph should be obtained to verify proper endotracheal tube placement and to evaluate the chest and lungs. After the initial assessment,

TABLE 49.7 Assessment of Ventilatory Support

Ancillary equipment in room	Crash cart (patient's condition unstable); cardiac monitor; chest tubes (pneumothorax, chest drainage, thoracic surgery); aortic balloon pump (heart failure); cooling blanket (fever); other
General appearance	Resting quietly, calm, relaxed (no distress); restless, anxious, distressed (pain, anxiety, inadequate oxygenation or ventilation)
Level of consciousness	Alert, awake, and oriented to person, place, and time (good mental status, neurologic function); confused (neurologic problems, hypoxia, low cardiac output, drugs); sleepy (tired, sedatives, narcotics); lethargic (exhaustion, impaired CNS status, sedation); somnolent (CNS impairment, sedation); coma (CNS malfunction, heavy sedation, severe hypoxia)
Extremities	Cyanosis (hypoxemia); pale, cold, and clammy (poor cardiac output, low blood pressure, shock); edema (fluid overload)
Respiratory rate and pattern	Normal (good cardiopulmonary status); tachypnea (pain, anxiety, hypoxemia, acidosis, CNS problems); bradypnea or apnea (severe hypoxia, CNS problems, heavy sedation, paralysis)
Head, eyes, ears, nose, and throat	Cyanotic lips and gums (hypoxemia); pupils dilated (drugs, severe hypoxia, low cardiac output, cardiac arrest); pupils dilated and fixed (brain death); pupils contracted (drugs, light); response to light (good if responsive)
Neck	Accessory muscle use (increased WOB, respiratory distress); jugular vein distention (right-sided heart failure, positive pressure impeding venous return)
Chest inspection	Right-left chest wall synchrony (normal); right-left chest wall asynchrony (right main stem intubation, pneumothorax, large unilateral pleural effusion, flail on one side); chest-diaphragm synchrony (normal); chest-diaphragm asynchrony—abdominal paradox (increased WOB, diaphragmatic fatigue)
Chest auscultation	Good bilateral breath sounds (normal); decreased breath sounds unilaterally (right main stem intubation, pneumothorax, unilateral lung disease); bilaterally decreased or absent breath sounds (inadequate or decreased ventilation, large leak, ventilator malfunction or disconnect, misplaced endotracheal tube); air leak around cuff (underinflation, cuff malfunction); wheezing (bronchospasm, tumor, narrowing of airway); bibasilar crackles in patients with congestive heart failure (pulmonary edema); rhonchi, coarse crackles (secretions in the larger airways); bronchial breath sounds (consolidation or microatelectasis)
Palpation	Subcutaneous air (pneumothorax, pneumomediastinum); tracheal shift (tension pneumothorax, large area of atelectasis); right-left chest motion symmetry (normal); right-left asymmetric breathing (unilateral disease, pneumothorax, bronchial intubation)
Percussion	Resonant over lung tissue (normal); dull (pleural effusion, lobar infiltrates, consolidation, atelectasis); hyperresonant (pneumothorax, overinflation—COPD, asthma exacerbation)
Vital signs	Normal heart rate and rhythm (normal); tachycardia (hypoxemia, pain, anxiety, distress); hypertension (anxiety, cardiovascular disease, head trauma); bradycardia (severe hypoxia, severe hypercapnia, cardiac disease); hypotension (blood loss, shock, gram-negative sepsis, heart failure)

CNS, Central nervous system; *COPD,* chronic obstructive pulmonary disease; *WOB,* work of breathing.

the method and level of ventilatory support are adjusted to optimize oxygenation, ventilation, WOB, acid–base balance, and cardiovascular status. The ventilatory adjustments for each of these areas are discussed next.

Patient–Ventilator Interaction

Patient–ventilator interaction refers to patient comfort, WOB, and synchrony during ventilator-assisted breaths. Generally, ventilatory support should be initially adjusted to minimize the WOB and to allow the ventilatory muscles to rest.[50] See Chapter 48 for a detailed discussion.

OXYGENATION

Oxygen Concentration

Initiation of treatment for most patients in the acute care setting is with 100% O_2, unless detailed information identifying the precise FiO_2 required is available. FiO_2 is titrated to achieve PaO_2 of 55 to 80 mm Hg or SpO_2 88% to 95%. Estimate of O_2 needs can be derived as follows:

$$FiO_2 = \left(\frac{PaO_2 \text{ desired}}{PaO_2/PAO_2 \text{ ratio}} + PaCO_2 \times 1.25\right) \times \frac{1}{P_B - P_{H_2O}}$$

where FiO_2 required is the FiO_2 needed to achieve a desired PaO_2, PaO_2/PAO_2 is the initial PaO_2 divided by the initial alveolar partial pressure of oxygen (PAO_2), $PaCO_2$ is the initial $PaCO_2$, PB is barometric pressure, and P_{H_2O} is water vapor pressure. A simpler but less accurate calculation is as follows:

$$\underset{\text{Initial}}{PaO_{2(1)}/FiO_2(1)} = \underset{\text{Desired}}{PaO_{2(2)}/FiO_2(2)}$$

Instead of a formula, a nomogram can be used to predict a patient's required FiO_2 (Fig. 49.5). In either case, it is suggested that O_2 levels be titrated down from 100% to minimal FiO_2 required in decrements not to exceed 20%; titration is followed by oximetry or measurement of arterial blood gases. When

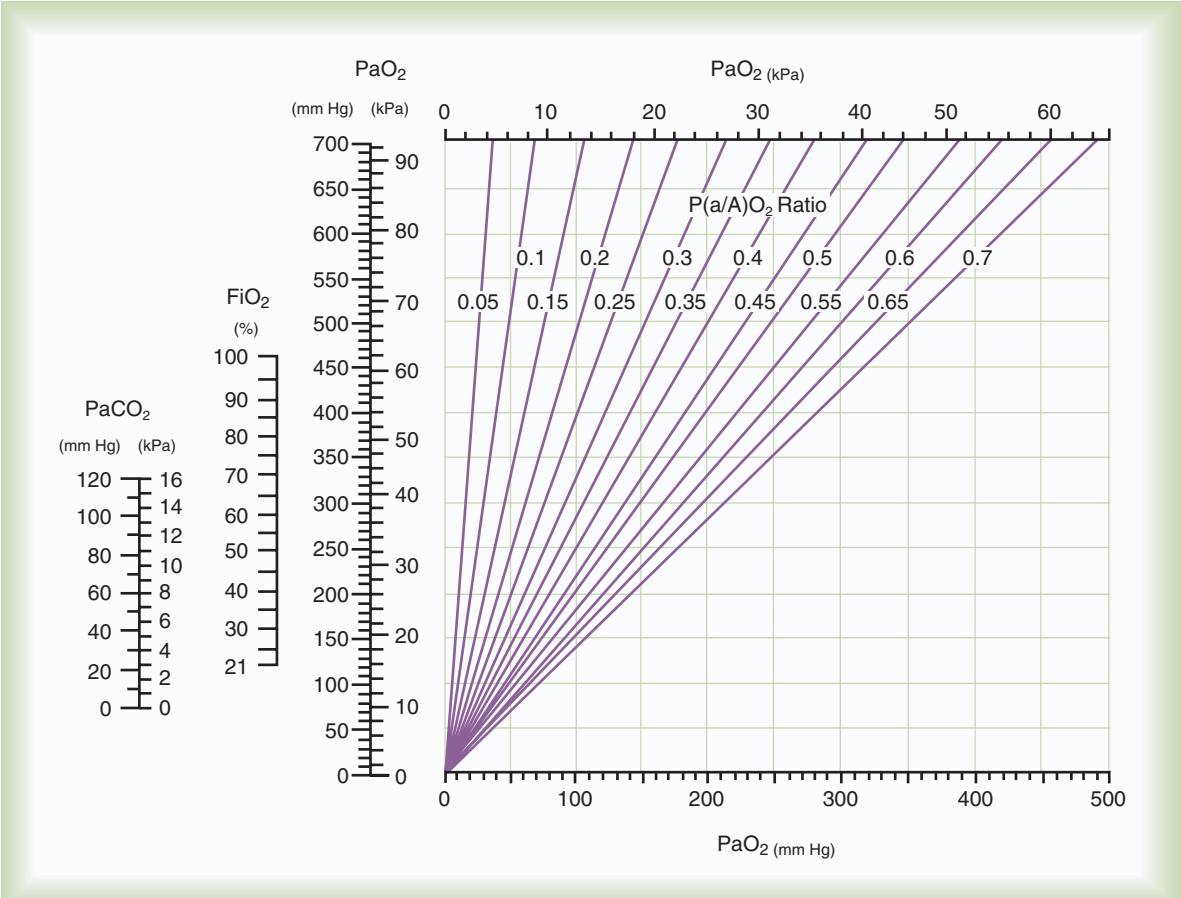

Fig. 49.5 Nomogram for computing PaO_2/PAO_2 ratio and predicting FiO_2 required for desired PaO_2. To use the nomogram, first align the patient's current $PaCO_2$ and FiO_2 *(left two columns)* with a straight edge. This line intersects the vertical line corresponding to the patient's PAO_2 *(third column)*. Draw a horizontal line from this point to the vertical line corresponding to the patient's PaO_2. The diagonal line at this point (or one interpolated from the nearest diagonal lines bracketing it) is the PaO_2/PAO_2 ratio. $PaCO_2$ of 40 mm Hg and FiO_2 of 50% give PAO_2 of approximately 310 mm Hg. If PaO_2 is 50 mm Hg, PaO_2/PAO_2 is approximately 0.15. To predict FiO_2 required for PaO_2 of 70 mm Hg, follow the diagonal line representing 0.15 up to where it intersects the vertical line representing PaO_2 = 70 mm Hg. From this point, draw a horizontal line to the left intersecting the PAO_2 column at approximately 450 mm Hg. Connect this point to the present $PaCO_2$ (40 mm Hg) and note that the line passes through the required FiO_2 of approximately 70%. (From Chatburn RL, Lough MD. *Handbook of respiratory care*, Chicago, 1990, Year Book Medical Publishers.)

titrating FiO_2 downward, the clinician should wait at least 15 to 20 minutes between changes in FiO_2 to allow O_2 levels to stabilize to a steady state. Patients with obstructive disease may need a longer period of approximately 30 minutes for equilibration after a change in FiO_2.When minimal FiO_2 is identified, further reduction in FiO_2 should be in steps of 5% to 10% followed by pulse oximetry measurements.

Once the desired PaO_2 and saturation are reached, monitoring should be continued. Generally, O_2 levels are titrated up and down as required, with adjustments in FiO_2 of 0.05 to 0.10 to maintain PaO_2 of 55 to 80 mm Hg with SpO_2 of 88% to 95%. Titration is followed by pulse oximetry.

RULE OF THUMB If a patient's oxygenation status is unknown, or if the patient's condition is unstable or critical, begin ventilatory support with FiO_2 of 100% until PaO_2, SaO_2, or SpO_2 can be assessed.

Positive End-Expiratory Pressure and Continuous Positive Airway Pressure

Various approaches to adjusting PEEP or CPAP have been suggested over the years, including minimum PEEP, optimal or best PEEP, use of PEEP tables, PEEP titrated by compliance or pressure-volume curves, and decremental PEEP trials. With acute restrictive disease, as PEEP or CPAP levels are increased, PaO_2, SpO_2, and static compliance tend to improve until the point at which lung overinflation occurs.[50,51] As mean airway pressure increases, venous return decreases. The result may be a decrease in cardiac output. Fig. 49.6 shows the physiologic factors that change during application of PEEP or CPAP. Several approaches to adjusting PEEP or CPAP are described later.

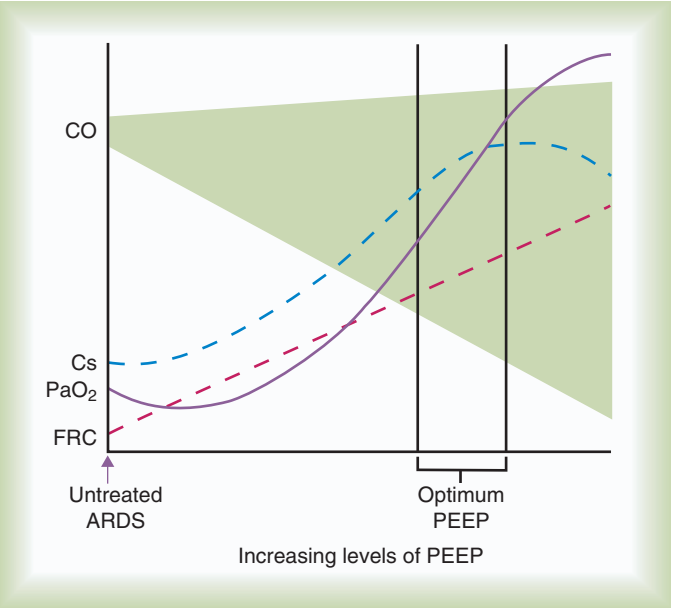

Fig. 49.6 Curves represent the physiologic factors that change during the application of positive end-expiratory pressure *(PEEP)* and continuous positive airway pressure (CPAP). As PEEP level is increased, PaO_2, functional residual capacity *(FRC)*, and static compliance (Cs) normally increase. Cardiac output (CO) *(shaded area)* can increase slightly, stay the same, or decrease. Optimum PEEP level can be expected to occur when PaO_2, FRC, and Cs are high. CO should be maintained near normal so that O_2 transport to the tissues remains high. *ARDS*, Acute respiratory distress syndrome. (Modified from Pilbeam SP: Mechanical ventilation: physiological and clinical applications, ed 3, St. Louis, 1998, Mosby.)

Minimum Positive End-Expiratory Pressure

Minimum PEEP can be defined as the minimal PEEP needed to maintain recruited lung open and achieve adequate PaO_2 (and SpO_2) with FiO_2 less than 0.6. Generally, the PEEP level needed to achieve PaO_2 of at least 60 mm Hg ($SpO_2 \geq 90\%$) with FiO_2 of 0.40 to 0.50 or less is the minimum PEEP. With this approach, the least PEEP or CPAP level needed to achieve this therapeutic end point is applied.[1]

RULE OF THUMB When titrating FiO_2 downward, the clinician should wait at least 15–20 min between changes in FiO_2 to allow O_2 levels to stabilize to a steady state. Patients with obstructive disease need a longer period of approximately 30 min for equilibration after a change in FiO_2.

Optimal or Best Positive End-Expiratory Pressure Based on Oxygen Delivery

Optimal or best PEEP may be defined as the PEEP that maximizes oxygen delivery (DO_2). Oxygen delivery is calculated as cardiac output ($\dot{Q}_T$) multiplied by oxygen content (CaO_2):

$$DO_2 = \dot{Q}_T \times CaO_2$$

For the optimal PEEP level, PEEP is increased in increments of 2 cm H_2O. Blood pressure, mixed venous O_2 levels (partial pressure of oxygen in mixed venous blood [$P\bar{v}O_2$], mixed venous oxygen saturation [$S\bar{v}O_2$], arteriovenous oxygen content difference [$C(a-\bar{v})O_2$]) cardiac output, and cardiac index are assessed. PEEP is increased incrementally until there is a decline in O_2 delivery, at which point the best or optimal PEEP has been exceeded. PEEP is adjusted down to the previous level that represents the "best" PEEP. Table 49.8 shows an example of a PEEP study for determining optimal PEEP based on O_2 delivery. In Table 49.8, as PEEP is increased from 8 cm H_2O to 10 cm H_2O to 12 cm H_2O, $P\bar{v}O_2$, $S\bar{v}O_2$, and O_2 delivery increase with no decline in cardiac output ($\dot{Q}_T$) or blood pressure; however, when PEEP is increased to 14 cm H_2O, $S\bar{v}O_2$, O_2 delivery, $\dot{Q}_T$, and blood pressure decline, indicating that optimal PEEP for this patient has been exceeded. The best PEEP for this patient would be 12 cm H_2O. Before determining PEEP using this approach, it is critical that the patient's hemodynamic status is stabilized. Patients with a compromised hemodynamic status generally do not tolerate PEEP titration without further compromise.

Compliance-Titrated Positive End-Expiratory Pressure

With the compliance-titrated technique, PEEP is increased in increments of 2 cm H_2O, and the patient's estimated static compliance (Cs) is measured:

$$Cs = \frac{\text{Volume delivered (ml)}}{P_{plat} - P_{baseline}(PEEP/CPAP)}$$

where total PEEP equals the sum of applied PEEP plus auto-PEEP.

MINI CLINI

Adjustment of Oxygen Concentration Down From 100%

Problem

At 9:00 a.m., mechanical ventilation is initiated with the following settings for a 70 kg (IBW) patient:
Mode: PA/C with the patient actively triggering the ventilator
PA/C level: 12 cm H_2O
V_T: 420 mL/ 6.0 mL/kg IBW
Rate: 20–26 breaths/min
FiO_2: 1
PEEP: 5 cm H_2O

An arterial blood gas is obtained 20 minutes after ventilator initiation:
FiO_2: 1
PaO_2: 225 mm Hg
pH: 7.42
$PaCO_2$: 40 mm Hg
HCO_3: 24 mEq/L
Base excess: +1 mEq/L

Calculated alveolar PAO_2 and PaO_2/PAO_2 ratios are:

$$PAO_2 = FiO_2(PB - P_{H_2O}) - PaCO_2 \times 1.25 = 663$$

$$PaO_2/PAO_2 = 225/663 = 0.34$$

What FiO_2 is required to achieve a target PaO_2 of 80 mm Hg?

Solution

The following equation and normal barometric pressure ($P_B = 760$), lead to the calculation:

$$FiO_2 \text{ required} = \left(\frac{PaO_2 \text{ desired}}{PaO_2/PAO_2 \text{ ratio}} + PaCO_2 \times 1.25\right) \times \frac{1}{P_B - P_{H_2O}}$$

$$= \left(\frac{80}{0.34} + 40 \times 1.25\right) \times \frac{1}{760 - 47} = 0.40$$

An alternative calculation would be:

Initial Desired

$$PaO_2/FiO_2 = PaO_2/FiO_2$$

$$225/1 = 80/FiO_2 \text{ desired}$$

$$FiO_2 \text{ desired} = 80 \times (1/225) = 80/225 = 0.36$$

What should the clinician do now?

The target O_2 concentration to achieve a PaO_2 in the range of 55–80 mm Hg (with 80 mm Hg as the specific target for the purpose of this calculation) would be approximately 40%; however, it is suggested that for adjusting down from 100% after initial ventilator setup, changes in FiO_2 be limited to 0.20 in the range of FiO_2 1–0.50 and 0.10–0.05 below FiO_2 of 0.50. Each change in FiO_2 should be followed by oximetry and patient assessment.

In this example, the FiO_2 can be decreased in a stepwise manner, as follows:

Time	FiO_2	SpO_2 (%)
9:30 a.m.	1	99
9:45 a.m.	0.80	99
10:00 a.m.	0.60	98
10:15 a.m.	0.50	97
10:30 a.m.	0.45	97
10:45 a.m.	0.40	95

Arterial blood gas on FiO_2 of 0.40 reveals a PaO_2 of 80 mm Hg.

MINI CLINI

Adjusting Fractional Inspired Oxygen

Problem

A 65 kg (IBW) patient in the ICU is receiving mechanical ventilation in the PA/C mode. The patient's arterial blood gas values and related ventilator settings are:
Mode: PA/C the patient is not breathing spontaneously.
FiO_2: 0.40
PaO_2: 50 mm Hg
PA/C level: 13 cm H_2O
V_T: 450 mL (7 mL/kg IBW)
pH: 7.4
Rate: 22 breaths/min
$PaCO_2$: 40 mm Hg
PEEP: 10 cm H_2O
HCO_3: 24 mEq/L
Base excess: +1 mEq/L

What FiO_2 would be required to increase this patient's PaO_2 to 60 mm Hg?

Solution

First, calculate the patient's current PAO_2 and PaO_2/PAO_2 ratio:

$$PAO_2 = FiO_2(P_B - P_{H_2O}) - PaCO_2/0.8$$

$$= 0.40(760 - 47) - 40/0.8$$

$$= 285 - 50 = 235 \text{ mm Hg}$$

$$PaO_2/PAO_2 = 50/235 = 0.21$$

Next, calculate the FiO_2 needed to achieve the desired PaO_2 of 60 mm Hg:

$$FiO_2 \text{ required} = \left(\frac{PaO_2 \text{ desired} + PaCO_2 \times 1.25 \times 1}{PaO_2/PAO_2 \text{ ratio } P_B - P_{H_2O}}\right)$$

$$= \left(\frac{60 + (40 \times 1.25) \times 1}{0.21760 - 47}\right)$$

$$= \frac{335.7 \times 1}{713} = 0.47$$

For this patient, if the FiO_2 is increased from 0.40 to 0.50, the PaO_2 should increase from 50 to 60 mm Hg. An alternative calculation, based on PaO_2/FiO_2 ratio, would be:

Actual Desired

$$PaO_2/FiO_2 = PaO_2/FiO_2$$

Solving for FiO_2, this becomes:

$$FiO_2 \text{ required} = PaO_2 \text{ desired} \times (FiO_2 \text{ actual}/PaO_2 \text{ actual})$$

$$= 60 \times (0.40/50) = 0.48$$

To increase this patient's PaO_2 to greater than 60 mm Hg would require increasing FiO_2 to approximately 0.50. Although FiO_2 of 0.50 or less is acceptable, as an alternative, the RT may consider increasing PEEP to 12 cm H_2O and then perform a clinical assessment, including evaluation of the effect of the increase on blood pressure, compliance, and arterial blood gases.

TABLE 49.8 Example of an Incremental Positive End-Expiratory Pressure Study[a]

Value	PEEP = 8	PEEP = 10	PEEP = 12	PEEP = 14	PEEP = 16
Time (min)	0	5	10	15	20
V_T (L)	4–8 mL/kg PBW	4–8 mL/kg PBW	4–8 mL/kg PBW	4–8 mL/kg PBW	4–8 mL/kg PBW
f (breaths/min)	22	22	22	22	22
FiO_2 (%)	60	60	60	60	60
I:E ratio	1:2	1:2	1:2	1:2	1:2
P_{peak} (cm H_2O)	30	32	35	42	50
P_{plat} (cm H_2O)	25	27	26	30	33
Cs (mL/cm H_2O)	24	27	32	29	26
SaO_2 (%)	86	92	96	95	95
Blood pressure (mm Hg)	131/78	133/82	130/79	125/74	110/69
Heart Rate	110	106	100	108	106

[a]When first reviewing a PEEP study, observe changes in the following: (1) airway pressure, (2) blood pressure, (3) heart rate, and (4) arterial oxygen (PaO_2, SaO_2). With increases in PEEP, PaO_2 and saturation improve; airway pressure may increase or decrease; compliance improves and then decreases at higher levels of PEEP. Optimum PEEP for this patient is 12 cm H_2O because it provides the best arterial oxygenation (PaO_2, SaO_2) and compliance without a decline in blood pressure or heart rate.
FiO_2, fractional inspired oxygen; *PEEP,* positive end-expiratory pressure.

Best PEEP has been exceeded at the point where an increase in PEEP is followed by a decrease in compliance. PEEP is reduced to the previous level, and this is optimal PEEP based on compliance.[51] For the example shown in Table 49.8, the best PEEP based on compliance would be 12 cm H_2O. Regional lung overdistention and declines in cardiac output can occur at levels less than compliance-titrated best PEEP, and, consequently, hemodynamic status should be optimized before any PEEP trial.

Positive End-Expiratory Pressure Titrated With Pressure-Volume Curves as Part of a Lung Protective Strategy

A lung protective strategy that has been shown to improve outcome in ARDS includes use of a low V_T (4 to 8 mL/kg) and PEEP set 2 cm H_2O above the lower inflection point (P_{flex}) on a pressure-volume curve or slow-flow pressure-volume curves to determine best PEEP. To obtain a static pressure-volume curve, the RT passively inflates the patient's lungs with varying volumes in increasing increments of 50 to 100 mL. At each end point, static pressure is obtained by means of application of an end inspiratory pause, and the resultant pressure-volume curve is plotted (Fig. 49.7). Upper and lower inflection points can typically be determined. The lower inflection point is thought to be the point at which alveolar recruitment begins. The upper inflection point indicates lung overdistention. PEEP is set at approximately 2 cm H_2O above the lower inflection point (P_{flex}). Determining PEEP level using the P_{flex} value may be done after a lung recruitment maneuver (see later). V_T is adjusted to ensure that the upper inflection point is not exceeded during inspiration.

Calculating the static pressure-volume curve is technically difficult and time-consuming.[12] An alternative is to use the slow-flow pressure-volume curve. A slow-flow curve (≤6 L/min) may also identify the lower inflection point for the purposes of setting PEEP (Fig. 49.8); however, in either case, some patients do not have a lower inflection point. In approximately 25% of patients, the P_{flex} cannot be identified from the pressure-volume curve.[25] In addition, observer variability in identifying the lower inflection point can be significant.[52]

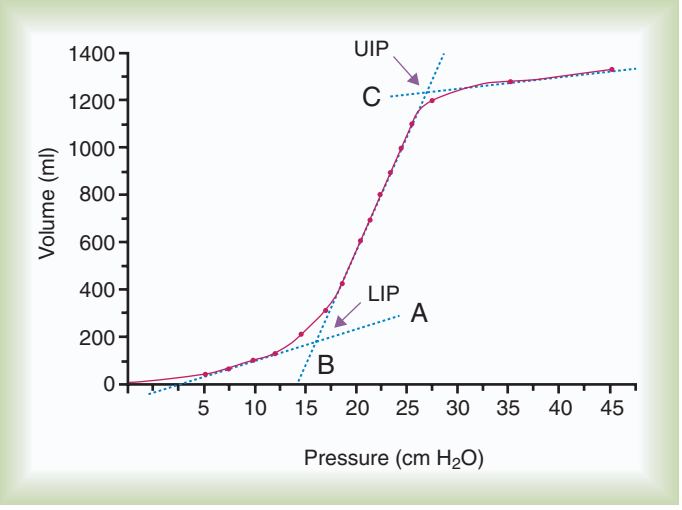

Fig. 49.7 Static pressure-volume curve of a patient with acute respiratory distress syndrome. Volume is increased in increments of approximately 100 mL, inspiratory P_{plat} is measured, and a pressure—volume curve is plotted. Straight lines (*A, B,* and *C*) are drawn tangent to the curve, and the lower inflection point *(LIP)* and the upper inflection point *(UIP)* are identified. Positive end-expiratory pressure is adjusted to approximately 2 cm H_2O above the *LIP*.

Positive End-Expiratory Pressure and Lung Recruitment Maneuvers

Various lung recruitment maneuvers have been suggested for improving $\dot{V}/\dot{Q}$ and reducing shunting in patients with ARDS. These maneuvers include several variations that incorporate CPAP[25,52,53] or the use of PCV with high PEEP levels.[54,55] Regardless of approach, before any lung recruitment maneuver is performed, the patient must be hemodynamically stable and sedated to apnea. Neuromuscular paralysis is unnecessary, but the patient must be accepting of passive ventilation at high pressures. Hemodynamic stability is crucial because of the high intrathoracic pressures established during all recruitment maneuvers, although few studies are available that indicate that pressure control recruitment maneuvers are better tolerated than CPAP recruitment

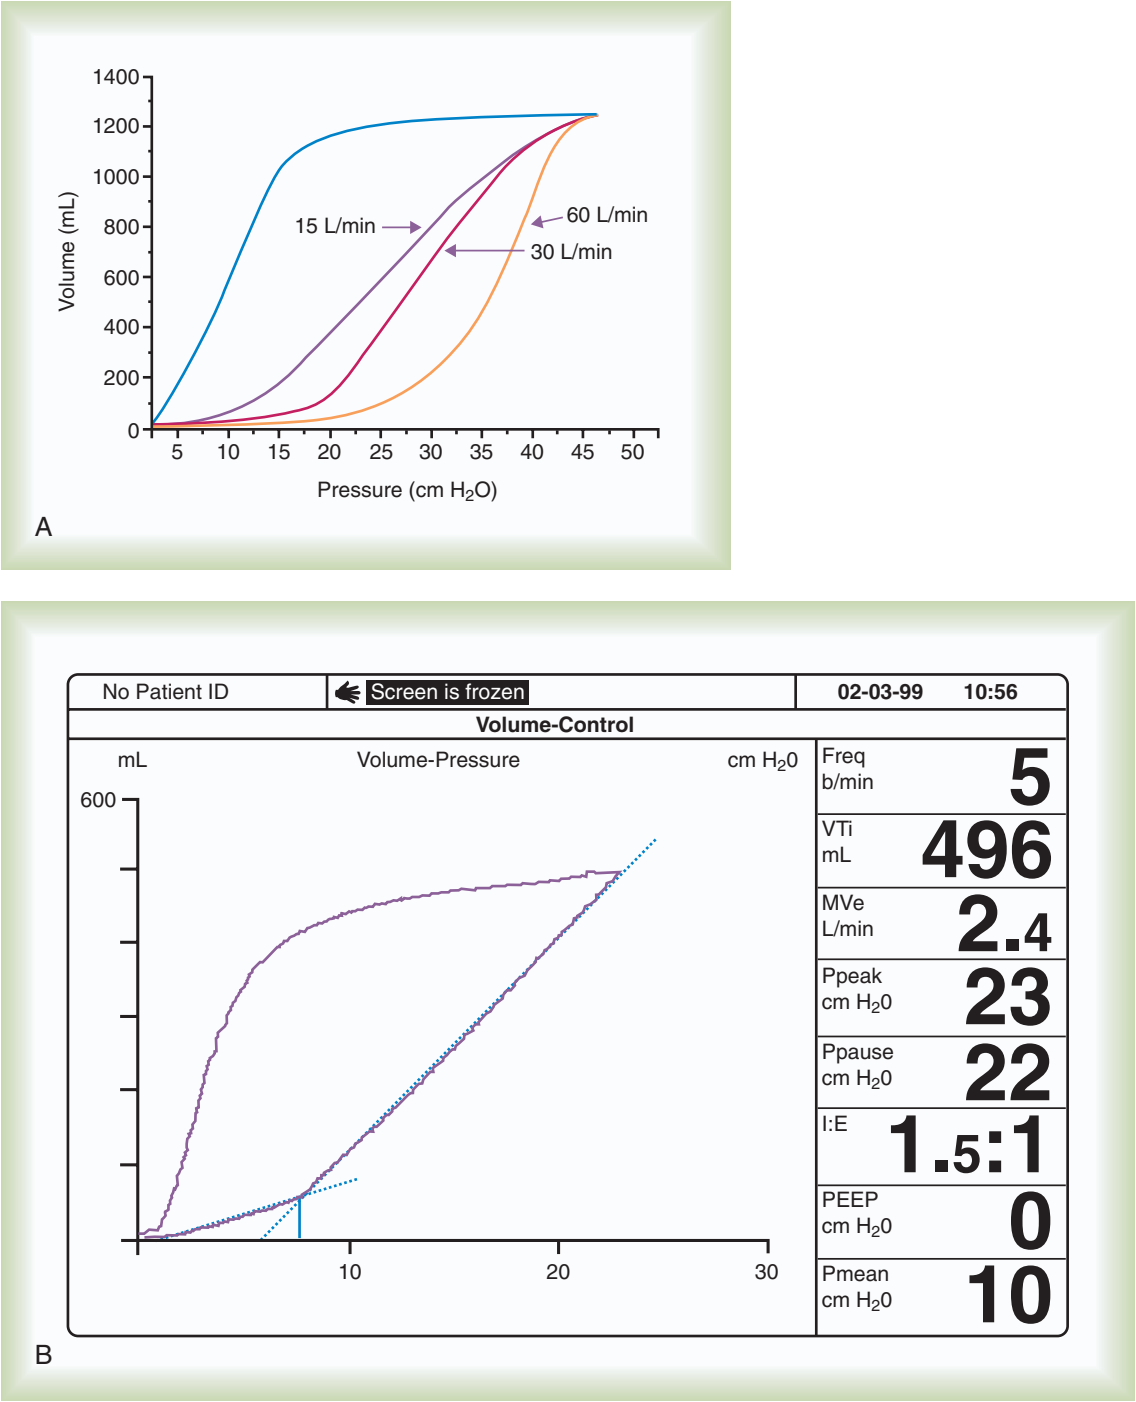

Fig. 49.8 (A) Pressure-volume curves generated by a ventilator graphics package with the flow set at 60 L/min, 30 L/min, and 15 L/min. As flow is decreased, the curve shifts to the left and more closely approximates a static pressure-volume curve. Flow of less than 6 L/min is recommended for identifying the lower inflection point (LIP) from a slow-flow pressure-volume curve. (B) Slow-flow pressure-volume curve with use of a set rate of 5 breaths/min, inspiratory-to-expiratory *(I:E)* ratio of 1.5:1, and V_T of 500 mL. LIP is approximately 8 cm H_2O. The respiratory cycle time is 12 s (cycle time = 60/f = 60/5 = 12 s). An I:E ratio of 1.5:1 results in an inspiratory time of 4.8 s. Inspiratory flow is V_T/T_i = 0.5 L/4.8 s = 0.104 L/s, or approximately 6 L/min. *PEEP*, Positive end-expiratory pressure.

maneuvers.[56,57] The original recruitment techniques applied 40 to 45 cm H_2O CPAP for 30 to 40 seconds.[25,53,58] For recruitment maneuvers to be successful, they should be performed as early as possible after the patient is stabilized on the ventilator.[53,55,58] The longer the length of mechanical ventilation before the recruitment maneuver, the greater the likelihood that the maneuver will fail. See Box 49.13 for details on the performance of lung recruitment maneuvers and decremental PEEP trials.

The most widely accepted approach to recruiting the lung is the use of PCV. With this approach, PEEP is set higher than

BOX 49.13 Performing a Lung Recruitment Maneuver and Decremental Positive End-Expiratory Pressure Trial

- General approach: PCV
- Pressure control setting: 10–15 cm H_2O
  Final PIP 40–50 cm H_2O
- Inspiratory time: 2 s
- Rate: 15–20/min
  Increase PEEP from team set level 3–5 cm H_2O every 3–5 breaths dependent on patient tolerance until PIP is reached
  Maintain at PIP 1 min then preform decremental PEEP trial
  Decremental PEEP trial
- Mode: Volume control
- PEEP: 20–25 cm H_2O
- V_T: 4–6 mL/kg IBW
- Rate: Highest rate avoiding auto-PEEP
- Ventilate until dynamic compliance stabilizes 30–45 s
- Record compliance
- Decrease PEEP by 2 cm H_2O
- Ventilate until dynamic compliance stabilizes 30–45 s
- Decrease PEEP by 2 cm H_2O
- Ventilate until dynamic compliance stabilizes 30–45 s
- Continue this until a PEEP level that results in the best compliance is identified
- Repeat the recruitment maneuver (doing a decremental PEEP trial results in derecruitment)
- Set PEEP at best compliance PEEP plus 2 cm H_2O

Before performing a recruitment maneuver, ensure that the patient is hemodynamically stable and sedated to apnea.

IBW, Ideal body weight; *PCV,* pressure-controlled ventilation; *PEEP,* positive end-expiratory pressure; *PIP,* peak inspiratory pressure.

levels required to maintain the recruited lung open, usually between 20 and 25 cm H_2O; a pressure-control level 15 cm H_2O above this is then set. Ventilation is provided with an I:E of 1:1 to 1:2 at a rate of 10 to 15 /min. All recruitment maneuvers are performed with 100% O_2. If this initial approach to lung recruitment does not open the lung, PEEP can be set higher in increments of 5 cm H_2O, and the recruitment repeated after the patient has totally stabilized from the previous maneuver (>30 minutes). The maximum safe peak pressure during a recruitment maneuver is 50 cm H_2O. Peak pressures greater than 50 cm H_2O increase the likelihood of barotraumas during the maneuver.[55,58]

The best method of establishing optimal PEEP after recruitment is a decremental PEEP trial.[53-55,59] It is best to perform the trial in volume ventilation because the easiest bedside method of identifying the optimal PEEP is to determine the best compliance PEEP. The best oxygenation PEEP can also be determined. It takes only approximately 30 to 45 seconds for the compliance to stabilize when PEEP is changed, but at least 20 minutes is required for PaO_2 to stabilize after a PEEP adjustment.

To perform the trial, PEEP should begin at 20 to 25 cm H_2O but always at PEEP higher than expected necessary to maintain the lung open. V_T during the decremental PEEP trial is usually set at 4 to 6 mL/kg IBW depending on P_{plat}. Inspiratory time is set at 0.6 to 0.8 second, and rate is at a level that does not result in auto-PEEP. First, the compliance is recorded at these settings after stabilization. Then, the PEEP is decreased 2 cm H_2O, and the compliance is again allowed to stabilize. The process is continued until the best compliance PEEP can be identified. Generally, compliance is low at the starting PEEP (20 to 25 cm H_2O) because of overdistention. As PEEP is decreased, compliance improves until it peaks and then starts to decrease because of derecruitment and atelectasis.[54] The best compliance PEEP is increased by 2 cm H_2O because the best compliance PEEP generally underestimates the best oxygenation PEEP by 2 cm H_2O.[54] After identifying the optimal PEEP level, the lung must be recruited again because derecruitment occurred during the decremental PEEP trial. After this second recruitment, PEEP is set at the optimal level determined during the decremental trial.

A recruitment maneuver should be stopped if there is a decrease in SpO_2 to less than 85%, a significant change in heart rate (>140 beats/min or <60 beats/min), a significant change in mean arterial blood pressure (<60 mm Hg or a decrease >20 mm Hg from baseline), the development of cardiac arrhythmia, or any indication that barotraumas occurred.[53] More recent meta-analyses indicate that the use of high PEEP benefits patients with moderate to severe ARDS but does not benefit patients with mild ARDS.[42,43]

Esophageal manometry. The best method of setting PEEP is ensuring that the PEEP level set results in a positive transpulmonary pressure.[60,61] Normally, the pleural pressure is negative, but in ARDS or when atelectasis is present, the pleural pressure can become markedly positive, resulting in a highly negative transpulmonary pressure unless appropriate PEEP is applied. The transpulmonary pressure that will prevent end-expiratory collapse of lung unit is approximately +2 cm H_2O.[60,61] With this approach, PEEP is best set after a lung recruitment maneuver at a level resulting in a positive end-expiratory transpulmonary pressure. PEEP set at a positive end-expiratory transpulmonary pressure of 2 cm H_2O following a recruitment maneuver is equal to the best compliance PEEP following a recruitment maneuver.

RULE OF THUMB For recruitment maneuvers to be successful, they should be performed as early as possible after the patient is stabilized on the ventilator.

Electrical impedance tomography. As discussed in detail in Chapter 52, electrical impedance tomography (EIT) is a noninvasive, radiation-free bedside approach to obtain qualitative images of the chest during ventilation.[62] Specifically, EIT can determine the percentage of lung that is collapsed and the percentage of lung that is over distended. When EIT is used during a recruitment maneuver followed by a decremental PEEP trial, it can identify the PEEP resulting in the least collapse and the least overdistension.[63] Recent research indicates that the most appropriate PEEP determined by EIT, esophageal manometry, and best compliance are all equal![63] In addition, it has been clearly established that the same PEEP level without lung recruitment results in a greater amount of collapse and overdistention than the same PEEP level following a recruitment maneuver.[63]

Positive End-Expiratory Pressure Tables

The ARDS Clinical Network study used an FiO_2-PEEP table to adjust PEEP levels.[2] Using this approach, PEEP and FiO_2 are

alternately adjusted to obtain PaO_2 of 60 to 80 mm Hg or SpO_2 90% or greater (see Box 49.7). The table offers higher and lower PEEP options. For the lower PEEP option, PEEP is set at 5 to 10 cm H_2O with FiO_2 of 0.30 to 0.70; the higher PEEP option sets PEEP at 12 to 20 cm H_2O in the same FiO_2 range. The higher PEEP option should be reserved for patients who may benefit from higher PEEP in terms of lung recruitment and who have a stable blood pressure and no barotrauma. Of all the approaches to setting PEEP, this is the approach least based on the physiology of the patient. It is a reasonable approach to establish initial PEEP, but it is generally a poor choice for further adjustment of PEEP.

Other Techniques for Improving Oxygenation

The primary techniques for optimizing oxygenation in patients receiving mechanical ventilatory support are adjusting FiO_2 and PEEP. Other techniques that may be helpful in improving arterial O_2 levels include optimizing the patient's hemodynamic status, providing good bronchial hygiene, prone positioning, pulmonary vasodilators such as Nitric Oxide and Epropostenol and extracorporeal membrane oxygenation (ECMO). Some clinicians have also used techniques to prolong inspiratory time and reverse the I:E ratio; however, approaches focused on increasing inspiratory time have not been shown to be better than properly set PEEP and are associated with marked hemodynamic compromise and poorer outcomes.[64]

Bronchial Hygiene

In many patients, turning, sitting up, and getting out of bed into a chair can be helpful in improving oxygenation. Upright positioning (30 to 45 degrees) seems to be beneficial for ventilated patients, and supine positioning may increase the risk of pneumonia, especially in patients receiving enteral feeding or with a decreased level of consciousness.[65] Elevation of the head of the bed greater than 30 degrees has been recommended in all ventilated patients to reduce the incidence of ventilator-associated pneumonia. Special rotational beds can be used to optimize PaO_2 in selected patients. Postural drainage, adequate humidification, and bronchodilator therapy may all improve oxygenation and should be considered in the care of ventilated patients when not specifically contraindicated.

Prone Positioning

Prone positioning may be an effective technique for improving oxygenation in some patients with ARDS.[66-69] Prone positioning may improve PaO_2, decrease shunt fraction, and reduce mortality in patients with severe ARDS when it is initiated early and applied for most of the day (a minimum of 12 hours).[70] Although improvement in PaO_2 may be dramatic and sustained (up to 12 hours), not all patients benefit from prone positioning. The procedure is not without risk. Care must be taken to ensure that endotracheal tubes, intravenous lines, and catheters are not blocked or dislodged. The patient may also have skin breakdown at specific pressure points (face, sternum, hips, knees), and facial or eyelid edema may occur, although the latter is primarily a cosmetic concern that resolves quickly when the patient returns to a supine or sitting position.[71] The most serious complication is corneal abrasion necessitating corneal transplantation.[71,72] Prone positioning is labor-intensive, often requiring two nurses, an RT, and a physician to "flip" the patient. If patients have to be turned in to the supine position because of an emergency (cardiac arrest), it is very difficult, frequently resulting in an unfortunate situation. Numerous early randomized controlled trials have evaluated the impact of prone positioning on survival in ARDS[66-69]; however, none of the trials have shown improved outcome. A more recent meta-analysis indicated improved survival in patients with the most severe lung injury—patients with a PaO_2/FiO_2 ratio less than 100 mm Hg.[70] A recent randomized control trial verified the meta-analysis finding.[73] As a result, prone positioning should be reserved for severe ARDS (PaO_2/FiO_2 < 100 mm Hg) and after lung recruitment and appropriate PEEP titration has been performed. Similar to all lung protective approaches to ventilatory support, prone positioning should be used early in the course of ARDS if it is to be beneficial.

The mechanism of action of prone positioning is unclear. In ARDS, dorsal lung injury tends to increase shunt and decrease $\dot{V}/\dot{Q}$, resulting in hypoxemia. Supine positioning tends to increase regional pressure in the dependent, or dorsal portions of the

MINI CLINI

Use of Positive End-Expiratory Pressure

Problem

A 30-year-old, 80 kg (IBW) man is in the critical care unit because of blunt trauma to the chest after a motor vehicle accident. The patient's initial mechanical ventilatory support settings are as follows:

Mode: = A/C pressure ventilation, V_T: 500 mL (6 mL/kg IBW)
Rate: 20 breaths/min
FiO_2: 0.70
PA/C level: 30 cm H_2O
P_{plat}: 25 cm H_2O
PEEP: 0

Arterial blood gas analysis yielded the following results:

pH: 7.38
PaO_2: 48 mm Hg
$PaCO_2$: 36 mm Hg
SaO_2: 81%

The RT considers a recommendation that PEEP be instituted. What are the goals of this type of therapy, and what are some of the potential adverse effects of PEEP that the RT should be aware of?

Solution

The general goals of PEEP are to stabilize and maintain open alveolar units to achieve adequate oxygenation and to avoid potentially unsafe levels of FiO_2 and inflation pressure. Improvement is most commonly assessed with PaO_2 or SpO_2, compliance and measurement of blood pressure and cardiac output.

At least 5 cm H_2O PEEP should be used in all acutely ventilated patients unless the patient is too hemodynamically unstable to tolerate the use of PEEP. When PaO_2 does not respond to a high FiO_2, the condition is referred to as *refractory hypoxemia*. An appropriate initial PEEP for this patient would be 10 cm H_2O because of the patient PaO_2/FiO_2 ratio of 69, classified as severe ARDS. Arterial blood gases, P_{plat}, and blood pressure should be assessed immediately after PEEP adjustment. As the level of PEEP is increased, the RT must be alert for signs of decreased cardiac output. Measurement of effective compliance and P_{plat} is also indicated. In all cases, the lowest PEEP level that provides acceptable oxygenation should be selected.

BOX 49.14 Prone Positioning

Preparation for prone positioning includes the following:
- Adequate sedation of patient
- Clear assignment of responsibilities between team members
- Moving the patient to one side of the bed
- Checking all lines for length
- Checking the security of the endotracheal tube
- Endotracheal suctioning
- Preoxygenation with 100% O_2
- Checking all vital signs

The turn includes:
- Tipping the patient to the side
- Securing electrocardiogram leads
- Turning the patient prone
- Turning the patient's head toward the ventilator

Care after the turn includes:
- Checking artificial airway
- Checking all lines
- Checking ventilator pressure and volume
- Monitoring vital signs
- Repositioning and recalibrating pressure transducers
- The patient needs support (pillows) for each side of the chest and forehead so that the endotracheal tube and head are not compromised.

lungs. Prone positioning may improve $\dot{V}/\dot{Q}$ and reduce shunting by removing the pressure of the heart on the dorsal regions, causing regional dorsal traction, which may promote lung opening. The recommended technique for prone positioning is outlined in Box 49.14.

VENTILATION

Alveolar ventilation is determined by respiratory rate, V_T, and dead space and is described by the following equation:

$$\dot{V}_A = (V_T - V_{Dphys})f$$

where $\dot{V}_A$ is alveolar ventilation, V_T is tidal volume, V_{Dphys} is physiologic dead space, and f is respiratory frequency or rate. The relationship between arterial $PaCO_2$, alveolar ventilation ($\dot{V}_A$), and CO_2 production ($\dot{V}CO_2$) is described as follows:

$$PaCO_2 = (0.863)(\dot{V}CO_2)/\dot{V}_A$$

Arterial $PaCO_2$ is considered the best index of effective ventilation. Increases in $\dot{V}_A$ or decreases in $\dot{V}CO_2$ result in a decrease in $PaCO_2$, whereas increases in $\dot{V}CO_2$ or decreases in $\dot{V}_A$ result in an increase in $PaCO_2$. If there is no change in $\dot{V}CO_2$, the following relationships can be used to estimate the effect of changes in $\dot{V}_A$ on $PaCO_2$:

$$\underset{\text{Initial}}{PaCO_{2(1)} \times \dot{V}_{A(1)}} = \underset{\text{Desired}}{PaCO_{2(2)} \times \dot{V}_{A(2)}}$$

The foregoing predictive equation can be used during mechanical ventilation with the following modifications:

$$PaCO_{2(1)}(V_{T(1)} - V_{Dphys(1)})f_{(1)} = PaCO_{2(2)}(V_{T(2)} - V_{DSphys(2)})f_{(2)}$$

For changes in rate alone, if there is no change in $\dot{V}CO_2$ or V_{Dphys}, this becomes:

BOX 49.15 Example of the Effect of Change in $\dot{V}_A$ on $PaCO_2$

If a patient has an initial $PaCO_2$ of 50 mm Hg with a corresponding alveolar ventilation ($\dot{V}_A$) of 4 L/min, what level of alveolar ventilation is required to decrease the $PaCO_2$ to 40 mm Hg (if there is no change in $\dot{V}_ACO_2$)?

If the patient's $\dot{V}_A$ is increased from 4–5 L/min, the $PaCO_2$ should decrease from 50–40 mm Hg.

$$\underset{\text{Initial}}{PaCO_{2(1)} \times f_{(1)}} = \underset{\text{Desired}}{PaCO_{2(2)} \times f_{(2)}}$$

For changes in V_T alone, this becomes:

$$\underset{\text{Initial}}{PaCO_{2(1)} \times V_{T(1)}} = \underset{\text{Desired}}{PaCO_{2(2)} \times V_{T(2)}}$$

A major goal of mechanical ventilation is optimization of the patient's ventilation and $PaCO_2$; however, this does not mean normalization of $PaCO_2$. Acceptable arterial pH and alveolar PCO_2 are assessed by P_{plat}. For many patients, the level of ventilatory support is adjusted to achieve a $PaCO_2$ of 35 to 45 mm Hg with a pH of 7.35 to 7.45. In the care of patients with acute exacerbation of COPD and accompanying chronic ventilatory failure, the clinician may target ventilatory support to achieve the patient's "normal" $PaCO_2$ and pH. For patients with COPD and chronic hypercapnia, the target $PaCO_2$ may be 50 to 60 mm Hg with a pH of 7.30 to 7.35. In patients with severe ARDS, a $PaCO_2$ of 70 mm Hg with an acidic pH may have to be accepted to protect the lung from ventilator-induced lung injury. The sicker the patient, the more likely the clinician is to accept oxygenation and acid–base values that greatly deviate from normal. Regardless of the patient's condition, optimizing pH is more important than targeting a specific $PaCO_2$ value.[1,9] Box 49.15 presents an example of the effect of change in $\dot{V}_A$ on $PaCO_2$.

Adjusting Tidal Volume and Rate

V_T and rate may be adjusted for a desired level of ventilation as assessed by $PaCO_2$. V_T is usually based on specific patient considerations but, ideally, should never result in P_{plat} greater than 28 cm H_2O. Respiratory rate is adjusted to achieve the desired $PaCO_2$. Normal resting V_T of healthy individuals is 6.3 mL/kg IBW. In most critically ill patients, V_T should be in the range of 4 to 8 mL/kg IBW. In patients with improving respiratory function ready for extubation, V_T of 9 to 10 mL/kg IBW may be acceptable; however, V_T greater than 10 mL/kg IBW should never be selected for a critically ill patient.

Apnea (Controlled Ventilation)

In an apneic patient, precise control of $PaCO_2$ can usually be achieved with pressure or volume ventilation because the ventilator rate and V_T are determined directly or indirectly by the clinician.

Rate. In the care of apneic patients, the clinician has complete control over the patient's rate, and changes in ventilator rate can be used precisely to alter $PaCO_2$. For example, if a patient's initial rate was 18 breaths/min and resultant $PaCO_2$ was 50 mm Hg,

the rate change needed to decrease the patient's $PaCO_2$ to 40 mm Hg could be calculated as follows:

$$\begin{array}{cc} \text{Initial} & \text{Desired} \\ PaCO_{2(1)} \times f_{(1)} = & PaCO_{2(2)} \times f_{(2)} \end{array}$$

$$50 \times 18 = 40 \times f_{(2)}$$

$$f_{(2)} = (50 \times 18)/40 = 23 \text{ breaths/min}$$

For this patient, an increase in machine rate from 18 to 23 breaths/min would decrease $PaCO_2$ from 50 to 40 mm Hg. Two warnings must be kept in mind in the use of this predictive equation. First, it is assumed that $\dot{V}CO_2$ is constant. If there is an increase or decrease in $\dot{V}CO_2$, the resultant $PaCO_2$ would be different from the predicted value. Common causes of increased $\dot{V}CO_2$ in the ICU include pain, agitation, anxiety, fever, overfeeding, increased activity, and fighting the ventilator. Decreases in $\dot{V}CO_2$ may be caused by decreased activity, sedation, paralysis, anesthesia, or sleep. Second, the equation is based on the assumption that the patient is apneic. Patients who are triggering the ventilator in the A/C mode determine their own $PaCO_2$ on the basis of the assist rate. Patients in the SIMV mode who are spontaneously breathing may simply increase or decrease their level of spontaneous breathing and make $PaCO_2$ prediction difficult. In addition, the primary factor that limits the selection of rate is the development of auto-PEEP. If auto-PEEP develops, plateau pressure increases in volume ventilation and tidal volume decreases in pressure ventilation.

Tidal volume. Changes in V_T can be used to alter $PaCO_2$. For a patient 80 kg IBW receiving ventilation in the control mode with V_T of 600 mL (7.5 mL/kg) and resultant $PaCO_2$ of 30 mm Hg, the change in V_T to achieve a PaO_2 of 40 mm Hg would be calculated as follows:

$$\begin{array}{cc} \text{Initial} & \text{Desired} \\ PaCO_{2(1)} \times V_{T(1)} = & PaCO_{2(2)} \times V_{T(2)} \end{array}$$

$$30 \times 600 = 40 \times V_{T(2)}$$

$$V_{T(2)} = (30 \times 600)/40 = 450 \text{ ml}$$

For this patient, a decrease in V_T from 600 to 450 mL results in an increase in $PaCO_2$ from 30 to 40 mm Hg. This is directly altered in volume ventilation by changing the tidal volume or indirectly by decreasing the pressure control level in pressure ventilation. Several warnings should be kept in mind for changes in V_T. First, V_T should be within the preferred range for a given patient condition. In the example, new V_T (450 mL) represents 5.6 mL/kg IBW, which is an acceptable value. V_T should be small enough to avoid lung injury and maintain P_{plat} at less than 28 cm H_2O. Second, in this equation, $\dot{V}CO_2$ and V_{Dphys} are assumed to be constant because changes in $\dot{V}CO_2$ or V_{Dphys} affect $PaCO_2$. Activity, agitation, fever, and overfeeding may increase $\dot{V}CO_2$, whereas sedation, paralysis, or sleep may decrease $\dot{V}CO_2$. V_{Dphys} changes with changes in airway pressure, and increases in ventilator V_T may result in increased dead space. Development of pulmonary emboli or hemodynamic instability may abruptly increase V_{Dphys}.

Mechanical dead space. Mechanical dead space is defined as the volume of gas rebreathed as the result of a mechanical device. Large-bore tubing attached between the ventilator circuit "wye" and the patient airway connection serves as mechanical dead space, and 6 inches (15 cm) of large-bore tubing represents a volume of approximately 50 to 70 mL.

For ventilation of tracheostomy patients, 6 inches (15 cm) of mechanical dead space is often used to keep the weight of the "wye" connection and tubing off the tracheostomy tube and to give additional flexibility to the circuit for patient movement. Mechanical dead space is usually not used for endotracheally intubated patients, and the addition of mechanical dead space can serve as a cause for an increase in $PaCO_2$. Mechanical dead space is a primary concern in patients with severe ARDS in whom V_T is 4 to 6 mL/kg IBW and, as a result, $PaCO_2$ is elevated. The simple removal of mechanical dead space in these patients can, in some cases, markedly improve CO_2 elimination. HME filters are another major cause of mechanical dead space. Depending on the brand, up to 80 mL of dead space can be added by these devices.

In healthy persons, the combination of V_{Dphys} and anatomic dead space can be estimated at approximately 1 mL/lb or 2.2 mL/kg IBW. Although healthy persons have a dead space-to-tidal volume (V_D/V_T) ratio of approximately 0.20 to 0.40, a V_D/V_T ratio greater than 0.50 is common among ventilated patients.

Control of $PaCO_2$ in Synchronized Intermittent Mandatory Ventilation Mode

In the SIMV mode, machine breaths are interspersed with spontaneous breathing, and the spontaneous breaths may be PSV. $PaCO_2$ can be decreased by increasing V_T, increasing PSV for spontaneous breaths, or increasing the machine rate. Levels of $PaCO_2$ may be increased by reducing the machine rate, decreasing V_T, or decreasing the level of PSV for spontaneous breaths. As with apneic (control) ventilation, an appropriate V_T should be selected on the basis of the patient's condition and with the goal of keeping P_{plat} less than 28 cm H_2O, with V_T ideally 4 to 8 mL/kg IBW depending on the patient's pulmonary status. PSV level in the SIMV mode should be adjusted to overcome WOB_I; the usual range is 5 to 15 cm H_2O, although higher levels may be needed by patients with high resistance. PSV should be adjusted to ensure that during spontaneous breathing, WOB is not excessive. Accessory muscle use or suprasternal, intercostal, or substernal retractions during spontaneous breathing indicate the need to increase the PSV level. When appropriate V_T and PSV level are selected, the primary method for adjusting $PaCO_2$ is to increase or decrease SIMV rate.

After ventilator initiation, two different approaches may be taken. For full ventilatory support, an initial SIMV rate and V_T are selected to provide 100% of the patient's ventilatory requirements; for most adults, this means starting with V_T of 6 to 8 mL/kg IBW with SIMV rate of 15 to 20 breaths/min. Generally, a minute ventilation of approximately 100 mL/kg IBW is achieved with these initial settings. Arterial blood gas values are obtained 20 to 30 minutes after initiation of mechanical ventilation, and SIMV rate is titrated up or down in increments of 2 breaths/min until desired $PaCO_2$ is achieved. Monitoring is continued,

MINI CLINI

Adjusting $PaCO_2$ During Volume Ventilation

Problem

A 22-year-old man, 5 ft 10 in (178 cm) tall, being treated for a drug overdose is being ventilated with the following settings:
Mode: PA/C
FiO_2: 0.40
V_T: 600 mL
Rate: 15 breaths/min
PA/C level: 15 cm H_2O
P_{plat}: 18 cm H_2O
PEEP: 5 cm H_2O

The patient's lungs are clear to auscultation and there is no evidence of aspiration. Arterial blood gas values obtained 15 min previously were:
PaO_2: 80 mm Hg
$PaCO_2$: 30 mm Hg
SaO_2: 95%
HCO_3: 24 mEq/L
pH: 7.52
Base excess: +2 mEq/L

The physician asks the RT to normalize this patient's oxygenation and ventilatory status. What should the RT do?

Solution

At this time, the patient is making no spontaneous breathing efforts. The patients' oxygenation status is fine and no adjustments are needed. In the absence of spontaneous breathing in the PA/C mode, $PaCO_2$ can be adjusted by changing machine rate (f) or PA/C level. Because the V_T is large (600 mL), the correct adjustment would be to decrease PA/C level to obtain a specific smaller V_T.

For prediction of the needed change in V_T to increase $PaCO_2$ to 40 mm Hg, the following calculation could be performed:

$$\text{Actual} \qquad \text{Desired}$$
$$V_{T(1)} \times PaCO_{2(1)} = V_{T(2)} \times PaCO_{2(2)}$$
$$V_{T(2)}\ \text{Desired} = (V_{T(1)} \times PaCO_{2(1)})/PaCO_{2(2)}$$
$$V_{T(2)}\ \text{Desired} = (600 \times 30)/40 = 458\ \text{ml}$$

If PA/C level is decreased to obtain a V_T 450 mL, $PaCO_2$ and pH should normalize.

BOX 49.16 Partial Ventilatory Support With Synchronized Intermittent Mandatory Ventilation

Mechanical ventilation is initiated in the SIMV mode for a 70 kg, spontaneously breathing 38-year-old man. Before initiation of ventilation, the patient's spontaneous rate was 30 breaths/min with a spontaneous V_T of 200 mL. Initial ventilator settings are:
V_T: 450 mL
SIMV rate: 14 breaths/min
FiO_2: 0.40
PSV: +8 cm H_2O
PIP: 20 cm H_2O
P_{plat}: 24 cm H_2O
PEEP: 8 cm H_2O

Arterial blood gases are obtained in 20 minutes, with the following results:
PaO_2: 88 mm Hg
SaO_2: 97%
pH: 7.38
$PaCO_2$: 40 mm Hg
HCO_3: 24 mEq/L
Base excess: +1 mEq/L

The decision is made to provide partial ventilatory support for this patient, and the SIMV rate is titrated as follows:

Time	V_T (mL)	SIMV Rate	Total Rate	$PaCO_2$ (mm Hg)
9:00 a.m.	450	14	20	40
9:30 a.m.	450	12	15	38
10:00 a.m.	450	10	18	38
10:30 a.m.	450	8	16	46
11:00 a.m.	450	16	20	42

The patient's condition should now be stabilized at a rate of 10 breaths/min with titration of SIMV to the patient's needs with observation and measurement of arterial blood gases. When the rate is decreased to 8 breaths/min, $PaCO_2$ begins to increase. The rate is increased to the previous setting of 10 breaths/min. Titrating the level of SIMV support to the patient's needs is not the same as weaning the patient. After improvement in the patient's condition, weaning may be tried (see Chapter 53) by daily spontaneous breathing trial.

FiO_2, Fractional inspired oxygen; *PEEP,* positive end-expiratory pressure; *PIP,* peak inspiratory pressure; *PSV,* pressure support ventilation; *SIMV,* synchronized intermittent mandatory ventilation.

and adjustments are made by increasing or decreasing SIMV rate to maintain full ventilatory support until the patient's condition improves and ventilator discontinuation is considered.

Partial ventilatory support in the SIMV mode requires a different initial approach. Ventilation begins with V_T and machine rate sufficient to provide full ventilatory support, and arterial blood gases are measured. If $PaCO_2$ is adequate, the patient is immediately challenged with a decrease in SIMV rate of 2 breaths/min. This procedure is followed by patient assessment and measurement of arterial blood gases, as indicated. If the resultant assessment values remain adequate, the patient continues to be challenged with decreases in SIMV rate until $PaCO_2$ increases. At that point, the patient's ventilatory capacity has been exceeded, and SIMV rate is returned to the previous value. Box 49.16 provides an example of titration of the SIMV rate for partial ventilatory support after ventilator initiation in a spontaneously breathing patient.

RULE OF THUMB Mechanical dead space is defined as the volume of gas rebreathed as the result of a mechanical device. Large-bore tubing attached between the ventilator circuit "wye" and the patient airway connection serves as mechanical dead space, and 6 inches (15 cm) of large-bore tubing represents a volume of approximately 50 to 70 mL.

Assist/Control Mode Volume Ventilation and $PaCO_2$

Ventilator initiation in the VA/C mode begins with selection of initial V_T and backup control rate to ensure a safe minimum level of ventilation. In PA/C, a pressure control level sufficient to establish desired V_T is selected along with a backup as in VA/C.

The patient is allowed to trigger the machine as often as desired above this backup rate, and the resultant assist rate is determined by the patient's ventilatory drive. If the respiratory drive is intact, patients tend to trigger the ventilator at an appropriate rate to achieve adequate $PaCO_2$ and pH. By allowing patients to set their own rates, the level of ventilation increases or decreases on the basis of the patient's physiologic needs. Should the patient become apneic owing to sedation or sleep, a minimum backup control rate is provided.

Because the patient determines the level of ventilation, $PaCO_2$ levels are regulated by the patient; however, problems arise when the patient triggers the ventilator at an inappropriately rapid rate. Pain, anxiety, hypoxemia, secretions in the airway, and metabolic acidosis may contribute to an excessive trigger rate and the result can be an inappropriate I:E ratio and an inadequate expiratory time. These abnormal values may increase mean airway pressure, reduce venous return, and result in auto-PEEP and overinflation and associated missed triggering of the ventilator, especially in patients with obstructive disease. Patients may fight the ventilator, resulting in high inspiratory pressure. In the event that a patient receiving ventilation in the A/C mode is triggering the ventilator at an inappropriately high rate, the first step the RT should take is to identify the cause of the increased rate. Patient anxiety may be diminished with simple reassurance and encouragement to relax and "let the machine breathe for you." Hypoxemia should be managed with appropriate O_2 therapy and PEEP, if indicated. Secretions should be removed by suctioning, and bronchial hygiene techniques should be applied. The cause of metabolic acidosis should be identified and managed, if possible.

In some patients, appropriate sedation reduced anxiety and appropriately reduces respiratory rate. Patients who begin fighting the ventilator after a previous period of calm may have a new and potentially life-threatening complication. If a patient begins fighting the ventilator, a careful assessment should be made to identify the problem. Often, careful attention to the ventilator trigger sensitivity, flow rate, volume, and pressure is helpful, and administration of analgesic and sedative agents may be needed.[12] If sedation is required, the use of intermittent sedation with daily interruption using a sedation protocol may reduce the duration of mechanical ventilation.[74,75] A last resort is pharmacologic-controlled ventilation.[12] In the presence of a metabolic acidosis, a sudden change from assisted ventilation at a rapid rate with the associated hyperventilation to controlled ventilation at a slower rate can result in severe acidosis, which can be life-threatening. Other problems with controlled ventilation include patient safety, ventilatory muscle atrophy, and prolonged muscle weakness if paralytic agents are used for a prolonged period.

Pressure Support Ventilation and $PaCO_2$

PSV is normally set at the level needed to establish a normal V_T of 4 to 8 mL/kg IBW. To increase or decrease V_T, the clinician simply increases or decreases the PSV level and observes the resultant V_T on the ventilator exhaled volume monitoring screen. Because PSV is an assist mode, the patient is allowed to trigger the ventilator as desired. The result should be an adequate $PaCO_2$ and pH. In patients with an unstable ventilatory drive or periods of apnea, PSV should be avoided.

Pressure-Controlled Ventilation and $PaCO_2$

Management of ventilation and $PaCO_2$ during PCV is similar to PSV; the only difference between these two modes in a spontaneously breathing patient is the method of breath termination. With PSV, the breath is terminated as a result of the patient's inspiratory flow decreasing to the termination cycling flow, whereas in PA/C, the breath is terminated when the inspiratory time is reached. No other real differences in these modes exist in a spontaneously breathing patient.

To increase or decrease $PaCO_2$ in the PCV mode, the RT can simply increase or decrease the pressure limit while observing the exhaled V_T on the ventilator display monitor until desired V_T is obtained. The most important problem with the use of V_T to adjust $PaCO_2$ in the PCV mode is that the peak pressure should not be increased greater than 28 cm H_2O to avoid ventilator-induced lung injury.

In a patient receiving PCV, a change in the rate affects $PaCO_2$ in the same manner as in **volume-controlled ventilation**. If V_T remains constant, an increase in rate decreases $PaCO_2$ and vice versa; however, in the PCV mode, percent inspiratory time ($\%T_i$) and I:E ratio may be fixed. If $\%T_i$ is constant, and respiratory rate is increased, actual inspiratory time decreases and V_T may also decrease. Decreases in rate ($\%T_i$ and pressure limit constant) may result in an increase in delivered V_T. The following example shows this principle.

A patient receiving ventilation in the PCV mode has a pressure control setting of 15 cm H_2O, PEEP of 5 cm H_2O, $\%T_i$ of 50%, I:E ratio of 1:1, and rate of 20 breaths/min. In this example, respiratory cycle time can be calculated as follows:

$$\text{Respiratory cycle} = 60/f = 60/20 = 3 \text{ seconds}$$

Inspiratory time (T_i) would be:

$$T_i = \%T_i \times \text{Respiratory cycle} = 0.50 \times 3 = 1.5 \text{ seconds}$$

A pressure of 25 cm H_2O applied for 1.5 seconds might achieve V_T of 400 mL for this patient.

If the rate were increased to 30 breaths/min, what would happen to respiratory cycle time, inspiratory time, and delivered V_T? Respiratory cycle and inspiratory time are calculated for a rate of 30 breaths/min as follows:

$$\text{Respiratory cycle} = 60/f = 60/30 = 2 \text{ seconds}$$

$$T_i = \%T_i \times \text{Respiratory cycle} = 0.50 \times 2 = 1 \text{ second}$$

At a constant pressure control setting of 15 cm H_2O, a decrease in inspiratory time from 1.5 seconds to 1 second may reduce delivered V_T. An increase in respiratory rate may reduce delivered V_T and increase (rather than decrease) $PaCO_2$.

When using PCV, the RT should observe the effect of inspiratory time and pressure limit on the patient's flow and volume curves as displayed by a ventilator graphics monitoring package. Generally, as inspiratory time increases at a given pressure, volume also increases until an inspiratory plateau or hold is reached. This point can be identified by observing the inspiratory flow curve. If the inspiratory flow curve decreases to zero and holds that value for a time before exhalation begins, an inspiratory plateau is present (Fig. 49.9). Further increases in inspiratory

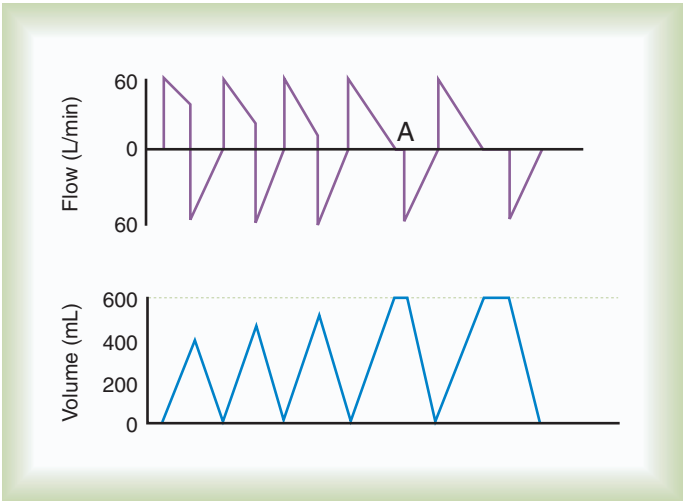

Fig. 49.9 Effect of inspiratory time and inspiratory plateau on delivered V_T in the PCV mode. Initially, as inspiratory time is increased, V_T increases. When an inspiratory plateau *(A)* is achieved, a further increase in inspiratory time does not result in increased V_T. The same effect occurs as inspiratory time is decreased. Initially, with small decreases in inspiratory time, there would be no change in V_T as long as an end inspiratory plateau was maintained. When the inspiratory time is less than that needed for an inspiratory plateau, further decreases in inspiratory time result in a decrease in V_T at the same pressure.

time do not result in additional V_T. Conversely, if an inspiratory plateau or hold is present, a decrease in inspiratory time does not decrease V_T (at the same pressure limit) until the inspiratory plateau is no longer present (see Fig. 49.9). Table 49.9 summarizes methods of altering $PaCO_2$ during volume-controlled ventilation (VCV) and PCV.

TABLE 49.9 Changing Ventilation and $PaCO_2$

Mode		
Increase	**Ventilation (↓ $PaCO_2$)**	**Decrease Ventilation (↑ $PaCO_2$)**
Volume-Controlled Ventilation		
VC-CMV control	↑ V_T; ↑ f; remove V_{Dmach}	↓ V_T; ↓ f
VC-CMV assist control	↑ V_T; ↑ f (to greater than assist rate); remove V_{Dmach}	↓ V_T; ↓ f (may require sedation, control mode)
SIMV	↑ V_T; ↑ f; add/increase PSV; remove V_{Dmach}	↓ V_T; ↓ f; reduce PSV (may require sedation)
Pressure-Controlled Ventilation		
PCV[a]	↑ ΔP; ↑ f (maintaining same T_i); remove V_{Dmatch}	↓ ΔP; ↓ f (maintaining same T_i)
PSV	↑ ΔP; remove V_{Dmatch}	↓ ΔP
Bilevel PAP	↑ IPAP (↑ ΔP); remove V_{Dmatch}	↓ IPAP (↓ ΔP)
APRV	↑ ΔP ↑ release frequency	↓ ΔP ↓ release frequency

Note: In assist (patient-triggered) mode, the patient may simply alter the trigger rate after a ventilator change, and it becomes difficult to predict the results of a ventilator change on $PaCO_2$ in the assist mode.

[a]In PCV, if $\%T_i$ is preset, an increase in respiratory rate results in a decrease in inspiratory time and may reduce V_T. If $\%T_i$ is set at 50% in PCV mode, an increase in rate from 15 to 20 breaths/min causes inspiratory time to decrease from 2 s (50% of 4 s) to 1.5 s (50% of 3 s). If the pressure limit is not changed, V_T is likely to decrease.

$PaCO_2$ When Using Lung Protective Strategies for Acute Lung Injury and Acute Respiratory Distress Syndrome

Ventilation strategies for lung protection include low V_T, rapid respiratory rates, and permissive hypercapnia, if necessary, to avoid overdistention ($P_{plat} > 28$ cm H_2O).

Open Lung Approach

The use of a high PEEP, low V_T lung-protective strategy using V_T of 4 to 8 mL/kg and PEEP set after a lung recruitment maneuver and decremental PEEP, as discussed previously, may improve mortality in patients with persistent ARDS.[24,25] Because V_T is reduced, respiratory rate should be increased incrementally up to 35 to 40 breaths/min. The limitation on rate is the development of auto-PEEP; if auto-PEEP does not develop, the rate can be increased. The primary concern in patients with severe ARDS is acidosis; however, most patients without severe sepsis, cardiovascular dysfunction, or renal failure can tolerate severe acidosis. The ARDS Clinical Network defined the limit for acidosis as pH less than 7.15.[2] $PaCO_2$, although important, should be allowed to increase before accepting V_T that results in P_{plat} greater than 28 mm Hg. The need to allow $PaCO_2$ to increase to avoid inducing lung injury is referred to as *permissive hypercapnia*; however, the goal is not to allow the $PaCO_2$ to increase but to avoid P_{plat} that may induce lung injury. With this approach in severe ARDS, V_T is frequently 4 to 5 mL/kg IBW, and $PaCO_2$ is greater than 60 mm Hg. Table 49.10 compares the effect of acute changes in $PaCO_2$ on pH.

When applying this approach, PEEP is set after it is determined by a lung recruitment maneuver and a decremental PEEP trial, Table 49.11. V_T or pressure level is adjusted, ensuring that P_{plat} or pressure control setting is less than 28 cm H_2O. Because V_T is small, inspiratory times can be short (frequently 0.6 to 0.8 second). The respiratory rate is set to achieve CO_2 elimination, with its limit being the development of auto-PEEP. Initially, FiO_2 is set to 1.0 but then titrated downward until PaO_2 is greater than 55 mm Hg. Generally, PEEP is sustained at the set level until FiO_2 is less than 0.5, and when PEEP is decreased it should be decreased in increments of 2 cm H_2O no more frequently than approximately every 6 to 8 hours. If PaO_2 decreases when PEEP is decreased, the correct decision is to reestablish PEEP level, *not* increase FiO_2, because if this occurs, the lung is derecruited and lung volume needs to be reestablished.

When to repeat a recruitment maneuver is a difficult question to answer, and data are insufficient at this time to provide an answer; however, if the PaO_2 does not decrease after the initial lung recruitment maneuver, there is no reason to perform an additional recruitment maneuver. Suctioning may cause derecruitment and hypoxemia, and ventilator disconnection always results in derecruitment. If either of these situations occurs, the

MINI CLINI

Adjusting Ventilation in PA/C Mode

Problem

A 70 kg (IBW) patient with ARDS is receiving PCV in the control mode with the following ventilator settings:
Pressure: 15 cm H_2O
Rate: 25 breaths/min
Inspiratory time: 0.8
FiO_2: 0.60
PEEP: 12 cm H_2O
V_T (exhaled): 425 mL

Arterial blood gas values with these ventilator settings are as follows:
PaO_2: 60 mm Hg
SaO_2: 90%
pH: 7.30
$PaCO_2$: 50 mm Hg
HCO_3: 23 mEq/L
Base excess: –2 mEq/L

The physician requests that the respiratory rate be increased to 18 breaths/min to decrease the patient's $PaCO_2$ to 40 mm Hg and normalize the pH. What should the RT do?

Solution

This patient has a PaO_2/FiO_2 ratio of 100 (60/0.60), which is consistent with the diagnosis of ARDS. Special considerations for the ventilatory management of ARDS include maintaining P_{plat} less than 28 cm H_2O. V_T is started at 8 mL/kg IBW and gradually reduced to 6 mL/kg IBW to achieve this goal and minimize ventilator-induced lung injury. Respiratory rate may be increased to maintain $PaCO_2$ and pH closer to normal, as long as volume and P_{plat} are acceptable. $PaCO_2$ may be allowed to increase if necessary to maintain P_{plat} less than 28 cm H_2O as long as pH is acceptable for the patient (usually >7.25). Oxygenation problems are managed initially with PEEP to achieve PaO_2 of 60 mm Hg or more with an acceptable FiO_2. If PEEP fails to improve PaO_2, lung recruitment maneuvers and prone positioning may be used.

For this patient, the V_T is acceptable at approximately 6 mL/kg (70 kg × 6 mL/kg = 420 mL), and P_{plat} is 27 cm H_2O. $PaCO_2$ (50 mm Hg) and pH (7.30) are acceptable, and PEEP of 12 cm H_2O may be appropriate for a patient with ARDS. To decrease $PaCO_2$, the rate could be increased as follows:

$$\text{Initial} \qquad \text{Desired}$$
$$f_{(1)} \times PaCO_{2(1)} = f_{(2)} \times PaCO_2$$
$$25 \times 50 = f_{(2)} \times 40$$
$$f_{(2)}\ \text{Desired} = (25 \times 50/40) = 31.25$$

If V_T is maintained at 425 mL, a rate of 30–32 breaths/min should bring $PaCO_2$ and pH into normal range; however, if respiratory rate is increased, air trapping and auto-PEEP may develop. If auto-PEEP develops, V_T is likely to decrease. In pressure ventilation, an auto-PEEP increase is equal to an equivalent decrease in pressure control level, decreasing V_T. The rate should be increased cautiously, constantly evaluating the impact of the rate increase on V_T. More importantly, there is no reason to try to normalize $PaCO_2$ in this patient. $PaCO_2$ of 50 mm Hg with pH of 7.30 is acceptable.

lung needs to be recruited again, but PEEP is reestablished at the previous PEEP level because the hypoxemia was *not* a result of deterioration in lung function. A recruitment maneuver and decremental PEEP trial should be repeated only if the patient's lung function deteriorates.

TABLE 49.10 Effect of Acute Changes in $PaCO_2$ on pH

$PaCO_2$	pH
80	7.16
70	7.22
60	7.28
50	7.34
40	7.40
35	7.45
30	7.50
25	7.55
20	7.60

From Malley WJ: *Clinical blood gases: assessment and intervention*, ed 2, Philadelphia, 2005, Saunders.

In all patients with severe ARDS, mechanical dead space should be eliminated, in-line suction catheters should be in place, and airway suctioning should be performed only to the level of the main stem bronchus. In addition, ideally the ventilator circuit should not be disconnected.

Other Lung Protective Strategies

Alternative techniques for facilitating CO_2 removal during lung protective ventilation in patients with ARDS include extracorporeal CO_2 removal (ECMO, see Chapter 51), reduction of CO_2 production by control of fever, avoidance of overfeeding, and neuromuscular paralysis. Patients with severe ARDS (PaO_2 < 150 mm Hg) should receive neuromuscular paralysis for the first 12 to 48 hours to allow for stabilization and titration of therapy. This has been shown to improve mortality in these patients.[48] Other authors have advocated the use of HFOV;[76–78] however, recent data in adults indicate that the use of HFOV in ARDS patients results in poorer outcome than the continued use of conventional ventilation.[21,22] As a result, HFOV cannot be recommended in the management of ARDS.

SUMMARY CHECKLIST

- P_{plat} should ideally be maintained at less than 28 cm H_2O in all patients to prevent ventilator-induced lung injury.
- Driving pressure should be maintained at less than 15 cm H_2O in all patients to prevent ventilator-induced lung injury and improve mortality.
- PEEP is used primarily to maintain lung volume, resulting in improved oxygenation and lower FiO_2 in patients with severe oxygenation problems and refractory hypoxemia.
- Initially, all acutely ill patients should be ventilated with V_T of 4 to 8 mL/kg IBW with a respiratory rate to maintain adequate CO_2 removal.
- Patients with ARDS may begin mechanical ventilation with V_T of 8 mL/kg but may need volume adjusted to less than 6 mL/kg IBW to maintain P_{plat} less than 28 cm H_2O.
- Lung protective strategies in the management of ARDS include use of lower V_T (6 mL/kg), maintaining P_{plat} less than 28 cm H_2O, permissive hypercapnia, and PEEP set above the lower inflection point on the static pressure-volume curve.

TABLE 49.11 Example of a Decremental Positive End-Expiratory Pressure Study Following a Lung Recruitment Maneuver[a]

Value	PEEP = 20	PEEP = 18	PEEP = 16	PEEP = 14	PEEP = 12

P_{peak} (cm H_2O)	36	34	32	30	34
P_{plat} (cm H_2O)	28	26	24	22	26
Cs (mL/cm H_2O)	24	27	32	34	28
SaO_2 (%)	96	97	98	100	98
Blood pressure (mm Hg)	131/78	133/82	130/79	125/74	110/69

[a]The best compliance PEEP is 14 cm H_2O. Because the process of doing a decremental PEEP trial results in derecruitment, the lung must be recruited again and then PEEP is set at the best compliance PEEP plus 2 cm H_2O.
FiO_2, fractional inspired oxygen; *I:E,* inspiratory-to-expiratory; *PEEP,* Positive end-expiratory pressure.

- FiO_2 should be adjusted in all patients who are mechanically ventilated to maintain PaO_2 55 to 80 mm Hg and SpO_2 88% to 95%.
- An open lung approach to mechanical ventilation includes the application of lung recruitment maneuvers, decremental PEEP trial, choosing V_T that maintains P_{plat} less than 28 cm H_2O, and accepting permissive hypercapnia.
- Inspiratory flow for most adult patients should initially be set at approximately 60 L/min or greater to achieve an inspiratory time of approximately 0.6 to 1 second.
- Patient ventilator synchrony is a major problem in patients during patient-triggered ventilation.
- In all modes of pressure ventilation, the pressure level should be set to ensure that V_T of 4 to 8 mL/kg IBW is delivered.
- When in doubt, initial FiO_2 should be set at 1.0.
- Auto-PEEP is a problem in patients with obstructive lung disease (COPD, asthma).
- In spontaneously breathing patients with COPD and auto-PEEP, applied PEEP should be added to ensure that all patient efforts result in triggering of the ventilator.
- An appropriate goal of PEEP would be to achieve PaO_2 55 to 80 mm Hg with FiO_2 less than 0.50.
- Alternative lung protective strategies in patients with ARDS include prone positioning and ECMO.
- Careful attention to acid–base homeostasis and the effect of $PaCO_2$ on pH is an essential part of ventilator management.

Noninvasive Ventilation

Purris F. Williams

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- List the goals and benefits of noninvasive ventilation (NIV).
- Discuss indications for NIV and the relative strength of the supporting evidence for each indication.
- List the selection and exclusion criteria for successful NIV.
- List the factors that predict successful NIV.
- Describe how to recognize NIV failure and discuss when and why this is important.
- Identify the types of patient interfaces available for NIV and describe how to choose an appropriate interface for a patient.
- List common interface-related adverse effects and discuss how to avoid them.
- Discuss the types of mechanical ventilators and ventilation modes used to provide NIV.
- Discuss the causes and resolution of patient–ventilator asynchrony in NIV.
- Describe the role of the respiratory therapist during the initial application of NIV.
- Describe the ongoing ventilator management of NIV in the acute care setting.
- List potential complications associated with NIV and possible solutions.

CHAPTER OUTLINE

KEY TERMS

chest cuirass
continuous positive airway pressure (CPAP)
erythema
expiratory positive airway pressure (EPAP)
hypercapnic respiratory failure
hypoxemic respiratory failure
inspiratory positive airway pressure (IPAP)
iron lung
negative pressure ventilator
nocturnal hypoventilation
noninvasive positive pressure ventilation (NPPV)
noninvasive ventilation (NIV)
obesity hypoventilation syndrome
palliative care
pneumobelt
rocking bed
Trendelenburg position

Noninvasive ventilation (NIV) is a means of delivering ventilatory support without using an invasive artificial airway, such as an endotracheal or tracheostomy tube. NIV can be provided by applying either negative or positive pressure to the airways. Almost any type of mechanical ventilator can be used to deliver NIV, and many noninvasive patient interfaces are available. However, at the present time, NIV is almost always delivered using a positive pressure ventilator designed specifically for noninvasive use or an ICU ventilator with a noninvasive mode in conjunction with an oronasal or nasal mask. *NIV* is generally understood to include both **noninvasive positive pressure ventilation (NPPV)** and the noninvasive application of **continuous positive airway pressure (CPAP)**.

Interest in NIV has increased in recent years with the publication of findings from clinical trials using NIV in the management of respiratory failure. At the same time, technologically advanced noninvasive ventilators have been introduced. Most intensive care unit (ICU) ventilators now include a specific noninvasive mode of ventilation. Improvements in the design of noninvasive interfaces have increased patient tolerance of NIV. The net effect of these developments is that NIV has become a familiar intervention in both acute and long-term care settings.[1] This chapter reviews the evidence supporting the use of NIV to manage various disease processes and makes recommendations on the types of patients and specific techniques for its successful application.

HISTORY AND DEVELOPMENT OF NONINVASIVE VENTILATION

Many of the early devices used for NIV were developed in the 20th century during the polio epidemic. These devices are most effective when used for patients with neuromuscular disease in the absence of primary pulmonary disease.

First described in the 1930s, the **pneumobelt** consists of a rubber bladder that is strapped around the abdomen and periodically inflated by a positive pressure ventilator (Fig. 50.1).[2] This simple, innovative device is most effective when the patient is in a sitting position. Inflation of the rubber bladder compresses the abdomen. The resulting increase in abdominal pressure pushes the diaphragm upward, actively assisting exhalation. When the rubber bladder deflates, abdominal pressure drops and the diaphragm moves down with the force of gravity, facilitating inspiration.[3]

The **rocking bed** (Fig. 50.2) is a motorized bed that frequently rocks from the **Trendelenburg position** to reverse Trendelenburg position. This repetitive motion facilitates inspiration and exhalation by using gravity to move the abdominal contents and the diaphragm upward and downward.[4] Rocking beds were used in the 1950s as an alternative to negative pressure ventilators for patients following recovery from polio.[2] The device can provide adequate minute ventilation but it is not tolerated by some patients.

Negative pressure ventilators were widely used during the polio epidemic and a few are still used in the home setting.[2] A **negative pressure ventilator** generates negative pressure within a chamber that surrounds the thorax. The chest wall expands, negative pressure is created in the alveoli and inspiration occurs when air flows into the lungs. When the negative pressure is released, elastic recoil causes the lungs and chest wall to return to their normal size, resulting in passive exhalation. The first electrically powered negative pressure ventilator, known as the **iron lung** (Fig. 50.3), surrounded the entire body from the neck down. Other designs were introduced, such as the **chest cuirass**, which enclosed only the chest.[2] A disadvantage of negative pressure ventilators is that their design limits access to the patient unless ventilation is interrupted. Effective negative pressure ventilation can be challenging to achieve if the device has air leaks or does not fit properly. In addition, collapse of the upper airway can occur during inspiration when excessive negative pressure is applied.[3]

The first reported use of NPPV was in 1780, when Chaussier used a bag and face mask during resuscitation.[1] However, widespread clinical use of NPPV did not begin until much later, with the introduction of intermittent positive pressure breathing (IPPB) in 1947.[1,2] IPPB was used extensively to deliver aerosolized medications until the mid-1980s[2] when new evidence showed

no benefit compared to small volume nebulizers.[5] Around this time, nasal mask CPAP was suggested as a therapy for obstructive sleep apnea.[6] In 1989, NPPV was used successfully to support patients with acute respiratory failure (ARF).[7] Since then, many studies have examined the use of NIV. The next section provides evidence-based recommendations for the application of NIV in the management of respiratory failure for selected clinical conditions.

INDICATIONS FOR NONINVASIVE VENTILATION

Goals and Benefits of Using Noninvasive Ventilation

Impaired gas exchange is the hallmark of ARF. Endotracheal intubation and mechanical ventilation are often necessary to improve gas exchange in patients with severe ARF. The primary goal of NIV is to improve gas exchange without endotracheal intubation and its associated complications. The potential benefits of using NIV in the acute care setting include improved survival, less time on mechanical ventilation, shorter hospitalization, and lower rates of ventilator-associated pneumonia. In the long-term care setting, major goals are improving the patient's quality of life and relieving symptoms of hypoventilation. The goals of NIV in acute and long-term care settings are listed in Box 50.1.

The primary indication for NIV is **hypercapnic respiratory failure** due to chronic obstructive pulmonary disease (COPD) exacerbation. Hypercapnic ARF is characterized by inadequate alveolar ventilation, elevated arterial PCO_2, and respiratory acidosis. Although patients with hypercapnic ARF are the most likely to benefit from the use of NIV, it is also indicated for selected patients with hypoxemic respiratory failure or with

BOX 50.1 Goals of Noninvasive Ventilation

Acute Care Setting
- Improve gas exchange
- Avoid intubation
- Decrease mortality
- Decrease length of time on ventilator
- Decrease length of hospitalization
- Decrease incidence of ventilator-associated pneumonia
- Relieve symptoms of respiratory distress
- Improve patient–ventilator synchrony
- Maximize patient comfort

Long-Term Care Setting
- Relieve or improve symptoms
- Enhance quality of life
- Avoid hospitalization
- Increase survival
- Improve mobility

Modified from Mehta S, Hill NS: Noninvasive ventilation, *Am J Respir Crit Care Med* 163:540, 2001.

BOX 50.2 Acute and Chronic Disease Processes for Which Noninvasive Ventilation May Be Indicated

Acute Conditions
- Hypercapnic respiratory failure
- Chronic obstructive pulmonary disease (COPD) exacerbation
- Asthma
- Facilitation of extubation, especially in COPD
- Hypoxemic respiratory failure but cautiously
- Acute cardiogenic pulmonary edema
- Respiratory failure in immunocompromised patients
- End-of-life care, do-not-intubate (DNI) and comfort-measures-only (CMO) orders
- Postoperative respiratory failure
- Prevention of reintubation in high-risk patients
- Postextubation respiratory failure

Chronic Conditions
- Nocturnal hypoventilation
- Restrictive thoracic disease
- Amyotrophic lateral sclerosis (ALS)
- COPD
- Obesity-hypoventilation syndrome (OHS)

respiratory failure resulting from numerous other conditions (Box 50.2).[8–12]

Acute Care Indications

Hypercapnic Respiratory Failure

Chronic obstructive pulmonary disease. NIV is the standard of care for treatment of hypercapnic respiratory failure secondary to COPD exacerbation and should be available as first-line therapy in all institutions treating patients with COPD. Current data show that patients with COPD and ARF require intubation less often when they receive NIV. Other benefits of NIV use in this group of patients include lower risk of mortality, fewer complications, and reduced length of hospital stay.[13,14]

Early intervention with NIV should be considered before severe respiratory acidosis develops. However, NIV can be used successfully and safely in much sicker patients. Successful application of NIV has occurred in patients with hypercapnic coma and in awake, noncomatose patients.

RULE OF THUMB The use of NIV in managing COPD exacerbation is strongly supported by evidence from numerous randomized, controlled trials.

RULE OF THUMB All patients with an acute COPD exacerbation should be evaluated for NIV as an alternative to intubation and invasive mechanical ventilation. NIV is the standard of care in these patients.

RULE OF THUMB Severe hypercapnia and decreased level of consciousness should not be considered absolute contraindications to a cautious trial of NIV in selected patients. The RT should be present until the patient is alert, oriented and able to protect his or her airway.

Asthma

The evidence for using NIV for severe asthma with ARF is inconclusive.[15–19] Therefore NIV is not routinely recommended in this setting. If patients with severe asthma receive a trial of NIV, they must be monitored closely. Unless significant improvement in the symptoms of respiratory failure is evident within 1 to 2 hours, intubation should proceed without delay.

Facilitation of Weaning in Chronic Obstructive Pulmonary Disease

There is reasonable evidence that patients with COPD who were intubated for ARF and have failed at least one spontaneous breathing trial (SBT) should be considered for a trial of extubation directly to NIV.[20,21] However, early extubation to NIV does not influence weaning time for similar difficult-to-wean patients if ARF is caused by a condition other than COPD. Success is more likely for COPD patients with no exclusion criteria, for example, excessive amount of secretions and for those who have used NIV previously (and many patients with COPD are familiar with NIV from prior exacerbations). Interestingly, the failure of NIV to prevent intubation does not preclude the successful use of NIV to facilitate extubation at a later time.

RULE OF THUMB A trial of extubation directly to NIV should be considered for patients with COPD and hypercapnic ARF who are likely to receive a tracheostomy for failure to wean.

Hypoxemic Respiratory Failure

Many conditions can cause **hypoxemic respiratory failure**, defined as impaired oxygenation (PaO_2/FiO_2 ratio <300) that is refractory to supplemental oxygen (O_2). Clinical trials of NIV to manage acute hypoxemic respiratory failure have yielded conflicting results. The success of NIV depends largely on the etiology of the hypoxemia. Further study is needed to determine clearly the types of patients who would benefit from NIV.

It is important to recognize that untreated hypoxemia is a serious condition with irreversible, life-threatening implications. For this reason, clinicians should use caution during an NIV trial for a patient with hypoxemic ARF. A recurrent theme in the discussion of hypoxemic respiratory failure is that close monitoring and frequent reassessment of oxygenation during the first 1 to 2 hours are essential to the patient's safety. If NIV does not result in significant improvement, endotracheal intubation should be strongly considered.[22–25]

Acute Cardiogenic Pulmonary Edema

CPAP has been shown to reduce the need for intubation in patients with severe cardiogenic pulmonary edema. The weight of evidence in randomized controlled trials strongly suggests that NIV improves outcome in these patients compared with simple O_2 therapy. Mask CPAP should be used to treat hypoxemia associated with severe cardiogenic pulmonary edema. NPPV should be reserved for patients with both hypercapnia and hypoxemia. Extra caution is recommended for patients who present with cardiac ischemia, hemodynamic instability, arrhythmias, or depressed mental status. Patients with these risk factors should generally be intubated and invasively ventilated.[26,27]

RULE OF THUMB CPAP of 8 to 12 cm H_2O with 100% O_2 is first-line therapy in acute pulmonary edema. NPPV should be used only when hypercapnia is present.

Pneumonia

NIV has been used with mixed results in the management of severe community-acquired pneumonia. The current recommendation for the use of NIV in pneumonia is to limit its routine use to patients who also have COPD.[28] A trial of NIV may be appropriate for carefully selected patients, but caution is advised. Patients with higher severity of illness on admission or with sepsis are much less likely to be managed successfully with NIV. If a trial of NIV does not improve oxygenation within a few hours, invasive ventilation should be initiated.[28–30]

Acute Lung Injury and Acute Respiratory Distress Syndrome

High failure rates are common when NIV is used to treat acute lung injury (ALI) and acute respiratory distress syndrome (ARDS). Patients with risk factors such as severe hypoxemia, hemodynamic instability, sepsis, or metabolic acidosis are more likely to fail NIV. Other factors associated with NIV failure are ongoing dyspnea after starting NIV and large tidal volumes (> 9 mL/kg PBW) during pressure support ventilation (PSV).

The impact of NIV success or failure on survival remains unclear. NIV failure results in worse outcomes than NIV success but better than outcomes when patients are initially intubated. Most importantly, profound hypoxemia (PaO_2/FiO_2 ratio <150) is associated with increased ICU mortality in ARDS patients receiving NIV.[31–35] There is insufficient evidence to support routine NIV use in patients with ALI/ARDS. However, a closely monitored trial of NIV in carefully selected patients may be appropriate. If NIV does not markedly improve hypoxemia within 1 to 2 hours, the patient should be intubated.

Respiratory Failure in Immunocompromised Patients

NIV has long been accepted as first-line therapy for immunocompromised patients with ARF because intubation significantly increases their risk of death. The use of NIV may improve short-term survival and decrease the intubation rate when compared to standard O_2 therapy but the evidence is conflicting and relatively weak. However, recent evidence supports the efficacy of high-flow oxygen via nasal cannula (HFNC) instead of either NIV or standard O_2 therapy in reducing the intubation rate and mortality.[36–41] More work is needed to define the best approach to treating ARF in this group.

Do-Not-Intubate and Comfort-Measures-Only Orders

When NIV is provided for patients with ARF who have orders to limit life-sustaining treatments, the goals and expectations of care change. For patients with comfort-measures-only (CMO) orders, the goal is to relieve the symptoms and stress of disease through **palliative care**. The primary goal of NIV is relief of

MINI CLINI

Noninvasive Ventilation to Treat Hypoxemic Acute Respiratory Failure

Problem

A patient with acute hypoxemic respiratory failure is receiving NIV via nasal mask with a noninvasive ventilator. The ventilator is delivering PSV with peak inspiratory pressure set at 12 cm H_2O and end expiratory pressure set at 4 cm H_2O. O_2 at 10 L/min is flowing into the nasal mask. After 40 minutes on NIV, the patient's condition is only slightly improved. She continues to have signs of respiratory distress with an ineffective breathing pattern (dyspnea, tachypnea with respiratory rate 30, heart rate 120 beats/min, SpO_2 87%). She is unable to keep her mouth closed. An arterial blood gas is drawn and the PaO_2 is 53 mm Hg. List some actions that may increase this patient's chance of success using NIV.

Solutions

1. Replace the interface with an oronasal mask. A chin strap could be tried but is not likely to be successful. A mask that covers both nose and mouth provides more effective ventilator support by minimizing mouth air leaks. Dyspneic patients tend to breathe preferentially through their mouths.
2. Change to a ventilator that can deliver precise, high FiO_2 has alarms and displays calculating exhaled volumes and graphics. Bleeding in O_2 to the mask or circuit provides only low, inconsistent FiO_2. Alarms are an important safety consideration for sick, unstable patients on NIV. Waveforms and calculated volumes are useful when assessing synchrony and the effects of changing the ventilator settings.
3. Increase positive-end expiratory pressure (PEEP) to 8 to 10 to maintain alveoli open and improve severe hypoxemia; 4 cm H_2O is probably inadequate in this situation.
4. If these interventions do not result in significant improvement in oxygenation within 30 to 45 minutes, the patient should be electively intubated and ventilated. Recognizing an unsuccessful NIV trial can be challenging, However, delaying intubation in the setting of hypoxemia increases the risk of death during intubation. Such delays can result if clinicians do not recognize an unsuccessful NIV trial in the setting of hypoxemia.

dyspnea in this setting. The goals for patients with do-not-intubate (DNI) orders are to reverse the ARF and restore health. If NIV fails to achieve those goals, it can still be used to reduce dyspnea along with other palliative measures such as sedative and anti-anxiety medications and O_2 therapy.

The success of NIV in treating patients with DNI orders varies depending on the cause of the ARF. Most DNI patients survive and are discharged from the hospital when ARF is caused by COPD or cardiogenic pulmonary edema. Survival is less likely with ARF from other causes, such as pneumonia.

NIV use remains controversial in patients with CMO orders. Some clinicians have suggested that the potential hardship and stress associated with using NIV outweigh the benefits. Evidence that NIV provides relief of dyspnea in CMO patients is mixed but those with hypercapnia are more likely to improve. Patients should be asked about the intensity of their dyspnea symptoms before and after initiation of NIV and regular, periodic reassessment is recommended. If NIV is not tolerated or if the goal of reducing dyspnea is not achieved, NIV should be discontinued for any patient with a CMO order. Decisions to limit life-sustaining treatment should be mindful of the wishes of the patient and his or her loved ones. In discussions involving palliative and end-of-life care, it is important for clinicians to take the time to explain the goals of NIV, treatment options and expected outcomes to the patient.[42–47]

RULE OF THUMB Patients with DNI or CMO orders should receive NIV to reverse or improve acute respiratory failure. NIV should be removed if it causes discomfort or does not improve dyspnea in the CMO patient.

Postoperative Respiratory Failure

Several investigators have reported favorable results using NIV instead of standard O_2 therapy for ARF during the postoperative period after major abdominal or thoracic surgery.[48–50] Positive findings include improved oxygenation, fewer infections, and lower rate of intubation. Although these results are encouraging, additional randomized trials are required to define the role of NIV in the treatment of postop ARF. At the present time, there is insufficient evidence to support routine use of NIV after major surgery.

Prevention of Reintubation in High-Risk Patients

Reintubation has been associated with increased mortality, longer hospital stay, and a greater need for long-term care than in patients who are initially successfully extubated. In recent studies, randomly assigned patients at risk for reintubation to NIV or standard care showed lower reintubation rates with NIV. Patients with hypercapnia gained the most benefit from NIV. Risk factors associated with extubation failure include a diagnosis of COPD or congestive heart failure, age more than 65 years, ineffective cough and excessive secretions, upper airway obstruction, history of previous weaning failures, and the presence of comorbid conditions.[51,52]

Sufficient evidence exists to support selective application of NIV to avoid reintubation and its associated negative impact on outcome.

RULE OF THUMB NIV should be started after extubation of patients with multiple risk factors, especially patients with COPD, congestive heart failure, or hypercapnia. These patients should be monitored closely and reintubated promptly if NIV does not prevent respiratory distress.

RULE OF THUMB Recognizing NIV failure is important in patients with hypoxemic respiratory failure. Patients with severe hypoxemia have an increased risk of death during elective intubation.

Postextubation Respiratory Failure

The use of NIV to manage postextubation hypoxemic respiratory failure requires a cautious approach. Clinical trials have demonstrated uncertain efficacy when NIV is used to manage postextubation respiratory failure. Patients with COPD and hypercapnic respiratory failure or with congestive heart failure have the best chance of success using NIV in this setting. Failure is more likely if NIV is rescue management after unplanned extubation.[52,53] If hypoxemia does not significantly improve with NIV, these patients should be reintubated without delay.

RULE OF THUMB Before using NIV in the management of ARF, be sure the process causing respiratory failure is reversible, selection criteria are met, and exclusion criteria are absent.

Long-Term Care Indications

Nocturnal Hypoventilation

Nocturnal hypoventilation is common with neuromuscular diseases, severe kyphoscoliosis, COPD, obesity, and sleep apnea. Patients with these disorders can breathe spontaneously without assistance but typically have symptoms related to hypoventilation and sleep-disordered breathing. These symptoms may include excessive sleepiness during daytime hours; fatigue; morning headaches; and cognitive dysfunction, such as difficulty concentrating.[54]

Normally, the onset of sleep is characterized by an increase in $PaCO_2$ during rapid eye movement (REM) sleep. It is thought that the increased work of breathing associated with obesity and COPD or the muscle weakness caused by neuromuscular diseases results in greater levels of hypercapnia. Some of these patients are hyporesponsive to carbon dioxide (CO_2), which contributes to even more CO_2 retention. In response, the kidneys attempt to compensate by retaining bicarbonate, reducing respiratory drive further. This vicious cycle of progressively worsening hypercapnia leads to pulmonary hypertension, cor pulmonale, CO_2 narcosis, and eventually death.[54] The cycle can be stopped if breathing is assisted by NIV for 4 to 5 hours per night for 1 to 3 months. Nocturnal NIV improves sleep quality and gas exchange during waking hours. Current evidence suggests that NIV is effective because it prevents nocturnal hypoventilation and preserves ventilatory response to increases in CO_2 in patients with COPD or restrictive thoracic diseases.

Restrictive Thoracic Diseases

Restrictive thoracic diseases successfully managed with NIV include postpolio syndrome, neuromuscular diseases, chest wall

deformities, spinal cord injuries, and severe kyphoscoliosis. Patients with severe kyphoscoliosis showed improved nighttime and daytime gas exchange, fewer symptoms of hypoventilation, and increased spontaneous V_T and FVC after using NIV.[55] In patients with Pompe disease, improvement of arterial blood gas abnormalities and sleep-disordered breathing has been demonstrated after one night of NIV, though disease progression is not slowed.[56] Diaphragmatic weakness is characteristic of this disease, in contrast to most other neuromuscular diseases. NIV prolongs survival of patients with Duchenne muscular dystrophy, a rapidly progressive neuromuscular disorder. Reports from international centers treating patients with Duchenne have demonstrated that patients using NIV can avoid tracheostomy and can be managed in the home for long periods without hospitalization.[57,58]

The current recommendation for patients with restrictive thoracic disorders is to initiate NIV when patients develop symptoms of nocturnal hypoventilation.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as *Lou Gehrig disease,* is a neurodegenerative disease that affects motor neurons, resulting in progressive skeletal muscle weakness and paralysis. In the United States, one to two new cases per 100,000 people are diagnosed annually. The average survival time is 3 to 5 years after diagnosis. All patients with ALS eventually need mechanical ventilation to survive. The first signs of muscle weakness occur in the arms and legs for most patients diagnosed with ALS. Approximately a third of cases are bulbar onset, affecting the muscles used in swallowing and speaking first.[59]

Clinical trials have demonstrated a significant survival benefit and improved quality of life for patients with ALS using NIV. Four or more hours of NIV per day slows the decline in vital capacity (VC) measurements, often used an indicator of lung function. The decline occurs more slowly and survival benefit increases when NIV is used for more than 4 h/day.[60] NIV is usually initiated when VC is 50% of the predicted value adjusted for gender and height. There may be an advantage to starting NIV earlier, at 80% of the predicted VC. Regardless of the timing of its initiation, patients with functional bulbar muscles and with orthopnea are more likely to tolerate NIV and benefit from using it. All patients with ALS should be offered a trial of NIV when they show signs of nocturnal hypoventilation and declining ventilatory function.[61–63]

RULE OF THUMB Patients with restrictive thoracic disorders should have symptoms of nocturnal hypoventilation before NIV is considered.

Chronic Obstructive Pulmonary Disease With Stable Hypercapnia

The use of NIV in the management of COPD patients with stable hypercapnia is controversial. Lower $PaCO_2$ has been associated with high inspiratory positive airway pressure (IPAP) setting (18 cm H_2O), compliance with therapy (5 hours of NIV per night), and higher baseline $PaCO_2$ (55 mm Hg).[64] The use of NIV settings (higher IPAP) that target a reduction in $PaCO_2$ resulted in better NIV tolerance and longer short-term survival in a small group of patients.[65] Some evidence supports the idea that NIV in hypercapnic COPD patients following an acute exacerbation was associated with prolonging the time to readmission and death.[66] Although substantial evidence supports the role of NIV in COPD patients with ARF, strong evidence is lacking in the chronic setting. At the present time, there is not enough evidence to support routine treatment with NIV in managing stable COPD.

RULE OF THUMB NIV should be offered to all patients with ALS because it probably slows the rate of decline of lung function and lengthens survival.

Obesity-Hypoventilation Syndrome

Forty percent of adults in the US are classified as obese, and an estimated 7%, or 15.5 million people, are extremely obese (BMI >40 kg/m^2).[67] The prevalence of obesity has increased significantly in the 21st century. **Obesity hypoventilation syndrome** is a common, underdiagnosed condition in hospitalized extremely obese patients. Obesity-hypoventilation syndrome (OHS) is characterized by chronic daytime hypercapnia, sleep-disordered breathing and obesity (body mass index >30 kg/m^2) when no other known cause for hypoventilation is present.

Excess weight on the chest wall and abdomen impose a load on the inspiratory muscles, especially in sitting or supine positions. Extreme obesity decreases the compliance of the chest wall and the respiratory system and increases resistance in the airways. These changes in pulmonary mechanics can cause small airways to close completely before exhalation is complete. The result of this air trapping is the development of intrinsic PEEP, further increasing work of breathing for these patients. Patients with OHS have a defective respiratory drive with a blunted response to increased $PaCO_2$.[68]

NIV improves daytime hypercapnia and relieves symptoms associated with nocturnal hypoventilation within 1 to 4 months. Respiratory drive improves but may not return to normal. CPAP and NPPV have been shown to be equally effective in decreasing daytime $PaCO_2$ in patients with OHS, and both are generally well tolerated. CPAP is usually the first-line treatment for OHS. If hypercapnia persists with CPAP, a switch to NPPV is recommended. Typically, an IPAP setting of at least 6 cm H_2O above expiratory positive airway pressure (EPAP) is necessary to increase alveolar ventilation.[69]

SELECTING APPROPRIATE PATIENTS FOR NONINVASIVE VENTILATION

Acute Care Setting

The success or failure of NIV depends to a large degree on the clinician's clinical judgment in choosing appropriate patients. Candidates for NIV in the acute care setting should show signs and symptoms of respiratory distress and have moderately abnormal gas exchange. NIV selection criteria for ARF are detailed in Box 50.3.[2]

Candidates for NIV must have an intact respiratory drive and stable vital signs. Patients with facial anatomy or injury that prevents use of a noninvasive interface should be excluded. The

BOX 50.3 Noninvasive Ventilation Selection Criteria for Patients With Acute Respiratory Failure

Signs of Impaired Gas Exchange (at Least One of the Following)

- $PaCO_2$ >45 mm Hg and pH <7.35
- PaO_2/FIO_2 ratio <200

Signs and Symptoms of Respiratory Distress (at Least One of the Following)

- Use of accessory muscles
- Paradoxical breathing
- Respiratory rate ≥25 breaths/min
- Moderate to severe dyspnea (increased dyspnea in chronic obstructive pulmonary disease [COPD] patients)

MINI CLINI

Preventing a High-Risk Patient From Requiring Reintubation

Problem

A 74-year-old man was intubated for hypercapnic respiratory failure 3 days ago. Past medical history is significant for hypertension, coronary artery disease, COPD, and former cigarette smoker ×35 years (quit 10 years ago). He is currently on low-level PSV (PS 8, PEEP 5 cm H_2O, FiO_2 0.3). Vital signs are heart rate 80 beats/min, blood pressure 130/70 mm Hg, respiratory rate 16 breaths/min, and SpO_2 95%. Endotracheal suctioning has been performed every 2 to 3 hours for moderate to large amounts of yellow secretions. Ipratropium metered dose inhalation (MDI), 2 puffs every 6 hours, is ordered. He was placed on a spontaneous breathing trial this morning and passed; however, his ability to clear secretions is a concern. After much discussion among the patient care team, the decision was made not to extubate as planned. What are the options for clinical management?

Solutions

1. Extubate and immediately start NIV. Evidence supports using NIV to prevent reintubation in high-risk patients. Patients with hypercapnia are most likely to benefit. Other factors associated with high risk of extubation failure are age older than 65, COPD, and excessive secretions.
2. Continue aerosolized bronchodilators by delivering the MDI to a collapsible holding chamber added to the NIV circuit. Place the chamber between the exhalation port and the mask. Coordinate MDI actuation as closely as possible to the patient's own inspiration. Shake the MDI canister between each actuation to mix the propellant and the drug. These three points are important to deliver maximum medication to the patient.

patient's risk of aspiration, ability to cooperate, and volume of secretions should be considered before a decision to start NIV (Box 50.4).[2] Decreased level of consciousness due to hypercapnia should not be considered an exclusion criterion for NIV in patients with COPD.[70,71]

It is important to consider the cause of ARF because the efficacy of NIV varies depending on the underlying condition being treated. In the acute care setting, most evidence supports the use of NIV in patients with COPD exacerbations or acute cardiogenic pulmonary edema. There is less evidence supporting NIV for the other indications discussed earlier; however, it is being used more frequently for patients with DNI orders, to facilitate extubation of high-risk patients, and as a means of preventing extubation failure and reintubation (Box 50.5). Ideally, NIV should be initiated before severe ARF develops because severe hypercapnia and acidosis are predictors of NIV failure. Success is unlikely if NIV is used as rescue therapy. Significant improvements in $PaCO_2$ and pH within 2 hours of NIV are predictive of success. In some cases, clinical judgment precludes an NIV trial based on the severity of the respiratory failure or the presence of comorbid conditions. However, in many situations, a reasonable plan would be a trial of NIV for 1 to 2 hours, with close periodic reassessment and plans to intubate if the patient's condition does not significantly improve. Successful application of NIV includes short-term goals of improving gas exchange and preventing endotracheal intubation and long-term goals of improved outcome, decreased length of stay, and decreased mortality.[72,73]

BOX 50.4 Noninvasive Ventilation Exclusion Criteria for Patients With Acute Respiratory Failure

- Apnea
- Inability to protect airway/high aspiration risk
- Hemodynamic or cardiac instability
- Lack of patient cooperation
- Inability to use a noninvasive interface because of facial burns, trauma, or abnormal anatomy
- Copious amounts of secretions

Modified from Mehta S, Hill NS: Noninvasive ventilation, *Am J Respir Crit Care Med* 163:540, 2001.

BOX 50.5 Predictors of Noninvasive Ventilation Success in the Acute Care Setting

- Minimal air leak
- Low severity of illness
- Respiratory acidosis ($PaCO_2$ >45 mm Hg but <92 mm Hg)
- pH <7.35 but >7.22
- Improvement in gas exchange within 1–2 h of initiation
- Improvement in respiratory rate and heart rate

Modified from Mehta S, Hill NS: Noninvasive ventilation, *Am J Respir Crit Care Med* 163:540, 2001.

Long-Term Care Setting

Selection criteria for NIV in the long-term setting include the presence of a disorder that can be managed with NIV and one or more signs of nocturnal and daytime hypoventilation (Box 50.6). Measurable parameters should also be obtained to document a decline in pulmonary function, nocturnal hypoventilation and/or daytime hypercapnia depending on the disorder being treated. For example, measurement of VC, maximum inspiratory pressure or cough peak flow rate can be indicators of decline in a patient with neuromuscular disease. A sleep study with monitoring of end-tidal or transcutaneous CO_2 and SpO_2 is required to document nocturnal hypoventilation. Arterial blood gas analysis

documents daytime hypercapnia with elevated $PaCO_2$ and serum bicarbonate and normal pH. In long-term care settings, a follow-up examination is suggested 1 month or so after starting NIV to assure that the patient has acclimated to the device. A 2-month follow-up is recommended to determine compliance with NIV and to assess benefit.[74]

Exclusion Criteria for Noninvasive Ventilation in a Long-Term Care Setting

NIV exclusions are similar in acute and long-term settings. Cooperation on the part of the patient is a major factor when NIV is used in the management of chronic conditions. Lack of support at home can have a negative impact on compliance with NIV.

EQUIPMENT USED FOR NONINVASIVE VENTILATION

Many factors, including the choice of patient interface, ventilator, mode of ventilation, and initial ventilator settings, play a role in determining whether NIV will be successful in a given patient. This section discusses the equipment and modes of ventilation used when applying NIV.

BOX 50.6 Signs and Symptoms Associated With Nocturnal Hypoventilation

- Dyspnea during activities of daily living
- Orthopnea
- Poor sleep quality, insomnia, frequent arousals
- Morning headaches
- Daytime fatigue or sleepiness
- Decrease in energy and intellectual performance
- Recurrent complications such as hospitalizations, respiratory infections, etc.
- Signs of cor pulmonale

Patient Interfaces

Many options are available to provide a noninvasive interface between the patient and the ventilator. A primary interface requirement is compatibility with the type of ventilator to be used. Certain mask designs interfere with proper functioning of ICU ventilators. Other design considerations may include volume of dead space in the mask and the position of the exhalation port in the system. The condition to be treated, needs of certain patients, and the care setting in which NIV is used can also influence the choice of interface.

Face masks are specifically designed for use with either ICU or noninvasive ventilators (Fig. 50.4). Face masks for noninvasive ventilators have entrainment valves that prevent asphyxia if the ventilator fails or the tubing becomes disconnected. Full-face masks designed for ICU ventilators do not have this feature. In addition, noninvasive ventilators using a single-limb circuit require a leak port either in the tubing or in the mask itself (Fig. 50.5). Masks with leak ports should be used only with noninvasive ventilators because the leak interferes with the function of ICU ventilators.

Clinicians should select an interface that is the right size for the individual patient, assess mask fit and placement on the face, and reposition the mask as needed, minimizing air leaks to the extent possible. These assessments have a direct impact on patient comfort and compliance with NIV, two important factors that can influence the overall effectiveness of NIV. The most common noninvasive interfaces in the acute care setting are oronasal masks followed by nasal masks. An oronasal mask is usually the best choice when NIV is used to treat ARF.[75]

Fig. 50.4 (A) Oronasal mask designed for use with a critical care ventilator. (B) Oronasal mask with anti-suffocation valve intended for use with a noninvasive ventilator. ([A] Courtesy Phillips Respironics, Murrysville, PA. [B] Courtesy Pulmodyne, Indianapolis, IN.)

Fig. 50.5 A leak port is required with noninvasive ventilators to ensure proper function, either as shown, in the ventilator circuit, or in the nasal or oronasal mask. Occlusion of the leak port will result in ventilator malfunction. (Courtesy Pulmodyne, Indianapolis, IN.)

Fig. 50.6 (A) Nasal mask that incorporates adjustable forehead support to minimize pressure on the bridge of the nose. (B) Nasal mask designed for small size and minimal facial contact. (A, Courtesy ResMed Corp, San Diego, CA. B, Courtesy of Phillips Respironics, Murrysville, PA.)

Nasal and Oronasal Masks

Nasal and oronasal masks are typically manufactured in two parts. The body of these devices is made of clear, hard plastic. Surrounding the outer edge of the mask body is either a soft plastic or silicone lip or a cushion filled with hydrogel, silicone gel, or air. The best design has a soft inner lip that forms a seal with the patient's face. When a higher positive pressure is applied, the mask fits more closely to the face, effectively decreasing the air leak around the mask. The opposite effect occurs when resuscitation masks are used for positive pressure ventilation. Higher airway pressures tend to force this type of mask away from the face, increasing the air leak.

NIV masks incorporate straps and headgear to maintain and stabilize the mask's position on the face (Fig. 50.6). It is important to avoid tightening the straps more than necessary. A perfect seal between the mask and the face is not required because ventilators used for NIV are designed to function properly in the presence of small air leaks. Pulling the straps excessively tight is likely to result in pressure-related damage to the skin on the bridge of the nose or sometimes on the cheeks. Clinicians must be vigilant for early signs of skin damage and take steps to minimize damage and prevent development of pressure ulcers, which are a potential source of infection and for which hospitals can be penalized by oversight organizations. The first sign of pressure-related skin damage is usually an area of **erythema**, or reddened skin that persists after removal of the mask. A liquid skin barrier and a hydrocolloid patch may be applied to protect the reddened area and some hospitals are now using such precautions as part of NIV protocols.[76]

To address the problem of skin breakdown, most masks incorporate some means of minimizing pressure on the bridge of the nose. These include foam wedges used as spacers and adjustable mechanical controls that prevent the apex of the mask from being pulled too close to the face. Some masks have foam pads that rest on the forehead to help maintain proper mask positioning. An easy way to check for excessive tightness is to insert two fingers between the straps and the patient's face. If it is not easy to do this, then the straps are too tight and should be loosened slightly. A strategy for minimizing the risk of pressure ulcer formation is to alternate the use of two or more masks with different points of facial contact.

The choice of an appropriately sized mask is a key factor in patient tolerance and NIV efficacy. Most masks include sizing

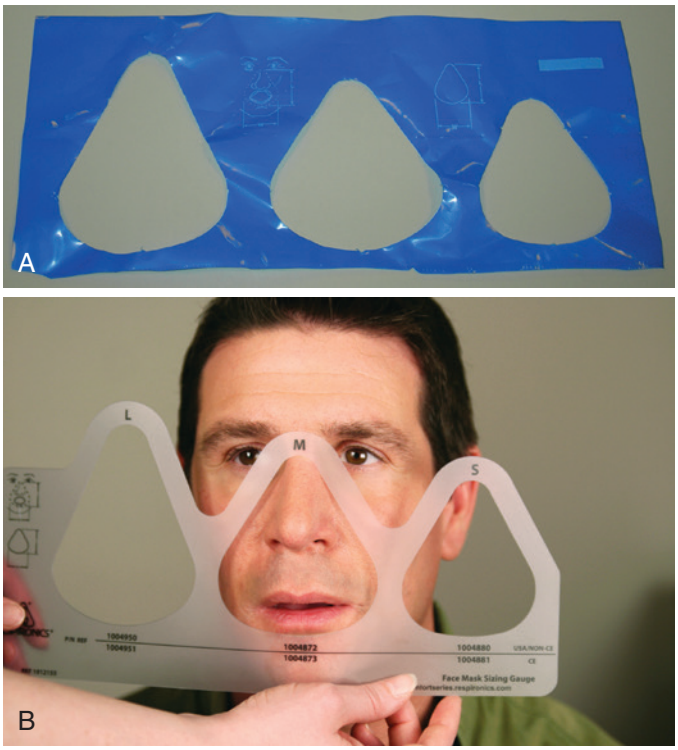

Fig. 50.7 (A) Templates help clinicians select an appropriately sized mask. (B) Oronasal masks should rest on the bridge of the nose between the eyes and in the indentation between the chin and the lower lip. (Courtesy ResMed Corp. San Diego, CA.)

Fig. 50.8 Nasal pillows are available in several designs and various sizes. (Courtesy ResMed Corp, San Diego, CA.)

templates that can be used before removing the mask from its packaging (Fig. 50.7). Nasal masks should be sized so that the cushion starts one-third of the way down from the top of the bridge of the nose, fits closely along the lateral aspects of the nose and rests above the upper lip, just under the nose. Oronasal masks fit similarly except the bottom of the mask rests in the depression above the chin and just below the lower lip. Mask sizes range from extra small to large, but for many individuals, a small or medium-small mask is a good fit. Ill-fitting masks can allow air leaks into the eyes, leading to poor tolerance. Small leaks around the mouth are generally less problematic because most ventilators used for NIV are designed to function with a baseline leak.

Nasal masks are more prone to air leaks than full-face masks, especially for patients who are mouth breathers. Chin straps are available that provide tension to help keep the mouth closed, but in practice they seldom work well. Oronasal masks are less prone to mouth leaks because both the mouth and the nose are covered. Disadvantages associated with oronasal masks include increases in dead space, risk of aspiration, and feelings of claustrophobia. Nasal masks may be better tolerated by patients with claustrophobia. Oronasal masks interfere with a patient's ability to communicate, eat, drink, and expectorate secretions without removing the mask.

In the past few years, new interfaces have been introduced in various designs, sizes, and shapes that are intended to promote patient comfort and tolerance. The respiratory therapist (RT) should be aware of all available designs to enhance the selection of a relatively comfortable, well-tolerated, correctly fitted interface through which the needed level of ventilatory support can be delivered.[77,78]

Nasal Pillows

Nasal pillows (Fig. 50.8) are round, soft cushions that fit directly into the nares. Specially designed headgear holds the prongs in place. This interface is used most often during nasal CPAP or by patients with chronic disease who do not tolerate a nasal mask. Nasal pillows are often a good option to deliver nocturnal CPAP for patients with skin breakdown on the bridge of the nose or those who prefer to sleep on their side. A newer design is the wedge-shaped mini-nasal mask that covers only the end of the nose.

Hybrid Oronasal Mask

The hybrid mask (Fig. 50.9) covers the mouth with a small mask and uses either nasal pillows connected to the top or a soft silicone lip to seal the nares. Like traditional oronasal masks, hybrid masks allow ventilation with fewer leaks. The risk of skin breakdown is reduced because the mask has no contact with the skin on the bridge of the nose. The hybrid mask feels less claustrophobic to some patients. Its design also allows patients to wear glasses during NIV.

Total Face Mask

Usage of the total face mask or full-face mask (Fig. 50.10), which covers the entire face, has increased in recent years. A soft,

Fig. 50.10 The total face mask. (Courtesy Phillips Respironics, Murrysville, PA.)

flexible layer around the edge of the total mask prevents leaking without touching the bridge of the nose or cheeks. The total face mask comes in one size, which allows quick application in the emergency department or critical care unit. It is generally well-tolerated and less likely to induce feelings of claustrophobia because it does not obstruct the visual field. The total face mask is a good choice for ARF, especially for patients with severe pressure-related skin breakdown who need to continue using NIV.

Helmet

The helmet is an interface that is unavailable in the United States at the present time (Fig. 50.11). This interface surrounds the entire head like a plastic bubble and is held in place by straps under the arms. A high continuous gas flow is required to prevent CO_2 from accumulating inside the helmet during CPAP. During NIV with the helmet, CO_2 is not eliminated as effectively compared with masks, and rebreathing can occur. Triggering and cycling of the ventilator can be adversely affected because of the large internal volume and high compliance of the helmet. Interesting recent data shows that patients using the helmet tolerate higher PEEP and lower ventilating pressures for longer periods than those using an oronasal mask, suggesting a potential role for the helmet in patients with mild ARDS without hypercapnia. The helmet facilitates early mobility without interruption of NIV, which may have an impact on quality of life long after hospital discharge.[79,80] Further investigation is needed to define the best application of this interface.

Few data are available in the literature to help guide the choice of an interface for NIV. There is no perfect NIV interface that meets the needs of every patient. Success is more likely if the interface can be tolerated for long periods and only a small air leak is present. An oronasal mask is the interface of choice for patients requiring NIV for ARF. For patients who cannot tolerate an oronasal mask, a nasal mask should be tried before accepting failure.

RULE OF THUMB Use an oronasal mask for patients in ARF. If the patient is unable to tolerate a mask covering both mouth and nose, try a nasal mask before accepting NIV failure.

Types of Mechanical Ventilators and Modes of Ventilation

Three types of ventilators are used for NIV: noninvasive ventilators, critical care ventilators, and portable home care ventilators. This section describes the characteristics and function of the three types of ventilators.

Noninvasive Ventilators

Most noninvasive ventilators are electrically powered, blower-driven, and microprocessor-controlled (Fig. 50.12). These ventilators utilize a single-limb circuit with one or more small leak ports in either the circuit or the patient interface. Gas flow through the leak ports is continuous but the flow rate varies depending on the pressure in the system. The leak ports also vent exhaled

MINI CLINI

Problems With Triggering During Noninvasive Ventilation

Problem

A patient with COPD is receiving NIV with a noninvasive ventilator using a full-face mask. The ventilator settings are as follows: PSV mode, peak pressure 14 cm H_2O, PEEP 4 cm H_2O, backup rate 10 breaths/min. Arterial blood gas was obtained after 30 minutes on NIV. $PaCO_2$ was 75 mm Hg, essentially unchanged since NIV was initiated. The RT notices that the ventilator is not triggering with every patient effort, and his respiratory distress has not improved. What should the RT do?

Solutions

1. The problems of failure to trigger and ineffective ventilation could be caused by a large air leak. Determine if an air leak is present. If so, reposition, refit, or select a better fitting mask; adjust strap tension; and consider adding a forehead spacer to minimize the leak.
2. These two problems could be related to intrinsic PEEP. Carefully observe the patient and ventilator graphics, if available, for missed trigger attempts. The ventilator should trigger with every inspiratory effort by the patient. Try increasing PEEP slowly from 4 cm H_2O to 6 cm H_2O or 8 cm H_2O. If the applied PEEP from the ventilator is set to minimize the difference between end expiratory pressure and the patient's intrinsic PEEP, the ability to trigger should improve. In some ventilators, increasing or decreasing PEEP in pressure-targeted ventilation modes does not affect the peak pressure. In this case, increasing PEEP could result in a decrease in the ventilating pressure and V_T. Check the peak pressure to determine if the ventilating pressure has changed, and increase the peak pressure by the same amount as PEEP is increased. Effective ventilation is usually achieved if the exhaled V_T is approximately 4 to 6 mL/kg.

gas because no exhalation valve is present. This design maintains low resistance in the circuit throughout the breathing cycle. As a result, noninvasive ventilators are sensitive to changes in flow and pressure and can respond quickly to patient demands. The main advantage of noninvasive ventilators over other types of ventilators is the ability to trigger and cycle appropriately when small to moderate air leaks are present.

Low baseline pressure settings have been associated with significant rebreathing of CO_2 in single-limb circuits. A PEEP or **expiratory positive airway pressure (EPAP)** setting of at least 3 to 5 cm H_2O generates adequate flow to flush exhaled gas from the ventilator circuit and prevent rebreathing of CO_2. For this reason, the expiratory pressure can be set no lower than 4 cm H_2O on many noninvasive ventilators. Masks used with noninvasive ventilators typically include an anti-asphyxia valve that opens automatically in the event of power loss or circuit disconnection, minimizing CO_2 rebreathing.[81,82]

Noninvasive ventilators used in the acute care setting for patients who would otherwise need intubation should have alarms for circuit disconnection, loss of power, and battery failure if a battery is present. An internal battery is a useful feature because it allows safe transport of critical patients without interruption of NIV. Information from graphics monitoring and calculated volumes that estimate leak, V_T, and minute ventilation can help clinicians assess patient–ventilator synchrony and make appropriate adjustments to NIV settings.

Noninvasive ventilators used in a critical care setting should be capable of delivering a high, precise FiO_2. For ventilators that do not have an internal air-oxygen blender, supplemental oxygen can be administered by adding an additional flow of O_2 into the ventilator circuit or mask. However, the FiO_2 delivered by this method is inconsistent and reaches a maximum of approximately 0.5.[83,84]

Modes available on noninvasive ventilators usually include CPAP, spontaneous (pressure support), and timed (pressure assist/control). Depending on the ventilator used, the ventilating pressure is referred to as **inspiratory positive airway pressure (IPAP)**, equal to peak airway pressure, or pressure support, which is the change in pressure above PEEP. In either case, this type of breath is usually pressure-limited and flow-cycled or time-cycled (Fig. 50.13). With pressure support and spontaneous modes, inspiration is patient-triggered. With pressure assist/control or spontaneous-timed modes, inspiration is either patient-triggered or time-triggered.[85]

Critical Care Ventilators

The main problem with using older critical care ventilators to provide NIV is their inability to compensate for leaks. Air leaks around the mask can cause problems including missed trigger attempts, auto-triggering, and failure to cycle. Critical care ventilators are now available with noninvasive modes that can deliver NIV effectively, but performance of different models varies widely (Fig. 50.14). These ventilators are equipped with internal air-oxygen blenders, graphics, and alarms, and can achieve high inspiratory flow rates that meet patient demand. They generally use dual-limb circuits that prevent rebreathing of exhaled CO_2.

In a few models, the NIV mode activates only new alarms (low pressure) and deactivates low V_T and minute volume alarms. However, most models incorporate some level of leak compensation during triggering, cycling, or both. A common feature of NIV modes is the ability to set a maximum inspiratory time during PSV. This setting does not deactivate flow cycling but provides an additional limit for inspiration in the presence of a large leak.

Fig. 50.12 Examples of noninvasive ventilators with monitoring and alarm capabilities. (A) Phillips Respironics V60. (B) Phillips Respironics Vision. (C) Phillips Respironics System One BiPAP S/T. (Courtesy Phillips Respironics, Murrysville, PA.)

To deliver NIV, ICU ventilators can be set in PSV mode, which is a patient-triggered, pressure-limited, flow-cycled mode. During inspiration, a high gas flow is delivered until the preset pressure limit is achieved. At that point, the flow begins to decrease until a predetermined level of flow is reached, cycling the breath to exhalation. Depending on the specific ventilator used, this flow level can be a fixed flow rate (e.g., 5 L/min) or a percentage of the peak flow (e.g., 25%). The flow-cycling mechanism of PSV can cause problems during NIV. In the presence of a large air leak, the flow may not decrease to the level necessary to cycle the breath to expiration. In this case, the patient may have to exhale actively, using abdominal muscles to increase airway pressure to cycle the ventilator to exhalation using secondary criteria.[86] This action increases work of breathing and can lead to failure of NIV.

Active exhalation can be recognized on the ventilator graphics by a spike in airway pressure at the end of the breath (Fig. 50.15). To correct this problem and allow passive exhalation to occur, the cycling criteria must be adjusted. Proper adjustment can markedly improve patient–ventilator synchrony during NIV. One method is to decrease the maximum inspiratory time setting, effectively changing the pressure-supported breath from flow-cycled to time-cycled. Time-cycled (instead of flow-cycled), pressure-limited ventilation markedly improves patient–ventilator synchrony, patient comfort, and compliance with therapy in the presence of air leaks.[87]

The second option is to adjust the expiratory sensitivity setting, which is the percentage of the peak inspiratory flow that terminates the breath. Most ICU ventilators allow adjustment of this setting over a wide range (Fig. 50.16). To prevent active exhalation, the percentage is simply increased until the spike disappears from the pressure waveform.[85–88]

PSV is the ventilation mode commonly used for NIV. Most RTs are familiar with using pressure-targeted ventilation for NIV on ventilators designed specifically for noninvasive application. The current recommendation by an international consensus conference on NIV in ARF is as follows: "Choice of mode should be based on local expertise and familiarity, tailored to the etiology and severity of the pathophysiological process responsible for ARF."[89] If a critical care ventilator is used for NIV, pressure ventilation makes sense because leak compensation is provided, triggering and cycling can be adjusted to suit patient needs, and

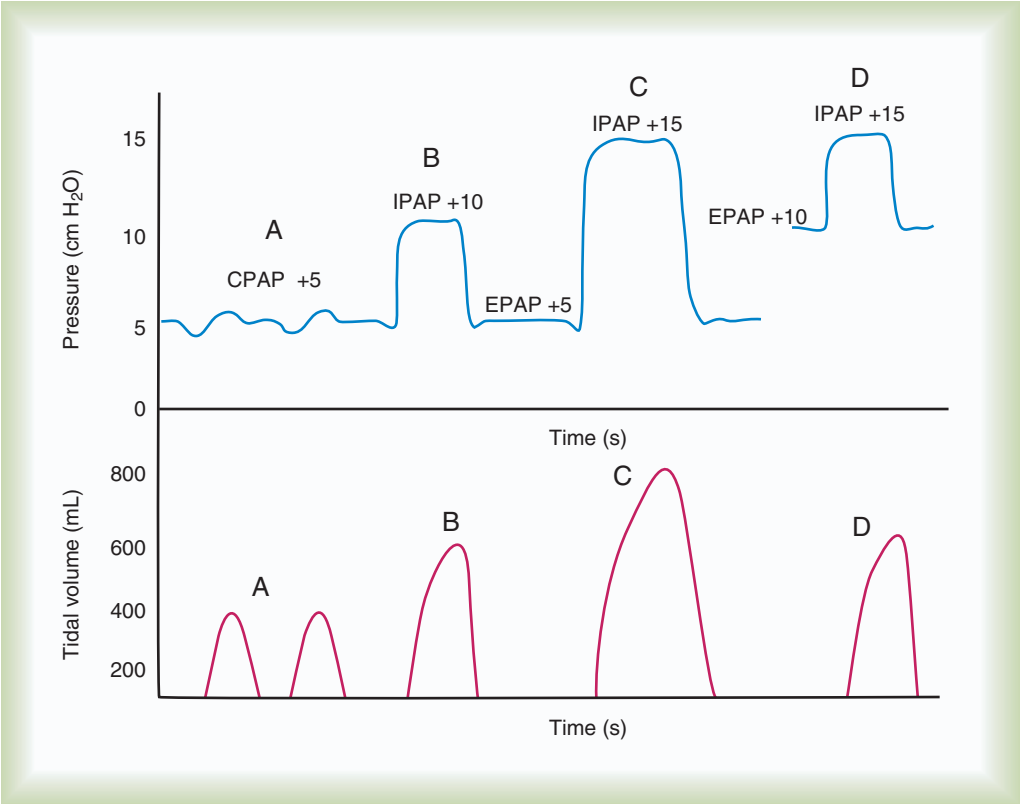

Fig. 50.13 The effects of changing noninvasive ventilator settings (inspiratory positive airway pressure *[IPAP]* and expiratory positive airway pressure *[EPAP]*). (A) Spontaneous breathing on continuous positive airway pressure *(CPAP)* of 5 cm H_2O. (B) Adding IPAP of 10 cm H_2O results in higher V_T. (C) Increasing IPAP to 15 cm H_2O delivers even higher V_T. (D) Increasing the baseline EPAP without a corresponding increase in IPAP results in lower V_T because the difference between IPAP and EPAP is less. (Copyright 2015 Covidien. All rights reserved. Used with the permission of Covidien.)

minute ventilation and end expiratory pressures are preserved. Volume-controlled modes are not recommended for NIV. Inability to compensate for the decrease in minute ventilation and loss of pressure caused by large leaks are major problems when volume-targeted modes are used for NIV.

Portable Home Care or Transport Ventilators

Most portable home care ventilators (Fig. 50.17) are electrically powered and microprocessor controlled. These devices can operate on alternating current (AC) or, if equipped with internal or external batteries, direct current (DC) power sources. The batteries can usually provide power for several hours. Batteries add a measure of safety in areas where AC power outages occur regularly. They also allow the patient to be more mobile, which may improve their quality of life. These ventilators use a single-limb or double-limb ventilator circuit with an exhalation valve that prevents rebreathing of CO_2. Updated technology has improved the performance characteristics of these ventilators to a level comparable to critical care ventilators with the added advantages of small size, light weight, and battery power that allow portability. Most newer models incorporate an NIV mode with the ability to compensate for leaks. Models with adjustable bias flow settings improve the ability of the ventilator to sense patient triggering. Additional features, such as variable termination criteria and maximum inspiratory time, are available on some of these devices to enhance breath termination in PSV.

Portable home care ventilators are currently recommended for patients who need continuous ventilatory support or high ventilating pressures, such as patients with severe chest wall deformities or obesity, or for patients who want greater mobility.[2] For acute care, these ventilators could easily be used to initiate NIV in nontraditional locations and allow transport to an emergency department or ICU without the need to interrupt ventilation.

Heated Humidifiers

An increase in nasal resistance and congestion has been reported with CPAP in patients with mouth leaks. Cold passover humidification does not provide relief but the addition of heated humidity improved nasal symptoms. To prevent the negative effect on patient compliance caused by this common complaint, and the potential accumulation of dried retained secretions in the back of the oropharynx, humidified gas, heated to a temperature that is comfortable to the patient (usually about 30°C), should be the standard when using NIV.[90]

RULE OF THUMB Heated humidity (approximately 30°C) should always be provided with NIV to avoid nasal symptoms, to avoid the accumulation of secretions in the back of the oral pharynx, and to enhance patient tolerance.

MANAGEMENT OF NONINVASIVE VENTILATION

Initial Application of Noninvasive Ventilation

Starting NIV requires the selection of a ventilator and an interface and a significant time commitment from the RT. The patient should be seated in a chair or bed at an angle of 30 degrees or greater (Box 50.7).[2] The RT should always explain the procedure and answer any questions about NIV before placing the mask on the patient. Clinicians should recognize that dyspnea can cause feelings of anxiety and fear. For this reason, the RT or the patient should hold the mask in place when applying the mask for the first time. Holding the mask allows it to be removed quickly if the patient begins to panic or wishes to communicate. A strategy of starting with low pressures can help patients adjust to NIV more readily. Ventilating pressures should be set as low as possible initially, especially if the patient is unfamiliar with the sensation of positive pressure ventilation. Then the ventilating pressures can be adjusted in small increments over 1 to 2 minutes until exhaled V_T is 4 to 6 mL/kg predicted body weight or respiratory distress improves. During this time, the RT should assess the patient frequently, adjusting the ventilator settings to synchronize breath delivery with the patient's breathing pattern and providing instructions and coaching as required. The mask should not be strapped on until the patient is comfortable with the application of NIV and the RT has adjusted pressures to provide proper ventilation.

The specific airway pressures required to support the patient during NIV are best determined by bedside assessment of the patient's response and tolerance. They cannot be determined with accuracy before NIV is started. However, most patients require PEEP levels of 4 to 8 cm H_2O and ventilating pressure of 8 to 12 cm H_2O. Peak airway pressures greater than 20 cm H_2O are rarely required and are best avoided. Airway pressure settings greater than 20 to 25 cm H_2O can force air into the stomach through the esophagus.[91] If the patient has a nasogastric tube in place, the probability of gastric distension increases dramatically, as does the probability of NIV failure.

Final adjustment of the ventilator should deliver a V_T of approximately 4 to 6 mL/kg ideal body weight with a respiratory rate less

than 30 breaths/min. The goal of NIV is not to deliver a large V_T but rather to maintain normal ventilatory patterns with acceptable gas exchange and decrease the work of breathing. FiO_2 should be titrated to PaO_2 of at least 60 mm Hg or SpO_2 88% to 95%.

RULE OF THUMB Most patients with ARF can be stabilized with an expiratory pressure setting of 4 to 8 cm H_2O and ventilating pressure of 8 to 12 cm H_2O. Avoid using peak pressures greater than 20 cm H_2O.

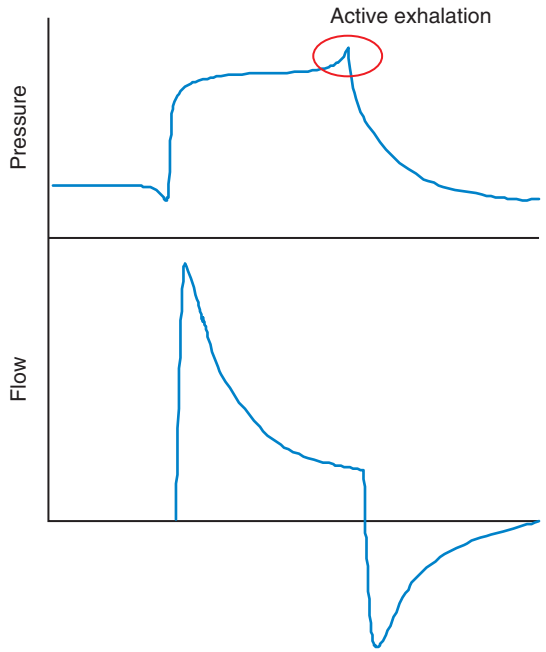

Fig. 50.15 Active exhalation is recognized by the spike on the pressure waveform at the end of inspiration. The patient uses abdominal muscles to increase airway pressure and cycle the ventilator into exhalation.

Clinical Assessment Criteria to Identify Success or Failure of Noninvasive Ventilation

Careful monitoring and frequent reassessment are very important during the first 1 to 2 hours of NIV. Successful application of NIV is easy to recognize—gas exchange improves, $PaCO_2$ decreases, pH normalizes, and PaO_2 and SpO_2 increase. Along with improvement of these measured values, the patient's clinical presentation improves; respiratory rate decreases, V_T increases, accessory muscle use decreases or is eliminated, and pulse rate and blood pressure normalize. If clinical status and gas exchange have not improved after 1 to 2 hours of NIV, intubation should be considered. This is especially true if the indication for NIV was hypoxemic respiratory failure. Evidence suggests an increased risk of cardiac arrest in patients with hypoxemic respiratory failure who do not improve after a trial of NIV for 1 to 2 hours.

Adjusting Noninvasive Ventilator Settings

Ventilator settings may need to be adjusted after the patient stabilizes and acclimates or when arterial blood gas analysis reveals gas exchange problems. Hypercapnia is addressed first by minimizing air leaks and, if necessary, by increasing the ventilating pressure. The result is an increase in the delivered V_T and minute ventilation and a decrease in $PaCO_2$. NIV is typically delivered in a spontaneous mode, where all breaths are patient-triggered and none is mandatory, so adjusting the ventilator frequency is not an option. For patients with chronic hypercapnia, ventilation should be adjusted to maintain an acceptable pH. No attempt should be made to normalize the $PaCO_2$ in such patients.

Increasing the PEEP level increases functional residual capacity (FRC), mean airway pressure, and PaO_2. Higher PEEP should also improve trigger synchrony in the setting of air trapping. In theory, decreasing PEEP should cause the opposite effects. In

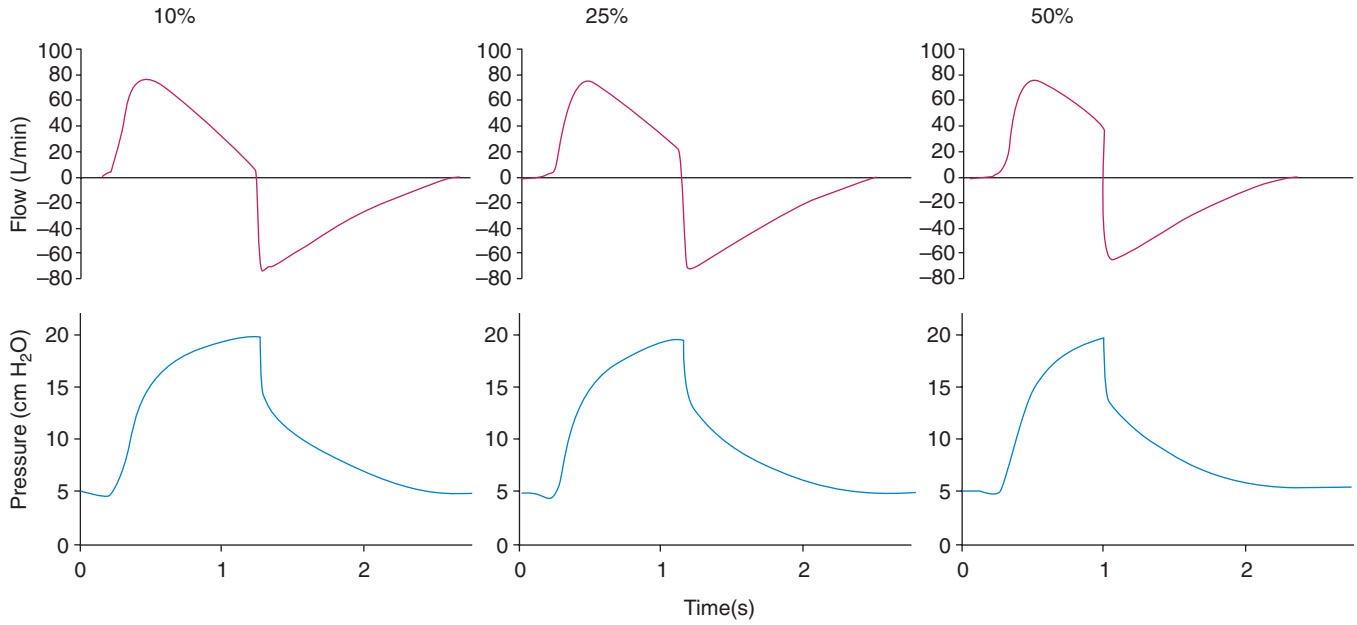

Fig. 50.16 Effects of changing the termination criteria during pressure support ventilation. Changing to a setting that ends inspiration at a higher percentage of peak flow results in shorter inspiratory time and lower tidal volume. This change is sometimes needed to improve patient–ventilator synchrony.

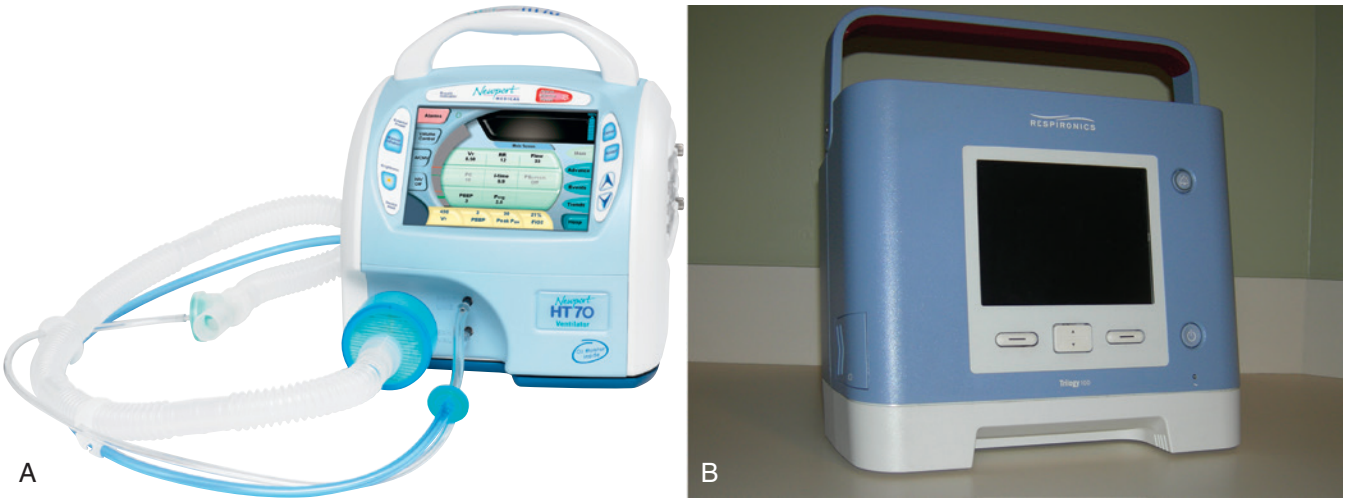

Fig. 50.17 Two examples of new generation portable ventilators that can be used in acute care, home care, or transport settings. (A) Covidien HT70. (B) Phillips Respironics Trilogy. (A, Courtesy Covidien; B, courtesy Phillips Respironics, Murrysville, PA.)

BOX 50.7 Initiation of Noninvasive Ventilation

1. Choose a location with appropriate monitoring based on the severity of the patient's condition. At a minimum, continuous pulse oximetry should be provided.
2. Position the patient with the head of the bed elevated ≥30 degrees.
3. Select a ventilator and an appropriately sized interface, assure interface compatibility with the type of ventilator to be used.
4. Turn on the ventilator and humidifier. Connect the interface to the circuit.
5. Explain the procedure and reason for therapy to the patient and answer any questions.
6. Set initial settings at a low level of support: PEEP 0–4 cm H_2O, ventilatory pressure 2–4 cm H_2O.
7. Hold the mask on the patient's face or have the patient hold the mask. Don't apply straps until he or she is familiar with the sensation of NIV. Provide coaching and encouragement
8. Adjust FiO_2 or bleed in O_2 flow to keep SpO_2 88%–95%.
9. When the patient becomes comfortable with the initial settings, assess for dyspnea and asynchrony. Increase inspiratory pressure until V_T is approximately 4–6 mL/kg predicted body weight or signs of respiratory distress improve. Increase PEEP to reduce asynchrony from missed triggers or to improve oxygenation.
10. Check for air leaks, especially around the eyes; reposition mask as required, adjust straps just tight enough to minimize air leak.
11. Reassess frequently for tolerance and efficacy of NIV (at least every 30 min) for the first 1 to 2 h.

TABLE 50.1 Expected Results of Changing Noninvasive Ventilator Settings

Setting	Adjustment	Expected Result
IPAP	↑	↑ V_T, ↑ minute ventilation, ↓ $PaCO_2$
	↓	↓ V_T, ↓ minute ventilation, ↑ $PaCO_2$
EPAP	↑	↑ FRC, ↑ PaO_2, ↓ V_T If intrinsic PEEP is present, fewer missed trigger attempts and improved patient–ventilator synchrony
	↓	↓ FRC, ↓ PaO_2, ↑ V_T, ↓ $PaCO_2$ Possible rebreathing of CO_2 with single-limb ventilator circuit if EPAP <4 cm H_2O
FiO_2	↑	↑ PaO_2; if bleeding O_2 into circuit, maximum expected FiO_2 is approximately 0.5; increasing O_2 flow >15 L/min may adversely affect triggering
	↓	↓ PaO_2
Rate control[a]	↑	↑ minute volume in timed modes, ↓ $PaCO_2$
	↓	↓ minute volume in timed modes, ↑ $PaCO_2$

[a]Rate control is generally set at 8–10 as a backup rate and not changed in spontaneous/timed mode.
EPAP, Expiratory positive airway pressure; *FRC,* functional residual capacity.

clinical practice, decreasing PEEP may not affect PaO_2 because the disease process resolves and alveolar stability improves.

If the assist/control mode is used for NIV, the rate setting should be less than the patient's spontaneous respiratory rate. Setting the rate in this manner allows the patient to maintain normal $PaCO_2$ by triggering the ventilator and provides a backup rate for safety if apnea occurs. If the patient's disease process limits the ability to trigger or breathe spontaneously, as in some neuromuscular disorders, the set rate has a direct relationship to minute ventilation and an inverse relationship to $PaCO_2$. These relationships may not always be the case in clinical practice and in a spontaneously breathing patient. Table 50.1 summarizes the effects of ventilator adjustments during NIV.

Aerosolized Medication Delivery

For patients on intermittent NIV, aerosol medications are often administered while the patient is off the ventilator. Removal of assisted ventilation from patients in ARF makes little sense and is unnecessary. Aerosol therapy can be delivered in the usual manner through an ICU ventilator used for NIV. With a noninvasive ventilator, positioning the nebulizer between the exhalation port and mask maximizes drug delivery.[92] A pressurized metered dose inhaler (pMDI) can be administered by placing an adapter or collapsible holding chamber in the same position in the circuit. Drug delivery should improve because the pMDI

MINI CLINI

Improving Patient–Ventilator Synchrony During Noninvasive Ventilation

Problem

An oncology patient with DNI orders is receiving NIV from a critical care ventilator with an oronasal mask. The ventilator is set in the PSV mode. Peak inspiratory pressure is 15 cm H_2O, PEEP is 5 cm H_2O, and flow trigger is 2 L/min. The patient has a nasogastric tube in place that is causing a large leak. The ventilator is self-triggering and fails to cycle into expiration when the patient exhales. The patient is dyspneic and appears uncomfortable.

Solutions

Large leaks can cause patient–ventilator asynchrony with ventilators that do not have leak compensation. Triggering and cycling are affected because the ventilator is unable to detect small changes in flow or pressure generated by the patient in the presence of a large leak.

1. Try to reduce the leak by repositioning the mask and placing a flat piece of gauze or hydrocolloid dressing between the mask and the nasogastric tube and another between the nasogastric tube and the patient's face.
2. Change to a critical care ventilator with a noninvasive mode or a noninvasive ventilator designed for ICU use.
3. If switching ventilators is not feasible, and a large leak is still present, adjusting the breath termination criterion or expiratory sensitivity to a higher setting can shorten inspiratory time, allowing the breath to end at a higher percentage of the peak flow.
4. If expiratory sensitivity is not adjustable, change to pressure assist/control mode. Observe the ventilator graphics to determine the patient's desired inspiratory time, and set the inspiratory time on the ventilator accordingly. Typically, critically ill patients should have inspiratory times of approximately 0.7 to 1 second (in some cases, 0.5 second).

is actuated only during inspiration. If the exhalation port is located in the mask or any other position distal to the nebulizer, much of the drug is lost via the exhalation port during both inspiration and expiration.

However, dosing for patients who need aerosolized bronchodilators should be adjusted based on patient response. The dose can safely be doubled to compensate for loss through the exhalation port and other inefficiencies.

Safe Delivery of Noninvasive Ventilation

Monitoring During Noninvasive Ventilation

In acute care or long-term care applications, clinicians must not lose sight of the goals of NIV.[2] The RT should confirm ventilator function and assess the patient on a regular basis for leaks, accessory muscle use, ventilator synchrony, comfort, and changes in vital signs and gas exchange. In the acute care setting, respiratory rate, heart rate, and gas exchange should improve within 1 to 2 hours after initiation of NIV. If there is no improvement after 1 to 2 hours on optimal settings, intubation should be considered. At a minimum, SpO_2 must be continuously monitored. In the acute care setting, continuous monitoring of heart rate and blood pressure is the safest practice. A higher level of monitoring is recommended for patients with acute hypoxemia, worsening condition, involvement of nonrespiratory organ systems, or persistent acidosis. If the patient cannot sustain ventilation independent of NIV for at least 1 hour, the same level of monitoring as any intubated patient should occur.

In the long-term care setting, improvement in gas exchange may require weeks to several months depending on daily use and compliance with the prescribed therapy.[2] Many ventilators have an internal memory card that records the hours of use and other data that can facilitate follow-up care. The patient should be assessed for complications, symptoms of hypoventilation and poor sleep quality, patient–ventilator synchrony, and other factors that affect compliance.

Patient Location

NIV can be initiated in any acute care location, including the emergency department, ICU, or general care floor. After NIV is initiated, patients should be transferred to an ICU or other inpatient location with continuous monitoring capabilities, skilled staff, and access to endotracheal intubation if required. Hypercapnic patients with COPD and a pH of 7.30 or greater and patients who can sustain ventilation without NIV for at least 1 hour can be managed safely on a general care floor. It is important that staff members be adequately trained before caring for patients on NIV. One-to-one monitoring of NIV patients for the first few hours by a trained, experienced RT, nurse, or physician is recommended.[93]

Weaning from Noninvasive Ventilation

At the present time, there is no standard approach to weaning from NIV. One weaning strategy is to decrease high levels of inspiratory and baseline pressure gradually to minimal settings as the acute disease process resolves. The length of time off the ventilator can be increased gradually as tolerated. Another approach is to continue NIV until there is a need to remove the mask. Patients often request to remove the mask after several continuous hours of NIV. The patient's ability to ventilate adequately is reassessed after 5 to 30 minutes based on tolerance. NIV is then either discontinued or restarted.

COMPLICATIONS OF NONINVASIVE VENTILATION

Serious complications of NIV, such as aspiration or pneumothorax, occur very rarely. On the other hand, undesirable side effects of NIV are more common, although less serious. Most side effects of NIV are related to the noninvasive interface, gas flow, or airway pressure. Table 50.2 lists the complications, their frequency of occurrence, and suggested remedies.

Air leaks can cause problems of various levels of concern, ranging from eye irritation and dry mouth to inability to trigger inspiration. Small air leaks should be expected during NIV. Large air leaks should be addressed immediately before they lead to patient–ventilator asynchrony or worsening gas exchange.[3] Choosing a right-sized mask for the patient can resolve or prevent many air leak problems. Changing to any mask that covers both nose and mouth resolves many problems related to large leaks through the mouth. Sometimes, ventilator settings must be adjusted if ventilation is adversely affected by the leak. Using a ventilator with leak compensation should resolve problems with leaks.

Mask-related side effects are the most common problems. Mask discomfort has been reported by up to 50%[2] of patients

TABLE 50.2 Side Effects and Complications of Noninvasive Ventilation

	Incidence[a]	Possible Solutions
Interface-Related Side Effects		
Discomfort	Common	Loosen straps Refit, reposition, or change interface
Erythema	Common	Apply skin barrier or hydrocolloid dressing or both Loosen straps, adjust forehead support, or add spacer Alternate the use of 2 masks
Claustrophobia	Infrequent	Change interface Consider anxiolytic
Pressure ulcer	Infrequent	Apply hydrocolloid dressing Change interface
Skin rash	Infrequent	Apply topical steroid or antibiotic
Air Pressure–Related or Flow-Related Side Effects		
Nasal congestion	Common	Administer inhaled corticosteroid or decongestant
Nasal dryness	Common	Avoid by using heated humidification with NIV Administer saline nasal spray
Sinus or ear pain	Common	Decrease ventilating pressure
Eye irritation	Common	Refit, reposition, or change interface
Gastric distention	Infrequent	Administer simethicone Decrease ventilating pressure
Serious Complications		
Aspiration	Rare	Avoid through careful patient selection Stop NIV, if status will allow
Pneumothorax	Rare	Decrease ventilating pressure Place chest tube, if tension pneumothorax
Hypotension	Rare	Decrease inflation pressure

[a]*Common*—occurs in 30% to 50% of patients; *infrequent*—occurs in approximately 5% to 20% of patients; *rare*—occurs in <5% of patients.

receiving NIV, and excessive discomfort decreases patient tolerance for NIV. Switching to a correctly sized mask or loosening the straps slightly is often all that it takes to resolve this issue. Skin damage is a problem that will worsen if not addressed immediately for patients who need to continue using NIV. RTs should keep a watchful eye on reddened areas, especially on the bridge of the nose. It is important to mitigate pressure-related skin damage through the use of various barriers to protect the skin and to use strategies to decrease actual pressure applied to the skin.

Complications related to air pressure and flow, such as nasal congestion and upper airway dryness, can be minimized by providing heated humidity whenever NIV is initiated. Decongestants and saline spray are sometimes needed to relieve symptoms of congestion. Sinus and ear pain and abdominal distension may be related to high inspiratory pressure; use of the lowest effective inspiratory pressure may prevent or alleviate these concerns.

Most major complications can be avoided with careful patient selection and use of the lowest inspiratory pressure that improves the patient's gas exchange and relieves symptoms. NIV should be avoided if the patient is at high risk for aspiration or is hemodynamically unstable. The risk of aspiration increases if inspiratory pressures greater than 20 cm H_2O are used. In general, the head of the bed should be maintained at 30 degrees to reduce the risk of aspiration during NIV.

TIME AND COSTS ASSOCIATED WITH NONINVASIVE VENTILATION

The cost-effectiveness of NIV is linked to appropriate patient selection, familiarity of staff members with NIV, and the success or failure of NIV in preventing endotracheal intubation. Staff time is one of the most valuable and expensive resources in hospitals. Time required by nurses and physicians during the first 48 hours of NIV is similar to the time required for invasive mechanical ventilation, but the time required by RTs for NIV is considerably greater than for invasive mechanical ventilation. However, another study showed that the time required by RTs was significantly greater for the first 8 hours but significantly lower during the next 8 hours. The RT must be present at the bedside during initiation of NIV to properly fit and reposition the mask, provide coaching and encouragement to the patient, titrate ventilator settings upward, and assess the effects of changes in settings. As the patient acclimates and begins to show improvement, the time required to maintain NIV should decrease to a level similar to invasive ventilation.[94–96]

SUMMARY CHECKLIST

- NIV is the application of positive pressure ventilation or CPAP with a mask or other noninvasive interface to improve gas exchange or decrease the work of breathing.
- The use of NIV to manage ARF has improved patient outcomes.
- Evidence supports NIV as the standard of care for managing patients with COPD exacerbations and acute cardiogenic pulmonary edema. There is less evidence supporting other indications for NIV.
- NIV may be justified in the management of ARF if selection criteria (see Box 45.2) are present, exclusion criteria (see Box 45.3) are absent, and the disease process is reversible.
- Acute cardiogenic pulmonary edema should be managed initially with CPAP of 8 to 12 cm H_2O. NPPV should be considered only if hypercapnia is present.
- NIV is beneficial in the management of patients extubated but at risk of reintubation and patients with DNI orders.
- Patients with ALS should receive NIV because it probably prolongs their lives.
- Caution should be used in applying NIV to patients with acute hypoxemic respiratory failure.
- NIV is most successful in the acute care setting when air leaks are minimal, the patient's severity of illness is moderate, respiratory acidosis is present, and improvement in gas exchange and vital signs occurs within 1 to 2 hours after NIV initiation.

- When NIV is used for hypoxemic ARF, intubation and invasive ventilation should be initiated if gas exchange and symptoms of respiratory distress do not improve within 1 to 2 hrs of NIV.
- NIV is typically administered in the PSV mode with PEEP.
- Airway pressure during NIV should be no higher than the setting needed to achieve therapeutic goals (ideally <20 cm H_2O).
- Oronasal and nasal masks meet most patient needs but various other designs are useful to address undesired side effects (mouth leak, skin damage, discomfort).
- Using an interface that is the proper size for the patient has significant positive impact on patient comfort and compliance with NIV.
- Although any ventilator can be used for NIV, ventilators designed to compensate for leaks can be expected to perform best.
- When NIV is provided to critically ill patients, the selected ventilator should have alarms and be capable of delivering a high FiO_2 range.
- Heated humidity (about 30°C) should always be provided with NIV.
- Aerosolized drugs can be administered without interrupting NIV.
- The initiation of NIV requires significant staff time, but after patients stabilize, the time required to maintain NIV is similar to invasive ventilation.

Extracorporeal Life Support

Clorinda B. Suarez and Alex George LeGassey

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe two primary goals of extracorporeal membrane oxygenation (ECMO).
- Describe the respiratory therapist's role as an ECMO specialist.
- List indications for initiating ECMO.
- Discuss ECMO physiology.
- Identify components of a typical ECMO circuit and their functions.
- Describe safety systems incorporated in or added to ECMO systems.
- Describe the reasons ECMO patients need to be anticoagulated.
- Describe how anticoagulation is typically monitored during ECMO.
- Identify typical sites for cannula placement for venoarterial (VA) support.
- Identify typical sites for cannula placement in venovenous (VV) support.
- Differentiate between VV, VA, extracorporeal CO_2 removal ($ECCO_2R$) and hybrid ECMO.
- Discuss the significance of ventilator support and management during ECMO.
- List risks and complications of ECMO.
- Discuss when and how to wean off ECMO support.

CHAPTER OUTLINE

tamponade
venoarterial (VA)
venous reservoir
venovenous (VV)

Extracorporeal life support (ECLS) encompasses several forms of mechanical support, all of which involve circulating blood from a patient to outside the body, through a mechanical gas exchanger, and returning it back to the patient. The most common form of ECLS is **extracorporeal membrane oxygenation (ECMO).** There are a few general types of ECMO support: **venoarterial (VA)**, **venovenous (VV)**, and the emerging **extracorporeal CO_2 removal ($ECCO_2R$)** and **hybrid** ECMO support. Distinctions between these types will be outlined later in this chapter.

ECMO is typically considered only in conditions when maximum conventional support has not been successful in delivering oxygen, removing CO_2, or providing adequate cardiac function. ECMO itself does not heal or fix the condition but rather is life-saving support for the most severe forms of acute heart and/or lung failure. Patients can be placed on ECMO for either cardiac or respiratory support, although at times both cardiac and respiratory support are indicated. ECMO will allow the heart and/or lungs to rest and help avoid the injury that can result from high levels of conventional mechanical ventilation. The primary goals of ECMO are to provide adequate **oxygen delivery** and remove carbon dioxide while the lungs and/or heart recover, or, in some cases, until the lungs or heart can be transplanted.

RULE OF THUMB ECMO is an option for the management of severe respiratory failure or cardiogenic shock refractory to conventional treatments for patients with reversible conditions or those eligible for transplantation.

THE RESPIRATORY THERAPIST AS EXTRACORPOREAL MEMBRANE OXYGENATION SPECIALIST

ECMO is provided to patients with life-threatening conditions. These situations require intense monitoring by clinicians with good critical thinking skills, strong knowledge of cardiopulmonary physiology, and technical adeptness. Clinicians who perform this role are referred to as ECMO specialists. Respiratory therapists (RTs) are often viewed as ideal professionals for this role due to their primary training; however, state licensure laws vary on whether RTs are permitted to perform ECMO. RTs have a strong science background, a thorough understanding of cardiopulmonary physiology, and the ability to handle and manage highly technical equipment. In many ECMO centers, RTs play a significant role in the ECMO program. They assist in the initiation of ECMO, provide hour-to-hour management of the ECMO support, and provide ECMO education for the many clinical services involved in the care of ECMO patients. Experienced RTs with good critical thinking skills receive additional training to take on the role of ECMO specialist. The specific role of an ECMO specialist varies among ECMO institutions but the essential education most often provided for this role follows the Extracorporeal Life Support Organization (ELSO) (Box 51.1).

INTERNATIONAL REGISTRY

With the development of an international ECLS registry in the late 1980s, centers providing ECMO began submitting data on the patients supported in centers from around the world. Since that time patient information, including patient age, diagnosis, type of support, complications, and outcomes have been compiled by the registry. Table 51.1 shows a summary of patients entered into the registry and their outcomes.[1]

BOX 51.1 ELSO Guidelines for Training of ECMO Specialists

- Introduction to ECMO
- Physiology of the diseases supported with ECMO
- Pre-ECMO procedures
- Criteria and contraindications for ECMO
- Physiology of coagulation
- ECMO equipment
- Physiology of VA and VV ECMO
- Daily patient and circuit management
- Emergencies and complications during ECMO
- Management of complex ECMO cases
- Weaning from ECMO
- Decannulation procedures
- Post-ECMO complications

Extracorporeal life support (ECLS) Registry Report, International Summary, July, 2018.

PATIENTS RECEIVING EXTRACORPOREAL MEMBRANE OXYGENATION

Newborns

In the 1980s, ECMO support was almost exclusively used for newborns with respiratory failure.[2] The primary conditions of patients placed on ECMO were meconium aspiration syndrome, respiratory distress syndrome, sepsis, congenital diaphragmatic hernia, and primary pulmonary hypertension.[2] Many of these patients also had pulmonary hypertension due to their primary condition. Improving oxygen delivery using ECMO support can greatly reduce pulmonary hypertension. ECMO was often the best option to improve oxygen delivery while the heart and lungs healed from the primary insult. According to the ECLS registry, more than 87,366 newborns have received ECMO for respiratory

BOX 51.2 Indications for Extracorporeal Membrane Oxygenation in Newborns

- Birth weight >2 kg
- Gestational age ≥34 weeks
- Maximum conventional ventilation
- Failure of optimal medical support including INO
- Lung disease considered reversible
- Absence of uncontrolled bleeding
- No uncorrectable cardiac anomalies
- No other lethal anomalies

INO, Inhaled nitric oxide.

BOX 51.3 Indications for Extracorporeal Membrane Oxygenation in Adult Patients

- Acute hypoxemic or hypercarbic respiratory failure
  - Sat <88 on FiO_2 1.0 with PEEP 15 cm H_2O
  - With plateau pressure >30 and trail of INO or epoprostenol
  - Respiratory acidosis with pH ≤7.20
- Normal RV/LV function
- Murray Score >3

PEEP, Positive-end expiratory pressure.

failure with survival rates to hospital discharge from 51% to 94% depending on the specific diagnosis.[1] Criteria for ECMO in newborns with respiratory failure are well established and are outlined in Box 51.2.[3] Contraindications for offering ECMO in the newborn population fall into two categories: absolute and relative. Absolute contraindications include lethal congenital anomalies, severe irreversible brain damage, and grade III or higher intracranial hemorrhage (ICH).[4] Relative contraindications include birth weight less than 2 kg, gestational age less than 34 weeks, irreversible organ damage (unless a transplant candidate), mechanical ventilation for greater than 10 to 14 days, as well as disease states with high probability of a poor prognosis.[4] The data collected over 25 years have been instrumental in establishing guidelines for newborn ECMO.

Development of less risky and less invasive therapies such as surfactants, nitric oxide, and improved ventilator strategies have decreased the number of newborns considered for ECMO.[5] ECMO support for newborn respiratory failure over the last few years has decreased significantly, accounting for less than 10% of total annual ECMO runs.[2]

Pediatric and Adult Patients

Although the number of newborns receiving ECMO continues to decline, ECMO cases in pediatric and adult patients are on the rise. This trend is likely due to improved strategies in ECMO management and advances in technology, which has led to better equipment for long-term support. During the past five years, the number of centers developing ECMO programs has increased greatly. Many new centers are providing ECMO primarily to pediatric and adult patients, with the largest increases in two categories: ECMO for cardiac support and ECMO as a bridge for lung transplant.[6] Unfortunately, guidelines for initiating ECMO support in pediatric and adult patients are less clear than the well-established guidelines for newborns. Criteria are generally associated with the type of support needed and are not always the same from center to center.[7] Box 51.3 provides an example of general indications for adult venoarterial extracorporeal membrane oxygenation (VA ECMO) and venovenous extracorporeal membrane oxygenation (VV ECMO). Contraindications for pediatric and adult patients generally fall into the absolute and relative categories. Some absolute contraindications typically include acute ICH or stroke, mechanical ventilation more than 7 days, in hospital CPR more than 60 minutes, irrecoverable heart disease, end stage liver disease, and contraindication to anticoagulation.[3] Some relative contraindications are advanced age, active cancer, chronic kidney disease, and multiorgan system failure more than three organs.[3]

RULE OF THUMB ECMO is inappropriate if (a) the condition is irreversible and/or (b) there is no timely, reasonable therapeutic option, and/or (c) there is a high likelihood of poor neurological outcome.[3]

PHYSIOLOGY

To understand ECMO physiology, it is essential to understand normal cardiopulmonary physiology. During normal circulation, blood is pumped from the right side of the heart to the lungs where oxygen and carbon dioxide are exchanged. From the lungs, blood is returned to the left side of the heart. The left heart then pumps oxygenated blood to the major organs and tissues. The amount of oxygen contained in blood leaving the heart is the arterial oxygen content. The absolute amount of blood pumped from the heart is **cardiac output.** Oxygen content times cardiac output equals the amount of oxygen delivered to the tissues.

Oxygen content is rarely measured directly at the bedside but it is critical in managing severely ill patients. Oxygen is carried in the blood in two forms: dissolved in plasma and in red blood cells bound to hemoglobin (as a percentage of the maximum saturation). These two components make up the total **oxygen content** in the blood. The amount of oxygen dissolved in plasma is a very minor portion of the total oxygen content. The dissolved portion is represented by the PO_2 (mm Hg) × 0.003. The majority of oxygen is bound to hemoglobin and is represented by the equation:

$$Hb \times \% \, SaO_2 \times 1.34.$$

Total oxygen content is calculated using the following equation:

$$O_2 \text{ Content } [(PO_2 \times .003) + (Hg \times SaO_2 \times 1.34)]$$

Therefore, with inadequate levels of hemoglobin, oxygen content is significantly diminished.

To understand the importance of hemoglobin, consider the following: A patient with a PO_2 of 40 mm Hg, with a typical oxygen saturation of 70% and a normal hemoglobin level (15 g), has more oxygen than a patient with a PO_2 of 100 (saturation 100%) and a low hemoglobin level (8 g). See Chapter 12 for more complete details on oxygen content and oxygen delivery.

EQUIPMENT

ECMO systems are intended to temporarily support the cardiac and pulmonary function of the patient who cannot maintain

MINI CLINI

Problem

Hemoglobin level in a patient who is bleeding has dropped from 15 to 10 g/dL. His PO_2 remains unchanged at 90 mm Hg. How much would his O_2 content change?

Calculate the change in O_2 content.

$$(PO_2 \times .003) \times (Hg \times SaO_2 \times 1.34)]$$

The O_2 content with a hemoglobin of 15 is 20.37.
The O_2 content with a hemoglobin of 10 is 13.67.

Discussion

This clearly demonstrates the importance of hemoglobin in providing adequate oxygen content. Delivery of oxygen is dependent on the oxygen content and the cardiac output. When oxygen content is low, the body will normally respond by increasing the cardiac output. Total delivered oxygen (DO_2) can be calculated using the following equation:

$$O_2 \text{ Delivery } [(PO_2 \times .003) + (Hg \times SaO_2 \times 1.34)] \times (HR \times SV) = DO_2$$

When cardiac function is impaired, the ability to increase cardiac output is altered and will result in inadequate amounts of oxygen delivered to the tissues. When this happens, anaerobic metabolism occurs and lactic acid is produced. Alternatively, carbon dioxide is produced from systemic metabolism. With normal adequate lung function and normal blood flow through the lungs, appropriate amounts of carbon dioxide are excreted and spontaneous ventilation keeps PCO_2 within acceptable ranges. When altered states of metabolism increase CO_2 production, it is imperative that the lungs are able to remove more CO_2. In diseased lungs or conditions that alter blood flow to the lungs, higher levels of CO_2 remain in the blood. When maximum conventional support fails to provide adequate delivery of oxygen to the tissue or inadequate removal of carbon dioxide occurs, a patient who has no absolute contraindications can be considered for ECMO.

MINI CLINI

Problem

The patient has a cardiac output of 5 L/min and is on 4 L/min of VA ECMO support. Eighty percent of the patient's cardiac output is therefore oxygenated by the artificial oxygenator and is 100% saturated. The patient has essentially no lung function. His SvO_2 is 65% with a PO_2 of 35 mm Hg. Twenty percent of the patient's cardiac output goes through the nonfunctional native lungs where no oxygen is added.

What is the patient's SaO_2 when blood from the ECMO-supported cardiac output and the native cardiac output mix?

Discussion

The combined saturation can be calculated by multiplying the % saturation of each portion of the cardiac output. This patient's combined saturation can be determined by multiplying the 80% (4 of 5 L/min) of the cardiac output that becomes 100% saturated by the ECMO oxygenator (0.8×1), and then multiplying the 20% (1 of 5 L/min) of the output that returns to the native lungs 65% saturated, (0.2×0.65) and adding the results of each

$$(0.8 \times 1) + (0.2 \times 0.65) = 0.93$$

The mixed saturation of this patient would be 93%. To achieve a higher saturation, a larger portion of the cardiac output could be pumped through the oxygenator and saturated to 100%. The portion of cardiac output that would remain through the native lungs would decrease. With a smaller portion of blood saturated to only 65%, the combined saturation would increase.

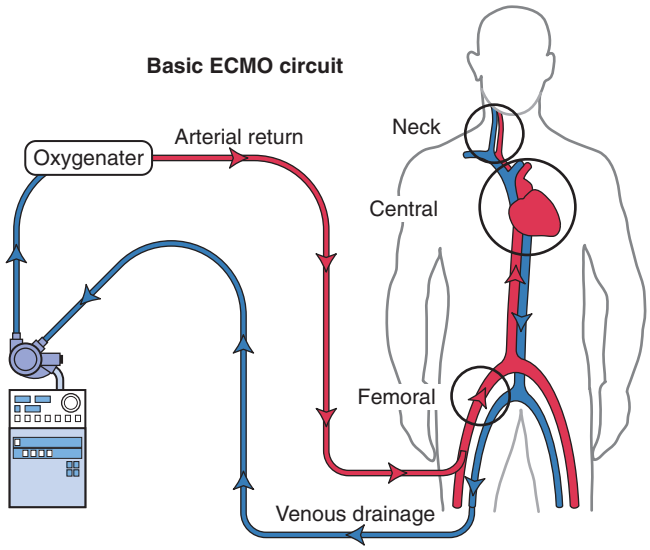

Fig. 51.1 Illustration of the blood pathway of an extracorporeal membrane oxygenation *(ECMO)* circuit. Blood drains through the circuit to a blood pump, which pushes it through an artificial lung oxygenating the blood and removing carbon dioxide (CO_2) before returning the blood to the body.

adequate tissue oxygen delivery. Basically, ECMO has the task of pumping the blood, delivering oxygen to the blood, and removing CO_2. The circuit consists of polyvinylchloride (PVC) tubing segments that have different inner diameters depending on the patient's size: ¼-inch for a neonate to ⅜-inch for pediatric/adult sized patients. Some circuits contain a heparin-based coating to reduce the response of blood to nonendothelial surfaces and to decrease the risk of clot formation. The circuit is generally custom designed using the shortest amount of tubing necessary to allow less resistance to flow and to decrease circuit volume. This is of particular importance for the newborn population because larger circuit volumes result in hemodilution and require additional transfusion of blood products. Infusion ports can be added along the tubing for infusing medications in patients who have limited intravenous (IV) access. These ports can also be an option for access when continuous veno-venous hemofiltration (CVVH) is required. Blood is drained from the patient into the circuit by either a centrifugal or roller pump. From the pump, it goes through an artificial lung, referred to as an oxygenator, where oxygen is added and CO_2 removed (Fig. 51.1).

The ECMO system is powered by the blood pump. The pump function is to draw blood in, either from a **venous reservoir** (the bladder) or directly from the venous circulation, pump it through the oxygenator, and then back into the patient. The two types of pumps frequently used are the centrifugal (or vortex) pump and the roller (or occlusive) pump.

The centrifugal pump is made up of polycarbonate cones attached to a magnetic disk that is attached to a controller (Fig. 51.2). The cones spin at an adjustable rate when attached to the controller and produce forward flow by imparting kinetic energy to the fluid (blood) in a rotating pump head. The **pump flow** provided is therefore dependent on both the patient's **preload** (the volume in the right side of the heart) and **afterload** (the

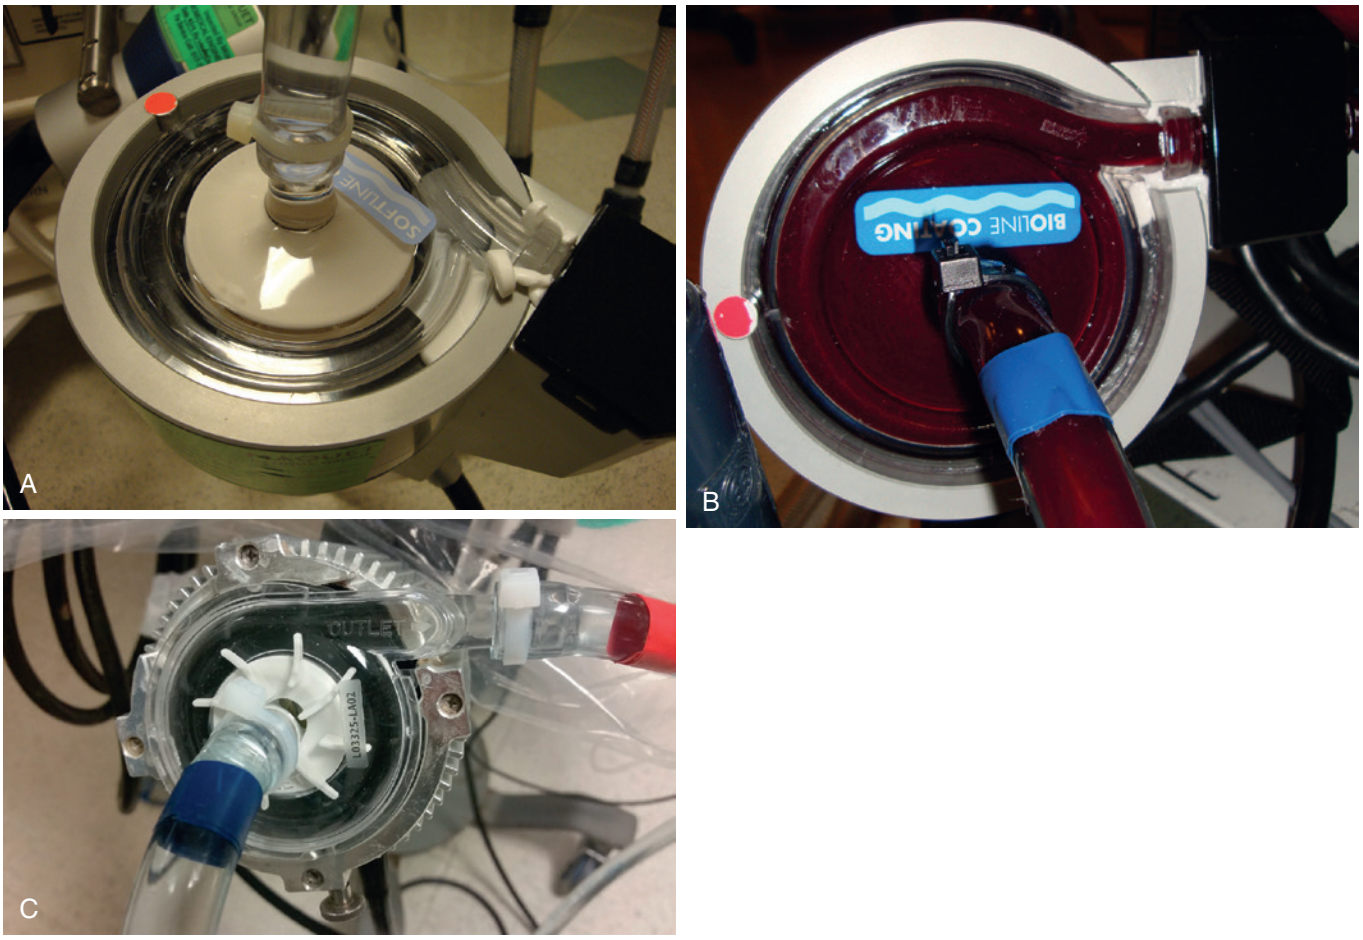

Fig. 51.2 The centrifugal pump is made up of polycarbonate cones, attached to a magnetic disk that is attached to a controller. The cones will spin at an adjustable rate when attached to the controller and produce forward flow by imparting kinetic energy to the fluid (blood) in a rotating pump head. (A) Maquet Rotaflow without blood. (B) Maquet Rotaflow with blood. (C) Abbott cetragam pump.

resistance against the pump outlet from the left side of the heart). Because the centrifugal pump is not occlusive (like the roller pump), pump flow will vary despite a set rate per minute (RPM). A decrease in preload or increase in afterload can cause a decreased pump flow. Centrifugal pumps have the advantage of not being affected by gravity for drainage. However, pump flow can change drastically at a set RPM with changes in preload and afterload. Therefore a mechanism for monitoring pump flow changes is essential. Centrifugal pumps can operate at a wide range of RPMs—often as high as 5000—but higher RPMs can result in significant hemolysis.

The roller pump functions by occluding a segment of the circuit tubing called the *raceway*. Blood is drained by gravity from a venous cannula into the venous reservoir, and then pulled into the pump at a given RPM. The pump contains two rollers positioned opposite each other. Blood is displaced by the appropriate compression of the rollers on the tubing. Roller pumps have been, for the most part, replaced by the safer, more compact centrifugal pumps and only remain at some centers to service the smaller neonatal populations.

Blood moves from the system pump to an oxygenator which functions as the lung of the ECMO system. The oxygenator contains hollow fibers for blood and gas to pass through. Gas flow, referred to as the **sweep flow,** is provided by a blender, which is flowing in the opposite direction of the blood flow (Fig. 51.3). The blender is adjusted to ensure the hemoglobin of the blood leaving the oxygenator is 100% saturated with a PO_2 greater than 250 mm Hg. As poorly saturated venous blood with very low partial pressure of oxygen is pumped into the oxygenator, it traverses through fibers that are aligned with other fibers containing gas with a high partial pressure of oxygen. Oxygen diffuses from the fibers with a high concentration of oxygen to the blood with a lower concentration. There is no CO_2 in the sweep flow. Therefore the carbon dioxide in the blood diffuses into the sweep fibers and is flushed out of the oxygenator. The higher the sweep flow is set, the more CO_2 is eliminated. There is a range of effective sweep flows along with maximum blood flow for the different sizes of oxygenators (Table 51.2). From the oxygenator, fully saturated blood with the desired carbon dioxide level is pumped back to the patient either to a vein (VV support) or to an artery (VA support). The pump speed (RPM) is adjusted to allow the appropriate amount of the patient's blood volume to be oxygenated while the sweep flow rate is adjusted to maintain the desired CO_2 level.

Fig. 51.3 An oxygen flowmeter is connected to the circuit blender. Sweep flow is delivered into the artificial lung delivering up to 100% oxygen. A second flowmeter allows for analysis of the actual percent of oxygen delivered.

Fig. 51.4 Blood warmer/cooler, a device that will warm or cool the blood, circulates sterile water (A) and sends the heated or cooled fluid through hoses attached to the artificial lung and surrounds the fibers containing the blood to warm or cool it (B) (right figure).

TABLE 51.2 Examples of Oxygenator Specifications

Oxygenator	Prime Volume	Maximum Sweep	Minimum Blood Flow	Maximum Blood Flow
Quadrox iD Adult	250 cc	15 lpm	500 cc/min	7 lpm
Quadrox iD Pediatric	81 cc	5.6 lmp	200 cc/m	2.8 lpm

RULE OF THUMB The ratio of sweep flow to pump flow is often 1:1. When using 4 L/min pump flow, typically the sweep flow would be initiated at 4 L/min. The oxygenator functions to provide gas exchange much like native lungs perform gas exchange—oxygen diffuses into the blood from a gas source with a higher partial pressure and CO_2 diffuses out of the blood into a gas source with a lower partial pressure.

Additional equipment used with ECMO support includes a thermoregulation device referred to as the heater/cooler (Fig. 51.4). As blood leaves the patient and circulates through the ECMO circuit, a considerable decrease in blood temperature can occur because the tubing that blood flows through is exposed to ambient temperature. Gas flow through the oxygenator is also cool, resulting in evaporative losses. Therefore, especially in neonates, active warming is required to maintain a normal body temperature. Temperature-adjusted sterile water circulates around the fibers containing blood and allows appropriate temperature control of the blood returning to the patient. These devices have the potential to maintain hypothermic states when appropriate. Recent evidence has demonstrated that mild decreases in core temperature may have a salvaging effect on the brain[8] and can be easily achieved during ECMO support.

Pressure monitoring is a standard part of the circuit. Circuit pressures are measured before and after the oxygenator and indicate the absolute pressure in the circuit along with changes in resistance across the oxygenator (Fig. 51.5). The change in resistance most often indicates development of clots within the oxygenator. Changes in pressures can alert the ECMO specialist to identify emerging situations such as kinks, clots, and, in VA support, changes in hemodynamics.

Fig. 51.5 Oxygenator/pressure monitoring. Pressure transducers are attached to ports before and after the artificial lung with reading displayed on the bedside monitor. "SP5" indicates the pressure before the oxygenator and "SP6" indicates the pressure after the oxygenator. The difference between the two pressures is an indication of the resistance to blood flow through the oxygenator. Increases in pressure difference are usually a result of clot formation.

RULE OF THUMB Monitor pre- and post-oxygenator pressures frequently. Changes will alert clinicians to clots in the oxygenator. Increases in pre-**membrane pressure** only = increased resistance within the oxygenator. Increases in pre- AND post-membrane pressures = increased resistance AFTER the oxygenator.

A pressure monitor can also be placed on the drainage line to detect excessive siphon on the system. Alarms and servo regulation can be used in association with these pressure monitors to create safer systems. Pressure monitoring is either integrated into the ECMO system or additional pressure transducers can be added.

As noted earlier, blood flow is regulated by dialing in a set RPM, which results in flow. The flow is monitored using ultrasonic devices that are either incorporated into the system or added to the circuit. Many systems will display a calculated flow but the accuracy of that flow is dependent on many factors. Flow is measured to assure appropriate occlusion when using roller pumps and to check variations in flow common with centrifugal pumps. Audible alarms are usually set to alert the ECMO specialist of changes in pump flow.

Air (bubble) detectors can be useful in identifying the presence of air in the ECMO circuit. They can be used on either the arterial or venous side of the circuit and detect inadvertent air passing through the system. These devices can function to stop support when air is detected or sound an alert. False alarms can be problematic because support to the patient is stopped and will often produce significant instability for the patient until support is resumed. The ECMO specialist must be able to immediately distinguish true presence of air bubbles from false alarms rapidly and take the appropriate action for either situation.

Fig. 51.6 Example of inline oxygen saturation monitoring that can be used to trend the saturation of blood draining into the extracorporeal membrane oxygenation circuit.

Additional blood parameter monitoring can be incorporated into an ECMO system through the integration of a noninvasive optical cable. These devices help trend continuous values such as venous saturations, arterial saturations, hemoglobin, hematocrit, and temperature (Fig. 51.6). They are generally considered optional, although newer consoles have integrated monitoring as standard and the use of each varies from institution to institution (Fig. 51.7).

Unlike some of the optional parameters monitored during ECMO support, monitoring of anticoagulation parameters on a routine basis is essential. The **activated clotting time** (ACT) is most often used as the primary test for anticoagulation at the bedside. The ACT is a low-cost point of care test that gives a quick assessment of anticoagulation. There are several types of devices using a small volume of blood that can determine the number of seconds it takes for blood to clot (Fig. 51.8). It is most often used in conjunction with other parameters to assess the patient's overall state of anticoagulation.

ANTICOAGULATION MANAGEMENT

Anticoagulation of the ECMO patient is a vital part of an ECMO run starting at **cannulation**. The blood's natural reaction is to activate coagulation when exposed to the nonbiologic surfaces of the cannulas and circuit. Therefore anticoagulation is essential prior to cannula insertion and throughout the ECMO course. Heparin, the most commonly used anticoagulant, is easily reversed and widely available. It is prepared from bovine lung or porcine intestines and can be monitored at the bedside. Heparin inhibits the conversion of prothrombin to thrombin and activates antithrombin III (AT III). It does not break up clots, but rather decreases the risk of their forming. A bolus of heparin is administered just prior to cannulation. ACT levels are assessed shortly after to ensure the desired levels of anticoagulation have been achieved. The bolus dose can vary based on the patient's baseline state of coagulation. Once the patient is on ECMO, periodic ACTs help assess the trend in coagulation and assist in fine-tuning the heparin

maintenance doses. The ACT can be affected by many factors including anemia, hypofibrinogenemia, hypothermia, hemodilution, thrombocytopenia, qualitative platelet abnormality, and other coagulation factor deficiencies. Reports in the literature[9] and the anticoagulation guidelines recently published from ELSO[10] suggest that using more than one parameter may be helpful in the assessment of anticoagulation during long-term support. Monitoring of additional parameters on a routine basis and implementing a guideline in response to the combined results may be useful in assessing the overall coagulation/anticoagulation status of patients requiring long-term extracorporeal support.

Fig. 51.7 Extracorporeal membrane oxygenation console with integrated pressure monitoring.

An example of an anticoagulation protocol can be seen in Table 51.3.

Heparin levels (anti Xa) may more accurately assess heparin-induced anticoagulation and are less affected by abnormal physiologic states than are ACT values. ACT levels may better reflect the overall anticoagulation status of the patient, but are not specific for heparin effects versus clotting deficiencies. The two values may be used together to better assess appropriate heparin and blood product needs. A number of studies in ECLS patients have shown a superior correlation of the anti Xa assay

MINI CLINI

Problem

The patient is being maintained on a heparin infusion to achieve the prescribed ACT range of 180–200 s. Over the past 2 h, chest tube output has increased significantly, resulting in a decrease in hemoglobin, requiring multiple blood transfusions.

Discussion

The ECMO specialist recommends lowering the desired ACT range to decrease the amount of bleeding, which can be achieved by lowering the hourly heparin infusion rate and repeating the ACT to assess the change. Vigilance in assessing the circuit for evidence of increased clot formation is essential.

Fig. 51.8 Two types of point-of-care activated clotting time *(ACT)* devices with their cartridges. *Left*, Medtronic ACT Plus. *Right*, Abbott i-STAT ACT monitor.

TABLE 51.3 Example of Anticoagulation Protocol

Laboratory Test	Frequency	Goals	Normal
ACT	Q1 until results in desired range ×2 h, then Q4 while on heparin	As ordered, typically 160–200 (as low as 140 in bleeding patients, 200–240 at pump flows <2 L/min	90–120 s
ATIII	Pre-ECMO baseline Monday, Wednesday, and Friday at 8 AM	Level maintained >40%	40–100%
anti-Xa	Q 24 h at 8 AM	Target levels of 0.3–0.7 IU/mL	N/A
aPTT	Q 24 h	50–80 s	22–35 s
PT	Q 24 h	Normal	11–14
Fibrinogen	Q 24 h	Keep in normal range (250–300 mg/dL)	250–300
Platelets	Q 6 h	>60,000/μL	150–400/μL

ACT, Activated clotting time; *ECMO*, extra corporeal membrane oxygenation; *PT*, prothrombin time.

to heparin dose.[11] The presence of AT III in blood is also essential to achieve the desired levels of anticoagulation. AT III levels may be increased by infusing fresh frozen plasma (FFP), a blood product that contains AT III, or using recombinant AT concentrate, a concentrated form of AT III that is more effective than FFP. However, AT concentrate is significantly more costly, and therefore the cost-benefit ratio is often considered. Thermoelastogram (TEG) is an emerging method of assessing anticoagulation.[10] A small sample of blood is taken from a patient and rotated gently in a specific fashion to imitate sluggish venous flow and activate coagulation. TEG provides comprehensive whole blood hemostasis testing that can help assess bleeding and thrombotic risks, and also monitor antithrombotic therapies. Some more common coagulation values assessed during an ECMO run include prothrombin time (PT) and activated partial thromboplastin time (aPTT). The aPTT may not be as accurate at assessing anticoagulation during ECMO in newborns and small children when heparin is used as the anticoagulant.[12] However, it can be a better assessment of anticoagulation when direct thrombin inhibitors are used to anticoagulate ECMO patients who have a sensitivity to heparin.[13] Patients with sensitivity to heparin, identified by heparin-induced thrombocytopenia, may be managed on ECMO through the use of direct thrombin inhibitors, such as lipirudin and bivalrudin. When using these forms of direct thrombin inhibitors, the accuracy of ACTs is less dependable. Despite diligence with maintaining appropriate levels of anticoagulation, clot formation within the circuit remains a major complication during ECMO.[1]

RULE OF THUMB Patients receiving ECMO support require significant levels of anticoagulation, making bleeding a risk and common complication incurring during ECMO.

CANNULAS

Cannulas are inserted to provide direct access to the patient. Cannula size is crucial to the amount of support an ECMO system can provide; the smaller the internal diameter of a cannula, the higher the resistance of the flow. When placing venous cannulas, the largest possible cannula should be placed to ensure adequate flows. Cannulas are sized by their outer diameter, in French units. All cannulas are tested for their pressure/flow relationship and an M number determined. The M number represents a resistive factor that can be used to approximate the expected flow at a specific pressure difference. Cannulas vary in internal size, length, port placement, size, and number (Table 51.4). This information is important to know during the cannula selection process. Selection of the appropriate cannulas is dependent on the intended insertion sites, age/size of the patient, and the type and amount of support needed. They are designed to be placed through a surgical cut-down, via sternotomy or by percutaneous insertion.

There are two types of venous cannulas: single and double lumen. Venous cannulas have several ports to allow for maximal drainage. Many are wire reinforced to decrease the potential for kinking. Some are coated to avoid an antiinflammatory response and decrease the risk of clot formation. Two types of double-lumen cannulas (DLCs) are available for VV support (Fig. 51.9). Newborn DLCs are inserted into a single vein and allow drainage of desaturated blood and return of oxygenated blood through the same vessel. They have multiple side ports to drain blood. The drainage lumen is typically larger than the return lumen, which allows for better drainage of venous blood. The return lumen has a single outlet and blood is pumped through the cannula by the positive pressure created from the pump's rotation.

The BiCaval DLC is another approach to VV support. It needs to be inserted under fluoroscopy or echocardiography guidance (Fig. 51.10) because appropriate positioning is crucial and can be difficult without imaging. The drainage ports are positioned in both the superior and inferior vena cava with the return lumen positioned at the entry of the right atrium. These DLCs are a single cannula with two lumens, the drainage lumen and the return lumen. Recirculation is expected when using a DLC. **Recirculation** occurs when oxygenated blood from the return

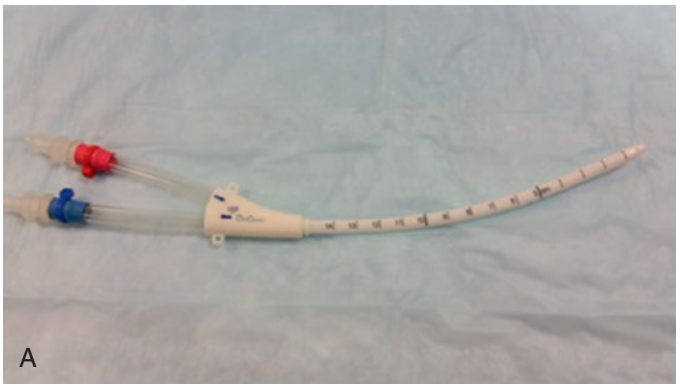

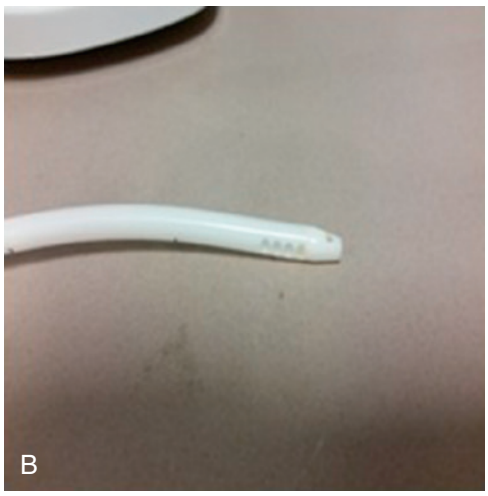

Fig. 51.9 Double-lumen, single-vessel cannulas used for venovenous extracorporeal membrane oxygenation. (A) Ports on one side of the cannula sit in the right atrium and are used to drain blood into the circuit. (B) The end return port is where blood is returned back into the respiratory therapist Atrium and directed toward the tricuspid valve.

lumen is siphoned back into the drainage side of the cannula. This is apparent when both drainage and return lines appear similar in color, with the patient showing signs of oxygen desaturation. Position is critical in a DLC to avoid recirculation. Careful monitoring of the cannula is essential. Excessive recirculation will occur if the cannula is rotated out of optimal position, resulting in inadequate support.

Arterial cannulas typically have a single outlet and they are often wire reinforced and coated. Ideal arterial cannulas should be as short as possible and have thin walls. The size inserted is based on the internal diameter of the artery selected for cannulation. The narrow diameter of the arterial cannula creates the highest amount of resistance in the ECMO circuit. It is the conduit that allows for the return of oxygenated blood back to the patient's circulation (Fig. 51.11).

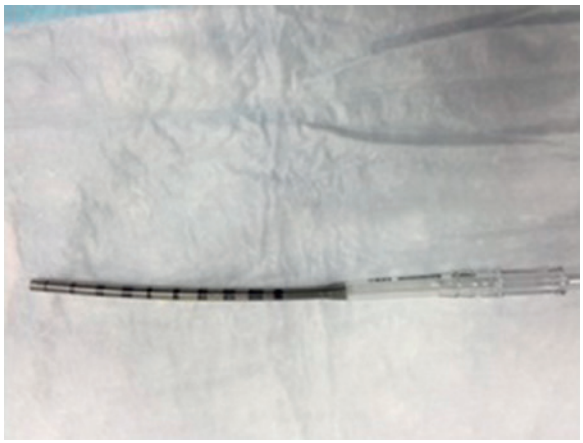

Fig. 51.11 Arterial cannula with a single end port.

TYPES OF SUPPORT

There are two primary types of ECMO support: VA and VV. VA support is partial cardiopulmonary bypass, providing both cardiac and pulmonary support. The degree of bypass depends on the underlying condition. VV does not bypass the cardiopulmonary circulation and thus only provides pulmonary support. Another emerging type is $ECCO_2R$, which is also referred to as pumpless ECMO. $ECCO_2R$ is primarily for CO_2 removal at low pump flows and requires the patient's own hemodynamics to pump blood through the oxygenator. This type of support is most effective at achieving adequate ventilation when native lung function is significantly impeded.[7]

Hybrid ECMO is also appearing in some institutions and involves extra drainage or return cannulas.

Venoarterial Extracorporeal Membrane Oxygenation

In VA ECMO a portion of the patient's blood volume is drained from the venous circulation to the ECMO circuit where gas exchange occurs (Fig. 51.12). Fully saturated blood is returned through a cannula in the arterial circulation, which results in hemodynamic support. In VA ECMO, a minimum of two cannulas are placed, with at least one in an artery and one in a vein. The cannulas can be placed by means of a surgical cut-down, through a sternotomy or percutaneously. The diameter, length, and position of the cannula will determine the potential flow that can be achieved. The typical artery accessed in the newborn would be the right common carotid artery. In larger patients, placement can be in a left or right femoral artery, axillary artery or placed transthoracically, directly into the aorta. When the femoral artery is cannulated, it is prudent to place a small reperfusion line to supplement blood flow to the lower leg and decrease the risk of limb ischemia (Fig. 51.13). In some patients, only a portion of their cardiac output is pumped through the ECMO circuit while some blood flow continues through the native circulation. The blood from the ECMO circuit returns to the patient, bypassing the heart and lungs, and mixes with the native circulation. The total oxygen content depends on the proportions of blood through the two circulations. Similarly, the measured PCO_2 in the patient's arterial circulation will be a result of the combined relatively low PCO_2 returned from the ECMO circuit and the PCO_2 in the blood coming through the native circulation. The primary advantages of VA ECMO are that it allows the heart to rest and reduces cardiac oxygen consumption while providing adequate systemic organ perfusion with oxygenated blood. There is no chance of recirculation and less ventilator support is needed. VA ECMO is best indicated for cardiogenic shock, or as a bridge to a ventricular assist device or heart transplantation. A disadvantage of VA ECMO is the need to cannulate an artery, which will require repair or ligation when support is no longer needed. See Box 51.4 for differences in VA and VV support.

Fig. 51.13 A secondary blood return line (reperfusion line) is placed in this femoral artery cannula to supplement blood flow to the lower limb and prevent limb ischemia.

RULE OF THUMB In VA ECMO, if a femoral artery is cannulated then a distal perfusor should also be placed. Because the arterial cannula occludes much of the blood supply to the lower leg, this reperfusion will help provide blood flow to the leg. They are smaller lines, so flow should be monitored to assess for clots.

Venovenous Extracorporeal Membrane Oxygenation

As in VA ECMO, VV support involves a portion of the patient's blood volume being drained from the venous circulation to the ECMO circuit where gas exchange occurs. However, blood is returned back to the venous circulation either through the same

BOX 51.4 Characteristics of Venoarterial and Venovenous Support

Venoarterial ECMO
- Typically used for patients with cardiovascular failure
- Partial cardiopulmonary bypass
- Decreases preload
- Increases afterload
- Effects hemodynamics

Venovenous ECMO
- Typically used for patients in respiratory failure
- Can be done with multiple cannulas or a DLC
- Provides no hemodynamic support
- RV function may improve with increased S_vO_2

DLC, Double-lumen cannula; *ECMO,* extracorporeal membrane oxygenation.

Fig. 51.14 Common cannula used for venovenous extracorporeal membrane oxygenation (VV ECMO) support in newborns. Babies are often cannulated with a double-lumen cannula through the right internal jugular for VV ECMO.

cannula via the return lumen or via a separate cannula into another vein (Fig. 51.14). The typical cannulation site for the newborn is in the right internal jugular vein. In larger patients, common sites are the right and left femoral veins, right internal jugular vein, pulmonary artery, or right atrium. Pulmonary artery and right atrium cannulations involve cannula placement via hemisternotomy or open chest surgery. Unlike VA ECMO, blood is returned to the venous circulation, therefore providing no direct cardiac support. Oxygenated blood that is lower in CO_2 returns to the venous circulation and mixes with the remaining cardiac output. The total oxygen content and measured CO_2 is a result of this mix and can be affected by the patient's mechanical ventilation settings or spontaneous minute ventilation. Two distinct advantages of VV ECMO are lower risk of cerebral air embolism and no need to ligate or repair an artery. VV ECMO is often indicated for patients with acute respiratory failure due to viral or bacterial pneumonias.[14] VV is emerging as a bridge to lung transplant.[15] ECMO in the pre–lung transplant patient allows for improved gas exchange and decreases the risk of complications from high levels of mechanical ventilation. It can also prevent further deconditioning. The patient on VV ECMO can be extubated, awake, and ambulated while waiting for available lungs.[16]

RULE OF THUMB VA ECMO is primarily used to support patients with cardiac failure. VV ECMO is used primarily to support patients with respiratory failure.

Extracorporeal Carbon Dioxide Removal

The primary goal of $ECCO_2R$ is the removal of carbon dioxide as opposed to the delivery of oxygen. This can be achieved using veno-venous support, which requires the additional use of a centrifugal pump to move the blood, or by using arterio-venous support. Arterio-venous support relies on the patient's native cardiac output to move the blood from the high (arterial pressure) system to the low (venous pressure) system, therefore eliminating the need for a centrifugal pump. There are advantages and disadvantages to both types of support. In veno-venous $ECCO_2R$, the use of a centrifugal pump generates negative pressure, which is both harmful to blood elements as well as a risk for entraining air. However, this type of support usually allows for single-site access, which allows the patient to ambulate and decreases the risk of infection from additional vessels being accessed. In arterio-venous support, the centrifugal pump is eliminated and the harmful effects on blood elements as well as risk of air is also eliminated. The disadvantage of arterio-venous support lies in the access of a major artery, which significantly increases the risk of bleeding and makes ambulation more difficult because a minimum of two vessels must be accessed.

Extracorporeal carbon dioxide removal has shown some limited benefit in patient populations of acute respiratory distress syndrome and acute-on-chronic lung disease. In the group of acute respiratory distress syndrome, the limitations of providing low tidal volume ventilation is the inability to eliminate carbon dioxide and improve the accompanying acidemia. $ECCO_2R$ may be able to provide a solution to this problem by clearing carbon dioxide and allowing for lower tidal volume ventilation as well as lower plateau pressures, both of which have been shown to improve survival. Currently, the REST-trial is undergoing enrollment in the United Kingdom to see whether lower tidal volume ventilation in combination with $ECCO_2R$ improves mortality in patients with hypoxemic respiratory failure.[17] The other patient population where $ECCO_2R$ may be considered is in patients with primary hypercapnic respiratory failure, such as chronic obstructive pulmonary disease (COPD) and asthma. This may be the most appealing patient population in its ability to avoid both noninvasive and invasive mechanical ventilation, thus avoiding the many complications that come with both. The VENT-AVOID trial is currently enrolling patients with COPD to see if there is a reduction in ventilator days by using $ECCO_2R$.[18]

Extracorporeal carbon dioxide removal is far more efficient than oxygenation, and therefore lower blood flow rates can adequately support the patient. This has some advantages as well as disadvantages. The major advantage is that the lower blood flow can allow for smaller tubing and cannulas, which allows for easier mobility of the patient as well as a smaller area for blood to come into contact with. The disadvantage of the lower blood flow rate is that it has a higher risk of forming clots in the circuit, and therefore anticoagulation may need to be

higher than in the other forms of extracorporeal support. This will then increase the risk of bleeding for the patient. Another limitation of $ECCO_2R$ is the patient population itself. Patients that have end-stage lung disease may be unable to be weaned from the circuit and discontinuing care may become difficult because most patients are awake and interactive.

Hybrid Extracorporeal Membrane Oxygenation

The use of additional drainage or return cannulas may be necessary, depending on the patient condition. Flow may be insufficient for patients with small venous drainage cannula and an additional drainage cannula may be added for increased support. If a patient is on VA ECMO and an additional drainage cannula is added, the abbreviation will be documented as VV-A. Another common type of hybrid ECMO is for patients who are cannulated in their femoral vein and artery for cardiac support. If those patients have respiratory failure in combination with their primary cardiac failure and their heart recovers before their lungs, deoxygenated blood will be ejected from their left ventricle to their brain causing cerebral hypoxia. If ventilator management cannot be optimized to correct this hypoxia, an additional return cannula can be added to their central venous system. This will provide both partial respiratory and cardiac support. The patient is supported from a respiratory standpoint by delivering fully saturated blood to the right atrium and increasing mixed venous oxygen saturation. The cardiac system also still receives a level of support by decreasing preload to a recovering heart. The abbreviation for this partial veno-venous and veno-arterial support will be V-AV. The letter to the left of the hyphen will always refer to the drainage cannula and the letter to the right of the hyphen will always refer to the return cannula. The above two descriptions are just a small example of ways to support an ECMO patient. Limitations to hybrid ECMO are based on accessible vessels as well as the experience of the surgeon.

RULE OF THUMB $ECCO_2R$ is used to treat primary hypercapnic respiratory failure without hypoxemia.

INITIATION OF SUPPORT

ECMO is frequently initiated in the intensive care unit (ICU). Specific circumstances may dictate ECMO being initiated in the operating room, cardiac catheterization lab, emergency room or many other locations in the hospital. A formal activation guideline should be established so that access to the ECMO team and equipment can be rapidly deployed.

Cannulas are inserted in the appropriate vessels and then attached to an ECMO circuit. The circuit is assembled using sterile technique, de-aired, and crystalloid primed. Newborn circuits are often primed with blood to decrease the hemodilution effect that can be encountered with a crystalloid primed circuit. The circuit is attached to the cannulas and ECMO support begins. Pump flows are adjusted according to the type of support the patient is receiving and vary based on the underlying diagnosis. Patients needing cardiac support (VA) will often need a large portion of their cardiac output supported while patients on VV support may be maintained on a relatively lower amount of pump flow. As the pump flow increases, a larger portion of the patient's desaturated blood flows through the oxygenator and returns to the patient fully saturated. Box 51.5 shows sample target pump flows for different age groups. Once pump flow is at the desired level, alarms should be set appropriately to alert the ECMO specialist of any acute changes in pump support. Sweep flow is attached to the oxygenator and adjusted based on guidelines to achieve target CO_2.

BOX 51.5 Target Pump Flows for Age Groups

- Infants: 120–150 mL/kg/min
- Children: 100–120 mL/kg/min
- Adults: 70–80 mL/kg/min
- Attempt to reach maximal flow early in run to determine buffer

RULE OF THUMB The ratio of sweep flow to pump flow is often 1:1. When using 4 L/min pump flow, typically the sweep flow would be initiated at 4 L/min.

Consideration of adjustments in ventilator support is necessary to avoid hyper- and hypoventilation. Patients' ventilator settings can gradually be weaned to "rest settings" as the sweep flow is increased. Rest settings are intended to minimize lung trauma while avoiding atelectasis. Typically, the FiO_2 from the ventilator can be reduced to 0.4 to 0.6. The goal for some long-term patients (i.e., pre–lung transplant) is often extubation to allow for activities of daily living to be maintained in conjunction with physical therapy and ambulation while on ECMO support. Circuit temperature is adjusted to maintain patients at the intended body temperature. A chest x-ray (CXR) is done to assess cannula placement. Serial blood gases and chemistries are obtained to ensure patient laboratory values are within acceptable ranges. Pump flow, sweep flow, and medications can be adjusted as needed. Blood products are transfused to maintain desired parameters. Baseline anticoagulation levels are obtained and a heparin infusion initiated at the dose necessary to achieve adequate anticoagulation. Sedation levels are adjusted to the appropriate level that will allow intermittent or continuous assessment of neurologic status. Levels of analgesia are provided as needed or as pain scores indicate. Emergency preparedness is an essential component of an ECMO start. Procedures to handle any complications during initiations should be developed for every ECMO center. Backup circuit components should be in a nearby location along with an alternative means to support the patient in the event of pump hardware failure.

MAINTENANCE OF AN EXTRACORPOREAL MEMBRANE OXYGENATION RUN

ECMO runs can be expected to last from a few days to as long as several months. An established flow sheet to document key variables should record the trends in specific parameters.

Monitoring the changes in these parameters allows the ECMO specialist to better assess a patient's progress, identify goals on a daily basis, and coordinate the best approach during the patient's course on ECMO (Box 51.6). Daily, the patient will receive a CXR to reaffirm cannula position and lung status. Periodic arterial blood gases are obtained as well as ACTs and other labs run at appropriate intervals to ensure values are maintained within the desired range. Interdisciplinary team rounds occur at the bedside daily. Every discipline should be encouraged to contribute their perspective and together a well-defined strategy is formed. It is at these rounds that clear patient goals can be identified and a plan of care is established for the day. In addition to patient trends, documentation should also be maintained on various aspects of the active ECMO system (Box 51.7). Frequent circuit assessments, from the drainage cannula through the entire system and back to the return cannula, are essential. Specialists must be mindful of the many risks and potential complications associated with extracorporeal support. Diligence with frequent inspections and evaluation of components as well as ensuring the proper backup equipment should be part of the daily task of an ECMO specialist.

Certain categories of ECMO patients may require procedures unique to their condition. Open chest cardiac patients might need to travel to the operating room (OR) for a chest washout

or explorations to stop bleeding and, depending on the urgency, some surgical procedures may have to be done at the bedside. Bedside echocardiograms are done to assess any changes in cardiac function and sometimes to rule out **tamponade**. Cardiac catherization lab visits may also be necessary for procedures required during the ECMO run. Bronchoscopies and bronchial lavages are a little more common in patients being supported for respiratory failure. As with any ICU run, there is a potential need to travel to computed tomography (CT) scan or interventional radiology for diagnostic testing.

RULE OF THUMB During an ECMO run, vent settings should be lowered considerably to allow the lungs to recover. As the CXR improves, vent settings should be increased to evaluate if the patient might be ready to wean.

TRANSPORTING A PATIENT ON EXTRACORPOREAL MEMBRANE OXYGENATION

Most ECMO systems are designed for intrahospital transport. However, detailed guidelines should be followed when preparing for transport. These should include a fully charged battery, adequate gas supply, transport ventilator, cardiac monitors, and defibrillator. A travel kit is advisable that includes connectors, clamps, additional medications, IV fluid, and other items that might be needed on route or at the destination. Provisions for temperature control may be necessary because the blood warmer/cooler may not be supported during the transport. Travelling on ECMO carries significant risks, and teamwork is essential to successful travel. Roles should be established prior to moving. It is wise to minimize the time of the transport by clearing hallways in advance and gaining easy access to elevators. During the transport, constant assessment of the patient along with battery charge level, gas supply, and close monitoring of the circuit should be practiced. When the destination is reached, close attention to detail should be made and reestablishment of piped gas and AC power obtained as soon as possible. Intrahospital transport includes elective patient ambulation in the ICU.

Preparing a patient to ambulate on ECMO takes collaboration among all services involved (Box 51.8). An agreement must be made on destination and maximum duration of time out of the patient's room. Roles of all providers should be clear. All necessary

BOX 51.8 Guidelines for Ambulating With Patients on Venovenous Extracorporeal Membrane Oxygenation (Central-Peripheral)

I. Patient Assessment:
  a. Patient is able to participate in care
  b. Patient is able to be safely directed
  c. Demonstrates stability on ECMO
    1. Consider the following parameters
    2. Discuss with medical team if falls outside criteria

II. Prepare for Ambulation:

Hematologic	ECMO	General Considerations
No sign of bleeding over 12 h	Stability of flow, speed and sweep for 6 h	Airway clearance
Plts >50	Cannulas: sites have been stable—no migration or bleeding	Afebrile
Hgb ≥8–9		Tolerated HOB up, dangling, OOB to chair
ACT at goal		

  a. Obtain MD order for ambulation after assessment by RN, PT, RT
  b. Ensure ECMO cannulas, airway and all other lines are secured
  c. Equipment checklist:
    1. Full O_2 tank
    2. Clamps
    3. Portable SpO_2 monitor
    4. Wheelchair/recliner
    5. ECMO emergency equipment
    6. Assess battery life for all equipment
  d. Contingency plan:
    1. Identify red plug outlets
    2. Identify location of backup circuit
  e. Team discussion prior to take off to include destination & roles
    1. RN: IVs, tubing, chest tubes
    2. RT: ECMO pump/cannula (circuit), monitor flow/speed, airway
    3. PT: manages patient mobility
    4. A minimum of three staff must be present during ambulation
    5. *Each discipline to monitor hemodynamic parameters and alert team members if significant changes noted
  f. Ensure hallways are clear of obstruction
  g. Limit ambulation to within the ICU

III. Ambulate

IV. Documentation Per Each Discipline's Standards

ECMO, Extracorporeal membrane oxygenation; *HOB*, head of bed; *ICU*, intensive care unit; *MD*, physician; *OOB*, out of bed; *PT*, prothrombin time; *RN*, nurse; *RT*, respiratory therapist.

MINI CLINI

Problem

A patient in the Cardiac Care Unit coded suddenly and was placed on VA ECMO. The patient is now somewhat stabilized on ECMO but needs to travel to the Cardiac Cath Lab as soon as possible to investigate and hopefully treat the cause of the arrest. He is on a pump flow of 5l pm and sweep flow of 4l pm. He is on multiple blood pressure medications. Who should travel with this patient besides the ECMO Specialist? What other considerations should be brought to the team's attention?

Discussion

Every effort should be made to support this patient in the event an arrest reoccurs. The ECMO Specialist will be focused on the equipment that moves along with the patient. There should be a doctor from the Surgical Team available in case any cannulas are dislodged. A nurse or anesthesiologist should also be available to handle the medication pumps and help monitor the vital signs. Team members should all agree that the patient is able to travel. A dry run to the destination should be made to clear any obstacles. Back-up equipment should be brought to the Cath Lab in case of any circuit failures.

BOX 51.9 Common Complications

Mechanical Complications

- Pump failure
- Tubing rupture
- Cannula problems
- Oxygenator failure

Physiologic Complications

- Seizures
- Hemolysis
- Renal failure
- Bleeding; intracranial, surgical site
- Neurologic complications
- Arrhythmias
- Pneumothorax

equipment should be identified and checked for function prior to beginning ambulation. There should be specific reasons to abort the exercise such as tachycardia, desaturation, patient fatigue or concerns for equipment or patient safety.

RISKS AND COMPLICATIONS

ECMO poses significant risks. The complications can be classified as mechanical as a result of equipment failure or patient from clinical issues. Box 51.9 outlines ECMO complications.[1] ECMO specialists are clinicians specifically trained in all aspects of ECMO. It is essential that the ECMO specialist have a thorough understanding of ECMO physiology and ECMO patient management. These individuals must have critical thinking skills and be technically adept at assessing all components of the ECMO circuit. Monitoring and frequent inspection of the circuit and evaluating circuit functions are among the primary roles of the ECMO specialist. The risk of the many complications inherent in providing ECMO support diminishes with diligence by the specialist.

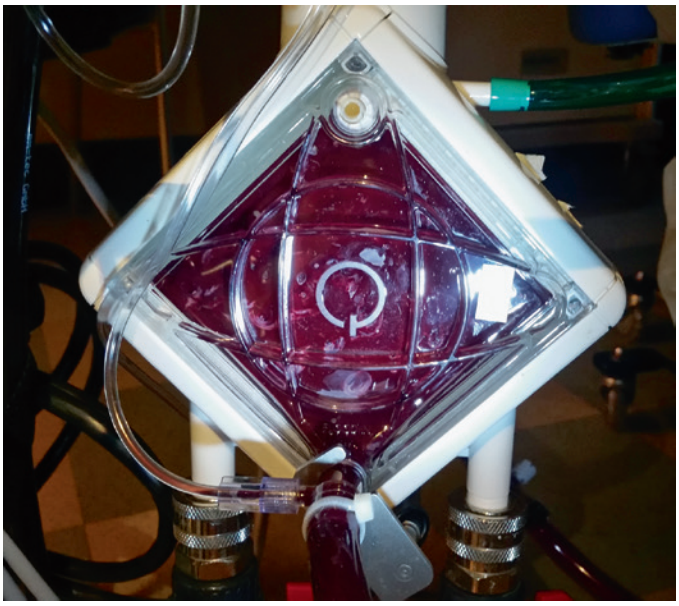

Fig. 51.15 Oxygenator with significant clot accumulation.

The most common mechanical complication during ECMO is clot formation.[1] Clots can occur anywhere in the circuit but more frequently occur in the oxygenator, at connectors, in the circuit bladder or any place with relatively low flow. Clots can result in increased resistance and may impede flow, limiting support of the patient. Clot formation within the fibers of the oxygenator will reduce gas exchange and, if significant, may require the oxygenator to be replaced (Fig. 51.15). Inadvertent **decannulation** and pump failure are other significant complications that can cause circuit interruption and require immediate attention. These conditions might result in the need for an entire circuit to be replaced. Replacement of oxygenators or circuits requires the patient to be briefly removed from support. Practitioners trained in this procedure need to maintain competency to efficiently change out the oxygenator or circuit in the least amount of time to minimize patient decompensation from interruption of support. Proper coordination with the team caring for the patient is essential during this loss of support.

Air in the circuit is a major risk during ECMO. Despite the ECMO system being a closed system, air emboli can occur when air is entrained into the system. This can occur inadvertently through cavitation—air being pulled out of a solution due to increased negative pressure—if venous return is inadequate. It can occur from drainage ports of a cannula migrating out of a vessel or from access lines, such as through the CVVH port, infusion lines or other monitoring lines. The presence of air in the circuit, if not redirected or withdrawn, may enter the patient's circulation. In VA ECMO this is particularly life threatening because air will not be filtered through the pulmonary circulation as it is in VV ECMO. As with most mechanical complications, prevention is vital.

Bleeding is a common risk of ECMO due to anticoagulation and the multiple surgical sites where bleeding can easily occur. Bleeding in the chest can lead to the complication of cardiac tamponade, an emergency needing immediate intervention,

without which the patient will not likely survive. Cannula placement in the awake and active patient on ECMO can also contribute to the occurrence of tamponade. Loss of pump flow, hemodynamic changes with a narrowing of pulse pressure, arrhythmias, and decreases in hemoglobin and hematocrit levels are symptomatic of tamponade. Bleeding from any source resulting in low pump flow causes risks not only to the patient but to the circuit as well. Lower flows result in higher potential for clot formation in a circuit. The drop in hemoglobin is also a major concern because the oxygen-carrying capacity is greatly reduced. Bleeding can occur from any surgical site, including cannula sites, chest tubes or IVs. Bleeding becomes a risk with any venopuncture, NG or OG tube placement, rectal tube placement, suctioning or anything that might cause mild trauma to the tissues. Internally, intracranial hemorrhage, GI and pulmonary bleeding are also bleeding risks associated with ECMO.

RULE OF THUMB A set up primed circuit and/or backup ECMO equipment should be kept easily accessible to the patient on an ECMO run in case any circuit complications that require a component or full circuit change.

BLOOD PRODUCTS DURING EXTRACORPOREAL MEMBRANE OXYGENATION

The most common blood product used during an ECMO run is packed red blood cells (PRBCs). PRBCs are transfused to maintain adequate levels of hemoglobin to ensure adequate oxygen carrying capacity. Typically, hemoglobin is maintained at approximately 8 to 10 g/dL. Platelets, FFP, and cryoprecipitate are often used to target specific clotting factors. Protocols identify when transfusion of each individual product is indicated. Albumin may also be used intermittently throughout the run for volume expansion.

WEANING AND DECANNULATION

Daily assessments for the possibility of weaning should be made first by considering why the patient was initially placed on ECMO and whether or not the problem has been resolved. Other questions to consider are if additional issues have been identified that either indicate the necessity to continue support or identify the need to discontinue support. Throughout the run, the team must consider if the risks of ECMO outweigh the benefits. The process of weaning off ECMO is different in VA support than in VV support. During VA weaning, the function of the heart must be assessed as increased blood flow is redirected to the native circulation. This evaluation is often accomplished via cardiac ultrasound while pump flow is decreased. At the same time, hemodynamic stability, right ventricule, left ventricule (RV, LV) function, and the degree of pulmonary hypertension should be evaluated. Ventilator support may need to be adjusted as pump flows are decreased, particularly ventilator FiO_2 to supplement the decrease in pump flow. At this time, the risk of clots developing in the circuit at the low flow states is present. Therefore the duration of the wean should be limited to no more than an hour, with close attention to anticoagulation.

MINI CLINI

Problem

A patient is cannulated for VV ECMO due to acute lung injury secondary to H1N1 flu. The patient initially required a pump flow of 4 L/min and sweep of 10 L/min to achieve the desired gas exchange. After 5 days on resting ventilator settings, an improvement in both CXR and lung compliance is noted. Additionally, PaO_2 with the ventilator FiO_2 at 1.0 is markedly improved: on day 1 it had been 50 mm Hg and after 5 days is now 220 mm Hg. What changes should be made to assess the patient's readiness to wean off of VV support?

Discussion

Gradually decreasing the sweep flow will allow assessment of the patient's native lung's ability to effectively ventilate. Simultaneously, ventilator adjustments should be made to support the transition when ECMO is discontinued. The patient is ready to be decannulated when gas exchange can be maintained without sweep flow and ventilator settings that will not induce any further lung injury (i.e., plateau pressures less than 28 and FiO_2 less than 0.6).

For the patient who requires VA ECMO for both cardiac and pulmonary support, there is the option to convert to VV ECMO if the heart function recovers before adequate lung function is achieved. The patient can be supported on VV ECMO until there is further evidence of lung improvement. Patients on VV ECMO must demonstrate improvement in their pulmonary status before weaning can be considered. This includes an increase in lung compliance, improved aeration on CXR, and the ability for effective gas exchange on conventional ventilator settings that are not likely to produce lung injury. A test to evaluate the native lung's ability to oxygenate can be achieved while maintaining the same ECMO support and obtaining an arterial blood gas with the ventilator FiO_2 at 1.0. A daily assessment using this "100% gas" can demonstrate the improvement in oxygenation. Early stages of support will not reveal much change, but as the lungs improve then significant increases in the PaO_2 will be obvious. The process of weaning off VV ECMO involves maintaining pump flow and weaning sweep flow to assess the native lung's ability to remove CO_2. Adjustments in ventilator support to accommodate the decrease in sweep flow should be made at this time. Once there is an improvement in ventilation evidenced by reasonable levels of PCO_2 on moderate ventilator settings with an improvement in the 100% oxygen gas, the sweep flow can be removed. The pump flow continues while a period of assessment off ECMO occurs to determine if the patient is ready for decannulation, with the decannulation approach determined by the cannulation sites. Percutaneously inserted cannulas may be simply withdrawn at the bedside if vascular repair is not anticipated. If surgical repair or reconstruction of the vessel is required or if the patient is centrally cannulated, decannulation will typically take place in the operating room. Post-decannulation anticoagulation is most often discontinued or adjusted to desired levels.

RULE OF THUMB Weaning from VA support is accomplished by turning down the pump flow and assessing hemodynamics. Weaning from VV support is accomplished by turning down the sweep flow and assessing gas exchange.

SUMMARY CHECKLIST

- ECMO is an option for newborn, pediatric, and adult patients with severe cardiac or respiratory failure who meet the criteria outlined in Boxes 51.2 and 51.3 and who otherwise have no absolute contraindications.
- The primary goals of ECMO are to deliver adequate amounts of oxygen, remove carbon dioxide, and, in cases of VA ECMO, provide hemodynamic support. ECMO physiology mimics native cardiopulmonary physiology in that it allows oxygen to diffuse into the blood and carbon dioxide to be removed. This is accomplished through a circuit that contains a pump and an artificial oxygenator.
- The patient is cannulated with either a double-lumen cannula or multiple single-lumen cannulas.
- During VV support, cannulas are usually placed in the right internal jugular vein, right atrium, and left or right femoral veins. In VA support, the venous cannulas are placed in the same locations as with VV support, with the arterial cannula inserted into the aorta or either femoral artery.
- Blood is either drained or siphoned into the pump, which propels it forward into an oxygenator. The oxygenator provides gas exchange before returning the blood to the patient containing hemoglobin that is fully saturated and has the desired carbon dioxide level.
- A blood warmer/cooler keeps the blood at the desired temperature and additional monitors provide clinicians with valuable information regarding circuit pressures, flows, and additional lab values. Several of the monitors can be set to sound audible alarms when the values of certain parameters are outside of the acceptable range.
- Additional safety components can be added to the ECMO system for additional blood parameter monitoring such as venous and arterial saturations, hemoglobin and hematocrit.
- The circuit and cannulas are made of materials foreign to blood. These surfaces will cause the normal activation of blood clotting reactions. Anticoagulation is necessary to decrease the risk of clots in the circuit, cannulas, and, most importantly, in the patient.
- Bedside coagulation testing is typically performed at regular intervals to keep a close watch on the level of anticoagulation, along with frequent inspection for clot development in any of the circuit components.
- A major advantage of ECMO is that ventilator support can be decreased once ECMO is initiated, thus reducing the potential of ventilator-induced lung injury. At times the ventilator can even be discontinued, reducing the potential of ventilator-associated pneumonia and allowing the patient to more actively participate in activities of daily living. This is of particular importance in the pre-transplant patient.
- As technology advances and proper candidate selection is achieved, ECMO is certain to be more frequently utilized in ICU management of the critically ill patient.
- Ambulating and/or intrahospital transports on ECMO are more common occurrences made possible by portable equipment, proper planning and team effort.

Monitoring the Patient in the Intensive Care Unit

Thomas Piraino

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the principles of monitoring the respiratory system, cardiovascular system, neurologic status, renal function, liver function, and nutritional status of patients in intensive care.
- Explain why the caregiver is the most important monitor in the intensive care unit (ICU).
- Describe various measures of patient oxygenation in the ICU.
- Explain why the partial pressure of carbon dioxide ($PaCO_2$) is the best index of ventilation for critically ill patients.
- Describe the approach used to evaluate changes in respiratory rate, tidal volume, minute ventilation, $PaCO_2$, and end-tidal pressure of carbon dioxide values for monitoring purposes.
- Identify monitoring techniques used in the ICU to evaluate lung and chest wall mechanics, auto–positive end-expiratory pressure, work of breathing, and respiratory drive.
- Describe the importance of measuring transpulmonary pressure in select patients.
- Discuss the importance of monitoring peak, plateau, and driving pressures in patients receiving mechanical ventilatory support.
- Identify monitoring techniques that have become available more recently, such as lung stress and strain, functional residual capacity, stress index, electrical impedance tomography, and lung ultrasound.
- Describe the approach used to interpret the results of ventilator graphics monitoring.
- Describe the cardiovascular monitoring techniques used in the care of critically ill patients and how to interpret the results of hemodynamic monitoring.
- Discuss the evaluation of renal function, liver function, and nutritional status in the ICU.
- List and discuss the use of composite and global scores to measure patient status in the intensive care unit, such as the acute physiology, age, chronic health evaluation system for scoring the severity of illness.
- Discuss the importance of monitoring neurologic status in the ICU and the variables that should be monitored.
- Discuss monitoring and troubleshooting of the patient-ventilator system in the ICU.

vital capacity

When patients are admitted to the intensive care unit (ICU), it is generally for the purpose of providing diagnostic and therapeutic interventions that require continuous or periodic monitoring of physiologic parameters. ICU patients often require multiple medications, fluids, and nutrition, as well as noninvasive or invasive ventilatory support for respiratory failure. The monitoring of these patients is essential to assess the effectiveness of treatment in the ICU and to minimize, limit, or prevent adverse events.

Although diagnostic procedures such as radiographic imaging can be used to monitor the progression of disease over time, this chapter focuses on the periodic and/or continuous monitoring of the respiratory system, cardiovascular system, renal function, liver function, nutritional status, and neurologic function of patients in the ICU.

PRINCIPLES OF MONITORING

The best monitoring options provide detailed, easily interpreted data, obtained noninvasively or minimally invasively with the fewest hazards and side effects. A monitoring tool that is highly invasive and carries a certain level of risk with use must provide a high level of valuable and required information to make the benefit of using it outweigh the risk.

New advancements in technology aim to make monitoring less invasive and at the same time provide the most clinically relevant data. The data provided should be accurate (reflect the true value) and precise (not vary widely when repeated). When monitoring involves images, graphs, or waveforms, the data must be easily distinguishable from **artifacts**, **factitious events**, or normal variation and still require an understanding of the overall status of the patient to understand their significance.

The best monitor in the ICU is the caregiver who understands how to use and interpret the various monitoring tools and techniques available to him or her. However, observing a monitor while ignoring the patient does not take into consideration the patient's global status. We must combine the "seen" with the "unseen" to truly understand the patient (Box 52.1).

BOX 52.1 Monitors and Monitoring Data

- Monitored values can exhibit physiologic and instrument variability.
- Monitoring devices can be noninvasive or invasive.
- Alarm systems should be set to alert caregivers properly yet avoid false alarms.
- Monitors can run continuously and measure what caregivers cannot see.
- The best monitors are caregivers who can assess and make decisions based on understanding the patient's global status.

BOX 52.2 Values Affecting Pulse Oximetry

- Motion artifact
- Environmental light (e.g., sunlight, fluorescence)
- Anemia
- Deeply pigmented skin
- Carboxyhemoglobin, methemoglobin
- Nail polish
- Blood-borne dyes

RULE OF THUMB The caregiver must understand and interpret the information provided through monitoring. The key to the proper interpretation of information is understanding how it applies to the global status of the individual patient.

HISTORY

Obtaining a history from a critically ill patient—in particular a patient with altered state of consciousness—can be difficult. However, attempting to obtain a history by speaking with the patient or family members can provide extremely useful information in the ICU. Information regarding the patient's past medical history, psychologic status, habits of smoking and alcohol use, and physical abilities is important, especially considering some of the challenges that may arise in the course of care in ICU. In particular, it is important to know how a patient's baseline state may affect the normal ranges of monitored values or the ability to be weaned quickly from mechanical ventilation.

PATHOPHYSIOLOGY AND MONITORING

The problem often faced at the bedside when one is presented with monitoring data is that clinicians may begin treating the numbers rather than the underlying pathophysiology. For example, when a patient is mechanically ventilated and the peripheral capillary oxygen saturation (SpO_2) level drops, the first step is to quickly determine whether the SpO_2 reading seems correct by confirming a good waveform or correlation with clinical findings such as the patient's appearance and objective measures such as the heart rate. If a drop in SpO_2 seems real, the respiratory therapist (RT) may recommend increasing the fraction of inspired oxygen (FiO_2) or adjusting the positive end-expiratory pressure (PEEP) in cases of refractory hypoxemia when there has been no response to moderate or high FiO_2. Treating the patient rather than the number requires the clinician to consider first if the readings seem accurate and then to address the underlying cause (Box 52.2).

RULE OF THUMB Treating the patient rather than the number requires the clinician to consider first whether the readings seem accurate and then to address the underlying cause.

The function of the lungs is the uptake of oxygen and the removal of carbon dioxide (see Chapter 12). The arterial blood gas (ABG) gives valuable information regarding the effectiveness of the gas exchange (discussed in Chapter 19). Although ABGs can be drawn at the bedside, they usually require processing outside of the patient's room, either at a point-of-care machine or by the hospital laboratory. The most common bedside monitoring surrogates for O_2 uptake and CO_2 clearance are the SpO_2 and respiratory rate (minute ventilation when the patient is mechanically ventilated). Both monitoring options have benefits, but each also has considerable limitations.

MONITORING OXYGENATION

Tissue oxygenation depends on FiO_2, inspired partial pressure of oxygen (PiO_2), alveolar oxygen tension (PAO_2), arterial oxygenation (PaO_2, SaO_2, oxygen content of arterial blood CaO_2), oxygen delivery, tissue perfusion, and O_2 uptake.

ARTERIAL PULSE OXIMETRY

ABG analysis has been the accepted method of detecting hypoxemia in critically ill patients, but obtaining arterial blood can be painful and cause complications; moreover, ABG analysis does not provide immediate or continuous data. For these reasons, SpO_2 has become the standard for a continuous, noninvasive assessment of SaO_2. However, it too has significant limitations (see Box 52.2).[1,2] SpO_2 does not measure $PaCO_2$, and patients breathing an elevated FiO_2 can retain CO_2 (increased $PaCO_2$), although SpO_2 values are acceptable. Ventilatory failure may go unnoticed unless ABGs are measured (see Chapter 19).

RULE OF THUMB There are two very important problems with relying on SpO_2 to monitor adequate respiratory function: (1) SpO_2 values reflect oxygenation, not ventilation; and (2) SpO_2 measurement is susceptible to numerous factors that can produce false values.

MINI CLINI

Trusting the Pulse Oximeter

Problem

A newborn of 32 weeks' gestation is intubated and receiving continuous positive airway pressure (CPAP) therapy. The patient appears to be in mild to moderate respiratory distress, yet her SpO_2 is 98%. Hurricane spray (20% benzocaine) had been used to reduce the irritation of the endotracheal tube. Analysis of ABG values reveals a PaO_2 of 325 mm Hg, and the co-oximeter shows a methemoglobin value of 38%.

MINI CLINI—cont'd

Trusting the Pulse Oximeter

Solution

The most common problems with the fidelity of pulse oximeter readings are motion artifacts, interference by external light sources, or malposition of the sensor. Each of these problems can be assessed easily and quickly. In this case, the clinical symptoms did not correlate with an acceptable SpO_2 value. Because adequate O_2 delivery is the ultimate goal, CO_2 and O_2-carrying ability must be considered as causes of the respiratory distress. The high methemoglobin value, most likely caused by the hurricane spray, necessitates immediate therapy with methylene blue dye. Although the pulse oximeter can be an excellent, safe means of monitoring blood oxygenation, there must be a wary vigilance regarding the values it provides.

OXYGEN CONSUMPTION

Oxygen consumption ($\dot{V}O_2$) is the volume of O_2 consumed by the body in milliliters (mL) per minute. Normal resting $\dot{V}O_2$ is approximately 250 mL/min, and $\dot{V}O_2$ increases with activity, stress, and temperature. Oxygen consumption and measurement are discussed in Chapter 12.

Alveolar-Arterial Oxygen Tension Difference

The **alveolar-arterial oxygen tension difference** ($P[A–a]O_2$) is a useful measurement of the efficiency of gas exchange. A healthy person breathing room air has a $P(A–a)O_2$ of approximately 5 to 15 mm Hg. This value increases with age to approximately 10 to 20 mm Hg in elderly adults. $P(A–a)O_2$ also increases normally with an increase in FiO_2. An abnormal increase in $P(A–a)O_2$ is associated with gas-exchange problems. This measurement is discussed in greater detail in Chapter 12.

PaO_2/FiO_2 Ratio

The PaO_2/FiO_2 ratio is easy to calculate and a reliable index of gas exchange; it is one of the commonly used oxygenation measurements in research studies involving patients in acute respiratory failure. The PaO_2/FiO_2 ratio provides an index for the effect of O_2 on PaO_2 when a range of FiO_2 settings may be prescribed. The index allows comparisons of severity between patients or when FiO_2 changes in the same patient. Every bedside clinician should be aware of the PaO_2/FiO_2 in their patients when ABG values are available. More information may be found in Chapter 12.

Murray Lung Injury Score

To monitor the severity of acute respiratory distress syndrome (ARDS), Murray and colleagues[3] developed a lung injury score. This score quantifies the injury level using the following four factors: chest radiographic findings, PaO_2/FiO_2 ratio, PEEP setting, and compliance. The **Murray lung injury score** is an example of a composite score that allows quantification of lung status according to different aspects of the injury—gas exchange, radiographic findings, and mechanics. This score is used as an index of the effectiveness of therapy or for interstudy comparisons. The method for calculating the Murray lung injury score is shown in Box 52.3. Other measures of lung injury are listed in Box 52.4.

BOX 52.3 Murray Lung Injury Score

Component	Value
Chest X-Ray	
No alveolar consolidation	0
Alveolar consolidation confined to one quadrant	1
Alveolar consolidation confined to two quadrants	2
Alveolar consolidation confined to three quadrants	3
Alveolar consolidation in all four quadrants	4
Hypoxemia Score	
PaO_2/FiO_2 >300	0
PaO_2/FiO_2 225–299	1
PaO_2/FiO_2 175–224	2
PaO_2/FiO_2 100–174	3
PaO_2/FiO_2 <100	4
PEEP Score (When Ventilated)	
PEEP ≤5 cm H_2O	0
PEEP 6–8 cm H_2O	1
PEEP 9–11 cm H_2O	2
PEEP 12–14 cm H_2O	3
PEEP >15 cm H_2O	4
Respiratory System Compliance Score (When Available)	
Compliance ≥80 mL/cm H_2O	0
Compliance 60–79 mL/cm H_2O	1
Compliance 40–59 mL/cm H_2O	2
Compliance 20–39 mL/cm H_2O	3
Compliance ≤19 mL/cm H_2O	4

The final value is obtained by dividing the aggregate sum by the number of components used.

Score

No lung injury: 0

Mild to moderate lung injury: 0.1–2.5

Severe lung injury (ARDS): >2.5

BOX 52.4 Measures of Decreased Blood Oxygenation or Lung Injury

- ↓ SpO_2
- ↓ PaO_2
- ↑ $P(A–a)O_2$ ($PAO_2–PaO_2$)
- ↓ P/F ratio (PaO_2/FiO_2)
- ↑ Shunt/venous admixture
- ↑ Murray lung injury score

Other Oxygenation Measurements

Other important measures of oxygenation (not as routinely measured), including oxygen consumption, the alveolar-arterial oxygen tension difference ($A–aO_2$), the oxygenation index (OI), and the quantification of shunt. These are covered in detail in Chapter 12.

MONITORING VENTILATION

As in the case of oxygenation, the adequacy and efficiency of ventilation is routinely evaluated in the ICU (Box 52.5). Monitoring of patients receiving mechanical ventilatory support in the ICU includes measurement of the patient's tidal volume (V_T), respiratory rate (f), and minute ventilation ($\dot{V}_E$). It is

BOX 52.5 Monitoring the Adequacy of Ventilation

- Respiratory volume and rate (V_T, f, $\dot{V}_E$)
- $PaCO_2$
- V_D/V_T
- Capnometry (not for routine use but in special situations, such as ensuring tracheal intubation and cardiac blood flow in resuscitation efforts)

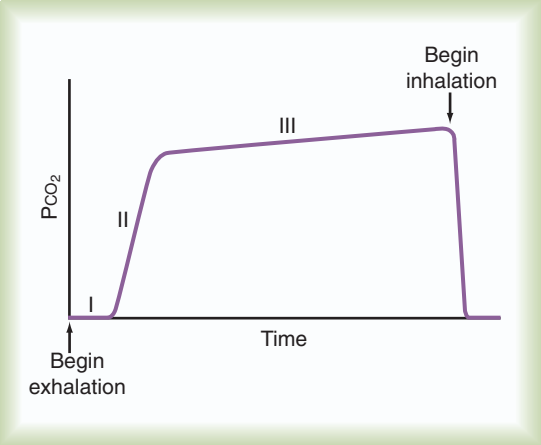

Fig. 52.1 Time-Based Capnograph. *Phase I,* anatomic dead space; *Phase II,* transition from anatomic dead space to alveolar plateau; *Phase III,* the alveolar plateau.

important to understand that the effectiveness of minute ventilation depends on alveolar ventilation ($\dot{V}_A$). Significant changes in arterial pH can still occur despite the maintenance of minute ventilation when patients have a significant change in dead space and intrapulmonary shunt.

CAPNOGRAPHY

As discussed in Chapter 19, **capnometry** is the measurement of CO_2 at the airway opening during the ventilatory cycle. **Capnography** refers to plotting CO_2 concentration against time or against exhaled volume. The normal CO_2 waveform is displayed in Fig. 52.1.

Patients for whom capnometry may be a useful monitoring tool include those with normal lungs but an unstable ventilatory drive who are breathing spontaneously or receiving low-level ventilatory support. In these patients, capnometry readings should initially be validated by comparison with $PaCO_2$. Changes in end-tidal PCO_2 ($P_{ET}CO_2$) can be used to alert the clinician to potential changes in patient ventilation. Thereafter, periodic reevaluation should be performed as the patient's clinical state changes. Capnometry has been extremely useful in emergency situations, such as to verify endotracheal intubation and assess blood flow during or after cardiac arrest. Small in-line CO_2 monitors that employ colorimetry are now routinely used to verify endotracheal intubation.[4]

Although $P_{ET}CO_2$ and $PaCO_2$ values tend to correlate at a single point in time, correlation between changes in $P_{ET}CO_2$ and in $PaCO_2$ is weaker.[5] Decreases in ventilation are reflected by increases in $P_{ET}CO_2$ and $PaCO_2$. However, with very small V_T, $PaCO_2$ increases, whereas $P_{ET}CO_2$ may decrease. Although the appropriate role of capnometry in critical care may be unclear, integration of capnometry into modern ventilators is reasonable because the primary role of the ventilator is CO_2 elimination. As a guide for clinicians, the American Association for Respiratory Care (AARC) has created a clinical practice guideline for using capnometry in ventilated patients.[6] Box 52.6 lists common causes of changes in monitored $P_{ET}CO_2$ values.

BOX 52.6 Causes of Increased and Decreased End-Tidal Carbon Dioxide Values

Increased $P_{ET}CO_2$

- Decreased effective ventilation (↓ V_T, ↓ $\dot{V}_E$, ↓ $\dot{V}_A$, ↑ $PaCO_2$)
- Increased CO_2 production ($\dot{V}CO_2$) (agitation, stress, shivering, fighting the ventilator, pain, anxiety, recovery from sedation or paralysis)

Decreased $P_{ET}CO_2$

- Increased effective ventilation (↑ V_T, ↑ $\dot{V}_E$, ↑ $\dot{V}_A$, ↓ $PaCO_2$)
- Marked decrease in effective ventilation (↓↓$\dot{V}_T$ approaching dead space volume; rapid shallow breathing)
- Decreased CO_2 production ($\dot{V}CO_2$) (sedation, sleep, cooling)
- Decrease in lung perfusion (pulmonary embolus, decreased CO)

Absent $P_{ET}CO_2$

- Apnea
- Cardiac arrest
- Ventilator disconnect or malfunction
- Airway obstruction

Volumetric CO_2 monitoring holds promise in continuously monitoring ventilation efficiency. VCO_2 can be continuously monitored in a patient being liberated from mechanical ventilation as an indicator of adequate or improving ventilatory efficiency.[7] The volumetric capnogram has been examined as a potential tool for detecting a pulmonary embolism,[8] tracking the efficiency of mechanical ventilation,[8] and calculating dead space.[9] The relationship between VCO_2 and dead space also makes it a valuable tool in the optimization of PEEP.

Dead Space

As discussed in Chapter 11, the **dead space/tidal volume (VD/VT) ratio** is a measure of the efficiency of gas exchange. This ratio is an estimate of the proportion of ventilation participating in the diffusion of CO_2. V_D/V_T can be calculated from the Enghoff modification of the Bohr equation, as follows:

$$V_D/V_T = (PaCO_2 - P_ECO_2)/PaCO_2$$

where P_ECO_2 is the CO_2 concentration in mixed expired gas.

Frequently, the V_D/V_T ratio is increased in patients with congestive heart failure, pulmonary embolism, ARDS, or pulmonary hypertension and in those undergoing mechanical ventilation. The V_D/V_T ratio has been used to evaluate patients being considered for liberation from mechanical ventilation. A V_D/V_T ratio greater than 0.60 generally requires continuation of ventilatory support. Increased V_D/V_T in the early phase of ARDS has been associated with an increased risk of death.[3,10]

MONITORING OF INSPIRED AND EXHALED GAS VOLUMES

Although the best index of effective ventilation is the measurement of $PaCO_2$, measurement of inspired and expired gas volumes is an important aspect of monitoring patients receiving mechanical ventilatory support. For patients receiving controlled mechanical ventilation, minute ventilation ($\dot{V}_E$), respiratory rate (f), and V_T are assessed by

$$\dot{V}_E = (V_T)(f) \text{ and } V_T \text{ average} = \dot{V}_E/f$$

With an adequate V_T, increases in $\dot{V}_E$ tend to increase alveolar ventilation and decrease $PaCO_2$, whereas decreases in $\dot{V}_E$ tend to have the opposite effect. However, in the presence of rapid shallow breathing with normal or elevated $\dot{V}_E$, a decrease in effective ventilation can result in an increase in $PaCO_2$. This effect is caused by ineffective shallow tidal breaths that are at or below the volume of the dead space. Spontaneous respiratory rate often is a sensitive indicator of the need for mechanical ventilation. Rates greater than 25 breaths/min in adults may indicate distress, and a rate greater than 30 breaths/min with a spontaneous V_T of less than 300 mL often indicates the need for mechanical ventilatory support in adults because a large proportion of ventilatory effort is being expended to move dead-space gases.

Inspired Versus Expired Tidal Volume During Mechanical Ventilation

Normal inspired V_T and expired V_T should be nearly the same. However, in the presence of an air leak, inspired V_T may be larger than expired V_T, and measurement of delivered V_T versus exhaled V_T may be useful in detecting and quantifying the size of a leak—a situation that may require immediate attention. When a significant mismatch between inspired and expired V_T is noticed, consider not only the possibility of a cuff leak with the endotracheal or tracheostomy tube but also check the circuit connections. Alternatively, be sure to monitor the ventilator waveform graphics and assess the patient's respiratory rate, looking for the presence of an insufficient expiratory time leading to auto-PEEP.

PEAK AND PLATEAU PRESSURES

The maximum value of pressure at the airway opening during a ventilatory cycle is routinely monitored in the ICU as peak airway pressure. Peak airway pressure greater than 50 to 60 cm H_2O is generally discouraged because high values of peak pressure carry an increased risk of lung injury and hypotension.[11] During volume-targeted modes of ventilation, an increase in peak pressure results from increased resistive pressure or increased elastic pressure from decreased lung or chest wall compliance. During pressure-targeted modes of ventilation, increased resistive pressure or increased elastic pressure results in a decrease in delivered tidal volume rather than the increase in peak or plateau pressure (P_{plat}). Measurement of P_{plat} helps to differentiate between the resistive and elastic components. The P_{plat} level should be monitored for all ventilated patients. P_{plat} ideally should not exceed 28 cm H_2O, because elevated P_{plat} increases the likelihood of developing ventilator-induced lung injury. However, the limit for P_{plat} depends on the resulting lung stress and strain.

MEAN AIRWAY PRESSURE

Mean airway pressure (MAP) represents the average airway pressure over the total ventilatory cycle. Correct measurement of this value requires continuous sampling of airway pressure at the airway opening; this is an automated feature of modern ventilators. MAP is related to mean lung volume, which correlates with oxygenation if perfusion is adequate. When MAP is increased, arterial O_2 levels often improve, but venous return and subsequently arterial pressure can be adversely affected.

In an effort to increase oxygenation while monitoring arterial pressure, the clinician can manage MAP by several means, including V_T, frequency, inspiratory-to-expiratory (I:E) ratio, and PEEP. The management of MAP relates to a concern for improving oxygenation balanced against its detrimental influence on venous return. Normally, expiratory resistance is greater than (twice) inspiratory resistance, and mean alveolar pressure normally is greater than MAP. For patients with chronic obstructive pulmonary disease (COPD) and elevated expiratory resistance, high mean alveolar volume can be significant during mechanical ventilation.

There is an understandable caution when MAP is being increased, usually by increasing PEEP, yet two ventilator modes apply dramatic increases in MAP—high-frequency oscillation and airway pressure release ventilation. The marked improvements in oxygenation seen with these modes can be attributed to high MAP. In the case of high-frequency oscillation, the lungs are never allowed to derecruit between breaths. Airway pressure release ventilation is more complicated because the lung deflates to varying unknown alveolar volumes on exhalation. In using either mode, end-expiratory alveolar lung volume status cannot easily be determined, but oxygenation is often improved.

DRIVING PRESSURE

Driving pressure is a measure of the pressure difference between P_{plat} and total PEEP (PEEP plus auto-PEEP). The swing in pressure from end-expiration to end-inspiration may be an independent stress factor on the lungs. Consider driving pressure as the amount of energy applied to the lung: the higher the energy applied to the lung, the greater the potential for lung injury. In general, the driving pressure should be kept below 15 cm H_2O.[12]

RULE OF THUMB Driving pressure is a simple bedside value obtained by determining the pressure difference between plateau pressure and total PEEP. Clinicians should attempt to keep this value below 15 cm H_2O. The use of lower tidal volume and proper levels of PEEP can help to achieve this ventilation goal.

RESISTANCE

Depending on the driving pressure measured, various resistances can be calculated, including airway, pulmonary, chest wall, and

total respiratory system resistance. An airway resistance (Raw) can be determined dynamically from simultaneous measurements of airflow and the pressure difference between the airway opening (Pao) and the alveoli (Palv) by Raw = (Pao – Palv)/flow. Because resistance changes throughout inspiration and expiration and expiratory resistance generally is greater than inspiratory resistance, instantaneous measures of resistance are not commonly performed clinically. Inspiratory resistance can be calculated simply during constant-flow volume ventilation by using a short (0.5-second) pause at the end of volume delivery. This allows for the separation of peak and plateau pressures in real time. It allows monitoring of airway status over time or after the effects of bronchodilator therapy and is determined by dividing the pressure change by the flow rate, as follows:

$$\text{Raw} = \Delta P/\Delta F = (P_{peak} - P_{plat})/\text{flow}$$

where P_{peak} is peak airway pressure and P_{plat} is plateau pressure. Automated methods of measuring expiratory resistance have been integrated into some ventilators.

In ventilated patients, a significant component of the total flow resistance is from endotracheal tubes.[13] In healthy persons, flow is relatively laminar during tidal ventilation and becomes turbulent only with increasing ventilatory demands. The flow resistance offered by the endotracheal tube increases markedly with increasing flow and varies with the size of the tube. Normal airway resistance is approximately 1 to 2 cm H_2O/L/s; however, intubated patients receiving mechanical ventilatory support typically have an airway resistance of 5 to 10 cm H_2O/L/s or more. Automated tube compensation modes have been added to mechanical ventilators to deliver flow that accounts for the added resistance of the endotracheal tube. Common causes of changes in airway resistance in mechanically ventilated patients are listed in Box 52.7.

BOX 52.7 Common Causes of Changes in Compliance and Resistance in Mechanically Ventilated Patients

Decreased Compliance
- ↓ Lung compliance (atelectasis, pneumonia, pulmonary edema, ARDS, pneumothorax, fibrosis, bronchial intubation)
- ↓ Thoracic compliance (ascites, chest wall deformity)

Increased Compliance
- ↑ Lung compliance (improvement in any of the foregoing conditions, pulmonary emphysema)
- ↑ Thoracic compliance (improvement in any of the foregoing conditions; flail chest; position change—sitting patient up)

Increased Resistance
- Small endotracheal tube, secretions plugging endotracheal tube, biting on endotracheal tube
- ↑ Bronchospasm, mucosal edema
- ↑ Secretions
- ↑ Airway obstruction
- High gas flow rate (or ↑ gas flow)

Decreased Resistance
- ↓ Improvement in any of the foregoing conditions
- ↓ Bronchodilator administration
- ↓ Suctioning and airway care
- ↓ Use of lower inspiratory gas flow rate

MINI CLINI

Airway Resistance

Problem

A patient receiving volume-assist controlled ventilation with a constant flow of 60 L/min has high peak airway pressures of 35 cm H_2O. You perform an inspiratory hold on the ventilator and determine that the plateau pressure is 22 cm H_2O. Upon auscultation you hear bilateral wheezes on exhalation. What does this finding indicate?

Solution

The patient has high airway resistance (13 cm H_2O), which could be caused by bronchospasm.

The response to any intervention, such as administering bronchodilators, can be monitored in real time by using a pause time on the ventilator of 0.2 to 0.3 seconds. This will allow a plateau pressure to be displayed in real time and breath by breath on the ventilator. The change in the difference between peak and plateau pressure will indicate a decrease in airway resistance.

MONITORING LUNG AND CHEST WALL MECHANICS

Ventilation of the lungs involves overcoming the flow-resistive, inertial, and elastic properties of the respiratory system. In a ventilated patient, change in airway pressure during ventilation is used to determine the compliance of the total respiratory system. Pressure changes measured by an esophageal balloon reflect compliance of the chest wall. The difference between the compliance of the respiratory system and chest wall is the lung compliance (lung compliance can also be measured in the passively ventilated patient using the change in **transpulmonary pressure**).

One method to assess the compliance of the respiratory system and its relation to lung volume is through the use of a pressure-volume (P-V) curve. There is normally a difference in the P-V relationship during inflation and deflation. However, a large difference between inflation and deflation, called hysteresis, typically implies that lung units have been recruited after a threshold level of pressure was applied.

To measure a static P-V curve of a ventilated patient from resting at functional residual capacity (FRC) to total lung capacity, until more recently a calibrated syringe (referred to as a supersyringe) ranging from 1.5 to 3 L was used to inject 50 to 100 mL increments into the lungs while airway pressure was recorded. A P-V curve can be measured more easily by the continuous delivery of a low flow of gas into the lung (<5 L/min) with the simultaneous recording of system pressure change. Current ICU ventilators allow the determination of an inflation P-V curve using this approach. The P-V curve is plotted as part of the ventilator graphics package with cursors available to identify specific points on the curve. Patients should be sedated during the maneuver, mostly because the flow delivered would be insufficient to satisfy

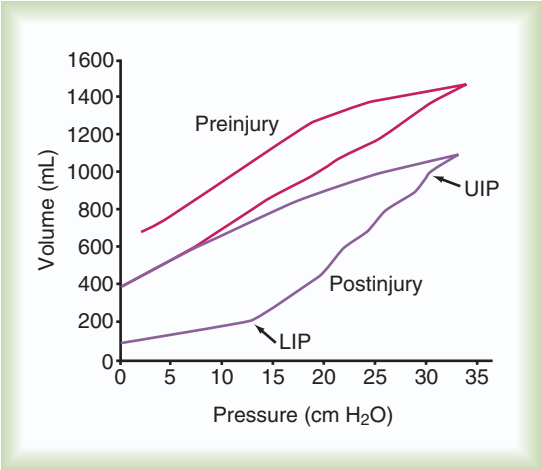

Fig. 52.2 P-V curves generated by a normal lung (preinjury) and after oleic acid injury (postinjury). In the preinjury curve, the linear relationship between pressure and volume with minimal hysteresis is evident. The postinjury curve displays marked hysteresis and two changes in compliance on the inspiratory limb: a lower inflection point *(LIP)* and upper inflection point *(UIP)*.

patient demand. Also, the amount of pressure or volume applied during the maneuver would likely cause discomfort.

The inflation P-V curve often but not always reveals two points at which the slope of the curve changes. The lower point at which the slope changes is called the lower inflection point. As depicted in Fig. 52.2, a lower inflection point may occur over the lower range of volumes, indicating a pressure above which total respiratory system compliance is improved owing to the beginning of alveolar recruitment, overcoming airway closure, or the peripheralization of secretions.[14] A recommended strategy is to set PEEP slightly above the lower inflection point with the goal of maintaining recruitment and stabilizing dependent alveoli that may otherwise sustain injury from repetitive opening, closing, and reopening during tidal ventilation. The other pressure change in the slope, called an upper deflection point, may be seen at a higher volume, indicating where compliance decreases owing to alveolar overdistension or a slowing of lung recruitment. The risk of alveolar overdistension is generally reduced if the P_{plat} is less than 28 cm H_2O in patients with ARDS.[15] More recently, attention has been focused on the deflation area of the curve and what is called the critical closing pressure, the area of the deflation curve where there is significant loss in compliance.[16] The rationale for paying attention to the critical closing pressure is that when there is a significant amount of recruitment (showing as hysteresis), the amount of pressure required to maintain an open lung may be lower than that needed during the inflation curve. The deflation area of the curve is discussed further later in this chapter.

RULE OF THUMB A P-V curve is obtained using a low-flow inflation P-V curve maneuver (flow <5 L/min). There is normally a difference in the P-V relationship during inflation and deflation. However, a large difference between inflation and deflation, called hysteresis, typically implies that the airways have been opened, and lung units have been recruited after a threshold level of pressure was applied (see Fig. 52.2).

RESPIRATORY SYSTEM COMPLIANCE

Respiratory system compliance should be routinely monitored in all ventilated patients. To attain an accurate assessment of compliance (static compliance), two maneuvers must be performed: an end-inspiratory hold and an end-expiratory hold. A short end-inspiratory hold maneuver in a passively ventilated patient allows for the equilibration of pressure across the lung and an estimation of peak alveolar pressure or the inspiratory P_{plat}. An end-expiratory hold is required to assess the total PEEP ($PEEP_{TOT}$) when auto-PEEP is present. Compliance (C) is calculated as follows:

$$C = \Delta V/\Delta P$$

where V_T (corrected for tubing compliance) is ΔV and ΔP is P_{plat}–$PEEP_{TOT}$ (driving pressure).

Normal compliance ranges from 60 to 100 mL/cm H_2O. Diseases of the lung parenchyma—such as pneumonia, pulmonary edema, or any chronic disease-causing fibrosis—cause decreased effective compliance. Acute changes—such as atelectasis, pulmonary edema, ARDS, and lung compression caused by tension pneumothorax—cause a rapid decrease in compliance. Compliance is often less than 25 to 30 mL/cm H_2O in patients with ARDS. Common causes of changes in respiratory system compliance are listed in Box 52.7. Several ventilators report breath-to-breath compliance and resistance values dynamically without the use of pause maneuvers. Monitoring of these estimates can indicate impedance problems and is useful for trending during the titration of ventilator settings (such as PEEP), but absolute values should be verified by static maneuver calculations.

CHEST WALL COMPLIANCE

In a significant proportion of patients, chest wall compliance can influence the P-V relationship during ventilation. Poor respiratory system compliance may be largely due to external pathologies of the chest wall. Normal chest wall compliance accounts for approximately 20% of the respiratory compliance but can commonly reach 50% or greater in critically ill patients. Chest wall abnormalities (including the abdomen) may cause an increase in pleural pressure both at rest and during positive-pressure ventilation. Direct measurement of pleural pressure at the bedside is highly invasive, which is why **esophageal balloon pressure** measurement is used as a surrogate (Box 52.8). Chest wall compliance (C_{CW}), by definition using esophageal pressure, is as follows:

$$C_{CW} = \Delta V/P_{esinsp} - P_{esexp}$$

where P_{esinsp} is the esophageal pressure during an end-inspiratory hold and P_{esexp} is the esophageal pressure during an end-expiratory hold.

Poor chest wall compliance (high chest wall elastance) may buffer the lung-damaging effect of elevated airway pressure by reducing end-inspiratory transpulmonary pressure (Ptp). Higher airway pressures may be required to ventilate these patients, but without the same risk of barotrauma as in patients with low pleural pressure or normal chest wall compliance. One of the

BOX 52.8 Monitoring of Esophageal Pressure

Esophageal pressure is used clinically as a surrogate for pleural pressure. The measurements are used to determine compliance of the chest wall and lung, measure work of breathing, determine the appropriateness of PEEP, and calculate lung stress. A thin esophageal catheter (approximately 2 mm in diameter) is simple to insert and poses little risk of esophageal perforation. Appropriate placement is achieved by first passing it into the stomach and then inflating the 10-cm-long balloon with approximately 0.5 to 1.0 mL of air. The catheter is carefully withdrawn until the final position of the balloon is within the lower third of the esophagus, as verified by the presence of cardiac oscillations within the pressure tracing. In adults, this is approximately 35 to 40 cm from the teeth when the balloon is inserted orally. Proper placement can also be confirmed by occluding the airway (done with an expiratory hold on the ventilator) and measuring the simultaneous deflections in pressure at the airway opening and esophageal pressure either during spontaneous efforts or by a gentle push on the chest or abdomen. The change in pressure in the airway during occlusion should be the same as the change that occurs in the esophageal pressure.

BOX 52.9 Common Causes of Elevated Pleural Pressure in the Intensive Care Unit

- Obesity
- Intra-abdominal hypertension
- Massive fluid resuscitation

most common causes of poor chest wall compliance is intra-abdominal hypertension. Regular monitoring of **bladder pressure** can be useful for confirming issues of poor chest wall compliance in the absence of esophageal pressure monitoring. Some causes of elevated pleural pressure (resulting in poor chest wall compliance) are listed in Box 52.9.

RULE OF THUMB Poor respiratory system compliance may be largely due to external pathologies of the chest wall. Normal chest wall compliance accounts for approximately 20% of the respiratory compliance but can commonly reach 50% or greater in critically ill patients. Esophageal pressure measurements are required to truly assess the impact the chest wall is having on respiratory system compliance.

TRANSPULMONARY PRESSURE

Airway pressure as measured by the ventilator does not take into consideration the pleural pressure or chest wall compliance of the patient. True distending pressure of the lung (the pressure that stretches the lung) is the transpulmonary pressure (Ptp). The appropriateness and safety of the airway pressures delivered by the ventilator, both at end-exhalation (PEEP) and end-inspiration (P_{plat}), depends on the resulting Ptp.[17]

The estimation of Ptp is commonly done through the use of esophageal pressure monitoring using the following simple equation:

$$P_{airway} - P_{es} = Ptp$$

where P_{aw} is the airway pressure and P_{es} is the esophageal pressure. Two variations are used in clinical practice, one for end-exhalation and one for end-inspiration. These variations are as follows:

$$P_{PEEP} - P_{esexp} = Ptp_{EX}$$

$$P_{plat} - P_{esinsp} = Ptp_{IN}$$

where the first equation is the transpulmonary pressure during an end-expiratory hold and the second equation is the transpulmonary pressure during an end inspiratory hold. Lung compliance (CL) can be derived from these measurements as follows:

$$C_L = \Delta V / Ptp_{IN} - Ptp_{EX}$$

Ptp_{IN} can be monitored to evaluate global lung stress and the potential for overdistension—usually allowing some liberty in accepting higher P_{plat} to deliver adequate ventilation in patients with elevated pleural pressures (stiff chest walls). It is currently unknown what the safest upper limit of Ptp_{IN} should be, as it may underestimate the stress felt in some areas of the lung, but it should be less than 20 cm H_2O of pressure. For patients with a large degree of lung inhomogeneity, efforts to maintain an even lower Ptp_{IN} should be made. The monitoring of Ptp_{EX} has been used more recently as a rationale for setting PEEP.[18] A negative Ptp_{EX} probably indicates lung closure (dependent lobe) during expiration, which can result in lung opening and closing during the ventilatory cycle. Adequate or "optimal" PEEP when measuring Ptp is the PEEP level that avoids a negative Ptp_{EX}. (See Chapter 49 for details.)

LUNG STRESS AND STRAIN

During mechanical ventilation, the lungs are exposed to positive pressure that exerts more stress and strain on the lungs than is experienced during spontaneous ventilation. This **lung stress and strain** may cause injury or extend existing lung injury along the injury/normal tissue border. When positive pressure becomes injurious, it is referred to as ventilator-induced lung injury. However, the concepts of stress and strain as applied to the lungs are not clearly defined. The physical definition of stress is a force per unit area. Strain is the deformation of a structure compared with its overall size. Hooke's law associates the two factors by the following relationship: stress = k * strain.

Working definitions for stress and strain applied to the lungs have been studied. The most common methods for assessing the pressure felt by the lung during inspiration are the directly measured method:[17]

$$Ptp_{IN} = P_{plat} - P_{pesinsp}$$

And the elastance-derived method, which requires the calculation of lung and respiratory system elastance,[19] is

$$E_L = (Ptp_{IN} - Ptp_{EX}) / \Delta V$$

$$E_{RS} = (P_{plat} - PEEP_T) / \Delta V$$

$$Ptp_{IN} = P_{plat} \times E_L / E_{RS}$$

Although these methods for Ptp_{IN} give different results, current research suggests that it is due to the pressure gradient of pleural pressure across the chest wall, and the elastance-derived method

may better reflect lung stress in the nondependent region of the lung, whereas the direct method may reflect stress in the middle of the thoracic space.[20]

Driving pressure, as previously discussed, may be an alternative measure of stress. However, when chest wall compliance is poor, it may be difficult to determine the potential for injury without measuring lung stress. Strain has been defined as V_T (the deformation) divided by FRC (the resting size of the lungs). These definitions have been associated as stress = 13.5 × strain, predicting that a stress of 27 cm H_2O (Ptp of 27 cm H_2O) and a strain of 2 (V_T of twice the FRC) reach injurious limits of ventilation.[21] The measurement of lung stress requires placement of an esophageal catheter. To measure strain, automated FRC determinations have become available on some modern ventilators.[22] Stress can also occur at lower pressures if lung units are opening and closing during the ventilator cycle.

MONITORING THE PATIENT–VENTILATOR SYSTEM

Monitoring of a patient during mechanical ventilatory support should include a physical examination (inspection, palpation, percussion, and auscultation), assessment of oxygenation and ventilation, and assessment of ventilatory load and capacity. Table 52.1 lists key physiologic monitoring data and acceptable values for patients receiving mechanical ventilation. Monitoring of all

TABLE 52.1 Physiologic Monitoring Data (Respiratory Values)

Function Assessed	Description of Value	Symbol/Formula	Acceptable Value
Oxygenation			
Lung Exchange (External)			
Adequacy	Arterial oxygen pressure	PaO_2	60–100 mm Hg
	Arterial oxygen saturation	SaO_2	≥90%
	Oxygen saturation by pulse oximeter	SpO_2	≥90%
	Transcutaneous oxygen partial pressure	$PtcO_2$	60–100 mm Hg
Efficiency	Alveolar to arterial oxygen tension gradient	$P(A–a)O_2$	<350 mm Hg (100% O_2)
	Arterial to alveolar	PaO_2/PAO_2	>0.6
	Respiratory index	$P(A–a)O_2/PaO_2$	<5
	P/F ratio	PaO_2/FiO_2	>300
	Percentage shunt	$\dot{Q}_S/\dot{Q}_T$	<15%–20%
Time exchange (internal)	Mixed venous oxygen content	$C\bar{v}O_2$	>10.0 mL/dL
	Mixed venous oxygen partial pressure	$P\bar{v}O_2$	>30 mm Hg
	Mixed venous oxygen saturation	$S\bar{v}O_2$	>65%
	Arterial-venous oxygen content difference	$C(a-\bar{v}O_2)$	<7 mL/dL
Ventilation			
Adequacy	Minute ventilation	$\dot{V}_E$	5–10 L/min
	Arterial carbon dioxide	$PaCO_2$	35–45 mm Hg (normal pH)
	Transcutaneous carbon dioxide partial pressure	$PtcCO_2$	35–45 mm Hg (normal pH)
	End-tidal carbon dioxide partial pressure	$P_{ET}CO_2$	35–43 mm Hg (4.6%–5.6%)
Efficiency	Dead space/tidal volume ratio	V_D/V_T	<0.6
	Minute ventilation vs. carbon dioxide partial pressure	$\dot{V}_E$ vs. $PaCO_2$	$\dot{V}_E$ <10 L/min with normal $PaCO_2$
Ventilatory Load			
Total impedance	Dynamic compliance	$(V_T–V_C)/(PIP–PEEP)$	35–50 mL/cm H_2O
Compliance	Effective compliance	$C_{eff} = \frac{(V_T - V_C)}{P_{plat} - PEEP}$	60–100 mL/cm H_2O
WOB	Work = kg × m/L or J/L	Work = P × V	<0.15 kg × m/L <1.5 J/L
Ventilatory Capacity			
Drive	Occlusion pressure	P0.1	<6 cm H_2O
	Mean inspiratory flow	V_T/T_i	Not established
	Diaphragm thickening fraction	TFdi	15%–30%
Strength	Vital capacity	VC	>10–15 mL/kg
	Maximal inspiratory pressure	MIP; PI_{max}	<–20 to –30 cm H_2O
	Maximum diaphragm thickening fraction	TFdi-max	>20%
Endurance	Maximum voluntary ventilation	MVV	>20 L/min or 2 × $\dot{V}_E$
	Ratio of minute ventilation to MVV	$\dot{V}_E$/MVV	<1:2
	Pressure-time index	$(Pdi/Pmax)*TI/T_{tot}$	<0.15

aspects of the patient–ventilator system is an important responsibility that must clearly be performed within the ICU. Monitoring a ventilated patient is the primary responsibility of the RT. Important areas of this responsibility include the following:

- Assessing the integrity of the airway and circuitry, including secretion clearance
- Maintaining the prescribed settings and assessing their appropriateness
- Ensuring acceptable gas exchange values
- Monitoring of respiratory system mechanics
- Evaluating the comfort and synchrony of the patient's breathing
- Setting of alarms
- Caring for any other safety issues, such as risk of unplanned extubation

A system of ensuring and documenting all aspects of safe and appropriate care must be in place. This system usually includes a manual or, more frequently, an electronic recording of all important settings, alarms, and ABG values at regular intervals. This monitoring process has been called a patient–ventilator assessment. An example of a recording form used for this purpose is shown in Fig. 52.3. Increasingly, electronic transfer of ventilator settings and monitored data is being added to the electronic medical record. The responsibility of the RT is much greater

than the task of recording values. This responsibility is care of a critically ill, vulnerable patient with respiratory failure who is being supported by a lifesaving machine. The procedure for assessing a patient–ventilator system is outlined in Table 52.2. Although the importance of monitoring the patient–ventilator system has increased, the necessity of entering and transcribing numbers into an assessment sheet is decreasing. The era of electronic transfer of monitored data directly to patients' charts is becoming the standard. All modern ventilators have the capacity for data transfer, but until standardized transfer protocols, charting formats, and archiving methods have been established, electronic monitoring of the patient–ventilator system will continue to be customized to the local setting.

Graphics Monitoring

Monitoring of graphic tracings generated during mechanical ventilation has become widely available and accepted in the ICU. A visual display of pressure, flow, and volume tracings is available on all modern ventilators. Graphic displays are possible through the development of improvements in sensing technology, integrated circuitry, and graphic–user interface. Ventilators measure inspiratory and expiratory flow and circuit pressure with pneumotachometers and transducers. The volume displays are generated through calculation of an integral of the flow tracings. All three values (flow, pressure, and volume) can be displayed and plotted against time or each other (Fig. 52.4).

Monitoring During Lung-Protective Ventilation

A lung-protective ventilation strategy that reduces the risk of pressure injury to the lungs has evolved from numerous animal studies and several key clinical studies.[23] Meticulous monitoring of the status of all mechanically ventilated patients but especially those with ARDS or patients at risk of ARDS is necessary to avoid ventilator-induced lung injury. Four principles have been

TABLE 52.2 Assessing a Patient–Ventilator System

Step	Key Points
Gather correct equipment and supplies.	Respirometer, O_2 analyzer, stethoscope, and watch with second indicator are needed. *Note:* Most modern ventilators incorporate volume-measuring devices into the system. Additional auxiliary equipment may include pulse oximeter, cuff pressure manometer, suction and airway equipment, and sterile distilled water.
Review patient record.	Note patient's admitting diagnosis or problem list, physician orders, medications, vital signs, history and physical examination findings, progress notes, results of laboratory studies, chest radiograph, blood gases, and respiratory care notes.
Enter patient area; wash hands and put on gloves.	Inattention to proper handwashing and poor aseptic technique are associated with nosocomial infection.
Identify the patient.	Wristbands may sometimes be attached to the patient's leg or to the foot of the bed. If there is no attached name band, check with the patient's nurse.
Explain what you are doing.	Communication with the patient is important; even patients who appear unaware of their surroundings may be able to hear and understand. Use broad terms, such as "I'm here to assess your breathing."
Observe overall situation and note general patient condition, including level of consciousness, condition of extremities, presence of pallor, skin color, capillary refill, airway patency, circuit connection and patency, and findings on the electrocardiogram.	Note patient's general appearance, sensorium, color, and level of activity. Note equipment in use, including ventilator, circuit, airway type, humidification, manual resuscitation bag, and related equipment and supplies Ensure that the patient's condition appears stable and that ventilation is adequate.
Drain tubing and service humidifier, if needed.	This procedure should be done before the actual ventilator check if possible.
Attend to patient's airway if necessary.	Suctioning and other airway manipulation should be done before actual ventilator check if possible; after suctioning, note volume and character of secretions. Note endotracheal or tracheostomy tube stability and position; measure tube cuff pressure and volume to inflate. If ventilator check is performed first and the patient circuit or airway is disrupted, errors may not be caught, and one of the purposes of ventilator monitoring—patient safety—is defeated.
Inspect chest and note accessory muscle use, retractions, jugular vein engorgement, bilateral symmetric chest wall movement, symmetric diaphragm–chest wall movement, respiratory rate and rhythm, and chest wall stability (flail).	Be alert for signs of respiratory distress, increased work of breathing, or patient-ventilatory asynchrony. Observe patient effort to ensure adequate trigger sensitivity and inspiratory flow rate.
Auscultate chest.	Always move stethoscope from side to side to compare right and left sides of chest. Note adventitious breath sounds (crackles, rhonchi, wheezing, bronchovesicular breath sounds). Note diminished or absent breath sounds; if breath sounds are absent, attempt to ascertain cause immediately. Water in the tubing, use of chest tubes, or PEEP may result in adventitious sounds.
Percuss chest for dullness, resonance, or hyperresonance.	Dullness may be caused by pleural effusion, atelectasis, or consolidation. Resonance is the percussion note found over normal lung tissue. Hyperresonance is associated with excess air in the chest (pneumothorax, pulmonary hyperinflation).
Note location of trachea.	Tracheal shift is associated with severe atelectasis and tension pneumothorax.
Note peak pressure, static or plateau pressure (P_{plat}), baseline pressure (PEEP/CPAP), driving pressure, pressure support level, MAP, and presence of auto-PEEP.	Sudden increase in peak airway pressure is associated with pneumothorax, secretions in the airway, bronchospasm, fighting the ventilator, biting the endotracheal tube, occlusion of the airway, and bronchial intubation. Sudden decrease in peak airway pressure is associated with reversal of any of the above-mentioned conditions, a leak in the system, or patient disconnection. MAP may be useful in predicting a decrease in CO or barotraumas; the lowest possible MAP needed to achieve adequate ventilation and oxygenation should be used. P_{plat} >28 cm H_2O is associated with the development of ventilator-induced lung injury; if P_{plat} is ≥28 cm H_2O, consider reducing delivered V_T. A driving pressure >14 cm H_2O is associated with increased risk of mortality. Consider using tidal volume 4–6 mL/kg of predicted body weight, or consider lowering PEEP.
Record exhaled volume (mL/kg predicted body weight) and respiratory frequency.	Ensure ventilator compensates for compressible volume. If volume is measured at the exhalation valve, volume loss caused by tubing compliance may be calculated and subtracted from the measured volume.

TABLE 52.2 Assessing a Patient-Ventilator System—*cont'd*

Step	Key Points
If intermittent mandatory ventilation (IMV)/SIMV system is in use, calculate delivered volume per machine breath, spontaneous volume between machine breaths, machine rate, total rate, patient spontaneous rate, and minute ventilation.	For IMV/SIMV: $V_{ISP} = \frac{\dot{V}_{Etot} - \dot{V}_{Emech}}{f_{tot} - f_{mach}}$ For assist/control: $\text{Average } V_T = \frac{\dot{V}_{Etot}}{f_{tot}}$
If a ventilator graphics package is in use, observe pressure-time, flow-time, volume-time, and P-V curves.	Mode of ventilation, patient trigger, adequacy of machine inspiratory flow, and patient–ventilator synchrony can be evaluated with a ventilator graphics package. Slow flow P-V curve can be used to assess lower and upper inflection points. Overdistension can be elevated with use of dynamic P-V curve. Flow-volume curve may be helpful in assessing effect of bronchodilator.
Note delivered FiO_2.	FiO_2 should be analyzed.
Record other ventilatory values.	Ventilatory values include inspiratory flow, inspiratory time, I:E ratio, inspiratory and expiratory positive airway pressures (IPAP and EPAP), sigh volume and rate, airway temperature, compliance and resistance, and alarm settings. Many departments chart endotracheal tube size, tube length, cuff pressure or volume, use of minimal occluding volume or minimal leak, ventilator day, circuit change, and other therapy.
Record blood gas values and related data as appropriate.	These data may include pH, PaO_2, $PaCO_2$, SaO_2, hemoglobin level, HCO_3^- level, IPAP, base excess, and CaO_2. Blood gas data should be recorded in such a way that the corresponding FiO_2, PEEP, V_T, frequency, mode, and other ventilator settings on which the sample was obtained are noted.
Record results of other physiologic monitoring of cardiopulmonary system as appropriate.	These values may include SpO_2, $PETCO_2$, $PtcCO_2$, $PtcO_2$, $\dot{Q}_S/\dot{Q}_T$, and V_D/V_T.
Record hemodynamic data as appropriate.	These values may include heart rate, blood pressure, CVP, PAP, PCWP, $\dot{Q}_T$, cardiac index, $S\dot{v}O_2$, $P\dot{v}O_2$, $CaO_2 - C\bar{v}O_2$, pulmonary vascular resistance, and systemic vascular resistance.
Record weaning values as appropriate.	These values may include spontaneous frequency, V_T, f/V_T ratio, $\dot{V}_E$ VC, and inspiratory force (MIP).
Return all alarm systems to optimal condition. Complete charting using appropriate departmental forms or computer entry systems.	Alarms include low pressure, high pressure, disconnection, and volume. Apnea values should be reviewed. Apnea values usually are set to deliver an adequate V_T, f_{mach}, and FiO_2 (100%) in the event of apnea development.

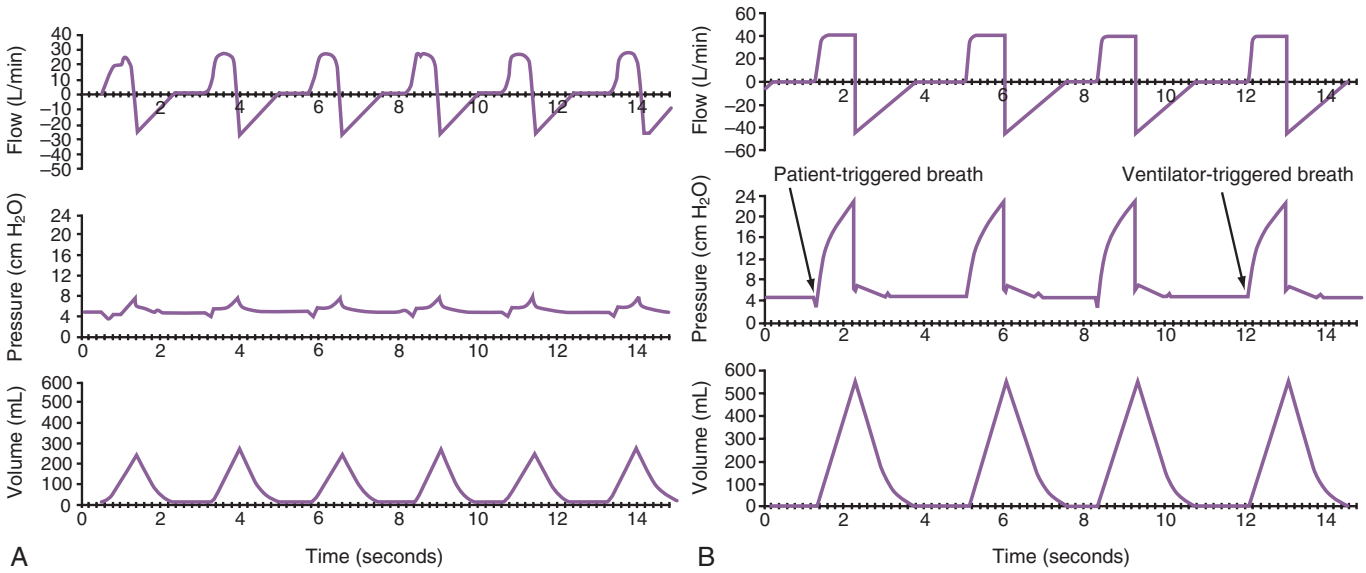

Fig. 52.4 Ventilator Graphics: Flow, Pressure, and Volume Tracings. (A) Spontaneous breathing at an elevated baseline pressure (continuous positive airway pressure [CPAP]). Flow, pressure, and volume curves show spontaneous breathing with a CPAP level of approximately 5 cm H_2O. The flow curve is sinusoidal, the pressure curve fluctuates approximately 1 to 3 cm H_2O around the baseline pressure, and the volume delivered varies. These are typical observations during spontaneous breathing. (B) Volume ventilation in the assist/control mode. Some breaths are time triggered and others are patient triggered. There is a square wave-flow pattern, and volume is constant breath to breath.

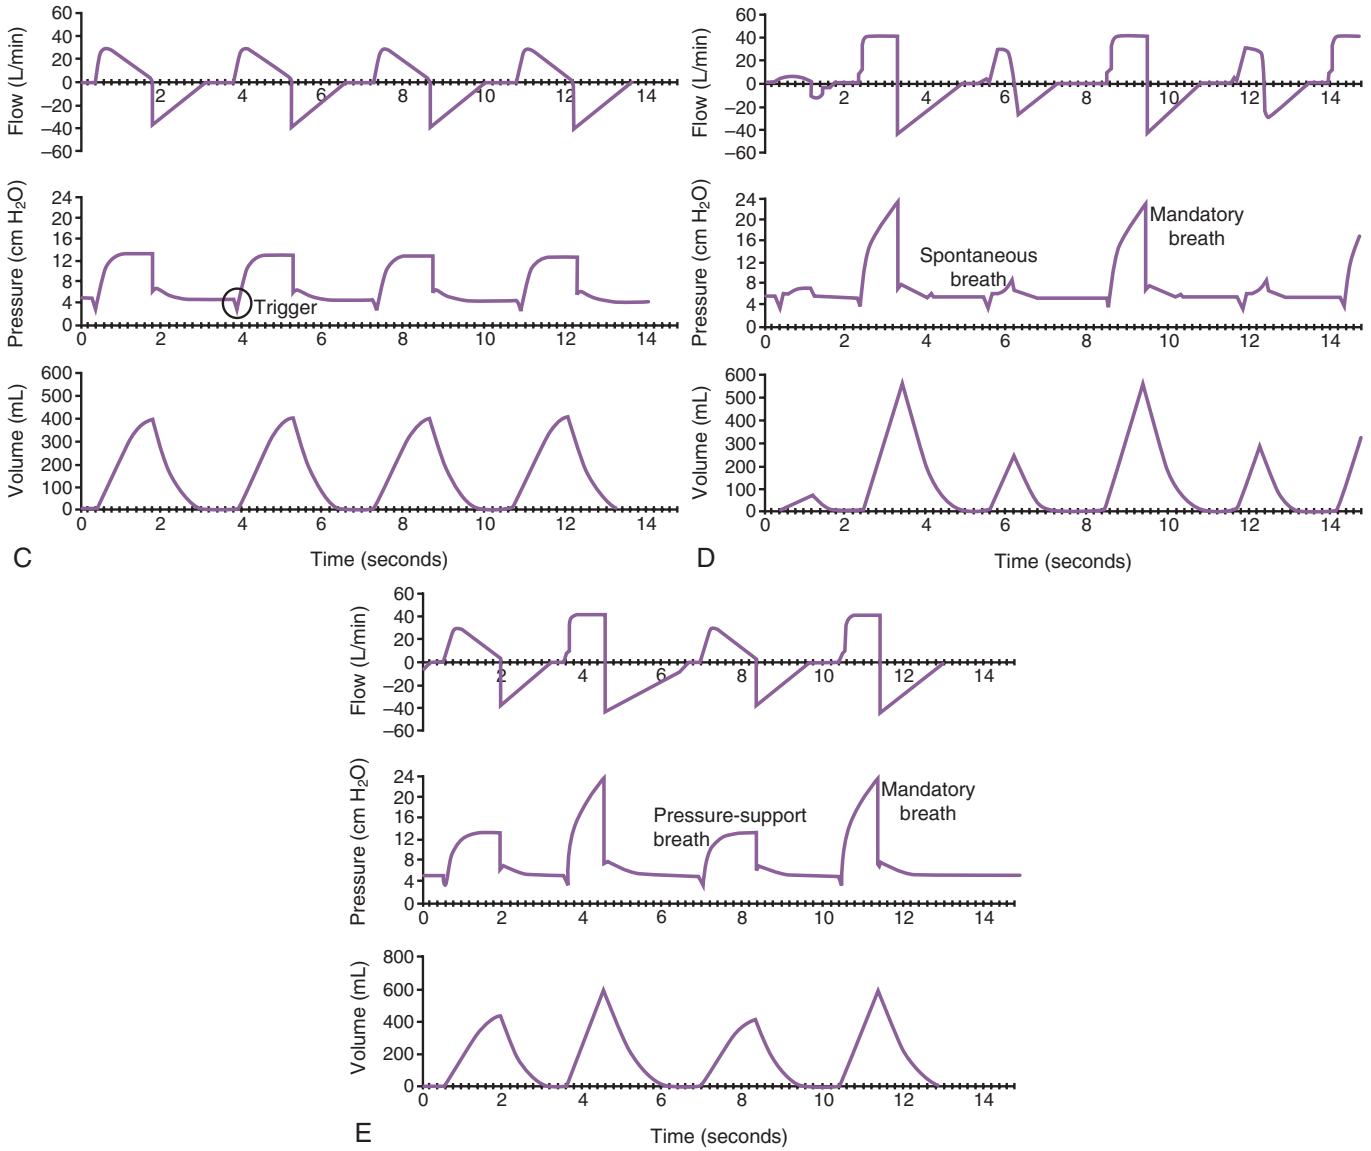

Fig. 52.4, cont'd (C) Pressure support breaths (pressure support ventilation). The patient trigger for each breath is evident. Flow is decelerating, and the pressure waveform approaches a square wave. (D) Synchronized intermittent mandatory ventilation (SIMV) with an elevated baseline positive end-expiratory pressure (PEEP). Spontaneous breathing and machine-mandatory breaths are interspersed. Spontaneous volume varies, but the SIMV breaths are constant at 600 mL. The square wave-flow pattern for mandatory breaths and sinusoidal flow during spontaneous breathing are evident. The baseline pressure (PEEP) is elevated at approximately 5 cm H_2O. (E) SIMV with pressure support. Mandatory breaths have a square flow waveform with a constant volume of 600 mL. The pressure support breaths have a decelerating flow waveform ad a pressure pattern approaching a square wave. In this example, there is also an elevated baseline of approximately 5 cm H_2O (PEEP).

confirmed: (1) reduce the risk of high-pressure exposure by limiting P_{plat} to less than 28 cm H_2O, (2) reduce the risk of excessive tidal ventilation stress by limiting driving pressure to less than 15 cm H_2O, (3) reduce V_T ventilation to 4 to 8 mL/kg of predicted body weight (PBW), and (4) maintain adequate end-expiratory lung volume with PEEP to avoid opening/closing injury.

Other considerations have received attention in monitoring patients with ARDS. Although P-V curves have been automated in ventilator algorithms, the clinical significance of curves determined from PEEP of 0 cm H_2O is questionable. However, current recommendations are to maintain ventilation on the upper portion of the deflation limb of the P-V curve to avoid alveolar derecruitment even though this position with the P-V hysteresis curve of a patient may be difficult to determine. A primary concern is to achieve adequate oxygenation in patients with lung injury, but this target can be deceptive if the price of adequate oxygenation is pressure injury to the lungs. An acceptable practice in ventilating these patients is permissive hypercapnia or pressure-protective ventilation that allows $PaCO_2$ to drift upward. This strategy is a higher frequency–lower V_T approach with the

predictable effect of decreasing pH (by increasing $PaCO_2$), which requires careful monitoring.

As previously discussed, poor chest wall or abdominal compliance must also be considered during lung-protective ventilation. This concern can be significant in obese patients. Essentially, the stiffer the chest wall or abdomen, the greater is the P_{plat} that can be established without inducing lung injury. Meta-analysis of higher versus lower PEEP suggests the use of higher levels of PEEP with patients suffering from moderate to severe ARDS, and high levels of PEEP should be used cautiously when mild ARDS is being treated.[24] Setting PEEP levels greater than 15 cm H_2O is often necessary in patients with moderate to severe ARDS to maintain oxygenation.[16] Elevated PEEP places greater importance on monitoring cardiovascular performance, plateau pressure, driving pressure, and development of barotrauma.

RULE OF THUMB Modern mechanical ventilators routinely display tracings of flow, pressure, and volume versus time. Ventilator graphics monitoring is a convenient visual method for monitoring patient–ventilator interaction. The graphic patterns allow rapid determination of mode of ventilation, breathing pattern, auto-PEEP, excessive pressure, secretions in the airway, synchrony, and triggering efforts.

STRESS INDEX

Another index involving the dynamic measurement of stress has been reported.[25] The **stress index** is a value derived from the airway pressure-time curve during constant flow delivery of a tidal breath. During constant flow (when resistance is constant), the slope of the pressure-time tracing is analyzed to evaluate the elastic properties of the lungs. The index is calculated by performing a curve fit of the slope of the pressure-time tracing, where pressure = a × time b + c. Ideally, a slope (b) of 1 indicates normal filling during lung expansion, whereas a slope greater than 1 indicates overdistension, and a slope less than 1 indicates lung recruitment (Fig. 52.5). This measure can be calculated for each delivered tidal breath, although an acceptance criterion should be used to exclude analysis of artifacts and factitious breaths. The stress index can be visually detected (without software) with good sensitivity and specificity and should be considered an additional tool for bedside monitoring of ventilator waveforms.[26]

Although the index may not determine a threshold for excessive stress or strain, it may be a useful indicator of lung response to positive pressure. If the chest wall contributes variably to airway pressure, the calculated index can be altered and deceptive.[27]

RULE OF THUMB During constant flow (when resistance is constant), the slope of the pressure-time tracing (stress index) can be analyzed to evaluate the elastic properties of the lungs. The stress index can be visually detected (without software) and should be considered an additional tool for bedside monitoring of ventilator waveforms.

MINI CLINI

Potential for Lung Injury

Problem

A patient with ARDS is being ventilated with volume assist control and constant flow. The pressure-time curve is visibly concave. Additionally, an inspiratory and expiratory pause is performed on the ventilator showing a plateau pressure of 32 cm H_2O and total PEEP of 14 cm H_2O. What could this indicate?

Solution

The patient appears to have a high stress index as demonstrated by a concave curvature of the pressure-time curve during constant flow. Also, the patient has a driving pressure of 18 cm H_2O (32 – 14 = 18). The patient is likely being ventilated near the upper inflection point of a pressure-volume curve. An attempt to lower tidal volume (if the patient does not have severe acidosis) should be made or to lower PEEP, as the patient may not be responsive to PEEP, and it is only causing overdistension of open lung regions.

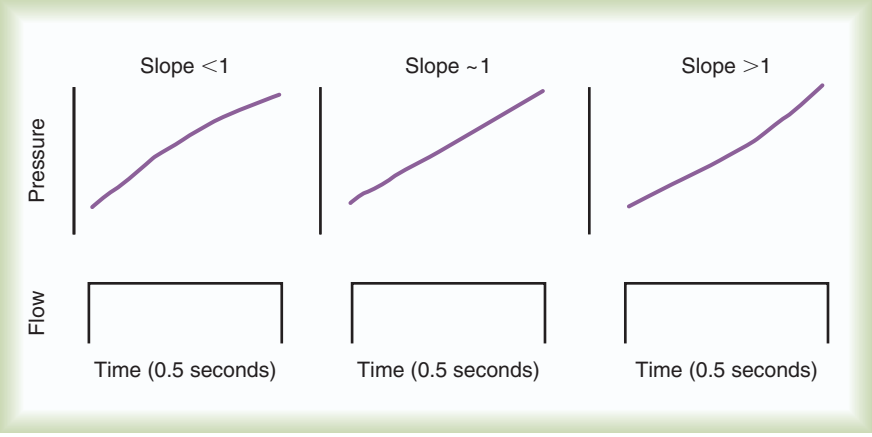

Fig. 52.5 Conceptual illustration of the dynamic pressure-time (p-t) curve. *Left,* convex curve (slope <1) indicating recruitment during the breath. *Center,* linear relationship between pressure and time (slope ~1), indicating no recruitment or overdistension. *Right,* concave curve (slope >1), indicating overdistension.

AUTO–POSITIVE END-EXPIRATORY PRESSURE (INTRINSIC POSITIVE END-EXPIRATORY PRESSURE)

PEEP is the pressure maintained in the airway by the ventilator at end-exhalation. An alveolar pressure that exists above the applied or extrinsic PEEP level at end-exhalation is termed intrinsic PEEP or auto-PEEP. At the bedside, total PEEP is the sum of extrinsic PEEP and intrinsic PEEP. Intrinsic or auto-PEEP is sometimes misunderstood when one considers "trapped" air versus breath stacking, which can occur when a patient is being passively ventilated with insufficient time to exhale. Intrinsic or auto-PEEP is often the result of small airway collapse or severe bronchospasm and can also occur when excessive tidal volume is delivered to a patient with a high ventilatory demand, causing dynamic hyperinflation when the patient has difficulty exhaling all of the excess volume.

Numerous factors, both internal and external to the patient, contribute to the development of auto-PEEP. Expiratory muscle activity can increase auto-PEEP and may interfere with attempts at assessment of auto-PEEP based solely on dynamic hyperinflation. Patients receiving mechanical ventilation for obstructive airways disease have a large degree of inhomogeneity in the emptying of lung units, and auto-PEEP can develop even at relatively low minute ventilation. Auto-PEEP is common in mechanically ventilated patients receiving high minute ventilation and occurs in patients with ARDS.[28] An increase in mean alveolar pressure owing to auto-PEEP may exacerbate the hemodynamic effects of positive-pressure ventilation and increase the likelihood of barotrauma in a manner similar to the application of PEEP. In addition, the presence of auto-PEEP makes it more difficult for the patient to trigger a ventilator-assisted breath because auto-PEEP imposes an inspiratory pressure threshold resistor, which the patient must overcome before any inspiratory flow begins.

Finally, if unrecognized, auto-PEEP leads to erroneous calculation of static lung compliance by underestimating total PEEP. Decreasing minute volume can reduce or eliminate auto-PEEP; however, minimal auto-PEEP can be benign. In addition, increasing expiratory time allows more time for airways to empty normally, thereby decreasing auto-PEEP. The use of extrinsic PEEP, when set appropriately, can partially overcome the trigger sensitivity problem seen with auto-PEEP and may provide a "stent" to allow more complete lung emptying and a decrease in patient effort, primarily in patients with dynamic airway collapse.[29] Setting PEEP slightly below the level of auto-PEEP can also help to offset the inspiratory pressure threshold by which auto-PEEP can hamper liberation from mechanical ventilation. Measuring auto-PEEP is therefore very important when liberation from mechanical ventilation is planned.

Methods for Determining Auto–Positive End-Expiratory Pressure

Dynamically, auto-PEEP varies throughout the lungs; however, all measurements of auto-PEEP reflect an average auto-PEEP level throughout the lungs. Assessment of auto-PEEP involves first its detection and then a measurement. Patients at risk for auto-PEEP include those in whom expiratory flow limitation is more common; this includes patients with COPD, obesity, heart failure, and ARDS (particularly at low PEEP).[30] Auto-PEEP may be further suspected if flow continues at end-expiration as seen on ventilator graphics monitoring (Fig. 52.6). In this case, auto-PEEP must be present unless there is active contraction of the expiratory muscles producing end-expiratory flow. The following methods are used to estimate auto-PEEP level.

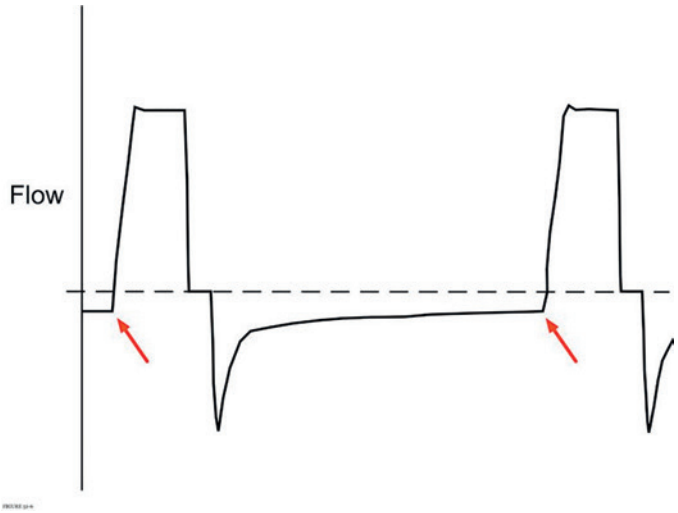

Fig. 52.6 Expiratory flow waveform that does not return to zero flow at end exhalation. Whenever this occurs, auto–positive end-expiratory pressure is almost always present.

End-Expiratory Hold by the Ventilator

Either automated or manual, an end-expiratory hold by the ventilator closes the expiratory valve at end-exhalation. The hold period must extend until the end-expiratory pressure has been stabilized; otherwise the value will be an underestimate of auto-PEEP.

Esophageal Pressure Measurements

An **esophageal balloon** is used to measure the deflection in the pleural space required to trigger the ventilator. The change in esophageal pressure from baseline to the pressure initiating flow at the airway is equal to the total PEEP that must be overcome to trigger a breath.

Using Positive End-Expiratory Pressure With Auto–Positive End-Expiratory Pressure

PEEP can be applied to a level that results in flow at end-exhalation being closer to zero (this is possible in some patients). The concept involves stenting of the airways by PEEP to allow lung emptying and a better equilibration of end-expiratory alveolar pressure with end-expiratory ventilatory circuit pressure minimizing the pressure needed to decompress the alveoli and trigger the ventilator.[29] This maneuver is essentially performed by slowly increasing applied PEEP until every patient effort triggers a ventilator breath. It is important not to exceed the patient's auto-PEEP when external PEEP is being increased. Targeting approximately

80% of the total PEEP should be sufficient to improve the patient's ability to trigger the ventilator.

MINI CLINI

Ventilator Graphics

Problem

The ventilator graphic display of a patient with COPD receiving mechanical ventilation is showing two distinct features: (1) a pressure-time tracing with spikes and dips that is generally irregular and (2) a flow-time tracing that does not reach zero flow at end expiration. What do these findings indicate?

Solution

Graphic displays of pressure and flow allow rapid identification of the presence of secretions, auto-PEEP, and asynchrony. The irregular tracing implies the presence of airway secretions. Auscultation of the lungs should be performed to assess the need for endotracheal suctioning. Without an active expiratory effort, the existence of flow at end expiration confirms the presence of auto-PEEP. Auto-PEEP can be detected in many COPD patients receiving mechanical ventilation. However, intervention to reduce or eliminate auto-PEEP may be unnecessary. Auto-PEEP should be estimated regularly. More importantly, the effects of auto-PEEP on the ability to trigger the ventilator or on cardiovascular dynamics (caused by reduced venous return) should be monitored. For reducing or eliminating auto-PEEP, adjusting the ventilator settings or bronchodilator therapy may be required. If the patient is unable to trigger every breath because of the auto-PEEP, then PEEP should be applied in steps of 1 to 2 cm H_2O until the patient is able to trigger the ventilator with every inspiratory effort.

Ventilator manufacturers have developed graphic displays that allow astute clinicians to base decisions on many more factors than gas exchange values (Box 52.10). However, the study and verification of features observed in ventilator graphics have not kept pace with the developing technology in ventilators. Ventilator graphics show many important patient–ventilator interactions, such as presence of auto-PEEP, elevated airway pressure, presence of secretions, and general pattern and dependability of supported ventilation (Fig. 52.7). The potential for expanded use of ventilator graphics awaits further investigation of the clinical importance of the graphic displays. For more details, see Chapter 48.

BOX 52.10 Purposes of Graphics Monitoring

- Confirm mode functions
- Detect inadequate flow in volume ventilation
- Detect too lengthy an inspiratory time
- Set appropriate rise time and termination criteria in pressure ventilation
- Detect auto-PEEP
- Determine patient–ventilator synchrony
- Assess and adjust trigger levels
- Measure work of breathing
- Adjust V_T and minimize overdistension
- Assess effect of bronchodilators
- Detect equipment malfunction
- Determine appropriate PEEP level

MONITORING BREATHING EFFORT AND PATTERNS

Work of Breathing

Work of breathing (WOB) is often increased in critically ill patients. Commercial systems are available for measuring WOB in ventilated patients. For measuring the WOB, changes in Ptp must be measured. The procedure requires an assessment of pleural pressure, which is normally estimated by esophageal pressure after placement of an esophageal balloon catheter. The measurement is estimated from the esophageal pressure–versus-volume curve (Fig. 52.8).

Patients with severe obstructive or restrictive lung disease "work" at levels two to three times this normal value at rest, with marked increases in work at higher minute ventilation. How much work a patient can tolerate before the ventilatory muscles fatigue is unclear. Maintaining adequate spontaneous ventilation is impossible in many patients when the workload exceeds 0.15 kg/m/L (1.5 J/L).

Monitoring WOB may be valuable in certain situations, such as liberation from mechanical ventilation. Clinicians are expected to assess a patient's WOB continually and to take appropriate action if WOB becomes excessive. Because a direct measurement of WOB requires esophageal manometry, simpler indicators are sought. Monitoring the patient's spontaneous breathing rate, V_T, and **frequency/tidal volume (f/VT) ratio** provides useful surrogates for WOB during ventilator weaning trials. Assessment of the patient's overall clinical presentation is also useful in assessing the WOB. Increased WOB is associated with a rapid shallow breathing pattern, rapid pulse rate, hypertension, and use of accessory muscles of ventilation. Values of f/V_T greater than 105 during spontaneous breathing predict failure of successful liberation from mechanical ventilation.

Pressure-Time Product

The **pressure-time product** (PTP) is the area encompassed by the esophageal pressure-time tracing during inspiration, as shown in Fig. 52.8. PTP is simpler to measure than WOB because it does not require simultaneous measurement of volume. PTP values parallel changes in effort and the O_2 cost of breathing because PTP includes a measure of the "isometric" component of muscle contraction.[31] This index includes work and effort components that may indicate endurance during a trial of liberation from mechanical ventilation.

Oxygen Cost of Breathing

The amount of O_2 consumed by the ventilatory muscles ($\dot{V}Q_2R$) is an estimate of respiratory effort at its most basic level. $\dot{V}Q_2R$ can be estimated by measurement of O_2 consumption during active breathing compared with the patient being fully supported in the control mode:

$$\dot{V}O_2R = \dot{V}O_2 \text{ active breathing} - \dot{V}O_2 \text{ apnea}$$

Normal $\dot{V}Q_2R$ is approximately 2% to 5% of total O_2 consumption; however, $\dot{V}Q_2R$ can be 30% of total O_2 consumption during hyperventilation owing to severe dyspnea. Theoretically, $\dot{V}Q_2R$ accounts for all factors that tax the respiratory muscles—that

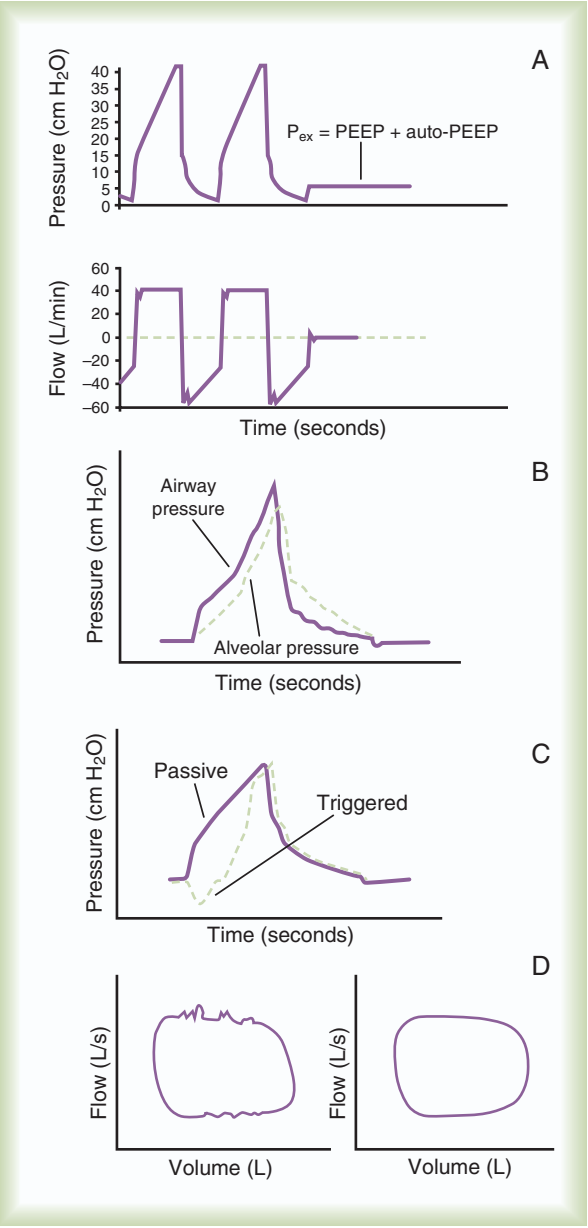

Fig. 52.7 Patient–ventilator interactions are easily identified from tracings of continuous monitoring of pressure, volume, and flow. (A) Auto–positive end-expiratory pressure (auto-PEEP). Flow and pressure tracings during ventilator-supported breaths and during end-expiratory occlusion. The airway pressure during the end-expiratory occlusion is an auto-PEEP estimate. (B) Overdistension. The upper concavity of the airway pressure-time tracing is indicative of overdistension. This example also shows alveolar pressure and its corresponding overdistension. (C) Patient effort. This is an example of mechanically ventilated passive inflation pressure and the airway pressure-time tracing deformation caused by patient effort. (D) Presence of secretions. P-V tracing of a ventilator-supported breath displays the presence of secretions. The inspiratory and expiratory limbs are irregular (not smooth) when secretions are present. An irregular airflow-time tracing can also indicate the presence of secretions.

is, the external workload and the efficiency of the conversion between cellular energy and useful work. $\dot{V}Q_2R$ is difficult to measure if the patient's condition is unstable. Other measures of respiratory muscle function are sought to assess the cost of breathing.

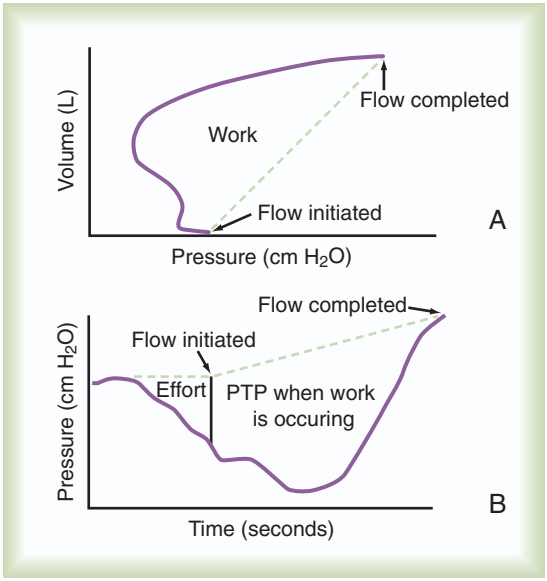

Fig. 52.8 Work of breathing (WOB) (A) and pressure time product (PTP) (B) from the same spontaneous breath of a patient receiving ventilatory support. *Dashed lines* represent a tracing of passive inflation by a ventilator-supported breath. Areas of work and PTP are not directly comparable because WOB units (pressure-volume curve [P-V]) and PTP units (pressure-time) differ. The area of effort in the total PTP area occurs before (and in addition to) the work measurement.

Assessing Ventilatory Drive

Until more recently, little attention was paid to measurement of respiratory drive during critical illness. During machine-assisted breathing, ventilatory drive can play an important role in determining the patient's energy expenditure. One study showed that patients not being liberated from mechanical ventilation often have an elevated drive to breathe and a limited ability to respond to increases in ventilatory load (e.g., increased $PaCO_2$).[32]

Airway Occlusion Pressure

A measure that has been used to index drive is the airway occlusion pressure ($P_{0.1}$ or P_{100}). $P_{0.1}$ is the pressure recorded 100 ms after initiation of an inspiratory effort against an occluded airway. $P_{0.1}$ is influenced by muscle strength and is a good measure of respiratory drive. Because the airway is occluded momentarily, there is no flow; therefore it is independent of resistance, and inhibitory reflexes cannot be influenced because there is no change in lung volume. In healthy subjects, $P_{0.1}$ is within the range of 0.5 to 1.5, but in mechanically ventilated patients, these levels can indicate excessive assistance by the ventilator.[33] Elevated $P_{0.1}$ (>5 cm H_2O) is associated with a continued need for mechanical ventilation and excessive effort. $P_{0.1}$ has also been used to detect a response to external PEEP in patients with hyperinflation and intrinsic PEEP; a decrease in $P_{0.1}$ with the application of PEEP indicates a decrease in intrinsic PEEP and WOB.[34]

In a sophisticated, commercially available system, a direct measure of the neural drive to breathe from the phrenic nerve can be measured by a catheter positioned within the esophagus. This signal is integrated into a feedback circuit in a modern ventilator. As a mode within the ventilator, flow delivery is

coordinated and augmented in response to the neural drive to breathe; this is known as neurally adjusted ventilatory assist (NAVA). (See Chapters 46 and 49 for details.)

MINI CLINI

Monitoring Patient Effort

Problem

A patient on pressure support ventilation of 10 cm H_2O with PEEP of 5 cm H_2O and FiO_2 0.55 is inspiring approximately 10 mL/kg of predicted body weight during pressure support ventilation. A P0.1 measurement is performed and demonstrates a value of 8 cm H_2O. What do these findings indicate?

Solution

The patient has an excessive amount of respiratory drive and is inspiring a high tidal volume.

This may contribute to lung injury if it continues. It is important to look at the trends of ventilator settings and minute ventilation to see if the patient is trending toward higher inspiratory effort or increasing ventilatory support needs. Additionally, look at blood work and patient temperature for any signs of infection. The solution may be to take over the work of breathing and control tidal volume with assist control ventilation until the underlying condition resolves.

RULE OF THUMB Elevated P0.1 (>5 cm H_2O) is associated with a continued need for mechanical ventilation and excessive effort. P0.1 has also been used to detect a response to external PEEP in patients with hyperinflation and intrinsic PEEP; a decrease in P0.1 with the application of PEEP indicates a decrease in intrinsic PEEP and WOB.

Diaphragm Ultrasound

Diaphragm ultrasound is a relatively new and promising method of evaluating and monitoring diaphragm function. Diaphragm excursion measurements have been used clinically in the past, but mostly during spontaneous breathing, and they are not considered to be an accurate measure of inspiratory effort when someone is receiving mechanical ventilation. The two techniques increasingly used during mechanical ventilation are the diaphragm's thickness measurement (Tdi) and the diaphragm's thickening fraction (TFdi). Changes in diaphragm thickness over time (both decreasing and increasing thickness) have been shown to be associated with prolonged mechanical ventilation. Diaphragm thinning is most likely due to atrophy, and diaphragm thickening is most likely due to excessive effort. A change in diaphragm thickness greater than 10% of baseline (after initiation of invasive mechanical ventilation) was associated with prolonged mechanical ventilation.[35] Measurement of TFdi with ultrasound is a noninvasive way of quantifying inspiratory effort. It is calculated as follows:

$$\text{Thickening fraction (\%)} = \frac{(Tdi_{peak-inspiratory} - Tdi_{end-expiratory})}{Tdi_{end-expiratory}} \times 100$$

where (Tdi-peak-inspiratory) is the diaphragm thickness at peak inspiration and (Tdi-end-expiratory) is the diaphragm thickness at end-expiration.

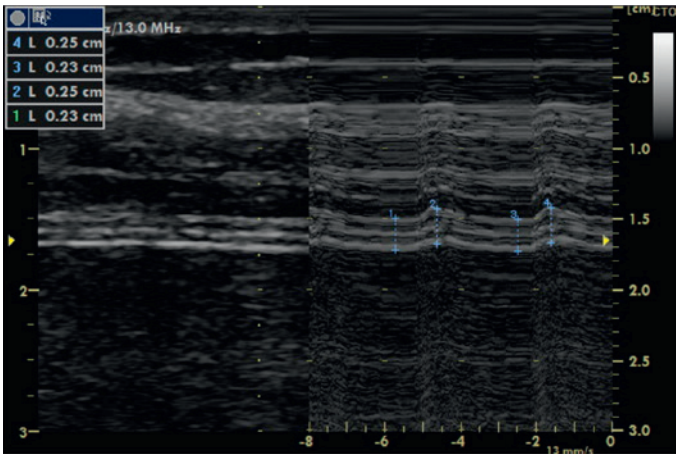

Fig. 52.9 A thickening fraction (TFdi) of 9%, indicating a weak effort from the patient. Demonstrates a TFdi of 72% to 79%, indicating excessive effort from the patient.

A TFdi between 15% and 30% has been shown to be an optimal range of inspiratory effort; inspiratory effort outside of this range (lower or higher) has been associated with an increased duration of mechanical ventilation (Fig. 52.9). Additionally, the maximum thickening fraction (TFmax) is performed without any ventilatory support or PEEP and can be used to assess diaphragm function, with a TFmax of less than 20% indicating severe diaphragm dysfunction.[36]

Rapid Shallow Breathing Index

When muscular strength is limited, patients tend to meet minute ventilation ($\dot{V}_E$) requirements by increasing frequency (f) while decreasing V_T. Although smaller breaths require less effort, rapid shallow breathing increases dead-space ventilation, causing a need for higher minute ventilation to eliminate CO_2. A very high and continuously increasing frequency (>30 breaths/min) is a sign of ventilatory muscle decompensation and potentially impending fatigue.

Considerable attention has been focused on the rapid shallow breathing index (f/V_T ratio), a simple bedside index that indicates whether mechanically ventilated patients can breathe without mechanical assistance.[29] The f/V_T ratio is easy to measure and is independent of the patient's effort and cooperation. Discontinuation of ventilator support is likely to prove successful if the f/V_T ratio is less than 105 breaths per minute per L within 1 to 2 minutes of a brief trial of fully spontaneous breathing.[37]

Respiratory Inductive Plethysmography

Respiratory inductive plethysmography is a noninvasive means of monitoring frequency, V_T, fractional duration of inspiration (Ti/Ttot), and respiratory muscle coordination. With this technique, loose elastic bands encircle the chest and abdomen. Band expansion and contraction during ventilation (spontaneous or supported) provides a volume-time plot that can also reflect short-term shifts in actual lung volume.

Monitoring Strength and Muscle Endurance

Two values commonly used for the bedside assessment of respiratory muscle strength are **vital capacity** (VC) and **maximal**

inspiratory pressure (MIP), also known as negative inspiratory force (NIF). A VC maneuver can be performed at the bedside with a simple respirometer connected to the patient's airway. Because VC is effort dependent, accurate measurements can be obtained only when the patient is conscious and cooperative. Because of an expected variability in bedside VC, three measurements should be obtained and the best result should be reported. Healthy persons are able to generate a VC of approximately 70 mL/kg. A VC less than 10 to 15 mL/kg indicates considerable muscle weakness. Spontaneously breathing patients with such weakness are unlikely to achieve liberation from mechanical ventilation, and those who are breathing spontaneously may require intubation and mechanical ventilation.

MIP is a more specific measure than VC. MIP provides information based solely on maximum output of the inspiratory muscles. A maximum stimulus is provided by total occlusion of the airway. In contrast to the VC maneuver, the MIP maneuver can be performed on unconscious or uncooperative patients. Measurement of MIP at the bedside requires an aneroid manometer with a maximum value indicator. In an effort to make the measurements more reliable, a modified technique has been described in which a one-way valve is attached to the airway to ensure that inspiratory effort is made at a low lung volume.[38] While a 20-second occlusion was maintained, the values with the one-way valve in place were approximately one-third more negative than values without such occlusion (Fig. 52.10).

Endurance: Maximal Voluntary Ventilation

Respiratory muscle fatigue (lack of endurance) may be a cause of respiratory failure. **Maximum voluntary ventilation (MVV)** is a measure used to assess respiratory muscle reserve, endurance, or fatigue. VC is measured to assess the patient's coordinated muscle function from a single breath; MVV is measured to determine the ability of a patient to sustain ventilation over time. Similar to the VC maneuver, the MVV procedure can be performed with a respirometer attached to the patient's airway as the patient is encouraged to breathe as deeply and as fast as possible over a predefined time interval (10 or 15 seconds). The value is extrapolated to a full minute.

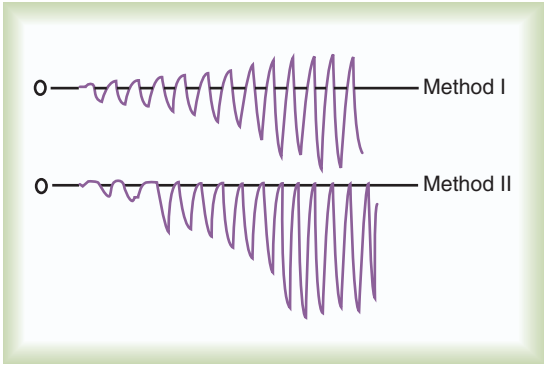

Fig. 52.10 Measurement of maximum inspiratory pressure during 25 seconds of airway occlusion. *Method I* occludes by sealing the airway to allow no movement of air. *Method II* occludes inspiratory flow but allows expiratory flow through a unidirectional valve.

Normal MVV values for adults range from 120 to 180 L/min. Values less than twice the spontaneous minute ventilation are associated with difficulty in maintaining spontaneous ventilation without mechanical assistance.[39]

RULE OF THUMB To achieve successful liberation from mechanical ventilation, the patient must have adequate gas exchange, respiratory muscle strength and endurance, and WOB that is not excessive. The process that caused respiratory failure must be partially if not completely resolved. Although numerous values have been studied to indicate the probability of successful weaning, a frequency-to-VT ratio less than 105 has been the best index of ability to achieve liberation from mechanical ventilation.

LUNG IMAGING AT THE BEDSIDE

The extent of gas exchange abnormalities is revealed by ABG values and SpO_2, but the location or source of the disorder remains unknown. The source but not the extent or type of the pathologic process can be assessed by auscultation. Localization of the disorder within the lungs is more precisely achieved by static images obtained by radiographic techniques, such as chest x-ray or computed tomography (CT). These assessments are key to directing therapeutic approaches and for tracking changes in pathology (see Chapter 21). However, thorough imaging studies frequently require transporting the patient to a radiology suite, and transport presents risks to the patient.[40] Also, the imaging is often static (not dynamically obtained throughout the ventilator cycle).

Lung imaging techniques that can be used at the bedside to actively locate regions of interest have been developed more recently. Two techniques that allow imaging of the lungs during ventilation are lung ultrasound and **electrical impedance tomography** (EIT). Each technique produces dynamic imaging of lung regions to assess the extent of injury. With lung ultrasound and EIT, there is an opportunity to perform bedside evaluation of the effects of PEEP, recruitment maneuvers, or other changes in ventilatory support.

LUNG ULTRASOUND

Ultrasound technology was traditionally thought to not be particularly helpful for imaging the lungs because air-filled lung tissue is not penetrated by ultrasound. However, the artifacts created by pathologic processes inside and outside of the lungs have led to the increasing use of **lung ultrasonography** in acute care, particularly in the emergency department. The common artifacts assessed during lung ultrasound are A-lines (horizontal lines), representing a normal artifact in air-filled lungs; B-lines (shining vertical lines), which appear when interstitial pulmonary edema is present; hyperechoic areas (brighter than normal), which appear in the presence of collapse and consolidation; and hypoechoic areas (darker than normal), which may indicate areas of pleural effusion. Pneumothorax, empyema, pleural effusions, alveolar consolidation, atelectasis, and interstitial pulmonary edema can all be assessed by lung ultrasonography; their extent can be defined and treated with the use of ultrasound. As a

diagnostic tool, lung ultrasonography is relatively inexpensive, usually available in the ICU, can be performed in 15 minutes, and does not emit ionizing radiation. There is potential for ultrasonography to evaluate the lung expansion effects on atelectatic lung tissue using recruitment maneuvers or after adjustment of PEEP in the ICU. Additionally, a "lung monitoring" scoring system has also been used to assess the daily progression of lung ultrasound findings while patients are in the ICU. The presence of A-lines contributes nothing to the score, whereas B-lines (Fig. 52.11) and consolidated areas (Fig. 52.12) are rated for severity and can be monitored daily.[41]

RULE OF THUMB Pneumothorax, empyema, pleural effusions, alveolar consolidation, atelectasis, and interstitial pulmonary edema can all be assessed by lung ultrasonography; their extent can be defined and treated with the use of ultrasound.

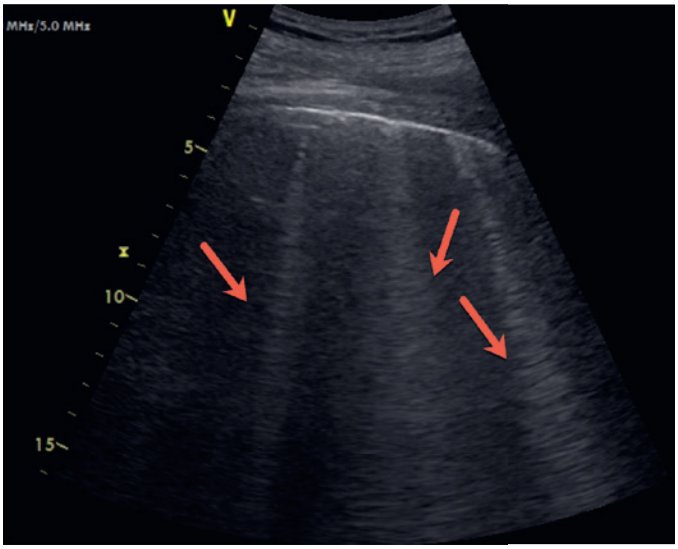

Fig. 52.11 B-lines present on lung ultrasound. The *red lines* show shining beam–like artifacts when there is interstitial pulmonary edema.

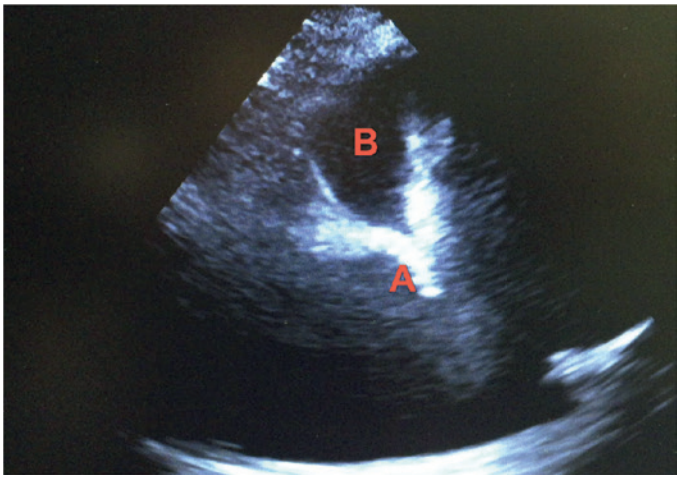

Fig. 52.12 (A) Hyperechoic area on lung ultrasound representing alveolar collapse and consolidation. (B) Hypoechoic area on lung ultrasound representing pleural effusion.

ELECTRICAL IMPEDANCE TOMOGRAPHY

EIT requires placement of electrodes (16 or 32 electrodes depending on the device used) around the chest, typically between the fourth and fifth intercostal spaces. Recent designs utilize an expandable rubber belt or adhesive strips (of various sizes) with embedded electrodes connected to a computing device with monitor. A small alternating current is sent from a reference electrode to each electrode around the chest, and impedance is measured between adjacent electrodes. The reference point rotates around the chest in a circular motion and repeats measurements approximately 50 times per second, capturing images that are reconstructed into a real-time animated graphic on the screen; this is referred to as the dynamic image. The thickness of the band is no more than a few inches, but—due to the method of sending the alternating current—it represents a lung field that is at least 14 cm in height. The images displayed represent a cross section, similar in perspective to a CT scan, looking from the foot of the bed toward the head of the bed (caudal→cranial view); the left side of the image on the screen represents the right side of the patient and right side of the image represents the left side of the patient. Global as well as regional information can be assessed.

The impact of changed ventilator settings on the distribution of ventilation can be assessed by comparing EIT images before and after the adjustment (Fig. 52.13). Trends can also be utilized to see stability of ventilator adjustments over time. With the integration of flow, volume, and pressure readings from the ventilator or pneumotach, EIT allows the monitoring of various forms of asynchrony, and built-in software can provide diagnostic tools to determine the PEEP level where overdistension and collapse are balanced. The effects of excessive spontaneous efforts causing "pendelluft" can also be seen with EIT—a new area of study providing evidence of the potential harmful effects of spontaneous breathing in patients with severe ARDS.[42,43]

EIT devices can also monitor changes in end-expiratory lung impedance (representing changes in FRC) during and after PEEP adjustment; this is particularly helpful in determining the impact of changing PEEP, particularly in patients with heterogeneous lung disease (Fig. 52.14). Modern EIT devices have also been equipped with the ability to measure the impedance of fluid distribution through the lung, allowing assessment of lung perfusion at the bedside.[44]

The ability to monitor ventilation distribution, response to PEEP, asynchrony, the impact of excessive spontaneous effort, and lung perfusion at the bedside has established an entirely new era of bedside monitoring focused on the individualization of mechanical ventilation.

CARDIAC AND CARDIOVASCULAR MONITORING

The cardiovascular system is routinely monitored in the critical care setting because patient survival depends on reliable, competent cardiac and cardiovascular performance. There is little question about the importance of monitoring electrocardiography

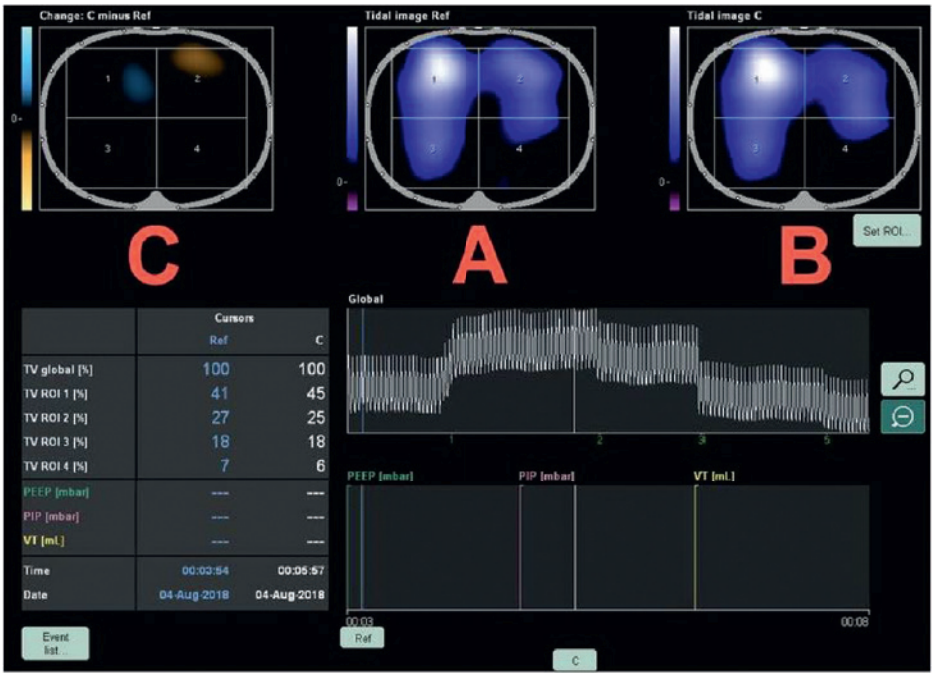

Fig. 52.13 Electrical impedance tomography (EIT) was applied to a patient with left-sided pneumonia. (A) EIT image showing the distribution of ventilation before an increase in positive end-expiratory pressure (PEEP). (B) EIT image showing the distribution of ventilation after an increase in PEEP. (C) EIT image showing the difference between A and B, where *blue* areas represent a gain in ventilation distribution the area and *orange* areas represent a loss. The increased iPEEP did appear to recruit the area affected by the pneumonia. This is evident by the lack of improvement in ventilation to the left dorsal region (region 4 in the bottom right corner of the image).

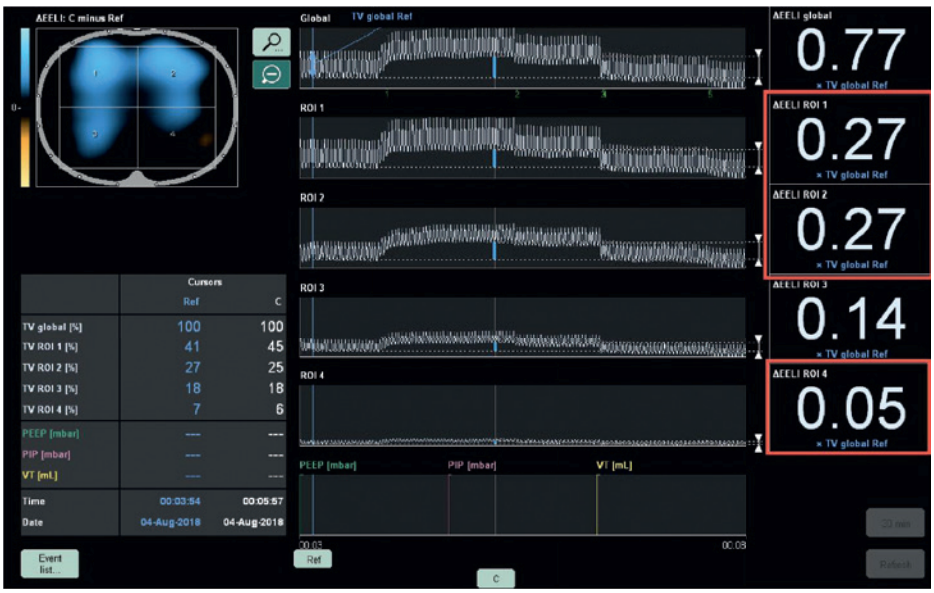

Fig. 52.14 Electrical impedance tomography trend showing the change in end-expiratory lung impedance (ΔEELI) after the increase in positive end-expiratory pressure (PEEP) described in Fig. 52.13. There was an increase in functional residual capacity (FRC) more than five times that of region 4 (the patient's left dorsal region). PEEP did not improve FRC in the affected area; therefore the area is not recruitable.

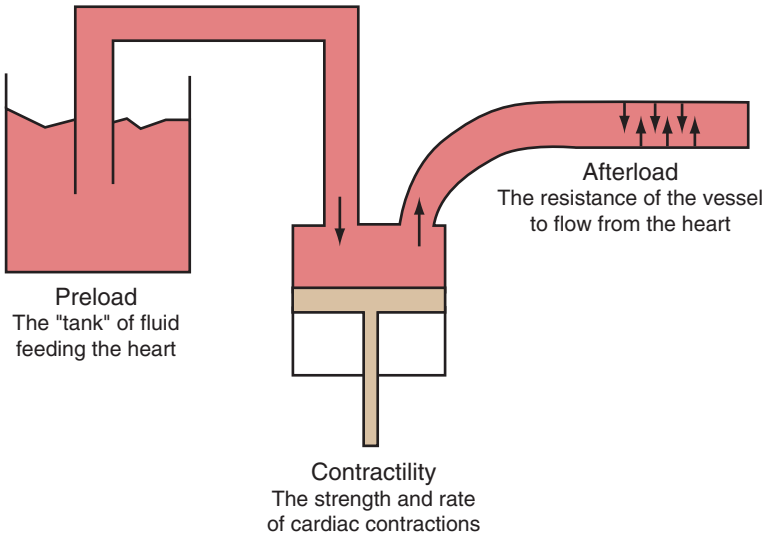

Fig. 52.15 Preload Contractility and Afterload.

(ECG), a noninvasive, continuous assessment of the performance of the conduction system of the heart. In the care of acutely ill patients, there may be clear justification for continuous monitoring of arterial blood pressure. More controversial has been the assessment of left ventricular function by right heart catheterization with measurement of pulmonary capillary wedge pressure (PCWP) and continuous monitoring of pulmonary artery pressure (PAP) (Fig. 52.15). Table 52.3 summarizes cardiovascular monitoring criteria with normal ranges and abnormal values.

ELECTROCARDIOGRAPHY

The conduction system of the heart is monitored in the ICU with a purpose different from that of the standard 12-lead ECG examination (see Chapter 18). The standard 12-lead ECG can be used to analyze disturbances in the conductive pathway that allow location and extent of injury or the source of arrhythmia. The ECG in the ICU is used primarily to detect and manage arrhythmias such as tachycardia, bradycardia, atrioventricular dissociation, ventricular tachycardia, atrial flutter, premature ventricular contractions, and ventricular fibrillation. For this purpose, there is a need for only three electrodes: right arm (or shoulder or right upper chest), left arm (or shoulder or left upper chest), and left lower chest. The deflections usually represent lead II of a standard 12-lead ECG. The direction or amplitude of the waves is of lesser concern than the rhythms being displayed.

When any arrhythmia is detected, therapy or intervention should be considered. The source of the arrhythmia often necessitates management of the underlying cause, such as O_2 therapy for hypoxemia or changes or addition to infusion therapy for fluid and electrolyte disturbances. In the ICU, certain interventions may be necessary and must be immediately available. A defibrillator must be available when ventricular fibrillation is detected.

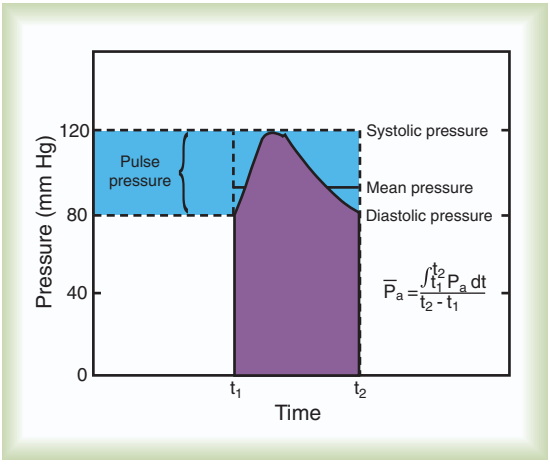

Fig. 52.16 Arterial Pressure Wave Form Systolic Pressure, Diastolic Pressure, Mean Arterial Pressure, and Pulse Pressure.

MONITORING OF ARTERIAL BLOOD PRESSURE

Arterial blood pressure is a crucial measurement for assessing the integrity of cardiovascular tone and the probability that O_2 delivery is dependable. Regulation of cardiovascular tone is under the influence of the autonomic nervous system, but there are other factors that affect blood pressure, such as fluid status or the effects of medications. Major concerns include the adequacy of O_2 delivery during hypotension and the risks of hypertension, such as increased hydrostatic pressure or stroke. Continuous monitoring of the actual blood pressure is performed by placing a catheter usually in the femoral or radial artery. Because fluid is not compressible, the catheter and connecting tubing are filled with saline solution so that the arterial pressure is transmitted to a transducer that allows display of the arterial pressure tracing (Fig. 52.16). The transducer must be properly zeroed and calibrated to reflect the true values of the deflections. The arterial line also provides access for obtaining arterial blood for ABG analysis.

TABLE 52.3 Cardiovascular Monitoring Criteria

Criterion	Normal Value (Range)	Abnormal Value
Heart rate (HR)	80 beats/min (60–100 beats/min)	>100 beats/min (tachycardia) <60 beats/min (bradycardia)
Arterial blood pressure (ABP)	120/80 mm Hg (90–140/60–90 mm Hg)	<140/90 mm Hg (hypertension) <90/60 mm Hg (hypotension)
Mean arterial blood pressure ($\overline{MAP}$)	90 mm Hg (80–100 mm Hg)	<80 mm Hg (hypotension) >100 mm Hg (hypertension)
ECG	Normal heart rate and rhythm	PR interval >0.2 s (tachycardia, bradycardia, heart block [first, second, or third degree], premature ventricular contractions, premature atrial contractions, atrial fibrillation, atrial flutter, elevated ST segment, inverted T wave, ventricular tachycardia, ventricular fibrillation, asystole)
Central venous pressure (CVP)	2–6 mm Hg	>6 mm Hg (fluid overload, right ventricular failure, pulmonary hypertension, valvular stenosis, pulmonary embolus, cardiac tamponade, pneumothorax, positive pressure ventilation, PEEP, left ventricular failure) <2 mm Hg (hypovolemia, blood loss, shock, peripheral vasodilation, cardiovascular collapse)
Pulmonary artery pressure (PAP)	25/10 mm Hg (20–35/5–15 mm Hg)	>35/15 mm Hg (PA systolic >35—pulmonary hypertension), (PA diastolic >15—left ventricular failure, fluid overload) <20/5 mm Hg (pulmonary hypotension, hypovolemia, cardiovascular collapse)
Mean pulmonary artery pressure ($\overline{PAP}$)	15 mm Hg (10–20 mm Hg)	>20 mm Hg (same as ↑ PAP) <10 mm Hg (same as ↓ PAP)
Pulmonary capillary wedge pressure (PCWP)	5–10 mm Hg (<18 mm Hg)	>18 mm Hg (left ventricular failure, fluid overload) >20 mm Hg (interstitial edema) >25 mm Hg (alveolar filling) >30 mm Hg (frank pulmonary edema) <5 mm Hg (hypovolemia, shock, cardiovascular collapse)
Cardiac output ($\dot{Q}_T$ or CO)	5 L/min (4–8 L/min)	>8 L/min (elevated) (see cardiac index) <4 L/min (decreased) (see cardiac index)
Cardiac index (CI)	2.5–4 L/min per m^2	>4 L/min/m^2 (elevated owing to stress, septic shock, fever, hypervolemia, or drugs [dobutamine, dopamine, epinephrine, isoproterenol, and digitalis]) <2.5 L/min/m^2 (left ventricular failure, myocardial infarction, pulmonary embolus, high levels of positive-pressure ventilation, PEEP, pneumothorax, blood loss, hypovolemia)
Systemic vascular resistance (SVR)	900–1400 dynes-s/cm^5 (11.25–17.5 mm Hg/L/min)	>1400 dynes-s/cm^5 (increased owing to vasoconstrictors [dopamine, norepinephrine, and epinephrine], hypovolemia, late septic shock) <900 dynes-s/cm^5 (decreased owing to vasodilators [nitroglycerin, nitroprusside, and morphine] or early septic shock)
Pulmonary vascular resistance (PVR)	110–250 dynes-s/cm^5 (1.38–3.13 mm Hg/L/min)	>250 dynes-s/cm^5 (hypoxemia, ↓ pH, $PaCO_2$, vasopressors, emboli, emphysema, interstitial fibrosis, pneumothorax) <110 dynes-s/cm^5 (pulmonary vasodilators, nitric oxide, O_2, calcium channel blockers)

CI = $\dot{Q}_T$/Body surface area.
SVR = [($\overline{MAP}$ − CVP)/CO] × 80 = dynes-s/cm^5.
PVR = [($\overline{PAP}$ − PCWP)/CO] − 80 = dynes-s/cm^5.

MONITORING OF CENTRAL VENOUS PRESSURE–RIGHT ATRIAL PRESSURE

Right atrial pressure or central venous pressure (CVP) is monitored in the ICU by placement of a central venous catheter. Right atrial pressure is normally the lowest of all the heart chamber pressures, ranging from 2 to 6 mm Hg. Mean right atrial pressure is the same as CVP. CVP is a measure of right atrial preload. Atrial preload is determined by the balance between the capacity of the cardiovascular system, its circulating volume, and the amount of venous return to the heart (see Chapter 10). Right atrial pressure also reflects right ventricular preload under normal circumstances. As a result, abnormally low right atrial pressure suggests inadequate filling of the right ventricle and is common in hypovolemia. Causes of abnormal right atrial pressure or CVP are summarized in Box 52.11.

MONITORING OF PULMONARY ARTERY PRESSURE

Placement of a right heart/pulmonary artery catheter (PAC; **Swan-Ganz catheter**) is invasive and associated with risk of pneumothorax, hemothorax, and arrhythmias. Placement of the

BOX 52.11 Causes of Increased Right Atrial and Central Venous Pressure

- Right ventricular failure (myocardial infarction, cardiomyopathy)
- Pulmonary valvular stenosis
- Tricuspid stenosis and regurgitation
- Pulmonary hypertension
- Pulmonary embolism
- Volume overload
- Compression around the heart, constrictive pericarditis, cardiac tamponade
- Increased tone of large vessels throughout the body, resulting in venoconstriction
- Arteriolar vasodilation, which increases blood supply to the venous system
- Increased intrathoracic pressure (positive-pressure breath or pneumothorax)
- Placement of transducer below the patient's right atrial level
- Infusion of solution, especially with pressure infusion pumps, into the central venous pressure line
- Left-sided heart failure

balloon-tipped 7.5-F catheter (Fig. 52.17) must be performed aseptically by an experienced clinician. The catheter is guided into the pulmonary artery while the clinician visualizes waveforms with a fluid-filled system identical to the arterial pressure monitoring system (Fig. 52.18).

Placement of a Swan-Ganz catheter allows determination of CVP, PAP, and PCWP. Data gathered with a Swan-Ganz catheter can be used to calculate thermodilution CO, pulmonary and arterial vascular resistance, and other associated indices (see Table 52.3). PAP monitoring may be helpful in the presence of shock (cardiogenic, hypovolemic, septic), left ventricular failure, myocardial infarction, pulmonary vascular disease, pulmonary edema, and ARDS. The reading and interpretation of Swan-Ganz catheter tracings can be inconsistent. There has been considerable controversy because of the risk-benefit ratio of the procedure.[45] The use of a PAC in patients without primary cardiovascular disease has decreased markedly in more recent years.

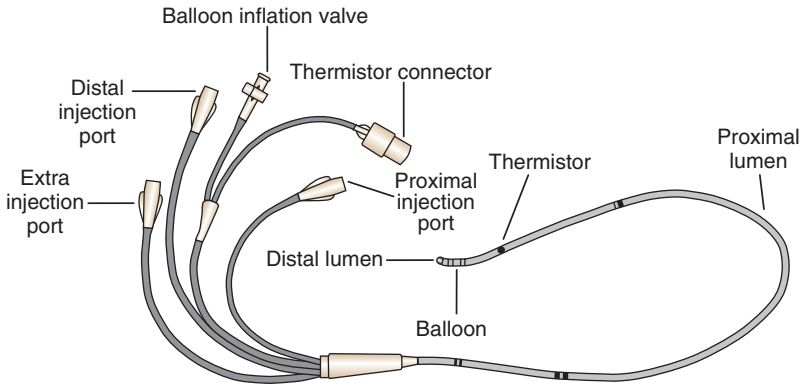

Fig. 52.17 Quadruple-Channel Pulmonary Artery Catheter. The distalmost channel (distal injection port) is for measurement of pulmonary artery pressure. Blood can be aspirated from this channel for mixed venous O_2 measurements. A second channel (balloon inflation valve) is used to inflate or deflate the distal balloon. A third channel (proximal injection port), which exits 30 cm from the catheter tip, is used for monitoring central venous pressure (right atrial pressure) and fluid infusion. The fourth channel (extra injection port), which is not present on all catheters, can be used for continuous infusion of hyperalimentation fluid.

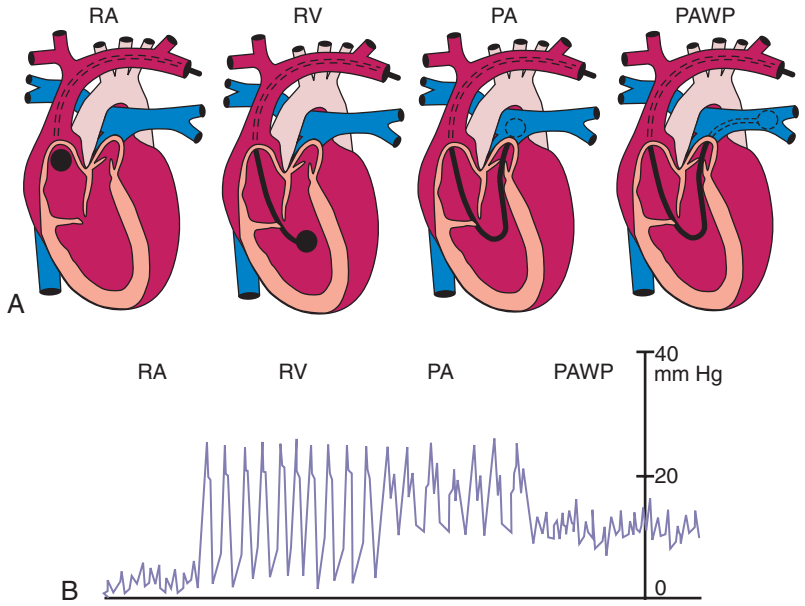

Fig. 52.18 (A) Position of pulmonary arterial catheter in the heart. (B) As monitored by pressure tracings. *PA*, Pulmonary artery; *PAWP*, pulmonary artery wedge pressure; *RA*, right atrium; *RV*, right ventricle

PRELOAD

Preload is defined as the pressure that stretches the ventricular walls at the onset of ventricular contraction. Preload can be approximated by measuring PCWP. PCWP is an estimate of left atrial pressure, which reflects left ventricular end-diastolic pressure. During left-sided heart failure, preload increases; the increase is reflected in elevated PCWP. Symptoms of congestive heart failure can sometimes be controlled with diuretic therapy.

CONTRACTILITY

Contractility is the forcefulness of the heart muscle contracting under a constant load. Numerous pharmacologic agents are used to cause a modest increase in ejection fraction (contractility) and are associated with improvement in symptoms in patients with congestive heart failure.

AFTERLOAD

Afterload is usually defined as the load against which the ventricles must contract. An increase in systemic vascular resistance increases left ventricular afterload. Although increased afterload is usually equated with increased blood pressure, the cause is better understood as the muscle tension required by the left ventricle to generate blood flow. Table 52.4 lists common conditions and associated alterations in hemodynamic variables. Table 52.5 summarizes steps to take in troubleshooting changes in monitored cardiovascular values and vital signs, including possible causes and appropriate corrective action.

CARDIAC OUTPUT

Cardiac performance is affected by preload, contractility, and afterload and is evaluated by the measurement of cardiac output (CO). The effect of cardiac pathology, medications, or mechanical ventilation on CO can be critical monitoring information. An accurate assessment of CO presents a challenge to the clinician. The physical examination (see Chapter 16) can reveal signs and symptoms of impaired cardiac performance, but a composite number provided by CO can provide more direct insight into problem and treatment options.

CO as determined by thermodilution by the use of a PAC (Swan-Ganz catheter) was the primary method of CO assessment for three decades and is considered the gold standard. The invasiveness of this method and inaccuracies in reading and interpretation led to a decrease in use of the Swan-Ganz catheter. Other methods of CO determination have become available based on algorithms that analyze the arterial pressure waveform and a rebreathing method based on **Fick's principle**. The NICO system (Philips Healthcare, Andover, MA) is a noninvasive monitor that uses Fick's principle indirectly to calculate CO by the use of volumetric capnography as well as information obtained from arterial and venous blood gases. It has some limitations, but considering its noninvasive nature, it can a useful tool when more invasive options are not feasible or safe. The FloTrac (Edwards LifeSciences. Irvine, CA) is a minimally invasive continuous CO monitor that uses the analysis of the arterial pulse contour. It requires an arterial line to function but has good correlation to the gold standard PAC.[46]

CARDIAC MUSCLE INJURY

Although heart function can be assessed by various methods, there are a number of blood tests that can indicate cardiac muscle injury. These tests include cardiac troponins, heart fatty acid–binding protein, creatinine kinase MB, and myosin light chain 1.[47]

MONITORING RENAL FUNCTION

The kidney is the main filter of waste products and the principal regulator of the volume and electrolyte composition of body

TABLE 52.5 Troubleshooting Changes in Vital Signs

Clue	Possible Problem	Advice
Hypotension	Hypovolemia, pump failure	Evaluate fluid balance and possible need for intravenous fluids or inotropic agents.
Hypertension	Anxiety; response to decreased PaO_2, decreased $PaCO_2$ or pain	Reassure, alleviate fear, check patient–ventilatory system; if not easily correctable, obtain and evaluate arterial blood gases.
Alteration of blood pressure with breathing	Decreased venous return (caused by changes in intrathoracic pressure)	If systolic/diastolic pressures are less than adequate perfusion levels, evaluate fluid balance; consider intravenous fluids.
New arrhythmias, tachycardia, bradycardia	Anxiety	Reassure, alleviate fear.
	Decreased PaO_2, decreased $PaCO_2$, increased $PaCO_2$	Check patient–ventilator system; if not quickly correctable, obtain and evaluate arterial blood gases.
Large swings in CVP or PCWP	Decreased venous return	Evaluate other hemodynamic values for adequacy of perfusion.
Decreased urinary output	Decreased CO	Evaluate other hemodynamic values for adequacy of perfusion.
	Hypovolemia	
Fever	Infection	Control infection; review preventive measures.
	Atelectasis	Check patient–ventilator system for secretions, plugs, slippage of tube into right main stem bronchus.
	Overheated humidifier	Check humidifier heater temperature.
Weight gain	Fluid retention	Evaluate hemodynamic values for adequacy of perfusion; consider diuresis.
Changes in respiratory rate	Altered settings	Check patient–ventilator settings.
	Change in metabolic needs	Evaluate metabolic rate.
	Anxiety	Reassure, alleviate fear.
	Sleep	Normal; metabolic rate is decreased.
Use of accessory muscles or paradoxical breathing	Increased work of breathing	Increase support level; check and change inspiratory flow.
	Patient–ventilator asynchrony	Provide pressure support ventilation. Increase sensitivity.
	Auto-PEEP	Eliminate auto-PEEP.

CO, Cardiac output; *CVP*, central venous pressure; *PCWP*, pulmonary capillary wedge pressure; *PEEP*, positive end-expiratory pressure.

fluid. Because the kidney is the primary excreter of nitrogenous waste, plasma concentrations of blood urea nitrogen (BUN) and creatinine are used to track renal function. As a general guideline, the BUN level increases 10 to 15 mg/dL/day, and the creatinine level increases 1 to 2.5 mg/dL/day after abrupt renal failure. With renal failure, the serum potassium level usually increases 0.5 mEq/L/day, and bicarbonate (HCO_3^-) level decreases approximately 1 mEq/L/day. Under the catabolic stress of burns, trauma, rhabdomyolysis (an acute and sometimes fatal disease in which products of skeletal muscle destruction produce acute renal failure), sepsis, or starvation, the rates of change in these values can double. In contrast to BUN, daily production of creatinine is relatively constant. An increasing creatinine level indicates that the rate of production exceeds clearance by means of glomerular filtration. A stable elevation in creatinine level implies that a new steady state has been achieved at a decreased glomerular filtration rate. Until the creatinine level stabilizes, the severity of acute renal dysfunction cannot be assessed reliably. The most common method of estimating glomerular filtration rate (renal function) is measurement of plasma creatinine and creatinine clearance rate. Although calculation of creatinine clearance is more accurate, the procedure entails 24-hour urine collection. The most important factor is whether the glomerular filtration rate is changing or stable, and the plasma creatinine level is tracked for most patients.

Urine volume usually reflects kidney perfusion. Polyuria and oliguria refer to a daily urine output of more than 3 L and less than 0.4 L in average-sized adults. Anuria is present when urine output is less than 50 mL/day. Polyuria should not be confused with increased urinary frequency, in which multiple small voidings occur but total output is less than 3 L/day.

RULE OF THUMB Anuria is present when urine output is less than 50 mL/day. A significant decrease in urine output can ultimately lead to difficulties in pulmonary function when patients develop a fluid overload.

MONITORING LIVER FUNCTION

Adequate liver function is essential for the survival of critically ill patients. The liver must detoxify wastes from metabolism and digestion and process poisons. Elevated results of liver function tests reflect the occurrence of liver parenchymal damage. Hepatic dysfunction may precipitate or worsen ARDS.[48] Routine indications for liver function testing in the treatment of critically ill patients include abdominal pain, jaundice, unexplained fever, nausea, malaise, failure to thrive, weight loss, and leukocytosis. Additional indications may be sought by the facilitation of acuity scoring and definition of the contribution of the liver to multisystemic organ failure.

Batteries of biochemical studies are routine in the evaluation of critically ill patients, but they reflect liver function minimally. Acute liver disease can develop in critically ill patients receiving total parenteral nutrition.[49] Liver disease may manifest as

increased liver size and tenderness. When abnormal results of liver function tests have been obtained, it is essential to determine the cause. Elevations in levels of canalicular enzymes (like alkaline phosphatase) and bilirubin should prompt a search for mechanical obstruction and appropriate imaging studies (like a liver ultrasound). Elevations of transaminase levels (e.g., alanine aminotransferase [ALT]) are unusual in cholestatic processes unless there is a superimposed ischemic event—a confounding factor in many critically ill patients. Elevated levels of aspartate aminotransferase (AST) and ALT suggest hepatic inflammation. Ischemia, viral hepatitis, and autoimmune hepatitis should be considered in the differential diagnosis of elevated AST and ALT.

NUTRITIONAL MONITORING

Assessment and monitoring of nutrition are required in the care of some critically ill patients because nutritional disorders are frequent and important determinants of outcome. Nutritional support is commonly needed by patients who have been critically ill for an extended period and those with increased metabolic demands and limited nutritional reserve.

Assessment of Nutritional Status

Early detection of malnutrition in critically ill patients, whether preexisting or a result of acute illness, enables prompt and aggressive intervention with supplemental nutrition. No single measurement or assessment tool can adequately characterize nutritional status, and the diagnosis of malnutrition is subjective. However, both functional and biochemical factors should be examined to identify whether a patient is at increased risk of malnutrition and its complications.

The functional nutritional assessment consists of the medical history, physical examination, and appraisal of muscle and organ function. However, preexisting malnutrition and dietary history may be difficult to obtain from a critically ill patient presenting to the ICU. Additionally, critically ill patients frequently have volume overload secondary to blood pressure management, which may be complicated by poor kidney function. When a patient has a fluid overload, measurement of dry weight becomes difficult to assess.

There are physical examination findings that may suggest the presence of nutritional and metabolic deficiencies. Inspection of the hair, skin, eyes, mouth, and extremities, including muscle mass and function, can all provide information about a patient's protein reserve and overall nutritional status. Serum chemistry values are important in determining the specifics of nutritional support but do not directly reflect nutritional status. Albumin, sodium, potassium, chloride, total CO_2, BUN, glucose, prothrombin time, partial thromboplastin time, iron, magnesium, calcium, and phosphate should be measured at admission and rechecked periodically. Estimation of a patient's nutritional requirements is also important to determine his or her energy or caloric needs; this applies particularly to weak patients showing signs of weaning failure. Chapter 23 provides a more detailed look at assessing patients' nutritional status.

Global Monitoring Indices

Organizing the flood of information made available by monitoring instruments is a skill and responsibility of critical care practitioners. In the ICU, the immediate concern is the welfare of the patient. Decisions frequently are based on prognosis with respect to the appropriate tests, treatments, and medications prescribed. Guiding these decisions is the weighing of risks and benefits to the patient and the responsible use of resources. Although the physician makes such decisions with all current information, specific data on the probability of survival can be estimated. In the past 30 years, prognostic indices have been derived from large clinical data sets that provide an indication of the seriousness of the patient's condition. These indices (Acute Physiology and Chronic Health Evaluation [APACHE I, II, III, and IV], Acute Physiology Score, Therapeutic Intervention Scoring System, and Burns Weaning Assessment Program) are determinations of scores from numerous monitored values obtained from isolated observations of the patient's condition, usually during the first 24 hours after hospital admission. A score may be assigned for that patient at that time, and risk of mortality can be calculated (Box 52.12).

The value of severity-of-illness scoring for individual patients is limited, and the accuracy and usefulness of physiology scoring are often questioned. Imposing a scoring system to judge intent to treat places too much emphasis on the validity of the system. Scoring systems have not been clearly associated with important outcomes such as length of stay or time on mechanical ventilation. At the present time, as a bedside tool in the care of an individual patient, scoring systems have limited value. A specific condition may "score" a 17% risk of death, but a patient has two possible outcomes: life (0%) and death (100%). The decision to withdraw or limit care would rarely be based on a score, because many other factors are involved in such a decision. Inaccuracies in predicting mortality are frequently reported. Discrepancies are probably due to patient mix differences, hospital factors, admission policies, data collection methods, and differences in quality of care. Currently, the global indices have limited use in the care of individual patients.

Global monitoring has a definite role in research. Global indices are valuable in the study of the effectiveness of new medications or therapy and the establishment of guidelines for care. When control and experimental (new treatment) groups are

BOX 52.12 Global Monitoring Indices

Indices (scores) have been developed that take into account several monitored values.

These scoring systems provide an estimate of illness acuity level and an estimate of the risk of mortality.

For clinical studies, scoring systems are required to ensure that the control and experimental groups are similar.

Scoring systems can be useful as a longitudinal monitor of acuity or a means of evaluating the effect of changes in services.

At this time, scoring systems have little value in the care of individual patients. The most commonly used acuity-of-illness scoring system is the Acute Physiology, Age, Chronic Health Evaluation II (APACHE II).

compared in a randomized, controlled trial, the severity scores of the groups must be similar, or differences in baseline condition may account for differences in results. As a tracking tool, scoring has significant value; the increasing severity of causes of ICU admissions can be followed over time with severity-of-illness scoring. The consequences of changes in services or policies or interhospital comparisons can be crudely tracked with the use of expected mortality calculations from APACHE scores. Some institutions calculate severity-of-illness scores for all patients.

ACUTE PHYSIOLOGY AND CHRONIC HEALTH EVALUATION (APACHE)

The **APACHE scoring system** was developed in 1981 to monitor severity of illness in clinical studies.[50] Studies have referenced a risk-of-mortality estimate as calculated from APACHE scoring, and such studies can be compared with similar studies in which the APACHE scoring system is used. The APACHE II scoring system assigns points to physiologic variables on the basis of whether the values are high abnormal, low abnormal, or normal. Variables rated include temperature, mean arterial pressure, heart rate, respiratory rate, PaO_2 or $P(A–a)O_2$, pH, sodium level, potassium level, creatinine level, hematocrit, white blood cell count, and Glasgow Coma Scale (GCS) score. Assigned points are added to derive a total APACHE score. There is imprecision in estimating the risk of mortality. To emphasize the importance of the neurologic examination, the scoring system is weighted toward the importance of the GCS score. Refinements of APACHE are ongoing, although the APACHE II system continues to be used more often than other systems.[51]

NEUROLOGIC MONITORING

Monitoring of the nervous system is most frequently overlooked in the ICU for several reasons. The first and most important is lack of knowledge of proper assessment of the nervous system of a ventilated, restrained, and often sedated patient in the ICU. Neurologic dysfunction is difficult to recognize in a sedated patient. Proper clinical assessment of the nervous system emphasizes the neurologic history and examination (Box 52.13).

Neurologic Status and Examination

The neurologic examination of a patient in the ICU should address several key issues. A history of an evolving focal deficit occurring over days to weeks before loss of consciousness suggests abscess, tumor, or subdural hematoma, whereas a progression to coma over minutes to hours favors a metabolic cause. Problems such as hypothyroidism, renal failure, cirrhosis, or psychiatric illness suggest greater likelihood of a metabolic cause. Uncontrolled hypertension can induce metabolic (e.g., hypertensive encephalopathy) or structural (e.g., intracerebral hemorrhage) coma. Unfortunately, patients with an altered level of consciousness often require intubation and subsequently are exposed to sedation, making neurologic assessment challenging.

The use of sedation in the ICU is often necessary when invasive mechanical ventilation is used, but its use should be guided by the needs of the patients, and patients' readiness for being awake and extubated should be assessed on a daily basis. To evaluate readiness for extubation, patients must first be rousable by voice; for this reason, sedation-agitation scales are used. Two examples of sedation-agitation scales are the Riker Sedation-Agitation Scale (SAS) and the Richmond Agitation Sedation Scale (RASS)[52,53] (Tables 52.6 and 52.7). Although these scores are not without limitations, they provide targets for sedation management and are key elements in ensuring not only that a patient can be neurologically assessed but also in gauging his or her ability to engage in various mobility exercises even while being ventilated. Daily interruption of sedation, or using minimal sedation guided by these scores, is a common and important aspect of ICU patient management.

Delirium is another common concern in ICU patients, and the routine assessment of delirium is common in daily ICU practice. Two frequently used tests recommended for assessing delirium in the ICU are the Intensive Care Delirium Screening Checklist (ICDSC) and the Confusion Assessment Method for the Intensive Care Unit (CAM-ICU).[54] The ICDSC score is a numeric score 0 to 8 (a score of 4 or greater is associated with delirium or neurologic dysfunction) (Table 52.8).[55] The CAM-ICU score is either a positive or negative score for delirium

BOX 52.13 Neurologic Monitoring

One of the most important and frequently overlooked areas of monitoring is the neurologic examination, which includes the following:

- History
- Assessment of mental status
- Pupillary response
- Eye movement assessment
- Corneal response
- Gag reflex
- Respiratory rate and pattern
- General motor and sensory evaluations

TABLE 52.6 Riker Sedation-Agitation Scale

Score	Term	Descriptor
+7	Dangerous agitation	Pulling at endotracheal tube, trying to remove catheters, climbing over bedrail, striking at staff, thrashing sideside
+6	Very agitated	Requiring restraint and frequent verbal reminding of limits, biting endotracheal tube
+5	Agitated	Anxious or physically agitated, calms to verbal instructions
+4	Calm and cooperative	Calm, awakens easily, follows commands
+3	Sedated	Difficult to arouse but awakens to verbal stimuli or gentle shaking, follows simple commands but drifts off again
+2	Very sedated	Arouses to physical stimuli but does not communicate or follow commands, may move spontaneously
+1	Unable to rouse	Minimal or no response to noxious stimuli, does not communicate or follow commands

(Table 52.9).[56] Delirium assessments are affected by the use of sedatives and/or pain medication; therefore the discontinuation of such drugs or the use of the previously described SASs is necessary for ensuring a proper assessment.

RULE OF THUMB Daily interruption of sedation, or using minimal sedation guided by SAS or RASS scores, is a common and important aspect of ICU patient management.

TABLE 52.7 Richmond Agitation Sedation Scale

Score	Term	Descriptor
+4	Combative	Overtly combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive
+2	Agitated	Frequent nonpurposeful movement, fights ventilator
+1	Restless	Anxious but movements not aggressive, vigorous
0	Alert and calm	
–1	Drowsy	Not fully alert, but has sustained awakening (eye-opening/eye contact) to voice (>10 s), visual stimulation
–2	Light sedation	Briefly awakens with eye contact to voice (<10 s)
–3	Moderate sedation	Movement or eye opening to voice (but no eye contact)
–4	Deep sedation	No response to voice, but movement or eye opening to physical stimulation
–5	Unarousable	No response to voice or physical stimulation

Pupillary Response

Pupil size, congruency, and response to light and accommodation should be described. Pupillary light reflexes provide information regarding the status of the brain and of the sympathetic and parasympathetic nervous systems. Pupillary function is controlled by the midbrain. If pupillary function is normal, the cause of coma is either metabolic or a structural lesion located above the midbrain. Small "pinpoint" pupils usually result from pontine hemorrhage or from the ingestion of narcotics or organophosphates. Pupillary responses almost always remain intact in metabolic causes of coma. Dilated and fixed (unresponsive to light) pupils are seen in patients who have been given atropine. Midposition and fixed pupils often indicate severe cerebral damage.

Traditionally, pupillary size has been subjectively documented in critical care, but this can lead to discrepancies between clinicians. The use of a pupillometer, a device that uses an infrared camera to measure pupillary size, can improve the accuracy of measurements and avoid disagreements among clinicians. This is particularly important when sequential measurements are required to determine the progression of a pathologic process.[57]

Eye Movements

Abnormalities of extraocular movement have prognostic importance in the ICU. Normal movement of the eyes requires an intact pontomedullary–midbrain connection. The resting position of the gaze, the presence of nystagmus (rapid involuntary movements), and the response to head movements and cold tympanic membrane stimulation should be identified. Cervical spine stability must be ensured before oculocephalic maneuvers are performed. If rotation of the head (oculocephalic) and vestibular stimulation (calorics) produce no change in eye position, the pons is nonfunctional. If only the eye ipsilateral (on the

TABLE 52.8 Intensive Care Delirium Screening Checklist

Characteristic	Description	Point
Altered level of consciousness	(A) No response or (B) the need for vigorous stimulation in order to obtain any response signified a severe alteration in the level of consciousness precluding evaluation.	A dash (-) is entered and there is no further evaluation during that period.
	(C) Drowsiness or requirement of a mild to moderate stimulation for a response implies an altered level of consciousness and scores.	1 point
	(D) Wakefulness or sleeping state that could easily be aroused is considered normal and scores.	No point
	(E) Hypervigilance is rated as an abnormal level of consciousness and scores.	1 point
Inattention	Difficulty in following a conversation or instructions. Easily distracted by external stimuli. Difficulty in shifting focuses.	1 point
Disorientation	Any obvious mistake in time, place, or person scores.	1 point
Hallucination, delusion, or psychosis	Clinical manifestation of hallucination or of behavior probably due to hallucination (e.g., trying to catch a nonexistent object) or delusion, or gross impairment in reality testing.	1 point
Psychomotor agitation, or retardation	Hyperactivity requiring the use of additional sedative drugs or restraints in order to control potential danger to oneself or others (e.g., pulling out intravenous lines, hitting staff). Hypoactivity or clinically noticeable psychomotor slowing. Any of these scores.	1 point
Inappropriate speech or mood	Inappropriate, disorganized, or incoherent speech. Inappropriate display of emotion related to events or situation.	1 point
Sleep/wake cycle disturbance	Sleeping less than 4 hours or waking frequently at night (do not consider wakefulness initiated by medical staff or loud environment). Sleeping during most of the day.	1 point
Symptom fluctuation	Fluctuation of the manifestation of any item or symptom over 24 h (e.g., from one shift to another) scores.	1 point

TABLE 52.9 The Confusion Assessment Method for the Intensive Care Unit

Features and Descriptions		
I. Acute Onset or Fluctuating Course A. Is there evidence of an acute change in mental status from the baseline? B. Or, did the (abnormal) behavior fluctuate during the past 24 h, that is, tend to come and go or increase and decrease in severity as evidenced by fluctuations on the Richmond Agitation Sedation Scale (RASS) or the Glasgow Coma Scale?	**Absent**	**Present**
II. Inattention Did the patient have difficulty focusing attention as evidenced by a score of less than 8 correct answers on either the visual or auditory components of the Attention Screening Examination (ASE)?	**Absent**	**Present**
III. Disorganized Thinking Is there evidence of disorganized or incoherent thinking as evidenced by incorrect answers to 3 or more of the 4 questions and inability to follow the commands? Questions 1. Will a stone float on water? 2. Are there fish in the sea? 3. Does 1 pound weigh more than 2 pounds? 4. Can you use a hammer to pound a nail? Commands 1. Are you having unclear thinking? 2. Hold up this many fingers. (Examiner holds 2 fingers in front of the patient.) 3. Now do the same thing with the other hand (without holding the 2 fingers in front of the patient). (If the patient is already extubated from the ventilator, determine whether the patient's thinking is disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject.)	**Absent**	**Present**
IV. Altered Level of Consciousness Is the patient's level of consciousness anything other than alert, such as being vigilant or lethargic or in a stupor or coma? Alert: spontaneously fully aware of environment and interacts appropriately Vigilant: hyperalert Lethargic: drowsy but easily aroused, unaware of some elements in the environment or not spontaneously interacting with the interviewer; becomes fully aware and appropriately interactive when prodded minimally Stupor: difficult to arouse, unaware of some or all elements in the environment or not spontaneously interacting with the interviewer; becomes incompletely aware when prodded strongly; can be aroused only by vigorous and repeated stimuli, and as soon as the stimulus ceases, stuporous subject lapses back into unresponsive state Coma: unarousable, unaware of all elements in the environment with no spontaneous interaction or awareness of the interviewer so that the interview is impossible even with maximal prodding **Overall CAM-ICU Assessment (Features 1 and 2 and either Feature 3 or 4): Yes____ No____**	**Absent**	**Present**

same side of the body) to the stimulus abducts, a lesion of the medial longitudinal fasciculus should be suspected.

Corneal Responses

The corneal reflex is used to test the afferent fifth and efferent seventh cranial nerves. This test is performed by lightly touching the cornea with a cotton swab; the patient should blink both eyes in response. The presence of this response implies an intact ipsilateral fifth cranial nerve, intact central pons, and intact bilateral seventh cranial nerve. Testing must be performed bilaterally to evaluate both afferent components of the fifth cranial nerve.

Gag Reflex

The gag reflex is tested by using a tongue blade to stimulate one side of the posterior pharynx of an intubated patient. Each side should be tested separately. A normal response is bilateral movement of the posterior pharyngeal muscles and implies intact ninth and tenth cranial nerves. The ability to cough on suctioning can be tested in an intubated patient and implies an intact tenth cranial nerve and the ability of the patient to protect their airway. This test should not be attempted on nonintubated patients in the ICU because of the risk of aspiration.

Respiratory Rate and Pattern

The brain stem is the primary site of the central control of respiration. This control occurs at a subconscious level and results in rhythmic contraction and relaxation of the respiratory muscles. The most common abnormal respiratory pattern seen in patients with neurologic disorders is Cheyne-Stokes respiration, which consists of phases of hyperpnea that regularly alternate with

episodes of apnea. Breathing waxes in a smooth crescendo and, when a peak is reached, wanes in an equally smooth decrescendo. Cheyne-Stokes respiration usually has an intracranial cause, although it can be caused by hypoxemia and cardiac failure. Ataxic breathing is a marker of severe brain-stem dysfunction. Despite the nonspecificity of most breathing patterns, the respiratory pattern can provide valuable clues to the cause of coma.

Motor Evaluation

A thorough motor evaluation should be performed for all patients. The systematic approach described earlier is key to localizing the site of a pathologic process. The symmetry and pattern of the motor response to noxious stimuli and associated neurologic symptoms should be documented for all patients.

Sensory Evaluation

Assessment of light touch, pinprick, and temperature sensation can be achieved by applying a cotton swab, a clean pin, and a cold or warm object to various parts of the upper and lower extremities. Symmetry of responses between sides and between upper and lower extremities should be documented and is valuable in localizing the site of a pathologic process.

Glasgow Coma Scale

The most widely used scoring system for acute neurologic disorders is the **Glasgow Coma Scale (GCS)** (Table 52.10). The GCS score is used to test best motor response, best verbal response, and opening of the eyes. The scale goes from 3 to 15 and can be used for rapid triage. Patients with head injury and GCS scores of 13 to 15 are often admitted to a non-ICU observational unit unless neurologic examination or a CT scan reveals a lesion or abnormality that warrants ICU admission. Scores of 9 to 13 on the GCS signify a significant insult with depressed level of consciousness. Patients with head injury and GCS scores equal to or less than 8 need close monitoring and often intubation and mechanical ventilation.

TABLE 52.10 Glasgow Coma Scale

Eyes	Open	Spontaneous	4
		To verbal command	3
		To pain	2
		No response	1
Best motor response	To verbal command	Obeys	6
	To painful stimulus	Localized pain	5
		Flexion—withdrawal	4
		Flexion—decorticate	3
		Flexion—decerebrate	2
		No response	1
Best verbal response		Oriented, converses	5
		Disoriented, converses	4
		Inappropriate words	3
		Incomprehensible sounds	2
		No response	1
Total			*3–15*

Intracranial Pressure Monitoring

There are two primary reasons to measure intracranial pressure (ICP): (1) to monitor patients at risk of life-threatening intracranial hypertension and (2) to assess the effects of therapy aimed at reducing ICP. Measuring ICP during a lumbar puncture (or spinal tap) may also be useful to suggest the presence of infection (e.g., meningitis). Mean ICP of a supine patient is normally 10 to 15 mm Hg, and the ICP waveform normally undulates gently in time with the cardiac cycle. Fluctuations of the ICP waveform (>10 mm Hg) suggest a position near the critical inflection point of the cranial P-V curve. Elevations in ICP to 15 to 20 mm Hg compress the capillary bed and compromise microcirculation. At ICP levels of 30 to 35 mm Hg, venous drainage is impeded, and edema develops in uninjured tissue. Even when autoregulatory mechanisms are intact, cerebral perfusion cannot be maintained if ICP increases to within 40 to 50 mm Hg of the mean arterial pressure. When ICP approximates mean arterial pressure, perfusion stops and the brain dies.

Two categories of ICP monitoring techniques are currently available. Fluid-filled systems have external transducers, such as an intraventricular catheter and subarachnoid bolts. Solid-state systems have miniature pressure transducers that can be inserted in the lateral ventricle, brain parenchyma, or subarachnoid or epidural space.

TROUBLESHOOTING

Identification and correction of patient- and ventilator-related problems during mechanical ventilatory support are primary responsibilities of the RT. Under ideal circumstances, potential problems are identified before they occur or before they can cause harm to the patient. Potential problems with the patient include anxiety, agitation, altered mental status, fighting the ventilator, hypoxemia, hypoventilation, and the development of metabolic acidosis. The patient may experience acute changes in respiratory rate, heart rate, blood pressure, and CO_2.

Other common patient-related problems include excessive secretions, bronchospasm, and other causes of decreased compliance or increased resistance. Recognition of signs of pneumothorax, pneumomediastinum or subcutaneous emphysema, airway malfunction or leaks, and chest tube leaks should receive prompt attention.

Problems associated with the ventilator include leaks or malfunctions in the system, inappropriate ventilator settings (including trigger sensitivity and inspiratory flow rate), development of auto-PEEP, and improper humidification. Box 52.14 lists causes of sudden respiratory distress in patients receiving mechanical ventilatory support. Box 52.15 lists steps for managing sudden respiratory distress. Table 52.11 summarizes troubleshooting of the patient–ventilator system.

Pharmacologic paralysis should be considered only when no other alternatives are effective. The one exception to this guideline is the patient presenting with severe ARDS (PaO_2/FiO_2 100 mm Hg). In order to gain control of the patient's physiologic status, it is now recommended to paralyze these patients for up to 48 hours. The use of neuromuscular blocking agents can mask other patient problems, and ventilator malfunction or disconnection

BOX 52.14 Causes of Sudden Respiratory Distress in a Patient Receiving Ventilatory Support

Patient-Related Causes

- Artificial airway problems
- Movement of endotracheal tube
- Cuff herniation
- Cuff leak
- Kinking of endotracheal tube
- Foreign body
- Transesophageal fistula
- Innominate artery rupture
- Malpositioned nasogastric tube
- Secretions
- Bronchospasm
- Pneumothorax
- Pulmonary edema
- Pulmonary embolism
- Acute hypoxemia
- Blood in endotracheal tube
- Dynamic hyperinflation
- Abnormal respiratory drive
- Alteration in body posture
- Drug-induced problems
- Abdominal distention
- Agitation

Ventilator-Related Causes

- Ventilator malfunction
- Circuit malfunction
- Leaks or disconnects
- Condensate
- In-line nebulizers
- Inadequate ventilatory support
- Patient–ventilator asynchrony

From Tobin MJ, Alex CJ, Fahey PJ: Fighting the ventilator. In: Tobin MJ, editor: *Principles and practice of mechanical ventilation*, New York, 2006, McGraw-Hill.

BOX 52.15 Steps for Managing Sudden Distress in a Patient Receiving Ventilatory Support

1. Remove the patient from the ventilator.
2. Initiate manual ventilation with 100% O_2.
3. Patient improvement indicates that the ventilator is the cause of distress.
4. Lack of improvement indicates the problem is within the patient.
5. If death appears imminent, consider and manage the most likely causes; check for airway obstruction (by passing a suction catheter), a dislodged endotracheal tube, or a pneumothorax.
6. If death is not imminent, wait until the patient's condition is stable before attempting a more detailed assessment including a chest radiograph.

Modified from Tobin MJ, Alex CJ, Fahey PJ: Fighting the ventilator. In: Tobin MJ, editor: *Principles and practice of mechanical ventilation*, New York, 2006, McGraw-Hill.

TABLE 52.11 Troubleshooting the Patient–Ventilator System

Clue to Problem	Possible Cause	Corrective Action
Decreased minute ventilation or V_T	Leak around endotracheal or chest tube	Check all connections for leaks.
	Decreased patient-triggered respiratory rate	Evaluate patient.
		Check sensitivity.
		Measure auto-PEEP.
		Increase set rate.
		Change mode.
	Decreased lung compliance	Evaluate patient.
	Airway secretions	Clear airway of secretions.
	Altered settings	Check patient–ventilator system.
	Malfunctioning volume monitor	Check with external respirometer.
Increased minute ventilation or V_T	Increased patient-triggered respiratory rate	Check respiratory rate.
		Check sensitivity.
		Change mode.
	Altered settings	Check patient–ventilator system.
	Hypoxia	Evaluate patient.
		Consider ABG and SpO_2 values.
	Increased lung compliance	Decrease pressure.
		Decrease inspiratory time.
	Malfunctioning volume monitor	Check with external respirometer.
Change in respiratory rate	Altered setting	Check patient–ventilator system.
	Increased metabolic demand	Evaluate patient.
	Hypoxemia	Evaluate patient.
		Consider ABG and SpO_2 values.

Continued

TABLE 52.11 Troubleshooting the Patient–Ventilator System—*cont'd*

Clue to Problem	Possible Cause	Corrective Action
Sudden increase in peak airway pressure	Coughing	Alleviate uncontrolled coughing.
	Airway secretions or plugs	Clear airway secretions.
	Ventilator tubing kinked or filled with water	Check for kinks and water.
	Changes in patient position	Consider repositioning patient.
	Endotracheal tube in right mainstem bronchus	Verify position.
	Patient–ventilator asynchrony	Correct asynchrony.
		Check for adequate peak flow.
		Verify with waveforms.
	Bronchospasm	Identify cause and treat.
	Pneumothorax	Insert chest tube.
Gradual increase in peak airway pressure	Diffuse, reactive, or obstructive process	Evaluate for problems, such as atelectasis, increasing lung water, bronchospasm.
Sudden decrease in peak airway pressure	Volume loss from leaks in the system	Check patient–ventilator systems for leaks.
		Verify with waveforms.
		Check for active inspirations.
		Evaluate patient.
FiO_2 drift	O_2 analyzer error	Calibrate analyzer.
		Change O_2 sensor.
	Blender piping failure	Correct failure.
	O_2 source failure	Correct failure.
	O_2 reservoir leak	Check ventilator reservoir.
I:E ratio too high or too low	Altered inspiratory flow	Check flow setting and correct.
	Alteration in other settings that control I:E ratio	Check settings and correct.
	Alteration in sensitivity setting	Check setting and correct.
	Airway secretions (pressure ventilator)	Clear airway of secretions.
	Subtle leaks	Measure minute ventilation.
Inspired gas temperature too high	Addition of cool water to humidifier	Wait.
	Altered settings	Correct temperature control setting.
	Adding cool gas by small-volume nebulizer treatment	Turn off heater during treatment.
	Thermostat failure	Replace heater.
Changes in PEEP	Change in V_T	Adjust PEEP level.
	Change in compliance	Adjust PEEP level.
	Altered settings	Check settings and correct.
Changes in static pressure	Changes in lung compliance	Evaluate patient and correct if possible.
Changes in ventilator setting	Changes in these settings resulting from deliberate or accidental adjustment of dials or knobs	Determine whether current settings are the intended ones.

PEEP, Positive end-expiratory pressure.

BOX 52.16 Pharmacologic Agents Used to Produce Sedation or Paralysis

I. Benzodiazepine tranquilizing agents
  A. Diazepam (Valium)
  B. Lorazepam (Ativan)
  C. Midazolam (Versed)
II. Sedative hypnotics and miscellaneous agents
  A. Sodium thiopental (Pentothal)
  B. Etomidate (Amidate)
  C. Haloperidol (Haldol)
  D. Propofol (Diprivan)
  E. Dexmedetomidine (Precedex)
III. Narcotic analgesics
  A. Morphine
  B. Fentanyl (Sublimaze)
IV. Neuromuscular blocking agents
  A. Nondepolarizing (competitive) agents
    1. Steroidal agents
      I. Pancuronium (Pavulon)
      II. Pipecuronium (Arduan)
      III. Rocuronium (Zemuron)
      IV. Vecuronium (Norcuron)
    2. Benzylisoquinolinium esters
      I. Atracurium (Tracrium)
      II. Cisatracurium (Nimbex)
      III. Doxacurium (Nuromax)
      IV. Metocurine (Metubine)
      V. Mivacurium (Mivacron)
      VI. Tubocurarine (Tubarine)
  B. Depolarizing agents
    1. Succinylcholine (Anectine, Quelicin)
    2. Decamethonium (Syncurine)

in the care of a paralyzed patient can be catastrophic. In addition, some patients receiving neuromuscular blocking agents in the ICU may experience prolonged neuropathy. Pharmacologic agents used to produce sedation or paralysis in the ICU are listed in Box 52.16.

SUMMARY CHECKLIST

- Caregivers must be experienced at filtering the noise from the changes in monitored variables that require attention. Caregivers must recognize false alarms. They must also discriminate real pathophysiologic changes from normal physiologic variations and variations inherent in the data.
- Because only caregivers can make choices about altering care, caregivers continue to be the most important monitors.
- Monitoring of the respiratory system includes assessment of ventilation, gas exchange, and respiratory system mechanics and function.
- Ventilation is monitored by measurement of V_T, respiratory rate, and minute ventilation and by assessment of dead space and alveolar ventilation.
- Gas exchange is routinely monitored with ABG analysis and pulse oximetry. Derived values such as V_D/V_T, $P(A–a)O_2$ difference, PaO_2/FiO_2 ratio, shunt, and lung injury score can clarify the nature and severity of gas-exchange abnormality. Arterial $PaCO_2$ is the best index of alveolar ventilation.
- Respiratory system mechanics are routinely monitored by tracking peak pressure, P_{plat}, driving pressure, auto-PEEP, compliance, and resistance.
- When any patient is being mechanically ventilated, ideally, the tidal volume should be 4 to 8 mL/kg of predicted body weight, and the plateau pressure should be less than 28 cm H_2O.
- Monitoring of transpulmonary pressure is becoming increasingly important in managing patients with decreased chest wall compliance and those with severe ARDS requiring high PEEP levels.
- Factors such as WOB, f/V_T, VC, MIP, and MVV can be extremely helpful in assessing the need to increase ventilatory support or in assessing the potential for weaning.
- Advanced monitoring techniques include EIT, diaphragm and lung ultrasound, lung stress and strain, stress index, and esophageal pressure monitoring.
- The most important responsibility of the RT in the ICU is monitoring of the patient–ventilator system.
- Monitoring of the patient–ventilator system includes overall assurance of the integrity and safety of the system. Monitoring requires complete knowledge of the ventilator settings; all aspects of ventilator function; the circuitry; airway status; gas exchange; ventilator graphics; lung mechanics; alarms; and the overall care, safety, and comfort of the patient.
- Acute changes in cardiac performance, cardiovascular status, or impulse conduction (ECG) can be life threatening; some form of monitoring of the heart, vascular system, and ECG is necessary in the care of nearly all patients in the ICU.
- Hemodynamic monitoring requires the use of invasive pulmonary arterial, central venous, and arterial catheters. Values obtained with these monitoring lines must be carefully interpreted by experienced caregivers. All ICU patients should receive ECG monitoring.
- Monitoring of changes in neurologic status is extremely important and is more often overlooked than the monitoring of other organ systems.
- The neurologic examination includes assessment of mental status, pupillary response, eye movements, corneal response, gag reflex, and respiratory rate and pattern and a general motor and sensory evaluation. ICP monitoring may be needed to detect or manage elevated ICP.
- Global index monitoring is calculation of an illness level score that is an estimate of the risk of mortality from numerous monitoring values. Illness scores are not used in the care plan for an individual patient, but scoring systems are widely used in clinical studies. The APACHE II system is among the most popular of these estimates.
- Troubleshooting the patient–ventilator system is aimed at identifying and correcting problems before they harm the patient.

Discontinuing Ventilatory Support

Robert M. Kacmarek

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the relationship between ventilatory demand and ventilatory capacity as well as their relationship with ventilator discontinuance.
- List the factors associated with ventilator dependence.
- Explain how to evaluate a patient before attempting ventilator discontinuation or weaning.
- List acceptable values for specific weaning indices used to predict a patient's readiness for discontinuation of ventilatory support.
- Describe factors that should be optimized before an attempt is made at ventilator discontinuation or weaning.
- Describe techniques used in ventilator weaning, including daily spontaneous breathing trials, synchronized intermittent mandatory ventilation, pressure support ventilation, and other newer methods.
- Contrast the advantages and disadvantages associated with various weaning methods and techniques.
- Discuss the use of esophageal pressure, diaphragm electrical activity (EAdi), and ultrasound to assess weaning capabilities and predict weaning success.
- Discuss weaning of the morbidly obese patient.
- Discuss the new weaning guidelines provided by the ATS/ACCP.
- Describe how to assess a patient for extubation.
- List the primary reasons why patients fail a ventilator discontinuance trial.
- Explain why some patients cannot be successfully weaned from ventilatory support.

CHAPTER OUTLINE

KEY TERMS

adaptive support ventilation (ASV)
airway occlusion pressure
automatic tube compensation (ATC)
continuous positive airway pressure (CPAP)
diaphragm electrical activity (EAdi)
esophageal pressure
Intellivent
mandatory minute volume ventilation (MMV)
pressure support ventilation (PSV)
progressive mobility
prolonged mechanical ventilation (PMV)
rapid, shallow breathing index (f/V_T)
spontaneous awaking trial (SAT)
spontaneous breathing trial (SBT)
synchronized intermittent mandatory ventilation (SIMV)
ultrasound, diaphragm

The purpose of mechanical ventilation is to support the patient until the disease state or condition that caused the need for ventilatory support is alleviated or resolved. Ventilatory support can sustain life, but it cannot cure disease. Further, many complications and hazards are associated with mechanical ventilation. Consequently, ventilatory support should be withdrawn as soon as the patient is able to adequately resume spontaneous breathing.[1] All patients who are mechanically ventilated should be evaluated daily, beginning with the day of intubation, for their ability to be liberated from ventilatory support.[2,3] Frequently this evaluation is very quick, but it should be performed at least daily regardless of the patient's status.

After the problem or condition that caused the need for mechanical ventilation is resolved, most patients can be quickly and easily liberated from ventilatory support. For example, for most patients who need mechanical ventilation as a result of a drug overdose or severe asthma, for those who are recovering from postoperative anesthesia, and for those who have received ventilation for 72 hours or less, one may simply discontinue ventilation when the precipitating condition has resolved.[1,4] However, some patients require mechanical ventilation for longer periods. The term *ventilator dependent* is usually reserved for patients who need ventilatory support for lengthy periods (i.e., 2 weeks or more) or who have not responded to attempts at ventilator discontinuation. For these patients, a more prolonged ventilator discontinuation process is required.[1]

Ventilator discontinuation should be carefully timed. Premature removal from the ventilator may severely stress the cardiopulmonary system and delay the patient's recovery.[4] Premature discontinuation also exposes the patient to the hazards of reintubation. However, delays in discontinuing ventilation expose the patient to an increased risk of complications, including nosocomial pneumonia, lung injury, myocardial infarction, and death.[4]

There are three basic historical methods for discontinuing ventilatory support, which can be used alone or in combination with one another[1]:

1. **Spontaneous breathing trials (SBTs)** alternating with mechanical ventilation
2. **Synchronized intermittent mandatory ventilation (SIMV)**
3. **Pressure support ventilation (PSV)**

Other techniques that may facilitate ventilator discontinuation include the use of volume-support ventilation (VSV); **adaptive support ventilation (ASV)**/**Intellivent**; automatic tube compensation (ATC); proportional assist ventilation (PAV), which is also known as *proportional pressure support* (PPS); neurally adjusted ventilatory assist (NAVA); and **continuous positive airway pressure (CPAP)**. However, little data exist that support the use of any of these techniques except for CPAP, which seems potentially beneficial during the ventilator discontinuation process, especially in morbidly obese patients.[5]

> **RULE OF THUMB** All patients who are mechanically ventilated should be evaluated at least daily, beginning with the day of intubation, for their ability to be liberated from ventilatory support.

Techniques for predicting when patients are ready for ventilator discontinuation and weaning have been studied extensively.[4] Many weaning indices designed to predict successful ventilatory discontinuation have been proposed. Despite this, there are no universally applicable indices for predicting success. Of all the methods studied, SBTs and PSV have been shown to be the most effective methods for ventilator discontinuation and weaning. Evidence-based reviews recommend the use of at least daily SBTs.[1] Protocols for ventilator discontinuation administered by an interdisciplinary team of respiratory therapists, nurses, and physicians can be highly effective, and have been recommended.[1,4,6–10] Regardless of the method used, success is unlikely unless the precipitating problems that caused the ventilator dependency have been resolved.[1,4,10] After these problems are resolved, an organized plan or protocol should be followed, and variations from the plan should be based on each patient's response.[1,4,6]

Some patients cannot be successfully removed from mechanical ventilatory support. This group of ventilator-dependent patients poses clinical, economic, and ethical concerns.[11,12]

The term *weaning* has been used as a general term to refer to the process of discontinuing ventilatory support, regardless of the time frame or method involved. The term has also been used to refer to reductions in fractional inspired oxygen concentration (FiO_2), positive end-expiratory pressure (PEEP), and CPAP. Alternatively, the term *ventilator discontinuation or liberation* has been used to refer to the process of disconnecting a patient from mechanical ventilatory support. For the purposes of this chapter, the term *weaning* is defined as a gradual reduction in the level of ventilatory support, whereas *liberating from or discontinuing ventilatory support* refers to the overall process of removing the patient from the ventilator, regardless of the method used. In general, patients who are being considered for removal from ventilatory support fall into one of five categories:

1. Those for whom removal is quick and routine, normally the majority of ventilated patients.
2. Those who need a more systematic approach to discontinuing ventilatory support, which is normally about 15% to 20% of ventilated patients.
3. Those who require days to weeks to wean from ventilatory support, which is usually less than 5% of ventilated patients.
4. Those ventilator-dependent or "unweanable" patients, who compose less than 1% of patients who require ventilatory support.
5. Those who have no chance for survival in whom the ventilator is discontinued while comfort measures are provided, normally referred to as terminal weaning or terminal extubation.[13]

RULE OF THUMB After the problem or condition that caused the need for mechanical ventilation is resolved, most patients can be quickly and easily liberated from ventilatory support.

REASONS FOR VENTILATOR DEPENDENCE

Patients may require mechanical ventilation because of apnea, acute or impending ventilatory failure, or severe oxygenation problems that necessitate high levels of PEEP or CPAP. Regardless of the reason for initiating mechanical ventilation, patients remain dependent on the ventilator because of respiratory, cardiovascular, neurologic, or psychologic factors.[1]

Ventilatory Workload and Demand

Patients who need mechanical ventilation often have a ventilatory workload and demand that exceeds their ventilatory capacity. This is the most common cause of ventilator dependence.[1,4] The term *ventilatory workload* refers to the amount of work that the respiratory muscles are asked to perform to provide an appropriate level of ventilation. A patient's total ventilatory workload is primarily determined by the following: (1) the level of ventilation needed, (2) the compliance of the lungs and thorax, (3) the resistance to gas flow through the airways, and (4) any imposed work of breathing (WOB_I) due to ventilatory system mechanical factors.[1,4]

The level of ventilation required is determined by the following: (1) the metabolic rate, (2) the central nervous system (CNS) ventilatory drive, and (3) the ventilatory dead space. Common causes of an increased demand for ventilation include increased carbon dioxide production (i.e., fever, shivering, agitation, trauma, or sepsis) and increased dead space (i.e., pulmonary emboli or chronic obstructive pulmonary disease [COPD]). Other common causes of increased ventilatory demand include metabolic acidosis, severe hypoxemia, pain, and anxiety.

Compliance is determined by the elastic nature of the lung–thorax system. Resistance is largely related to the nature of the conducting airways. Common causes of decreased lung compliance include atelectasis, obesity, pneumonia, pulmonary edema, pulmonary fibrosis, acute lung injury, and acute respiratory distress syndrome. Thoracic compliance may be reduced because of ascites, or abdominal distention. Airway resistance increases with bronchospasm, excessive secretions, and mucosal edema.

BOX 53.1 Factors That May Increase Ventilatory Workload

Increased Ventilatory Demand: Increased Level of Ventilation Required

- Increased central nervous system drive: hypoxia, acidosis, pain, fear, anxiety, and stimulation of J receptors (e.g., pulmonary edema)
- Increased metabolic rate: increased carbon dioxide production, fever, shivering, agitation, trauma, infection, and sepsis
- Increased dead space: chronic obstructive pulmonary disease and pulmonary embolus

Decreased Compliance

- Decreased lung compliance: atelectasis, obesity, pneumonia, fibrosis, pulmonary edema, and acute respiratory distress syndrome
- Decreased thoracic compliance: ascites, abdominal distention, and pregnancy

Increased Resistance

- Increased airway resistance: bronchospasm, mucosal edema, and secretions
- Artificial airways: endotracheal tubes, tracheostomy tubes, and partial obstruction of the artificial airway or the patient airway
- Other mechanical factors: ventilator circuits, demand flow systems, and inappropriate ventilator flow or sensitivity settings

BOX 53.2 Factors That May Reduce Ventilatory Drive

- Decreased $PaCO_2$ (respiratory alkalosis)
- Metabolic alkalosis
- Pain (visceral)
- Electrolyte imbalance
- Pharmacologic depressants (narcotics, sedatives)
- Fatigue
- Decreased metabolic rate
- Increased $PaCO_2$ associated with chronic carbon dioxide retention
- Neurologic or neuromuscular disease

Mechanical factors that can increase the work of breathing (WOB) include artificial airways (i.e., endotracheal and tracheotomy tubes), partial obstruction of the airway, ventilator circuits, demand flow systems, auto-PEEP, and inappropriate ventilator flow and sensitivity settings. Factors that may increase ventilatory workload are summarized in Box 53.1.

Ventilatory Capacity

Ventilatory capacity is determined by ventilatory drive, ventilatory muscle strength, and ventilatory muscle endurance. Most patients who are being withdrawn from ventilatory support have a normal or an increased drive to breathe. Patients with neuromuscular disorders and those who are receiving sedatives, narcotics, or neuromuscular blocking agents may have a reduced or absent drive to breathe or impaired neuromuscular transmission. Patients with metabolic alkalosis, hypothyroidism, and sleep deprivation also may have a reduced ventilatory drive. Box 53.2 summarizes the factors that may reduce ventilatory drive.

Muscle strength is influenced by age, sex, muscle bulk, and overall health. Malnutrition, starvation, and electrolyte imbalances (especially involving calcium, magnesium, potassium, and

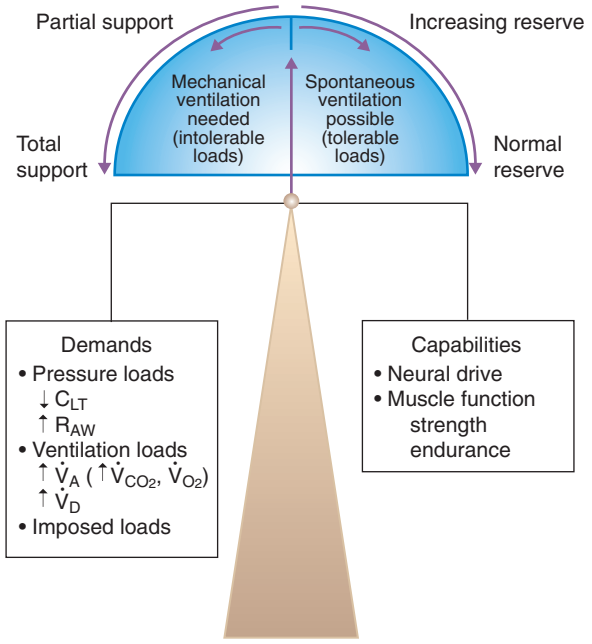

Fig. 53.1 Ventilatory failure and the need for ventilatory support depend on the balance between ventilatory muscle demands (i.e., loads) and ventilatory muscle capabilities. C_{LT}, Lung–thorax compliance; *RAW,* airway resistance, $\dot{V}$, minute alveolar ventilation; $\dot{V}$, minute dead space ventilation. (Modified from MacIntyre NR: Respiratory factors in weaning from mechanical ventilatory support. *Respir Care* 40:244–259, 1995.)

phosphate) can lead to ventilatory muscle weakness. Critical illness myopathy, critical illness polyneuropathy, and the prolonged use of neuromuscular blocking agents are major causes of the development of ventilatory muscle weakness in the intensive care unit (ICU).[14] Controlled ventilation for prolonged periods can result in ventilatory muscle discoordination and atrophy. Ventilatory muscle endurance is a function of energy supply versus demand. Energy supply is related to nutrition, perfusion, and cell energy use, whereas demand is related to the amount of work performed and is a function of minute ventilation, compliance, and resistance. Fig. 53.1 summarizes the relationship between ventilatory demands and capabilities.

RULE OF THUMB If patient workload exceeds capacity, the patient will not be successfully weaned from ventilatory support.

Global Criteria for Discontinuing Ventilatory Support

Success with liberation from ventilatory support is related to the patient's condition in four main areas[1–4]:

1. Ventilatory workload versus ventilatory capacity
2. Oxygenation status
3. Cardiovascular function
4. Psychologic factors

Simply put, when ventilatory workload or demand exceeds ventilatory capacity, successful ventilator discontinuation is unlikely. Excessive ventilatory workload may lead to ventilatory muscle fatigue. When the ventilatory muscles fatigue, they must be rested for at least 24 hours to recover.[15] Ventilatory workload increases with decreased compliance, increased airway resistance, or an increased requirement for ventilation. Ventilatory capacity can be reduced by ventilatory muscle fatigue and by a loss of muscle strength and endurance.

Other factors that may contribute to ventilator dependence include inadequate arterial oxygenation, poor tissue oxygen delivery, myocardial ischemia, arrhythmias, low cardiac output, and cardiovascular instability. Neurologic problems that may contribute to ventilator dependence include decreased central drive to breathe and impaired peripheral nerve transmission. Psychologic issues that may contribute to ventilatory dependence include the fear of removal of the life-support system, anxiety, stress, depression, and sleep deprivation. Box 53.3 summarizes the major factors that contribute to ventilator dependence.

BOX 53.3 Factors That Contribute to Ventilator Dependence

Respiratory Factors

- Ventilatory workload exceeds ventilatory capacity
- Decreased compliance: lung or chest wall
- Increased resistance: artificial airways, bronchospasm, mucosal edema, secretions, and mechanical demand flow systems
- Increased dead space: pulmonary embolus and chronic obstructive pulmonary disease
- Ventilatory muscle weakness or fatigue
- Oxygenation problems
  - ↓ $\dot{V}/\dot{Q}$
  - Increased shunt
  - ↓ DO_2
  - ↓ Oxygen extraction ratio

Nonrespiratory Factors

- Cardiovascular factors
- Myocardial ischemia
- Heart failure
- Hemodynamic instability, hypotension, and arrhythmias
- Neurologic factors
- Decreased or increased central drive to breathe
- Decreased peripheral nerve transmission
- Psychologic factors
- Fear and anxiety
- Stress
- Confusion or altered mental status
- Depression
- Poor nutrition
- Multiple-system organ failure
- Equipment shortcomings

PATIENT EVALUATION

Careful patient assessment is required to determine which patients are ready to be quickly removed from ventilatory support, which patients may need a prolonged ventilator discontinuation phase, and which patients are not yet ready for the discontinuation of ventilatory support.

An important factor to consider as part of this assessment is the length of time that the patient has been receiving mechanical ventilation. In general, those who receive support for 72 hours

BOX 53.4 Factors Associated With Readiness for the Discontinuation of Ventilatory Support

- Reversal or partial reversal of reason for instituting mechanical ventilation
- Good baseline functional status
- Ventilatory capacity that is capable of meeting ventilatory workload
- Good oxygenation status
- Good cardiovascular performance
- Good functional status of other organs and systems
- Short duration of the critical illness
- Short duration of mechanical ventilation
- No psychologic factors affecting current status

Modified from Pierson DJ: Nonrespiratory aspects of weaning from mechanical ventilation. *Respir Care* 40:263–270, 1995.

or less often can be removed quickly from the ventilator.[16,17] Those who need a longer period of support may need a more prolonged approach. Current guidelines recommend that patients who need mechanical ventilation for more than 48 to 72 hours be carefully assessed to determine the possible causes of ventilator dependence.[1,4] These include the respiratory, cardiovascular, neurologic, and psychologic causes of ventilator dependence that are listed in Box 53.3. This recommendation is especially important for the care of patients who have had unsuccessful attempts at the discontinuation of ventilation.[1,4] Factors associated with readiness for the discontinuation of ventilatory support are summarized in Box 53.4.

The Most Important Criterion

The single most important criterion to consider when evaluating a patient for ventilator liberation or weaning is whether there has been significant alleviation or reversal of the disease state or condition that necessitated use of the ventilator in the first place.[1,4,10] The clinician should determine whether the patient's condition is improving, whether the initial reason for providing ventilatory support is improved or resolved, and whether the patient's clinical condition is stable. The following specific questions for patient evaluation have been suggested[1]:

1. Is there evidence of improvement or reversal of the disease state or condition that caused the need for mechanical ventilation?
2. Is the patient's oxygenation status adequate? Specific criteria may include the following: PaO_2 of 60 mm Hg or more, FiO_2 of less than 0.40 to 0.50, PEEP of less than 5 to 10 cm H_2O; PaO_2/FiO_2 of 150 to 200 or greater; and pH of 7.25 or greater.
3. Is the patient medically and hemodynamically stable? Specific criteria may include the absence of acute myocardial ischemia or marked hypotension. Patients should have adequate blood pressure without vasopressor therapy or with only low-dose intermittently delivered vasopressor therapy (i.e., less than 5 mcg/kg/min of dopamine or dobutamine).
4. Can the patient breathe spontaneously? The patient must be able to breathe spontaneously at sufficient tidal volumes and have a sufficient drive to breathe if ventilator liberation is being considered.

If the patient's condition is improving, if the alleviation or reversal of the precipitating disease state or condition has occurred, if the patient is capable of spontaneous breathing, and if the oxygenation status and hemodynamic values are stable, then ventilator liberation should be attempted.[1]

RULE OF THUMB In general, those who receive support for 72 hours or less often can be removed quickly from the ventilator.

Weaning Indices

Mechanical ventilation is hazardous, and unnecessary delays in ventilator discontinuation increase the associated complication rate. Unfortunately, premature ventilator discontinuation may also cause serious problems, including difficulty with reestablishing the artificial airway and serious compromise of the patient's clinical status. General clinical judgment alone has been found to be a poor guide to determining whether a patient is ready for ventilator discontinuation, and as a result, more specific indicators have emerged. Specific indicators or weaning indices that clearly show whether a patient is ready to have the ventilator removed and help avoid inappropriate ventilator discontinuation have been sought. Unfortunately, none of the current weaning indices predict readiness for ventilator discontinuance with a high level of accuracy.[1,4]

Traditional discontinuation indices include the PaO_2/FiO_2 ratio, the alveolar-to-arterial partial pressure of oxygen difference [$P(A - a)O_2$], the maximum inspiratory pressure (MIP), the vital capacity (VC), the spontaneous minute ventilation (V_{Esp}), and the maximum voluntary ventilation (MVV).[3,18] Newer indices include the **rapid, shallow breathing index (f/V_T)**, **airway occlusion pressure** ($P_{0.1}$), and measures of WOB.[1,4] Although all of these values can be useful, there are enormous discrepancies in the literature regarding their accuracy with regard to the prediction of "weanability."[1,4] With respect to the more traditional discontinuation indices, VC and MIP can be highly variable, whereas minute ventilation, respiratory rate (f), and f/V_T tend to be more reliable.[1,4] However, these measures may not correlate well with discontinuation success among all patients and especially among those receiving long-term ventilatory support, the elderly, and those with major pulmonary abnormalities.[1,4,19]

A comprehensive review of related research identified a possible role for 66 specific measurements as predictors of weaning success.[4] Of these, eight values were found to be the most useful for the prediction of successful ventilator discontinuation.[1,4] Useful predictive measures included spontaneous respiratory rate, spontaneous tidal volume, f/V_T, minute ventilation, MIP, $P_{0.1}$, $P_{0.1}$/MIP, and a combined index called the *CROP (Compliance Rate Oxygenation and Plmax) score* that included compliance, respiratory rate, oxygenation, and MIP.[1,4] Unfortunately, these measures all have limitations and can falsely suggest that a patient is ready for weaning.

It is doubtful that a single index will be found that can be used for consistent discrimination between discontinuation success and failure. Moreover, none of these traditional indicators alone has proved useful for the prediction of improvements in patient outcome or in the selection of a particular discontinuation method.[5,19]

Notwithstanding these limitations, the measurement of discontinuation indices in the difficult-to-wean patient may provide guidance regarding the reasons that patients fail discontinuation trials. Many find it useful to trend these indicators daily for those patients who require lengthy weaning times.[11,16] Specific values for respiratory indices that are used to predict the successful discontinuation of ventilatory support are found in Table 53.1.

RULE OF THUMB None of the indices predicting success or failure of weaning predict with sufficient accuracy the results of a weaning trial. The trial itself is the BEST determinant of ability to be liberated from the mechanical ventilator.

Ventilation

Increased thoracic cage movement during spontaneous breathing and asynchronous chest wall–to–diaphragm movement are related to an increased workload that may lead to ventilatory muscle fatigue and failure. Tachypnea (i.e., more than 30 to 35 breaths/min in adults) is a sensitive marker of respiratory distress, but it can prolong intubation if it is used as the only criterion. One explanation for this is that when sedation is lessened to facilitate weaning, the more awake patient may become anxious about having an endotracheal tube in place and being on a ventilator, which may itself cause their tachypnea. On the other end of the spectrum, irregular spontaneous breathing or periods of apnea indicate that the patient is at risk for weaning failure. Asynchronous and rapid shallow breathing patterns—although not definitive—suggest respiratory decompensation.[19] However, decreased ventilatory variability over time (rate, V_T, minute ventilation) has been clearly shown to identify patients who will fail an SBT.[20,21]

The evaluation of patients for the presence of palpable scalene muscle use during inspiration, an irregular ventilatory pattern, palpable abdominal muscle tensing during expiration, and the inability to alter the ventilatory pattern on command can be helpful for the assessment of the potential for prolonged spontaneous ventilation. Patients with none of these signs have a very high probability of successful ventilator discontinuance. Patients with one or two of these signs usually need continued support. The presence of three or more of these signs can mean that the patient's condition is unstable and that the patient has a poor prognosis for ventilator removal.[22]

$P_{0.1}$ is the inspiratory pressure that is measured 100 ms after airway occlusion.[1,4] The $P_{0.1}$ is effort-independent, and it correlates well with central respiratory drive. Patients who have a $P_{0.1}$ more negative than −5 cm H_2O have an increased WOB; the more negative the $P_{0.1}$ the less likely it is that the patient will be able to be liberated from ventilatory support.[1,4] Daily monitoring of $P_{0.1}$ can provide very useful information on patients' ventilatory drive and WOB (see Chapter 48 for more details).[1,4]

The f/V_T is the ratio of spontaneous breathing frequency (breaths/min) to tidal volume (liters), and it has been found to be a good predictor of discontinuation success for many patients who need mechanical ventilation.[1,4,19] The f/V_T has less predictive ability for patients who need ventilatory support for longer than 8 days, and it may be less useful for predicting discontinuation success among elderly patients.[1,4] Despite these limitations, an f/V_T of less than 105 can be an accurate and early predictor of weaning outcome, and an f/V_T of 80 is associated with an almost 95% probability of successful liberation.[19] The ratio must be calculated during 1 minute of unsupported spontaneous breathing, and the

TABLE 53.1 Indices That Are Used to Predict the Success of Weaning and Ventilator Discontinuation

Measurement	Criterion
Oxygenation	
FiO_2	≤0.40–0.50
PEEP (cm H_2O)	≤5–8

Maximum voluntary ventilation (MVV) (L/min)	>20; more than twice the $\dot{V}_E$

Data from MacIntyre NR, Cook DJ, Ely EW, et al: Evidence-based guidelines for weaning and discontinuing ventilator support: a collective task force facilitated by the American College of Chest Physicians, the American Association for Respiratory Care, and the American College of Critical Care Medicine. *Chest* 120:375S–395S, 2001; AHRQ publication no. 01-E010, Rockville, MD, 2000, Agency for Healthcare Research and Quality; American College of Chest Physicians: *Chest* 104:1833, 1993; Burns SM et al: *Am J Crit Care* 4:4, 1995; Sharar S: *Resp Care* 40:239, 1995; Bassili HR, Deitel M: *J Parenter Enteral Nutr* 5:161, 1981.

MINI CLINI

Calculating and Interpreting the Rapid, Shallow Breathing Index

Problem

You measure the following spontaneous breathing values for two patients who are being considered for weaning from mechanical ventilation:

Patient	Rate (f) (breaths/min)	V_T (L)
A	32	0.28
B	28	0.42

For which patient is successful weaning least likely?

Solution

First, compute the rapid, shallow breathing index for each patient as follows:

Patient	Rate (f) (breaths/min)	V_T (L)	f/V_T
A	32	0.28	114
B	28	0.42	67

Patient A clearly exceeds the threshold criterion of 105 breaths/min/L, whereas patient B falls well below this criterion. All else being equal, patient A is least likely to be successfully weaned.

addition of pressure support during measurement significantly reduces the predictive value of the ratio.[19]

RULE OF THUMB Adult patients with spontaneous respiratory rates >35 breaths/min, tidal volumes of <5 mL/kg PBW, and $P_{0.1}$ more negative than –5 cm H_2O are difficult to wean.

The $P_{0.1}$/MIP ratio has been found to be a good early predictor of discontinuation success,[1,4] and it may be more useful than the MIP by itself. The f/V_T also has been found to be a better predictor of discontinuation success than the MIP alone.[1,4] However, even with f/V_T of less than 105, as many as 20% of patients have false-positive results (i.e., they cannot be discontinued from ventilation despite a favorable index) as a result of unpredictable factors such as congestive heart failure, aspiration, other comorbidities or the development of a new pulmonary lesion. In addition, some patients can be successfully discontinued from ventilatory support despite poor f/V_T values (>105).

WOB would seem to be an excellent way to gauge spontaneous ventilatory workload. Successful weaning has been found to be less likely among patients with spontaneous WOB levels of more than 1.6 kg/m/min (16 J/min) or 0.14 kg/m/L (1.4 J/L).[1,4] However, WOB may not be predictive of weaning success for specific patients.[1,4] This may be because WOB does not take into account ventilatory muscle capacity or fatigue. Consequently, WOB may be less accurate than other conventional discontinuation indices, and it is very difficult to measure at the bedside.

Oxygen cost of breathing (OCB) is the difference between oxygen consumption during spontaneous breathing and oxygen consumption during apnea (i.e., during full ventilatory support), which is determined as follows:

$$OCB = VO_{2sp} - VO_2 \text{ (controlled ventilation)}$$

VO_{2SP}, oxygen consumption during spontaneous breathing; VO_2, oxygen consumption during controlled ventilation.

After the OCB has been estimated, the relative proportion of oxygen consumed by the respiratory muscles as compared with the body as a whole can be calculated as follows:

$$\%VO_2 \text{ (Resp)} = (OCB/VO_{2sp}) \times 100$$

Both OCB and $\%VO_2$ have been correlated with the number of days required to wean patients. Patients with an OCB of 15% or less of the total VO_2 may be more likely to achieve discontinuation success.[1,4]

Pressure–time product (i.e., the area under the inspiratory pressure–time curve) and pressure–time index (PTI) may be the best measures of ventilatory workload of patients who are receiving mechanical support.[1] The PTI can be calculated as follows:

$$PTI = (\text{Mean inspiratory pressure}/MIP) \times T_i/T_{tot}$$

where MIP is maximum inspiratory pressure, T_i is the inspiratory time in seconds, and T_{tot} is the total respiratory cycle time. The T_{tot} can be calculated by dividing 60 by the respiratory rate (f) (i.e., 60/f). A PTI of more than 0.15 to 0.18 has been associated with diaphragmatic fatigue, and a PTI of more than 0.15 cannot be sustained indefinitely.[1,4] There is currently no well-accepted and reliable way to measure ventilatory muscle fatigue in patients who are receiving mechanical ventilation.

Oxygenation

Poor oxygenation status is associated with weaning failure. Arterial blood gas (ABG) analysis, pulse oximetry, and continuous mixed venous oximetry have been used to monitor and assess the oxygenation status of patients before and during a discontinuation trial. In general, a PaO_2 of more than 60 mm Hg (or of more than 55 mm Hg for patients with COPD with carbon dioxide retention) with an FiO_2 of less than 0.40 to 0.50 and a PEEP of 5 to 10 cm H_2O or less should be adequate for ventilator discontinuation. The PaO_2/FiO_2 ratio should be 150 to 200 mm Hg or more. With these values, a normal hemoglobin level, a normal oxygen saturation (SaO_2), and adequate cardiac output and tissue perfusion are assumed. Specific indices used to assess oxygenation status are found in Table 53.1.

Acid–Base Balance

Ideally the patient should have a normal acid–base balance (i.e., a pH of 7.35 to 7.45), and abnormalities in acid–base status have been corrected, if possible, before weaning. Patients with metabolic acidosis often have an increased ventilatory drive that can make weaning difficult. Patients who have metabolic alkalosis or those who have been mechanically hyperventilated for several days may have a reduced ventilatory drive. In these cases, a gradual method of discontinuing ventilatory support may be necessary: one that restores acid–base balance to normal.

Metabolic Factors

Metabolic factors primarily affect discontinuation in those patients who require long-term ventilatory support. Although nutritional factors are important for all patients, they are unlikely to affect discontinuation in those who only require short-term ventilatory

support. Nutrition should be adequate to maintain respiratory muscle mass and contractile force. Feeding should be adjusted according to individual patient needs; most patients need 1.5 to 2.0 times their resting energy expenditure. In addition, protein intake should be between 1 and 1.5 g/kg per day. Excessive carbohydrate feeding can increase carbon dioxide production and may precipitate acute hypercapnic respiratory failure. Parenteral nutrition solutions that contain amino acid formulations (e.g., arginine/lysine) can cause metabolic acidosis and thus increase ventilatory demand. Metabolic rate can increase as a result of fever or sepsis. Increased WOB, shivering, seizures, and agitation can also increase oxygen demand and should be evaluated (see Chapter 23).

Renal Function and Electrolytes

Adequate renal function is required to maintain acid–base homeostasis, electrolyte concentrations, and fluid balance. Ideally, adult patients should have an adequate urine output (i.e., more than 1000 mL/day), and there should be no inappropriate weight gain or edema.

Renal insufficiency can lead to metabolic acidosis, which increases respiratory drive. Electrolyte disorders can impair ventilatory muscle function. Key electrolytes should be normal (see Chapter 17 for details). Fluid overload can lead to congestive heart failure and pulmonary edema, which may impair pulmonary gas exchange.

Cardiovascular Function

Adequate cardiovascular function is needed to provide sufficient oxygen delivery to the tissues. Cardiac rate and rhythm and blood pressure should be evaluated. Tachycardia (i.e., a heart rate of more than 100 beats/min) and bradycardia (i.e., a heart rate of less than 60 beats/min) should be controlled. The presence of arrhythmias, hypotension (i.e., a blood pressure of less than 90/60 mm Hg), and severe hypertension (i.e., a blood pressure of more than 180/110 mm Hg) should be evaluated carefully before the discontinuation of ventilatory support is considered.

Cardiac output and index measurements as well as central venous pressure measurements may be helpful for the evaluation of cardiovascular function. Left ventricular dysfunction, myocardial ischemia, and cardiovascular instability are associated with decreased discontinuation success.[1,4] Table 53.2 provides criteria for confirming cardiovascular stability (see Chapter 10).

TABLE 53.2 Criteria for Confirming Cardiovascular Stability

Criterion	Normal Value	Values That May Be Inconsistent With Weaning
Heart rate (beats/min)	60–100	<60, >120
Blood pressure (mm Hg)	90/60–150/90	<90/60, >180/110
$\dot{Q}_t$ (L/min)	4–8	<4, >8
Cardiac index (L/min/m^2)	2.5–4	<2.1
Cardiac rhythm	No major arrhythmias present	Tachycardia, bradycardia, multiple premature ventricular contractions, heart block
Hemoglobin (g/dL)	12–15	Anemia, <8
Hematocrit	40%–50%	<35%
No angina present		
No lactic acidosis		

Psychologic Factors and Central Nervous System Assessment

Adequate CNS function is needed to ensure stable ventilatory drive, adequate secretion clearance (i.e., coughing and deep breathing), and the protection of the airway (i.e., gag reflex and swallow). In addition, the level of consciousness, dyspnea, anxiety, depression, and motivation can affect discontinuation success.[1,4]

The patient ideally is awake and alert, free of seizures, and able to follow instructions. Patients should have an intact central drive to breathe and peripheral nerve function. Brainstem strokes, electrolyte disturbances, sedation, neuromuscular blocking agents, and narcotic drugs can impair the central neurologic control of ventilation. Mental status is a good predictor of discontinuation success, and patients who are not alert are at risk for upper airway obstruction, aspiration, and secretion retention. Obtunded patients should, at a minimum, have an adequate gag reflex and cough. Decreased levels of consciousness are associated with aspiration after extubation. The level of consciousness is affected by narcotic, sedative, and analgesic drugs. Drugs with CNS depressant effects should be discontinued, if possible, before the withdrawal of ventilatory support and extubation. Protocols to reduce sedation and the daily cessation of sedative drugs may reduce weaning time[7,23] (see the section on "Spontaneous Awaking Trials"). Neuromuscular blocking agents to allow for controlled ventilation should only be administered when absolutely necessary to insure patient–ventilator interaction and for the shortest period possible.[24,25]

Psychologic factors may be among the most important nonrespiratory contributing factors that lead to ventilator dependence.[1,4] Fear, anxiety, pain, and stress should be minimized, and frequent communication among the staff, the patient, and the patient's family can be helpful. Box 53.5 summarizes nonrespiratory factors that affect discontinuation success.

Integrated Indices

Many factors are associated with discontinuation success. Integrated indices may improve prediction by combining several measures of ability to breathe without ventilatory support. Current examples of integrated indices include the CROP score, the Adverse Factor/Ventilator Score, the weaning index, and the Burns Weaning Assessment Program.[1,4] The CROP score combines measures of ventilatory load, respiratory muscle strength, and gas exchange.

The Adverse Factor/Ventilator Score combines ratings of 15 adverse factors, including hemodynamic values, infection, nutrition, and neurologic/psychiatric state, with ratings of six ventilator factors, including FiO_2, compliance, minute ventilation, and rate.[1,4] The weaning index combines measures of ventilatory strength, endurance, and efficiency of gas exchange. A weaning index of less than 4 suggests successful discontinuation from mechanical ventilation. The Burns Weaning Assessment Program

BOX 53.5 Nonrespiratory Factors That Affect Weaning

- Acid–base status
- Metabolic alkalosis: decreased ventilatory drive
- Metabolic acidosis: increased ventilatory demand
- Mineral and electrolyte balance
- Hypophosphatemia: ventilatory muscle weakness
- Hypomagnesemia: ventilatory muscle weakness
- Hypokalemia: ventilatory muscle weakness
- Hypothyroidism: decreased ventilatory drive and impaired muscle function
- Stability of other organs and systems
- Cardiac: excessive preload (e.g., overall volume overload and increased preload on discontinuation of positive pressure ventilation) and impaired contractility
- Renal: renal insufficiency and metabolic acidosis
- Hepatic: encephalopathy and protein synthesis
- Gastrointestinal: stress-related hemorrhage and ability to take enteral nutrition
- Neurologic: level of consciousness, ability to protect the airway, and clear secretions
- Effects of drugs: narcotics, benzodiazepines, other sedatives and hypnotics, muscle relaxants, and aminoglycosides
- Nutritional status
- Ventilatory muscle function
- Ventilatory drive
- Immune defense system
- Psychologic and motivational factors

Modified from Pierson DJ: Nonrespiratory aspects of weaning from mechanical ventilation. *Respir Care* 40:289, 1995.

is a 26-item assessment that combines 12 general and 14 respiratory factors into a single score.[1,4] Although integrated indices appear promising, none of these indices has emerged as superior for use in diverse patient populations. *Despite the success of these integrated indices in very specific settings, the best approach to determining if a patient can be successfully discontinued from ventilatory support is the patient's performance on a SBT.* All patients should be assessed daily, and their ability to breathe spontaneously should be the primary variable to determine if the ventilator can be discontinued.

Evaluation of the Airway

The ability to maintain a patent natural airway and the likelihood of aspiration should be evaluated as a part of the process of discontinuing ventilatory support. It is important for the clinician to separate the decision to discontinue ventilatory support from the decision to extubate. The clinician must also be aware that most weaning indices do not evaluate airway patency or protection (see the section on "Extubation"). The inability to protect or maintain the natural airway is a clear contraindication to extubation. Some patients who can be successfully removed from a ventilator should not be extubated. Although controversial, evaluating if gas moves freely around the endotracheal tube (ETT) with the cuff deflated may identify an increased likelihood of postextubation airway obstruction. If auscultation of the lateral neck does not identify gas flow around the EET, extubation should be delayed until airway edema is properly treated with steroids.

MINI CLINI

Assessment of Readiness for a Spontaneous Breathing Trial

Problem

A 64-year-old man who underwent a lung resection and who has a long history of COPD is now 24 hours postoperative, and he is being evaluated for readiness for an SBT. The data currently available for this patient include the following:

- Ventilator settings:
  - Mode pressure support 10 cm H_2O
  - Average V_T 450 mL (6.5 mL/kg ideal body weight)
- Respiratory rate of 28 breaths/min
- FiO_2 of 0.40
- PEEP of 5 cm H_2O

The patient is alert and cooperative.

The patient is not receiving any vasoactive drugs, and he is only receiving intermittent sedatives and narcotics.

Should this patient be placed on an SBT?

Solution

By 24 hours, the patient should have initially recovered from the effects of the surgical procedure. The patient's ventilator settings are offering minimal support. Because the patient is alert and able to breathe spontaneously and because he requires only intermittent sedatives or narcotics, it is very appropriate to perform an SBT on this patient.

Tracheotomy may be considered for patients who need artificial airways for an extended period.

Tracheotomy may improve patient comfort, allow for more effective suctioning, decrease airway resistance (due mainly to shorter tube length), enhance mobility, and allow the patient to eat and speak. Some patients also need high levels of sedation to tolerate the endotracheal tube. Consequently, tracheotomy should be considered for the care of patients who are likely to benefit and for those who need prolonged mechanical ventilatory support. See Chapter 37 for details about airway management and extubation.

Other patients with good airway patency and protection may be unable to maintain spontaneous breathing for prolonged periods without assistance.[26] These patients may be candidates for noninvasive ventilation (NIV) after extubation; see Chapter 50 for details.[26,27]

RULE OF THUMB The decision to discontinue ventilatory support and the decision to extubate the patient are independent decisions. Many patients may be ready for the discontinuation of one but not the other! This is particularly true of patients with airway obstruction. They may be able to ventilate but removal of the ETT results in obstruction of the upper airway.

PREPARING THE PATIENT

Optimizing the Patient's Medical Condition

Before removal of ventilatory support is attempted, the patient's oxygenation status, ventilation, cardiovascular status, and overall medical condition should be optimized. Disease-imposed ventilatory load is minimized with the management of infection, bronchospasm, and airway edema. Bronchodilator therapy should

be maximized and the appropriate use of antiinflammatory agents considered. Techniques to facilitate secretion clearance (e.g., suctioning, adequate humidification, bronchial hygiene techniques), good nutrition, and optimal positioning should be used. The patient should be rested and not fatigued nor sleep deprived, which can be common in the ICU. The patient should be allowed to sleep at night while maintained on a level of ventilatory support that ensures ventilatory muscle rest.[28] Intrinsic PEEP during mechanical ventilation may increase trigger work, and appropriate amounts of PEEP or CPAP can help overcome this problem (see Chapter 48).[1,2] Box 53.6 lists factors that should be optimized before ventilatory support is discontinued.

RULE OF THUMB Despite the success of indices of readiness for ventilator discontinuation in very specific settings, the best approach to determining if a patient can be successfully discontinued from ventilatory support is the patient's performance on a spontaneous breathing trial.

Patients' Psychologic and Communication Needs

As many as 47% of patients who spend more than 5 days in an ICU experience psychologic disturbances.[28] The cause may be the stress of critical illness, the interruption of nighttime sleep, or the use of sedatives, tranquilizers, hypnotics, narcotics, and other drugs that affect the CNS.[28] The patient's environment should be optimized; anxiety, depression, and delirium should be evaluated; and communication should be maximized.

Environmental considerations that may improve the patient's sense of well-being and outlook, reducing the likelihood of developing delirium, include reducing extraneous noise and providing clocks, calendars, pictures, a radio, a television, and, if possible, a room with windows. Daily mobility should be considered, including getting the patient up in a chair or placing the patient in the hall in a chair. Patients whose condition has been stable can sometimes even be helped to walk with the use of an E cylinder for oxygen, a transport ventilator or ICU ventilator with appropriate battery support, and two or more healthcare workers for support. The process of increasingly mobilizing ICU patients including those on mechanical ventilation is known as **progressive mobility**. Preliminary clinical research on progressive mobility is promising but it tends to be very resource-intensive.

A method for the patient to communicate with staff and visitors should be devised, if possible. Writing tablets, picture boards, and alphabet boards have been used effectively by patients to communicate with staff and visitors.

Anxiety and agitation should be minimized, and communication and encouragement may be helpful. The patient should be told what is planned and be given some control over the situation. Patients should be asked to participate and help in the weaning process. Depression or a lack of motivation may increase weaning time. If depression or delirium is present, assessment and treatment by an appropriate healthcare provider should be considered.

BOX 53.6 Factors That Should Be Optimized Before the Discontinuation of Ventilatory Support Is Attempted

- Oxygenation
- PaO_2 and SaO_2
- Anemia, if present
- Atelectasis, pneumonia, and acute pulmonary disease
- Ventilation
- Humidification
- Secretion clearance (e.g., bronchial hygiene and suctioning)
- Bronchodilator therapy
- Respiratory alkalosis
- Imposed work of breathing
- Respiratory muscle fatigue or atrophy
- Acid–base balance and electrolytes
- Metabolic acidosis (e.g., lactic acidosis and ketoacidosis)
- Metabolic alkalosis (e.g., decreased serum potassium or chloride ions, nasogastric tube, and vomiting)
- Low phosphate level
- Low magnesium level
- Cardiac and cardiovascular status
- Blood pressure and cardiac output
- Arrhythmias, if present
- Myocardial ischemia
- Left ventricular function
- Renal factors
- Kidney function
- Fluid balance
- Fever, infection, or sepsis
- Pain (i.e., minimize without over-sedation)
- Sleep deprivation
- Drugs (narcotics, sedatives, tranquilizers, hypnotics, aminoglycosides, and neuromuscular blocking agents can depress or block the ventilatory drive)
- Psychologic status
- Level of consciousness (e.g., delirium, coma)
- Agitation
- Motivation
- Fear and anxiety
- Psychologic dependence on the ventilator
- Depression
- Intensive care unit psychosis
- Hypothyroidism
- Nutritional factors
- Overfeeding (i.e., increased carbon dioxide production)
- Malnutrition or protein loss
- Consider a high-fat, low-carbohydrate diet to minimize the production of carbon dioxide
- Gastrointestinal bleeding or obstruction
- Abdominal distention or ascites
- Time of day (avoid evenings, nights, and shift changes)
- Adequate staffing
- Interruptions and disruptions
- Technical factors

Modified from Kacmarek RM, Mack CW, Dimus S: *Essentials of respiratory care*, ed 4, St. Louis, 2005, Mosby.

CAREGIVER PREPARATION

Just like careful patient preparation, caregiver preparation should occur before the onset on an SBT, the respiratory therapist needs

to be properly prepared to perform the SBT. The orders should be checked and equipment should be gathered. Specifically, oxygen therapy, NIV, and reintubation equipment should be gathered and readied for use. The patient should be carefully assessed, the ventilator alarms properly set, and the patient emotionally prepared for the SBT. Patients should be aware that the SBT is a trial and that they may fail the trial. The patient should NOT consider a failed trial as a step backward but as a part of a process to become independent of the ventilator and should know that a number of SBTs are commonly necessary before the ventilator is discontinued.

RULE OF THUMB As many as 47% of patients who spend more than 5 days in an ICU experience psychologic disturbance.

METHODS

There are three basic methods of discontinuing ventilatory support[1,4]:

1. SBTs (via the mechanical ventilator or with a T-piece) alternating with mechanical ventilatory support
2. SIMV
3. PSV

Box 53.7 summarizes evidence-based criteria and related conclusions regarding methods for ventilator discontinuation.

Rapid Ventilator Discontinuation

When the precipitating disease state or condition that necessitates support has been significantly alleviated or reversed, most patients can be rapidly removed from mechanical ventilation.[1,4] These patients typically have acceptable blood gas levels with mechanical ventilation, adequate myocardial function, and no underlying cardiovascular, pulmonary, neurologic, or neuromuscular disorders. After a careful evaluation, patients in stable condition who have been treated with a ventilator for less than 72 hours and who have a good spontaneous respiratory rate and minute ventilation may undergo an SBT on the ventilator or with a T-piece for 30 to 120 minutes.[1,4,29] If the patient does well, the endotracheal tube can then be removed if there is no reason to maintain an artificial airway.

Today, most SBTs are performed with the patient attached to a ventilator that is set with the FiO_2 unchanged, on PSV zero cm H_2O and zero CPAP. This allows for a stable FiO_2 and ongoing monitoring. Others have recommended treating the patient with a low level of PSV (i.e., 5 to 8 cm H_2O) to overcome the resistance caused by the ventilator circuit, the demand flow system, and the artificial airway.[1,4] Others may prefer simply using CPAP (i.e., 5 to 7 cm H_2O). These methods have the advantage of allowing the clinician to maintain ventilator alarm settings that can provide a margin of safety in the event of apnea or severe hypoventilation. Low levels of CPAP may be useful for maintaining lung volumes and overcoming intrinsic PEEP. Some experts recommend PSV in combination with PEEP or CPAP.[2] However, the most widely accepted guidelines recommend a simple spontaneous breathing trial for the first SBT using the ventilator at zero CPAP and PSV 0 to 8 cm H_2O.[1,4]

BOX 53.7 Agency for Healthcare Research and Quality Summary of Evidence for Criteria for Weaning From Mechanical Ventilation

- Differences in clinicians' intuitive thresholds for the reduction or discontinuation of ventilatory support have a far greater impact on the failure of spontaneous breathing trials and on reintubation than do modes of discontinuation. When clinicians set a high threshold, many patients who could tolerate weaning remain on mechanical support longer than is necessary.
- There may be an interaction between the threshold and the mode of discontinuation; in other words, one mode may be superior when the threshold is high, whereas another may be superior when the threshold is low.
- Research to date suggests that the best answer to the question of when to start discontinuation trials is to develop a protocol that can be implemented by nurses and respiratory therapists that begins testing for the opportunity to reduce support immediately after intubation and reduces support at every opportunity.
- For stepwise reductions in mechanical support, pressure support mode or multiple daily spontaneous breathing trials are superior to synchronized intermittent mandatory ventilation.
- For trials of unassisted breathing, low levels of pressure support may be beneficial in select patients.
- There may be substantial benefits to the use of noninvasive positive pressure ventilation immediately following discontinuation and extubation.
- After cardiac surgery, early extubation is achieved with a variety of interventions and intensive care unit protocols.
- Although steroids can reduce postextubation stridor in children, the impact of steroids on reintubation in children and adults remains uncertain.
- Most theoretically plausible predictors of discontinuation and extubation success have no predictive power. Those with some predictive power include the rapid, shallow breathing index, which has been most intensively studied, the $P_{0.1}$/MIP ratio, and the Compliance Rate Oxygenation and Plmax index. However, these are relatively weak predictors of discontinuation success.
- Tests are rarely useful for increasing the probability of discontinuation success; on occasion, the results can lead to moderate increases in the probability of success.
- In general, discontinuation predictors are probably found to perform poorly because physicians have already considered the results when they select patients for studies.

Modified from the Agency for Healthcare Research and Quality: *Evidence report/technology assessment Number 23 (AHRQ Publication No. 01-E010)*, Rockville, MD, 2000, Agency for Healthcare Research and Quality.

RULE OF THUMB The best initial approach to liberating a patient from mechanical ventilation is the spontaneous breathing trial. Ideally applied with zero pressure support and zero PEEP for 30 to 120 min via the mechanical ventilator so that the ventilators' monitoring of the patient continues during the SBT.

Patients Who Need Progressive Weaning of Ventilatory Support

Patients who have been receiving mechanical ventilation for more than 72 hours and those with marginal oxygenation, ventilatory, cardiovascular, or medical statuses may need a more prolonged period for ventilator discontinuation.[1,4] The most common method for accomplishing this is SBTs interspersed with continued ventilatory support.

RULE OF THUMB The most common cause of the inability to wean is an imbalance between ventilatory capability and ventilatory demand.

Spontaneous Breathing Trials

The oldest discontinuation method is an SBT via either the ventilator or T-piece, which allows for spontaneous breathing several times per day interspersed with periods of mechanical ventilatory support. For gradual weaning, initial SBTs may last only 5 to 10 minutes. Full ventilatory support is resumed for a 4-hour rest period in the assist/control or pressure-support mode. The time off the ventilator is gradually increased until the patient stays off the ventilator for an extended period. SBTs can progress rapidly to ventilator removal.

When weaning is very difficult, the process can last days or even weeks. When a T-piece is used instead of the ventilator, the patient must be more carefully monitored, because none of the ventilator alarms are active during the SBT. If distress occurs, mechanical ventilation is resumed. In no case should the patient be overstressed during the SBT, because exhaustion can delay weaning.[2,8] An example of an SBT is presented in Box 53.8.

Advantages of SBTs include the early and frequent testing of the patient's ability to breathe spontaneously without support. The use of SBTs several times per day has become unpopular, because it requires a great deal of time on the part of ICU staff, and a single daily SBT seems to be just as effective for most patients.[1,4] PSV and CPAP are sometimes used during the SBT, and patients who tolerate spontaneous breathing with a low level of PSV (i.e., 8 cm H_2O or less) should be able to tolerate extubation.[30] Current recommendations suggest a single daily trial of spontaneous breathing may be preferable to other methods of weaning.[1,4] Results of randomized, controlled studies have shown SBTs to be faster than SIMV and at least as effective as PSV.[5,29,30,31] Furthermore, performing an SBT one time per day is as effective as performing SBTs several times per day, and 30-minute trials are as effective as 120-minute trials.[1,4]

BOX 53.8 Steps for Spontaneous Breathing Trials

1. Prepare the patient psychologically.
2. Set the ventilator at zero pressure support ventilation and zero continuous positive airway pressure (CPAP).
3. Maintain the FiO_2 at the baseline FiO_2 that the patient is receiving.
4. Monitor the patient's appearance, pulse, oxygen saturation measured by pulse oximeter, and blood pressure; observe the cardiac monitor for arrhythmia. Use the ventilator to monitor respiratory rate, tidal volume, and minute ventilation.
5. If the patient tolerates the spontaneous breathing trial (SBT) for 30–120 min, consider extubation.
6. If the patient does not tolerate the SBT for at least 30 min, reestablish the ventilator settings, and allow the patient to rest for at least a few hours before reattempting another SBT.
7. If repeated SBTs over multiple days are needed, individualize the patient's schedule, depending on his or her condition. In general, the weaning schedule should be stopped during the night so that the patient can rest and sleep.

A collective task force representing the American College of Chest Physicians, the American Association for Respiratory Care, and the American College of Critical Care Medicine published in 2001 evidence-based guidelines for weaning and discontinuing ventilatory support.[1] These guidelines were based in part on a comprehensive review of the evidence collected under the direction of the U.S. Agency for Health Care Policy and Research.[4]

RULE OF THUMB Care should be taken once a patient demonstrates signs of failing the SBT. The trial should be discontinued and the patient provided ventilatory support. If patients develop ventilatory muscle fatigue during the SBT it will take more than 24 h to completely recover from that fatiguing experience, delaying ventilator liberation.

The task force made 12 specific recommendations (Box 53.9). These include the regular use of formal and carefully monitored SBTs to guide clinical decision-making regarding the discontinuation of ventilatory support.[1] Specifically, the task force recommended that, for the care of patients who need mechanical ventilation for more than 24 hours, a search for all possible causes of ventilatory dependence should be conducted and an attempt should be made to reverse or optimize each condition. Spontaneously breathing patients with evidence of reversal of the underlying condition that necessitated the ventilatory support, adequate oxygenation, and hemodynamic stability should be assessed with an SBT. Table 53.3 lists criteria to be used when determining whether patients who are receiving high levels of ventilatory support can be considered for SBTs.

TABLE 53.3 Criteria Used to Determine Whether Patients Who Are Receiving Ventilatory Support Can Be Considered for Spontaneous Breathing Trials

Criteria	Description
Objective measurements	Adequate oxygenation (e.g., PO_2 of ≥60 mm Hg with an FiO_2 of ≤0.40–0.50; PEEP of ≤5–8 cm H_2O; PO_2/FiO_2 ratio of ≥150–200)
	Stable cardiovascular system (e.g., heart rate ≤100 beats/min; stable blood pressure; no [or minimal] vasopressors)
	Afebrile (i.e., temperature about 37°C)
	No significant respiratory acidosis
	Adequate hemoglobin (e.g., ≥8–10 g/dL)
	Adequate mentation (e.g., arousable, Glasgow coma score of ≥13, no continuous sedative infusions)
	Stable metabolic status (e.g., acceptable electrolyte levels)
Subjective clinical assessments	Resolution of acute phase of disease; physician believes discontinuation is possible; adequate cough

Modified from MacIntyre NR, Cook DJ, Ely EW, et al: Evidence-based guidelines for weaning and discontinuing ventilator support: a collective task force facilitated by the American College of Chest Physicians, the American Association for Respiratory Care, and the American College of Critical Care Medicine. *Chest* 120:375S–395S, 2001.

BOX 53.9 Evidence-Based Guidelines for Weaning and Discontinuing Ventilatory Support

Recommendation 1: For patients who need mechanical ventilation for more than 24 h, a search for all of the causes that may be contributing to ventilatory dependence should be undertaken. This is particularly true for the patient who has failed attempts at withdrawing the mechanical ventilator. Reversing all possible ventilatory and nonventilatory issues should be an integral part of the ventilatory discontinuation process.

Recommendation 2: Patients who are receiving mechanical ventilation for respiratory failure should undergo a formal assessment of discontinuation potential if the following criteria are satisfied:

1. Evidence for some reversal of the underlying cause for respiratory failure
2. Adequate oxygenation (e.g., PaO_2/FiO_2 ratio of more than 150–200; requiring positive end-expiratory pressure of no more than 5–8 cm H_2O; FiO_2 of no more than 0.4–0.5) and pH of more than 7.25
3. Hemodynamic stability as defined by the absence of active myocardial ischemia and the absence of clinically significant hypotension (i.e., a condition that necessitates no vasopressor therapy or therapy with only low-dose vasopressors such as dopamine or dobutamine [<5 mcg/kg/min])
4. The capability to initiate an inspiratory effort. The decision to use these criteria must be individualized. Some patients who are not satisfying all of these criteria (e.g., patients with chronic hypoxemia values of less than the thresholds cited) may be ready for attempts at the discontinuation of mechanical ventilation

Recommendation 3: Formal discontinuation assessments for patients who are receiving mechanical ventilation for respiratory failure should be performed during spontaneous breathing rather than while the patient is still receiving substantial ventilatory support. An initial brief period of spontaneous breathing can be used to assess the capability of continuing on to a formal spontaneous breathing trial (SBT). The criteria with which to assess patient tolerance during SBTs are the respiratory pattern, the adequacy of gas exchange, hemodynamic stability, and subjective comfort. Tolerance of SBTs that last 30–120 min should prompt consideration for permanent ventilatory discontinuation.

Recommendation 4: The removal of the artificial airway from a patient who has successfully been discontinued from ventilatory support should be based on assessments of airway patency and the ability of the patient to protect the airway.

Recommendation 5: Patients who are receiving mechanical ventilation for respiratory failure who fail an SBT should have the cause of the failed SBT determined. After any reversible causes of failure are corrected and if the patient still meets the criteria listed in Table 53.3, subsequent SBTs should be performed every 24 h.

Recommendation 6: Patients who are receiving mechanical ventilation for respiratory failure who fail an SBT should receive a stable, nonfatiguing, and comfortable form of ventilatory support.

Recommendation 7: Anesthesia and sedation strategies and ventilatory management that are aimed at early extubation should be used for postsurgical patients.

Recommendation 8: Weaning and discontinuation protocols that are designed for nonphysician healthcare professionals should be developed and implemented by intensive care units (ICUs). Protocols that are aimed at optimizing sedation should also be developed and implemented.

Recommendation 9: Tracheotomy should be considered after an initial period of stabilization on the ventilator when it becomes apparent that the patient needs prolonged ventilatory assistance. Tracheotomy should then be performed when the patient appears to be likely to gain one or more of the benefits ascribed to the procedure. Patients who may derive particular benefit from early tracheotomy include the following:

- Those who need high levels of sedation to tolerate translaryngeal tubes
- Those with marginal respiratory mechanics (often manifested as tachypnea) in whom a tracheostomy tube with lower resistance may reduce the risk of muscle overload
- Those who may derive psychological benefit from the ability to eat orally, communicate by articulated speech, and experience enhanced mobility
- Those in whom enhanced mobility may assist with physical therapy efforts

Recommendation 10: Unless there is evidence for clearly irreversible disease (e.g., high spinal cord injury, advanced amyotrophic lateral sclerosis), a patient who requires prolonged mechanical ventilatory support for respiratory failure should not be considered permanently ventilator dependent until 3 months of weaning attempts have failed.

Recommendation 11: Critical care practitioners should familiarize themselves with facilities in their communities or units in hospitals that are staffed with individuals that specialize in managing patients who have prolonged dependence on mechanical ventilation. Such familiarization should include reviewing published peer-reviewed data from those units, if available. When they are medically stable for transfer, patients who have failed ventilatory discontinuation attempts in the ICU should be transferred to those facilities that have demonstrated success and safety with accomplishing ventilator discontinuation.

Recommendation 12: Weaning strategies in the patient who requires prolonged mechanical ventilation should be slow paced and should include gradually lengthening self-breathing trials.

Modified from MacIntyre NR, Cook DJ, Ely EW Jr, et al.; American College of Chest Physicians; American Association for Respiratory Care; American College of Critical Care Medicine: Evidence-based guidelines for weaning and discontinuing ventilatory support: a collective task force facilitated by the American College of Chest Physicians; the American Association for Respiratory Care; and the American College of Critical Care Medicine. *Chest* 120(6 Suppl):375S–395S, 2001.

A daily screen that includes the assessment of oxygenation, PEEP, and the use of vasopressors and sedatives should be conducted. A PaO_2/FiO_2 ratio of more than 150 to 200, a PEEP value of less than 5 to 8 cm H_2O, and a lack of a continuous infusion of vasopressors or sedatives (i.e., less than 5 mg/kg/min of dopamine) were good predictors of successful extubation and survival.[32]

The formal SBT may be performed in combination with low levels of PSV (i.e., 5 to 8 cm H_2O), CPAP (i.e., 5 cm H_2O or less), or ATC applied to just offset the imposed WOB caused by the endotracheal tube.[1] During the SBT, the patient is carefully observed for breathing comfort, anxiety, agitation, dyspnea, or diaphoresis. Respiratory rate, heart rate, blood pressure, and SpO_2 are monitored. The SBT is terminated if signs of distress are observed, including the following:

- Agitation, anxiety, diaphoresis, or a change in mental status
- A sustained respiratory rate of more than 35 breaths/min
- A sustained SpO_2 of less than 90%
- A more than 20% increase or decrease in heart rate or a heart rate of more than 120 to 140 beats/min
- A systolic blood pressure of more than 180 mm Hg or of less than 90 mm Hg

Patients with unsuccessful results of an SBT are returned to full ventilatory support for 24 hours to allow the ventilatory muscles to recover. During this period, the causes of failure are identified and corrected, if possible, and the patient is then reevaluated.

BOX 53.10 Weaning Protocol for a Spontaneous Breathing Trial

1. Verify that the patient is a candidate for ventilator discontinuation.
   a. Is there evidence of the reversal or alleviation of the disease state or condition that required mechanical ventilatory support?
   b. Is the patient able to breathe spontaneously?
   c. Has the patient's medical condition been optimized (i.e., afebrile, adequate hemoglobin, and acceptable electrolyte levels)?
   d. Are oxygenation, ventilation, and blood gas values adequate?
      - PaO_2 of at least 60 mm Hg with FiO_2 of no more than 0.40–0.50 with PEEP/CPAP of no more than 5–8 cm H_2O
      - PaO_2/FiO_2 ratio of 150–200 mm Hg or more
      - pH of 7.25 or more
   e. Is the patient awake and alert, free of seizures, and able to follow instructions?
   f. Is there evidence of hemodynamic stability? Are vasopressors only administered intermittently?
2. Prepare the patient for the SBT.
   a. Be sure that adequate personnel are present.
   b. Ensure that there are no other ongoing procedures or other major activities.
   c. Eliminate or minimize respiratory depressants (e.g., sedatives, narcotics).
   d. Suction the airway, as needed.
   e. Sit the patient up in bed, if possible.
3. Set the ventilator at zero CPAP and zero pressure support.
4. Continuously monitor the patient.
5. If any of the following occurs and are sustained, return the patient to mechanical ventilatory support:
   a. Respiratory rate of at least 35 breaths/min
   b. Oxygen saturation measured by pulse oximeter of less than 90%
   c. 20% increase or decrease in heart rate or heart rate of more than 120 beats/min
   d. Systolic blood pressure of more than 180 mm Hg or of less than 90 mm Hg
   e. Agitation, diaphoresis, or anxiety
6. Continue the trial for at least 30 min but not more than 2 h. If no signs of intolerance develop (see step 5), consider extubation.

CPAP, Continuous positive airway pressure; *PEEP*, positive end-expiratory pressure; *SBT*, spontaneous breathing trial.
Modified from MacIntyre NR, Cook DJ, Ely EW, Jr, et al; American College of Chest Physicians; American Association for Respiratory Care; American College of Critical Care Medicine: Evidence-based guidelines for weaning and discontinuing ventilatory support: a collective task force facilitated by the American College of Chest Physicians; the American Association for Respiratory Care; and the American College of Critical Care Medicine. *Chest* 120(6 Suppl):375S–395S, 2001.

If the criteria listed in Table 53.3 continue to be met, SBTs are repeated every 24 hours.[3] Patients who tolerate the formal SBT for 30 to 120 minutes are ready for ventilator discontinuance, and extubation is considered. Box 53.10 is a sample protocol for an SBT for the discontinuation of ventilatory support.

Continuous Positive Airway Pressure

CPAP is used during an SBT in many facilities. CPAP has the advantages of maintaining the lung volume during the weaning phase and thus of improving the patient's oxygenation status. Minimal levels of CPAP may be useful for reducing WOB and compensating for auto-PEEP, particularly in patients with obstructive lung disease.[1,4] CPAP is usually provided by the CPAP mode available on most mechanical ventilators. By using the ventilator in the CPAP mode, the clinician can take advantage of the alarm systems that are available. In fact, most institutions use the CPAP mode with zero CPAP level to take advantage of the ventilator alarms during weaning. This always provides an improved margin of safety as compared with the use of a T-piece and should today be the standard approach to an SBT.

Synchronized Intermittent Mandatory Ventilation

Weaning from SIMV involves the gradual reduction of the machine rate on the basis of the results of ABG analysis and patient assessment. Early claims that SIMV allowed for faster weaning times[8] have not been substantiated by subsequent studies.[29–31]

Patients who are receiving ventilation in the SIMV mode uncouple their breathing efforts from the support provided by the machine.[1,4] They continue to make spontaneous breathing efforts during the delivery of a "mandatory breath." Evidence also suggests that, once the machine cycling rate is reduced to approximately 50% of the full ventilatory support value, the patient breathes approximately as hard per cycle during the mandatory breaths as during the unsupported spontaneous breaths.[33,34] This additional work can be overcome with the use of pressure support (i.e., 5 to 10 cm H_2O). However, the addition of pressure support further complicates the weaning process. For initial ventilator setup, the SIMV rate and the tidal volume usually are set at values that are equivalent to those used during volume control-continuous mandatory ventilation (VC-CMV) or pressure control-continuous mandatory ventilation (PC-CMV). When the patient's condition has been stabilized, one of two approaches have been used. Some clinicians prefer to continue at these settings until the patient's precipitating disease state or condition has improved considerably. At that point, the rate is reduced in a stepwise manner until complete spontaneous breathing can be achieved. Other clinicians prefer to immediately reduce the level of mechanical ventilation to an SIMV rate of 4 to 8 per minute, thereby forcing the patient to perform additional WOB. From the beginning, attempts are made to reduce the SIMV rate, and the patient is challenged to provide a portion of the required ventilation. Unfortunately, research indicates that SIMV prolongs ventilatory support and that it is the least effective method of weaning from ventilatory support as compared with either SBT or PSV.[1,4,29,30,31]

Pressure Support Ventilation

PSV is a mode of ventilatory support that allows the patient to have significant control over the process of ventilatory support. The only gas-delivery variable directly controlled by the ventilator is peak airway pressure; see Chapters 46 and 49 for details.

For initial ventilator setup in the PSV mode, the beginning pressure level can be adjusted to deliver an appropriate tidal volume, which is usually approximately 4 to 8 mL/kg of the ideal body weight based on the patient's condition and the desired tidal volume. PSV is then gradually reduced to a minimal value that only compensates for the WOB imposed by the artificial

BOX 53.11 Protocol for Pressure Support Weaning

1. Verify that the patient is a candidate for ventilator discontinuation:
   - Evidence of alleviation or reversal of the disease state or condition that necessitated ventilatory support
   - Stable, spontaneous breathing pattern without irregular breathing or periods of apnea
   - Optimization of the patient's medical condition
   - Adequate oxygenation, ventilation, and acid–base balance
2. Begin with a pressure support ventilation (PSV) level that achieves a tidal volume of 4–8 mL/kg of the ideal body weight. A PSV of more than 20 cm H_2O rarely is needed. The need for a high level of PSV indicates that the patient may not be ready for ventilator discontinuation.
3. Reduce the PSV 2–4 cm H_2O as tolerated, ideally at least twice daily, and reassess the patient for signs of intolerance:
   - Rate of at least 25–30 breaths/min
   - 20% or greater increase in heart rate or a heart rate of more than 120 beats/min
   - 20% or greater increase in systolic blood pressure or systolic blood pressure of more than 180 mm Hg or of less than 90 mm Hg
   - Agitation, anxiety, and diaphoresis
4. If the patient does not tolerate a reduction in PSV, return to the previous value, and reassess.
5. Continue to reduce PSV as tolerated at least twice per day and more frequently if the patient does not have signs of distress.
6. Consider extubation when the patient is able to tolerate a PSV of 5–8 cm H_2O for 2 h with no apparent distress.

Modified from Esteban A, Frutos F, Tobin M, et al: A comparison of four methods of weaning patients from mechanical ventilation. Spanish Lung Failure Collaborative Group. *N Engl J Med* 332:345–350, 1995; and Brochard L, Rauss A, Benito S, et al: Comparison of three methods of gradual withdrawal from ventilatory support during weaning from mechanical ventilation. *Am J Respir Crit Care Med* 150:896–903, 1994.

airway.[29–31] Generally this is about 5 to 8 cm H_2O. After this reduction is accomplished, extubation can be performed directly from the low-level pressure support, or an SBT may be conducted for 30 to 120 minutes.[1,4]

PSV allows the clinician to manipulate the level of patient work, but the benefit of this to weaning is questionable.[1,4] In general, patients who can spontaneously breathe comfortably at 5 to 8 cm H_2O of PSV can be extubated without problems. However, if upper airway edema is present, WOB after extubation may be about the same as that caused by the endotracheal tube. In these cases, low levels of pressure support may give a false impression about the patient's ability to tolerate extubation (Box 53.11).[1,4]

Synchronized Intermittent Mandatory Ventilation With Pressure Support Ventilation

With SIMV, the addition of pressure support can overcome the WOB imposed during "spontaneous" breaths because of the presence of endotracheal and tracheostomy tubes, demand flow systems, and ventilator circuits. In this setting, pressure support is set to achieve the desired tidal volume during the spontaneous breaths (i.e., 4 to 8 mL/kg of the ideal body weight).

MINI CLINI

Setting Pressure Support Levels

Problem

An intubated patient is receiving mechanical ventilation in the SIMV mode with the following settings:

- V_T = 400 mL
- Rate = 12 breaths/min
- Peak inspiratory pressure = 40 cm H_2O
- Plateau pressure (P_{plat}) = 20 cm H_2O
- Ventilator inspiratory flow ($\dot{V}$) = 60 L/min (1 L/s)

The patient is breathing spontaneously with a spontaneous rate of 12 breaths/min and a spontaneous peak inspiratory flow of 30 L/min (0.5 L/s). Find the level of PSV that is needed to overcome the imposed WOB.

Solution

$$PSV = ([PIP - P_{plat}]/\dot{V}_{mach}) \times \dot{V}_{Imax}$$

$$PSV = ([40\ cmH_2O - 20\ cmH_2O]/1\ L/s) \times 0.5\ L/s$$
$$= 10\ cmH_2O$$

The calculated PSV level to overcome the imposed WOB for this patient is 10 cm.

Although it is clear that the addition of PSV during SIMV can reduce or eliminate imposed work caused by mechanical factors, it has not been shown how this affects weaning. In one study, SIMV with PSV increased tidal volume and reduced respiratory rate but did not significantly reduce weaning time or success as compared with SIMV alone.[35] On the basis of all of the weaning trials, it can be concluded that this approach to weaning can only increase the length of ventilatory support. Current guidelines recommend the use of SBT to rapidly wean patients from ventilatory support.[1,4]

RULE OF THUMB SIMV should not be used as a mode of weaning from ventilatory support. It prolongs the weaning phase and the total length of ventilatory support.

Spontaneous Awaking Trials

Concern regarding the use of sedation in critically ill patients has increased markedly during the last few years. This concern has focused on the issue of delirium.[36] The indiscriminate use of sedatives in the ICU is considered inappropriate patient management. In general, sedatives should always be considered last when trying to handle an agitated patient (Chapter 48). Something has caused the patient's agitation, and it should be addressed and corrected, if possible, before sedation is administered. In addition, it is becoming clearer that the use of excessive sedation lengthens the time of mechanical ventilation. The use of **spontaneous awaking trials (SAT)** along with daily SBT results in the faster weaning of patients from ventilatory support as well as a decrease in mortality.[37] The decrease in mortality is attributed to patients being exposed for a shorter time to the complications of mechanical ventilation. Throughout the course of mechanical ventilation, sedation should be kept to the bare minimum necessary; patient sedation should be periodically carefully assessed before additional sedation is given.[37,38] Before sedation is given the cause of the agitation should be addressed. Frequently this a result of patient–ventilator asynchrony, which can be minimized

TABLE 53.4 The Riker/Sedation Agitation Scale, the Ramsay Sedation Scale, and the Richmond Agitation Scale

Riker/Sedation Agitation Scale

Score	Level of Sedation/Agitation	Response
7	Dangerous agitation	Pulling ETT, Climbing out of bed, etc.
6	Very agitated	Does not calm, requires restraints
5	Agitated	Calms to instructions
4	Calm and cooperative	Obeys commands
3	Sedated	Difficult to verbally arouse
2	Very sedated	Arouses to physical stimuli
1	Unarousable	Minimal or no response to noxious stimuli

- Prior to conducting a SBT the SAS scale should be reduced to insure a score of 3–5, ideally 4.

The Ramsay Sedation Scale

Clinical Score	Patient Characteristics
1	Anxious, agitated, or restless
2	Cooperative, oriented, and tranquil
3	Sedated but responds to commands
4	Asleep; brisk response to light glabellar tap or loud auditory stimulus
5	Asleep; sluggish response to light glabellar tap or loud auditory stimulus
6	Asleep; no response to painful stimuli

- Prior to conducting a SBT the Ramsey Sedation Scale should be at a score of 2–4, ideally 2.

Richmond Agitation Sedation Scale (RASS)

Score	Term	Description	
	Combative	Overtly combative, violent, immediate danger to staff	
	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive	
	Agitated	Frequent nonpurposeful movement, fights ventilator	
	Restless	Anxious but movements not aggressively vigorous	
	Alert and calm		
–1	Drowsy	Not fully alert, but has sustained awakening (eye-opening/eye contact) to *voice* (>10 s)	Verbal stimulation
–2	Light sedation	Briefly awakens with eye contact to *voice* (<10 s)	Verbal stimulation
–3	Moderate sedation	Movement or eye opening to *voice* (but no eye contact)	Verbal stimulation
–4	Deep sedation	No response to voice, but movement or eye opening to *physical* stimulation	Physical stimulation
–5	Unarousable	No response to *voice or physical* stimulation	Physical stimulation

SAS, Sedation Agitation Scale; *SBT*, spontaneous breathing trial.

by careful adjustment of the ventilator. One of the currently available systems to rate the level of sedation should be in use on all mechanically ventilated patients [Riker/Sedation Agitation Scale (SAS), Ramsay Sedation Scale, or Richmond Agitation Scale (RASS)] Table 53.4.

RULE OF THUMB The use of spontaneous awaking trials (SAT) along with daily SBT results in the faster weaning of patients from ventilatory support as well as a decrease in mortality.

NEWER TECHNIQUES FOR FACILITATING VENTILATOR DISCONTINUANCE

Mandatory Minute Volume Ventilation

Mandatory minute volume ventilation (MMV) was described and introduced in 1977.[39] With this mode of ventilation, the total minute volume is set, and the patient may elect to inspire all of the minute volume, part of the minute volume, or none of the minute volume spontaneously. The ventilator would automatically provide a clinician-set remainder of the minute volume. It was originally assumed that, as the patient's status improved, he or she would assume by spontaneous breathing a greater and greater percentage of the set minute volume, eventually inspiring it all spontaneously. However, this did not occur; patients generally settled into a ventilator pattern where the overall WOB was shared between the patient and the ventilator, and the patient never assumed a greater percentage of the work.[40] There is no data to support the use of MMV over SBT or PSV to wean patients from ventilatory support.

Adaptive Support Ventilation/Intellivent

ASV is a newer mode of ventilation that maintains a minimum minute ventilation with an optimal breathing pattern (tidal volume and rate) that is based on the work of Otis;[41,42] see Chapters 46 and 49 for details. ASV automatically adjusts inspiratory pressure and ventilator breath rate to achieve the target minute volume set. As the patient's status improves, the target minute

volume is reduced, and the level of pressure required for each breath diminishes. When a minimal level is reached, the patient is considered weaned from ventilatory support and ready for extubation.

Preliminary studies of ASV for the care of patients who are recovering from cardiac surgery show a reduction in the duration of mechanical ventilation as compared with an SIMV weaning protocol.[42,43] Additional data about ASV indicates that it works very well for patients who are under controlled ventilation,[44] but data from large heterogeneous groups of patients will be necessary to determine if ASV truly improves the speed of ventilator discontinuation.

A recent upgrade of ASV is referred to as Intellivent.[45] With this modification the ventilator becomes a total closed loop controller of not only ventilation but also oxygenation. Incorporated into the management algorithm are the ARDSnet PEEP/F_IO_2 tables. Thus all aspects of gas delivery are controlled. As with ASV, Intellivent works well on patients under controlled ventilation and those requiring simple postoperative ventilation, and has shown the ability to wean patients from ventilatory support.[46] However, no comparison to SBT is currently available. Intellivent use in the complex patient spontaneously triggering the ventilator is still controversial. However, one can expect this type of closed loop control of ventilation will begin to appear on other mechanical ventilators.

Computer-Based Weaning

Current versions of MMV and ASV/Intellivent are examples of computer-controlled mechanical ventilation. Several more complex systems have been developed, including Ventilation Manager, VQ-attending, ESTER, Continuous Respiratory Evaluator (CORE), KUSIVAR, and WEAN-PRO.[47] The desire to develop computer-based weaning protocols is based on two factors. First, weaning is a time-consuming and labor-intensive process. If computer control can expedite or simplify this process, considerable time and money can be saved. Second, because most weaning decisions are based on objective data, computer-based weaning protocols are relatively easy to develop.[47]

The most successful computerized application for weaning is the Smart Care approach.[48,49] The system adjusts pressure support on the basis of the patient's tidal volume, respiratory rate, and end-tidal carbon dioxide level. When the pressure support has been decreased to a predefined level, the ventilator automatically begins an SBT. If the patient fails the SBT, which is determined by changes in the patient's respiratory rate, tidal volume, and end-tidal carbon dioxide level, then the ventilator automatically reassumes ventilatory support. If the patient passes the SBT, the ventilator also returns to baseline ventilatory support but notifies the clinician that the patient is ready for ventilator discontinuation. Two studies comparing SmartCare to clinician-controlled SBT have demonstrated that patients wean faster and both the total number of days that patients are maintained in the ICU and the need for postextubation NIV are reduced with SmartCare.[48,49] One criticism of this research was that the clinician-applied SBTs were not always performed consistently. However, this is clinical reality—in the ICU there are always good intentions to do an SBT, but emergencies, new admissions, and other important job functions too often delay or prevent clinicians from performing the SBT in a timely manner. With SmartCare, if the patient meets criteria, the SBT is performed regardless of the activity in the ICU. It should be noted that at least at the time of this revision the FDA only allows SmartCare in the United States to notify clinicians of the readiness for an SBT and the patient's status during the SBT. The clinician must adjust the ventilator into and out of the SBT. In the rest of the world this is performed automatically by the ventilator. It can be expected that automated weaning systems will increasingly have a place in the care of critically ill patients.

Automatic Tube Compensation

Automatic tube compensation (ATC) is an option on newer mechanical ventilators that compensates for the flow-dependent pressure decrease across the endotracheal tube during both inspiration and expiration; see Chapters 46 and 49 for details. ATC reduces WOB and may improve patient comfort.[50] Because it compensates for the imposed WOB caused by the artificial airway, ATC has been referred to as *electronic extubation.* Patients who can breathe adequately with the addition of ATC at low peak airway pressure (i.e., <8 cm H_2O) should tolerate extubation. ATC is similar to pressure support in that an inspiratory pressure is used to compensate for imposed WOB; however, ATC varies the pressure, depending on the size of the endotracheal tube and the patient's inspiratory flow rate. Alternatively, PSV delivers a preset inspiratory pressure that may overcompensate or undercompensate imposed WOB at any given point in time. However, at this time no research indicates that ATC weans patients faster than SBTs or PSV.

Volume Support

VC is a newer mode of ventilation that combines pressure support and volume ventilation by allowing the level of pressure support to be automatically adjusted to maintain a target tidal volume. In the VC mode, inspiration is initiated by the patient. During the inspiratory phase, the pressure level is regulated to a value that is based on the previous breath's pressure-volume relationship as compared with a target tidal volume. The pressure-support level is automatically adjusted in a stepwise manner by up to ±3 cm H_2O from one breath to the next to maintain the target tidal volume.

A major problem with VC is the excessive reduction of airway pressure in the presence of high ventilatory demand, thereby increasing patient effort.[51] With most ventilators offering this mode, no lower limit to ventilating airway pressure is set, and inspiratory airway pressure can decrease all the way to the PEEP level. Volume support may offer a sort of automatic weaning from pressure support. As the patient's spontaneous tidal volume improves, the level of pressure support is automatically reduced. However, clinical trials indicate no benefit to the use of VC to wean patients.[52]

Proportional Assist Ventilation and Neurally Adjusted Ventilatory Assist

PAV and NAVA are two of the newest modes of ventilatory support.[53] These modes differ from all other modes of ventilation

since they do NOT force a ventilatory pattern. Instead they follow the ventilatory pattern desired by the patient. As a result, patient–ventilator synchrony is greater with these modes than with any of the other ventilatory modes.[54–56] Unfortunately, there are no data regarding the use of these modes to facilitate ventilator discontinuation. At this time, regardless of how these modes improve patient–ventilator interaction, the decision to discontinue ventilatory support should be made based on performance of an SBT. Future research should be able to define if these modes have a greater role in the ventilator discontinuation process.

Newer Techniques for Evaluation of Diaphragm Function and Prediction of Successful Discontinuation

Recently the use of **esophageal pressure**, **diaphragm ultrasound**, and the **diaphragmatic electromyographic signal (EAdi)** have been used to assess diaphragm function and predict performance during SBTs.[5] Normal **esophageal pressure** swings during normal resting breathing are limited, normally from about a negative 3 to 5 cm H_2O during inspiration to a positive 3 to 5 cm H_2O during exhalation, or a transpulmonary pressure of plus 3 to 5 during inspiration and a transpulmonary pressure of minus 3 to 5 during exhalation. Transpulmonary pressure is equal to alveolar pressure minus esophageal pressure. During maximum stressed increased WOB, esophageal pressure may decrease to –30 cm H_2O.[5] It is believed there is a threshold of negative pressure swing that will predict weaning failure. Currently this area has not been well researched, but expect to see more information in the near future on the use of esophageal pressure/transpulmonary pressure measurements to determine readiness to wean and the likelihood of successful weaning.

Diaphragm ultrasound can determine the thickness of the diaphragm and percent increase of diaphragm thickness during normal and stressed breathing.[57] During ventilatory support three things can happen to the diaphragm: (1) Its resting thickness can remain unchanged, (2) its resting thickness can decrease because of disuse atrophy, or (3) diaphragm thickness can increase (hypertrophy) because of excessive workload.[58] Preliminary work indicates that the greater the diaphragm thickness varies from baseline—whether atrophy or hypertrophy—the less likely the patient is to wean from ventilatory support.[58] Again, this work is preliminary, but expect to see increasing amounts of data using this technique.

Diaphragm EAdi, with the introduction of NAVA, was not only a method of providing synchrous mechanical ventilation but a method of monitoring the electrical activity of the diaphragm. The change in baseline EAdi to peak EAdi during inspiration provides an evaluation of ventilatory drive and effort.[59] As with esophageal pressure measurements and ultrasound, work is being done to determine how weaning is affected by the magnitude of the EAdi change during inspiration.

Expect to see increasing research on the use of these three techniques to assist in the evaluation of readiness to wean and the likelihood of successful extubation.

Noninvasive Ventilation/Continuous Positive Airway Pressure

A number of groups have studied the use of NIV as an adjunct to ventilator discontinuance. Essentially, NIV/CPAP has been used in this setting in three different manners:

1. Transitioning patients with COPD who failed SBTs from invasive ventilation to spontaneous breathing[60–62]
2. Supporting patients who passed SBTs but who are at high risk for failing the extubation[26,27,63]
3. Supporting patients who developed hypercarbic/hypoxemic respiratory failure after extubation[64,65]

The literature strongly supports the first two indications but does not support the third application. Refer to Chapter 50 for details regarding the application of NIV/CPAP during weaning and the use of NIV/CPAP in general.

High-Flow Nasal Cannula

As with NIV/CPAP, some patients at high risk for reintubation should receive HFNC for 24 to 48 hours post extubation.[66] In adults, HFNC establishes about 1 cm H_2O CPAP for 10 L/min flow delivered to the patient. Patients requiring support of ventilation should receive NIV, patients requiring PEEP should receive CPAP, and patients whose hypoxemia does not require a high and fixed level of PEEP to reverse atelectasis should receive HFNC.[66] See Chapters 42 and 50 for details.

Role of Mobility

If you do not move it, you lose it! This has become increasingly clear when it comes to patients in the process of weaning from ventilatory support. Mobilization of the mechanically ventilated patient should begin as soon as the patient is stabilized, requires minimal sedation, and is capable of interacting with the

MINI CLINI

Response to a Spontaneous Breathing Trial

Problem

A 70-year-old woman with a long history of congestive heart failure has been mechanically ventilated for 6 days. She has failed three previous SBTs, but today, at the end of a 45-minute SBT, her clinical presentation was as follows:

- Respiratory rate of 24 breaths/min
- Tidal volume of 300 mL (6 mL/kg ideal body weight)
- Pulse of 98 beats/min
- Blood pressure of 138/86 mm Hg

The patient did not appear to be short of breath, and she did not demonstrate excessive use of her accessory muscles of ventilation to breathe during the trial.

Should this patient's ventilatory support be discontinued?

Solution

On the basis of the given data, this patient passed her SBT and should be discontinued from ventilatory support and extubated if there is no reason for her to remain intubated. However, because of her age, history of congestive heart failure, and multiple failures of SBT, she should ideally be placed on NIV immediately after she is extubated and slowly transitioned to independent spontaneous breathing over the next 12 to 48 hours. See the following discussion below and Chapter 50.

ventilator.[67,68] Mobilization may begin simply by sitting the mechanically ventilated patient at the side of the bed. However, in many cases it may mean that the patient is walked in the hallway while receiving ventilatory support. Of course, this requires the cooperation of respiratory therapy, nursing, and physical therapy, and the use of equipment that facilitates mobilization: transport ventilator, portable suction, and walker/chair that maintains support of the patient but also allows the patient to sit and rest. Mobilization is increasingly important the longer the patient requires ventilatory support.

Respiratory Therapist–Driven Protocols

A number of studies have demonstrated that patients are weaned faster with the use of protocols than with individual physician orders.[69–72] In all of these studies, the therapists, nurses, and physicians who normally manage patients in the unit jointly developed the protocol. In addition, in the individual physician order group, the physicians who wrote the protocol also wrote the individual weaning orders. In these trials, patients weaned via protocol were extubated faster and with fewer complications.[69–72]

What these results do not mean is that therapists wean patients better than physicians. However, what they do mean is that, when an evidence-based approach to patient management is developed and followed precisely, care is generally better than with individual physician orders. The reason for this is that protocols empower the clinician at the bedside to advance care when the patient meets specific criteria without waiting for the physician to come and write an order. In many community hospitals, the wait for the physician weaning order can be lengthy, perhaps a whole shift or more. Thus, with protocols, care proceeds rapidly on the agreed-upon course. In addition, the individual bias of the caregiver does not affect the care provided. Thus the approach does not change from day to day depending on which physician is at the bedside. An example of a respiratory therapist–directed ventilatory discontinuance protocol is presented in Box 53.12.

RULE OF THUMB Therapist-driven weaning protocols result in faster weaning from ventilatory support than the writing of individual patient-specific weaning orders.

Recent ATS/ACCP Ventilation Liberation Guidelines

The American Thoracic Society and American College of Chest Physicians recently provided new guidelines for the liberation of patients from mechanical ventilation.[73] The recommendations were focused on a few areas:

(1) Acutely hospitalized patients ventilated for more than 24 hours should have their SBT performed with 5 to 8 cm H_2O pressure support. As indicated above, prior guidelines were not specific on this issue, recommending zero to 8 cm H_2O PSV. This is the single most controversial of these guidelines. The intent is that the PSV will simply overcome the added work of the artificial airway. However, there is essentially no data indicating that the use of pressure support during an SBT affects outcome compared to the use of zero pressure support.

BOX 53.12 Respiratory Therapist–Directed Weaning Protocol

- The physician's written order identifies the patient as being eligible for the respiratory therapist–directed weaning protocol.
- The timing of weaning initiation is defined as part of the protocol.
- All patients must undergo continuous oxyhemoglobin saturation monitoring by pulse oximetry.
- When the patient meets weaning criteria, the ventilator is set to zero CPAP and zero PEEP.
- The SBT continues for a minimum of 30 min to a maximum of 120 min if none of the following weaning failure conditions are present:
  - SaO_2 of less than 90% or diaphoresis
  - Spontaneous respiratory rate of at least 35 breaths/min that is sustained for at least 5 min
  - Agitation or a decreased level of consciousness
  - A heart rate increase of at least 20%
  - A blood pressure change of at least 20%
  - A cardiac output reduction of at least 30% or ventricular arrhythmia
- Results of the SBT are discussed with the unit physician
- If the SBT is well tolerated and there is no reason not to extubate the patient, the patient is extubated.

CPAP, Continuous positive airway pressure; *PEEP*, positive end-expiratory pressure; *SBT*, spontaneous breathing trial

(2) In acutely hospitalized patients ventilated for more than 24 hours sedation should be minimized throughout the ventilation period and particularly during weaning periods.

(3) High-risk patients receiving mechanical ventilation for more than 24 hours who have passed an SBT should be transitioned to NIV immediately following extubation to allow for a smooth transition to spontaneous breathing.

(4) Acutely hospitalized adults who have been mechanically ventilated for more than 24 hours should receive early mobilization in the form of a well-defined rehabilitation protocol.

(5) Acutely hospitalized adults who have been mechanically ventilated for more than 24 hours should be weaned with a well-defined ventilator liberation protocol.

(6) Before extubation of adults with high risk of postextubation stridor, a cuff leak test should be performed. For those failing a cuff leak test but otherwise ready for extubation it is recommended that systemic steroids should be administered for at least 4 hours before extubation.

SELECTING AN APPROACH

Current evidence suggests that, for ventilator discontinuance and progressive weaning from mechanical support, it is best to avoid SIMV.[1,4] It has also been suggested, regardless of approach used, that protocols administered by respiratory therapists and other healthcare workers be implemented.[3,7,11] These protocols should be designed to begin testing for the opportunity to reduce support very soon after intubation and to reduce the level of ventilatory support at every opportunity.[1,71] The approach to weaning that seems to wean patients most rapidly is the SBT. This should be the approach that is used to identify readiness for ventilator discontinuance in the vast majority of patients.[1]

In addition, NIV, CPAP, and HFNC should be considered as part of the total ventilator discontinuance process.[70]

One area that requires additional research is the role of ventilatory muscle conditioning in patients who require long-term ventilatory support. Endurance conditioning of the ventilatory muscles can be achieved by the continuous repetition of low levels of ventilatory work. Strength conditioning can be achieved by maximal ventilatory effort for short periods. In theory, PSV would allow for improving ventilatory muscle endurance, whereas intermittent SBTs would favor the development of muscle strength. Inspiratory resistive training to improve ventilatory muscle strength has been tried as an adjunct to weaning for the care of patients undergoing long-term ventilation.[14] Unfortunately, the role of ventilatory muscle rest and load in the care of difficult-to-wean patients has not been established.[14]

In summary, a single daily SBT that lasts from 30 minutes to 2 hours has been recommended as the primary approach to weaning.[1,4] If the trial is successful, extubation is considered. If the trial is unsuccessful, a period of rest is provided before another trial is attempted.[1] There are advantages and disadvantages to each of the methods used to conduct ventilator weaning. Table 53.5 compares SBT, SIMV, and PSV as weaning techniques. The best approach currently supported by the literature is an SBT. The method chosen should include careful patient assessment, and the patient's condition should be optimized before weaning. For the vast majority of patients, a protocolized approach to ventilator discontinuance is most efficient.

The Morbidly Obese Patient

In almost all trials assessing approach to mechanical ventilation and weaning, patients with a body mass index of greater that 30 to 35 were excluded. As a result, guidelines on the management of these patients are lacking (see Chapter 30). As noted, the new ATS/ACCP guidelines do not mention the use of CPAP. Increasing data indicate that CPAP should be used during the SBT and post extubation in the obese population. The larger the patient the greater the likelihood that atelectasis is a major problem requiring high levels of PEEP to stabilize the lung during mechanical ventilation. The vast majority of these patients have sleep apnea and use or should use CPAP at home. In addition, the larger the patient the greater the likelihood that the patient never sleeps in the supine position. Many sleep in a chair. As a result, it is highly likely that these large patients will fail a SBT on zero CPAP, since they require PEEP to avoid atelectasis. Thus the use of CPAP during SBT and post extubation seems most appropriate.[5] In many of these patients, the level of CPAP should be the level used on their nocturnal CPAP device, or at least 10 cm H_2O. Post extubation the amount of time spent with the CPAP can be decreased to simply sleep periods as the patient transitions to unsupported spontaneous breathing.

RULE OF THUMB Every patient at high risk of failing ventilator liberation should receive noninvasive ventilation, CPAP or HFNC, for the first 24 to 48 hours post extubation to avoid the need for reintubation.

TABLE 53.5 Comparison of Available Weaning Methods

Method	Advantages	Disadvantages
SBT	Tests patient's spontaneous breathing ability Allows periods of work and rest Weans faster than synchronized intermittent mandatory ventilation (SIMV) A single daily SBT may be as effective as multiple trials May be performed with 0–5 cm H_2O continuous positive airway pressure (CPAP), 0–8 cm H_2O PSV, or both	More staff time Abrupt transition may be difficult for some patients May overstress the patient if not monitored carefully Requires careful supervision
SIMV	Less staff time Gradual transition Easy to use Minimum minute ventilation guaranteed Sophisticated alarm systems may be used May be used in combination with PSV or CPAP	Patient–ventilator asynchrony Prolongs weaning May worsen fatigue Not a recommended approach
PSV	Less staff time Gradual transition Prevents fatigue Maintains activity of diaphragm Increased patient comfort Weans faster than SIMV Overcomes resistive work of breathing (WOB) caused by the following: Endotracheal and tracheostomy tubes Ventilator circuits Demand flow systems Patient can control cycle length, rate, and inspiratory flow Every breath is supported	Large changes in minute ventilation can occur Increased mean airway pressure as compared with SBT Tidal volume not guaranteed; low tidal volumes possible May prolong weaning

PSV, Pressure support ventilation; *SBT*, spontaneous breathing trial.

MONITORING THE PATIENT DURING WEANING

Ventilatory Status

Respiratory rate and pattern are easy to monitor and may be the most reliable indicators of patient progress during weaning.[1,4] Weaning may proceed as quickly as the patient's respiratory rate and subjective tolerance allow. However, in no case should patients be pushed beyond their physiologic limits; to do so may result in diaphragmatic dysfunction and further delay the weaning process. If the patient fatigues during a weaning trial, it will require at least 24 hours for the muscles to recover.[74,75] Dyspnea should be monitored during weaning and may be quantified with a visual analog scale or a modified Borg scale (Table 53.6).[76] The onset or worsening of discomfort, respiratory distress, fatigue, sweating, signs of increased WOB (e.g., accessory muscle use and abdominal paradox), deterioration in vital signs, or changes in mental status (e.g., agitation, anxiety, somnolence, and coma) may be signs of intolerance of a weaning trial.[1]

TABLE 53.6 Modified Borg Scale for Dyspnea

Grade	Degree of Dyspnea
0	None
0.5	Very, very slight (just noticeable)
1	Very slight
2	Slight
3	Moderate
4	Somewhat severe
5	Severe
6	Very severe
7	
8	
9	Very, very severe (almost maximal)
10	Maximal

Modified from Mahler DA: *Dyspnea*, Mt. Kisco, NY, 1990, Futura.

The single best index of ventilation remains the measurement of $PaCO_2$. However, the assessment of a patient's tolerance of an SBT should be based on clinical presentation rather than $PaCO_2$. A patient with a $PaCO_2$ of 40 mm Hg but a clinical presentation defined by a rapid, shallow breathing pattern with abdominal paradox, tachycardia, and hypertension has not passed an SBT. The results of capnography should not be used to guide the weaning of patients. End-tidal $PaCO_2$ values can be highly misleading as an estimate of effective ventilation in sick patients.[77] Gastric pH has been used as a predictor of patient status, and gastrointestinal acidosis may be an early sign of weaning failure.[78]

Oxygenation

During the SBT, FiO_2 should be the same as during ventilatory support or 10% higher. Continuous pulse oximetric (SpO_2) monitoring can provide a sensitive indicator of oxygenation status during weaning.[1] Arterial blood gas analysis for PaO_2, $PaCO_2$, and SaO_2 and the calculation of the oxygen content of the arterial blood (CaO_2) may be performed after the patient has been considered a weaning failure to determine the extent of the failure. Success, however, can be based on the SpO_2. SpO_2 monitoring during the SBT is generally the standard of care.

Cardiovascular Status

Pulse, blood pressure, and cardiac rhythm should be monitored, and arrhythmias should be assessed to determine whether weaning should be continued. Tachycardia, bradycardia, and abnormalities in blood pressure should be promptly evaluated and the patient returned to ventilatory support or a higher level of support, if indicated. Silent myocardial ischemia may occur frequently in some postoperative patients during weaning.[79] Table 53.7 summarizes changes that may occur during the withdrawal of ventilatory support.

TABLE 53.7 Changes During the Withdrawal of Ventilatory Support

Expected Change	Deleterious Change
Respiratory	
Respiratory rate minimally increased	Respiratory rate of ≥35 breaths/min
Stable $\dot{V}$	Large increase or decrease in $\dot{V}_E$
SpO_2 ≥90%	Decrease in SpO_2 to ≤90%
5–10 mm Hg swing in PaO_2	PaO_2 of <60 mm Hg
5–10 mm Hg swing in $PaCO_2$	An increase of >10 mm Hg in $PaCO_2$
pH of >7.30 and <7.50	pH of <7.30
Minimal use of accessory muscles	Increased use of accessory muscles
No paradoxical breathing	Paradoxical breathing
	Diaphoresis
	Dyspnea
Cardiovascular	
Heart rate increased by 15–20 beats/min	Persistent tachycardia of ≥120–140 beats/min
Blood pressure increased 10–15 mm Hg	Hypotension (blood pressure of <90/60 mm Hg)
	Hypertension (systolic blood pressure of >180 mm Hg)
Increased cardiac index	Decreased cardiac index
Increased stroke volume	Decreased stroke volume
	Angina
	New arrhythmias
Other	
Mental status good (i.e., awake, alert, responsive)	Anxiety, agitation, somnolence, coma

EXTUBATION

Artificial Airways and Weaning

The effect on a patient of a properly sized artificial airway on WOB is controversial.[80] However, many endotracheal tubes are partially obstructed and as a result impose a significant increase in WOB. Removing the endotracheal tube may markedly improve the patient's clinical status. There is little difference in the airway resistance of healthy adults with low minute ventilation (i.e., <8 L/min) breathing through endotracheal tubes with an internal diameter (ID) of 7.0 to 9.0 mm.[81] However, in critically ill patients decreases in ID and increases in minute ventilation increase WOB. Adults have a critical increase in workload when the tube has an ID of less than 7.0 mm.[81] It is thought that the added work due to the presence of an artificial airway may contribute to ventilator dependency among patients with borderline pulmonary function or ventilatory muscle weakness.[82]

Biofilm buildup on the inside of the endotracheal tube can cause dramatic increases in airway resistance, especially among infants and children.[83,84] Taking care to provide adequate humidification and careful suctioning can help avoid this problem.

Tracheotomy may substantially reduce the WOB of patients who need mechanical ventilatory support. The short length of tracheostomy tubes results in an overall decrease in resistance as compared with the resistance of an endotracheal tube, even though the curvature of the tracheostomy tube is greater.[1] It appears that the performance of a tracheotomy improves airway resistance and reduces the load of the ventilatory muscles. It may be the ability to avoid secretions/biofilm buildup on the inside of the tracheostomy tube that makes the difference.

Weaning and extubation should be separate decisions. Weaning indices are not predictive of the adequacy of airway patency or

BOX 53.13 Practical Guidelines for Extubation

- There is no immediate need for mechanical ventilation or intubation.
- The medical course does not suggest impending respiratory failure or other indications for mechanical ventilation.
- Procedures that require intubation and general anesthesia are not immediately planned.
- There is adequate oxygenation and ventilation with spontaneous ventilation.
- The patient's FiO_2 requirement can be achieved with a mask or a nasal cannula.
- The patient no longer needs mechanical ventilatory assistance.
- Weaning is successful.
- There is a minimal risk of upper airway obstruction.
- The patient has minimal edema or mass encroachment of the oropharynx and upper airway.
- There is adequate airway protection and a minimal risk of aspiration.
- The level of consciousness and neuromuscular function ensures a gag reflex and an adequate cough.
- Gastric contents are minimized by the discontinuation of tube feedings for 4–6 h before extubation.
- A positive gag reflex is present.
- There is adequate clearance of pulmonary secretions.
- The level of consciousness and muscular strength allow for an effective cough.
- Secretion volume and thickness are not worsening.

the need for protection of the airway. The reintubation rate among patients with prolonged postoperative ventilation as a result of respiratory failure can range from 5% to 20%.[1,4]

Patients who have been successfully extubated generally have the following characteristics: (1) the resolution of the disease state or condition; (2) hemodynamic stability; (3) the absence of sepsis; (4) adequate oxygenation status with a decreased FiO_2 and decreased PEEP or CPAP; and (5) adequate ventilatory status and $PaCO_2$. The decision to extubate should be based on the assessment of upper airway patency and protection. No one indicator is 100% sensitive and specific with regard to the prediction of successful extubation. Practical guidelines for extubation are presented in Box 53.13. Regardless of the weaning technique used, an SBT is recommended before extubation to ensure that the patient can sustain spontaneous unsupported ventilation.[1]

Some patients may be successfully extubated even if extubation criteria are not met. If the patient is at risk, trained personnel able to perform reintubation must be immediately available before extubation is attempted. At a minimum, those who perform the extubation must be prepared to provide an airway and ventilatory support if problems develop immediately after extubation. Extubation should be postponed when myocardial ischemia is present, when the patient has upper gastrointestinal hemorrhage, or when a procedure that necessitates reintubation is impending. If difficult reintubation is anticipated, trained personnel should be immediately available.

Post Extubation Complications

Many patients report hoarseness and sore throat after extubation, and patients should be advised that these symptoms may occur (see Chapter 37 for details). Other common problems after extubation include airway obstruction, increased risk of aspiration, and difficulty with secretion clearance. Patients with neurologic or neuromuscular disorders and those with excessive secretions are at increased risk after extubation. The compression of the airway as a result of a traumatic or postoperative hematoma of the neck, infectious masses or abscesses, and malignant tumors or compression after major head or neck surgery can lead to upper airway obstruction after extubation. The cuff leak test may detect airway obstruction before extubation.[85,86] An air leak of less than 11% to 12% or 110 to 130 mL has been shown to be predictive of stridor.[85,86] Box 53.13 provides a protocolized guide for extubation.

After extubation, glottic edema can result in partial airway obstruction, which can cause mild to severe stridor. Postextubation stridor occurs in 2% to 16% of patients in the ICU and should be viewed with concern.[87] Severe edema after extubation can lead to complete airway obstruction. Children, patients with epiglottitis or angioedema (i.e., dermal, subcutaneous, or submucosal edema of the face or larynx), and patients who have sustained smoke inhalation are at greater risk. Postextubation edema occurs in as many as 47% of children with trauma injuries or burns.[1,4] See Chapter 37 for detailed information about airway management and postextubation care.

RULE OF THUMB The use of CPAP during SBT and post extubation seems most appropriate for obese patients. In many of these patients the level of CPAP should be the level used on their nocturnal CPAP device or at least 10 cm H_2O.

VENTILATOR DISCONTINUANCE FAILURE

As many as 25% of patients who have been removed from ventilatory support experience respiratory distress that is severe enough to necessitate the reinstitution of mechanical ventilation. In patients who are unlikely to be successfully weaned, rapid, shallow breathing begins almost immediately after the ventilator is disconnected. As spontaneous breathing continues, respiratory mechanics worsen in these patients for reasons that are not clearly understood. Approximately half of patients who have poor results after the discontinuation of ventilation experience marked hypercapnia with rapid, shallow breathing. An unsuccessful SBT also causes considerable cardiovascular stress. Myocardial ischemia may occur frequently among ventilator-dependent patients, and it has been associated with weaning failure.[88] Critical illness polyneuropathy has been cited as a frequent cause of neuromuscular weaning failure among critically ill patients.[89] Unsuspected neuromuscular disease may be an important factor in ventilator dependency.

Inability to wean can sometimes be attributed to psychologic dependence, poor oxygenation status, or cardiovascular instability (i.e., congestive heart failure or ischemia).[1,4] However, the most common cause of the inability to wean is an imbalance between ventilatory capability and ventilatory demand. Inability to wean is usually caused by a concurrent pathologic process that necessitates treatment. Common causes of weaning failure are summarized in Box 53.14.

BOX 53.14 Common Causes of Weaning Failure

- Poor respiratory mechanics or wheezing
- Untreated cardiac disease
- Electrolyte imbalances
- Anxiety
- Secretions
- Aspiration
- Alkalosis
- Neuromuscular weakness
- Sepsis
- Excessive sedation
- Inadequate nutrition
- Opiates
- Obesity
- Thyroid disease

MINI CLINI

Patient Who Requires Long-Term Weaning

Problem

A 68-year-old man with a history of COPD was hospitalized after a motor vehicle accident. Over the course of the next 2 weeks, the patient became septic and developed acute respiratory distress syndrome. For the last week, the patient has met the criteria for an SBT, but he has failed every attempt. How should this patient's ventilator care progress from this point forward?

Solution

This patient should be classified as a difficult-to-wean patient who would benefit from a program that has been designed specifically for patients who are failing to wean. This program should systematically evaluate all systems to determine the cause of weaning failure and include the assistance of other healthcare providers, specifically physical therapy, occupational therapy, and speech and language pathology; he may also benefit from the efforts of social services. Ideally, this should take place in a unit that has been specifically designed for the difficult-to-wean patient.

PROLONGED MECHANICAL VENTILATION

Prolonged mechanical ventilation (PMV) may be required for 3% to 7% of patients who are receiving mechanical ventilation.[1,4] Patients who require a lengthy course of ventilatory support after the acute phase of their disease has resolved may be suffering from some of the items listed in Table 53.8. Any patient who is repeatedly failing SBTs should undergo a complete review of all systems to determine if something has been overlooked that may add to the patient's workload, thereby preventing them from weaning. In many patients, their pulmonary mechanics have not been optimized, and thus they are unable to assume the workload required of spontaneous breathing. In others, underlying cardiac disease may not have been properly treated. Always a concern is the patient's acid–base status. If a patient had baseline compensated respiratory acidosis, then he or she will not be able to wean if the compensation has been eliminated. Every time these patients are trialed on an SBT, their carbon dioxide levels will rise, and they will develop respiratory failure. If this is the problem, the baseline acid–base status must be slowly reestablished if these patients are to wean. In other patients, sedation, opiates, nutritional status, electrolytes, and other underlying issues many be the concern. The more carefully all systems are reviewed, the greater the likelihood that the problem will be identified and the patient weaned from ventilatory support.

BOX 53.15 Goals for Weaning After Long-Term Mechanical Ventilation

- Reduce the amount of support.
- Decrease the invasiveness of any support.
- Increase independence from mechanical devices.
- Preserve function.
- Maintain medical stability.

CHRONICALLY VENTILATOR-DEPENDENT PATIENTS

Chronically ventilator-dependent patients (i.e., <1% of those requiring ventilatory support) present ethical, economic, and practical problems.[90] From an economic point of view, the long-term care of ventilator-dependent patients in an ICU is prohibitively expensive. Often these patients are transferred to subacute or long-term care facilities, where they can be cared for in an environment that is less intrusive and more like home (see Chapter 57).[90] For cases in which the family has adequate resources, the patient may be cared for in the home. Regional weaning centers have been developed and have reported success with weaning most patients who are undergoing long-term mechanical ventilation.[1,90] Current guidelines suggest that, unless there is clear evidence of an irreversible cause of ventilator dependency (e.g., a high spinal cord injury, amyotrophic lateral sclerosis), patients should not be considered permanently ventilator dependent until 3 months of weaning attempts have failed. If the patient is unweanable, the goal should be to restore the patient to the highest level of independent function possible. For example, portable wheelchair-mounted ventilators have been effective for providing a surprising level of mobility and independence to persons who are quadriplegic. Table 53.8 describes the management of common problems among difficult-to-wean patients. Box 53.15 lists the goals for weaning of patients who are receiving long-term ventilation.

TERMINAL WEANING

The term *terminal weaning* has been used to refer to the discontinuation of mechanical ventilatory support in the face of a catastrophic and irreversible illness (see Chapter 58).[91] The decision to proceed with disconnecting the ventilator when such an act is likely to cause the death of a patient is fraught with ethical, emotional, and practical problems. The decision should be made by the family in consultation with the patient's physician and in accordance with established ethical and legal guidelines.[91] Determinants of the decision to withdraw ventilation include the patient's desire to not continue with life support, the predictions of a low chance of survival in the ICU (i.e., less than 10%),

TABLE 53.8 Management of Problems Among Difficult-to-Wean Patients

Problem	Management Strategy
Anemia	Transfuse when hemoglobin level is ≤10 g/dL and hematocrit level is ≤30% if these are thought to be factors in decreased tissue oxygenation
Increased work of breathing (WOB)	1. Tube related a. Apply pressure support or ATC b. Change the size of the small endotracheal tube c. Deflate the cuff if all breathing is spontaneous and the risk of aspiration is minimal d. Consider tracheotomy 2. Secretion related (see later) 3. Bronchospasm related a. Administer bronchodilators • β_2-agonists • Anticholinergics • Steroids b. Minimize auto-PEEP and apply PEEP to ensure triggering of ventilation. c. Manage the cause 4. Ventilator related a. Assure synchrony for machine breaths b. Eliminate auto-PEEP c. Flow-trigger ventilation with or without pressure support
Secretions, atelectasis, or plugging	1. Systemically hydrate 2. Provide adequate humidity (i.e., humidifier temperature 35°C–37°C at airway connection) 3. Maximally bronchodilate when necessary 4. Suction
Dyspnea	1. Use positioning (i.e., out of bed, dangling, and leaning forward) 2. Reassure and communicate with the patient 3. Increase endurance, alternate weaning with rest to promote endurance 4. Provide distraction
Malposition	1. Position the patient to maximize diaphragmatic excursion and to improve lung volume and gas exchange (i.e., sitting or dangling) 2. Use a rocking chair 3. Follow $\dot{V}_E$, V_T, rate, values for optimum positioning
Respiratory muscle fatigue	1. Direct management at the cause 2. Ensure adequate oxygen transport and cardiac output 3. Nourish the patient 4. Replace depleted electrolytes 5. Decrease the WOB a. Administer supplemental oxygen b. Clear secretions c. Decrease airway resistance
Hemodynamic and fluid problems	1. Administer volume replacement and drugs to increase contractility, increase or decrease preload, and decrease afterload 2. Delay weaning until the patient's cardiovascular status is stable 3. Use techniques and the mode of ventilation to decrease the mean airway pressure
Infection	1. Identify potential sites of infection 2. Remove lines early, or replace them periodically 3. Control infection 4. Nourish the patient
Metabolic problems	1. Control the cause and postpone weaning if the patient has acidosis 2. Keep the carbon dioxide level at baseline if the patient has COPD, or allow progressive renal compensation during long-term weaning 3. Provide moderate carbohydrate loading with total parenteral nutrition
Low magnesium level High magnesium level	4. Give supplements 5. Provide dialysis or calcium chloride
Low calcium level	6. Control the cause before weaning
Low phosphate level	7. Replace phosphate before weaning
Nutrition	1. Assess weight, albumin, and total lymphocyte count at admission 2. Label the degree of malnutrition, and calculate protein needs 3. Nourish the patient

Continued

TABLE 53.8 Management of Problems Among Difficult-to-Wean Patients—*cont'd*

Problem	Management Strategy
Exercise	1. Provide exercise therapy to increase muscle function, prevent contracture, and maintain joint integrity (i.e., passive-to-active range of motion and sitting to walking) 2. Increase strength during activities of daily living 3. Secure a physiotherapy consultation 4. Consider the use of an exercise bicycle 5. Encourage wheelchair rides or walks with a portable ventilator 6. Provide breathing retraining
Psychologic problems	1. Secure early psychiatric consultation 2. Allow for patient control 3. Demonstrate staff accountability and honesty 4. Provide a communication method 5. Decrease environmental stress 6. Teach relaxation methods 7. Provide mental stimulation 8. Provide recreation 9. Provide rewards for reaching short-term goals 10. Encourage self-care 11. Allow other patients to visit 12. Provide flexible visiting hours 13. Take the patient out of the ICU environment
Sleep disturbances	1. Provide a quiet environment (i.e., dim lights), reposition the patient, give a back rub, and administer sedation 2. Provide for uninterrupted sleep 3. Avoid weaning at night 4. Provide relaxation method (e.g., hypnosis, biofeedback, and progressive muscle relaxation) 5. Prescribe short-acting sedative hypnotics
Pain	1. Administer minimal analgesia

ATC, Automatic tube compensation; *COPD*, chronic obstructive pulmonary disease; *ICU*, intensive care unit; *PEEP*, positive end-expiratory pressure.
Modified from Norton LC, Neureuter A: Weaning the long-term ventilator-dependent patient: common problems and management. *Crit Care Nurse* 9:42–52, 1989.

the likelihood that future cognitive function would be severely impaired, and the continuous need for inotropes or vasopressors to maintain blood pressure.[91] After the decision has been made, the process is generally one of ventilator disconnection rather than weaning. The method of terminal weaning should be as humane and as comfortable as possible and should not be done in a way that further burdens the family.[92]

SUMMARY CHECKLIST

- The most common cause of ventilator dependence is a ventilatory workload that exceeds the patient's ventilatory capabilities.
- Other common causes of ventilator dependence include oxygenation problems, cardiovascular instability, and psychologic factors.
- The most important criterion for determining whether a patient is ready for ventilator discontinuation or weaning is a significant improvement or reversal of the disease state or condition that caused the patient to need ventilatory support.
- Factors that should be optimized before weaning include oxygenation, ventilation, acid–base balance and electrolyte levels, cardiovascular status, kidney function and fluid balance, sleep deprivation, psychologic status, nutrition, and overall medical condition.
- Weaning techniques include spontaneous breathing trials, PSV, and SIMV.
- Spontaneous breathing trials and PSV result in faster discontinuation of ventilatory support as compared with SIMV.
- The ideal approach to weaning patients is a therapist-driven protocol that makes use of an SBT.
- Esophageal pressure monitoring, diaphragm ultrasound, and diaphragm EAdi may be useful in identifying readiness for a SBT and the likelihood of successfully passing the SBT.
- The ATS/ACCP new mechanical liberation guidelines indicate that 5 to 8 cm H_2O PSV should be used during the SBT.
- When preforming an SBT on a morbidly obese patient, CPAP should be applied during the SBT and post extubation.
- The monitoring of the patient during weaning should include SpO_2, respiratory rate and pattern, dyspnea, cardiac rate and rhythm, and blood pressure assessments.
- The use of daily SATs or the maintenance of minimal sedation not only improves the speed of weaning but has also been shown to improve mortality.
- Before extubation, patients should be assessed for the ability to maintain and protect their airway and for the presence of upper airway edema.
- Common causes of weaning failure include an excessive ventilatory workload in the presence of ventilatory muscle weakness or fatigue, oxygenation problems, cardiovascular instability,

the inability to clear secretions, poor mental status, and the presence of an underlying concurrent pathologic condition that necessitates treatment.

- The goals of the weaning of long-term ventilator-dependent patients include reducing the amount of support, reducing the invasiveness of support, and increasing the patient's level of independent function.
- Only less than 1.0% of patients that require mechanical ventilation end up as long-term ventilator-dependent patients.
- The decision to terminally wean a patient should be made by the family in consultation with the patient's medical team and in accordance with established ethical and legal guidelines.

Neonatal and Pediatric Respiratory Care

Daniel W. Chipman

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the correct approach to assessment of the fetus and newborn infant.
- Discuss the use of oxygen therapy, bronchial hygiene therapy, aerosol drug therapy, airway management.
- Discuss resuscitation of the newborn infant experiencing respiratory or cardiac distress.
- List the components of an Apgar score.
- Identify the different pulse oximetry (SpO_2) target ranges for preterm and full-term infants and those with primary pulmonary hypertension.
- List normal blood gas values for a newborn infant.
- Discuss the administration of surfactant in premature infants.
- Differentiate low-birth-weight, very low-birth-weight, and extremely low-birth-weight infants.
- Describe the correct approach to assessment of the pediatric patient.
- Discuss the use of high-flow nasal cannulas in infants and children.
- Discuss the use of continuous positive airway pressure in infants and children.
- Discuss the use of noninvasive ventilation in infants and children.
- Discuss the basics of mechanical ventilation including high-frequency ventilation in the care of infants and children.
- Discuss the advantages and disadvantages of self-inflating, flow-inflating and T-piece resuscitators.
- List clinical situations where nitric oxide is used and discuss its basic application.
- Explain the correct approach to ventilator management for a patient in status asthmaticus.
- Discuss the use of heliox for a patient with asthma.
- Discuss the steps to ventilator discontinuance for infants and children including a safety screen and assessment of ability to breathe spontaneously.

CHAPTER OUTLINE

KEY TERMS

Apgar score
appropriate for gestational age (AGA)
continuous positive airway pressure (CPAP)
extremely low birth weight (ELBW)
grunting, flaring, and retracting
high-frequency ventilation (HFV)
inhaled nitric oxide (INO)
large for gestational age (LGA)
meconium
patent ductus arteriosus (PDA)
primary pulmonary hypertension of the newborn (PPHN)
retinopathy of prematurity (ROP)
small for gestational age (SGA)
surfactant
very low birth weight (VLBW)

Caring for infants and children is one of the most challenging and rewarding aspects of respiratory care. Competent clinical practice in this area requires knowledge of the many pathophysiologic differences among infants, children, and adults. Understanding the unique pathophysiology involved in neonatal and pediatric respiratory disorders (see Chapter 35) can assist the respiratory therapist (RT) in providing quality care to infants and children. A thorough understanding of how the respiratory system develops in the fetus is the first step toward acquiring the specialized knowledge needed to practice neonatal respiratory care (see Chapter 9). This chapter begins with an overview of neonatal and pediatric patient assessment and then describes respiratory care modalities used to treat these patients.

ASSESSMENT OF THE NEWBORN

Assessment of the newborn begins before birth with assessment of the maternal history, the maternal condition, and the status of the fetus.

Maternal Factors

Maternal risk factors include many medical, physical, and social conditions. Maternal health and individual physiology, pregnancy complications, and maternal behaviors affect the health of the fetus. Any condition that causes an interference with placental blood flow or the transfer of oxygen (O_2) to the fetus can result in an adverse outcome. The clinician must be prepared for the possibility of resuscitation at delivery. This possibility is best anticipated by identifying risk factors that relate to neonatal compromise. Table 54.1 lists maternal risks and related outcomes of which the team preparing to receive the infant should be aware when the infant is delivered.

TABLE 54.1 Maternal Condition and Neonatal Outcomes

Maternal Condition	Fetal or Neonatal Outcome
Previous pregnancy complication	Same outcome as previous fetus
Diabetes mellitus	LGA, congenital malformations, RDS, hypoglycemia
Pregnancy-induced hypertension	Prematurity, SGA (preeclampsia)
Maternal age <17 years	Low birth weight, prematurity
Maternal age >35 years	Prematurity, chromosomal defects
Placenta previa	Prematurity, bleeding, SGA
Abruptio placentae	Fetal asphyxia, bleeding
Alcohol consumption	SGA, CNS dysfunction, mental retardation, facial dysmorphology
Smoking	SGA, prematurity, mental retardation, SIDS
Drug use	Placental abruption, IUGR, prematurity, CNS abnormalities, withdrawal disorders

CNS, Central nervous system; *IUGR,* intrauterine growth restriction; *LGA,* large for gestational age; *RDS,* respiratory distress syndrome; *SGA,* small for gestational age; *SIDS,* sudden infant death syndrome.

Fetal Assessment

Fetal assessment is performed with ultrasonography, amniocentesis, fetal heart rate monitoring, and fetal blood gas analysis. Ultrasonography uses high-frequency sound waves to obtain an image of the infant in utero. This image allows the physician to view the position of the fetus and placenta, measure fetal growth, identify possible anatomic anomalies, and assess the amniotic fluid qualitatively.

Amniocentesis involves direct sampling and quantitative assessment of amniotic fluid. Amniotic fluid may be inspected for **meconium** (fetal bowel contents) or blood. In addition, sloughed fetal cells can be analyzed for genetic normality. Lung maturation can be assessed with amniocentesis. The lecithin-to-sphingomyelin ratio (L:S ratio) involves measurement of two phospholipids, lecithin and sphingomyelin, synthesized by the fetus in utero. The L:S ratio increases with increasing gestational age. At approximately 34 to 35 weeks' gestation, this ratio abruptly increases to greater than 2:1. An L:S ratio greater than 2:1 indicates stable **surfactant** production and mature lungs.[1] Phosphatidylglycerol is another lipid found in the amniotic fluid that is used to assess fetal lung maturity. Phosphatidylglycerol first appears at approximately 35 to 36 weeks' gestation. If phosphatidylglycerol is more than 1% of the total phospholipids, the risk of respiratory distress syndrome (RDS) is less than 1%.[2] A technique using three-dimensional (3D) ultrasonography for the assessment of fetal maturity has recently been described, and this may serve as a useful alternative to amniotic fluid phospholipids in analyzing fetal lung maturity.[3] Fetal heart rate monitoring includes the measurement of fetal heart rate and uterine contractions during labor. Examination of fetal heart rate changes related to uterine contractions identifies a fetus in distress. Fetal well-being is obtained by examining the variability and reactivity of the fetal heart rate. A normal fetal heart rate ranges from 120 to 160 beats/min. Fetal tachycardia can be a sign of fetal hypoxemia or could be related to other factors, such as prematurity or maternal fever. Temporary declines in fetal heart rate are called *decelerations* and can be mild (<15 beats/min), moderate (15 to 45 beats/min), or severe (>45 beats/min). Decelerations are classified by their occurrence in the uterine contraction cycle.

Fig. 54.1 illustrates the three common patterns of early decelerations, late decelerations, and variable decelerations. Early decelerations occur when the fetal heart rate decreases in the beginning of a contraction. This type of deceleration is benign and in most cases is caused by a vagal response related to compression of the fetal head in the birth canal. A late deceleration occurs when the heart rate decreases 10 to 30 seconds after the onset of contractions. A late deceleration pattern indicates impaired maternal-placental blood flow, or uteroplacental insufficiency. With variable decelerations, there is no clear relationship between contractions and heart rate. This pattern is the most common of the three and probably related to umbilical cord compression. Short periods of cord compression are generally benign, but prolonged periods of compression result in impaired umbilical blood flow and can lead to fetal distress. Fetal heart rate variability is the beat-to-beat variation in rate that occurs because of normal sympathetic or parasympathetic influences. A completely monotonous heart rate tracing may be indicative

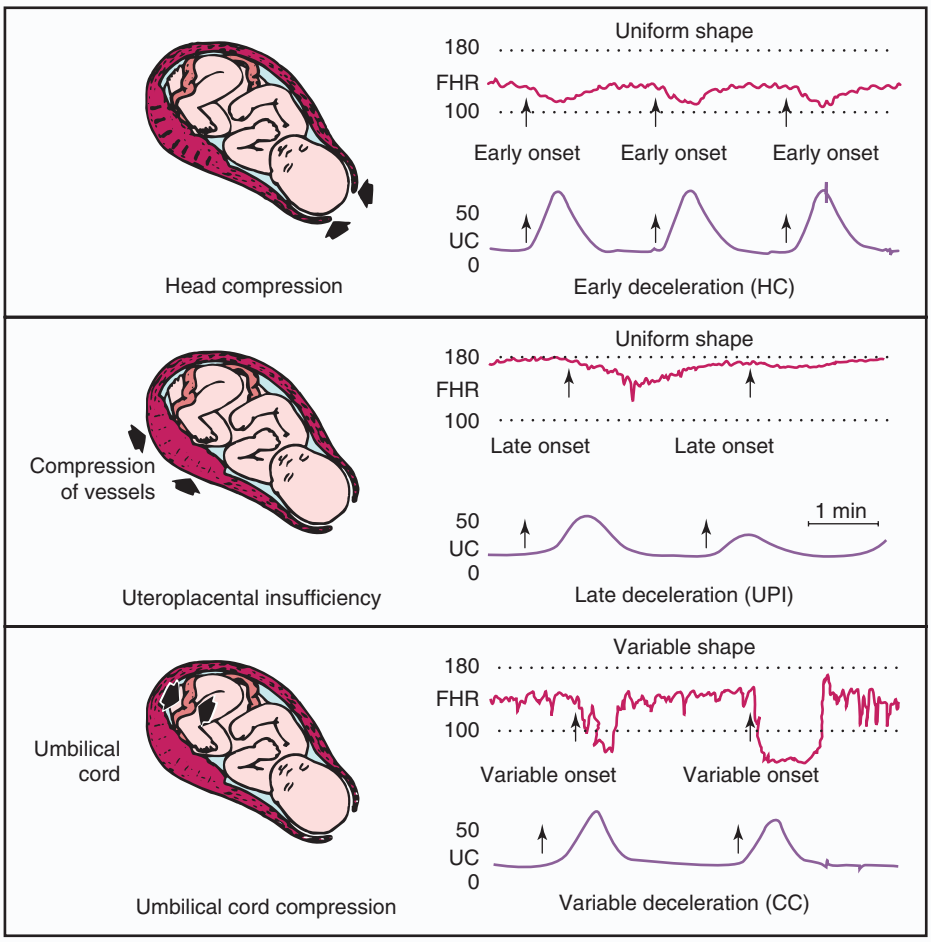

Fig. 54.1 Fetal heart rate patterns. (Modified from Avery GB, ed. *Neonatology: Pathophysiology and management of the newborn.* 2nd ed. Philadelphia: JB Lippincott; 1981.)

of fetal asphyxia. Fetal heart rate reactivity is the ability of the fetal heart rate to increase in response to movement or external stimuli. A healthy fetus has two accelerations within a 20-minute period.

In utero, the fetus receives its blood supply from the placenta. Only a small portion of the blood that enters the fetal right heart flows through the lungs. This is a result of fetal pulmonary blood vessels being constricted with a high resistance to blood flow. There are two openings in the fetal heart through which most fetal blood flows. These normal anatomic shunts in the fetus are called *patent foramen ovale* and *patent ductus arteriosus (PDA)*. Blood flows through these openings and into the umbilical vessels before returning to the mother. Pressure in the umbilical vessels is low. During the transition from fetal life to newborn life, the umbilical cord is clamped, and the infant's systemic blood pressure is increased. The infant begins to breathe, and O_2 enters the infant's blood. Oxygenated blood entering the pulmonary vessels causes the vessels to dilate and decreases pulmonary resistance. With higher systemic resistance and lower pulmonary resistance, less blood flows through the anatomic openings, and these openings begin to close. Evidence of normal transitional circulation is noted as the infant's skin turns from a bluish hue to pink over the first several minutes of life.

RULE OF THUMB Infants presenting with a monotonous heart rate or a fetal scalp pH less than 7.2 may be experiencing asphyxia.

Fetal Blood Gas Analysis

When other factors indicate potential problems during labor and delivery, fetal blood pH can be used to determine severity. Normally, fetal blood is obtained from a capillary sample taken

from the presenting body part, usually the scalp. Normal fetal capillary pH ranges from 7.25 to 7.35, with the lower values occurring late in labor. A pH less than 7.20 may indicate that the fetus is experiencing asphyxia. There is no direct correlation between fetal scalp and arterial blood pH; scalp pH should be used only to assist in interpreting clinical signs of fetal distress.

Evaluation of the Newborn

All newborns should be assessed immediately upon delivery. The American Heart Association and American Academy of Pediatrics have developed guidelines for the assessment and treatment of newborn infants. These guidelines, collectively referred to as the Neonatal Resuscitation Program (NRP) should be familiar to all caring for newborns. They cover a wide range of topics, including initial preparation and assessment, interventions such as positive pressure ventilation (PPV) and chest compressions, emergency equipment and medications, specific emergency procedures including intubation and needle decompression of the chest for pneumothoraces, postresuscitation care, and ethics and care at end of life. Special consideration is given to ethical principles associated with neonatal resuscitation and withholding resuscitation and how to help parents and staff through the grieving process.

Most newborns (>90%) do not need intervention when transitioning from intrauterine to extrauterine life. The two categories of newborns most likely to need intervention are infants born with evidence of meconium in their airway and premature infants. The need for intervention is determined by assessing for the presence of meconium, breathing or crying, muscle tone, color, and gestational age.

Meconium is the medical term for the infant's first stool. It is a sticky green-black substance that if inhaled by the infant can cause significant respiratory problems. It is more likely to be present in a term or postterm newborn than one born prematurely. Term infants delivered without evidence of meconium who are crying or breathing and have good tone should not routinely be separated from the mother. They should be dried, covered, and given to the mother and observed for breathing, activity, and color. If meconium is present and the infant is vigorous, pharyngeal suctioning with a bulb suction is appropriate. Simultaneously, the infant should be dried and placed under a warmer and assessed for signs of respiratory distress.

If meconium is present in a nonvigorous infant, stimulation should be avoided. Immediate endotracheal intubation before beginning PPV is indicated as a means to clear meconium from the airway. The endotracheal tube should be attached to a meconium aspirator, and a suction device should be regulated for −70 to −100 mm Hg. As soon as the endotracheal tube is inserted, suction should be applied to the tube, and then the endotracheal tube is withdrawn. Reintubation and repeat suctioning may be necessary if meconium is still visible in the airway. Frequent assessment of the heart rate is indicated during this process, and if the heart rate is less than 100 beats/min, bag-mask ventilation should be performed.

Preterm infants frequently need interventions. The more preterm the infant, the more likely the infant will need some level of resuscitation. If an infant is preterm, is not breathing, is not vigorous, or does not have good tone, resuscitation efforts should be initiated. Efforts are directed at warming the infant because cold stress may increase O_2 consumption and impair all subsequent resuscitation efforts.

After the infant is dried and warmed, the infant is positioned supine, with the head in a neutral position or slightly extended. A bulb syringe or 8- to 10-F suction catheter may be used for secretion removal; however, in the absence of blood or meconium, catheter suctioning should be limited because aggressive pharyngeal suctioning may cause laryngospasm or bradycardia. Suction pressure should not exceed −100 mm Hg. Once the infant is suctioned, dried, and warmed, if apnea or inadequate respirations are present, tactile stimulation may be used to encourage spontaneous breathing. Many infants respond to stimulation and need no further resuscitative efforts. If after 30 seconds, the infant has a heart rate of less than 100 beats/min or is apneic, bag-mask ventilation at a rate of 40 to 60 breaths/min should be initiated.

The *most* important and effective action in neonatal resuscitation is effective ventilation. Recommendations from the American Academy of Pediatrics are to attach a pulse oximeter to the infant, begin resuscitation efforts using room air, and assess carefully the amount of O_2 needed.[4] Effective PPV usually results in rapid improvement of heart rate. Initial ventilating pressures of 30 to 40 cm H_2O may be necessary to achieve noticeable chest movement, particularly in a preterm newborn with surfactant deficiency. Continuous assessment of the lowest pressure needed to observe the chest rise is essential throughout the resuscitation. After application of PPV for 30 seconds, the heart rate is reassessed. If the heart rate is less than 60 beats/min, chest compressions are begun and PPV is maintained. If the heart rate remains less than 60 beats/min after adequate ventilation with 100% O_2 and chest compressions for 30 seconds, appropriate medications are given. As soon as the heart rate is noted to be greater than 100 beats/min, compressions are discontinued. If spontaneous breathing is present, PPV may be gradually reduced and then discontinued. If spontaneous breathing remains inadequate or if heart rate remains less than 100 beats/min, assisted ventilation is continued via bag-mask or endotracheal tube. Fig. 54.2 outlines a newborn resuscitation algorithm and includes the targeted saturation levels for the first 10 minutes of life.

RULE OF THUMB The most important and effective action in neonatal resuscitation is to ventilate.

Apgar Score

An Apgar score is assigned at 1 minute and 5 minutes of life. The **Apgar score** is an objective scoring system used to rapidly evaluate a newborn. As shown in Table 54.2, the score has five components: heart rate, respiratory effort, muscle tone, reflex irritability, and skin color. Each component is rated according to standard definitions, resulting in a composite assessment score. In general, infants scoring 7 or higher at 1 minute are responding normally. An infant with a score of 7 may require supportive care, such as O_2 or stimulation to breathe. Infants with a 1-minute Apgar score of 6 or lower may require more aggressive support.

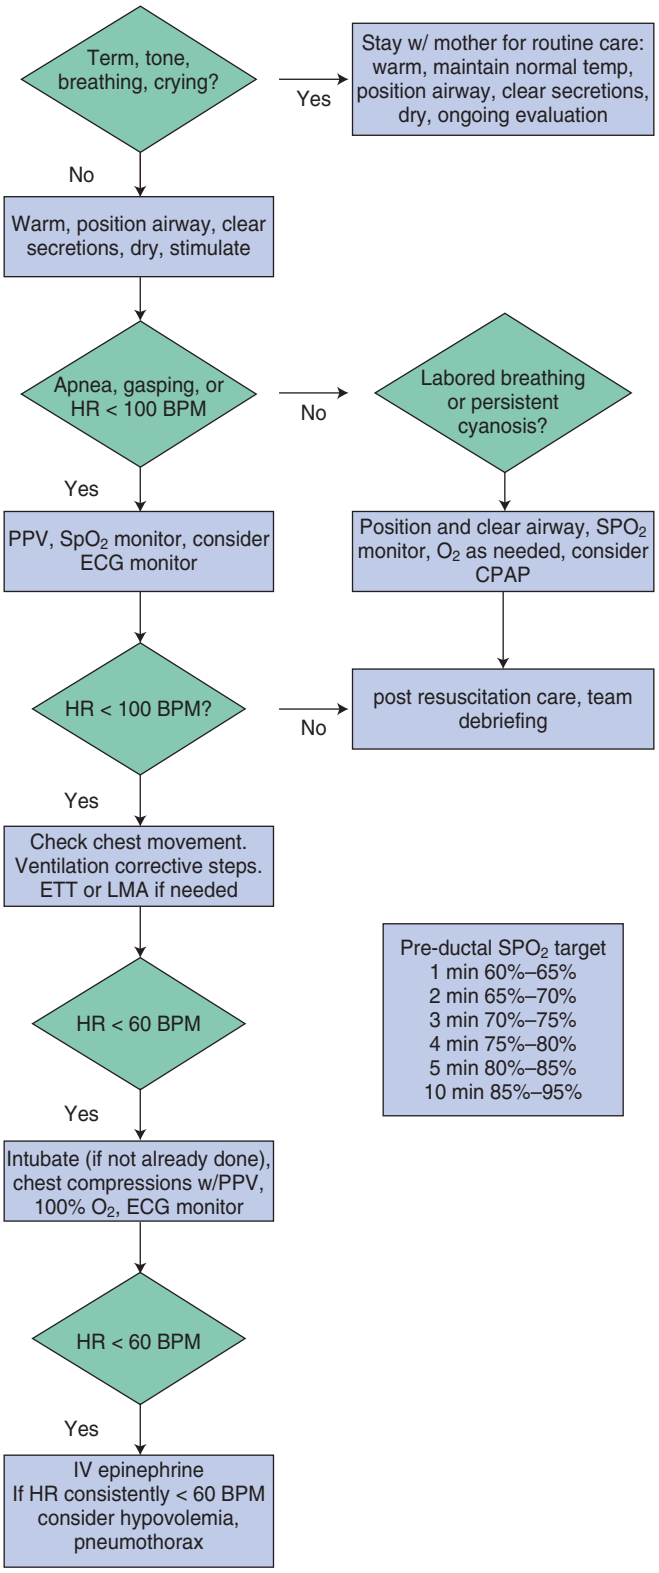

Fig. 54.2 Neonatal resuscitation algorithm. *CPAP,* Continuous positive airway pressure; *ETT,* endotracheal tube; *LMA,* laryngeal mask airways; *PPV,* positive pressure ventilation.

TABLE 54.2 Apgar Scoring System for Newborn Assessment

	SCORE		
Sign	**0**	**1**	**2**
Heart rate	Absent	<100/min	>100/min
Respirations	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion	Active motion
Reflex irritability (catheter in nares, tactile stimulation)	No response	Grimace	Cough, sneeze, cry
Color	Blue or pale	Pink body with completely blue extremities	Pink

Assessment of Gestational Age

Gestational age assessment and assessment of relationship of weight to gestational age are performed shortly after delivery. Determination of gestational age involves assessment of multiple physical characteristics and neurologic signs. Two common systems are used to determine gestational age: the Dubowitz scales and the Ballard scales. The Dubowitz scales involve assessment of 11 physical and 10 neurologic signs.[5] Physical criteria include assessment of skin texture, skin color, and genitalia. Neurologic criteria include posture and arm and leg recoil. The Ballard scales are a simplified version of the Dubowitz scales and include six physical and six neurologic signs as illustrated in Fig. 54.3. The New Ballard Scale is an updated version expanded to include extremely preterm infants. Both the Dubowitz and New Ballard scales may predict gestational age ± 14 days.[6] Soon after delivery, the newborn is stabilized and weighed, followed by determination of gestational age. Infants born between 38 weeks and 42 weeks are considered term gestation. Infants born before 38 weeks are preterm. Infants born after 42 weeks are post term.

All newborns weighing less than 2500 g are considered low birth weight. Newborns weighing less than 1500 g are considered **very low birth weight (VLBW).** Newborns weighing less than 1000 g are considered **extremely low birth weight (ELBW).** A newborn with a weight that is either too large or too small or who has been born preterm or post term has a higher risk of morbidity and mortality. As shown in Fig. 54.4, by plotting the infant's gestational age against weight, the newborn's relative developmental status can be classified. Infants whose weight falls between the 10th and 90th percentiles are **appropriate for gestational age (AGA).** Infants whose weight is greater than the 90th percentile are **large for gestational age (LGA).** Infants whose weight is less than the 10th percentile are **small for gestational age (SGA).**

RULE OF THUMB Infants weighing less than 2500 g are normally considered low-birth-weight (LBW) neonates. Infants weighing less than 1500 g are considered VLBW (very LBW) neonates, and neonates weighing less than 1000 g are considered ELBW (extremely LBW) neonates.

Neuromuscular maturity

	–1	0	1	2	3	4	5
Posture	—						—
Square window (wrist)	>90°	90°	60°	45°	30°	0°	—

Fig. 54.3 The Ballard gestational age assessment. (Modified from Ballard JL, et al. Assessment of gestational age, *J Pediatr.* 1979;95:769.)

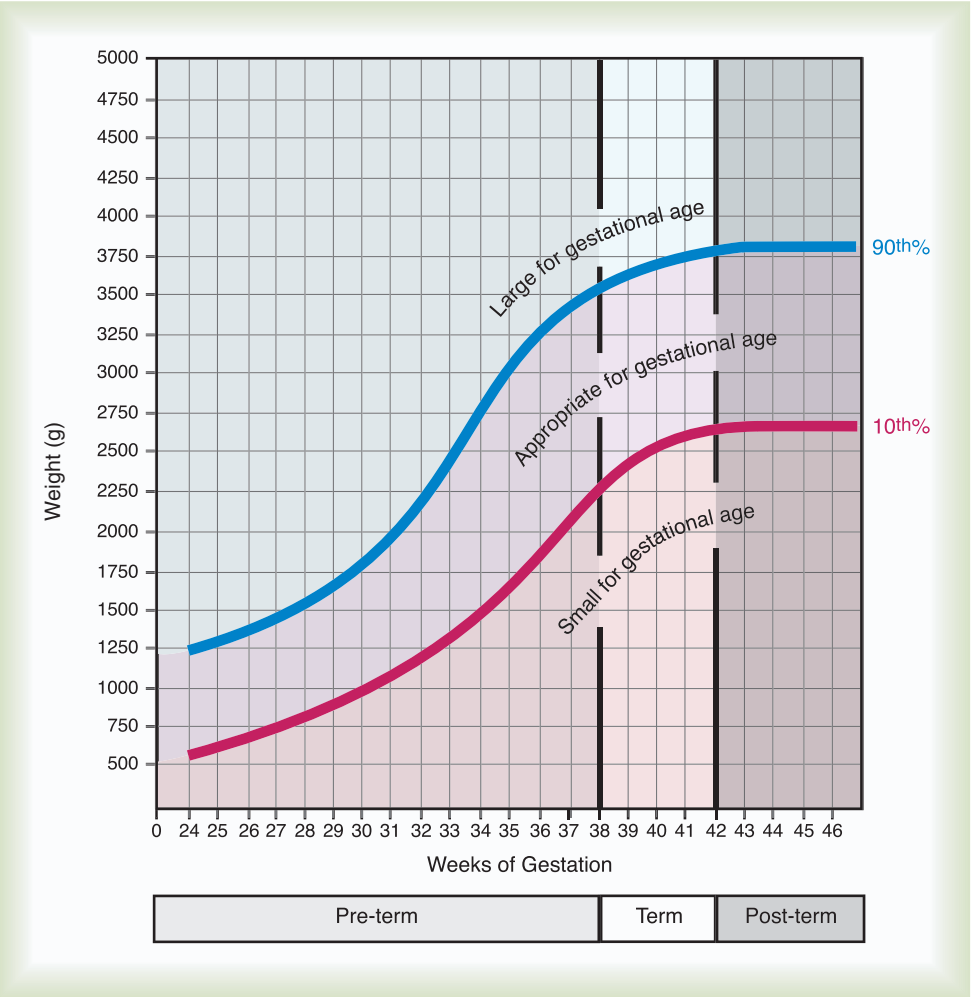

Fig. 54.4 Colorado intrauterine growth chart. (Modified from Avery GB, ed. *Neonatology: Pathophysiology and management of the newborn*. 4th ed. Philadelphia: JB Lippincott; 1994.)

By classifying infants into one of the combined categories, such as "preterm, AGA," the clinician can help to identify infants at highest risk and predict the nature of the risks involved and the likely mortality rate. Small, preterm infants are at highest risk. Compared with term infants, the lungs of these infants are not yet fully prepared for gas exchange. In addition, their digestive tracts cannot normally absorb fat, and their immune systems are not yet capable of warding off infection. Small, preterm infants also have a very large surface area-to-body weight ratio; this increases heat loss and impairs thermoregulation. Finally, the vasculature of these small infants is underdeveloped, increasing the likelihood of hemorrhage (especially in the ventricles of the brain).

RULE OF THUMB Infants born before 38 weeks' gestation are considered preterm.

Respiratory Assessment of the Infant

Not all respiratory problems occur at birth; many respiratory disorders develop after birth and may develop slowly or suddenly. RTs are commonly called on to help assess and treat infants who develop respiratory distress after birth.

Physical Assessment

Physical assessment of the infant begins with measurement of vital signs. A normal newborn respiratory rate is 40 to 60 breaths/min. The lower the gestational age, the higher the normal respiratory rate will be. A 28-week gestational age infant may normally breathe 60 times a minute, whereas the rate more typical of a term newborn is 40 breaths/min. Tachypnea (>60 breaths/min) can occur because of hypoxemia, acidosis, anxiety, or pain. Respiratory rates less than 40 breaths/min should be interpreted with previous trends of the newborn's respiratory rate. A baseline respiratory rate of 36 breaths/min in a term newborn is within normal limits; however, a respiratory rate of 36 breaths/min in a preterm newborn previously breathing at 70 breaths/min may indicate compromise. Causes of slow respiratory rates include medications, hypothermia, or neurologic impairment.

Normal infant heart rates range from 100 to 160 beats/min. Heart rate can be assessed by auscultation of the apical pulse, normally located at the fifth intercostal space, midclavicular line. Alternatively, the brachial and femoral pulses may be used. Weak

pulses indicate hypotension, shock, or vasoconstriction. Bounding peripheral pulses occur with major left-to-right shunting through a **patent ductus arteriosus (PDA).**[7] A strong brachial pulse in the presence of a weak femoral pulse suggests either PDA or coarctation of the aorta. Table 54.3 lists normal ranges of blood pressure for neonates of different sizes.

RULE OF THUMB The normal respiratory rate for a full-term infant is 40–60 breaths/min.

Chest examination in an infant is more difficult to perform and interpret than in an adult because of the small chest size and the ease of sound transmission through the infant chest. Thorough observation of the infant greatly enhances the assessment data obtained. Infants in respiratory distress typically exhibit one or more key physical signs: nasal flaring, cyanosis, expiratory grunting, tachypnea, retractions, and paradoxical breathing. Nasal flaring is seen as dilation of the ala nasi on inspiration. The extent of flaring varies according to facial structure of the infant. Nasal flaring coincides with an increase in the work of breathing. In concept, nasal flaring decreases the resistance to airflow. It also may help to stabilize the upper airway by minimizing negative pharyngeal pressure during inspiration.[8] Cyanosis may be absent in infants with anemia, even when arterial partial pressure of oxygen (PaO_2) levels are decreased. In addition, infants with elevated fetal hemoglobin levels may not become cyanotic until PaO_2 decreases to less than 30 mm Hg. Hyperbilirubinemia, common among newborns, may mask cyanosis. Grunting occurs when infants exhale against a partially closed glottis. By increasing airway pressure during expiration, grunting helps to prevent airway closure and alveolar collapse. Grunting is most common in infants with RDS, but it is also seen in other respiratory disorders associated with alveolar collapse. Fig. 54.5 illustrates the Silverman score, which is a system of grading severity of lung disease.

Retractions refer to the drawing in of chest wall skin between bony structures. Retractions can occur in the suprasternal, substernal, and intercostal regions. Retractions indicate an increase in the work of breathing, especially because of decreased pulmonary compliance. Paradoxical breathing in infants differs from paradoxical breathing normally seen in adults. Instead of drawing the abdomen in during inspiration, an infant with paradoxical breathing tends to draw in the chest wall. This inward movement of the chest wall may range in severity. As with retractions, paradoxical breathing indicates an increase in ventilatory work. Applying high-flow nasal cannula (HFNC) or continuous positive airway pressure (CPAP) to a newborn exhibiting signs of respiratory distress including **grunting, flaring, and retracting** may help to increase lung volume by preventing alveolar collapse and improve gas exchange. The benefits of HFNC and CPAP in children are discussed in more detail later.

TABLE 54.3 Normal Neonatal Blood Pressures

Weight (g)	Systolic (mm Hg)	Diastolic (mm Hg)
750	35–45	14–34
1000	39–59	16–36
1500	40–61	19–39
3000	51–72	27–46

Surfactant

Surfactant production begins around the 24th week of gestation and continues through gestation. Surfactant contributes to the stability of the alveolar sacs by reducing the surface tension of the fluids that coat the alveoli. Surfactant deficiency places an

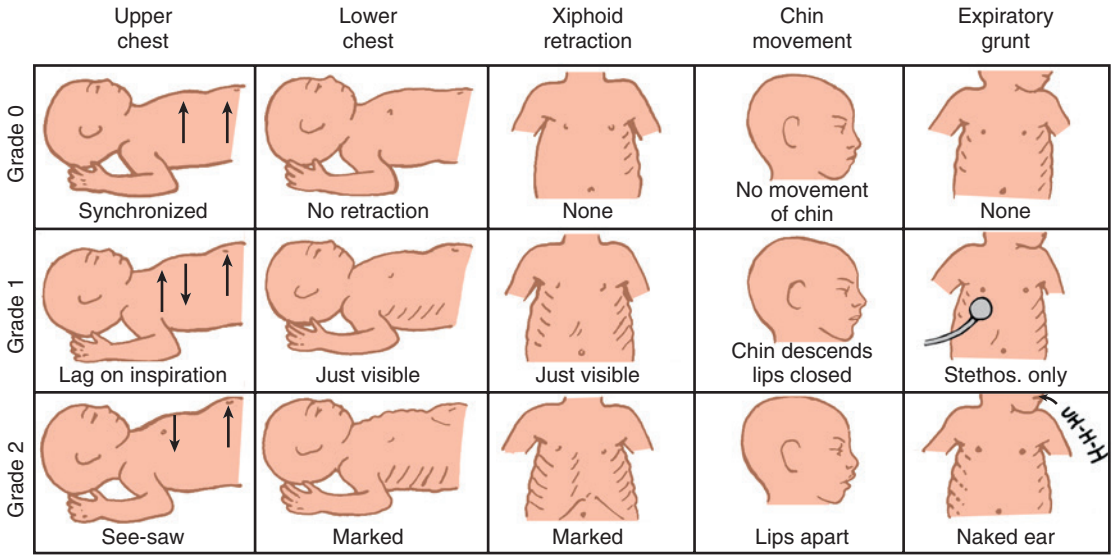

Fig. 54.5 Silverman score—a system for grading severity of underlying lung disease. (Modified from Silverman WA, Anderson DH. A controlled clinical trial of effects of water mist on obstructive respiratory signs, death rate and necropsy findings among premature infants, *Pediatrics*. 1956;17(1):1–70.)

infant at increased risk for respiratory distress. By approximately 34 weeks' gestation, most infants have produced enough surfactant to keep the alveoli from collapsing. Surfactant deficiency is due to lung immaturity. There are two specific approaches to preventing and treating surfactant deficiency. When a premature delivery is anticipated, steroids are given to the mother to help promote lung maturation. In addition, infants born before 35 weeks' gestation, especially infants born very prematurely (<30 weeks), should be assessed clinically for the need to receive exogenous surfactant. The need for surfactant is determined by assessing the infant's lung volume on chest x-ray, evaluating the inspired O_2 concentration to maintain O_2 saturations greater than approximately 88%, and clinically assessing the infant's work of breathing.

Evidence supports early surfactant replacement, immediately following delivery, for infants less than 27 weeks' gestation. Infants 27 to 30 weeks' gestation should be placed on HFNC or CPAP and evaluated clinically for the need to receive surfactant.[9–12]

Surfactant administration has also been shown to be useful in conditions in which surfactant structure and/or function has been altered. These conditions include meconium aspiration, neonatal pneumonia, pulmonary hemorrhage, and primary surfactant deficiency. See later section regarding administration of surfactant.

Blood Gas and Pulse Oximetry Analysis

Blood gas analysis is helpful in assessing respiratory distress in an infant. Many noninvasive techniques, such as transcutaneous partial pressure of oxygen ($PtcO_2$), transcutaneous partial pressure of carbon dioxide ($PtcCO_2$), end-tidal carbon dioxide (CO_2), and pulse oximetry (SpO_2), are used to obtain comparable data, although blood gas analysis is more precise when results are critical. An infant blood gas sample can be obtained from an artery or capillary. Chapter 19 summarizes the advantages, disadvantages, and complications of these sampling methods. Care must be taken in assessing the results of capillary sampling. Capillary blood gases provide information regarding only ventilation and acid–base status, and accuracy is highly dependent on technique.[13] Normal values for infant blood gases are listed in Table 54.4.

Monitoring O_2 saturation using a pulse oximeter is a standard of care for sick newborns. Saturation probes must be carefully placed on the newborn; the most common sites are the wrist, the medial surface of the palm, or the foot. Sufficient cardiac output and skin blood flow are essential to provide an accurate saturation value. The pulse rate indicated on the oximeter should correlate with the infant's actual pulse before any conclusions regarding saturation can be drawn. Intracardiac shunting and intrapulmonary shunting are causes of decreased saturation in sick infants. When interpreting saturation levels in a newborn, it is important to consider where the saturation is being monitored. Saturation probes placed on the right hand assess preductal saturations. Probes placed on other extremities indicate postductal saturation levels. Infants at risk for pulmonary hypertension should have saturation probes placed to monitor preductal and postductal saturations. A large difference (>5%) between the two readings should prompt the clinician to consider pulmonary hypertension as a potential concern. Conditions that prevent the closing of the ductus arteriosus and foramen ovale result in decreased saturation. Many congenital heart defects result in significant intracardiac shunting. Interpreting adequate saturation for a newborn requires knowledge of any cardiac defect along with the infant's pulmonary condition.

MINI CLINI

Neonatal Ventilation

Problem

A 1.8-kg, 28-week newborn is transported from the delivery room to the neonatal intensive care unit (NICU). The patient was apneic and bradycardic at birth and failed to respond to initial stimulation and resuscitation. He was intubated with a 3.0 uncuffed endotracheal tube. His heart rate increased to 120 beats/min, and he has been manually ventilated with a T-piece resuscitator at a peak inspiratory pressure (PIP) of 20 cm H_2O and Positive end-expiratory pressure (PEEP) of 7 cm H_2O during transport. When the neonate is admitted to the NICU, the respiratory therapist (RT) is asked to recommend appropriate ventilator settings.

Solution

- Mode—assist/control (A/C) pressure ventilation
- PIP—20 cm H_2O
- PEEP—7 cm H_2O
- Set respiratory rate—40 breaths/min
- Inspiratory time—0.3 s

Modified from Orzalesi MM, Mendicini M, Bucci G, et al. Arterial oxygen studies in premature newborns with and without mild respiratory disorders. *Arch Dis Child.* 1967;42:174. From Koff PB, Eitzman DV, Neu J. *Neonatal and pediatric respiratory care.* 2nd ed. St Louis: Mosby; 1993.

Because the patient was manually ventilated during transport, it is unclear what tidal volume (V_T) has been delivered. Initial PIP of 20 cm H_2O and PEEP of 7 cm H_2O are safe and common settings. Immediate observation of the chest would allow the RT to evaluate chest expansion and adjust PIP as required. Over the next several minutes if V_T monitoring is available, targeting V_T of 6 to 8 mL/kg would guide subsequent settings.

Set respiratory rate of 40 breaths/min is at the lower end of the normal range for this patient; however, use of the A/C mode with a time-cycled, pressure-limited breath, and appropriately set trigger sensitivity would allow the patient to establish a more comfortable respiratory rate. Adjustment of the inspiratory time may also be necessary to increase patient comfort and improve patient–ventilator synchrony. Further adjustments may be guided by $PaCO_2$. Because this patient was born prematurely, rapid assessment of pulse oximetry (SpO_2) is essential, and FiO_2 should be adjusted to maintain SpO_2 between 89% and 94%.

This patient should receive surfactant replacement therapy. The clinician may consider volume-targeted, pressure-limited ventilation (e.g., pressure-regulated volume control, volume guarantee) during and immediately after surfactant delivery. This modality may help to prevent lung overdistension until compliance has stabilized.[14–16]

Respiratory Assessment of the Pediatric Patient

Normal breathing in children is evidenced by quiet inspiration and passive expiration at an age-appropriate rate. Respiratory rates are rapid in neonates and decrease in toddlers and older children. Table 54.5 lists normal respiratory rates. The American Heart Association, in conjunction with the American Academy of Pediatrics, has developed a Pediatric Advanced Life Support (PALS) program. This program is similar to the Advanced Cardiac Life Support (ACLS) program used for adults, with a focus on the pediatric patient. The program includes such topics as primary assessment, diagnostic testing, respiratory failure and other emergencies, emergency equipment and medications including pediatric dosing guidelines, shock, cardiac arrythmia, cardiac arrest, and postresuscitation management. PALS certification should be an integral part of the curriculum for RTs specializing in care of the pediatric patient.

The initial assessment of a pediatric patient starts with evaluating airway patency. Normal heart rates are higher in younger children and decrease with age. In assessing a pediatric patient, establishing if the airway is patent or has any obstructive component is essential. Signs that suggest upper airway obstruction include increased inspiratory effort with retractions or inspiratory efforts with no airway or breath sounds.

TABLE 54.5 Normal Respiratory and Heart Rates by Age

Age	Breaths/Minute	Heart Rates
Infants (<1 year)	30–60	90–120
Toddler (1–3 years)	24–40	80–100
Preschooler (4–5 years)	22–34	70–90
School age (6–12 years)	18–30	70–90
Adolescent (13–18 years)	16–22	60–80

The clinician should assess for movement of the chest and abdomen. The clinician listens for breath sounds focusing on both inspiratory sounds and expiratory sounds. Chest or abdominal movement without breath sounds may indicate total airway obstruction, and basic life-support maneuvers are indicated. High-pitched sounds heard on inspiration (stridor) are often indicative of upper airway conditions, whereas expiratory noises are more often associated with lower airway obstruction.

Causes of stridor in children can be infections, such as croup; foreign body aspiration, particularly in a small child; congenital or acquired airway abnormalities; allergic reactions; or edema after a procedure. Inhaled epinephrine via nebulizer and intravenous steroids are commonly used to treat stridor. Common causes of lower airway obstruction are bronchiolitis and asthma. When wheezing is noted, inhaled bronchodilators are indicated. If the patient is able to use a metered dose inhaler (MDI), repeated inhalations can act quickly to improve aeration. When the patient is unable to use the MDI appropriately or when severe symptoms are present, delivering a bronchodilator with a nebulizer can bring relief. More than one nebulizer treatment often is necessary to relieve airway inflammation. A common approach is to deliver three consecutive treatments. If the patient continues to be symptomatic, continuous bronchodilator therapy may be delivered with a nebulizer attached to an infusion pump set to administer a bronchodilator continuously. Tachycardia secondary to the beta-1 effect of inhaled bronchodilators may occur. Frequent reassessment of any patient receiving continuous bronchodilator therapy is essential. Heliox, an inhaled mixture of helium and O_2 (described in the section on specialty gases), has been shown to be beneficial in cases of some airway conditions in children.

As noted in the section describing newborn assessment, use of accessory muscles, grunting, flaring, and retracting all can be signs of respiratory distress. Head bobbing, noted by chin up and neck extended during inspiration with chin falling during expiration, and seesaw respirations, indicated by the chest retracting and the abdomen expanding during inspiration, are signs of impending respiratory failure. Assessing the child's level of alertness is essential. Levels of alertness range from fully awake, agitated, minimally responsive, to unresponsive. A child's ability to protect his or her airway should be questioned in a minimally responsive or unresponsive child.

RESPIRATORY CARE

Respiratory care of infants and children incorporates approaches taken from adult practice. Important physiologic and age-related differences between adults and children require variations in the provision of respiratory care. This section focuses on neonatal and pediatric O_2 therapy, bronchial hygiene, humidity and aerosol therapy, airway management, and resuscitation.

Oxygen Therapy

Goals and Indications

O_2 should be administered as any other drug, using the lowest dose necessary to achieve the intended goal. The goal of O_2 therapy is to provide adequate tissue oxygenation. However, O_2 therapy is most frequently adjusted according to O_2 saturation

levels. A clear understanding of the limitation of O_2 saturation (See Chapter 19) is needed to interpret the saturation reading and make appropriate decisions. Infants and children receiving O_2 therapy have variable O_2 saturation target ranges depending on age and underlying condition.

Lower saturation levels are targeted in infants less than 32 weeks' gestation. There is evidence that exposure to supplemental O_2 in a premature infant is a risk factor for the development of **retinopathy of prematurity (ROP).** ROP is caused by an abnormal vascularization of the retina, which in the most severe cases leads to retinal detachment. Preterm neonates weighing less than 1500 g are most susceptible. Hyperoxia is not the only factor associated with ROP, but close monitoring and adjusting of O_2 therapy to avoid hyperoxia are crucial to decrease the risk of ROP. A specific saturation goal of 88% to 94% should be established for this age group, and O_2 should be adjusted to maintain the intended target. Avoiding very high or very low saturation levels is critical. Adjusting the delivered O_2 concentration by small increments avoids large swings in saturation levels.[17–21]

In a term infant with **primary pulmonary hypertension of the newborn (PPHN),** a higher targeted saturation level is desired to avoid further pulmonary constriction associated with hypoxemia. The position of the saturation probe needs to be considered when interpreting saturation. Intracardiac shunting can occur in the presence of PPHN. One saturation probe positioned on the upper right extremity represents preductal saturations and is indicative of the saturation of blood being delivered to the brain. O_2 saturation measured on other extremities is considered postductal and represents saturation to other parts of the body.

Newborns with certain cardiac anomalies are dependent on their intracardiac shunt through the ductus arteriosus to survive. An increased saturation in newborns promotes constriction of the ductus arteriosus. Although this constriction is normally a positive response, it may cause premature closure of the ductus arteriosus in infants with ductal-dependent congenital heart defects. An infant born with hypoplastic left heart syndrome, a defect in which the left-sided heart structures are poorly developed, relies on the patency of the ductus arteriosus for systemic blood supply. In addition, hyperoxia can increase aortic pressures and systemic vascular resistance, decreasing the cardiac index and O_2 transport in children with acyanotic congenital heart disease. The emphasis for O_2 therapy for all newborns should be to provide only as much O_2 as indicated by the infant's condition. O_2 therapy should be administered using a written care plan with specified clinical outcomes (e.g., titrate flow/FiO_2 to maintain SpO_2 89% to 92%, notify physician if FiO_2 is >0.40). An example of an oxygen therapy guideline/order is shown in Table 54.6.

Methods of Administration

The effectiveness of O_2 devices depends on the performance characteristics of the device (delivered FiO_2, flow rate, relative humidity), the interface of the device, and the tolerance of the patient for using the device. Children are often frightened and combative, making it impractical to use some O_2 administration devices. Selection of an O_2 device must be based on the degree of hypoxemia and the emotional and physical needs of the child and family (see Chapter 42 Medical Gas Therapy). O_2 can be administered to infants and children by mask, cannula, high-flow nasal cannula, or oxyhood. Table 54.7 compares the advantages and disadvantages of standard O_2 delivery methods.

Surfactant Administration

Exogenous pulmonary surfactant replacement therapy is indicated in the delivery room for infants 27 weeks' gestation or less. Surfactant should also be given to infants born at 27 to 29 weeks' gestation if they are intubated for severe RDS, surfactant deficient neonates with RDS evident by clinical presentation and term or

TABLE 54.6 Oxygen Saturation Goals

Preterm, ROP risk: on SpO_2 89%–94%
Preterm, ROP risk: on room air SpO_2 89%–100%
Preterm, 31–34 weeks: SpO_2 91%–96%
Preterm, ≥ 35 weeks or term: SpO_2 93%–100%
Pulmonary hypertension: SpO_2 96%–100%

ROP, Retinopathy of prematurity.

TABLE 54.7 Oxygen Delivery Devices

Device	Age	FDO_2	Advantages	Disadvantages
Air entrainment mask	≥3 years	High flow; 0.24–1	Precise FiO_2; good for transport; ease of application	Low relative humidity; pressure necrosis to face; difficult to fit and maintain on active child, not recommended for infants; risk of aspiration
Nasal cannula	Premature infants to adult	Low flow; 25 mL/min–6.0 L/min	Tolerated well by all ages	Inaccurate FiO_2; low relative humidity; excessive flows may cause inadvertent CPAP in infants; precise FiO_2 may be achieved with O_2 blender
Incubator	Newborns ≤28 days	<0.40 FiO_2, combine use with cannula or hood for precise FiO_2	Low FiO_2 for stable infants; neutral thermal environment for premature infants	Varying FiO_2; long stabilization time; limits access to child for patient care
Oxyhood	Premature infants to ≤6 months	0.21–1 FiO_2 with O_2 blender maintained at 30°C–34°C	Warmed and humidified gas at stable FiO_2 during routine patient care	Overheating may cause apnea and dehydration; underheating may cause O_2 consumption; inadequate flow causes CO_2 buildup; noise produced by humidification device may cause hearing loss

CPAP, Continuous positive airway pressure; *FDO_2,* delivered oxygen concentration.

MINI CLINI

Neonatal High-Flow Nasal Cannula

Problem

A baby girl 30 weeks' gestation is delivered by emergency C-section for fetal distress (nonreassuring fetal heart tracing [NRFHT]) and admitted to the neonatal intensive care unit (NICU) for issues of prematurity and moderate respiratory distress. Respiratory rate is 70 breaths/min, and pulse oximetry (SpO_2) is 84%. The respiratory therapist places a high-flow nasal cannula on the patient at 6 L/min and 40% oxygen. Respiratory rate decreases to 50 breaths/min, and SpO_2 increases to 99%.

Solution

The respiratory therapist should decrease the FiO_2 to meet SpO_2 goal of 89%–94%. The flow should be maintained at 6 L/min, the same level of continuous positive airway pressure (CPAP) which has decreased the patient's work of breathing and oxygen requirement. The flow should not be decreased until the FIO_2 requirement falls below 0.3.

postterm neonates with meconium aspiration syndrome (MAS) or pneumonia/sepsis.

The recommended first dose for treatment of RDS or MAS is 2.5 mL/kg. Repeat doses of 1.25 mL/kg may be given q12hr for a maximum of three doses. Redosing is not advised within 12 hours. Maximum total dose is 5 mL/kg.

Administration of surfactant requires intubation. It is essential to ensure the endotracheal tube is properly positioned, approximately 0.5 to 1 cm above the carina, before delivering surfactant. The dose depends on the specific brand of surfactant being administered. Close monitoring of the infant's vital signs, O_2 saturation, and compliance is necessary during and after surfactant administration. Soon after surfactant is delivered, the infant's compliance should begin to increase resulting in improved gas exchange. Ventilating pressures and FiO_2 need to be decreased to avoid lung injury and excessive partial pressure of O_2. The ventilating pressure should be decreased to the level that maintains a tidal volume (V_T) of 5 to 7 mL/kg. FiO_2 should be decreased to maintain an oxygen saturation level (SpO_2) of approximately 89% to 94% in preterm infants and to the lowest FiO_2 possible to maintain SpO_2 greater than 92% in term or postterm infants. Those with primary pulmonary hypertension should have an SpO_2 greater than 95%.

Secretion Clearance Techniques

Secretion clearance techniques that can be applied to infants and children include chest physiotherapy, positive expiratory pressure therapy, autogenic drainage, flutter therapy, and mechanical insufflation-exsufflation (MIE)[22, 23] (see Chapter 44). Secretion clearance techniques are considered when accumulated secretions impair pulmonary function and an infiltrate is visible on a chest radiograph. Secretion retention is common in children who have pneumonia, bronchopulmonary dysplasia, cystic fibrosis, bronchiectasis, and some neuromuscular diseases. Fig. 54.6 shows postural drainage and percussion positions for infants and children.

Methods

Infants and young children cannot cough on command. For this reason, secretions often must be removed by suctioning. For

MINI CLINI

Secretion Clearance Using Mechanical Insufflation-Exsufflation

Problem

A 1-year-old boy with a diagnosis of type I spinal muscle atrophy (SMA) and history of intermittent left lobe collapse is admitted to the pediatric intensive care unit. The patient's home regimen includes use of around the clock room air noninvasive ventilation (NIV), with intermittent periods off for up to an hour, 4–6 times daily. For the past week the patient has required increasing use of NIV and is unable to tolerate periods off for more than 15–20 min. He currently has an increase from his baseline NIV settings and an oxygen requirement of 3 L/min attached to his NIV device. Breath sounds reveal bilateral rhonchi with decreased aeration on the left. The patient is started on mechanical insufflation-exsufflation (MIE) therapy with an inspiratory pressure of 40 cm $H_2O \times 1$ second, expiratory pressure of –40 cm $H_2O \times 1$ s, and a 1 s rest period. This is performed for five breaths, followed by tracheal suctioning and the cycle is repeated 5 times every 2 h. After 48 h the patient has been returned to baseline NIV settings, and use of the MIE has been reduced to every 4 h. He is able to tolerate increasing periods of time, 45 min to 1 h, off NIV up to 4 times daily.

older children with excessive secretions, directed deep breathing and coughing may help to improve pulmonary clearance. The use of MIE in children with neuromuscular disease can be helpful in clearing secretions. Adjunctive therapy devices such as positive expiratory pressure, flutter, or intermittent percussive ventilation therapy have been effective in secretion clearance in patients with cystic fibrosis.[24]

Patients with SMA and other forms of neuromuscular disease are unable to generate an effective cough sufficient to mobilize retained secretions. Use of an MIE in conjunction with tracheal suctioning and increased NIV settings may provide sufficient additional respiratory support to assist patients in overcoming an acute crisis, preventing the need for intubation and invasive mechanical ventilation, allowing them to return to their baseline level of support.

Monitoring

Given the instability of most critically ill infants and children, a thorough initial assessment and ongoing patient evaluation during and after treatment are mandatory. Traditional assessment of vital signs, blood pressure, color, and breath sounds before, during, and after treatment should be supplemented with pulse oximetry monitoring if hypoxemia is suspected.

Humidity and Aerosol Therapy

Key differences in humidity and aerosol therapy in infants and children include assessment of patient response to therapy, age-related physiologic changes, and equipment application (see Chapter 39).

Humidity Therapy

In children with an intact upper airway, O_2 therapy devices, such as low-flow nasal cannulas, do not routinely need to be humidified. However, any time the upper airway is bypassed by intubation, supplemental humidification must be provided using a heated

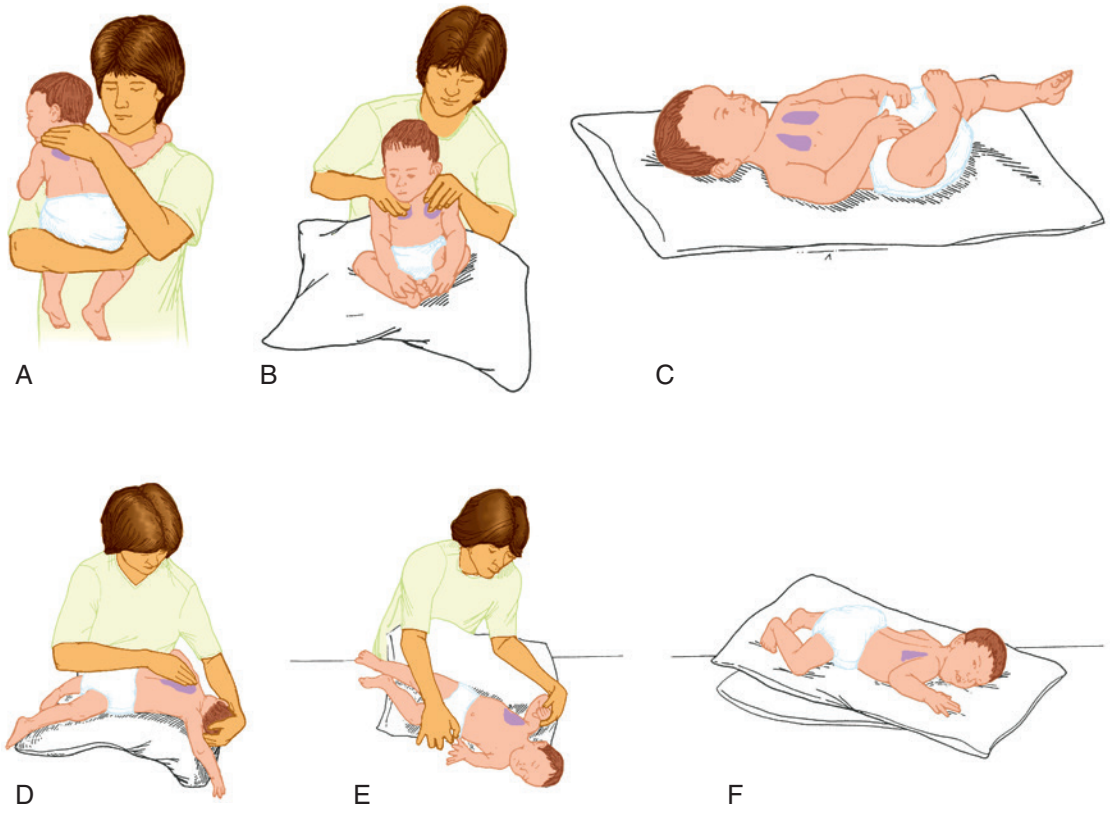

Fig. 54.6 Postural drainage and percussion positions for infant and child. Angles of drainage for infant are not as obtuse as those for child. (A) Posterior segments of right and left upper lobes are drained with patient in upright position at 30-degree angle forward. Percuss over upper posterior thorax. (B) Apical segments of right and left upper lobes are drained with patient in upright position, leaning forward 30 degrees. Percuss over area between clavicle and tip of scapula on each side. (C) Anterior segments of right and left upper lobes are drained with patient in flat, supine position. Percuss anterior side of chest directly under clavicles to around nipple area *(shaded)*. Avoid direct pressure on sternum. (D) Right and left lateral basal segments of lower lobes are drained at 30 degrees Trendelenburg. Patient lies on appropriate side, rotated 30 degrees forward. Percuss over uppermost portions of lower ribs. (E) Right and left anterior basal segments of lower lobes are drained at 30 degrees Trendelenburg. Patient lies on appropriate side with a 20-degree turn backward. Percuss above anterior lower margin of ribs. (F) Right and left superior segments of lower lobes are drained at 15 degrees Trendelenburg, with patient in prone position. Percuss below scapula in midback area.

humidifier. Humidification of inspired gases for infants and children receiving mechanical ventilation is commonly provided by a servo-controlled humidifier. Ideal features for these systems include the following: (1) low internal volume and constant water level to minimize compressed volume loss; (2) closed, continuous feed water supply to avoid contamination; (3) distal airway temperature sensor and high/low alarms. Common problems with humidifier systems include condensation in the tubing, inadequate humidification, and hazards associated with the heating coil.[25,26] Using heated wire circuits can also reduce condensation in the circuit. Frequent evaluation of the humidification system is necessary to increase the potential of adequate humidity delivered to the airway. Inadequate humidification occurs in nonheated circuits when the humidifier temperature probe is placed too far upstream from the airway connector. Variable humidification problems occur when ventilator circuits pass through an environment and then into a warmed enclosure, such as an incubator or radiant warmer.

Aerosol Drug Therapy

Drug action in infants and children differs significantly from drug action in adults because of differences in physiology, which may include immature enzyme systems, immature receptors, and variable gastrointestinal absorption (see Chapters 36 and 40). Dosing may be imprecise, and systemic effects may be hard to predict. Table 54.8 lists aerosolized medications commonly used in children.

Small volume nebulizers (SVNs), vibrating mesh nebulizers, MDIs, and dry powder inhalers (DPIs) can be used to deliver aerosolized drugs via mouthpiece or face mask to infants and children.[27] Continuous aerosol drug therapy is also used for patients unresponsive to intermittent SVN treatments. Aerosol drug administration to intubated infants and children is challenging because of the decreased deposition from baffling of small endotracheal tubes in these patients, which prevents approximately 90% of the drug from entering the lungs, regardless of delivery system. In addition, careful adjustments must be

TABLE 54.8 Commonly Used Aerosolized Medications

Medication Name	Dosage Form	Usual Child Dose	Comments
Bronchodilators			
Beta-2 Agonists			
Albuterol (Proventil, Ventolin)	MDI (90 mcg/puff)	1–2 puffs MDI q 15 min to q 6 h ± PRN	May be used 15 min before exercise to prevent exercise-induced bronchospasm; should be used as a rescue medication
	Nebs (0.5%, 5 mg/mL)	0.01–0.05 mL/kg/dose (maximum 1 mL/dose) neb q 15 min to q 6 h ± PRN	
	Rotohaler (200 mcg caps)	1–2 caps inhaled q 15 min to q 6 h ± PRN	
Levalbuterol (Xopenex)	Nebs (0.63 mg/3 mL, 1.25 mg/3 mL)	0.32–1.25 mg neb q 6–8 h ± PRN	May still cause extrapulmonary side effects including tachycardia and hypokalemia
Salmeterol (Serevent)	MDI (21 mcg/puff)	2 puffs inhalation q 12 h	Not to be used as a rescue medication; long-acting beta-2 agonist; QT_C prolongation has occurred in overdose
	DPI-Diskus (50 mcg/inhalation)	1 inhalation q 12 h	
Anticholinergic			
Ipratropium (Atrovent)	MDI (18 mcg/puff)	2 puffs inhalation q 4–6 h ± PRN	MDI is contraindicated in patients with peanut allergy; for neonates, use 25 mcg/kg/dose neb tid; may cause mydriasis if aerosolized drug gets into the eye
	Nebs (0.02%)	0.25–0.5 mg neb q 4–6 h ± PRN	
Antiinflammatory Agents			
Corticosteroids			
Beclomethasone (Beclovent, Qvar), Vanceril)	MDI (42 mcg/puff)	1–2 puffs inhalation qid or 2–4 puffs inhalation bid	Start at lower end of dosing range if patient not previously on steroids; titrate to lowest dose that is effective; always rinse mouth after each treatment
	MDI double strength (84 mcg/puff)	2 puffs inhalation bid	
Budesonide (Pulmicort)	DPI-Turbuhaler (200 mcg/inhalation)	1–2 puffs inhalation bid	May take several weeks to see benefit; not to be used as a rescue medication
	Nebs-Respules (0.25 mg/2 mL, 0.5 mg/2 mL)	0.25–0.5 mg neb bid *or* 0.5–1 mg neb qd	
Flunisolide (Aerobid, Aerobid-M)	MDI (250 mcg/puff)	2–3 puffs inhalation bid	
Fluticasone (Flovent)	MDI (44 mcg/puff, 110 mcg/puff, 220 mcg/puff)	2 puffs inhalation bid (maximum 880 mcg/d)	
	Rotadisk (50 mcg/blister)	50–100 mcg inhalation bid	
Mometasone (Asmanex)	Twisthaler (100 mcg puff, 200 mcg puff)	2 puffs inhalation bid	For use in patients 12 years and older
Ciclesonide (Alvesco)	80 mcg puff 160 mcg puff	2 puffs bid	For use in children 12 years and older
Mast Cell Stabilizers			
Nedocromil (Tilade)	MDI (1.75 mg/puff)	2 puffs inhalation qid	
Mucolytics			
N-acetylcysteine (Mucomyst)	Nebs (20%, 200 mg/mL)	3–5 mL neb qid	Consider pretreatment with albuterol 15 min before *N*-acetylcysteine secondary to bronchospasm
Dornase alfa (Pulmozyme)	Nebs (2.5 mg/2.5 mL)	2.5 mg neb qid-bid	May cause hemoptysis
Antiinfectives			
Pentamidine (Pentam)	Nebs (300 mg)	8 mg/kg/dose (maximum 300 mg/dose) neb q month	Used for PCP prophylaxis
Ribavirin (Virazole)	Powder (6 g vial)	2 g over 2 h neb q 8 h × 3–7 days *or* 6 g over 12–18 h neb q 24 h × 3–7 days	Used for RSV treatment; mutagenic, teratogenic
Tobramycin (TOBI)	Nebs (300 mg/5 mL)	300 mg neb q 12 h	Used for pseudomonal infection of the lungs

made to the ventilator so that nebulizer flows do not alter delivered V_T and inspiratory pressure and interfere with triggering efforts.[28] Newer vibrating mesh type nebulizers provide a more stable particle size and do not add additional flow to the breathing circuit. As a result, there is no change in the delivered V_T and patient triggering is not affected.

Airway Management

Airway management methods in infants and children are unique because of the anatomic differences between neonates and adults. Specifically, equipment and technique must be tailored to each child according to his or her size, weight, and postpartum age. Masks, resuscitation bags, oral airways, suction catheters, laryngoscope blades, and endotracheal tubes in a wide selection of infant and child sizes are needed to account for variations in patient age and weight. Table 54.9 provides recommendations regarding endotracheal tube and suction catheter sizes for infants and children.

Intubation

Endotracheal intubation is a generally safe method of airway management in infants and children, even when used for extended periods.[29,30] Complications and hazards associated with intubation in these age groups are listed in Box 54.1. The infant's age or weight can be used to estimate proper endotracheal tube size and depth of insertion. If the tube is too small in diameter, a leak may result, decreasing delivered minute ventilation. Small endotracheal tubes have high resistance, increasing the spontaneous work of breathing for the child. An inappropriately large endotracheal tube can cause mucosal and laryngeal damage that is evident after extubation, resulting in upper airway obstruction.[31]

Most neonatal and pediatric endotracheal tubes are uncuffed. The narrowest point of the airway in an infant and small child is the cricoid cartilage. When an appropriately sized uncuffed tube is positioned in the airway, the fit of the tube in the airway "seals" the airway enough so that adequate ventilation can usually be maintained. Cuffed endotracheal tubes are an option if a large leak persists around the tube and stable ventilation cannot be maintained. Similar to adults when a cuffed tube is used, careful attention to the pressure in the cuff on the tracheal wall is essential. Because the tongue is large and the epiglottis is anatomically high in infants and small children, practitioners generally find the Miller (straight) laryngoscope blade best for intubation. Infant endotracheal tubes are small and can be easily kinked or obstructed. In addition, slight changes in the position of the endotracheal tube in movement can result in bronchial intubation.

Once a tube is inserted, immediate securing of the tube to the infant's face and ongoing evaluation of the security of the tube are essential. Proper head positioning and avoidance of cumbersome connecting apparatus help to reduce the potential of accidental extubation. Estimates of the distance the tube should be inserted into the airway based on patient weight are provided in Table 54.10. Further confirmation of correct tube position should be evaluated with a chest x-ray. Noting the infant's head position when the chest x-ray is obtained is helpful in assessing appropriate tube position in the airway. Slight changes in head position can result in the tube position sitting too high or too low in the airway. In very small infants, slight flexion of the head can move the tube into the right main stem bronchus.

Breath sounds may be of limited value in infants and small children for evaluation of tube position. Portable end-tidal CO_2 monitoring devices may be used to help assess tracheal versus

BOX 54.2 Indications for Suctioning

Absolute Indications
- Secretions visible in endotracheal tube
- Aspiration of gastrointestinal or oropharyngeal contents
- Inadvertent water aspiration from ventilator circuit

Relative Indications
- Rhonchi noted during auscultation raising suspicion of retained secretions
- Change in compliance (↓ tidal volume [V_T] at same peak pressure or ↑ pressure for same V_T)
- ↑ Work of breathing
- ↓ SpO_2 with same or ↑ FiO_2

TABLE 54.11 Appropriate Sizes and Maximum Cuff Volumes of Laryngeal Mask Airways for Varying Weights

LMA Size	Patient Weight (kg)	Maximum Cuff Volume
1	1–5	4

2	10–20	10
2.5	20–30	14
3	30–40	20

LMA, Laryngeal mask airways.

esophageal intubation, although they should be used only as additional assessment tools with recognition of their limitations. Factors associated with accidental extubation of infants include tension on the tube from the ventilator circuit, patient agitation, suctioning, head turning, chest physiotherapy, too short a tube distance between lip and adapter, moving the patient during procedures, and inadequately taped endotracheal tube.[32–34] Infant-sized endotracheal tube holders are available, but use of these devices is sporadic and subjective

Laryngeal mask airways (LMAs) are available as an alternative to intubation. LMAs are typically used in children when a short-term airway is indicated, such as during some surgical procedures or when endotracheal intubation cannot be accomplished and an airway needs to be established. Table 54.11 outlines appropriate sizes and maximum cuff volumes of LMAs for varying weights.

Suctioning Intubated Pediatric Patients

The goal of suctioning is to remove secretions from large airways and stimulate a cough. Although suctioning can be beneficial, significant risks are associated with the procedure, including lung derecruitment, hypoxia, hypertension, increased intracranial pressure, tracheal trauma, and infection. Absolute and relative indications for suctioning are listed in Box 54.2.

Additional considerations include the use of closed suction catheters for all mechanically ventilated patients. The closed suctioning technique helps to minimize derecruitment, which is more likely to occur during ventilator disconnections. Care should be taken to minimize the addition of mechanical dead space associated with closed suction apparatus. An increase in O_2 concentration after suctioning may be necessary but should

be evaluated for each patient. To reduce the risk of tracheal trauma, suction catheters should not be inserted beyond the tip of the endotracheal tube or tracheostomy tube. Routine instillation of normal saline is not recommended. Increasing ventilator support to regain volume lost during the procedure may be necessary but should be assessed each time the patient is suctioned. Because of the risks associated with suctioning, the procedure should be performed only when a clinical indication exists, not on a fixed interval.

Suctioning. Nasopharyngeal and tracheal suctioning helps to minimize aspiration, prevents endotracheal tube occlusion, and reduces airway resistance in infants and children. Suctioning is a hazardous procedure, and complications can occur. Box 54.3 lists the common complications and hazards associated with tracheal suctioning of infants and children. Tracheal suctioning of preterm infants and neonates should be performed only when clinical signs indicate a need.

Oral and pharyngeal suctioning of infants can be done with a bulb syringe. A DeLee trap or a mechanical vacuum source with catheter may be used for nasopharyngeal and nasotracheal suctioning of neonates. Equipment for suctioning larger infants and children is similar to the equipment used with adults, with modifications in vacuum pressure and catheter size. Recommended suction pressures for neonates range from approximately −70 to −100 mm Hg. With large infants and children, pressures in the range of −100 to −120 mm Hg are generally safe and effective. Catheter sizes are chosen according to the age of the patient and the size of the tracheal airway. Other techniques for averting hypoxemia include use of endotracheal tube adapters that allow preoxygenation and suctioning without disconnection of the ventilator and use of closed tracheal suction systems.[35,36]

CONTINUOUS POSITIVE AIRWAY PRESSURE

Spontaneous breathing can be supported with **continuous positive airway pressure (CPAP),** a breathing mode that maintains a constant pressure above baseline throughout inspiration and expiration. Newborn infants have increased chest wall compliance along with decreased lung compliance, which makes them

prone to developing atelectasis. CPAP maintains inspiratory and expiratory pressures above ambient, which improves functional residual capacity (FRC) and static lung compliance.[37] It is essential that the patient is able to maintain adequate minute ventilation while breathing spontaneously because ventilatory support is not provided.

CPAP is indicated when arterial oxygenation is inadequate despite elevated FiO_2. This condition is usually accompanied by certain signs of respiratory distress. CPAP is commonly used when PaO_2 is less than 50 mm Hg while the infant is breathing an FiO_2 of 0.60 or greater, provided that the $PaCO_2$ is 50 mm Hg or less and the pH is greater than 7.25. In most cases, once CPAP is applied and the FRC is restored, the oxygen requirement is significantly reduced. The indications for CPAP are described in Box 54.4.

Methods of Administration

The application of CPAP is most commonly accomplished noninvasively. In preterm and term neonates, short nasal prongs or oronasal masks are preferred. Continued improvement of interface devices has led to more consistent CPAP delivery, better patient comfort, and reduced incidence of pressure ulcers (Fig. 54.7). These interfaces include nasal masks, soft, pliable nasal CPAP cannulas, and the RAM cannula, all of which provide a comfortable interface without applying excessive pressure to maintain an effective seal.

For larger children, nasal masks, oronasal masks, nasal pillows, and other interfaces similar to interfaces used in adults may be used. In all patients, it is important to assess the patient–device interface at regular intervals to allow prevention or early detection and intervention in the event of pressure ulcers.

CPAP may be delivered using a mechanical ventilator in the CPAP mode, a CPAP driver, or continuous flow system with an underwater seal, also referred to as bubble CPAP. Mechanical ventilators provide better patient monitoring and may be connected to a central alarm system. CPAP drivers have the capability of adjusting flow to maintain set CPAP in the presence of a leak and/or increased patient inspiratory demand and typically have some type of built in disconnect alarm. The continuous flow bubble CPAP systems are the simplest and least expensive of all the devices but generally lack the ability to automatically adjust flow and do not have an integrated alarm system in the event of a patient disconnect. All are equally effective as long as the interface is appropriately sized and fitted to the patient. The choice of one device over another is often based on equipment availability or user or institutional bias. Once the delivery device has been selected, gas flow is directed though a heated humidifier into the main flow circuit and patient interface (mask, cannula, or prongs) and the temperature is allowed to stabilize. The interface is then attached to the patient and secured with appropriate head gear, transparent dressing or tape. The patient is observed for tolerance and/or adverse reactions, effectiveness of CPAP is assessed, and pressure and F_IO_2 are adjusted as necessary.

CPAP levels are selected and adjusted based on clinical observation. Initial CPAP levels are usually 5 to 7 cm H_2O and are adjusted in increments of 1 to 2 cm H_2O. The patient's SpO_2, respiratory rate, work of breathing, breath sounds, and blood pressure are monitored. The appropriate CPAP level is achieved when the respiratory rate decreases to near-normal ranges, signs of respiratory distress are lessened, and SpO_2 increases while O_2 requirements are reduced. Arterial and capillary blood gas analysis may provide additional information in determining the effectiveness of CPAP, and chest radiographs are obtained to determine the degree of lung inflation.

Weaning and eventually discontinuing CPAP are considered when oxygenation is adequate at FiO_2 less than 0.30 to 0.40, there is a sustained reduction in work of breathing, and chest radiograph and clinical assessment indicate resolution of the underlying disorder. The use of CPAP for prolonged periods in preterm infants helps to reduce the work of breathing and prevent intubation. Long-term and intermittent use of CPAP is indicated in children with obstructive airway problems, chronic lung disease, and neuromuscular disorders.

High-Flow Nasal Cannula

Supplemental O_2 administration by nasal cannula is the most comfortable and simplest means of providing O_2 for infants and children. Evidence in preterm and term neonates indicates that using a nasal cannula at flow rates of 2 to 8 L/min may be as effective as and is easier to apply than a nasal CPAP system.[38–44]

Specially designed humidification systems have been developed and allow the use of nasal cannulas at flow rates of 2 to 50 L/min.[45] These devices maximize humidification and minimize condensation accumulating in the small-diameter supply tubing. The gas should always be conditioned (warmed and humidified) for approximately 2 to 3 minutes before it is connected to the patient. High-flow nasal cannula systems have been used successfully in neonates for the same indications that CPAP has been used. Instead of titrating levels of CPAP, the flow rate is incrementally adjusted. The amount of positive pressure that the high-flow nasal cannula potentially produces cannot be

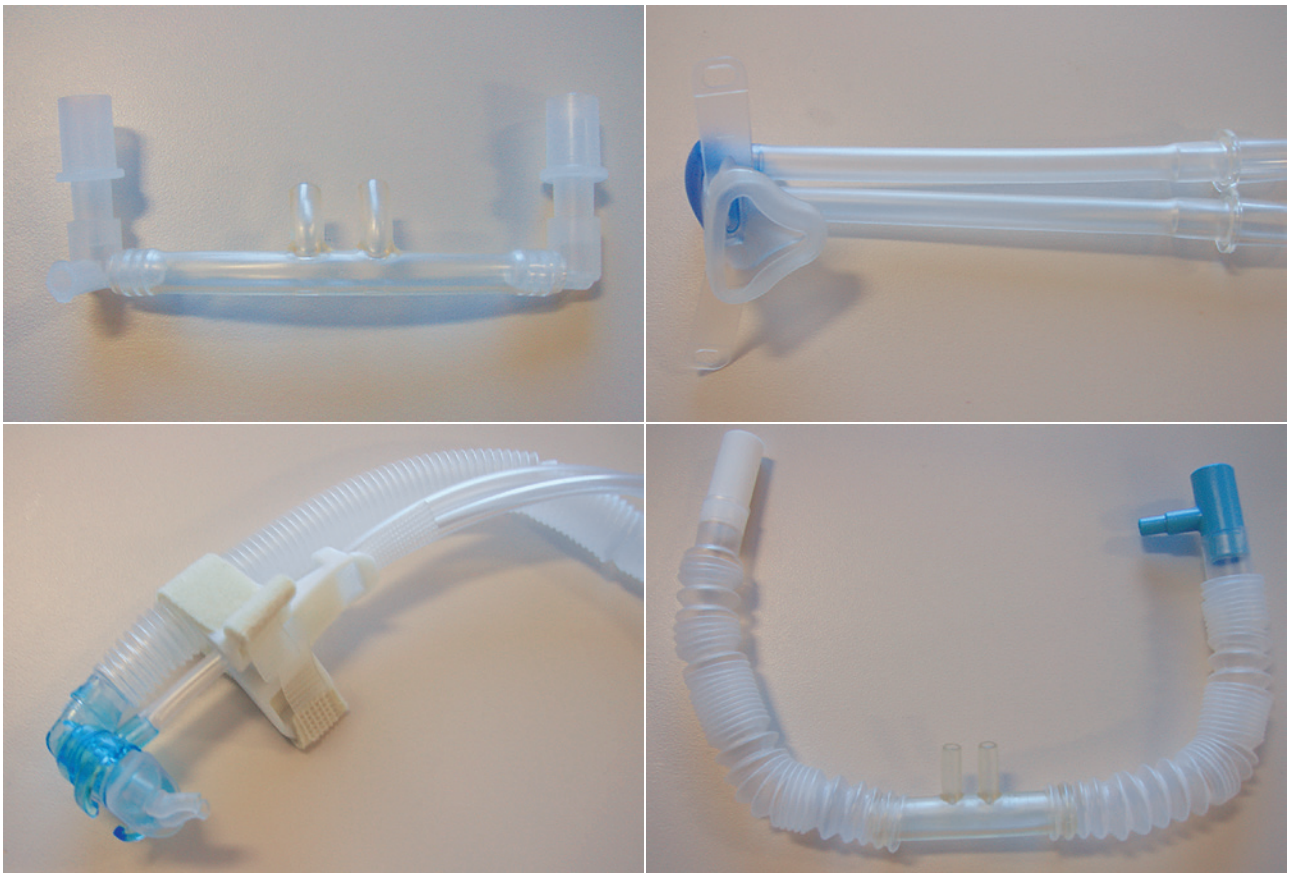

Fig. 54.7 Patient interfaces for continuous positive airway pressure or noninvasive positive pressure ventilation (NPPV).

measured, and there may be some concern that inadvertent high levels may occur, particularly if the nasal cannula fits snugly in the nares.[46,47] However, in most cases excess flow exits the patients mouth, preventing this excess pressure from being generated.

High-flow nasal cannula systems have the potential for maximizing supplemental O_2 administration because the O_2 concentration delivered to the patient should approximate the set FiO_2. This approximation occurs because the set flow meets or exceeds the patient's inspiratory demand and the anatomic reservoir of the upper airway is continuously flushed, greatly reducing the entrainment of room air. High-flow nasal cannula systems may be beneficial in stabilizing acute respiratory failure caused by hypoxemia, which may reduce the need for noninvasive or invasive assisted ventilation, such as in the case of a pulmonary exacerbation in a patient with bronchiolitis, cystic fibrosis, or congestive heart failure.

RULE OF THUMB High-flow nasal cannulas may be as effective as a continuous positive airway pressure (CPAP) device in reducing the work of breathing and improving oxygenation.

Noninvasive Ventilation

Noninvasive ventilation (NIV), also known as *noninvasive positive pressure ventilation,* has become more popular recently in neonatal patients. In the past, use of NIV was limited by the lack of available interfaces; however, these are becoming more readily available. NIV for neonates has been used successfully for premature infants in the delivery room and as an accepted mode of ventilation in the neonatal intensive care unit (NICU), where it has been used to prevent initial intubation or secondarily to prevent reintubation in the setting of extubation failure. NIV has also been used as

MINI CLINI

Pediatric High-Flow Nasal Cannula

Problem

A 10-month-old boy with a past medical history of increased temperature, runny nose, cough, and irritability is admitted to the emergency department with tachypnea, tachycardia, and use of accessory muscles. He is receiving oxygen via a non-rebreathing mask and his SpO_2 is 88%, respiratory rate 72 breaths/min, and heart rate is 140 beats/min. A clinical diagnosis of viral bronchiolitis is established.

Solution

The patient should be placed on a high-flow nasal cannula at 8 L/min and FiO_2 of 1.0. After 20 minutes his respiratory rate has decreased to 44 breaths/min, heat rate is 100 beats/min, and SpO_2 is 100%. The respiratory therapist is now able to slowly decrease the FiO_2 to 0.3, while maintaining the flow rate at 8 L/min. At this FiO_2, the respiratory therapist may attempt to decrease the flow rate. If the patient exhibits signs of increased work of breathing and/or increased oxygen requirement the flow rate should be restored to the previous setting.

a primary mode of ventilation for patients with acute respiratory failure.[48–50] However, there is scant evidence to support the use of NIV over CPAP or as a method of reducing the incidence of bronchopulmonary dysplasia. Patient triggering may be problematic given the large leaks that may occur with most patient interfaces, even with some current ventilators' "Noninvasive Modes," which generally include various forms of sophisticated leak compensation. However, there is ample evidence to support the use of both synchronized and nonsynchronized NIV in the NICU.[51,52]

Outside the NICU, NIV has been used extensively in patients of all ages, including pediatric patients.[53–56] Indications may include short-term support of hypoxemic respiratory failure, such as that seen with pulmonary edema associated with left-sided heart failure; prevention of intubation; postextubation support; and long-term support of patients with neuromuscular disease. Some limitation of available interfaces persists, particularly in smaller patients; however, most patients can be fitted without too much difficulty. As with CPAP and other noninvasive interface devices, care must be taken to prevent or minimize patient injury owing to iatrogenic pressure ulcers from a tight or poorly fitted device.

NIV may be provided with simple, single-limb devices such as bilevel positive airway pressure ventilators, or sophisticated intensive care unit (ICU) ventilators. Care must be taken whenever a single-limb circuit is used to provide sufficient positive end-expiratory pressure (PEEP) in the system to prevent rebreathing of gases (see Chapter 50).

MECHANICAL VENTILATION

Early attempts to provide assisted ventilation to infants and children were largely derived from the experiences gained in adults, including the type of ventilators used and the associated techniques. Recognition of the physiologic differences of neonates and children led to further advances in ventilator design and modes and a wider range of capabilities. Modern microprocessor controlled, critical care ventilators offer an ever-evolving array of options capable of supporting the full range of patient sizes, including ELBW infants, and physiologic conditions.[57] RTs caring for infants and children need to be familiar with their physiologic differences to select and modify the appropriate ventilatory strategy.[58–60]

Basic Principles

Conventional mechanical ventilation is the delivery of a bulk flow of humidified gas into and out of the lungs. The removal of CO_2, typically measured by PCO_2, is directly related to alveolar ventilation (frequency × V_T). Gas moves from the ventilator across an artificial airway or noninvasive interface in response to a change in pressure (pressure gradient). The magnitude of pressure required to move a volume of gas is derived from the compliance of the pulmonary system and the resistance of the airways.

Compliance is a measure of the distensibility of the lungs and is expressed as the volume change per unit of pressure change ($C = \Delta V/\Delta P$). *Resistance* is the tendency for airflow across the tracheobronchial tree to be impeded at a particular pressure per unit of gas flow ($R = \Delta P/\text{flow}$). The product of compliance and resistance is the respiratory time constant, or the measure of time necessary for the equilibration of a change in airway pressure ($TC = C \times R$). A patient with stiff or noncompliant lungs, such as a preterm infant with surfactant deficiency, has short time constants, meaning less time is required for equilibration, and filling and emptying of lungs occur faster, requiring shorter inspiratory and expiratory times. A patient with a disease characterized by impaired airflow or high resistance, such as a child with asthma, has longer time constants, in which more time is required for filling and emptying, thus longer inspiratory and expiratory times are needed.

Goals of Mechanical Ventilation

The basic goals of mechanical ventilation are to improve O_2 delivery to meet metabolic demand and eliminate CO_2, while reducing the work of breathing. The basic aim of assisted ventilation is to meet the goals while minimizing the associated deleterious effects. One approach to mechanical ventilation begins with the selection of an appropriate breath type, either pressure controlled or volume controlled, and a mode that best meets the physiologic needs of the patient's condition.[61] Box 54.5 lists the indications for mechanical ventilation in infants and children.

Modes of Ventilation and Breath Delivery Types

Historically, the most common mode of ventilation used in neonates and children was intermittent mandatory ventilation (IMV). Because early infant ventilators were unable to respond

to the small triggering efforts of these patients, mandatory timed breaths were superimposed over a continuous flow of gas. These asynchronous, mandatory breaths provided most of the ventilation, while the patient was allowed to breathe spontaneously from the continuous gas source. Eventually, technologic improvements resulted in triggering devices that provided synchronization of the mandatory breaths with patient effort synchronized intermittent mandatory ventilation (SIMV) followed by the ability to provide assist/control (A/C) and pressure support ventilation (PSV). Despite evidence that SIMV is more likely to result in patient-ventilator asynchrony, most neonatal and pediatric patients are managed by using one of these three modes or a combination (i.e., SIMV + PSV).[62–64] The most common triggering device for infant ventilators is a pneumotachygraph placed in the ventilator circuit, often proximal to the airway, which in many cases also serves as a monitoring device. The pneumotachygraph allows for the integration of a flow signal, which can be displayed as inhaled and exhaled V_T and minute ventilation. Fig. 54.8 displays graphic representations of A/C, SIMV, and PSV.

Another mode of ventilation that may be used for neonates and small children is called *neurologically adjusted ventilatory assist* (NAVA) in which the ventilator responds to electrical activity of the diaphragm (EAdi). This requires use of a special nasogastric tube with electrodes that sense EAdi. In this highly responsive mode, patient ventilator asynchronies are virtually eliminated, because ventilation is provided by adjusting the amount of airway pressure applied per 1 microvolt change in EAdi.

Proper placement of the NAVA catheter is essential for patient ventilator synchrony. Initial depth of insertion is estimated using the distance from the nose, to the ear, to the xyphoid. Further adjustment is determined from electrical activity using the ventilator's "Positioning Window." The ventilator displays an electrocardiogram (ECG) type graphic, and the catheter is manipulated to a position where there are no P waves and the ventilator tracing indicates good (green) positioning. The electrical activity from the phrenic nerve (EAdi) signals the ventilator to deliver gas to the patient at a pressure gradient determined by the NAVA level. Settings range from 0 to 15 cm $H_2O/\mu V$ with a trigger range up of 0 to 2 μV. The greater the patient's inspiratory demand, as determined by increased EAdi, the greater the level of support provided and vice versa. In the event of catheter movement or misplacement, ventilation is provided with traditional flow or pressure-triggered pressure support or pressure-controlled breaths.

In almost all cases of neonatal ventilation, the mechanical breaths delivered during SIMV and A/C are time-cycled, pressure-limited breaths. Inspiration is initiated by patient effort or timing of the set respiratory rate (whichever comes first). Based on the available flow, continuous, demand, or both, the set inspiratory pressure is reached early in the inspiratory phase and maintained throughout the remainder of the inspiratory time, after which the ventilator cycles to expiration. In many cases, appropriate setting of the *inspiratory rise time* (the speed in which gas flow is delivered controlling how rapidly set airway pressure is achieved)

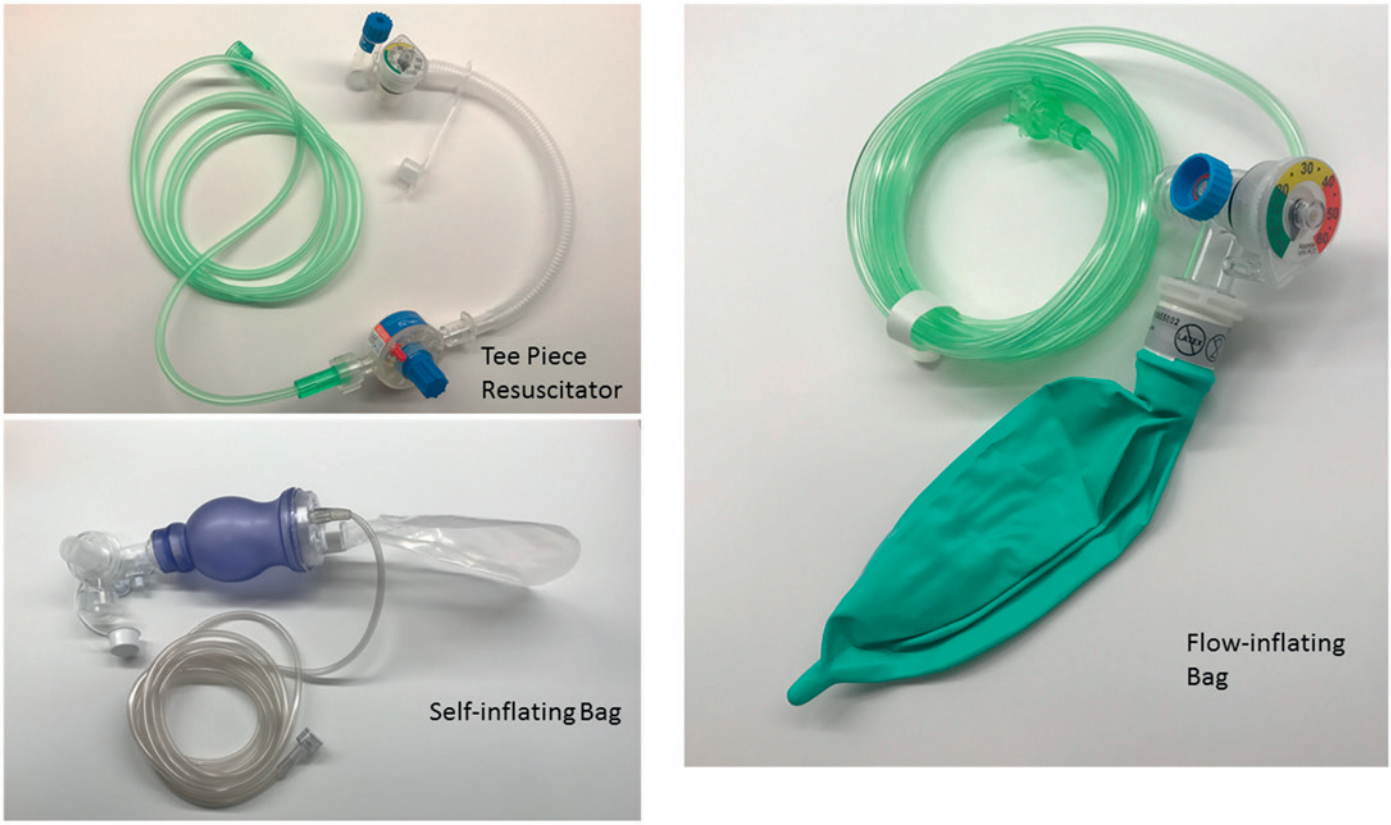

Fig. 54.8 Three types of manual (bag-mask) ventilation devices.

improves patient–ventilator synchrony. Most current-generation ventilators provide volume-targeted, pressure-limited ventilation, often referred to as *pressure-regulated volume control*, *volume guarantee, or volume control plus*. In this dual mode of ventilation, the inspiratory V_T is compared with a preset target V_T, and the inspiratory pressure on the next breath is adjusted up or down to meet the target volume. True volume-controlled breaths are rarely used for ventilating neonatal patients. (See Chapters 46, 47, and 49 for details.)

RULE OF THUMB When ventilating neonates, choose time-cycled, pressure-limited mechanical breaths.

Bag-Mask Ventilation

In all cases the ability to provide manual ventilation must be immediately available. Several manual ventilation devices exist, including traditional self-inflating bags, flow inflating bags, and T-piece resuscitators. Pediatric and infant self-inflating bags are similar to those used for adults, but contain a pressure relief (pop off) valve to prevent the application of excessive pressure. The primary advantage of these devices is the ability to provide ventilation without a gas source; the main disadvantage is the inability to allow spontaneous breathing/CPAP. A pressure manometer may be added to help regulate applied pressure. Flow inflating bags and T-piece resuscitators both require a gas source to provide ventilation. Loss of flow to the device renders it unusable. These devices allow spontaneous breathing and CPAP and include a pressure manometer to help monitor and regulate the amount of inspiratory pressure and PEEP/CPAP. The choice between the two is mostly user preference; however, the T-piece resuscitator allows better control over inspiratory and expiratory pressures and inspiratory time.[65] Fig. 54.8 shows examples of these three devices.

Pediatric patients may be ventilated with either volume-controlled or pressure-controlled breaths. The choice may be based on healthcare team or institutional preference, prior experience, and equipment availability or may be evidence-based for specific diseases (e.g., asthma).

Patients with severe status asthmaticus are among the most challenging patients to ventilate. The pulmonary time constants are increased such that it is equally difficult to inflate the lungs as it is for the patient to exhale. The inspiratory flow rate must be controlled by the clinician by means of volume-controlled ventilation, and sufficient time must be provided to allow the lungs to inflate. Expiratory time must be sufficient to allow exhalation, preventing the accumulation of trapped gas or auto-PEEP. The result is a decrease in minute ventilation, which leads to permissive hypercapnia as a lung protective strategy. $PaCO_2$ should be allowed to increase as long as the pH is ≥7.10.

The inspiratory time must be increased (up to 1 second for this patient and longer in older teenagers) to allow inspiratory gas flow to the patient. Although this increase in inspiratory time may seem counterintuitive in a patient with prolonged expiratory time constants, it is necessary to deliver gas during inspiration because the inspiratory time constant is also increased. Decreasing the inspiratory time to less than 1 second does little to prevent the development of auto-PEEP and frequently markedly decreases the level of ventilation.

In the presence of an elevated $PaCO_2$ and decreased pH, a higher FiO_2 is required to maintain SpO_2 greater than 90% owing to shifting of the oxyhemoglobin dissociation curve. FiO_2 should be set initially at 1.0 and titrated to maintain SpO_2 89% to 95%.

MINI CLINI

Pediatric Ventilation

Problem

A 12-year-old girl with asthma is admitted to the emergency department. She was intubated in the field by paramedics and is currently ventilated with a transport ventilator at the following settings:

- Mode—synchronized intermittent mandatory ventilation (SIMV)
- Tidal volume (V_T)—10 mL/kg
- Peak inspiratory pressure (PIP)—60 cm H_2O Maybe 60 to be more realistic?
- Positive end-expiratory pressure (PEEP)—0 cm H_2O
- Set respiratory rate—16 breaths/min
- Total respiratory rate—20 breaths/min
- Inspiratory time—0.25 s
- FiO_2—1.0

The paramedics inform the respiratory therapist (RT) that since the patient has been placed on the mechanical ventilator, PIP has steadily increased, blood pressure has begun to decrease, and breaths sounds consisting of bilateral inspiratory and expiratory wheezes have become increasingly diminished. What should the RT recommend?

Solution

The ventilator circuit should be immediately disconnected from the endotracheal tube allowing the patient to exhale fully. This patient should be fully sedated and possibly paralyzed to allow the RT to set and control ventilation. The ventilator settings should be set as follows:

- Mode—assist/control (A/C)
- Breath delivery type—volume controlled
- V_T—4–6 mL/kg
- Plateau pressure—maintain at ≤28 cm H_2O
- Driving pressure <15 cm H_2O
- Respiratory rate—set at whatever rate allows ventilation without an increase in auto-PEEP or increased plateau pressure or both
- Inspiratory time—1.0 s
- PEEP—5 cm H_2O
- FiO_2—1.0

Ventilator Settings and Parameters

After the mode of ventilation is selected, the RT begins to adjust the various settings associated with the mode, while keeping in mind the goals of ventilation and the patient's predicted body weight, underlying problem, and reason for mechanical ventilation.

Peak Inspiratory Pressure

For time-cycled, pressure-limited breaths, the peak inspiratory pressure (PIP) is set according to predetermined criteria (e.g., 20 to 25 cm H_2O) or by observing the pressure required to move the chest during manual ventilation with a flow inflating bag or

BOX 54.6 Interrelationship of Tidal Volume (V_T), Flow, and Time

V_T = Flow in L/s × Inspiratory time

Inspiratory time = V_T / Flow rate

T-piece resuscitator. In all cases the RT should attempt to maintain a driving pressure less than 15 cm H_2O. The delivered V_T is monitored, and adjustments may be made. Increasing the PIP normally results in an increase in V_T, whereas a decrease in PIP results in decreased V_T. In the absence of V_T monitoring, PIP may be adjusted based on subjective assessment of chest movement and auscultation of breath sounds. Efforts should be made to maintain the lowest possible pressure that delivers the target V_T. PIP greater than 28 cm H_2O and driving pressure greater than or equal to 15 cm H_2O in time-cycled, pressure-limited (pressure-controlled) breaths have been shown to increase the likelihood of ventilator-induced lung injury.

RULE OF THUMB Always strive to maintain peak inspiratory pressure (PIP) ≤28 cm H_2O and driving pressure <15 cm H_2O

Positive End-Expiratory Pressure

PEEP, referred to as the *baseline pressure,* is used to prevent alveolar collapse at end-expiration. PEEP results in improved oxygenation for a given O_2 concentration. If the PEEP is set too low, alveolar collapse may occur, resulting in decreased FRC, altered ventilation/perfusion ($\dot{V}/\dot{Q}$ matching), and hypoxemia. If the PEEP is set too high, overdistension may occur, increasing the likelihood of lung injury. Typically, PEEP is set between 5 cm H_2O and 10 cm H_2O, although higher levels may be used if necessary. PEEP is set in conjunction with PIP, and the difference between the two is often referred to as the delta P *or driving pressure*. As the delta P is increased, either by increasing PIP or decreasing PEEP, the V_T will most likely increase as well (unless overdistension occurs). Conversely, decreasing the delta P results in lower V_T.

Tidal Volume

When selecting V_T, the clinician must consider a volume that provides adequate lung inflation without overstretching the alveoli. Setting V_T too high most likely would result in lung injury. V_T of 6 to 8 mL/kg is generally considered safe in most patients. However, in some patients with extremely low lung compliance, such as patients with severe acute respiratory distress syndrome (ARDS), it may be necessary to reduce V_T to 4 to 5 mL/kg.

If the clinician chooses to deliver volume-controlled breaths, V_T is set as a control variable. Every mechanical breath delivers an identical V_T at either a preset inspiratory time or a preset flow rate. Set V_T, inspiratory time, and flow all are interrelated. If V_T is set at 300 mL and flow rate is 30 L/min (0.5 L/s), the inspiratory time is 0.6 second. See formulas in Box 54.6.

When ventilating patients with pressure-controlled breaths, V_T is not set, but it should be monitored. The clinician must compare the monitored V_T with a predetermined target and adjust the driving pressure to meet that target.

BOX 54.7 Determining Effective or Corrected Tidal Volume

Effective V_T = Delivered V_T − Compressible volume

Compressible volume = Compressible factor × (PIP-PEEP)

Example: A 12-year-old child weighing 28 kg requires assisted ventilation. Tidal volume (V_T) is set at 240 mL, peak inspiratory pressure (PIP) is 25 cm H_2O, and positive end-expiratory pressure (PEEP) is 5 cm H_2O. The compressible factor for the ventilator is 2 mL/cm H_2O.

Compressible volume = (2 ml/cm H_2O) × (25 − 5 cm H_2O) = 40 ml

Effective V_T = 240 ml − 40 ml = 200 ml

Effective V_T/kg = 200 ml ÷ 28 kg = 7.1 ml/kg

Regardless of whether the clinician chooses volume-controlled or pressure-controlled breaths, he or she must recognize that some of the V_T is compressed in the circuit and not delivered to the patient; this is referred to as *compressible volume loss*. Most current-generation ventilators automatically compensate for compressible volume loss and adjust the delivered and displayed (monitored) V_T accordingly. With older ventilators and current, less sophisticated ventilators, such as some of those used for transport, during volume-controlled breaths the clinician must calculate the compressible volume loss and increase the set V_T to deliver the desired volume to the patient. During both volume-controlled and pressure-controlled breaths, the calculated compressible volume loss must be subtracted from the ventilator displayed exhaled V_T. See Box 54.7 for calculation of compressible volume loss.

RULE OF THUMB Large tidal volume (V_T; >8 mL/kg) is likely to overstretch the lung, resulting in acute lung injury, and should be avoided. Patients with severe acute respiratory distress syndrome (ARDS) may require even lower V_T (4–5 mL/kg). In addition, peak inspiratory pressure (PIP) and/or plateau pressure should be maintained <28 cm H_2O and driving pressure ≤15 cm H_2O.

Although this patient receives NIV for nocturnal support when stable, he currently has an acute infection superimposed on chronic restrictive lung disease. Beginning NIV now may provide sufficient support to prevent intubation during this acute condition. Initial PIP of 10 to 12 cm H_2O titrated to patient comfort may provide additional support, increasing tidal volume (V_T) and allowing respiratory rate to return to baseline. Choosing an oronasal mask may prove to be a more efficient interface than the patient's usual nasal mask at this time. The set respiratory rate of 12 breaths/min is intended to be a backup rate because this patient is spontaneously breathing and should be allowed to establish his own breathing pattern. FiO_2 should be adjusted to maintain an SpO_2 of 89% to 95%.

Ventilator Rate

The ventilator rate is the set number of breaths delivered in 1 minute. During A/C ventilation, the set respiratory rate is the

MINI CLINI

Pediatric Ventilation

Problem

A 10-year-old boy with a complex medical history including trisomy 21, intractable infantile spasms, seizure disorder, and developmental delay (nonverbal) is admitted with increased difficulty breathing. His temperature on admission is 101°F, and a chest x-ray shows a left lower lobe infiltrate consistent with pneumonia. His home regimen includes nocturnal noninvasive ventilation (NIV) via nasal mask with an inspiratory pressure of 8 cm H_2O, 3 cm positive end-expiratory pressure (PEEP), and 2 L/min of O_2 added to the breathing circuit. On admission, the patient complains of shortness of breath. His respiratory rate is 40 breaths/min, and SpO_2 is 88% on a nonrebreathing mask. What should the respiratory therapist (RT) suggest?

Solution

- NIV—consider beginning NIV via oronasal mask
- Peak inspiratory pressure (PIP)—10–12 cm H_2O
- PEEP—3–5 cm H_2O
- Set respiratory rate—12 breaths/min
- FiO_2—1.0

minimum number of breaths the patient will receive and is increased if the patient triggers the ventilator at a respiratory rate faster than that which is set. The actual or total respiratory rate multiplied by V_T determines the minute ventilation, which is directly related to alveolar ventilation and PCO_2. Because V_T is usually set according to the patient's ideal or calculated body weight, adjusting minute ventilation is most often accomplished by changing the respiratory rate. The clinician must be aware of the total respiratory rate when making changes to adjust minute ventilation. If the set respiratory rate is 16 but the total respiratory rate is 22 because of patient triggering, decreasing the set rate to 12 or increasing the set rate to 18 would have no effect on minute ventilation.

Inspiratory Time

The inspiratory time is often defined as the time required to deliver V_T; however, this may be misleading. As described earlier, with volume-controlled breaths, the inspiratory time is determined by V_T and inspiratory flow rate and is the time required to deliver the preset V_T at the preset flow rate. However, with pressure-controlled breaths, the inspiratory time is set by the clinician and may be shorter, longer, or equal to the time required to deliver the breath. In the case of increased airway resistance, such as a patient with asthma, if the inspiratory time is not set long enough, flow delivery to the patient may not decelerate to zero by the end of the set inspiratory time. Under these circumstances, increasing inspiratory time would result in an increase in delivered V_T. Conversely, under the same conditions, shortening the inspiratory time would result in a decrease in delivered V_T. In the case of decreased compliance, as in pneumonia, increasing inspiratory time beyond the time necessary to allow full flow deceleration would result in an inspiratory pause or breath-hold, which may not be tolerated by the patient. Strict attention must be given to setting an inspiratory time that matches the patient's neuroinspiratory time. Failure to do so is likely to result in patient–ventilator asynchrony, making it difficult to adequately ventilate the patient and may require increased use of sedation. Some ventilators are configured such that the clinician sets inspiratory: expiratory (I:E) ratio, which along with respiratory rate will determine the inspiratory time. In such cases, changing the respiratory rate will result in a change in inspiratory time. The clinician must be aware of this and make the necessary adjustment to the I:E to restore the inspiratory time to its previous setting.

RULE OF THUMB Inspiratory time is usually set between 0.2 and 0.4 s for neonates and up to 1.0 s in teenagers. With patients who are awake and have spontaneous breathing efforts, inspiratory time must be set at a level that matches patient neuroinspiratory time to avoid patient–ventilator asynchrony.

Oxygen Concentration

The O_2 concentration or FiO_2 is kept as low as possible to avoid the risk of O_2 toxicity. Although the precise mechanisms are not fully understood, the best approach is to maintain the lowest FiO_2 possible. The immature lung is particularly susceptible to O_2 toxicity, which can result in the development of bronchopulmonary dysplasia. In a preterm infant, FiO_2 is titrated to a narrow SpO_2 range (e.g., 89% to 94%) so that retinal damage (ROP), which is caused by elevated PO_2, does not develop.[17]

RULE OF THUMB O_2 is considered a drug and should be used appropriately. High O_2 concentrations are potentially injurious and may cause O_2 toxicity in the immature lung and retinal damage in preterm infants.

Mean Airway Pressure

Mean airway pressure ($\overline{P}_{aw}$) is the average airway pressure during a 1-minute period. It is affected by changes in PIP, PEEP, inspiratory time, and respiratory rate. An increase in $\overline{P}_{aw}$ is often associated with improved oxygenation but is not without hazards. Increasing PEEP would result in increased $\overline{P}_{aw}$ and potentially increased oxygenation. However, if the PEEP is set too high, the alveoli may become overinflated, resulting in worsening $\dot{V}/\dot{Q}$ matching, and lung injury may occur.

Monitoring Mechanical Ventilation

The RT should develop a systematic approach to monitoring the effects of mechanical ventilation. Components of a ventilator assessment should include an evaluation of the artificial airway, physical examination, assessment of patient–ventilator interaction, analysis of laboratory and radiographic data, adjunct ventilator monitoring, and a systematic ventilator safety assessment including alarm function and assessment of humidification. Alarms should be connected to a central monitoring system to alert clinicians away from the bedside to a change in the patient's condition.

A flow sheet is used to prompt the user and guide the clinician through the process of assessing the patient, while serving as documentation of the ventilator settings and outputs. In the past, these flow sheets were paper and were maintained as part of the patient's medical record. Currently, most flow sheets are integrated into an electronic medical record that is readily available

MINI CLINI

Pediatric Mechanical Ventilation

Problem

A 14-month-old child, who weighs 13 kg and has a history of chronic lung disease (bronchopulmonary dysplasia), requires mechanical ventilation after surgery for correction of gastric reflux. The surgeon requests that the respiratory therapist (RT) select ventilator parameters and develop a weaning plan for this child. The child has an uncuffed 4.5 oral endotracheal tube in place. SpO_2 is 100% with manual ventilation and 100% O_2. Sedation is prescribed to keep the child comfortable but allow spontaneous breathing.

Solution

This child needs a ventilatory strategy taking into account his age, disease process, amount of sedation, and current ventilation needs. What would be the appropriate choices for his initial ventilator management in terms of mode, tidal volume (V_T), set rate, FiO_2, and positive end-expiratory pressure (PEEP) level?

- Mode—Pressure assist/control (A/C)
- Pressure level set to ensure V_T 6–8 mL/kg or 100–130 mL
- Respiratory rate—20–30 breaths/min
- FiO_2—1.0 then titrated to a SpO_2 between 89% and 95%
- PEEP—5 cm H_2O

to the entire patient care team. Although many elements of the patient–ventilator assessment may be automatically entered by means of an electronic interface and require validation only by the clinician, some data must still be entered by hand. As standardization improves and these systems become more sophisticated and interchangeable, all data, including ventilator information, laboratory values, and radiographic and other imaging data, should automatically download, eliminating transcription errors, providing a more comprehensive assessment, and allowing the clinician to focus on the patient and patient–ventilator interaction.

If this child had previously been mechanically ventilated, reviewing the preoperative settings may be helpful in deciding a ventilator plan. If not, a rationale for the suggested parameters follows.

By using the pressure A/C mode, patient–ventilator synchrony can be achieved more easily; this reduces the need for sedation later, after the pain of surgery has dissipated. The target V_T is based on current recommendations. The ventilator rate is determined by the normal respiratory rate for the age of the child, the desired PCO_2 level, and the number of assisted or triggered breaths the child is having. Because this child has chronic lung disease, a higher PCO_2 may be optimal at this time. A younger child with a higher PCO_2 and with a decreased respiratory rate may have a higher set rate. Initial FiO_2 is usually reflective of the amount currently being delivered with hand ventilation but quickly titrated to maintain a SpO_2 89% to 95%. In addition, plateau pressure should not be greater than 28 cm H_2O, and the driving pressure should not be higher than 15 cm H_2O.

Physical Examination

Examination of the patient can yield quick and useful information. The chest is examined for adequacy of chest rise, the presence of asymmetric movement and deformities, and signs of increased work of breathing such as nasal flaring, grunting, and retractions. Breath sounds are helpful in gauging the degree of air entry, verifying bilateral aeration, and identifying airflow problems and areas of diminished aeration. Skin appearance can also give the clinician a sense of the patient's perfusion—an indirect measure of cardiac output. A mottled appearance, poor capillary refill, and pale or gray color indicate poor perfusion.

Patient–Ventilator Interaction

The patient–ventilator interaction is the assessment used to determine the ease with which the patient can trigger and interact with the ventilator throughout the complete ventilatory cycle. This assessment is made by simultaneously observing the trigger indicator, waveforms, and the patient. Refinements in the trigger threshold may need to be made if there is a leak present or the work to trigger or initiate a breath is too great. Most ventilators may be flow triggered or pressure triggered. There is little difference between the two when they are set correctly. The trigger sensitivity should be set as sensitive as possible without auto-triggering. The manner in which the breath is terminated is also assessed. Pressure-supported breaths are flow cycled based on the patient's spontaneous inspiratory time and flow demand. Mechanical breaths are time cycled. Theoretically, flow-cycled, pressure-supported breaths should be more comfortable and promote improved patient–ventilator synchrony because the patient has more control over the breath than with mechanical breaths. Together, patient synchrony and comfort are determined. Patient–ventilator asynchrony occurs when the patient's efforts to breathe are unmatched with the preselected ventilator support. Airway graphics are also helpful in identifying nuances and refining ventilator settings.[66,67] Airway graphics routinely displayed are scalar waveforms of flow, airway pressure, and volume. In addition, each of these parameters can be plotted against the others. Pressure-volume and flow-volume loops can be particularly helpful in assessing alterations in work of breathing, overdistention of the lung, and compliance. Fig. 54.9 shows sample waveforms that are available on most current generation ventilators. See Chapter 48 for more detail on patient–ventilator interaction.

Additional Monitoring

The use of noninvasive monitors, particularly measurements of end-tidal CO_2 and SpO_2, has become routine. Periodic blood gas analysis is a useful tool to quantify acid–base status and to refine ventilator settings further. Other laboratory data, such as electrolytes and hematologic information, are also assessed. Periodic chest radiographs are obtained to identify suspected problems and to assess the progress of lung disease.

Patient–Ventilator Periodic Assessment

A systematic patient–ventilator assessment should be conducted periodically. Prescribed ventilator settings are confirmed and documented along with verification of ventilator outputs. Measurements of mandatory and spontaneous V_T values are made and expressed per the patient's weight to determine if targets are being achieved. Alarms must be set and tested and should detect loss of pressure, high pressure, and patient disconnection at a minimum. Additional alarms should alert

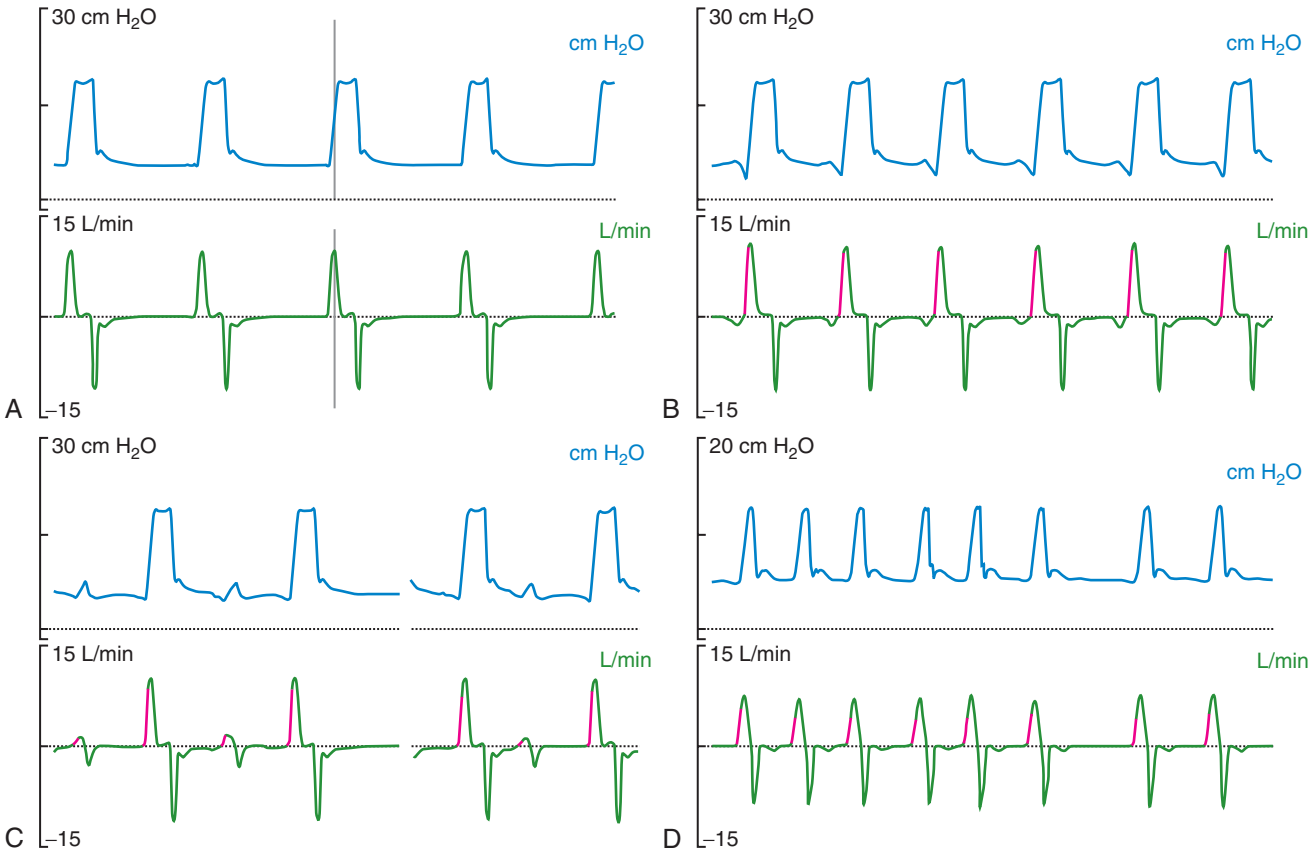

Fig. 54.9 Airway graphics. (A) Patient is apneic. Regardless of synchronized intermittent mandatory ventilation (SIMV) or assist/control (A/C) mode, all breaths are mandatory at set rate. (B) A/C mode. Total respiratory rate is determined by patient's spontaneous rate. (C) SIMV mode. Mechanical breaths are delivered at a set rate. Patient is allowed to breathe spontaneously in between mandatory breaths. (D) Pressure support ventilation mode. There are no set mandatory breaths. All breaths are pressure supported at patient's spontaneous rate.

the clinician to changes in V_T, minute ventilation, respiratory rate, and PEEP.

The humidification system is evaluated, including airway temperature and the presence of condensation in the ventilator circuit. Some visible condensation or "rain-out" is important because a completely dry circuit may be a sign of inadequate humidification, which results in thickened secretions and possible airway obstruction.

RULE OF THUMB Routine monitoring of ventilated patients is essential and should include an assessment of the patient's physiologic status, including vital signs and a systematic assessment of the patient–ventilator interaction.

Weaning From Mechanical Ventilation

Weaning or, more appropriately, liberation from mechanical ventilation is a topic that has become more standardized over the past several years in pediatric patients.[68–70] Clear guidelines for "assessment of readiness to extubate" and "spontaneous breathing trials" have become standard practice.[71] However, some controversy remains and this assessment has not yet become standard practice in neonatal patients even though there is considerable literature available to guide clinicians in this area.[72–74]

BOX 54.8 Considerations for Extubation

- Spontaneous respiratory rate appropriate for age and weight
- Absence of apnea or periodic breathing
- FiO_2 requirement ≤0.4
- Ability to protect airway
- Normal work of breathing
- Acceptable amount and consistency of respiratory secretions
- Normal vital signs
- Minimal sedation needs
- SpO_2 >90%
- Spontaneous tidal volume (V_T) >4–5 mL/kg

Considerable variation in practice exists among institutions and even among clinicians within institutions. Nevertheless, these patients should be assessed daily to determine their readiness for liberation from mechanical ventilation. Some general considerations for extubation are presented in Box 54.8. Once it is agreed that a patient may be ready for extubation, a systematic coordinated approach should be undertaken. This includes a safety screen followed by some agreed-upon evaluation of the patient's ability to breathe spontaneously without ventilatory assistance Box 54.9. If a spontaneous breathing trial is attempted, it should

BOX 54.9 Pediatric/Neonatal Ventilator Discontinuance Protocol

Step 1

Safety Screen (Lack of the Following)

- Brain death, ICP >15 mm Hg, suspected high ICP, or difficult to control ICP
- Neuromuscular blockade
- Significant hemoptysis (significant amounts of blood from endotracheal tube or tracheostomy)
- Hemodynamic instability
- Unstable airway
- FiO_2 >0.6
- PEEP ≥8 cm H_2O
- Lack of ICU team consensus
- Extracorporeal life support
- Chronic disease requiring ventilation

Issues to Address Before Extubation

- Fluid overload
- Secretions
- Neurologic impairment
- Medication requirement precludes safe extubation
- NPO time insufficient
- Unstable, unsafe, swollen airway
- Imminent procedure
- Psychosocial factors (e.g., unclear code status, assent)
- Imminent return to home hospital

Step 2

If none of the above conditions exist, the pediatric ICU team discusses the feasibility of extubation.

Consider the Following

- Stage of ventilation
  I—initial or acute stage (escalation)
  II—ventilator management stage (plateau)
  III—discontinuance stage (deescalation)
- Immediate extubation (may include reversal of sedation)
- Spontaneous breathing trial (may include some level of pressure support)
- Reduction of ventilator settings

If Spontaneous Breathing Trial Is Performed, Stop Trial at any Point for the Following

- Tachypnea, bradypnea, apnea (age appropriate)
- Excessive use of accessory muscles, nasal flaring present, subjective dyspnea (consider baseline)
- Significant, unresolved change in agitation or anxiety
- Significant tachycardia or bradycardia
- Hemodynamic changes
- Unacceptable decrease in SpO_2

Step 3

Critical care team discusses extubation plan.

ICP, Intracranial pressure; *ICU,* intensive care unit; *NPO,* nothing per mouth; *PEEP;* positive end-expiratory pressure.

be coordinated with a reduction in the level of sedation, often referred to as a *spontaneous awakening trial*. However, in some cases this may not be feasible because a reduction in sedation may result in the patient pulling the endotracheal tube (and intravenous lines, etc.) and unplanned extubation may occur. Whenever a patient is extubated, either planned or unplanned, there should be appropriate supplies, equipment, and personnel immediately available to reintubate if necessary (see Chapter 53 for details on weaning).

High-Frequency Ventilation

High-frequency ventilation (HFV) is a form of invasive mechanical ventilation that uses small V_T values (less than dead space) at rapid frequencies, up to 900 breaths/min (15 Hz). The primary goal of HFV is to provide adequate ventilation and oxygenation while limiting the development of lung injury. HFV has been used as a primary mode of ventilation, as well as a rescue therapy for patients determined to be failing conventional mechanical ventilation. Although early studies showed a beneficial effect on gas exchange compared with conventional ventilation, there has been no demonstrated improvement in outcome compared with current lung protective strategies.[75–80] In fact, studies have shown a trend toward increased mortality in patients treated with HFV.[81–83] Despite the lack of evidence supporting its use, HFV remains a controversial mode of ventilation for pediatric and neonatal patients but should be used only by clinicians expert in its clinical application and knowledgeable about its physiologic effects.

There are three basic types of HFV: high-frequency oscillatory ventilation, high-frequency jet ventilation, and high-frequency percussive ventilation. High-frequency oscillatory ventilation is the most common form of HFV. Oxygenation is achieved by inflating the patient's lungs to a high resting level, or FRC, by establishing a high $\overline{P}_{aw}$, similar to CPAP, at levels typically ranging from 16 to 30 cm H_2O. This "recruitment" improves the $\dot{V}/\dot{Q}$ ratio by opening previously collapsed alveoli. Ventilation is provided by the to-and-fro movement of a large piston in the ventilator circuit that results in high-frequency oscillations in the patient's airways. Gas exchange results from a combination of six mechanisms: bulk flow of gas, longitudinal dispersion, pendelluft, asymmetric velocity profiles, cardiogenic mixing, and molecular diffusion.

Gas exchange during high-frequency jet ventilation is believed to occur via two mechanisms—convection and diffusion. Fresh gas is injected into the endotracheal tube at a high velocity and travels down the midportion of the airways, reducing dead space. Bidirectional flow occurs as gas simultaneously travels up the outer lumen of the airways. Diffusion occurs in the lower airways as cross-sectional area increases and velocity decreases, similar to conventional ventilation.

During high-frequency percussive ventilation, a series of small, rapid breaths accompanied by air trapping are delivered that result in a steady increase in airway pressure, similar to a conventional breath. This is followed by a release phase to allow exhalation. The rapid "percussive" breaths are maintained through the entire breathing cycle, which facilitates gas exchange and simultaneously promotes movement of secretions to larger airways and eventually the trachea where they may be more easily removed.

Cardiovascular Effects

The cardiovascular effects of HFV vary with the strategy used. Using the high lung volume strategy, lung volume is recruited, and $\overline{P}_{aw}$ can be slowly reduced while maintaining alveolar

ventilation. This strategy limits the adverse side effects of PPV on cardiovascular performance and may result in increased systemic blood flow. However, if $\bar{P}_{aw}$ greater than that used during conventional ventilation is required during HFV, cardiovascular compromise may occur. Increases in intravascular volume and use of vasoactive drugs help to support mean arterial blood pressure, cardiac output, and O_2 delivery. Increases in central venous pressure or decreases in mean arterial pressure indicate decreases in systemic blood flow as a result of overdistension of the lung and inappropriately high $\bar{P}_{aw}$ after adequate intravascular volume has been established.

Weaning From High-Frequency Ventilation

When FiO_2 is equal to or less than 0.6, $\bar{P}_{aw}$ is weaned slowly. When $\bar{P}_{aw}$ is less than 15 to 18 cm H_2O, the patient may be trialed off or transitioned to conventional ventilation. Alternatively, the patient may be extubated directly from HFV once the $\bar{P}_{aw}$ and F_IO_2 have been reduced to 8 to 9 cm H_2O and 0.3, respectively.

Complications of Mechanical Ventilation

Box 54.10 summarizes the most common complications associated with mechanical ventilation in newborns and other pediatric patients.

BOX 54.10 Complications of Mechanical Ventilation in Infants and Children

- Ventilator-induced injuries
- Air leak syndromes
- Pneumothorax
- Pneumomediastinum
- Pneumopericardium
- Pneumoperitoneum
- Pulmonary interstitial emphysema
- Subcutaneous emphysema
- Parenchymal lung damage
- Bronchopulmonary dysplasia
- Cardiovascular complications
- Decreased venous return
- Decreased cardiac output
- Increased pulmonary vascular resistance
- Increased intracranial pressure
- Increased incidence of intraventricular hemorrhage
- O_2-induced injuries
- O_2 toxicity
- ROP
- Airway complications
- Accidental extubation
- Atelectasis
- Inadequate humidification
- Endobronchial intubation
- Equipment contamination
- Postintubation stridor
- Endotracheal tube plugging or kinking
- Tracheal lesions
- Infection
- Ventilator-associated pneumonia

ROP, Retinopathy of prematurity.

SPECIALTY GASES

Inhaled Nitric Oxide

Inhaled nitric oxide (INO) is a selective pulmonary vasodilator used to treat newborns who require mechanical ventilation for hypoxemic respiratory failure.[84,85] See Chapter 42 for more discussion of INO. INO improves oxygenation and reduces the need for extracorporeal membrane oxygenation (ECMO). See Chapter 51 for details. The approved indications for INO are listed in Box 54.11. INO also has been studied in preterm infants with the aim to reduce the incidence of chronic lung disease. These clinical investigations showed a modest improvement in pulmonary outcomes, but other problems associated with prematurity, such as intracranial hemorrhage, were unchanged. At the present time, INO is not routinely used in the management of respiratory failure associated with prematurity.

INO is administered in conjunction with mechanical ventilation via a specially designed delivery and monitoring system that provides precision drug dosing and safety features (Fig. 54.10). The recommended inhalation oxide (INO) dose is 20 parts per million (ppm), with an optimal response achieved when lung inflation is maximized.[86,87] When a response has been achieved and sustained, the INO dose is gradually reduced, typically by 50% each step, to a final dose of 1 ppm, at which point the drug is discontinued. During withdrawal of INO, FiO_2 is increased to minimize any recurrence of pulmonary hypertension, referred to as a rebound effect.[88]

During INO therapy, concentrations of nitric oxide and O_2 are continuously monitored. The combined exposure of nitric oxide and O_2 leads to the formation of nitrogen dioxide, which is toxic and is continuously monitored. INO doses typically used are considered to be very low and have a good safety profile. A

BOX 54.11 Indications for Inhaled Nitric Oxide

Term and near-term neonates (>34 weeks' gestation) with PPHN

metabolite of INO is the formation of methemoglobin as the nitric oxide molecule is bound to hemoglobin. During INO administration, the patient's ability to metabolize methemoglobin is assessed by periodically monitoring methemoglobin levels.[89]

INO should be available in any hospital that has a level III intensive care nursery. INO should be an integral part of any high-risk transport team, and it is important that non-ECMO centers have a plan for treatment failure that takes into account the distance to an ECMO center.[90] INO therapy has also been used for diagnosing and treating certain congenital heart diseases; although used in the management of ARDS, it has no effect on outcome and the oxygenation benefit is normally lost within 48 hours.[91]

Heliox

Heliox is a gas mixture of O_2 and helium (see Chapter 42). Typical concentration of a tank of heliox is 80%/20% or 70%/30% (helium/oxygen). Helium is less dense than air. Inhaling a less-dense gas can reduce the pressure needed to overcome airway resistance and results in decreased work of breathing. Heliox has been used in conjunction with other therapies in the treatment of partial large airway obstruction and asthma where airway resistance is high. It may be used to deliver bronchodilators but due to its lower density is not as efficient as air or oxygen, so a higher flow rate should be used. Heliox may serve as a temporizing measure while steroids are administered to reduce airway swelling. When high O_2 concentrations are necessary, heliox is not likely to be effective as the amount of inspired helium is diminished. Signs of decreased work of breathing, decreased use of accessory muscles, improved aeration, and decreased respiratory rate after initiating heliox are indications of its effectiveness.

NEONATAL AND PEDIATRIC TRANSPORT

Treatment of a critically ill infant or child is usually provided at a tertiary care facility. Many of these facilities have established transport teams that go to the referring facility, initiate ICU-type support, and transport the patient back to the tertiary care center. The composition of transport teams varies from one institution to another; however, typical team members include some combination of registered nurse, RT, paramedic, nurse practitioner, and physician. Regardless of the composition of the team, there are some characteristics that all transport teams should have in common.[91] All members should have exquisite assessment and critical thinking skills. They should be technically adept and have good communication skills. Each team develops minimum criteria that a team member must possess. Many teams cross-train in multiple disciplines to perform certain technical tasks. Establishing and maintaining proficiency with all skills is a must for team members.

The team essentially functions as an extension of the ICU. To do this, much of the same equipment used in the ICU is taken to the referring hospital. Establishing responsibility for assessing function and maintaining appropriate inventory is essential. Many centers use elaborate checklists to be certain not to be without necessary equipment, disposables, or medications. Teams generally prepare for the worst. Many times when the team arrives at the referring facility, the patient's condition is not the same as when the initial call for help was made. Being prepared for the worst helps in stabilizing the patient for transport. The American Academy of Pediatrics has guidelines for all ages and common conditions requiring transport to a tertiary facility. Box 54.12 lists the basic equipment and supplies needed to provide respiratory care during neonatal and pediatric transport.

BOX 54.12 Equipment and Supplies Needed to Provide Respiratory Care During Neonatal and Pediatric Transport

Equipment

- Adequate supply of O_2 and compressed air
- Air-O_2 blender
- Mechanical ventilator with circuit
- Manual resuscitator capable of giving 100% O_2 with PEEP
- Noninvasive O_2 monitor (SpO_2 or $PtcO_2$)
- O_2 analyzer
- Airway pressure monitor (electronic or mechanical)
- Electrocardiograph monitor
- Portable suction apparatus
- Laryngoscope handle
- Laryngoscope blades (sizes newborn to adult)
- Extra laryngoscope bulbs and batteries
- Stethoscope

Supplies

- Resuscitation masks (sizes 0, 1, 2, 3, 4)
- Feeding tubes (sizes 6, 8, and 10 F)
- Disposable O_2 hood
- O_2 connecting tubing
- Disposable hand held nebulizer with tubing (for bronchodilators)
- Cloth adhesive tape for taping endotracheal tubes
- Tincture of benzoin for taping endotracheal tubes
- Pulse oximeter probes (at least two, in case one fails)
- Endotracheal tubes (sizes 2.5–7)
- Stylet

PEEP, Positive end-expiratory pressure.

RULE OF THUMB A high-risk transport team must be prepared to provide the same level of care and highly trained personnel as would be available in the intensive care units (ICUs) they are transporting patients to and from.

SUMMARY CHECKLIST

- Neonatal and pediatric care is one of the most sophisticated specialty areas in the field of respiratory care. Competent practice in this area requires a firm understanding of the many anatomic and physiologic differences between infants, children, and adults.
- A critical component in the respiratory management of infants and children is thorough clinical assessment. Because of the significant anatomic and physiologic differences between adults and infants, many of the assessment techniques useful with adults do not apply to infants.
- General assessment of the infant begins before birth and involves the maternal history and the fetal and newborn status.

As a child grows and develops, more of the assessment methods used with adults become applicable.

- Respiratory care plan development is based on accurate patient information, detailed knowledge of the disease process, and current treatment guidelines and recommendations.
- Respiratory care modalities provided to pediatric and neonatal patients include: O_2, aerosol and humidity therapy, secretion management, airway care, and mechanical ventilation.
- HFNC and CPAP are commonly used to overcome atelectasis and oxygenation problems.
- In many cases HFNC may be as effective as CPAP, but the precise amount of pressure generated is unknown.
- NIV has become an acceptable choice of ventilation.
- Improved design of nasal masks and nasal prongs should help to prevent the development of pressure ulcers during CPAP and NIV.
- For mechanically ventilated patients, plateau pressure or PIP during pressure-targeted ventilation should not exceed 28 cm H_2O and driving pressure should not exceed 15 cm H_2O.
- V_T should be maintained between 4 and 8 mL/kg.
- Compressible volume loss may account for a significant portion of the small V_T used for infants and small children.
- Infants and children can be effectively managed with conventional ventilation. The use of HFV has become increasingly controversial. Mechanically ventilated infants and children should be assessed daily for readiness for liberation from mechanical ventilation.
- Nitric oxide is considered standard therapy for the management of term infants who present with PPHN and should be available in all level III NICUs.
- Surfactant replacement has become the standard of care for preterm (gestation <32 weeks) or low-birth-weight infants (<1300 g) and infants with known surfactant deficiency.
- Highly specialized transport teams are available to transport newborn and pediatric patients to tertiary care facilities.

Patient Education and Health Promotion

Donna D. Gardner

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Discuss the importance of patient education
- Describe the components of a patient's culture.
- Explain the impact culture has on a patient's perception of health.
- Identify two strategies respiratory therapists may use when educating and caring for patients from different cultures.
- Reflect on your own cultural background.
- Discuss two communication strategies when teaching a patient identified as having low health literacy.
- Determine patient education goals from the patient's perspective.
- Write learning objectives in the cognitive, affective, and psychomotor domains.
- Compare and contrast the different stages of learning based on age.
- Describe learning differences between children and adults.
- Describe the methods used to evaluate patient education.
- Discuss the impact health literacy has on patient education
- Explain when to use the teach back or show me method
- Define patient centered care
- Define population health
- Describe the importance of incorporating a patient's culture into patient education.
- Discuss the chronic care model as it applies to patient centered care.
- Identify the settings that are appropriate for the implementation of health promotion activities.
- Describe the respiratory therapist's role as patient educator.

CHAPTER OUTLINE

KEY TERMS

affective domain
chronic care
cognitive domain
culture
disease management
health education
health literacy
health promotion
patient-centered care
population health
psychomotor domain
recidivism

Effective patient education is invaluable to the healthcare of society. Respiratory therapists (RTs) educate patients by providing information about their condition, disease processes, risks and benefits of treatment, medication, or procedures. They teach patients how to perform diagnostic tests, such as basic spirometry, and educate patients about health promotion issues such as tobacco cessation and taking ownership to manage their cardiopulmonary disease. RTs educate patients in all age groups, including geriatric, adult, adolescent, and pediatric patients. In certain situations, RTs educate the parents or the spouse of the patient in the hospital setting before discharge and in the home-care setting (see Chapter 57). RTs are also frequently called on to provide educational programs to patients with pulmonary diseases such as chronic obstructive pulmonary disease (COPD), asthma, and cystic fibrosis to help minimize hospitalizations and short-term readmissions. For these reasons, this chapter reviews important issues related to patient education, disease management, and health promotion.

The top three causes of death in the United States are heart disease, cancer, and chronic lower respiratory system disease, with chronic obstructive lung disease (i.e., bronchitis and emphysema) being the deadliest.[1] Public education about risk factors is the key to preventing these diseases and probably has the greatest potential for making an impact on healthcare in this country. Therefore, in the future, RTs should focus on and emphasize health promotion and disease prevention.

PATIENT EDUCATION

If we think of patient care as customer service—which it indeed is—then we cannot ignore education as a crucial component of that service. If we buy a car or a television set, for example, we expect the salesperson to educate us about the essential aspects of our purchase. We also expect this information to be provided in writing. Likewise, education is an essential component of patient care. For patients to assume or resume control of their health, they must be educated. Because they rely on the healthcare practitioner to provide this education, every respiratory care education program should include instruction regarding patient education.

RTs are able to assess patient learning needs and readiness to learn by asking patients what they know about their condition and therapies. By asking these questions, the RT will be able to identify the patient's gap in knowledge or skills to help identify where to start the patient education. There is limited time to teach patients, therefore the RT must speak in a manner the patient can understand and focus on the health problem to assist the patient becoming engaged in his/her own care.

Cultural Awareness

Behaviors, values and patterns of beliefs shared by a group is referred to as **culture.** Culture is not limited to gender, socioeconomic status, racial background, or ethnicity. Culture is learned and communicated from one generation to another. For example; families, social organizations, and religions are where individuals learn to follow the norms, traditions or customs, practices or taboos, and values of the culture that impact the thinking or behavior common to members of the group. In addition, some cultures have subcultures based on ethnicity, occupation, sexual orientation, or religion and the subculture may have its own language or behaviors. Therefore individuals may identify with more than one cultural group. (e.g., an individual may be considered "black" and be African American or Caribbean and not American nor African. Native American Indians are lumped into one group when there are over 550 different tribes in the United States).[2] RTs must be aware that culture and health perspectives go hand in hand (Table 55.1).

The health of a patient is influenced by their cultural background, which determines the individual's definition of health and how to deal with illness. A patient's culture impacts their willingness to seek healthcare when experiencing symptoms of illness and influences their actions associated with any intervention or treatment. Therefore some strategies RTs may use when educating and caring for patients from different cultures are displayed in Table 55.2.

RULE OF THUMB A person's health condition may be impacted by their culture.

Health Literacy

Health literacy is the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.[6] Health literacy encompasses educational, social, and cultural factors that influence an individual. Entire books have been devoted to patient education and health literacy because people are neither familiar with medical terms nor how their bodies work. People with strong literacy skills may also face health literacy challenges. Low health literacy affects the patient's ability to participate in their own care, results in patient safety concerns and poor health outcomes.

RTs must be aware of the stereotypes that surround low literacy such as lower socioeconomic level, poor language, and low education levels. There are studies that correlate literacy and economic status with education level. In the United States most individuals with low literacy are Caucasian and low literacy is found in all types of individuals and not limited to one specific group or educational or socioeconomic status, which then become barriers to patient education and patient learning.[7] Because there is limited health literacy in the United States, patients may not be able to read; however, this does not provide information regarding a patient's intellect, but it may impact their ability to use a handout or pamphlet with paragraphs of words. Results from the most recent survey of literacy skills among adults has been used to develop a literacy scale that describes the different levels of health literacy in Table 55.3.[7]

Respiratory patients with low health literacy will not be able to be self-directed and navigate the healthcare system nor follow an educational program or instructions provided. Reading and comprehension may not always go hand in hand. Patients often will not voluntarily admit that they do not understand to avoid embarrassment. Therefore to determine whether a patient understands, RTs should look for clues that indicate reading or writing

TABLE 55.1 Health Perspectives for Emerging Majority Groups in the United States

Group	Traditional Definitions of Health	Traditional Definitions of Illness	Traditional Methods of Maintaining and Protecting Health	Traditional Methods of Restoring Health
American Indian and Alaska Native population	Living in total harmony with nature and being able to survive under extremely challenging situations	Illness is the price to be paid for past or future negative events. Details are specific to different nations. Illness may result from the presence of evil spirits. These types of illness are contagious with generalized symptoms	Maintain positive relationship with nature. Treat body with respect. Purification acts using water, herbal remedies and rituals	Removal of the external causative factor by a traditional healer after spiritual ceremony to determine cause and treatment. Drumming
Asian population	Living in total physical and spiritual harmony with the universe. Four major religious traditions pose variations on cultural values. Examples: respect for life, moderation of basic relationships, balance between evil and good	Human body considered as whole, with harmony between organs and superficial structures. Integration of human body within context of environment. Imbalance of ying and yang (Chinese).	Body is a gift from parents and ancestors and must be protected. Dietary practices Formal daily exercise for example, tai chi; Amulets (Chinese)	Acupuncture Applying poultices Cupping Bleeding Massage Herbal remedies Other products Use of physicians, with women treating women. Use of immunizations Important to keep the body intact (Chinese).
African population	A process of energy force, rather than a state. Consists of body, mind and spirit. State of harmony with nature. Elderly held in high regard	Process of disharmony attributed to demons and evil spirts. Pain as a sign of illness. If no pain, then illness is gone	Dietary practices Rest and clean environment Use of laxatives and cod liver oil taken internally, sulfur and molasses on back Protective materials of various substances, for example, copper or silver, dried flesh Prayer	Voodoo and magic Use of immunizations Cared for by the entire community Prayer Use of healers Pictures of catholic saints or relics Sugars and turpentine orally Poultices, herbs, minerals, oral preparations, including hot water and lemon, garlic, flannel with camphorated oil
Hispanic population	Gift from God	Imbalance in body or punishment for wrongdoing. Imbalance between hot and cold or wet and dry (definitions vary). Dislocation of body parts. Magic or supernatural causes such as evil eye. Strong emotions envy	Maintain equilibrium in the universe through behavior, diet, and work	Prayer Dietary practices of hot and cold Magical and religious rituals, artifacts frequently in Catholic and Pentecostal traditions, such as offerings confession, candles, laying on of hands. Folk, holistic healers called *curanderos*, using herbs, prayer, massage, social rapport, spiritual. Amulets

Modified from Wilson and Dorne: Impact of culture on the education of the geriatric patient.[3]

is a concern and to be sensitive to prevent any feelings of shame. Lack of understanding clues are listed in Box 55.1.

RULE OF THUMB Health literacy influences a patient's ability to adhere to self-management medication or a therapy regimen.

Patients' ability to understand health information is a prerequisite to patient adherence. Patients need to be able to read and understand the instructions, prescriptions, informed consent, and written documents to optimize their potential. Health literacy experts emphasize important behaviors to be developed for clear communication with patients (Table 55.4).

BOX 55.1 Clues Indicative of a Lack of Understanding

- Patient repeatedly is noncompliant
- Patient uses the excuse being too busy, tired, or sick to maintain attention when given instruction
- Claims that the patient did not feel like reading the information, gave the information to a family member, or lost or forgot their glasses
- Insistence on taking the information home to read
  - Demonstrates nervousness and stress, confused about the materials
  - Talks about something else and not on topic
  - Returns documents that are not complete or are illegible

TABLE 55.2 Recommended Patient Teaching for Cultural Awareness

Learn about the ethnic/cultural/religious/spiritual traditions of the patients in your clinic or healthcare facility to establish inclusion	Pay attention to body language (nonverbal communication), lack of response or expressions of anxiety that may signal the patient or family is in conflict about the education or treatment and hesitant to tell you
Arrange for language translators when necessary	Be aware of cues from the patient and/or family comprehend the teaching and assess with the cultural awareness in mind. (nodding does not guarantee understanding, ask the patient to state the information in his/her own words)
Ask the patient and family or healthcare provider open-ended questions to gain more information about their assumptions and expectations	Remain nonjudgmental when given information that reflects the values that differ from your own
Follow the advice given by the patient about appropriate ways to facilitate communication within or between the family and healthcare providers	Healthcare providers should assess their own ethnic/cultural/religious or spiritual beliefs that may not reflect the patients
Expand knowledge about sexual orientation, gender identity, and learn the definitions for Lesbian, Gay, Bi-sexual Transgender, Queer (LGBTQ) populations	Healthcare providers must be aware of their own biases and prejudices and these need to be examined and recognized

Modified from McLaughlin L, Braun K, and Siebert PS.[4,5]

TABLE 55.3 Levels of Health Literacy

Levels of Health Literacy	
Proficient	Able to perform complex activities such as searching documents to define medical terms or other information
Intermediate	Able to conduct moderately challenging task such as finding an age range for a specific vaccination from a childhood vaccination chart
Base	Able to complete simple tasks such a giving two precautions to follow if taking a specific medication, based on information in a clearly written pamphlet
Below basic	Demonstrates lower level of performance such as identifying what can be eaten or drunk before having a medical test based on a set of short instructions
Not literate in English	Not literate in English

Establishing Goals for the Patient Teaching

When considering the content to teach patients depends on the needs of the patient and the goals to be accomplished. Setting collaborative goals with the patient will direct the patient teaching. Sometimes RTs are overwhelmed with the amount of information to teach and try to cover everything, which may appear disorganized or haphazard. This type of teaching is neither efficient nor effective. The RT needs to have an organized predetermined plan with short- and long-term goals and objectives that include the patient and will be used to evaluate the patient's progress. Setting goals that are aligned with the patient's needs will contribute to successful learning activities. This can be accomplished by asking what should the patient be able to do because of this education session? What information should the patient need to carry out the instruction? These two questions have different answers for each patient. Different goals will be required for teaching respiratory patients with acute or chronic conditions and for those related to health promotion. For example, when teaching a respiratory patient how to use the prescribed controller medication for asthma in the MDI with a spacer, the short-term goals may be to fill the prescription and to take the medication correctly using the MDI with a spacer.

After this the patient needs to know the name and type of medication, when to take the medication, why the patient should take the medication as directed, what should the patient expect to occur when taking the medication (breathing is improved, and to keep taking the medicine because it is working, do not stop taking the medicine), and any special action the patient should take (if the patient stops taking the medicine the patient is more likely to have an exacerbation). Understanding the why, what, and how increases the likelihood that the patient will take the medication. Establishing long-term goals will decrease the frequency of asthma exacerbations. This information will need to be simplified and broken down into smaller or shorter time segments for the patient.

Performance Objectives

Initially it is helpful for the RT to develop learning objectives that are appropriate for the specific patient and the education topic to be addressed. These learning objectives will help the

MINI CLINI

A Hispanic parent of a child with asthma is a concerned mother who wants to do the best for her child. She is a single parent with no other family. The child is prescribed a controller medication in a metered-dose inhaler (MDI) with a spacer. The respiratory therapist (RT) teaches the mother how to use the MDI with a spacer and provides the mother with a pamphlet to use for reference. The RT also shares the importance of taking the medication twice a day every day to prevent asthma exacerbations. The mother nodded in agreement. A week later the mother and child are back in the clinic for an asthma exacerbation. The RT asks the mother about using the MDI and spacer twice daily and asked about her referring to the pamphlet. The mother nodded and smiled and informed the RT she had bought a hairless chihuahua to take the asthma away from the child. Unknowingly to the RT, in some Hispanic cultures, there is belief that a chihuahua will cure the child's asthma.[9] The RT assumed the mother would be able to read the pamphlet, understand the steps to use the MDI with a spacer, and would know that a dog is an asthma trigger. What the RT does not know is that the mother is unable to read. The RT must take time to have the patient demonstrate the use of the MDI and spacer correctly and ask questions about understanding the pamphlet or make sure there are plenty of pictures on the pamphlet that a person who is unable to read can follow, and to inquire about cultural beliefs related to the disease processes.

TABLE 55.4 Recommended Strategies for Clear Communication With Patients With Low Health Literacy

1. Assess the patient understanding at baseline before moving forward with detailed information. (This usually takes 30 s or less.) For example, for a patient newly diagnosed with asthma ask the following question; "Before we go on, could you tell me what you already know about asthma?" This will provide the respiratory therapist with an understanding of the patient's information needs and where to tailor the educational content
2. Explain using plain language or lay terms. Avoid using medical terms, jargon, or vague terms. Example say: "increased breath rate" instead of tachypnea
   Example say: "causes of asthma attacks" instead of "triggers asthma exacerbations"
   Example say: Instead of "You have asthma", say "Your breathing test results were positive for asthma"
3. Focus on 1 to 3 key points

Repeat these points throughout the education session

4. Encourage the patient to ask questions by asking open-ended questions.
   Example: ask "What questions do you have?" instead of "Do you have any questions?"
5. Use the **teach-back method** to confirm the patient understands and to make sure you have explained the information clearly to the patient; be specific when asking the patient to demonstrate back to you.
   Example: "I always ask my patient to repeat things back to me to make sure I have explained the information to them clearly. I would like you to tell me when you will take the new medication we talked about today."
   Example: "When you get home, your wife or spouse will ask you what happened today and what will you tell them?"

To confirm the patient understands how to use their medication or a different skill, ask the patent to demonstrate back to you. This usually takes 1–2 min
   For example: have the patient demonstrate how to use the puffer metered-dose inhaler (pMDI) with a spacer

6. Write down important instructions to inform the patient what they do after meeting with you
7. Provide useful patient education materials

The education materials provide the patient (and spouse or family member) with the information to reference when at home

Modified from Kripalani S, Weiss BD: Teaching about health literacy and clear communication. *J Gen Intern Med* 21(8):888–90, 2006.[8]

learner focus on more relevant topics and will help the educator clarify the teaching strategies that are needed for patient education sessions. Objectives should be stated in attainable and measurable terms so that the RT and the patient can recognize when the objective has been accomplished. Clear objectives describe what is to be accomplished and how evaluation will occur.

The format for writing an objective is as follows:

1. Begin with the phrase, "At the end of the lesson, the patient will…"
2. Write the action verb (e.g., "list," "describe," "demonstrate").
3. Write a condition, if needed (e.g., with or without the use of notes).
4. Write a standard, if needed (e.g., how fast, how accurate).

For example: At the end of the session, the patient will be given an MDI and a spacer and be able to demonstrate the correct technique for using it without error.

Action verb: "demonstrate" (from the psychomotor domain; the relevant domains are discussed later in this chapter)

Condition: "given an MDI and a spacer"

Standard: "without error"

Learning Domains

Learning occurs in three domains: **cognitive**, **psychomotor**, and **affective**. Some learning sessions will involve only one domain, whereas others may involve all three. The cognitive domain is very important, because it will address the knowledge that a patient needs regarding his or her illness and how to manage it. The psychomotor domain addresses the skills that the patient will need to acquire to perform specific treatment modalities (e.g., the use of MDIs). The affective domain involves teaching patients about the necessary attitudes and motivations for successfully living with their diseases.

MINI CLINI

Developing Learning Objectives for the Use of an Albuterol Metered-Dose Inhaler

Problem

Your 31-year-old patient is newly diagnosed with asthma, and she is being discharged tomorrow. She requires instruction regarding how to properly use her controller medication, Advair diskus, and the reliever medication albuterol metered-dose inhaler. Develop learning objectives for her and address each learning domain.

Solution

Use a variety of learning objectives, including the following:

Cognitive domain: Describe the action of albuterol on the bronchial smooth muscle; recognize when it is necessary to seek medical attention.

Affective domain: Agree that it is important not to skip a dose; verbalize willingness to use the Advair diskus daily; feel satisfaction by controlling the disease.

Psychomotor domain: Demonstrate the ability to assemble the metered-dose inhaler and the spacer; inhale slowly and deeply with an inspiratory hold.

Cognitive Domain

The cognitive domain is probably the easiest to translate into learning objectives because it involves the facts and concepts that the RT wants the patient to know and apply by the end of the education session. Objectives for the cognitive domain might include the following:

1. List the indications for oxygen therapy.
2. Discuss the importance of using the prescribed liter flow.
3. Explain the relationship between oxygen and combustion.

Any factual information that you expect the patient to understand and apply falls under the cognitive domain. Action verbs for the cognitive domain are included in Table 55.5.[10]

Psychomotor Domain

Repetition and active involvement are important when teaching a psychomotor skill. RTs who teach new skills to patients need to provide plenty of opportunity for the patient to practice the activities. Simple demonstration of the skill to the patient is not enough. To confirm performance in the psychomotor domain, have your patients provide a return demonstration. Be sure to provide help and encouragement as needed. Be patient; not everyone develops skills at the same rate.

Examples of action verbs for the psychomotor domain are included in Table 55.6.[10]

RULE OF THUMB People learn by doing. Get the learner involved.

Affective Domain

The patient's attitudes and motivations influence his or her ability to learn. It is important to remember that, with patient education, timing is everything. Patients who have recently been given a poor prognosis or who are in pain are not in an optimal position to learn. Maslow suggested a hierarchy of

TABLE 55.5 Cognitive Domain

Level	Samples	Ambiguous terms to avoid
Knowledge	Define, identify, list, label, name, state Example: List your medications.	Know, memorize
Comprehension	Describe, defend, explain, generalize, summarize Example: Describe how your medication works on your condition.	Understand, believe
Application	Apply, construct, demonstrate, calculate, operate Example: Demonstrate how you take your medication.	Realize
Analysis	Analyze, break down, contrast, differentiate, distinguish, infer Example: Distinguish between the types of pain.	Conceptualize
Synthesis	Categorize, combine, create, design, formulate, integrate, plan, revise, rearrange, write Example: Integrate diet and exercise into your rehabilitation plan.	Experience
Evaluation	Appraise, assess, compare, conclude, critique, evaluate, judge, weigh Example: Compare your level of wellness now to this time last year.	Perceive

Data from Borich GD: *Effective teaching methods*, et 3, Englewood cliffs, NJ, 1996, Merrill; Bloom BS: *Taxonomy of educational objectives, Handbook I: The cognitive domain.* New York, 1956, David McKay Co Inc.; French D, Hale C, Johnson C, et al: *Blended learning: An ongoing process for internet integration.* Austin, TX: 2003, e-Linkages, Inc and Trafford, p 231.

TABLE 55.6 Psychomotor Domain

Level	Samples	Ambiguous terms to avoid
Perception/awareness	Choose, describe, detect, distinguish, identify, relate, select Example: Identifies body language.	Perceive, comprehend, recognize
Mindset/ready to act	Begin, display, explain, move, react, show, state, volunteer Example: Shows willingness to change health behavior.	Think, understand, feel
Guided response/imitation	Copy, duplicate, imitate, trace, follow, react, reproduce Example: Follows instructions when learning crutch gait.	Appear
Mechanism/efficiency	Assemble, calibrate, manipulate, demonstrate, improve, perform, produce Example: Demonstrates proficiency in crutch gait.	Experience
Complex overt response/skilled	Assemble, calibrate, manipulate, demonstrate, improve, perform, produce Example: Performs crutch gait confidently and without hesitation.	Become familiar with
Adaptation	Adapt, alter, change, rearrange, reorganize, revise, vary Example: Adapts to new terrain and obstacles confidently when using crutches.	Conceptualize, display interest in
Origination	Arrange, combine, create, design, initiate, make, originate Example: Creates new ways to meet needs while adapting to functional limits.	Self-actualize

Data from Borich GD: *Effective teaching methods*, ed 3, Englewood cliffs, NJ: 1996, Merrill; French D, Hale C, Johnson C, et al: *Blended learning: An ongoing process for internet integration.* Austin, TX: 2003, e-Linkages, Inc and Trafford, p 231; Simpson EJ: *The classification of educational objectives in the psychomotor domain,* Washington, DC, 1972, Gryphon House.

TABLE 55.7 Affective Domain

Level	Samples	Ambiguous terms to avoid
Receive/awareness	Accept, acknowledge, alert, choose, give, attend, notice, tolerate, select Example: Acknowledges loss.	Realize, comprehend, perceive, become conscious of
Respond/display interest	Agree, assist with, aid, answer, comply, communicate, consent, volunteer Example: Consents to treatment.	Think, know, feel
Value	Adopt, behave, choose, demonstrate, commit, desire, initiate, join Example: Demonstrates a desire to change.	Understand, enjoy
Organize	Adapt, adjust, arrange, balance, compare group, rank, verify, strengthen Example: Balance work and home life.	Experience, become familiar with
Characterize/internalize values	Advocate, avoid, defend, demonstrate, exhibit, justify, resolve, support Example: Demonstrates a change in lifestyle.	Self-actualize

Data from Borich GD: *Effective teaching methods*, ed 3, Englewood cliffs, NJ: 1996, Merrill; Bloom BS: *Taxonomy of educational objectives, Handbook I: The cognitive domain.* New York, 1956, David McKay Co Inc.; French D, Hale C, Johnson C, et al: *Blended learning: An ongoing process for internet integration.* Austin, TX: 2003, e-Linkages, Inc and Trafford, p 231.

needs, and he identified physiologic needs as the most basic of human needs, followed by safety, love, esteem, and self-actualization. Lower-level needs must first be satisfied before moving on to higher-level needs. For example, if a patient is dyspneic or in pain, he or she will probably not be receptive to learning the steps that are involved in cleaning a small-volume nebulizer. It is important for RTs to assess a patient's readiness to learn by talking with the patient and his or her family and by listening to the patient's concerns. It is important to develop a relationship of trust and to be empathetic with the patient.

The RT should begin with easy-to-master facts and skills. After the patient conquers these, motivation should increase, and the patient will have a feeling of accomplishment. Motivation is also enhanced by presenting material clearly with the use of a variety of teaching methods and by relating the facts and skills to practical applications. Getting patients to see how these skills will benefit them is the key to motivation. Communicating to the patient that there is something that he or she can do to maintain or improve his or her health and sense of well-being is important.

Objectives in the affective domain—using the oxygen therapy example mentioned earlier—might include the following:

1. Express genuine concern for yourself by using your oxygen therapy correctly.
2. Commit to learn by being an active participant in the program.

Affective domain action verbs are included in Table 55.7.[10]

RULE OF THUMB Measuring the patient's commitment to caring for him/herself is essential for behavior change.

Provide Educational Resources

When using a short period of time for teaching, there is a need for the patient to repeat or practice, and therefore the patient must be given educational resources to reference about their condition. These educational resources may be in a format such as a brochure, handout, and app on a cell phone, YouTube videos, website or other technology as appropriate. The educational materials must be at a readability level that is equal to the fourth or fifth grade for most patients to understand. Because the internet is a valuable resource for patient education, make sure the websites shared are appropriate for the patient population. However, YouTube videos are not peer reviewed and may not be balanced information; therefore RTs should make sure the source is credible.

TABLE 55.8 Defined Ages Across the Lifespan

Age Range	Title
Children	
Birth to 28th day of life	Newborn, neonate
1 month to 1 year of age	Infant
1-3 years	Toddler
3-5 years	Preschooler
6-12 years or onset of puberty	School-age
13-20 years	Adolescent
Adults	
18-25	Emerging adult, young adult
30-65	Middle adult
Over 65 years	Late adulthood, older adult

Data from Potter PA, Perry AG, Stockert PA, et al: *Fundamentals of nursing*, ed 9, St Louis, 2017, Elsevier.

Teaching Children, Adolescents, Adults, and Older Adults

Teaching children and their parents, adults, and older adults requires different formats, time spans, and educational tools. This section will provide the RT with various strategies to address each age group. To be clear on age definition, refer Table 55.8.

TABLE 55.9 Teaching Methods Based on Patient's Developmental Capacity

Infant	• Keep routines (e.g., feeding, bathing) consistent. • Hold infant firmly while smiling and speaking softly to convey sense of trust. • Have infant touch different textures (e.g., soft fabric, hard plastic).
Toddler	• Use play to teach procedure or activity (e.g., handling examination equipment, applying bandage to doll). • Offer picture books that describe story of children in hospital or clinic. • Use simple words such as cut instead of laceration to promote understanding.
Preschooler	• Use role play, imitation, and play to make learning fun. • Encourage questions and offer explanations. Use simple explanations and demonstrations. • Encourage children to learn together through pictures and short stories about how to perform hygiene.
School-age child	• Teach psychomotor skills needed to maintain health. (Complicated skills such as learning to use a syringe take considerable practice.) • Offer opportunities to discuss health problems and answer questions.
Adolescent	• Help adolescent learn about feelings and need for self-expression. • Use teaching as collaborative activity. • Allow adolescents to make decisions about health and health promotion (safety, sex education, substance abuse). • Use problem solving to help adolescents make choices.
Young or middle adult	• Encourage participation in teaching plan by setting mutual goals. • Encourage independent learning. • Offer information so adult understands effects of health problem.
Older adult	• Teach when patient is alert and rested. • Involve adult in discussion or activity. • Focus on wellness and person's strength. • Use approaches that enhance patient's reception of stimuli when they have a sensory impairment. • Keep teaching sessions short.

From Potter PA, Perry AG, Stockert PA, et al: *Fundamentals of nursing*, ed 9, St Louis, 2017, Elsevier.

Teaching Children and Their Parents

Teaching children often includes educating their parents because of the dependence of the age group and the parents are considered the primary learner. Therefore the parents must be included to participate with the child as much as possible, which includes setting goals, objectives, and evaluation or feedback. Teaching parents of a child with a cardiopulmonary disease allows them to better understand the diagnosis, common signs and symptoms, and specifics associated with the treatment or care plan. The parents need to be assessed for a readiness to learn by listening for cues the parent is using to ask for more information (e.g., "I am having a really hard time getting my child to take his/her medication). Stages of learning for infants to older adults are listed in Table 55.9.

RULE OF THUMB Parents need to be communicated in a manner that is easily understood and includes their culture.

When teaching parents of toddlers, the toddler should be included in the teaching and encouraged to participate in the education activities. Toddlers are more motivated by external factors (e.g., prizes) and may need a more obvious reward system in place before learning can take place. Toddlers can grasp a cause-and-effect relationship between two things but have a very short attention span; therefore the education sessions may need to be limited to no longer than 15 to 20 minutes.

Older children may learn by example and RTs may use simple or familiar terms the child is used to using. As the child matures and enters adolescence, the parent needs to shift the responsibility to the adolescent who is able and willing to assume the responsibility. Other important issues related to differences between children and adult learners are listed in Box 55.2, and allocated time for teaching is given by age in Box 55.3. Ideally, a child can concentrate for 2 to 5 minutes per year of age.

Teaching Adolescents and Adults

When teaching adolescents and adults we need to remember they have internal motivating factors and will learn quicker if they can easily see the intrinsic value of knowing more about their illness. Some refer to this internal motivating factor as the "WIIFM (what's in it for me) concept. Adults are more independent and self-directed, and they do not like being dependent on others. Adults are task- or problem oriented and prefer practical activities such as discussion or hands on activities to drive the important points home. They also bring experience to the situation and this can be a rich resource and used to connect to new information. This suggests that

BOX 55.2 Learning Differences Between Children and Adults

Child	Adult
• Motivated by external factors like grades • Directed by others • Learning is a big part of his or her life • Trusts teacher • Has limited experience • Learns for the future • Learns quickly • Tends to learn in accordance with his or her developmental stage • Has no problem with a slow pace of learning • Subject oriented	• Motivated internally • Is self-directed • Learning is only one part of his or her life • Questions the teacher • Has rich life experiences • Learns for the present • May learn more slowly • Varies regarding learning ability • Dislikes a slow pace of learning • Problem oriented

BOX 55.3 Attention Spans for Different Ages

Toddlers:	about 4–10 min
School-aged children:	about 10–20 min
Adolescents and adults:	about 20–30 min

adults should be more involved in setting program goals and that they will readily learn skills that make them more independent.

Teaching Older Adults

Older adults may have special considerations because of functional, cognitive, and psychosocial changes that occur over time. Also, remember many older adults have comorbidities that impact coexisting conditions on the functional capacity of the individual. Quality of life or life expectancy may be considered when prioritizing content for older adults. Older adults may require more time to assimilate the information and benefit from slower paced education sessions. Also, a caregiver may need to be incorporated into the education session if the patient is not able to assume full responsibility for his/her self-care. Other important issues related to differences between children and adult learners are listed in Box 55.2, and allocated time for teaching is given by age in Box 55.3.

TEACH BACK OR ECHO METHOD

Many of the patients RTs care for have chronic diseases, and teaching these individuals about their chronic disease and self-management is best done using the teach-back method or show me method to improve the individual's understanding of the disease, and ask the individual to repeat or demonstrate back the key points of the education.[12] Asking a patient "Do you understand?" will usually elicit a response of head nodding or an answer of "yes" and will communicate to the RT the patient actually lacks comprehension about the information provided. The teach-back method was introduced to reinforce education to patients. This method has been shown to have positively affected patient adherence and self-efficacy, improved self-care, and reduced hospital readmission rates. This method includes using questions to determine what the individual understood from the education session such as "We have discussed quite a bit today, would you please tell me two things you will share with your family that we discussed today?" Or "Before you leave today, please show me how to use the puffer MDI?"[12] If the individual responds incorrectly or seems to be deficient in understanding, the RT should reinforce the positive actions or behaviors of the patient first and then repeat the information missed for clarification, or re-demonstrate the steps for the use of the equipment or medication delivery device. This cycle repeats itself until the individual can answer or demonstrate correctly. The teach-back or echo method is not a test of the individual's knowledge as much as ascertaining how well the information was taught and what needs to be reviewed. The Agency for Healthcare Research and Quality (AHRQ) created the Teach-back Observation Tool to evaluate the RT and his/her ability to use the Teach back method.

The teach-back method also allows those with low literacy levels to actively engage and for information to be reiterated. This method is useful for teaching individuals to understand treatment regimens and disease warning signs. Chronic disease management incorporates self-management strategies that are designed to assist patients and their families to better manage the disease. These programs focus on symptom recognition, self-monitoring, medication adherence, exercise, and reduction in smoking. These programs have contributed to reducing hospitalizations, readmission rates, days in the hospital, outpatient visits and healthcare utilization and costs. Box 55.4 provides recommendations for the teach-back method.

RULE OF THUMB The teach-back method reflects the respiratory therapist's ability to communicate the information correctly to the patient.

Evaluation of Patient Education

The critical question that remains when all the patient education sessions are complete is, "Has the patient learned?" Evaluation is the process that answers that question. The method used to evaluate learning is determined by the measurable learning objectives (i.e., cognitive, affective, or psychomotor). Cognitive objectives are often evaluated with the use of a written examination. Objectives in the affective and psychomotor domains are evaluated with the use of performance checklists.

RULE OF THUMB Evaluation results reflect the quality of instruction as much as the degree of learning.

BOX 55.4 Recommendations for the Teach-Back Method

Plan the approach
- Think how you will incorporate the teach-back method into the information provided
  - "We covered a lot today and I want to make sure I explained everything clearly. Let's review what was discussed. Could you tell me 3 things you agreed to do to help you control your disease?"

Chunk and check
- Do not wait until the end of the session to have the teach back session. Chunk out the information into small segments and have the patient teach it back to you. Repeat this several times during the education session

Clarify and check again
- When the teach-back method uncovers misunderstanding, explain the information again and ask the patient to teach back again until they can correctly describe in their own words or demonstrate how to use the medication or equipment again.

Start slowly and use it consistently
- Use the teach back method with every patient every time you provide education session

Practice
- Practice your delivery and make teach back part of your routine

Use this teach-back AND show me methods when using new medications or equipment by asking the patient to show you how to use these devices.
- "I have noticed many people have trouble remembering how to take their puffer metered-dose inhaler with a spacer. Can you show me how you will take your medication?"

Use handouts with the teach-back method

It is important to have written instructions for follow-up when the patient is at home. Point out the important steps by reviewing the written instructions and reinforce your patient's understanding. The patient may use the handout when teaching you.

MINI CLINI

Metered-Dose Inhaler Instruction for a Pediatric Patient

Problem

How would you change the approach to the metered-dose inhaler situation described in the previous Mini Clini if your patient was a 7-year-old boy with asthma?

Solution

Although the learning objectives may remain the same, the methods may be different. You may compare the slow, deep inspiration to getting ready to blow out the candles on a birthday cake. You may use swimming under water as an image to encourage breath holding. Use simple diagrams to show how the medication will act on the patient's lungs. If he likes sports, tell him about athletes who compete well despite having asthma (you may also use this illustration to stress the importance of controlling asthma). An abundance of resource materials is available for children with asthma; make use of them. Many local, state, and national lung associations (www.ala.org) offer such learning aids as age-appropriate books, coloring books, and puppets to make the learning process more fun for children. To utilize the teach-back and show me method ask the patient to tell you what was discussed during the education session to see if what you told the patient was clear. Also ask the patient what three things will he/she do when he/she gets home to manage his/her disease. Last, ask the patient to show you how to use the puffer MDI (pMDI) correctly. Any misunderstandings should be addressed immediately, and the patient should re-demonstrate the use of the pMDI.

Patient Education Teaching Tips

Following is a list of time-honored suggestions for improving patient education:
- Address the patient's immediate concerns first.
- Include the patient in setting the goals and objectives.
- Create an optimal learning environment. Teach in a quiet and relaxed setting.
- Avoid using medical jargon; use lay terms to explain the information
- Have patients use as many of their senses as possible during their learning session. Whenever possible, include hearing, seeing, smelling, speaking, touching, and doing.
- Keep sessions short. If the material is complex, break it down into brief segments.
- Repeat, repeat, repeat!
- Provide many opportunities for the patient to ask questions and state in their own words about the education. Also, provide ample time to practice psychomotor skills and demonstrate back to you using the teach-back method.
- Be specific when emphasizing key points.
- Be prepared.
- Be organized. People learn more quickly when they are presented with information that is well organized.
- Demonstrate enthusiasm for what you are doing. The learner can always sense your level of motivation.
- Evaluate in a nonthreatening manner and provide helpful feedback. Use evaluation as a learning tool.

HEALTH EDUCATION

Health education may have been the earliest form of organized health promotion in the United States. Health programs in schools is a result of Lemuel Shattuck's report in 1850 to the Sanitary Commission of Massachusetts, which described the value of schools helping contain communicable diseases. However, it was not until 1875 that health education became widespread. During that year, the Women's Christian Temperance Union lobbied for alcohol education in the schools. Because of these efforts, 38 states passed legislation to require this education, which later turned into tobacco, alcohol, and drug education. From that time, health education has been enhanced and expanded in schools. There are public health agencies at the local, state, national, and international levels that provide health education and care for those who would otherwise have none.

Health education is a process of planned learning that is designed to enable individuals to make informed decisions and to take responsible actions regarding their health. The primary goal of health education is behavior change, and it is designed to promote, maintain, and improve both individual and community health. Health education covers the continuum between health and disease and between prevention and treatment.

Health promotion helps people change their lifestyles through coping strategies to prevent illness in a variety of settings, from the home or school to the workplace or the healthcare agency or institution, which require different approaches to patient care planning. The RT assesses patterns and uses their assessment to facilitate an individual's maintenance of well-being toward

BOX 55.5 American Association for Respiratory Care Health Promotion and Disease Prevention Statement

Health Promotion and Disease Prevention

- The AARC acknowledges that respiratory therapists in both the civilian and uniformed/military services are integral members of the healthcare team, in hospitals, home healthcare settings, pulmonary laboratories, rehabilitation programs, and all other environments (including ICUs and critical care transport) where respiratory care is practiced.
- The AARC recognizes that education and training of the respiratory therapist is the best method by which to instill the ability to improve the patient's quality and longevity of life, and that such information should be included in their formal education and training in CoARC accredited programs.
- The AARC recognizes the respiratory therapist's responsibility to participate in pulmonary disease teaching, smoking cessation programs, pulmonary function studies for the public, air pollution alerts, allergy warnings, and sulfite warnings in restaurants, as well as research in those and other areas where efforts could promote improved health and disease prevention. Furthermore, the respiratory therapist is in a unique position to provide leadership in determining health promotion and disease prevention activities for students, faculty, practitioners, patients, and the general public in both civilian and uniformed service environments.
- The AARC recognizes the need to (1) provide and promote consumer education related to the prevention and control of pulmonary disease; (2) establish a strong working relationship with other health agencies, educational institutions, federal and state government, businesses, military, and other community organizations; and (3) monitor such activities. Furthermore, the AARC supports efforts to develop personal and professional wellness models and action plans that will inspire and encourage all respiratory therapists to cooperate on health promotion and cardiorespiratory disease prevention.

BOX 55.6 American Association for Respiratory Care Role Model Statement

- As healthcare professionals engaged in the performance of cardiopulmonary care, RTs must strive to maintain the highest personal and professional standards.
- In addition to upholding the code of ethics, the RT shall serve as a leader and advocate of public health.
- The RT shall participate in activities leading to awareness of the causes and prevention of pulmonary disease and the problems associated with the cardiopulmonary system. The RT shall support the development and promotion of pulmonary disease awareness programs, to include smoking cessation programs, pulmonary function screenings, air pollution monitoring, allergy warnings, and other public education programs.
- The RT shall support research to improve health and prevent disease.
- The RT shall provide leadership in determining health promotion and disease prevention activities for students, faculty, practitioners, patients, and the general public.
- The RT shall serve as a physical example of cardiopulmonary health by abstaining from tobacco use and shall make a special personal effort to eliminate smoking and the use of other tobacco products from the home and work environment.
- The RT shall strive to be a model for all members of the healthcare team by demonstrating responsibility and cooperating with other healthcare professionals to meet the health needs of the public.

Effective March 1990.
Revised March 2000.

RT, Respiratory therapist.

wellness. To be effective, health education must be combined with strategies for health promotion; the two are strongly linked. In the United States, *Healthy People 2020*, the national health promotion initiative establishes national goals and provides a framework for prevention.[13] *Healthy People 2020* publishes national health objectives that identify the most significant preventable threats to health. The objectives and associated evaluation tools demonstrate progress toward the goals of attaining high-quality, longer lives, decreasing health disparities, and creating an environment—all of which promote health and improve quality of life.[13] The American Association for Respiratory Care has created a statement for health promotion and disease prevention (Box 55.5).

Although individuals must ultimately assume responsibility for their own health, promoting healthy behaviors through education is an important part of being an RT. In this capacity, the RT should serve as a role model for the public. Unless healthcare professionals' model healthy behaviors, successful health outcomes cannot be expected from the public. To this end, the American Association for Respiratory Care has created a role-model statement to encourage RTs to set a positive example for the public (Box 55.6).

Providing a good example is not enough to ensure successful health education programming. For the desired outcomes to be achieved, certain conditions must first be met. The components are remarkably like patient education requirements. The essential components of effective health education are listed in Box 55.7.

For RTs to assist patients, caregivers, or the public about the development of healthier lifestyles, greater emphasis must be placed on health promotion and disease prevention strategies Box 55.8.

HEALTH PROMOTION AND DISEASE PREVENTION

In 2015, the United States spent $3.2 trillion, or $9,990 per person, on healthcare, the highest spending by far of any developed country.[14] The top three causes of death in the United States are heart disease, cancer, and COPD. All three lead to chronic conditions and might be preventable by avoiding tobacco use, poor diet, and physical inactivity.

Current medical practice is designed to respond to the acute problems of patients by focusing on diagnosis and treatment of the presenting symptoms. Only focusing on the acute or episodic health problems creates a discrepancy when using this model of care for chronic conditions that may be prevented or

BOX 55.7 Essential Components of Effective Health Education

1. Program participants must be actively engaged in the learning process.
2. Activities must incorporate the values and beliefs of the learner. Familial, cultural, societal, and economic factors must be considered.
3. The role of the health educator is to facilitate behavioral change. Thus the learning process should be approached together by both the learner and the educator.
4. The process of predisposing an individual toward improved health as well as enabling and reinforcing health attitudes requires effort, which will only reap results over time.
5. The healthcare educator must be willing to listen nonjudgmentally to the concerns of the learners. Empathy and understanding are necessary to foster a trusting relationship.
6. The level of the learners' self-esteem and self-concept may either enhance or inhibit their ability to make decisions about their own health. The healthcare educator should be willing to provide emotional support as necessary.
7. The healthcare educator's personal characteristics have a direct impact on the outcome of the educational program. Generally, successful outcomes occur because of a confident and professional approach.

BOX 55.8 Health Promotion and Disease Prevention

- The AARC submits this paper to identify and illustrate the involvement of the RT in the promotion of health and prevention of disease and supports these activities. The AARC realizes that RTs are integral members of the healthcare team, in hospitals, home healthcare settings, pulmonary laboratories, rehabilitation programs, and all other environments where respiratory care is practiced.
- The AARC recognizes that education and training of the RT is the best method by which to instill the ability to improve the patient's quality and longevity of life, and that such information should be included in their formal education and training.
- The AARC recognizes the RT responsibility to participate in pulmonary disease teaching, smoking cessation programs, pulmonary function studies for the public, air pollution alerts, allergy warnings, and sulfite warnings in restaurants, as well as research in those and other areas where efforts could promote improved health and disease prevention. Furthermore, the RT is in a unique position to provide leadership in determining health promotion and disease prevention activities for students, faculty, practitioners, patients, and the general public.
- The AARC recognizes the need to provide and promote consumer education related to the prevention and control of pulmonary disease and to establish a strong working relationship with other health agencies, educational institutions, federal and state government, businesses, and other community organizations and to monitor such. Furthermore, the AARC supports efforts to develop personal and professional wellness models and action plans that will inspire and encourage all RT to cooperate on health promotion and disease prevention.

Effective 7/85.
Revised 3/00.

managed. This type of care requires refocusing on the prevention of disease by identifying risk factors and providing methods for behavioral changes. Preventative healthcare is very different from **chronic care.**

A quote from Rufus Howe is appropriate: "What a rare privilege it is to be in a position to improve the lives of others."[14a] A patient with asthma goes to the emergency department and is treated effectively and efficiently. The patient received good quality care, and, in many people's minds, the patient was "fixed." However, asthma is manageable to the point that the patient should not have to be in the emergency department. There are excellent international and national guidelines (www.GINA.org and www.NAEPP.org) that outline how to manage asthma, state the importance of patient education, and follow up with evaluating the patient inhaler technique. There are medications that control asthma and keep the patient out of this situation. Usually, the reason for the emergency visit is that the patient's asthma is not in control; this may occur because the patient is not using inhaled steroids because he or she has a poor understanding of the disease and how to manage it, because the national guidelines are not being used, or because of a combination of all these issues. Either way, this chronic disease can be better self-managed by a patient with the proper multidisciplinary education and follow-up.

The public health model attempts to reduce disease in the nation through mass education campaigns. Examples include education about the hazards of drinking and driving, tobacco use (both smokeless and smoking) education, and food labeling to indicate fat and cholesterol content. This is known as *health promotion and disease prevention*.[15] By participating in public education programs, RTs have the potential to affect the health of individuals and the population as a whole.[16] This approach is intended to look at the health disparities from infancy through to older age and to highlight opportunities to promote health and improve quality of life for all Americans.

RTs can take an active role in the development of educational materials to assist both the public and other health professionals about health promotion activities. Many medical manufacturers have also developed health promotion or education kits for a variety of diseases such as asthma, COPD, or tobacco and e-cigarettes use. These kits are generally developed with input from the medical community and from RTs. An example of an asthma program is given in Table 55.10.[12] Respiratory care educational programs need to be diligent when incorporating health promotion and disease prevention activities into all learning domains as part of their curricula.

Another specific area of health promotion that receives much attention in both hospital and public health settings is nicotine intervention. Hospitalized patients are more motivated to try to quit smoking for two reasons: the illness that resulted in the patient being in the hospital may have been made worse due to tobacco use, and hospitals have smoke-free environments. Therefore RTs should use this opportunity to promote nicotine treatments.

Nicotine intervention is a progressive, comprehensive program that incorporates a series of steps from risk identification to maintenance support. Smoking is the leading cause of preventable disease and death in the United States. January 11, 2014

TABLE 55.10 Components of an Asthma Disease Management Program

Component 1: Assessment and monitoring	Assessment: • Detailed patient history • Thorough physical examination • Spirometry to document the reversibility of airflow obstruction Monitoring: Periodic assessment and ongoing monitoring of asthma to determine if goals are being met • Minimal or no chronic and troublesome symptoms, day or night • Normal or near-normal pulmonary function • No limitations on activities • Minimal or no recurrent exacerbations of asthma • Optimal medications with minimal or no adverse side effects • Satisfaction with asthma care
Component 2: Control of the factors that contribute to asthma	Identify the allergens and irritants • House dust mites, cockroach feces, molds, and animal dander • Tobacco smoke, emissions from wood-burning stoves, strong odors and sprays, such as perfume and hairspray • Nitrogen dioxide and sulfur dioxide • Rhinitis and sinusitis • Gastroesophageal reflux disease • Viral respiratory infections • Aspirin • Sulfites Reduce exposure to the allergens and irritants, and provide medications or immunotherapy
Component 3: Pharmacologic therapy: managing asthma for the long term	Classify the asthma severity into one of the four levels based on the severity of recurrent symptoms and lung function Prescribe medications for the level of asthma • All patients with asthma need a quick-relief medication (i.e., short-acting β2-agonists) • Those with persistent asthma need daily long-term control medications to achieve control (e.g., an inhaled corticosteroid) • Start treatment in a stepwise approach (i.e., begin at a higher level to achieve rapid control; when control is achieved and sustained, cautiously step down treatment)

Component 4: Patient education for a partnership in asthma care	Patient education begins at the time of diagnosis.
	• Provide basic facts about asthma
	• Identify the roles of the medications
	• Skills: correct use of the medication delivery devices, the peak flow meter, and the symptom diary
	• Discuss environmental control measures
	• Discuss when and how to take rescue actions
	Education techniques
	• Basic facts about asthma
	  • Describe the contrast between asthmatic and normal airways
	  • Describe what happens to the airways during an asthma attack
	• Describe the roles of the medications
	  • How the medications work
	  • Long-term control: medications that prevent symptoms, often by reducing inflammation
	  • Quick relief: short-acting bronchodilators relax muscles around the airways
	Stress the importance of long-term control medications, and emphasize that the patient should not expect quick relief
	• Skills
	  • Inhaler use (patient demonstration)
	  • Spacer and holding chamber use
	  • Symptom monitoring, peak flow monitoring, and recognizing early signs of deterioration
	• Environmental control measures
	  • Identifying and avoiding indoor and outdoor environmental precipitants or exposures
	  • When and how to take rescue actions
	• Responding to changes in asthma severity (i.e., daily self-management plan and action plan)

marked the 50th anniversary of the first Surgeon General Report on smoking and health that linked smoking with lung cancer and heart disease, and the 32nd Surgeon General Report, "The Health Consequences of Smoking—50 years of progress: A report of the Surgeon General," which presents the most recent data on the consequences of smoking.[17,13] Also, in 2016, the Surgeon General's Report: E-Cigarette Use Among Youth and Young Adults is the first issued by the federal agency that comprehensively reviews the public health issue of e-cigarettes and their impact on young people.[18] This is the 33rd Report of the Surgeon General on tobacco. The Affordable Care Act's (ACA) Public Health and Prevention Fund expanded access to smoking cessation services

through most health insurance companies to include Medicaid. The ACA supports community-based programs and public education campaigns promoting prevention and helping people quit; 1.6 million smokers have tried to quit.[17,13] Safe and effective tobacco treatment enhances the success for quitting. Nicotine replacement therapies (NRT) such as nicotine gum, lozenges, or patches are available over the counter. NRT combined with behavioral therapy is more effective for tobacco cessation. Varenicline tartrate (Chantix) and bupropion (Zyban) do not contain nicotine. They are both available by prescription only.[17] Chantix interacts at the sites in the brain that are influenced by nicotine.

National, state, and local agencies, such as the American Cancer Society, the American Lung Association, and the American Heart Association offer educational materials and behavioral counseling. The educational materials that these agencies offer is available via mail, telephone, and the internet. The National Cancer Institute as part of the U.S. Department of Health and Human Services cessation initiative established a nationwide toll-free number (800-QUIT-NOW [800-784-8669]) to serve as an access point for smokers who are seeking assistance with quitting. Components of the Office of Surgeon General's tobacco cessation program is included in Tables 55.11 and 55.12.[15]

CHRONIC DISEASE MANAGEMENT AND POPULATION HEALTH

More than 190 million people have at least one chronic disease and 75 million live with two or more chronic conditions or comorbidity.[19] The key risk factors for developing a chronic disease include tobacco use, physical inactivity, poor nutrition choices, and excessive alcohol use. Also, the aging population as well as the cost of care are markedly increasing. These chronic diseases are extremely expensive and lead to unnecessary readmissions also known as **recidivism**. Short-term readmissions have always been undesirable for patients and their families. However, the Hospital Readmission Reduction Program penalizes hospitals for excessive unpreventable readmissions for diseases such as COPD and pneumonia. Hence there are financial implications for effective chronic disease management programs.

Managing chronic diseases takes more than a magic bullet, surgery, or medical rescues. They require holistic, **patient-centered care** with collaboration of an interdisciplinary team of providers (RTs, physicians, nurses, pharmacists, and other allied health providers). The team must coordinate the patient care across a continuum.

The term "**population health**" is more common and has several interpretations. The standard definition is "the health outcomes of a group of individuals, including the distribution of such outcomes within a group."[20] The people included in the population being discussed may vary depending on the situation, the organization, or the community of interest. In our hospital settings, the patient population are those individuals who use the hospital health services; in our outpatient clinics, the population are those individuals using the outpatient clinical facilities for pulmonary rehabilitation or education. Population health incorporates social determinants of health: housing, education level, economic level, race or ethnicity, and exposure to risk factors of disease. Our patients spend most of their lives outside our hospital or clinic doors and they make decisions about their health based on their culture, community, and family practices. Efforts to improve population health must include assessing the community needs, providing interventions or services for patients at risk for these chronic diseases, which may include monitoring health risk and status.

Disease management applies the best healthcare practices to a population diagnosed with a chronic illness one person at a time. The measures of health of a person with a chronic disease participating in a disease management program improves while patient satisfaction increases, mortality decreases, quality of life increases, and unnecessary medical treatment decreases, which, in turn, the cost of healthcare decreases. These disease management programs have similar components, which include a coordinated comprehensive interdisciplinary care team that has identified a process for measuring improvement. Most programs have the following attributes:

- The provision of interdisciplinary comprehensive care (i.e., health promotion, prevention, and acute care involving interdisciplinary or multidisciplinary teams—physician, RT, nurse, physical therapist (PT), occupational therapist (OT), pharmacist, and other health team members)
- A population-identification process (for a specific disease or condition)
- The use of evidence-based guidelines, protocols, and pathways
- Collaborative and coordinated components of care
- Active patient self-management and education (e.g., empowerment, behavior modification)
- Quality improvement methods to include outcomes measurement and evaluation
- The use of information technology to create a routine reporting and feedback loop

If you were interested in creating a disease management program, you would want to make sure to include these components. There are many disease management programs offered to patients with chronic diseases such as COPD, asthma, amyotrophic lateral sclerosis, and cystic fibrosis. RTs are ideal to create, coordinate, and participate as members of a disease management program. The patients whom RTs care for have chronic diseases, and these individuals need to be taught about the health risks associated with the disease, the prophylactic measures used to maintain quality health, and disease-specific respiratory therapy. For example, in a disease management program for patients with COPD, RTs would provide one-on-one counseling for tobacco cessation education (if the patient continued to use these products); discuss pulmonary rehabilitation that included exercise as well as strength and endurance training; and recognize and manage an acute situation and appropriate medication management. The RT would work with the patient to establish personal goals, including changing the person's behaviors and reducing the risks associated with the chronic disease. Outcomes such as healthcare utilization, hospital admissions, dyspnea scores, or missed school or work days, ER visits, and quality-of-life surveys would be reported for all patients with COPD. These outcome measurements are used to determine success or failure of the program for the patient population diagnosed with COPD.

TABLE 55.11 The "5 As" Model for Treating Tobacco Use and Dependence as a Chronic Disease

Ask about tobacco use	Identify and document the tobacco use status of every patient at every visit • Expand the vital signs to include tobacco use
Advise to quit	Strongly urge all tobacco users to quit Advice should be clear, strong, and personalized
Assess every tobacco user's willingness to make a quit attempt	Ask every tobacco user if he or she is willing to make a quit attempt: "Are you willing to give quitting a try?" • If the patient is willing, provide assistance • If the patient is unwilling, provide a motivational intervention • If the patient is a member of a special population (e.g., pregnant, adolescent, minority), consider providing him or her with additional information
Assist by providing counseling and medication	• Set a quit date that is ideally within 2 weeks • Tell family and friends about quitting • Anticipate challenges, including nicotine withdrawal symptoms • Remove tobacco products from the environment Recommend the use of approved medications, except when they are contraindicated or if the patient is a member of a specific population (e.g., pregnant women, smokeless tobacco users, adolescents) • Explain how the medications work to increase success with quitting and to reduce withdrawal symptoms The medications approved for this purposed by the U.S. Food and Drug Administration include the following: • Bupropion SR • Nicotine gum • Nicotine inhaler • Nicotine lozenge • Nicotine nasal spray • Nicotine patch • Varenicline Provide practical counseling (i.e., problem solving, skills training): • Abstinence: striving for total abstinence is essential (i.e., "not one puff after the quit date") • Anticipate triggers and challenges: determine how the patient will successfully overcome these (i.e., avoid the triggers) • Alcohol should be avoided because it is associated with relapse (however, reducing alcohol intake could precipitate withdrawal in alcohol-dependent persons) • Other smokers in the home: quitting is more difficult when there is another smoker in the home; patients should encourage all to quit with them or to not smoke in their presence Provide intratreatment social support • Provide a supportive clinical environment while encouraging the patient in his or her quit attempt (i.e., "My office staff and I are here to assist you") Help the patient obtain extra social support during treatment • Help the patient develop social support in his or her environment outside of the treatment by asking the patient's spouse or partner, friends, and coworkers to support the quit attempt Provide supplementary materials, including information about quit lines • Sources: Federal agencies, nonprofit agencies, national quit line network (1-800-QUIT-NOW), and local/state/tribal health departments and quit lines • Type: culturally, racially, educationally, and age appropriate for the patient • Location: readily available Recommend counseling (there are three types): Practical counseling (i.e., problem solving, skills training) • Recognize danger situations • Develop coping skills • Provide basic information Supportive treatment counseling • Encourage the patient to quit • Communicate a sense of caring and concern • Encourage the patient to talk about quitting
Arrange for follow-up contacts, either in person or via the telephone	Timing: Follow-up contact should begin soon after the quit date, preferably during the first week; a second follow-up is recommended within the first month, and follow-up should be scheduled as indicated • Actions to take during the follow-up contacts: for all patients, identify problems that have been encountered, and anticipate challenges Assess the medication use and any associated problems • Remind the patient of the support offered by quit lines • Address tobacco use at the next clinical visit • When patients have been abstinent, congratulate them on their success

TABLE 55.12 Components of a Tobacco Education Program for Those Who Are Unwilling to Quit Enhancing Motivation to Quit Tobacco: The "5 Rs"

Relevance	Encourage the patient to indicate why quitting is personally relevant and to be as specific as possible. Motivational information has the greatest impact if it is relevant to a patient's disease status or risk, to a family or social situation (e.g., having children in the home), or to health concerns, age, gender, and other important patient characteristics (e.g., prior quitting experience, personal barriers to cessation)
Risk	Ask the patient to identify potential negative consequences of tobacco use and suggest those that seem to be the most relevant to the patient. Emphasize that smoking low-tar or low-nicotine cigarettes or using other forms of tobacco (e.g., smokeless tobacco, cigars, pipes) will not eliminate these risks. Examples of risks include the following: • Acute risks: shortness of breath, exacerbation of asthma, harm to a pregnancy, impotence, infertility • Long-term risks: heart attack, stroke, lung and other cancers, chronic obstructive pulmonary disease, disability, need for extended care • Environmental risks: increased risk of lung cancer and heart disease in spouse, increased rates of smoking among children of tobacco users, sudden infant death syndrome, respiratory infections in the children of smokers
Rewards	Ask the patient to identify the potential benefits of stopping tobacco use: • Improved health • Food will taste better • Save money • Feel better • Home, car, clothing, and breath will smell better • Can stop worrying about quitting • Set an example for children • Have healthier babies and children • Reduce wrinkling and aging of skin
Roadblocks	Ask the patient to identify barriers to quitting: • Withdrawal symptoms • Fear of failure • Weight gain • Lack of support • Depression • Enjoyment of tobacco
Repetition	Repeat the motivational intervention information every time an unmotivated patient is seen

Implications for the Respiratory Therapist

Because the RT can practice as both an individual counselor and a public health advocate focused on population health, depending on the setting or circumstances, it is useful to examine the most likely settings in which the RT's health promotion and disease prevention knowledge can be put to good use.

Healthcare Institutions

Healthcare institutions in which RTs provide both health education and promotion include inpatient facilities (e.g., hospitals, skilled nursing facilities) and ambulatory care centers (e.g., physicians' offices, clinics, health insurance organizations). RTs may practice in outpatient or long-term acute care settings as well as in corporate wellness programs for staff and patients that are aimed at improving cardiopulmonary health through disease management education, which includes nutrition, medication management, and exercise (e.g., pulmonary rehabilitation, asthma management education programs).

Work Site

Healthier workers are absent from work less often; they are also more satisfied with their jobs and are more productive. This all translates into a more cost-effective workplace. RTs may find themselves involved in work-site wellness by participating in the following: (1) performing pulmonary function or blood pressure screenings; (2) developing and implementing stress management or nicotine intervention programs; and (3) consulting on policies related to smoking and occupational or environmental exposure to foreign dusts (e.g., silica, asbestos) or noxious fumes (e.g., smog).

Home

Home healthcare continues to be a rapidly growing segment of the healthcare industry. It has been proved repeatedly to be more cost-effective than hospital care. RTs can perform a wide variety of services in the patient's home, including oxygen therapy and mechanical ventilation on either a temporary or long-term basis. Generally, the focus is on prevention (i.e., preventing further decline). Patient education is of primary importance in the home so that the patient may become as self-reliant as possible (see Chapters 56 and 57).

Community

Most of the health promotion activities described earlier pertain to the individual. At the community level, the focus is on the group. Community health promotion activities provided by the RT may include the following: pulmonary function screening at health fairs, smoking cessation programs, family asthma management education programs, and COPD (i.e., better breathing) support groups. RTs who are certified in basic cardiac life-support instruction may also volunteer to perform certification in this practice for various groups.

Educational Institutions

Because many unhealthy behaviors begin during early childhood or adolescence, elementary, middle, and secondary schools are excellent places to begin health education activities. Education about smoking is one example.

Cigarette smoking is a primary risk factor that is associated with many of today's leading causes of death. Because most smoking begins during late childhood or early adolescence, schools provide the best settings in which to educate children about the dangers of tobacco. RTs are trained to provide these educational experiences. It is never too early to begin sending the antismoking message.

SUMMARY CHECKLIST

- Patient education and general approaches to health promotion are key issues in healthcare today.
- Incorporating health literacy and cultural beliefs into patient education programs affects patient compliance.
- Health literacy and cultural beliefs impact patient's decisions about their health
- Educators should use learning objectives to direct teaching strategies toward individuals or large groups of patients.
- Learning objectives call for the use of an action verb to define the performance that is expected of the patient at the end of instruction.
- Learning occurs in three domains: cognitive (knowledge), psychomotor (skills), and affective (attitudes).
- Patients tend to learn by doing. Passive participation usually does not cause a change in behavior.
- Evaluate the cognitive domain objectives with written tests. Evaluate psychomotor and affective domain objectives with a skills checklist.
- Use the teach-back method to gain an understanding of your own teaching and the patient's understanding of what was taught.
- The clinician should evaluate his or her teaching to improve.
- Population health focuses on a group of patients or people with a common disease and disease management focusing on the individual with the disease.
- The respiratory therapist can have an impact on several areas of health education and health promotion, including tobacco cessation programs, asthma education programs, pulmonary rehabilitation, and community health screenings.
- Respiratory therapists can be key players in disease management programs because of their understanding of the manifestations of the chronic cardiopulmonary diseases and their abilities to teach patients self-management with the use of the patient education tools discussed in this chapter.

Cardiopulmonary Rehabilitation

Andres Osorio and Albert J. Heuer

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Understand and explain the definition and goals of pulmonary rehabilitation.
- Explain the rationale for exercise conditioning and psychosocial support of patients with chronic pulmonary disease.
- Understand and explain how to evaluate and select patients for pulmonary rehabilitation.
- Delineate among the different parts of a pulmonary rehabilitation program, including its implementation.
- Describe and develop educational guidelines for individuals enrolled in a pulmonary rehabilitation program.
- Understand the resources needed to develop and offer a program, including professional staffing, facilities, class size, equipment, costs.
- Review the emergence of web-based pulmonary rehabilitation.
- Describe the process and necessary documentation for reimbursement.
- Discuss the outcome measures that can be used to evaluate pulmonary rehabilitation programs.
- Understand and identify the risk factors associated with pulmonary rehabilitation.
- Understand similarities and differences between pulmonary rehabilitation and cardiac rehabilitation programs.

CHAPTER OUTLINE

KEY TERMS

6- or 12-minute walk
aerobic exercises
cardiopulmonary exercise evaluation (CPX)
comprehensive outpatient rehabilitative facilities (CORFs)
Karvonen's formula
onset of blood lactate accumulation (OBLA)
Patient Protection and Affordable Care Act (PPACA)
progressive resistance
psychosocial support
pulmonary rehabilitation
reconditioning
target heart rate
telerehabilitation
ventilatory threshold

Chronic respiratory diseases are affecting thousands of people around the world each year. This group of diseases can be defined as diseases affecting different structures of the lungs and airways. Asthma, chronic obstructive pulmonary disease (COPD), and pulmonary hypertension are part of this group. Given that COPD accounts for 6% of all deaths worldwide and almost 400,000 deaths annually are due to asthma, many organizations like the World Health Organization (WHO) are supporting programs in an effort to reduce the impact of these diseases in terms of mortality, disability, and quality of life. Not surprisingly, asthma and COPD are the main foci of these programs.[1]

Although differences in diagnoses can have an impact on treatment outcomes and survival, patients with chronic pulmonary disorders have much in common. These patients have difficulty coping with the physiologic limitations of their diseases, and these physiologic limitations cause many psychosocial problems. The result is often an unsatisfactory quality of life. The high incidence of repeated hospitalizations and the progressive disability of these patients can be reduced by well-organized programs of rehabilitative care. Hence **pulmonary rehabilitation** (PR) aims to help improve quality of life in such patients and reduce the burden of chronic respiratory diseases. In addition, with the passage of the **Patient Protection and Affordable Care Act (PPACA)** in 2010, the reduction of early hospital readmissions for various chronic diseases, including COPD, is a major concern and focus of health care today. Since PR follows hospital discharge and involves clinical monitoring and interventions, it can act as an early-warning system for patients with a deteriorating clinical status to help prevent readmissions. This chapter provides foundational knowledge regarding the goals, methods, and issues involved in providing planned programs of rehabilitation for individuals with chronic pulmonary disorders.

DEFINITIONS AND GOALS

The Council on Rehabilitation defines rehabilitation as "the restoration of the individual to the fullest medical, mental, emotional, social, and vocational potential of which he or she is capable."[2] The overall goal is to maximize functional ability and to minimize the impact the disability has on the individual, the family, and the community. The American Thoracic Society in conjunction with the European Respiratory Society characterize PR as a comprehensive intervention, based on a complete patient assessment and followed by tailored multidisciplinary therapy and education to improve the physical and emotional conditions of patients with chronic respiratory diseases and to promote adherence to healthy behaviors. The reason for the multidisciplinary approach is to have a comprehensive, goal-oriented plan of care to reduce symptoms, increase exercise tolerance, and promote independence.[3] It is important to highlight that PR does not reverse or stop progression of the disease. However, it can help address deconditioning and lack of ongoing disease management associated with chronic lung disease, therefore, improving the patient's overall quality of life.[3]

HISTORICAL PERSPECTIVE

PR is not a new concept. In 1952, Barach and colleagues recommended reconditioning programs for patients with chronic lung disease to help improve their ability to walk without dyspnea.[4] Decades passed before clinicians paid any attention to this concept because oxygen therapy and bed rest were the modality of treatment at the time. The lack of reconditioning programs resulted in a vicious cycle of skeletal muscle deterioration, progressive weakness and fatigue, and increasing levels of dyspnea.

In 1962, published results confirmed Barach's insight into the value of reconditioning.

They observed that patients with COPD who participated in physical reconditioning exhibited lower pulse rates, respiratory rates, minute volumes, and carbon dioxide (CO_2) production during exercise, without significant improvements in pulmonary function.[5] Soon thereafter, it was shown that reconditioning could improve both the efficiency of motion and O_2 consumption in patients with COPD.[6]

In 2003, Bourbeau and colleagues provided evidence that PR can reduce hospitalizations by 40% for patients with COPD exacerbations and unscheduled physician appointments by 59% when proper education is available. As a result of this and other related research, in 2006, the American College of Chest Physicians (ACCP) and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) released their evidence-based guidelines relating to PR aimed at improving the way the programs are designed, implemented, and evaluated through patient outcomes.[7-12] It is currently understood that PR benefits patients with chronic obstructive and restrictive pulmonary disease in several ways. When combined with smoking cessation, optimization of blood gas results (arterial pO_2, pCO_2, and pH), and proper medication use, PR offers the best treatment option for patients with symptomatic pulmonary disease. The latest research indicates that PR decreases healthcare utilization and hospital stays, thus reducing health care cost.[8]

PHYSICAL AND PSYCHOSOCIAL BASIS

Rehabilitation must focus on the patient as a whole and not solely on the underlying disease. For this reason, effective PR programs combine knowledge from both the clinical and the social sciences. Knowledge from the clinical sciences can help quantify the degree of physiologic impairment and establish outcome expectations for reconditioning. Application of the social sciences is helpful in determining the psychological, social, and vocational impact of the disability on the patient and family and in establishing ways to improve the patient's quality of life.

Physical Reconditioning

At rest, an individual maintains homeostasis by balancing external, internal, and cellular respiration. Physical activity, such as **aerobic exercises**, increases energy demands. To maintain homeostasis during exercise, the cardiorespiratory system must keep pace. Fig. 56.1 shows how the body responds to exercise. Ventilation and circulation increase to supply tissues and cells with

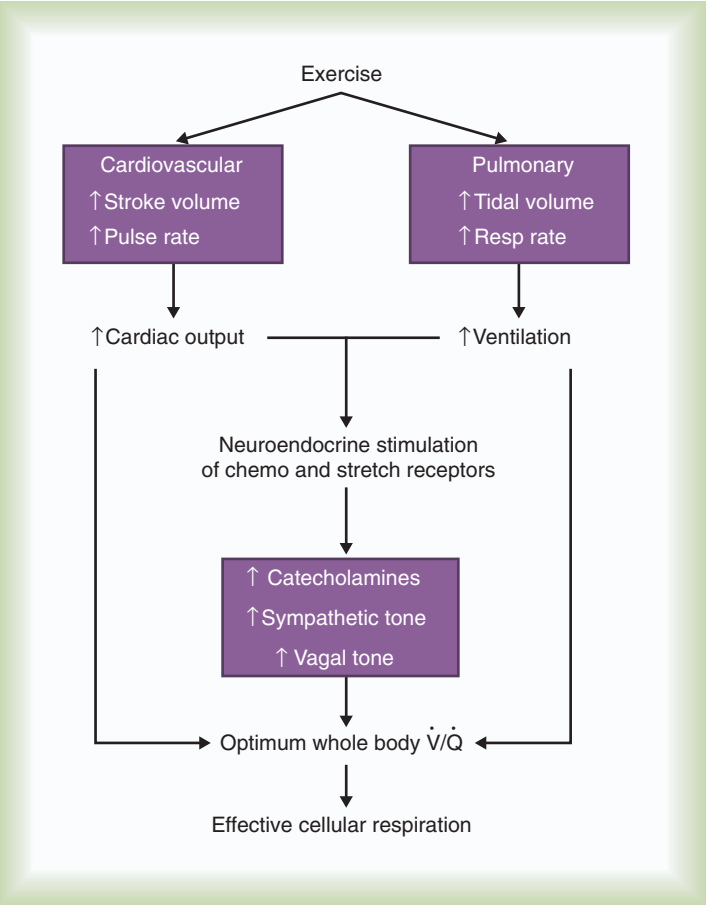

Fig. 56.1 The Body's Response to Increased Levels of Activity Such as Exercise.

additional O_2 and to eliminate the higher levels of CO_2 produced by metabolism.

As depicted in Fig. 56.2, as exercise intensity increases, both O_2 consumption and CO_2 production increase in a manner closely related to one another. If the body cannot deliver sufficient O_2 to meet the demands of energy metabolism, blood lactate levels increase above normal. In exercise physiology, this point is called the **onset of blood lactate accumulation (OBLA)**. As this excess lactic acid is buffered, CO_2 levels increase and the stimulus to breathe increases. The result is an abrupt upswing in both CO_2 and $\dot{V}_E$ (referred to as the **ventilatory threshold**). Beyond this point, metabolism becomes anaerobic, the efficiency of energy production decreases, lactic acid accumulates, and fatigue sets in.

COPD patients with impaired pulmonary function often have limited exercise capacity. Their high rate of CO_2 production during exercise results in respiratory acidosis and shortness of breath that is out of proportion to the level of activity. In addition, as ventilation increases, the rate of O_2 consumption in a patient with COPD increases significantly (Fig. 56.3). Together, these factors limit patient tolerance for any significant increase in physical activity.

PR must include physical **reconditioning**, which involves strengthening essential muscle groups, improving overall O_2 utilization and enhancing the body's cardiovascular response to physical activity as noted in Box 56.1.

Psychosocial Support

If the overall goal of PR is to improve the quality of patients' lives, physical reconditioning alone is insufficient. Psychosocial indicators are generally good predictors of morbidity in patients with COPD. As a result, a plan of care should be designed to help patients and caregivers to develop the consciousness and the psychosocial adjustment of the disease process, which is important for a successful diseases management.[13]

There is a well-established relationship between physical, mental, and social well-being in humans. However, emotional states such as anxiety and stress can aggravate an existing physical problem. The diagnosis of COPD can negatively impact an individual, especially during the late stages of the disease process, when physical limitations are more evident. There are some psychosocial challenges shared by patients with respiratory diseases, but individual differences like comorbidities and **psychosocial support** may change the impact for each particular person. Since depression, anxiety, and other disorders can negatively impact the outcome of a plan of care, early recognition of these symptoms is vital in the management of chronic diseases.[14]

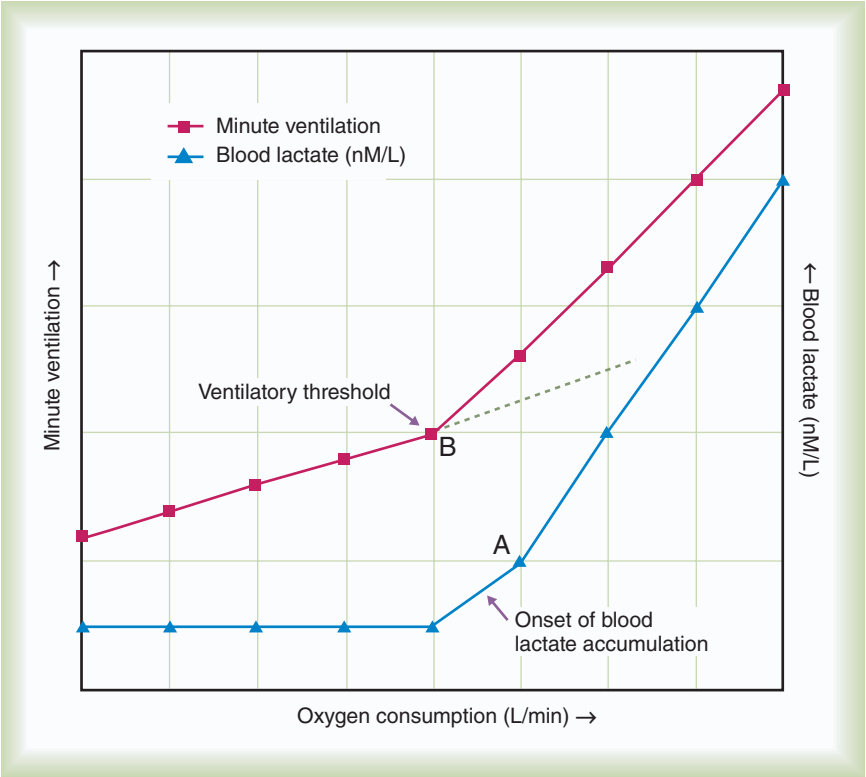

Fig. 56.2 Minute ventilation, blood lactate, CO_2 production, and O_2 consumption during graded exercise to maximum. The dashed line represents the linear extrapolation between $\dot{V}E$ and $\dot{V}O_2$ during submaximal exercise. Point A represents OBLA. At the same time, $\dot{V}E$ and $\dot{V}CO_2$ "break" from their extrapolated rate of increase and abruptly rise (point B). This is referred to as the ventilatory threshold. (Modified from McArdle WD, Katch FL, Katch VL: *Exercise Physiology: energy, nutrition and human performance*, ed 6, Baltimore, 2007, Williams and Wilkens.)

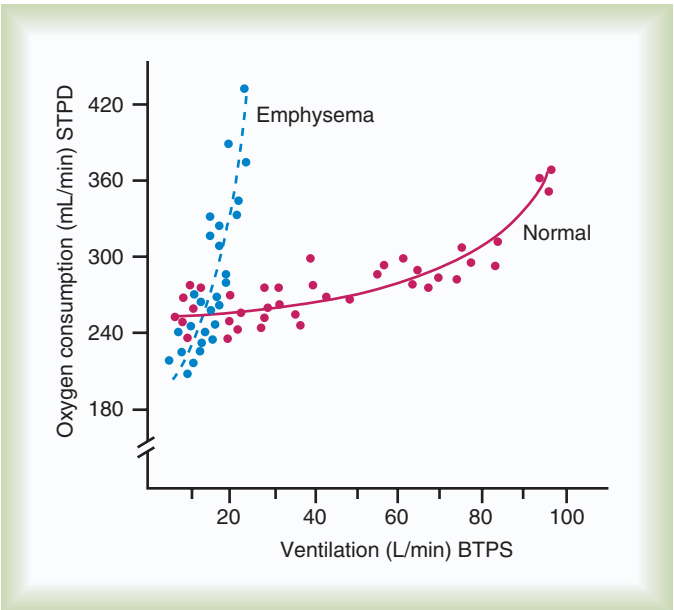

Fig. 56.3 Changes in O_2 consumption with increasing ventilation in a normal subject and in a patient with emphysema. *BTPS*, Body temperature, body pressure saturated; *STPD*, volume of dry gas at 0°C and 760 mm Hg atmospheric pressure. (Modified from Cherniack RM, Cherniack L, Naimark A: *Respiration in health and disease*, ed 3, Philadelphia, 1984, Saunders.)

BOX 56.1 Benefits From Exercise Reconditioning

Accepted Benefits

Increased physical endurance
Increased maximum O_2 consumption
Increased activity levels with:
- Decreased ventilation
- Decreased $\dot{V}O_2$
- Decreased heart rate
- Increased ventilatory threshold
- Improved blood lipids

Potential Benefits

Increased sense of well-being
Improved secretion clearance
Increased hypoxic drive
Improved cardiac function

Unproven Benefits

Prolonged survival
Improved pulmonary function test results
Decreased pulmonary artery pressure
Improved blood gases
Change in muscle O_2 extraction
Change in step desaturation

Data from references 17 and 26.

Because patients are fearful of economic loss and death, they can develop hostility toward the disease and toward the people around them. In terms of social function, the physiologic impairment of chronic lung disease combined with other variables can severely restrict a patient's ability to perform routine tasks requiring physical exertion. Moreover, patients' potential loss of confidence in their ability to care for themselves reduces feelings of dignity and self-worth.

It is here that the link between the physical reconditioning and psychosocial support components of rehabilitation becomes most evident. By increasing exercise tolerance and enhancing the body's cardiovascular response to physical activity, patients can develop a more independent and active lifestyle, thus enhancing their psychosocial well-being. For some patients, simply being able to walk to the market or play with their grandchildren can contribute to a greater feeling of social satisfaction. For others, physical conditioning may allow a return to near-normal levels of activity, including vocational pursuits.

Many patients disabled by pulmonary disease are in their economically productive years and are anxious to return to economic self-sufficiency. For these patients, occupational retraining and job placement are key ingredients of a good rehabilitation program.

STRUCTURE OF A PULMONARY REHABILITATION PROGRAM

Program Qualification

The Centers for Medicare & Medicaid Services (CMS) has provided guidelines for patients under Medicare to qualify for this program. Every healthcare insurance has its own guidelines and requirements, but they often follow CMS guidelines. Patients need to have a treating physician for the chronic respiratory disease, and the initial order is sufficient for the first 30 days of enrollment. The referring physician must certify that the patient has had a physical examination within 90 days of initial referral. The physician needs to be specific on the type of service ordering, including frequency and duration of the service. If a patient requires PR services after the certification date, the physician must certify that the patient remains capable and the benefits from continuing in the program.[15]

Documentation is a key factor for qualification and reimbursement for PR. It needs to show that a multidisciplinary plan is appropriate for the patient and has measurable and potentially obtainable objectives.[16]

Program Goals and Objectives

PR programs vary in their design and implementation but generally share common goals (Box 56.2). These general goals assist planners in formulating more specific program objectives. When determining objectives, both patients and members of the rehabilitation team should have input. These objectives should always be realistic and stated in measurable terms, because this helps monitor progress towards achieving outcomes and, ultimately, the success of the PR program. Depending on the specific needs of the participants, program objectives can include the following:

BOX 56.2 Common Goals for Pulmonary Rehabilitation Programs

- Control of respiratory infections
- Basic airway management
- Improvement in ventilation and cardiac status
- Improvement in ambulation and other types of physical activity
- Reduction in overall medical costs
- Reduction in hospitalizations
- Psychosocial support
- Occupational retraining and placement (when and where possible)
- Family education, counseling, and support
- Patient education, counseling, and support

- Development of diaphragmatic breathing skills
- Review of stress management and relaxation techniques
- Involvement in a daily physical exercise regimen to condition both skeletal and respiratory-related muscles
- Adherence to proper hygiene, diet, and nutrition
- Smoking cessation (if applicable)
- Proper use of medications, O_2, and breathing equipment (if applicable)
- Application of airway clearance techniques (when indicated)
- Participation in group support
- Provisions for individual and family counseling

When program objectives are specifically defined and structured in a measurable way, strategies should be developed to help ensure they are achieved. For example, if smoking cessation is an objective for a PR participant, then strategies such as enrollment in smoking cessation programs, the use of nicotine replacement and other medications should use and progress towards reducing and eliminating daily tobacco use should be closely monitored.

RULE OF THUMB

When program objectives are established for PR participants, they should be relevant, realistic, and measurable. In addition, strategies should be adopted to help participants achieve such objectives, and progress should be closely monitored.

Patient Evaluation and Selection

Patient selection requires comprehensive evaluation and testing. Before beginning a PR program, clinicians need to define and establish criteria for selection. They need to be aware of the patient's comorbidities and the anticipated effects of exercise on the patient's overall status as well as laboratory results.[17]

Patient Evaluation

PR programs must have a qualified physician medical director, usually a pulmonologist, to provide overall direction for the program and to help screen prospective patients.[18] Because PR is a supervised program under Medicare regulations, some programs have a supervising physician in addition to the medical director. This physician must be physically available

and accessible for consultation and emergencies at all times when the program is being provided. Non–hospital-based settings must prove compliance with the supervising physician by keeping records of policies and procedures, calendars, schedule or call logs, and records must be available for inspection by Medicare staff. [19]

Although many PR participants may share the same diagnosis and comorbidities, it is important to understand that every patient is different and that everyone requires a personalized plan of care. The patient evaluation is the foundation for a thorough plan of care, and it begins with a complete patient history and addresses medical, psychological, vocational, and social elements. A well-designed patient questionnaire and interview form often assist with this step. The patient history should be followed by a complete physical examination (see Chapter 16). A recent chest x-ray, resting electrocardiogram (ECG), complete blood count, serum electrolytes, and urinalysis provide additional information about the patient's current medical status (see Chapter 17).

To determine the patient's cardiopulmonary status and exercise capacity, both pulmonary function testing and a CPX should be performed. Pulmonary function testing includes assessment of pulmonary ventilation, lung volume determinations, diffusing capacity (DLCO). Spirometry is an essential tool during this assessment, and it should include before and after bronchodilator use to determine the severity of the airflow limitation and the stage of the chronic pulmonary disease (see Chapter 20).[20]

The **cardiopulmonary exercise evaluation (CPX)** serves two key purposes in PR. First, it is important to patient evaluation because it quantifies the patient's initial exercise capacity. This quantification provides the basis for the exercise prescription (including setting a **target heart rate**) and yields the baseline data for assessing a patient's progress over time. In addition, the CPX helps determine the degree of hypoxemia or desaturation that can occur with exercise; this provides the objective basis for titrating O_2 therapy during the exercise program. The CPX plays an important role by providing a reliable and accurate functional assessment of the patient, the lungs, cardiac function, and the muscles contributing to exercise performance. However, the CPX requires specialized equipment and as a result, is often underutilized by many clinicians despite its advantages.[21] As an alternative to the CPX, the European Respiratory Society and the American Thoracic Society have published the technical standard for field walking testing of patients with chronic respiratory diseases to guide practitioners in implementing exercise capacity evaluations. The technical standard helps to identify exercise capacity and exercise performance limitations, among other factors, and can be used as a predictor of possible hospitalizations, patient's response to treatments or therapies and survival. [22]

RULE OF THUMB

The cardiopulmonary exercise stress test (CPX) is an extremely valuable tool in screening patients for suitability for PR program participation. However, due to cost and other practical limitations associated with CPX, field exercise walking testing may be considered as an alternative for evaluating such patients.

BOX 56.3 Common Physiologic Parameters Measured During Exercise Evaluation

- Blood pressure
- Heart rate
- Electrocardiogram
- Respiratory rate
- Arterial blood gases/O_2 saturation
- Maximum ventilation ($\dot{V}E_{max}$)
- O_2 consumption (either absolute $\dot{V}O_2$ or METS)
- CO_2 production ($\dot{V}E/\dot{V}CO_2$)
- Respiratory quotient (RQ)
- O_2 pulse ($\dot{V}O_2$:heart rate)

METS, Metabolic equivalents of O_2 consumption.

Modified Borg Dyspnea Scale (With Dyspnea Descriptors)

The Modified Borg Dyspnea Scale (MBS) is another assessment tool used to evaluate patients with chronic lung disease. It is used to classify the level of dyspnea as perceived by such patients and can therefore grade the level of dyspnea by assigning the number next to the words that best describe their shortness of breath.

10	Maximal (worst possible you can imagine)
9	Very, very severe
8	Very, very severe
7	Very severe
6	Very severe
5	Severe
4	Somewhat severe
3	Moderate
2	Slight
1	Very slight
0.5	Very, very slight (just noticeable)
0	None at all

RULE OF THUMB

The Modified Borg Dyspnea scale can be quite useful in quantifying the level of dyspnea in COPD and other potential PR candidates.

The exercise evaluation procedure involves serial or continuous measurements of several physiologic parameters during various graded levels of exercise on either an ergometer or a treadmill (Box 56.3). To allow for steady-state equilibration, these graded levels are usually spaced at 3-minute intervals. Work levels are increased progressively until either: (1) the patient cannot tolerate a higher level, or (2) an abnormal or hazardous response occurs.

Blood gas and arterial oxygen saturation measurements are obtained at rest and at peak exercise. If the peak exercise puncture is unsuccessful, a sample drawn within 10 to 15 seconds of test termination usually suffices. Pulse oximetry is used to monitor and to warn clinicians of gross desaturation events during testing, including the patient's response to supplemental O_2 during exercise.

Relative contraindications to exercise testing include the following:

- Inability or unwillingness of the patient to perform the test
- Severe pulmonary hypertension or cor pulmonale
- Known electrolyte disturbances (hypokalemia, hypomagnesemia)
- Resting diastolic blood pressure greater than 110 mm Hg or resting systolic blood pressure greater than 200 mm Hg
- Neuromuscular, musculoskeletal, or rheumatoid disorders exacerbated by exercise
- Uncontrolled metabolic disease (e.g., diabetes)
- SaO_2 or SpO_2 less than 85% with the subject breathing room air
- Untreated or unstable asthma
- Angina with exercise
- Severe aortic stenosis

Exercise evaluation also can help differentiate among patients with primary respiratory or cardiac limitations to increased work capacity. Table 56.1 summarizes these key similarities and differences. Besides helping to differentiate between the underlying cause of exercise intolerance, test results can assist in placing patients in the appropriate type of rehabilitation program. For example, patients with critical cardiac and respiratory complications should receive cardiac rehabilitation before starting a pulmonary program.

To minimize patient risk during exercise evaluation, certain safety measures are implemented. First, the patient should undergo a physical examination just before the test, including a resting ECG. Second, a qualified physician or advanced practitioner (e.g., nurse practitioner or physician assistant) should be present throughout the entire test. Third, emergency resuscitation equipment (cardiac crash cart with monitor, defibrillator, O_2, cardiac and respiratory drugs, suction equipment, and airway equipment) must be readily available. Fourth, staff conducting and assisting with the procedure should be certified in basic and advanced life-support techniques. Last, the test should be terminated promptly at the patient's urging or with any adverse effect.

With regard to test preparation, patients should fast for 8 hours before the procedure. If the purpose of the test is to formulate an exercise prescription, the patient can take his or her regular medications. The patient should wear comfortable, loose-fitting clothing and footwear with adequate traction for treadmill or ergometer activity. Test conditions should be as standardized as possible to allow for comparison of results before and after rehabilitation periodically from year to year as the patient is treated and followed.

Patient Selection

Patients most likely to benefit from participation in PR are patients with persistent symptoms caused by COPD who have low maximum O_2 uptakes at baseline. Since PR is a complementary therapy for patients receiving pharmacotherapy, it should be a part of the hospital's discharge planning process after an exacerbation of the existing chronic respiratory condition. The feasibility of rehabilitation should be reviewed with the patient, physician, and respiratory therapist (RT) to educate patients and families on the benefits of the program in improving health-related quality of life and survival of people with COPD. There are studies showing that PR should be standard in the management and treatment of COPD patients.[23] Other indications for PR are listed in Box 56.4. Regardless of underlying conditions, candidates for this program should have stopped smoking. Active smokers should enroll in a smoking cessation program before starting PR. Patients are excluded from the program activities if: (1) concurrent problems limit or preclude participation in exercise, or (2) they have a very limited life expectancy (e.g., with metastatic malignancy, etc.; see Box 56.4).

Objectively, candidates for PR generally fall into one of the following groups:[24]

TABLE 56.1 Exercise Parameters Distinguishing Cardiac and Ventilatory (Chronic Obstructive Pulmonary Disease) Limitations

Parameter[a]	Cardiac[b]	COPD[b]
Maximum $\dot{V}O_2$	↓	↓
Maximum HR	N or ↓	↓
O_2 pulse	↓	N
Maximum $\dot{Q}$	↓	↓
$\dot{Q}/\dot{V}O_2$	↓	N
PaO_2	N	↓
$PaCO_2$	↓	↑
$\dot{V}E_2/\dot{V}CO_2$	↑	↑
VT	↓	N

[a] *HR*, Heart rate; $\dot{Q}$, cardiac output; $\dot{V}E_2/\dot{V}CO_2$, ratio of minute ventilation to CO_2 production; $\dot{V}O_2$, oxygen consumption; *VT*, ventilatory threshold.
[b] *N*, Normal; ↑, increased; ↓, decreased.

BOX 56.4 Indications and Contraindications for Pulmonary Rehabilitation

Indications

Symptomatic patients with COPD—usually GOLD stage III (severe) and stage IV (very severe), but stage II (moderate) may also be considered
Patients with bronchial asthma and associated bronchitis (asthmatic bronchitis)
Patients with combined obstructive and restrictive ventilatory defects
Patients with chronic mucociliary clearance problems
Patients with exercise limitations because of severe dyspnea

Contraindications

Cardiovascular instability requiring cardiac monitoring (consider cardiac rehabilitation)
Malignant neoplasms involving the respiratory system
Severe arthritis or neuromuscular abnormalities (a relative contraindication—refer to physical therapy for case-by-case review)

- Patients in whom there is a respiratory limitation to exercise resulting in termination at a level less than 75% of the predicted maximum O_2 consumption ($\dot{V}O_{2max}$)
- Patients in whom there is significant irreversible airway obstruction with a forced expiratory volume in 1 second (FEV_1) of less than 2 L or an $FEV_{1\%}$ (ratio of FEV_1 to forced vital capacity [FVC]) of less than 60% (refer to the Global Initiative on Obstructive Lung Disease [GOLD] standards for COPD severity)
- Patients in whom there is significant restrictive lung disease with a total lung capacity (TLC) less than 80% of predicted and single breath carbon monoxide diffusing capacity (DL_{CO}) less than 80% of predicted
- Patients with pulmonary vascular disease in whom the single breath DL_{CO} is less than 80% of predicted or in whom exercise is limited to <75% of maximum predicted O_2 consumption (predicted $\dot{V}O_{2max}$)

MINI CLINI

Patient Selection for Pulmonary Rehabilitation

Problem

A patient is being evaluated for possible inclusion in a pulmonary rehabilitation program. The patient undergoes a complete history and physical examination and pulmonary function testing, arterial blood gas analysis, and exercise evaluation. During the exercise test, the patient develops severe hypertension and premature ventricular contractions. The physician recommends that the patient be admitted to PR and prescribes a modified exercise routine. The RT performing the test disagrees. How should the RT proceed?

Solution

The RT should contact the department medical director for intervention. Although this patient could possibly be admitted to PR, there is a high risk that some type of adverse response might occur during the exercise component of the program. The best direction would be to treat the cardiac abnormalities first. After identifying the causes of the exercise-induced hypertension and arrhythmia, these problems can be properly treated. When the patient's cardiac status has been stabilized, the patient may be admitted to PR and safely participate in and complete the program.

Program Design

A good design helps achieve specific programming objectives with the selected group of participating patients. Key design considerations involve both format and content, with an emphasis on patient reconditioning and education.

Format

Programs can use either an open-ended or a closed design, with or without planned follow-up sessions. With an open-ended format, patients enter the program and progress through it until they achieve certain predetermined objectives. There is no set time frame. Depending on his or her condition, needs, motivation, and performance, an individual patient can complete an open-ended program over weeks or months. This format is good for self-directed patients or patients with scheduling difficulties. It also may be the best format for patients requiring individual attention. The major drawback of the open-ended format is the lack of group support and involvement. In addition, obtaining insurance reimbursement may be challenging when the program is open-ended.

The more traditional closed design uses a set time period to cover program content. These programs usually run 6 to 16 weeks, with classes meeting one to three times a week. Class sessions usually last 1 to 2 hours. Presentations are more formal, and group support involvement is encouraged. A major drawback of the closed program format is that the duration of the rehabilitation is determined by a predetermined schedule rather than by achievement of the goals.

Ultimately, insurance coverage may dictate the duration of the rehabilitation program.[25] It is important to highlight that PR may represent a cost savings for insurance companies by decreasing healthcare cost and readmissions.

There are several studies showing the benefits of PR and its long-term improvements when programs are extended. Continuation of supervised exercise training after initial PR will prevent decreasing exercise capacity.[26] Follow-up must be ongoing and available to all patients who complete the program. Frequently, this essential element of the process is difficult, especially when it is not covered by most insurance plans, but program coordinators must ensure that it is routinely scheduled. Follow-up or reinforcement could be open-ended (available during regular rehabilitation sessions and offering open attendance) or could be scheduled weekly, monthly, bimonthly, or quarterly. The important thing is to have some type of follow-up available.[27,28]

Content

The content of the rehabilitation program usually combines physical reconditioning with education activities (Table 56.2). Programs providing reconditioning or education alone are unlikely to be effective.

As shown in Table 56.2, the ideal rehabilitation session should last about 2 hours. Group size, available equipment, and group interaction also dictate session length. Patients should be advised to arrive 10 to 15 minutes before a scheduled session to allow for informal group interaction and support. Classes should begin on time and conclude promptly as scheduled. Educational presentations should be brief and to the point. Audiovisual aids or live demonstrations can enhance patient understanding and

TABLE 56.2 Sample Pulmonary Rehabilitation Session (Good)

Component	Focus	Time Frame
Educational	Welcome (group interaction)	5 min
	Review of program diaries (activities of past week)	20 min
	Presentation of educational topic	20 min
	Questions, answers, and group discussion	15 min
Physical reconditioning	Physical activity and reconditioning	45 min
	Individual goal setting and session summary	15 min
Total session		120 min (2 h)

compliance. To facilitate patient understanding, the program should be explained in plain language and avoid technical terms whenever possible. The medical staff should be aware of possible language barriers and offer educational materials in different languages when possible and should be available to facilitate understanding. A folder or notebook to record program activities and progress and gather handout materials should be maintained by each patient.

Physical Reconditioning

The physical reconditioning component of the program consists primarily of an exercise prescription with a target heart rate based on the results of the patient's initial exercise evaluation. For most patients, an initial target heart rate may be set using **Karvonen's formula** (see accompanying Rule of Thumb) or can be estimated as 20 beats/min greater than resting rate. Because of the severity of ventilatory impairment, some patients may begin exercise reconditioning without a prescribed target heart rate.

> **RULE OF THUMB**
> To set a target heart rate for patient exercise, use Karvonen's formula:
>
> $$\text{Target heart rate} = [(\text{MHR} - \text{RHR}) \times (50\% - 70\%)] + \text{RHR}$$
>
> where MHR is maximum heart rate at limit of exercise tolerance and RHR is resting heart rate.
>
> A good target exercise heart rate for a patient with COPD with MHR of 150 beats/min and RHR of 90 beats/min would be $[(150 - 90) \times 0.60] + 90 = 126$ beats/min.

Typically, the exercise prescription includes the following four related components[29,30]:

1. Lower extremity (leg) aerobic exercises
2. Timed walking (**6- or 12-minute walk**)
3. Upper extremity (arm) aerobic exercises
4. Ventilatory muscle training

To ensure success with physical reconditioning, patients must actively participate both at the rehabilitation facility and at home. While exercising, such patients should be monitored with pulse oximetry. Blood pressure measurements may also be made, but these are usually done at the start and end of each session unless a patient's condition dictates otherwise. In addition, exercise sessions should be upbeat.

To ensure compliance with the program and progress in achieving goals and objectives, a daily log or diary sheet is completed (Fig. 56.4). These log or diary forms are reviewed each time the patient attends a session. Based on this information, further individualized reconditioning goals are set.

> **RULE OF THUMB**
> Patients participating in PR should maintain a log or diary of related activities in order to monitor compliance and progress.

Lower extremity exercises may include either walking or bicycling. Patients can walk on a stationary treadmill (with set goals for distance or time and grade) or on a flat, smooth surface. Patients can bicycle on an exercise cycle. With the treadmill or stationary bicycle, patients are required to cover a certain distance or duration every day that they are in the program. Commonly, the duration is set to 30 min daily, with patients encouraged to increase both their distance and equipment tension or resistance as tolerated. Patients with significant orthopedic disabilities can participate in aerobic aquatic exercises.

Walking also improves overall conditioning; this usually takes the form of a 6- or 12-min walk performed once a day, depending on the patient's condition and tolerance. These walk exercises are a convenient way for patients to carry out a well-defined amount of activity with increasing vigor and results over a number of weeks. During the 6 or 12 min, patients should walk on flat ground for as far as possible. If dyspnea occurs, they should stop and rest, with the rest time included as part of the time interval. After resting briefly, they should try to continue walking at a comfortable pace. The objective is to walk as far as possible during the allotted time. Landmarks such as telephone poles, city blocks, or actual distance measures can be used to quantify progress. Walking indoors is an alternative during adverse weather conditions.

Aerobic upper extremity exercises improve rehabilitation outcomes for patients whose regular activities involve lifting or

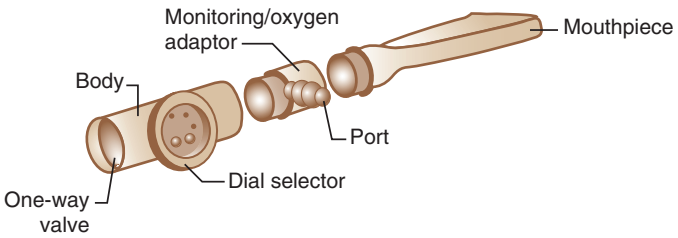

Fig. 56.5 Flow-Resistive Breathing Device.

raising the arms.[29] It is beneficial to combine upper and lower extremity exercises since they can improve exercise tolerance, provide better quality of life, increase tolerance of daily activities, and even reduce the risk of death in COPD patients.[31]

Arm ergometers or rowing machines are available for this purpose; however, simple calisthenics using either a broomstick or free weights (by prescription and with training) are a satisfactory alternative. Upper body endurance is generally more limited, with many patients capable of only 2 to 3 min of daily activity to start. This limitation is usually related to the fact that patients may revert to using accessory muscles for breathing while doing the upper body exercise. Patients need to breathe diaphragmatically and perform the exercises at the same time. Arm exercises should get progressively longer, up to 20 min if possible. Upper body conditioning helps patients perform numerous useful activities at home and can increase overall physical endurance.

Inspiratory muscle training in patients with COPD provides great clinical results by increasing functional exercise capacity, improving quality of life, and decreasing dyspnea.[32]

Ventilatory muscle training is based on the concept of **progressive resistance**. By imposing progressively greater loads on the inspiratory muscles (mainly the diaphragm) over time, the patient's strength and endurance should increase. These improvements should increase the patient's exercise tolerance.

Fig. 56.5 shows a typical inspiratory resistance breathing device. The device is an adjustable flow resistor with a one-way breathing valve. The inspiratory load is created by forcing the patient to inhale through a restricted orifice. Varying the size of this orifice varies the inspiratory load, as do changes in the patient's inspiratory flow. During expiration, gas flows unimpeded out the one-way exhalation valve. Other devices are also available. One model replaces the variable-size orifice with an adjustable spring-loaded valve. This valve ensures a constant load regardless of how quickly or slowly the patient breathes.

Because variations in breathing strategy during ventilatory muscle training can affect outcomes, proper patient evaluation, training, and follow-up are required. The RT initially measures the patient's maximum inspiratory pressure (PI_{max}) using a calibrated pressure manometer. The RT next compares the patient's maximum with established norms as noted in Table 56.3. This preliminary measure of inspiratory pressure helps to establish initial loads and provides the basis for the subsequent monitoring of patient progress.

Before beginning ventilatory muscle training, the patient should assume a position that relaxes the abdominal muscles, such as the position used for cough training. If using a flow-resistive device, the RT begins at the maximum orifice setting,

TABLE 56.3 Normal Maximum Inspiratory Pressure by Age and Sex

AGE GROUP (YEAR)	PI_{MAX} FROM RESIDUAL VOLUME ($CM\ H_2O$), MEAN ± SD	
	Male	Female
9–18	96 ± 35	90 ± 25
19–50	127 ± 28	91 ± 25
51–70	112 ± 20	77 ± 18
>70	76 ± 27	66 ± 18

From Rochester DF, Hyatt RE: Respiratory muscle failure, *Med Clin North Am* 67:573, 1983.

while measuring the inspiratory pressure generated through monitoring using the O_2 adapter (a second adapter may be needed if the patient is receiving supplemental O_2). The RT encourages the patient to breathe slowly through the device at a rate no greater than 10 to 12 breaths/min. If the patient's inspiratory pressure is less than 30% of the measured PI_{max}, the next smaller orifice is selected, with this procedure repeated until the 30% effort is consistently achieved.

At this point, the RT instructs the patient to exercise with the device in one or two regular daily sessions lasting 10 to 15 minutes. As the level of resistance becomes more tolerable over time, the patient should progressively increase the session duration up to 30 minutes. A self-maintained log of treatment times can help motivate the patient and assist the RT in subsequent progress monitoring.

Educational Component

The educational portion of the program covers topics that are both useful and necessary for the patient to achieve the goals of the plan of care (Table 56.4). Other topics can be included, depending on the program schedule, but in terms of relative importance, the ones listed in Table 56.4 generally have the highest priority.

These topics should be presented in an orderly, coherent fashion using supplementary audiovisual tools and demonstrations, where appropriate. Team members should allocate sufficient time for the class sessions themselves and for setup and breakdown of equipment.

The program facilitator or leader must ensure that sessions begin on time and encourage maximum participation by each patient. If available, health care professionals such as dietitians, occupational therapists, physical therapists, and psychologists should be invited to present their respective topics and discuss the subject matter with the group. In addition to technical knowledge, session leaders must possess group facilitation skills and be able to motivate patients to participate both in class and at home and to adhere to program guidelines.

Breathing control methods. Breathing control methods serve as the cornerstone for the physical reconditioning effort. Through structured educational sessions, patients can learn how to control their breathing efforts to ensure maximum result (ventilation) at a minimum of effort (energy expenditure). Diaphragmatic

TABLE 56.4 Typical Educational Topic Schedule for a 12-Week Pulmonary Rehabilitation Program

Session (Week)	Topic(s)	Recommended Facilitator(s)
1	Introduction and welcome; program orientation	Program administrator or rehabilitation team
2	Respiratory structure, function, and pathology	Physician or RT
3	Breathing control methods	PT or RT
4	Relaxation and stress management	Clinical psychologist
5	Proper exercise techniques and personal routines	PT or RT
6	Methods to aid secretion clearance (bronchial hygiene)	PT or RT
7	Home oxygen and aerosol therapy	RT
8	Medications—their use and abuse	Pharmacist, physician, or nurse practitioner
9	Medications—use of MDIs and spacers	RT

breathing with pursed lips helps to accomplish this, but this technique requires education and daily practice on the part of the patient and continued reinforcement throughout the entire program by the group facilitator. Eupnea, another name used for deep breathing or diaphragmatic breathing, helps to use the diaphragm correctly in patients suffering from air trapping from pulmonary diseases like COPD. There are different ways to perform this technique; it can be performed lying down, sitting in a chair, or standing. The main goal of this respiratory technique is to control the diaphragm during normal breathing to decrease the work of breathing, use less oxygen during physical activities, and decrease energy consumption, which improves exercise tolerance.[33]

The COPD Foundation recommends the following steps for diaphragmatic breathing:

1. Place one hand on your abdomen. Place one hand on your upper chest.
2. Focus your breathing on your abdomen.
3. As you breathe out, the hand on your abdomen should lower.
4. As you breathe in, the hand on your abdomen should rise.
5. Breathe in through the nose. Breathe out slowly through pursed lips.
6. Practice this 2 to 3 times a day for 5 to 10 minutes. Start by doing it while lying on your back. Then try it while sitting. Then try it while standing. Finally, try it while doing an activity.

It is important that patients are instructed by the RT or trained clinician in the correct technique since diaphragmatic breathing can be difficult when combined with pursed-lips breathing.[34]

Methods of relaxation and stress management. Patients must also learn to avoid aggravation and upsetting circumstances and to adopt a more relaxed attitude about their particular life circumstances. These circumstances, including stress, affect the body, mood, and normal behavior of patients with chronic respiratory diseases. Being able to recognize these factors is going to avoid possible exacerbations and to reduce unnecessary O_2 use, conserve energy, and avoid undesirable cardiovascular and nervous responses to stress. There are multiple techniques for self-control that provide health benefits to the individual; for example, deep breathing routines, physical activities, socialization, meditation, hobbies, walking away from stressful situations, etc.[34]

Secretion clearance and bronchial hygiene techniques. This educational topic is especially helpful to patients who have secretion clearance problems associated with chronic bronchitis and bronchiectasis. Family members and friends may be invited to attend this session to acquire basic skills with these procedures and equipment, when appropriate (see Chapter 44).

Home oxygen and aerosol therapy. Preferably, an RT with home care experience should provide the educational session on home oxygen and aerosol therapy. The focus should be on the use and basic maintenance of home-care equipment and the self-administration of therapy. Patients who have not yet been prescribed this type of therapeutic regimen may be misinformed by other patients and may have questions or fears and become unreceptive to the concept. Presenting the modalities available and having patients discuss their positive experiences with respiratory home-care personnel can help alleviate the fears and anxieties of others (see Chapter 42).

MINI CLINI

Equipment Problems

Problem

The RT has been asked to check the portable concentrator (POC) for a patient who just finished a session and is ready to go home. When the nurse transferred the patient from the tank to his POC, the unit started alarming; the patient started getting anxious because of the situation and started to hyperventilate. What should the RT do to assess and solve the problem?

Solution

The solution is to return the patient to the oxygen tank, ask the nurse or a team member to work with the patient to decrease hyperventilation, and for the RT to check the POC. The RT working in a PR program should be familiar with different respiratory home-care equipment and troubleshooting techniques, since patients may bring the equipment to the program.

This scenario may have different approaches and solutions. In this case, the nurse accidentally changed the mode of the POC from continuous to pulse flow. Since the patient was exhausted from the exercise routine, the patient was breathing through the mouth and unable to trigger the POC via nasal breathing (pulse mode will sense nasal breathing and deliver oxygen), initiating an alarm. Depending on the POC, the unit may switch to previous continuous mode or alarm continuously until the situation is corrected.

Medications. Proper use of medications is another topic about which patients have numerous questions and concerns. Content should emphasize the proper use of medications, along with possible abuses and adverse effects. Participants' current prescriptions should dictate which specific drugs to cover. Common categories include β-adrenergic agents, anticholinergic agents, steroids, and diuretics. The section leader, preferably the RT, should demonstrate proper use of metered dose inhalers, including spacers or holding chambers, dry powder inhalers, and hand-held nebulizers. Sufficient time should be provided for questions and answers. Two sessions should be allotted for this topic (see Chapters 36 & 40).

Dietary guidelines. Dietary topics should focus on weight management and good nutrition as it relates to cardiopulmonary health. Emphasis should be on the importance of a sound high-protein, low-carbohydrate diet. The facilitator also should cover proper eating habits, methods of gaining and losing weight, foods to avoid, ways to increase appetite, adequate hydration, and daily menu planning. This session can stimulate patients to eat better and supply their bodies with the necessary fuel for increased energy production (see Chapter 23).

Recreational and vocational counseling. Another educational topic should be aimed at motivating the patient to participate in recreational activities and, according to his or her ability, return to work. This topic is often presented at the end of the program when patients have increased their physical endurance and are preparing for a more active and productive lifestyle.

Psychosocial and Behavioral Components

Psychological and emotional stress is a common problem for patients with moderate to severe chronic lung disease. Around 40% of COPD patients have symptoms of anxiety or depression, with a higher percentage after an Acute Exacerbation of COPD (AECOPD). The effects of AECOPD have been associated with post-traumatic stress symptoms (PTSS) and post-dramatic stress disorder (PTSD).[3] PR programs can bring in experts to cover topics related to psychosocial and behavioral therapies that provide patients with the opportunity to learn coping strategies.

RULE OF THUMB

Because anxiety and depression are often present in COPD and other patients with chronic respiratory diseases, PR education sessions should include topics related to psychosocial and behavioral therapy.

Program Implementation

In 1987, the AARC and the AACVPR jointly conducted the first national survey of PR programs. This National Pulmonary Rehabilitation Survey was published in 1988 and showed the variation existing in rehabilitation program structure, content, staffing, and cost throughout the United States.[35] In 2006, the ACCP, in conjunction with the AACVPR, released new evidence-based guidelines pertaining to the design and implementation of PR programs.[12] These guidelines are summarized below.

Staffing

PR is a multidisciplinary endeavor. PR teams generally include various health care professionals, such as RTs, nurses, physical therapists, and dietitians who plan, implement, and evaluate components of the program (Fig. 56.6). It is recommended that any staff conducting PR sessions be certified in basic life support or advanced cardiac life support in the event that a patient has an adverse response to a PR session. In addition to professional involvement, family members are needed to provide feedback and ensure that instructions and the exercise prescription are carried out at home.

RULE OF THUMB

RTs and other clinicians involved in pulmonary rehabilitation know the benefits that a well-designed program can represent for patients with pulmonary diseases, especially to recover some lost functioning. Support from the clinical staff and family members combined with early interventions may help patients in a hospital-based or home program. For COPD patients, early interventions may reduce acute exacerbation as described in the new guidelines.

It is important to highlight that the new guidelines are recommending that pulmonary rehabilitation should start 3 weeks after a hospitalization for COPD patients. The guidelines also recommend that pulmonary rehabilitation should not be started during a hospital stay. These recommendations are based on multiple studies showing the benefits of outpatient programs, especially reducing hospital readmissions, since patients may have a better quality of life and adherence to the plan of care. A well-designed home-based plan of care may help to reduce exacerbations and readmissions when patients have the correct family support.

Facilities

Location and quality of facilities can directly affect patient attendance. Patients are less likely to attend programs that are inaccessible by public transportation, have poor parking arrangements, or are physically difficult to reach. The facility must be wheelchair accessible. For elderly patients who do not drive, arrangements can be made with community organizations to provide transportation to and from the program. Ideally, the facility should provide two separate rooms for the program—one room for educational activities and one room for physical reconditioning. Rooms should be spacious and comfortable, with adequate lighting, ventilation, and temperature control. Chairs should be comfortable with good back support. Restroom facilities need to be readily accessible. A room for individual counseling is helpful, but any private office would suffice. It is also preferable to have pulmonary function testing and blood gas analysis capabilities on site. If this space is used by other departments for other functions, proper scheduling of rehabilitation sessions needs to be considered.

Scheduling

Another aspect of program implementation involves timely, advanced scheduling of the rehabilitation sessions. Class times need to be scheduled when the largest number of patients can attend; often late morning or early afternoon. Traffic patterns, bus schedules, and availability of rides are concerns that need

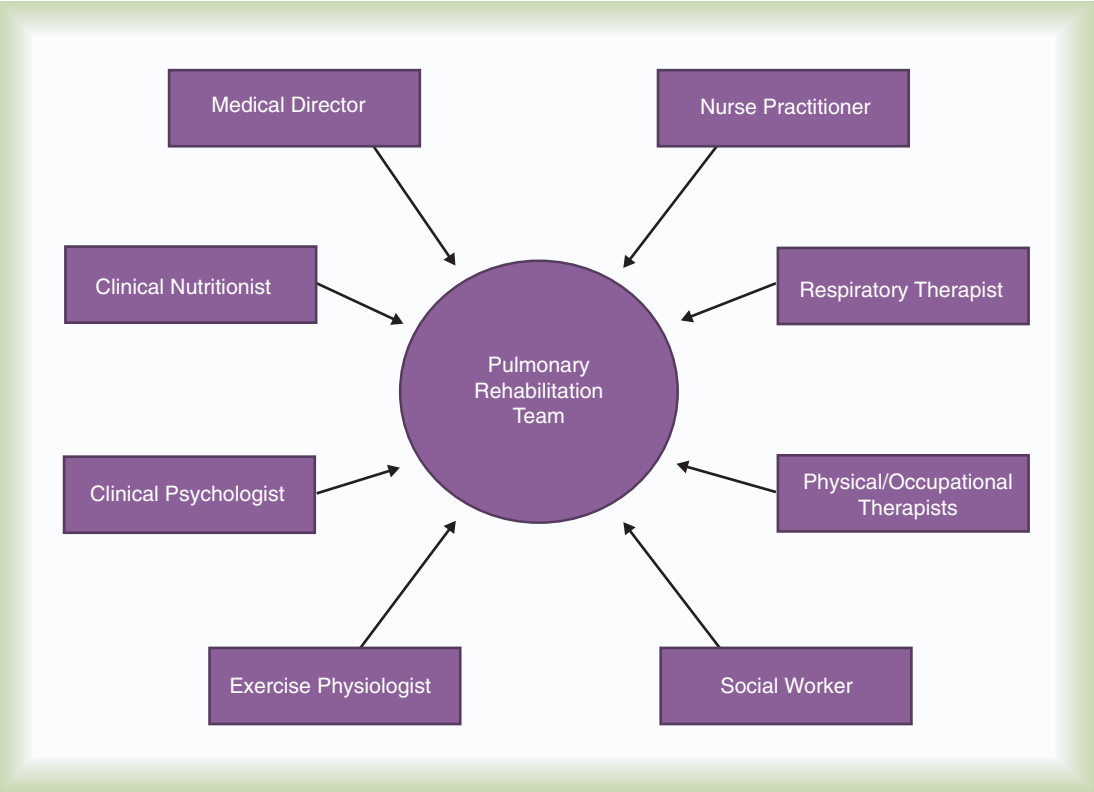

Fig. 56.6 Multidisciplinary Nature of Pulmonary Rehabilitation.

to be addressed. Proper scheduling helps to encourage participation and removes potential stumbling blocks, which could undermine the rehabilitation process.

Class Size

Class size is another issue that must be addressed. Theoretically, class size for a rehabilitation program could range from 1 to 15 participants, depending on available space, equipment, staff, and patient condition/needs. However, to foster group identity, interaction, and support, small-group discussions are encouraged. The ideal class size should range from 5 to 10 participants. Keeping the class size manageable facilitates vital group interaction processes and allows for more individualized attention. These factors help sustain motivation, reducing the likelihood of participant attrition.

Equipment

Both the instruction and the reconditioning component of the program require equipment. To meet the educational needs of the program, a whiteboard or flipchart, computer with a PowerPoint projector screen, and CD/DVD player can be very useful. Videos and formal learning packages dealing with the educational topics covered during the rehabilitation program should be available for group and individualized presentation. If possible, learning materials should be available in different languages or the predominant language in the community surrounding the location; this alternative may facilitate learning when language barriers are present.

MINI CLINI

Facilities Planning for Pulmonary Rehabilitation

Problem

The RT has been asked to assist in the planning process for starting a PR program to support a 350-bed, full-service hospital. According to the strategic plan, the physical location of the rehabilitation center is about three blocks away from the hospital. The RT has not seen the proposed site but was asked to approve a recommendation that the facility be used. What factors should the RT take into account before making a decision on site selection?

Solution

Because the hospital is currently in the planning process for starting a PR program and has not made a final facility selection, the RT is in a key position to assess, among other areas, issues related to the proposed site. Patient attendance and participation would be adversely affected if the facility is unreachable, such as at the top of a hill. If the location is in a high-crime or unsafe area with little or no security, this too would discourage patients from attending. As is true with any program, public transportation that does not permit accessibility to the proposed facility would be a limiting factor, as would little or no available parking. Numerous other facility considerations outside the actual physical location of the rehabilitation center would also need to be addressed.

Naturally, economic concerns surface when class size is considered. Although program quality must be the first priority, program viability realistically depends on the number of participants. Programs should generally be conducted with a class size that is comfortable with regard to space and staffing and that is economically feasible. Such an approach helps ensure that programs produce meaningful patient outcomes.

For physical reconditioning, stationary bicycles, treadmills, rowing machines, upper extremity ergometers, weights, pulse oximeters, and inspiratory resistance breathing devices constitute the minimum equipment requirements. The quantity of equipment needed depends on class size, available space, and financial resources available. Sufficient equipment should be on hand to keep all patients exercising and to monitor their activity. It is important to maintain equipment clean and in good working conditions for safety; dirty or malfunctioning equipment may discourage patients from attending.

Emergency O_2 and bronchodilator medications, as well as an automated external defibrillator (AED) should also be maintained in the rehabilitation area. Equipment guidelines for a class of 5 to 10 participants include the following: five stationary bicycles, two treadmills, two rowing machines, two upper extremity ergometers, five pulse oximeters for monitoring heart rate and O_2 saturation, one emergency O_2 cylinder (E), and bronchodilator medications. In addition, each patient should be supplied with an inspiratory resistance breathing device.

Because equipment can be expensive, care must be taken in its selection and purchase. Devices and appliances should be durable, easy and safe to use, simple to maintain, and not overly expensive. Initially, basic items are purchased. As a program develops and expands, equipment resources can be enhanced. Other program needs include the following:

- Maintaining individual patient manuals, including daily log forms or activity diaries
- Providing light refreshments for program participants
- Developing a communication network to announce schedule changes because of emergencies or cancellation of class sessions because of illness or weather
- Identifying available durable medical equipment providers for participants in need of specialized home care equipment
- Developing a system of charges and a mechanism for patient payment

By considering all of the factors needed for effective implementation of PR, programs have lower patient attrition and a greater chance for overall success. As programs are conducted, regular evaluations must be made by both patients and staff. Needed changes should be implemented on an ongoing basis. Only in this manner can one expect continued refinement of the process and improvement in patient outcomes.

Web-Based Pulmonary Rehabilitation

In addition to traditional face-to-face PR programs, web-based offerings known as telerehabilitation platforms are becoming a viable alternative and are now being offered by an increasing number of health service providers. Such **telerehabilitation** packages use a combination of a personal computer or device, a reliable internet connection, a patient monitoring module and relatively low-cost exercise equipment to allow patients to participate in PR. In such programs, a physician-led, multidisciplinary team, often including an RT in a central location with a digital interface, permit patients to participate in such programs from their home. Preliminary research suggests that all benefits of face-to-face PR programs, including fewer hospitalizations, can be achieved through telerehabilitation. In addition, these types of offerings have the added advantages of lower cost and the ability to include patients who are home-bound or live in remote locations and who may otherwise be excluded.[36]

RULE OF THUMB
Web-based telerehabilitation is an alternative to traditional PR programs for home-bound patients or those in remote geographic areas.

FINANCIAL CONSIDERATIONS

Costs and Fees

Rehabilitation programs usually project their fees based on the average cost per participant. According to regional labor and material prices, costs vary throughout the United States. Several factors must be considered when projecting program costs (Box 56.5). The larger the class size and the more participants involved in the overall program, the lower the per-patient cost. The aim should be to offer and conduct the highest-quality program possible at a reasonable cost that meets any existing budgetary constraints.

When determining patient charges, consideration must also be given to the type and amount of funding that has been received to offset program expenses and available insurance reimbursement. Pre-program and post-program testing and evaluations naturally generate revenues but should not be included in the formulation of program charges. However, payments for pulmonary function testing, exercise testing, arterial blood gas analysis, and other evaluations may help to keep a PR program financially viable.

Charges for an entire program or for each session must be structured in a way that does not deter patient attendance. Many patients with a chronic pulmonary disease are on a fixed income and have other living and medical expenses. A happy medium between a patient's ability to pay and program expenses must be identified. Funding from local charitable organizations, foundations, or agencies such as the American Lung Association and the COPD Foundation can help ease the financial burden. The most comprehensive and effective program available can have no impact if patients are unwilling or unable to attend and participate because of financial limitations.

Along with health care costs in general, the cost of providing PR has increased over the years. Nationwide charges for

BOX 56.5 Factors Affecting Pulmonary Rehabilitation Program Costs

- Marketing and program promotion
- Number of personnel involved in program facilitation and administration
- Space and utility expenses
- Audiovisual, exercise, and monitoring equipment (purchase and maintenance)
- Production and duplication of course materials
- Patient supplies
- Office supplies
- Refreshments
- Miscellaneous expenses
- Changes in the amount of funding and insurance coverage

PR vary, depending on program length, whether the offering is in-person or web-based, and, most importantly, insurance coverage. With most insurance plans reimbursing programs at 80% after a deductible, each patient would be responsible for the remaining 20% or copayment. The out-of-pocket amount may vary if the program is offered in a doctor's office (20% after insurance payment) or hospital outpatient program (copayment per session). Additional or supplemental medical coverage may cover this balance.

Charges for participation in these programs and inpatient rehabilitation reimbursement policies vary throughout the United States. The CMS, has published the final rules for Medicare reimbursement guidelines for **comprehensive outpatient rehabilitative facilities (CORFs)**. Under Part B of Medicare, the scope of services of a CORF includes reimbursement for outpatient activities and one home visit. Reimbursement requires that the CORF meet the conditions of participation established in section 933 of Public Law 96-499; this also includes provisions for certification of the program. To establish reimbursement mechanisms, each CORF must present its program description and anticipated results to local third-party payers.[37] The AACVPR has also developed guidelines for program design, implementation, and recognition.

By following recognized guidelines, Medicare has established an allowable charge for PR and reimburses 80% of this rate after the patient meets the annual prescribed deductible. In the past, inpatient and outpatient PR programs obtained reimbursement from third-party payers by charging for rehabilitation sessions as physical therapy exercises for COPD, reconditioning exercise sessions, office visits with therapeutic exercises, serial pulse oximetry determinations, or physician office visits. The goal was to obtain as much insurance reimbursement as possible, decreasing the financial burden on the patient (Box 56.6).[38]

RULE OF THUMB

To help ensure adequate reimbursement for PR, identify patient goals and objectives; formulate and implement an effective exercise prescription for each patient; use diagnostic codes from the International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-*10*-CM); use current and proper CPT (Current Procedural Terminology) coding and documentation from patient's medical record to support the need for PR. A new revision of the ICD will be released in the near future to replace the current ICD-10-CM.

There is now a national coverage policy for PR under Medicare. Programs have to obtain reimbursement from their Medicare beneficiaries following accepted protocol, policies, and provisions specified by Medicare. Coverage is for patients with stage II, III, and IV COPD (moderate to very severe according to the GOLD standards). The programs must include five components, which must be documented in the patient's medical record:

1. Physician-prescribed exercise
2. Education and training that relate to an individual patient's needs
3. Psychosocial assessment
4. Outcomes assessment
5. Individualized treatment plan.[39]

BOX 56.6 Sources of Reimbursement for Pulmonary Rehabilitation Programs

- Nongovernment health insurance programs—private, single, or group health insurance plans
  - Health maintenance organizations (HMOs)
  - Preferred provider organizations (PPOs)
  - Medicare supplement
- Federal and state health insurance programs
  - Medicare
  - Medicaid
  - Uncompensated services (Hill-Burton)
  - Comprehensive outpatient rehabilitative facility
  - Veterans Administration benefits
  - Civilian Health and Medical Programs of the Uniformed Services (CHAMPUS)
  - Federal workers insurance
- Ancillary liability and casualty insurance programs
  - Automobile insurance—related to automobile accidents
  - Workers' compensation—related to accidents on the job
  - Business insurance coverage—related to injuries sustained on business premises
  - Homeowner's insurance—related to injuries sustained on the owner's premises
  - Malpractice insurance on providers of health care
  - Product and service liability insurance—related to injuries caused by a product or service
- Other options of reimbursement
  - Senior care
  - Rehabilitation hospitals
  - Grants

Reimbursement Qualifications

Under current guidelines, Medicare covers PR when it is determined to be medically necessary and patients meet the necessary criteria. Many insurance plans follow Medicare guidelines for eligibility and coverage:

- The patient must be diagnosed with moderate to very severe COPD (GOLD Classification II, III, & IV) or any chronic respiratory disease with disabling implications before being referred to the program by the treating physician. Pulmonary Function Test (PFT) results can be utilized to support the diagnosis in addition to the GOLD Classification.
- A physician's order. The chart must have documentation showing that a physician prescribed an exercise plan for each day.
- Documentation showing the patient completed each daily plan of care.
- Documentation showing education and training provided to the patient and specific to the patient's needs.
- Documentation showing psychosocial assessment.
- Outcome assessment after the program is completed.
- An individualized treatment plan reviewed and signed by the physician must be provided. This plan has to be reviewed by the physician every 30 days.
- Correct billing code for the services provided. For pulmonary rehabilitation, it is G0424.
- The reviewer from the insurance company has the authority to request additional documentation for determination, if

the person considerers that current documents do not support the filed claim.

According to CMS, claims for Medicare patients should be submitted to Medicare Part A for any component of PR performed during a hospital stay and claims for rehabilitation components provided on an outpatient basis must be submitted to Medicare Part B. This payment mechanism has already undergone changes and it is anticipated that Medicare will continue to change its reimbursement policy for PR in the future. It is incumbent on clinicians who provide PR to stay abreast of any changes in reimbursement policy and procedure and to make necessary adjustments to receive payment.

At the present time, there is provision to reimburse programs for two 1-hour rehabilitation sessions per patient per day up to 36 sessions. An additional 36 sessions over an extended period can be approved by the individual Medicare contractor based on patient need for continued rehabilitation and physician referral. Provision has been made for face-to-face patient sessions and for group (two or more patients) sessions. Individual sessions must be at least 31 minutes in length. If two sessions are performed on the same day, services may be reported only if the duration of the combined treatments is at least 91 minutes. It is essential that the practitioner who conducts PR is familiar with all current practices so that therapy that is provided and billed for complies with current Medicare policy, is properly documented for each patient, and is submitted in a timely manner.[38-40]

MINI CLINI

Obtaining Insurance Payment for Pulmonary Rehabilitation

Problem

The RT is asked to design and implement a PR program on an outpatient basis at her hospital. After completing the first class that ran for 12 weeks, the hospital scheduled another one. However, although the institution had been submitting bills on a timely basis to numerous insurance providers, including Medicare, no payment has been received. What is the problem, and how can it be corrected?

Solution

The insurance companies apparently either have denied claims or have not responded to the claims being submitted. There are several reasons for not receiving a payment. The most common one is improper or inaccurate claim filing. Usually Medicare provides payment or denials between 14 and 21 days after filing a claim. When insurance denies payment, it provides an explanation for the denial and sometimes with an alternative to resubmit the claim or appeal the denial. Another reason is an inefficient internal process within the insurance company (i.e., poor communication with clients, disorganized internal processes, and high workload).

The RT should work closely with the billing department at the hospital to ensure that all information is complete for each patient (i.e., correct patient identification numbers), that the hospital has the correct addresses to submit claims, and that diagnoses and procedures have been properly coded. Some insurance companies have their own coding schemes, and these must be followed accordingly. Managed care companies also require preauthorization, which must be obtained before entering any patient with a managed care plan into pulmonary rehabilitation. Finally, follow-up telephone calls are always helpful and should be conducted if payment is not received in a timely fashion.

Program Results

Patient and program outcomes must be evaluated at the conclusion of the program and periodically thereafter as described in Box 56.7. This evaluation must compare patient status before the program with current patient status and may include physiologic, psychological, and sociologic data. Common outcome measures include exercise tolerance, levels of dyspnea at rest and with exertion, and quality-of-life surveys. The data collected may support reimbursement claims or if the physician needs to order additional sessions for the patient to achieve the plan of care.

Results of PR must be communicated to the patient, referring physician, and family, if appropriate. Further goals and objectives for continued improvement may be established to provide the basis for follow-up and reinforcement activities. Tracking and documenting PR programs and patients' outcomes are important to achieve the current guidelines and to promote the benefits of the programs. For example, the AACVPR offers a registry to track the positive impact of the programs on mortality, physical activity, quality of life, etc.[41] The data can be used by providers to negotiate reimbursement rates based on the positive outcomes obtained.

If no improvements in physical or psychosocial measures occur within a class or group, program deficiencies are often the cause. Specifically, insufficient professional training in rehabilitation methods, a lack of a uniform approach, inadequate program length, and lack of follow-up are the major reasons for unsatisfactory outcomes. If a very small number of patients (i.e., one or two) from a large class show no improvement, it may be the result of a lack of patient's compliance to the plan of care.

Finally, PR has become recognized as an ideal setting for certain patients with severe chronic respiratory diseases who are able to undergo lung volume reduction or lung transplant surgery. The program can provide information before the procedure to help to educate patients about benefits, risk, and outcomes of the surgery;

BOX 56.7 Evaluation of Rehabilitation Program Outcomes

- Changes in exercise tolerance
- Before and after 6- or 12-minute walking distance
- Before and after pulmonary exercise stress test
- Review of patient home exercise logs
- Strength measurement
- Flexibility and posture
- Performance on specific exercises (e.g., ventilatory muscle, upper extremity)
- Changes in symptoms
- Dyspnea measurement comparison
- Frequency of cough, sputum production, or wheezing
- Weight loss or gain
- Psychological test instruments
- Activities of daily living changes
- Postprogram follow-up questionnaires
- Compliance improvement with pulmonary rehabilitation medical regimen
- Frequency and duration of respiratory exacerbations
- Frequency and duration of hospitalizations
- Frequency of emergency department visits
- Return to productive employment
- Other clinical and nonclinical changes

physical reconditioning helps to stabilize exercise tolerance and muscle function to improve survival and outcomes after surgery.[42]

Potential Hazards

Although most patients with COPD can expect to realize benefits through physical reconditioning and PR, certain potential hazards do exist, as follows:

I. Cardiovascular abnormalities
   A. Cardiac arrhythmias (can be reduced with supplemental O_2 during exercise)
   B. Systemic hypotension and hypertension
II. Blood gas abnormalities
   A. Arterial desaturation
   B. Hypercapnia
   C. Acidosis
III. Muscular abnormalities
   A. Functional or structural injuries
   B. Diaphragmatic fatigue and failure
   C. Exercise-induced muscle contracture
IV. Miscellaneous
   A. Exercise-induced asthma (more common in young patients with asthma than in patients with COPD)
   B. Hypoglycemia
   C. Dehydration

Proper patient selection, education, supervision, and monitoring are key factors in reducing possible hazards.

RULE OF THUMB

To help avoid potential hazards and identify contraindications, it is necessary to conduct an initial individualized assessment to identify any medical condition that may interfere with the success of the program and achieving the plan of care and goals. The assessment will help the team to determine the patient's willingness and possible adherence to the program. In all situations, patient safety must be a high priority for the PR team.

MINI CLINI

What to Expect From Pulmonary Rehabilitation

Problem

The RT is asked to consult on a 63-year-old man hospitalized with severe COPD for possible participation in an outpatient program. During the patient interview, the patient tells the RT that if the program will not cure him, he sees no reason to participate. How should the RT respond to the patient, keeping in mind his expectations of what PR should accomplish?

Solution

It is crucial for all RTs and other caregivers involved in PR to recognize that the focus of any program should attempt to treat the patient as a whole and not solely the underlying disease. A well-constructed program should be able both to quantify the extent of physiologic impairment and to assist in establishing outcome expectations for physical reconditioning. Regardless of setting or design, such programs must address the psychological, social, and vocational impact of the disability on the patient and family and seek ways to improve the patient's quality of life. In this case, the RT should describe the benefits of PR outside the traditional measures of pulmonary function. Although PR cannot affect the progressive deterioration in lung function that occurs with COPD, both education and exercise may improve the patient's ability to perform activities of daily living and exercise tolerance. In addition, effective breathing techniques may lessen the frequency and severity of "panic breathing" episodes.

CARDIAC REHABILITATION

Similar to PR, good cardiac rehabilitation programs are multidisciplinary in approach and focus. Goals include patient education promoting heart-healthy living, physical reconditioning to improve work capacity, weight loss, and a return to work when possible.

Pulmonary and cardiac rehabilitation share many similarities and differences. Similarities include the need for patient evaluation before program enrollment, patient education, the focus on exercises to increase fitness and stamina, and the need to monitor patients during exercise and for compliance. Differences include disease focus, patient age (most cardiac patients range in age from late 30s to 60s and 70s, whereas pulmonary patients for the most part are ≥50 years), and exercises used within the program. Breathing exercises to improve ventilation are essential to the pulmonary patient but are not that important to cardiac patients.

Finally, respiratory involvement in cardiac rehabilitation is significantly lower. For the most part, the RT is involved with instruction on O_2 use and may assist with patient exercise sessions during cardiac rehabilitation.

MINI CLINI

Responding to Adverse Outcomes

Problem

A 73-year-old man with stage III COPD was accepted into a PR program. Because of the severity of his disease, his preprogram CPX was stopped after 5 min because of excessive dyspnea and oxygen desaturation. He was placed on O_2 but was unable to complete the study. However, because of the desire of the patient's physician to get him into a program of pulmonary rehabilitation and the patient's desire to participate, the patient was put on home O_2 and admitted to the program. While exercising on a treadmill with supplemental O_2, the patient complained of headache and nausea. The RT stopped the exercise session and documented a significant increase in the patient's blood pressure (220/130 mm Hg). How should the RT proceed in this case?

Solution

The RT should notify the physician overseeing the program and the patient's prescribing physician (if different) immediately and document the elevated blood pressure. It is likely that the preprogram cardiopulmonary exercise test was stopped before the excessive increase in blood pressure was noted. While in PR, the patient (on supplemental O_2) was able to exercise to a level greater than that during the exercise test. This elevated blood pressure will likely result in the patient being started on some type of antihypertensive therapy and being reevaluated during another exercise test to determine the extent of his hypertensive condition. Depending on the pattern of the patient's hypertension, it is also possible that this patient will be admitted to cardiac rehabilitation first before returning to the pulmonary rehabilitation program. This case shows the importance of a thorough and complete assessment of a patient's status before any admission to PR.

CONCLUSION

A properly planned and implemented program can produce positive and measurable patient outcomes. Goals and objectives of PR should be written in these measurable terms and be explained to the patient in a clear, concise fashion to achieve

optimum therapeutic outcomes. The success of PR depends on this along with careful application of current clinical knowledge and the use of a multidisciplinary approach throughout all phases of program organization, implementation, and evaluation. Within this context, PR will help to achieve the healthcare initiatives to reduce healthcare cost and reduce readmission rates and will continue to gain greater acceptance. The role of the RT in PR will likely increase.

SUMMARY CHECKLIST

- PR has two major aims: (1) to control and alleviate disease symptoms, and (2) to help patients achieve optimal levels of activity.
- Candidates for PR are patients with moderate to very severe COPD (stage II, III, and IV according to the GOLD standards).
- Rehabilitation does not alter the progressive deterioration in pulmonary function that occurs with chronic lung disease.
- Effective rehabilitation programming requires a multidisciplinary approach and combines physical reconditioning with education and psychosocial support.
- The educational portion of a rehabilitation program should provide patients with knowledge they can use to help cope with their disease and manage symptoms better.
- Educational materials should be available in different languages when necessary.
- Increased exercise tolerance, decreased intensity of symptoms, and improved activity levels are the best-documented benefits of pulmonary rehabilitation.
- PR is still underutilized despite its documented benefits.
- Every patient must receive an initial assessment to create a personalized plan of care based on that patient's needs. Follow-up assessments are necessary to manage progress.
- The exercise evaluation provides the basis for the exercise prescription, yields the baseline data needed to assess a patient's progress, and helps determine the degree of hypoxemia or need for supplemental O_2 during exercise.
- Reconditioning should combine lower extremity and upper extremity aerobic exercises with ventilatory muscle training.
- Decisions regarding facilities, scheduling, class size, and equipment can all affect rehabilitation program outcomes.
- PR may reduce readmissions and decrease healthcare costs.
- Web-based telerehabilitation PR programs are an alternative to traditional face-to-face programs.
- Proper claim filing with proper supporting documentation will improve reimbursement.
- Cardiac rehabilitation should be considered first if a patient with pulmonary disease also has an underlying cardiac condition that needs to be addressed and appropriately managed.

Respiratory Care in Alternative Settings

Albert J. Heuer and Daryl Rogers

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe alternative care settings in which respiratory care is often performed
- Discuss more recent developments and trends in respiratory care at alternative sites
- Identify who regulates alternative care settings
- List the standards that apply to the delivery of respiratory care in alternative settings
- Describe how to help formulate an effective discharge plan
- List factors to evaluate when alternative care sites and support services are being assessed
- Discuss how to justify, provide, evaluate, and modify oxygen (O_2) therapy in alternative care settings
- Explain how to select, assemble, monitor, and maintain O_2 therapy equipment in alternative settings
- Identify the special challenges associated with providing ventilatory support outside an acute care hospital
- Describe how to instruct patients and caregivers and confirm their ability to provide care in alternative settings
- Identify which patients benefit the most from ventilatory support outside acute care hospitals
- Identify the most appropriate device needed to treat patients in the postacute setting
- Explain how to select, assemble, monitor, and maintain portable ventilatory support and continuous positive airway pressure equipment, including applicable interfaces or appliances
- Describe proper documentation regarding patient evaluation and progress in alternative settings
- State how to ensure safety and infection control in alternative settings

CHAPTER OUTLINE

KEY TERMS

alternative (nonacute) care
Centers for Medicare and Medicaid Services (CMS)
conditions of coverage
conditions of participation
durable medical equipment (DME) supplier
durable medical equipment, prosthetics, orthotics, and supplies (DMEPOS)
home sleep test (HST)
insufflator-exsufflator
long-term acute care hospitals (LTACHs)
noninvasive ventilation (NIV)
O_2-conserving device
portable oxygen concentrator (POC)
skilled nursing facility (SNF)
transtracheal oxygen therapy (TTOT)

Although home care remains the most common alternative site for providing health care, numerous other **alternative (nonacute) care** settings—including subacute facilities, **long-term acute care hospitals (LTACHs)**, rehabilitation facilities, and **skilled nursing facilities (SNFs)**—provide respiratory care to patients.[1] Alternative health care settings offer advantages over acute care facilities—advantages that include lower costs and enhanced patient comfort. However, improper or premature discharging of patients to alternative care settings and poor care planning and implementation can erase these benefits and result in short-term readmission.

This chapter summarizes recent policy developments and discusses aspects of optimal discharge and patient care planning; it also reviews various therapeutic respiratory modalities in alternative care sites. A major alternative site is the sleep laboratory, where respiratory therapists (RTs) may conduct polysomnography, or sleep, studies. The pathophysiology, diagnosis, and treatment of disorders of sleep are covered in Chapter 34.

MORE RECENT DEVELOPMENTS AND TRENDS

There have been several developments in the area of respiratory care in alternative sites. Such changes range from governmental initiatives affecting reimbursement to enhancements involving the respiratory equipment used in such settings.

Over the past two decades, an assortment of laws and regulations were enacted that have reduced reimbursement for respiratory care in alternative settings. Furthermore, unlike the situation in many other health professions, reimbursement for the time that RTs spend in setting up the equipment and assessing and administering prescribed treatments is not generally available. This lack of reimbursement has presented challenges to organizations and agencies attempting to provide high-quality respiratory care in alternative settings.[2,3]

In addition, the federal government has introduced the **durable medical equipment, prosthetics, orthotics and supplies (DMEPOS)** competitive bidding program, awarding contracts to some respiratory care suppliers and not awarding respiratory bids to others based on selected criteria. This affected many home-care RTs, as some companies discontinued their respiratory service lines entirely or were unable to support them due to significant rate reductions. As a result, patient satisfaction suffered because of the lack of access to care.[4]

A further development stemming mainly from the aging US population is a significant increase in alternative care sites known as *assisted living facilities*. These facilities permit residents, who are generally elderly or disabled, to live in their own units either alone or with a companion and with health services available, including RTs in some facilities. Hence, these facilities are yet another alternative site at which respiratory services are provided.

RELEVANT TERMS AND GOALS

As the elderly population grows and managed care becomes the dominant delivery model, more health care services are being provided outside the acute care hospital in such settings as SNFs, LTACHs, and within homes. Rather than representing distinct entities, these alternative settings are part of an evolving continuum of care and are often elements of Accountable Care Organizations (ACOs), which are groups of doctors, hospitals, and health care providers who voluntarily come together to deliver coordinated patient care in a cost-effective manner.

Similar to the acute care setting, alternative care settings accomplish this goal through a coordinated team effort comprising many disciplines. The patient care team in alternative settings uses various specialized respiratory care services and equipment, including continuous O_2 therapy, long-term mechanical ventilation, aerosol drug administration, airway care, sleep apnea monitoring and treatment, and pulmonary rehabilitation. The respiratory equipment used within each of the major alternative settings and other relevant considerations, including patient and family education, are discussed in subsequent sections of this chapter.

Long-Term Subacute Care Hospitals

Advances in technology, research, and clinical specialization have permitted more acutely ill patients to be treated outside of large-scale acute care hospitals. Over the past decade, LTACHs have become more prevalent. These facilities provide highly focused care to patients with complex medical conditions, including patients who are ventilator-dependent and difficult to wean. LTACHs generally employ a highly experienced clinical staff, including RTs, to provide integrated interdisciplinary care using the latest equipment and evidence-based protocols. During the 20- to 30-day typical length of stay at an LTACH, many patients experience significant improvement, including successful ventilator weaning and increased functionality.[5]

Subacute Care

According to the National Association of Subacute/Post Acute Care, *subacute care* is a comprehensive level of inpatient care for stable patients who (1) have experienced an acute event resulting from injury, illness, or exacerbation of a disease process; (2) have a determined course of treatment; and (3) require diagnostic or invasive procedures but not those requiring acute care. The severity of the patient's condition typically requires active physician direction with frequent on-site visits, professional nursing care, significant ancillary services, and an outcomes-focused interdisciplinary approach employing a professional team.

The goal of acute care is to apply intensive resources to stabilize patients after severe episodic illness, whereas subacute care aims to restore the whole patient back to the highest practical level of function—ideally self-care. This holistic approach requires goal-oriented care by an interdisciplinary team, with frequent assessment of progress and a time-limited plan of care.

Although most patients receiving subacute care are elderly, all age groups can be found at these sites. Pediatric, adolescent, and adult patients requiring ventilatory support or extensive care, depending on their diagnosis, are also cared for at these sites.[6,7]

Home Care

Currently, most respiratory care in the alternative setting is provided in the home. The primary goal of home care is to provide

high-quality health care services to patients in their home settings, thus minimizing their dependence on institutional care. In regard to respiratory home care, several specific objectives are evident. Respiratory home care can contribute to the following:

- Supporting and maintaining life
- Improving patients' physical, emotional, and social well-being
- Promoting the self-sufficiency of both patient and family
- Ensuring cost-effective delivery of care
- Maximizing patient comfort near the end of life

Although not all aspects of respiratory home care have proven effective, various studies have shown that carefully selected treatment regimens can benefit patients significantly. These benefits include improved quality of life and functional performance as well as a reduction in the individual and societal costs associated with hospitalization.[8-10]

STANDARDS

Standards for the delivery of respiratory care in the subacute and home settings are derived from several different sources. First, the Clinical Practice Guidelines created and published by the American Association for Respiratory Care (AARC) offer RTs an evidence-based clinical framework for performing numerous respiratory procedures, including many procedures used in alternative care settings. Other standards are established by federal and state laws and private-sector accreditation.

Regulations

As the largest purchaser of health services, the federal government (in connection with state and local governments) plays a major role in setting standards and regulating this industry. The federal agency responsible for the overall administration of Medicare and Medicaid is the **Centers for Medicare and Medicaid Services (CMS)**. Created in 1997, CMS oversees the framework for providing health coverage to elderly adults, disabled adults, and many disadvantaged young children in the United States.[5]

As part of this structure, CMS created the Medicare Provider Certification Program. This program ensures that providers that serve Medicare beneficiaries—including hospitals, skilled nursing facilities (SNFs), LTACHs, home health agencies, and assisted living facilities—meet health and safety requirements. These requirements are called **conditions of coverage** and **conditions of participation**. Current conditions of participation emphasize quality indicators, outcome measures, and cost efficiency designed to improve the quality and effectiveness of care provided to beneficiaries.[5] Institutions undergo certification surveys by either state survey agencies or private accrediting organizations such as The Joint Commission (TJC), which is discussed in more detail in the following section.

State survey agencies are partners with the federal government and principal agents in performing institutional certification. Typically, a state survey agency is either the state department of health or state licensing authority for health care facilities. The main function of the state survey agency is to ensure that facilities providing Medicare or Medicaid services comply with state and federal health, safety, and quality standards as determined by periodic on-site inspections.

Private Sector Accreditation

The primary organization responsible for standard setting and voluntary accreditation of care providers in alternative settings is the TJC. To assist hospitals and health care organizations with the accreditation process and overall performance improvement, the TJC develops and publishes standards and National Patient Safety Goals for long-term and subacute care, home care, and assisted living facilities. The standards and goals relate to the delivery of high-quality patient care and the process and structure needed to do so. These categories include patient rights, ethics, and assessment and organizational leadership and management of information. The patient safety goals set targets for the improvement or resolution of common problems for health care organizations such as proper patient identification, medication safety, and infection control.[11,12]

Approximately 90% of all hospitals and other health care organizations voluntarily subscribe to TJC accreditation and as a result are surveyed at least every 3 years. Insufficient or unsatisfactory compliance is flagged and requires formal follow-up to ensure correction. In certain circumstances, unfavorable results may result in a facility's or organization's failing to maintain TJC accreditation.[11,12]

TRADITIONAL ACUTE CARE VERSUS ALTERNATIVE SETTING CARE

For the RT, working in the alternative care setting is distinctly different from working in an acute care hospital. Key differences involve resource availability, supervision and work schedules, documentation and assessment, and provider–patient interaction (Table 57.1).[13] Although some practitioners do not like the alternative work settings, many find the greater independence, professional team orientation, creativity, and higher level of patient and family interaction to be rewarding.

DISCHARGE PLANNING

Effective discharge planning provides the foundation for high-quality care in the alternative care setting. A properly designed and implemented discharge plan guides the multidisciplinary team in successfully transferring a respiratory care patient from the health care facility to an alternative site of care.[14] Effective implementation of the discharge plan also ensures the safety and efficacy of the patient's continuing care. In addition, CMS's Readmission Reduction Program penalizes hospitals that have high short-term readmission rates for the following diseases:

- Acute myocardial infarction (AMI)
- Chronic obstructive pulmonary disease (COPD)
- Heart failure (HF)
- Pneumonia
- Coronary artery bypass graft (CABG) surgery
- Elective primary total hip arthroplasty and/or total knee arthroplasty (THA/TKA)

As a result, it has become essential for hospitals and other health care providers to adopt and evaluate the effectiveness of evidence-based discharge protocols. In general, the key elements of such protocols include the following:

TABLE 57.1 Major Differences Between the Traditional Acute Care Setting and Alternative Settings for the Delivery of Respiratory Care Services

Area	Traditional Setting (Acute Care Hospital)	Alternative Settings (Long-Term Acute Care, Subacute Care, Home Care)
Diagnostic resources	In-house laboratory, x-ray, ABG analysis, PFT	Must rely on outside vendors to provide diagnostic tests
Equipment support	Extensive; supported by piped-in O_2 and suctioning	Limited availability; must use portable O_2 and suctioning systems
Travel requirements	None; remain in one facility	Must travel between facilities or residences
Level of supervision	Direct supervision	Respiratory care provider works independently with minimal supervision
Patient assessment	Moderate—primarily provided by attending physician or residents	Heavy—core responsibility related to care planning
Documentation requirements	Moderate—limited to medical record keeping	Heavy—includes initial justification, ongoing follow-up, and often detailed financial record keeping
Work schedule	Specific hours	Varied work schedule, often including "on-call" off hours coverage
Time constraints	More than one shift to deliver therapy	Must complete all therapy during shift or visit
Patient-family interaction	Limited treatment time available; little family interaction	One-on-one therapy; intensive family interaction
Provider interaction	Primarily attending physicians and patients' nurses	Continuous interaction with all members of professional team

ABG, arterial blood gas; *PFT,* pulmonary function testing

- Proper patient screening and evaluation
- Early identification of patients at high risk for short-term readmission
- Intensive patient and family education
- Interdisciplinary discharge planning that addresses all major potential barriers
- Patient follow-up[4]

Multidisciplinary Team

Although a physician normally initiates an order to discharge a patient to an alternative site, many other health care professionals are involved in the discharge process. Table 57.2 identifies these key professionals and their major responsibilities.[14] As with pulmonary rehabilitation (see Chapter 56), a team approach produces the best results. Communication and mutual respect for the talents and abilities of each team member are two key elements in making patient care in the alternative care setting work. Any breakdown in the system may delay or adversely affect patient discharge and the patient's physical health and mental well-being.

RULE OF THUMB To help ensure a successful discharge and confirm that a nonprofessional caregiver can perform a particular skill, the RT must go beyond demonstration and verbal confirmation of the caregiver's understanding. The RT must observe a return demonstration, whereby the caregiver properly performs the same procedural steps the RT has demonstrated. In addition, providing the caregiver with written information relating to the procedural sets and equipment setup, maintenance, and basic troubleshooting can help reinforce key areas and ensure caregiver mastery of the competency. A written competency checklist should be completed by the home-care RT to document that all details regarding equipment setup and safe use were covered. Also, most home-care companies provide 24-h coverage in the event of an emergency or if the patient or caregiver has additional questions.

TABLE 57.2 The Patient Care Team in Alternative Settings

Discipline	Responsibilities
Utilization review	Advises or recommends consideration of patient discharge, documents patient's in-hospital care
Discharge planning (social service or community or public health)	Brings all the needed elements together and ensures that a patient can be discharged to alternative care sites, makes contact with outside agencies that may assist with patient care
Physician	Writes order for patient discharge, evaluates patient's condition and prescribes needed care, establishes therapeutic objectives
Respiratory care	Evaluates patient and recommends appropriate respiratory care, provides care and follow-up
Nursing	Writes and implements nursing care plan for patient, assesses patient's status and provides necessary follow-up
Dietary and nutrition	Assesses patient's nutritional needs and writes dietary plan for patient, makes arrangements for meals as necessary
Physical and occupational therapy	Provides necessary physical therapy and recommends any additional modalities or procedures
Psychiatry or psychology	Assesses patient's emotional status and provides any needed counseling or support
Durable medical equipment supplier or home care company	Provides needed equipment and supplies and handles any emergency situations involving delivery or equipment operation

Beyond the performance of a particular skill, it is imperative for the discharge team to ensure that an adequate number of professional and nonprofessional caregivers are part of the care plan to provide appropriate patient care coverage; this is particularly true when more complicated modes, such as mechanical ventilation or multiple therapies are required by the patient. Substantial caregiver strain is often associated with the care of such patients in alternative settings. Proper assessment of the capabilities and number of potential caregivers in light

MINI CLINI

Minimizing Readmissions

Problem

A COPD patient who was admitted to the hospital for an exacerbation is now improving and is targeted for discharge in 2 days. Owing to patient quality-of-life considerations and newer financial penalties for excessive readmissions, the patient care team wishes to help minimize the likelihood of a readmission for this individual as well as similar patients. What are some of the major considerations that should be addressed in the discharge plan for this patient to help avoid a readmission?

Solution

COPD patients, especially those with moderate to severe disease, may often be deemed more clinically "fragile" and therefore especially prone to readmission. Hence it is imperative for the multidisciplinary patient care team to quickly recognize the predisposition and to carefully plan to address the major risks. Education and patient follow-up are at the core of most short-term readmission reduction protocols. In this case, the education should focus on the pathophysiology of COPD and, more importantly, the purpose and importance of each element of the care plan. Reinforcing proper medication use such as bronchodilators and steroids as well as safe use of home oxygen are priorities. Phone, computer-aided, or in-person patient follow-up should focus on continued compliance with the treatment plan, adherence to scheduled physician visits, and participation in any prescribed pulmonary rehabilitation programs. Barriers such as those related to transportation issues and assistance with activities of daily living should also be promptly identified and addressed. In some instances, transportation to physician visits, pulmonary rehabilitation sessions, or certified home-health aids can be arranged in advance by the discharge planning team or patient follow-up clinicians. Additionally, some home-care companies have developed COPD programs where RTs follow up with patients as soon as they are discharged and then complete comprehensive respiratory assessments.

of the therapy needed at home and appropriate training of such individuals can help to address this concern.

Equipment support and selected clinical services for patients receiving respiratory home care are often provided by a **durable medical equipment (DME) supplier**. DME suppliers range in size from multimillion-dollar national corporations offering a broad range of services to small local companies. Both large and small companies usually provide the following services:

- Service 24 hours, 7 days a week
- Third-party insurance processing
- Home instruction and follow-up by an RT

In addition, the patient's residence must meet safety standards and be suitable for managing the patient's specific condition. It must be free of fire, health, and safety hazards; provide adequate heating, cooling, and ventilation; provide adequate electrical service; and provide for patient access and mobility with adequate patient space (room to house medical and adaptive equipment). The selected site must be capable of operating, maintaining, and supporting all equipment needed by the patient, including both respiratory and ancillary equipment and supplies as needed, such as the ventilator, suction, O_2, intravenous therapy, nutritional therapy, and adaptive equipment.[15] Box 57.1 lists key factors one should assess in planning the discharge of a respiratory care patient to the home environment.

BOX 57.1 Assessing the Home Environment

Accessibility

- In and out of house or apartment
- Accessibility between rooms
- Doorway width and threshold heights
- Stairways
- Wheelchair mobility
- Bathroom
- Kitchen
- Carpeting
- Uneven floors

Equipment

- Available space
- Electrical power supply
- Amperage
- Grounded outlets
- Presence of hazardous appliances

Environment

- Heating and ventilation
- Humidity
- Lighting
- Living space
- Possible fire hazards
- Smoke alarms
- Fire extinguishers

A variety of equipment is available when a patient with a pulmonary disorder is discharged to an alternative setting. Many of the modalities used are discussed in other chapters throughout this textbook.

OXYGEN THERAPY IN ALTERNATIVE SETTINGS

O_2 therapy is the most common mode of respiratory care in alternative care settings. This high use is based on the fact that O_2 therapy improves both survival and quality of life in selected patient groups, especially patients with advanced COPD.[16,17] In particular, studies have shown improved nocturnal O_2 saturation, reduced pulmonary artery pressure, and lower pulmonary vascular resistance with appropriate outpatient O_2 therapy.[18-20]

Oxygen Therapy Prescription

A prescription for oxygen therapy must be based on documented hypoxemia as determined by overall clinical assessment, including an arterial blood gas or pulse oximetry. When the need for O_2 therapy is established (see Chapter 42), the physician writes a prescription for O_2 therapy, which must include the following elements:[21]

- Flow rate in L/min, concentration, or both
- Frequency of use in hours per day and minutes per hour (if applicable)
- Mode of delivery
- Duration of need

MINI CLINI

Assessing the Home Environment

Problem

A wheelchair-bound patient with a tracheostomy who requires mechanical ventilation is being discharged to the home-care setting. Inspection of the two-story home reveals front and rear elevated porch entrances, with all bedrooms upstairs. All room floors (except the kitchen and bathrooms) are covered with high-pile carpeting. The largest bedroom is 12 by 14 ft. The electrical service is rated at 75 amps, and the only grounded outlets are in the kitchen and garage. Heating is provided by a forced hot-air system; there is a single window air conditioner in the patient's bedroom.

What problems do you see, and what changes would you recommend to provide the proper home environment for this patient?

Solution

Although wheelchair-bound, this patient is still mobile. Both the elevated porch entrances and the high-pile carpeting restrict mobility. A ramp entrance must be constructed, and the carpeting must be removed or covered with a flat, hard surface material. Given the size of the patient's upstairs room and the obstacle of the stairwell, it would be best to identify a large first-story room for conversion to a bedroom. Because the patient is likely to need at least an electrical bed, ventilator, and suction machine, the electrical service capacity is inadequate and needs upgrading to ensure at least 15 to 20 amps in the patient area, with 200 amps overall. Appliance, counter, sink, and toilet heights must be assessed for easy patient access.

- Diagnosis (severe primary lung disease, secondary conditions related to lung disease and hypoxemia, related conditions or symptoms that may improve with O_2)
- Laboratory evidence (arterial blood gas analysis or oximetry under the appropriate testing conditions), as home-care companies cannot provide this testing
- Additional medical documentation (no acceptable alternatives to home O_2 therapy)

For home use, the ordering physician must authorize O_2 therapy using the CMS Certification of Medical Necessity form for O_2. After the need for long-term therapy has been documented, repeat arterial blood gas analysis or SpO_2 measurements are generally not needed. However, CMS requires that patients on home oxygen follow up with their physicians once a year, showing clinical documentation that demonstrates the need for continuation.[22]

Oxygen Qualification Criteria

In addition to a physician's prescription, in order to be eligible for reimbursement for home oxygen, patients must qualify by meeting the clinical criteria established by CMS or their health insurance companies. Such qualification criteria are largely based on arterial blood gas or pulse oximetry thresholds, as follows:

- Patients on room air while at rest and awake when tested
- Arterial oxygen saturation at or below 88%
- or
- Arterial partial pressure of oxygen (PO_2) at or below 55 mm Hg
- Patients on room air at rest while awake when tested but who have a confirmed diagnosis of congestive HF, pulmonary hypertension, or erythrocythemia with a hematocrit greater than 56%:
- Arterial oxygen saturation of 89% (or less) at rest (awake)
- or
- Arterial PO_2 of 56 to 59 mm Hg or less

Variations on these thresholds exist for patients tested under other conditions, such as while sleeping or during exercise.[22]

RULE OF THUMB In order for patients to receive reimbursement coverage for their oxygen therapy, CMS requires that they meet initial qualifications demonstrating hypoxemia and follow up with their physicians once a year, showing clinical documentation that demonstrates the need for continued services.

Supply Methods

Most alternative care sites do not have bulk O_2 storage or delivery systems. In these settings, O_2 is normally supplied from one of the following three sources[23]: (1) compressed O_2 cylinders, (2) liquid O_2 systems, or (3) O_2 concentrators. Table 57.3 summarizes the major advantages and disadvantages of each.

Compressed Oxygen Cylinders

For practical reasons, the primary use of compressed O_2 cylinders in alternative settings is either for ambulation (small cylinders) or as a backup to liquid or concentrator supply systems. Safety measures for O_2 cylinders are the same as those discussed in Chapters 41 and 42. For home use, the RT should thoroughly review these safety measures with both the patient and family members. After instruction, the RT should always confirm and document the abilities of caregivers to use the delivery system safely.

In addition to the cylinder gas, a pressure-reducing valve with a flowmeter is needed to deliver O_2 at the prescribed flow. Such a flowmeter may be preaffixed to the tank or removable. Standard clinical flowmeters deliver flows up to 15 L/min; however, flows used in alternative settings are typically in the range of 0.25 to 5 L/min. For this reason, the RT should select a calibrated low-flow flowmeter whenever possible (see Chapter 41). Home-fill stations are useful, as these cylinders have a preaffixed regulator that is filled right from an O_2 concentrator. These devices are exceptionally desirable as they are easy to use and allow patients to have portable oxygen whenever they need it simply by filling the cylinder. As in the hospital, there is usually no need to humidify nasal O_2 at flows of 4 L/min or less.[23] If humidification is needed, a simple unheated bubble humidifier can be used. Because the mineral content of tap water may be high (hard water), the water used in these humidifiers should be distilled. Otherwise the porous diffusing element may become occluded. Although complete blockage is unlikely, occlusion of the diffusing element can impair humidification and alter flow.

Liquid Oxygen Systems

Although the higher cost of liquid O_2 delivery system versus others has greatly reduced their use, they do offer some advantages and are therefore still used under certain conditions in alternative settings. One of the main advantages of a liquid O_2 system relates to the fact that 1 ft^3 of liquid O_2 equals 860 ft^3 of

TABLE 57.3 Advantages and Disadvantages of Major Alternative Oxygen Supply Systems

System	Advantages	Disadvantages
Compressed O_2	Good for small-volume user	Large cylinders are heavy and bulky
	No waste or loss	High-pressure safety hazard
	Stores O_2 indefinitely	Provides limited volume
	Widespread availability	Requires frequent deliveries
	Portability (small cylinders)	Tight valves can be a problem
Liquid O_2 system	Provides large volumes	Must be delivered as needed
	Low-pressure system (20–25 psi)	Loss of O_2 because of venting of system when not in use
	Portable units can be refilled from reservoir (up to 8-h supply at 2 L/min)	Low-temperature safety hazard
		Cannot operate ventilators or other high-pressure devices
	Valuable for rehabilitation	Some difficulty in filling portable units
O_2 concentrator	No waste or loss	Disruption in electrical service renders system inoperable
	Low-pressure system (15 psi)	Backup O_2 is needed
	Cost-effective when continual supply of O_2 is needed	Cannot operate ventilators or other high-pressure devices
		FiO_2 decreases with increasing flow
	Eliminates need for deliveries	High electricity costs possible

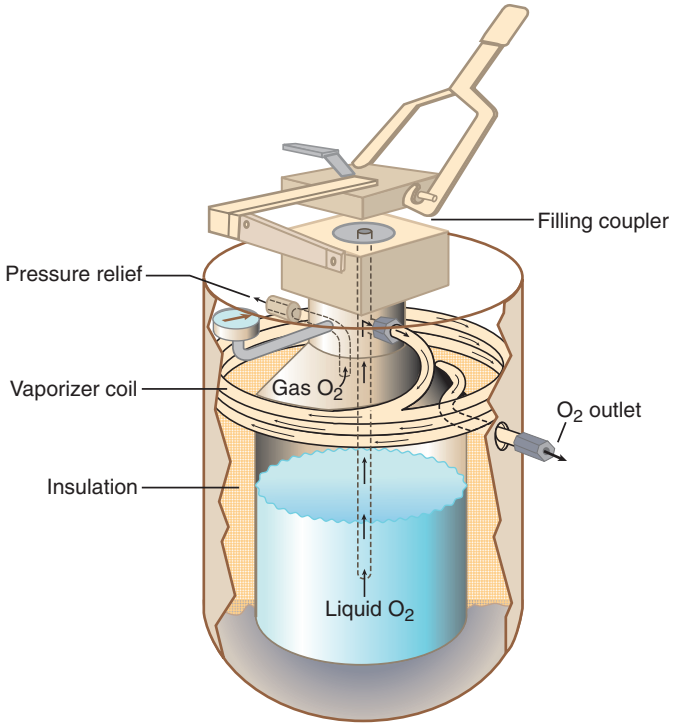

Fig. 57.1 Diagram of a personal liquid oxygen supply system. (Modified from Lampton LM: Home and outpatient oxygen therapy. In: Brashear RE, Rhodes ML, editors: *Chronic obstructive lung disease*, St Louis, 1978, Mosby.)

gas; therefore it is possible to store large quantities of oxygen in small spaces. As shown in Fig. 57.1, a typical personal liquid O_2 system is a miniature version of a hospital liquid O_2 system. Similar to its larger counterpart, this system consists of a reservoir unit similar in design to a thermos bottle. The inner container of liquid O_2 is suspended in an outer container, with a vacuum in between. The liquid O_2 is kept at approximately –300°F. Because of constant vaporization, gaseous O_2 always exists above the liquid. When the cylinder is not in use, this vaporization maintains pressures between 20 and 25 psi. When pressures increase above this level, gas vents out of the pressure relief valve.

Depending on manufacturer and model, small liquid O_2 cylinders hold 45 to 100 lb of liquid O_2. To calculate duration of flow of a liquid O_2 system, one first converts the weight of liquid O_2 in pounds to the equivalent volume of gaseous O_2 in liters. At normal liquid cylinder operating pressures, 1 lb of liquid O_2 equals approximately 344 L of gaseous O_2.

It is important for the RT to identify who is the appropriate candidate for liquid oxygen. Because of newer delivery models, most patients opt for a different stationary setup such as a concentrator coupled with a portable system.

Oxygen Concentrators

The oxygen concentrator is the primary piece of equipment used in delivering oxygen to patients in postacute settings. The output of many concentrator models has been limited to 5 L/min. However, more recently, models capable of delivering 10 L/min have been introduced, including high-intensity concentrators that deliver higher pressures and flows to patients who require high-flow devices such as Venturi or nonrebreathing masks (see Chapter 42). In addition, technologic advances have accounted for other enhancements to O_2 production and delivery devices in alternative care settings. One example is the **portable oxygen concentrator** (POC) with demand-flow conserving capabilities. Such a battery-operated unit affords the patient receiving low-flow O_2 increased mobility, and this item has been approved for use in most commercial aircrafts. In order for a patient to clinically qualify for a POC, the RT must assess the patient's saturation levels while ambulating, making sure that acceptable oxygen levels are maintained.

O_2 concentrators represent the most cost-efficient supply method for patients in alternative care settings who need continuous low-flow O_2. For home use, a concentrator running 24 hours/day increases the average monthly electrical bill by only 5% to 10%. Depending on the season, heat given off by the concentrator's compressor can also affect energy usage by increasing room temperature. Nonetheless, when used with patients receiving low-flow O_2, concentrators are just as effective in increasing blood O_2 levels as other systems. Oxygen concentrators also

require yearly preventative maintenance to make sure that they are functioning properly.[23]

Problem Solving and Troubleshooting

Technical problems with O_2 supply systems in alternative settings are similar to problems encountered in the acute care hospital (see Chapter 41). In addition to these technical problems, situations can arise where patients or caregivers fail to follow instructions properly. To avoid communication problems, verbal instructions should always be reinforced by simple written instructions for subsequent reference. In addition, the clinician should always confirm and document the ability of caregivers to use the delivery system safely, including how to troubleshoot simple problems. The ability of caregivers and patients to give an adequate return demonstration on proper equipment usage should also be recorded.

To avoid problems before they occur, the patient or caregiver should be instructed to check all O_2 delivery equipment at least once a day. The proper function of all equipment, including liter flow and connections should be checked. Oxygen concentrators have internal alarms that will audibly alert the patient if the oxygen being delivered does not have a high enough FiO_2. If the analyzed FiO_2 of the gas coming out of the oxygen concentrator is less than 95%, the problem often stems from exhausted pellet canisters, which should be replaced. In addition, air inlet filters must be cleaned weekly. In the home setting, providing the patient or caregiver with a simple checklist can help to ensure that these important tasks are performed regularly.

In contrast to the hospital setting, O_2 supply problems in the alternative care setting cannot always be addressed immediately. For this reason, the clinician must ensure that every such system has an emergency backup supply. This backup supply is normally provided by a large gaseous cylinder or, at a minimum, an E cylinder. If the primary O_2 supply of a home-care patient is by concentrator, the home-care RT should notify the electric power company in writing that life-support equipment is in use. In the event of a power outage, many utility companies will try to give priority to that location. In addition, it is important for the home-care company to notify the local fire department that a patient has oxygen in his or her home. For patients in more remote geographic areas, an emergency gasoline electrical generator is recommended. If that is not possible, several large oxygen cylinders can be left with the patient. A perfect example of contingency planning working well is when Hurricane Sandy hit New Jersey and power was out for a week or more with little to no accessibility. As a result of power company responsiveness and other backup measures, most patients were safely able to receive their oxygen therapy without interruption.

Possible physical hazards to patients and caregivers include unsecured cylinders, ungrounded equipment, mishandling of liquid (resulting in burns), and fire. Careful preliminary instruction, followed by ongoing assessment of the environment, can help to minimize these problems. Bacterial contamination of nebulizers or humidification systems is another potential problem. Infection-control procedures designed to minimize bacterial contamination are discussed later in this chapter.[23,24]

MINI CLINI

Home Safety Assessment

Problem

An RT does a home assessment on a patient who was recently prescribed long-term oxygen therapy (LTOT). The RT smells an odor similar to cigarette smoke. The patient denies smoking in the house and states that she has recently quit.

Solution

First, it is essential for the RT to perform a visual inspection of the patient's residence. This would include looking for ashtrays, matches, packs of cigarettes, burnt candles, and so on. This must all be thoroughly documented on the home assessment checklist. Second, the patient should be advised that no one, including friends and family, should be allowed to smoke in the home. Third, it is important that a "no smoking" sign is visibly present, alerting those in the home of the presence of O_2. The RT should also make sure that the patient has a working fire extinguisher and a working smoke alarm. If at any point the RT identifies that the patient is smoking, the incident should be reported to both the physician and the risk management team.

RULE OF THUMB If an O_2 concentrator cannot supply at least 85% O_2 at 5 L/min, the pellet canisters are probably exhausted and should be replaced.

Delivery Methods

The most common O_2 delivery system for long-term care is the nasal cannula. Simple O_2 masks and air entrainment masks may also be used but are much less common. To decrease O_2 use and costs, numerous O_2-conserving devices have been developed, including transtracheal O_2 catheter, reservoir cannula, and demand or pulsed-dose O_2 delivery systems.

The performance characteristics, advantages, and disadvantages of transtracheal O_2 catheters and reservoir cannulas are described in detail in Chapter 42. We focus here on the application of the transtracheal O_2 catheter and the technical aspects of demand-flow systems.

Transtracheal Oxygen Therapy

Transtracheal oxygen therapy (TTOT) is O_2 delivered via a catheter with a small orifice that is inserted through the skin and neck tissue into the trachea. As detailed in Chapter 42, this delivery method offers advantages of improved cosmetic appearance and lower flows to achieve the same therapeutic effect.

As with most modalities in alternative care settings, the success of TTOT depends mainly on effective patient education and ongoing self-care with professional follow-up. Key patient responsibilities include routine catheter cleaning and recognizing and troubleshooting common problems.[25]

Demand-Flow Oxygen Systems

A demand-flow O_2 delivery device, also known as a pulsed-dose **O_2-conserving device**, uses a flow sensor and valve to synchronize gas delivery with the beginning of inspiration.[25] These O_2-conserving devices exhibit performance comparable to that of a nasal cannula at approximately one-third to one-half the

MINI CLINI

Selecting a Long-Term Oxygen Delivery System

Problem

The following three patients require LTOT: (1) a stable home-care patient with restricted activity needing low FiO_2; (2) an active home-care patient with low FiO_2 needs who desires increased mobility; and (3) a patient in a long-term-care facility with a tracheostomy who needs moderate levels of O_2 and high humidity. Select the best O_2 delivery system for each patient.

Solution

Patient 1: Because most home-care patients who need O_2 are relatively stable and their FiO_2 needs are minimal, traditional low-flow therapy by nasal cannula (using a concentrator) is the most common and accepted approach. When it is combined with a portable gas cylinder (for backup and limited walking), this combination is ideal for patients with restricted activity.

Patient 2: For an active patient with low FiO_2 needs who desires increased mobility, a conserving device used in conjunction with a portable concentrator (coupled with a home-based concentrator) is the ideal choice. Given that selected models of reservoir cannulas are poorly accepted by some patients, the choice of conserving device usually narrows to a demand-flow/pulse-dosed system, alone or coupled with a portable concentrator.

Patient 3: Patients with artificial airways in alternative sites who need O_2 present a special problem. Because of high O_2 use and infection concerns, an O_2-powered air entrainment nebulizer is unsatisfactory. Instead, a compressor-driven humidifier with supplemental O_2 bled in at low flows from a concentrator or liquid system should be used. In this case, the RT must confirm the FiO_2 with a calibrated analyzer.

MINI CLINI

Troubleshooting a Home Oxygen Contractor

Problem

A patient calls after hours and states that his concentrator is sounding an alarm and it feels like there's no oxygen coming out.

Solution

The first thing the home-care RT should do is advise the patient to remove the oxygen cannula from the concentrator and move to the backup cylinder. This will allow the patient to troubleshoot the equipment while still receiving his oxygen therapy. There could be several different solutions to fixing the issue.

1. Ask the patient to put the cannula in a cup of water. If there is bubbling in the cup, the concentrator is delivering flow. The alarm could likely be going off because the concentrator is not taking in enough room air. The patient should then be asked to make sure that the concentrator is at least 18 in away from a wall or dresser and that the filters are clean.
2. If the alarm is sounding but no light is on, it is usually due to a loss of power. The patient should be advised to try replugging the unit. If this does not work, he or she should check the electric breaker switch on the front of the concentrator to make sure that it has not tripped.
3. If the concentrator continues to alarm, it may be a malfunction issue and the patient should contact the DME company for a replacement. Most companies have technicians available 24 h a day to replace such equipment.

flow. With these devices, most of the effective O_2 delivery occurs during the first half of inspiration. As a result, these systems deliver a synchronized pulse of O_2 delivered at the beginning (first 25%) of inspiration. Under these conditions, a properly functioning pulsed O_2 system can produce SaO_2 levels equal to levels seen with continuous flow while using 60% less O_2.[26]

In theory, demand-flow O_2 systems provide the greatest savings in O_2 use for a given level of arterial saturation. Recent improvements to demand-flow systems have made them more reliable and user friendly, addressing the major disadvantages of earlier versions. As a result of these improvements and the ability of these devices to increase the duration of flow by two or three times, they have now gained wide acceptance. This includes newer portable technology that can allow patients to use up to 10 hours of battery life before needing to recharge their concentrators. POCs also come with car chargers that will maintain and charge the concentrator.[27,28]

Selecting a Long-Term Oxygen Delivery System

As when selecting hospital-based O_2 therapy systems, the "three P's" should always be considered when selecting a long-term O_2 system: purpose, patient, and performance. The goal is always to match the *performance* of the equipment to both the objectives of therapy *(purpose)* and the *patient's* special needs. Patients requiring low-flow home O_2 and enhanced mobility should be considered for a portable concentrator alone or one with a conserving feature or a liquid O_2 setup with a pulsed-dose O_2-conserving device.

Problem Solving and Troubleshooting

Most problems with long-term O_2 delivery systems are related to patients and caregivers who fail to follow instructions or comply with the prescribed therapeutic or maintenance regimen.[23] Generally, home-based caregivers should be allowed to operate and maintain O_2 delivery devices only after they have been instructed by credentialed RTs and have demonstrated the appropriate level of skill. In no case should the patient or caregiver be allowed or instructed to alter flow settings. Instead, when in doubt, they should be taught to switch to the backup supply at the same liter flow and either contact their physician if they are feeling ill or their home-care company if they think the equipment is not functioning properly.

To be proactive and avoid complications or product failure, catheters and tubing should be replaced every 3 months, at which time a checkup by the physician is also recommended. The patient or caregiver should clean the oxygen delivery device every day, per the self-care guidelines listed in this chapter. Patients should always be instructed to put on a nasal cannula and to call the physician if any major problem occurs.

VENTILATORY SUPPORT IN ALTERNATIVE SETTINGS

Providing successful ventilatory support outside the acute care hospital requires careful patient selection and meticulous discharge planning.[29] Key factors include an interdisciplinary team approach, effective caregiver and family education, thorough assessment and preparation of the environment, and careful selection of needed equipment and supplies. Properly planned ventilatory support delivered in alternative settings can provide

TABLE 57.4 Profiles of Patient Groups Requiring Ventilatory Support in Alternative Settings

Group Description	Diseases Involved
Profile 1	
Mainly composed of neuromuscular and thoracic wall disorders; particular stage of disease process allows patient certain periods of spontaneous breathing time during the day; generally requires only nocturnal mechanical support	Amyotrophic lateral sclerosis Multiple sclerosis Kyphoscoliosis and related chest wall deformities Diaphragmatic paralysis Myasthenia gravis
Profile 2	
Requires continuous mechanical ventilatory support associated with long-term survival rates	High spinal cord injuries Apneic encephalopathies Severe chronic obstructive pulmonary disease Late-stage muscular dystrophy
Profile 3	
Usually returns home at request of patient and family; patient's condition is terminal, life expectancy is short, and patient and family wish to spend remaining time at home; patients usually pose management problems in the home because of their rapidly deteriorating conditions	Lung cancer End-stage chronic obstructive pulmonary disease Cystic fibrosis

major benefits for both the patient and family as well as yielding substantial savings in health care costs.[30]

Patient Selection

Most patients needing ventilatory support outside the acute care hospital fall into one of the following three broad categories[31]:

1. Patients unable to maintain adequate ventilation over prolonged periods (in particular, noninvasive nocturnal or intermittent use)
2. Patients requiring continuous mechanical ventilation for long-term survival
3. Patients who are terminally ill with short life expectancies

Table 57.4 provides more detailed profiles of these patient groups. In addition to adults, a growing number of ventilator-assisted children are being managed in alternative settings. The same basic principles of discharge planning and patient care as for adult patients should be followed for ventilator-assisted children.[32]

Regardless of diagnosis, patients being considered for ventilatory support in alternative settings must be medically and psychologically stable. In regard to assessing patient stability, Box 57.2 outlines the criteria developed by the American College of Chest Physicians (ACCP).[33]

Settings and Approaches

The most common setting for ventilatory support outside the acute care hospital is the home. Additional sites include long-term care facilities, including specialized long-term units such as LTACHs, designed specifically for ventilator patients.[34,35]

BOX 57.2 Criteria to Determine Patient Stability for Ventilatory Support in Alternative Care Settings

- Ability to tolerate mechanical ventilation
- Acceptable arterial blood gas results and other blood chemistry (e.g., complete blood count)
- Relatively low FiO_2 needs (generally ≤40%)
- Psychological stability
- Absence of life-limiting comorbidities, including cardiac dysfunction and arrhythmias
- Positive end-expiratory pressure should not exceed 10 cm H_2O
- Ability to clear airway secretions by cough, suction, or cough-assist device
- Tracheostomy tube as opposed to endotracheal tube for invasive ventilation
- No readmissions expected for >1 month

Based on individual evaluation of patient need, one of the following two major support approaches may be considered: (1) invasive or (2) noninvasive support. In alternative settings, invasive ventilatory support always involves application of positive pressure ventilation by tracheotomy. Noninvasive approaches include positive-pressure and very rarely negative-pressure ventilation.[36]

Standards and Guidelines

Standards and guidelines for ventilatory support outside the acute care hospital continue to evolve. The AARC developed a Clinical Practice Guideline on long-term invasive mechanical ventilation in the home, which can be found at the AARC's website (AARC.org).[37]

Special Challenges in Providing Home Ventilatory Support

Institutions that provide ventilatory support in alternative settings differ from acute care facilities mainly in their level of technology support. The home setting not only lacks this support but also must depend extensively on nontechnical, nonprofessional caregivers. For these reasons, providing ventilatory support in the home presents many special challenges.

Prerequisites

For home ventilatory support to be successful, several prerequisites must be met, including the following[38]:

- Willingness of family to accept responsibility
- Adequacy of family and professional support
- Overall viability of the home-care plan
- Stability of patient
- Adequacy of home setting
- Adequate financial stability and insurance coverage

In regard to the home setting, the same factors listed in Box 57.1 should be evaluated for patients being considered for home ventilatory support.

Planning

Successful home ventilatory support requires extensive planning, education, and follow-up by all members of the home-care team.

Basic steps in the discharge process for a ventilator-dependent patient include the following:

1. Family is consulted regarding feasibility.
2. Discharge planner coordinates efforts of team members and discharge plan is formulated.
3. Insurance has been verified and patient has coverage for services at home.
4. Team members discuss plan with family and caregivers.
5. Home layout is assessed, with necessary changes made.
6. Education and training are initiated and completed.
7. Patient and family are prepared for discharge.
8. Equipment and supplies are readied.
9. Discharge planner meets with team and makes final preparations.
10. Patient is discharged (with trial period if necessary).
11. Local power company is notified regarding the presence of life-support equipment; appropriate backup power (battery or compressed gas source) is made available.
12. Local fire department is notified regarding the presence of life-support and appropriate equipment.
13. Ongoing and follow-up care is provided by visiting nurse, RT, and other health care professionals as necessary.

Caregiver Education

To properly prepare patients, family members, and other caregivers for home discharge, a comprehensive educational program must be undertaken and completed. Essential skills that must be taught including the following[38]:

- Simple patient assessment
- Airway management, including tracheostomy and stoma care, cuff care, suctioning, cough-assist, changing artificial airways or ties
- Chest physical therapy techniques, including percussion, vibration, and coughing
- Medication administration, including oral and aerosol
- Patient movement and ambulation
- Equipment operation and maintenance
- Equipment troubleshooting
- Cleaning and disinfection
- Emergency procedures

Emergency situations that caregivers must be trained to recognize and deal with properly include the following:

- Ventilator or power failure
- Ventilator circuit problems
- Airway emergencies
- Cardiac arrest

All caregivers should successfully complete this educational process. Training generally requires a minimum of 1 to 2 weeks, over which time several education sessions can take place and cover instruction, demonstration, caregiver practice, and evaluation. Caregivers should be strongly encouraged to complete a course in basic life support, such as that offered by the American Heart Association, before the patient is discharged. Ideally, the patient should have a trial period on the actual home ventilator before discharge. In the early stages after discharge, patient follow-up by an RT likely should occur every day. As patient and caregivers become more familiar with the equipment and procedures, the frequency of follow-up visits generally decreases to about once per month.[39,40]

Invasive Versus Noninvasive Ventilatory Support

Until recently, invasive positive-pressure ventilation by tracheostomy was the default standard for long-term mechanical ventilation, especially for patients requiring 24-hour support. However, long-term tracheostomy is associated with some potential problems, including secretion retention, infection, aspiration, and ventilator-associated pneumonia as well as communication difficulties between caregivers and patients. Because many long-term care facilities treat a tracheostomy as an open wound, patient placement at certain alternative care sites is prohibited.[41] Last, invasive ventilation by tracheostomy poses significant limits on the patient's quality of life. For these reasons, noninvasive support is becoming increasingly popular in general and in alternative settings. Noninvasive ventilatory support (see Chapter 50) involves any method designed to augment alveolar ventilation without an endotracheal airway. **Noninvasive ventilation (NIV)** is usually the first choice. An individual requiring mechanical ventilation can be supported with NIV if the following conditions are met[42]:

- The patient is mentally competent, cooperative, and not using heavy sedation or narcotics.
- Supplemental O_2 therapy is generally minimal ($FiO_2 \leq 40\%$).
- SaO_2 can be maintained at greater than 90% by aggressive airway clearance techniques.
- Bulbar muscle function is adequate for swallowing and airway protection.
- No history exists of substance abuse or uncontrollable seizures.
- Unassisted or manually assisted peak expiratory flows during coughing exceed about 3 L/s.
- No conditions are present that interfere with NIV interfaces (e.g., facial trauma, inadequate bite for mouthpiece, presence of orogastric or nasogastric tube, or facial hair that can hamper an airtight seal).

Patients who can benefit from NIV generally fall into one of two categories (see Chapter 50).[43] Patients in the first category have conditions in which cessation of ventilation could lead to imminent death. This category includes both acutely ill patients (patients with asthma, acute exacerbation of COPD, or pulmonary edema) and patients requiring long-term 24-hour support (some patients with quadriplegia or patients with certain neuromuscular disorders). Patients in the second category have conditions in which NIV may offer clinical benefit but cessation is usually not life-threatening. These patients generally require only intermittent or nocturnal support and are more commonly found in alternative care settings. Patients in this category include those with chronic neuromuscular and chest wall diseases, such as amyotrophic lateral sclerosis (ALS), muscular dystrophy, and kyphoscoliosis. The application of long-term NIV for patients with obstructive disorders such as end-stage COPD or cystic fibrosis is much less common. Relative contraindications to NIV include severe upper airway dysfunction, copious secretions that cannot be cleared by spontaneous or assisted cough, and O_2 concentration requirements exceeding 40%.[43,44]

BOX 57.3 Essential Equipment and Supplies for Ventilator-Dependent Patients in Alternative Care Settings

Equipment

- Ventilator(s)
- Manual resuscitator (bag-valve-mask unit)
- Heated ventilator/humidifier with thermostat and heat and moisture exchanger
- Monitoring or alarm devices (including remote where necessary)
- 12-V battery and battery charger
- Air compressor
- O_2 source
- Power strip or surge protector
- Suction machine with backup (manual or battery)
- Stethoscope and sphygmomanometer
- O_2 analyzer
- Pulse oximeter
- Hospital bed with table
- Patient lift
- Bedside commode, urinal, or bedpan
- Wheelchair

Supplies

- O_2
- O_2 delivery devices, including manual resuscitator
- Airway interface (masks, mouthpieces, tracheostomy tubes)
- Tracheostomy tube inner cannulas
- Extra tracheostomy tubes including a tube one size smaller
- Tracheostomy care kits
- Ventilator circuits
- Bacterial filters
- Heat and moisture exchangers
- Passy Muir valve (if appropriate)
- Connecting tubing (aerosol, O_2, suction)
- Suction catheters
- Disposable gloves
- Distilled or sterile water
- Small-volume nebulizer or metered dose inhaler with ventilator adapters if appropriate
- Cleaning and disinfection supplies (10-mL syringe, 15- to 22-mm tubing adapters)

Equipment

Box 57.3 lists the essential equipment and supplies needed for ventilator-dependent patients in alternative settings.[36]

Selecting the Appropriate Ventilator

The choice of ventilator for a patient in an alternative care setting should be based on the patient's clinical need and the available support resources. In some cases, patient needs may dictate that more than one ventilator be provided.[36] A second backup ventilator should be considered for patients who cannot maintain spontaneous ventilation for more than 4 consecutive hours, for patients living in an area where a replacement ventilator cannot be secured within about 2 hours, and for patients whose care plan requires mechanical ventilation during mobility.[44] Generally ventilators chosen for care in alternative settings must be dependable and easy for caregivers to operate. If mobility is an essential element of the patient's care plan, the ventilator system selected should be portable. If the patient is receiving continuous ventilatory support in any alternative setting, external battery backup is required, and emergency AC power by way of a generator is recommended. It is also important to verify with the patient's insurance carrier as to what the financial allowance is for each piece of equipment including the accessories.

If invasive ventilation by tracheostomy is the selected approach, the best choice is a positive-pressure ventilator. The invasive route also requires a humidification system, preferably a servo-controlled heated humidifier with alarms. Patients with a tracheostomy without retained secretions may use a heat and moisture exchanger (HME) during transport or to enhance their mobility. For patients with an intact upper airway, a device capable of NIV is the first choice unless contraindicated. Box 57.4 lists the absolute contraindications to using NIV.[45]

BOX 57.4 Absolute Contraindications to Using Noninvasive Ventilation

- Need for immediate intubation
- Hemodynamic instability
- Uncooperative patient
- Facial burns or trauma
- Inadequate airway protection
- Patent tracheoesophageal fistula

TABLE 57.5 Essential, Recommended, and Optional Features of a Positive Pressure Ventilator for Use in an Alternative Care Setting

Feature	Necessity
Positive pressure tidal breaths	Essential
Mandatory rate	Essential
Flow or inspiratory-to-expiratory ratio or inspiratory time	Recommended[a]
Positive end-expiratory pressure (PEEP)	Recommended[a]
FiO_2 to 1	Optional
Patient's spontaneous breath (e.g., continuous positive airway pressure [CPAP], intermittent mandatory ventilation)	Optional
Breath-triggering mechanism (flow or pressure sensors to initiate ventilator breath)	Recommended[a]
Flow-timing interaction (e.g., pressure support)	Optional
Feedback control (e.g., pressure-regulated volume control)	Optional

[a]Essential if the patient has intact ventilatory drive and respiratory muscles or if the possibility of partial or complete ventilator independence is anticipated.

Positive Pressure Ventilators

Table 57.5 lists the essential, recommended, and optional features of positive-pressure ventilators used in alternative care settings. An *essential* feature is basic to safe and effective operation in most patient care settings. A *recommended* feature helps provide optimal patient management. An *optional* feature is possibly useful in limited situations but not needed for most patients.[45,46]

As shown in Fig. 57.2, there are many new positive pressure ventilators designed for use in alternative settings. These ventilators

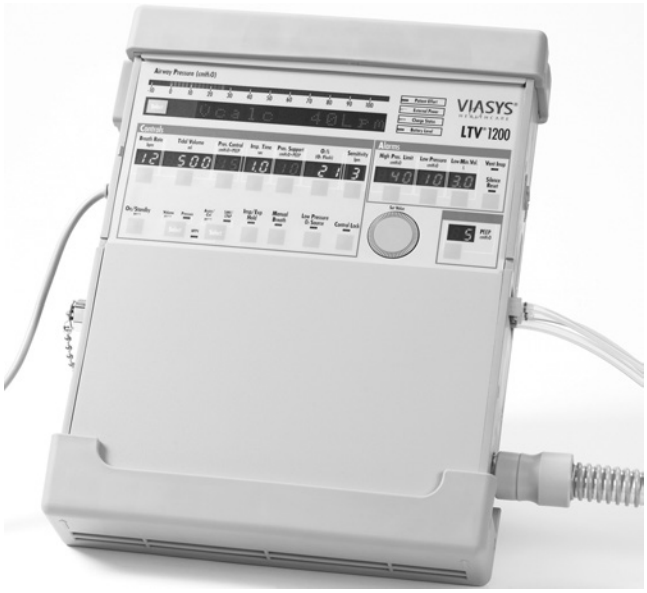

Fig. 57.2 LTV 1200 ventilator. (Courtesy Vyaire Medical, Mettawa, IL.)

Fig. 57.3 Dreamstation BiPAP. (Used with permission of Philips Respironics, Murrysville, PA.)

can be used on adults or pediatric patients weighing at least 5 kg.

Some are approximately the size and weight of a laptop computer and have many of the capabilities of much larger mechanical ventilators used in alternative sites and in acute care. These new ventilators offer ventilator-dependent patients the advantages of greater mobility and space conservation. Many of these models also offer pressure support and can provide positive end-expiratory pressure (PEEP) without having to add an adapter to the ventilator circuit.[47]

Many new positive-pressure ventilators designed for alternative care settings have an internal battery, which can provide several hours of use in the event of a power failure. For longer periods of use away from typical line power, many of these devices can run for 10 to 12 hours using an external battery.

Additionally, time-triggered or patient-triggered, pressure-limited, flow-cycled devices (pressure support with timed backup) have been successfully applied in alternative settings.[48,49] Many units are currently available (Fig. 57.3) that are specifically designed to provide this type of support, usually noninvasively by nasal or oronasal (full face) masks.

TABLE 57.6 Adverse Effects of Noninvasive Ventilation Interfaces and Possible Corrective Actions

Interface	Adverse Effect	Remedy
Nasal and oronasal masks	Discomfort	Proper fit, adjust strap tension, change mask type
	Nasal bridge redness, pressure sores, conjunctivitis	Try different size or type of mask, reduce strap tension, use forehead spacer, try nasal pillow, use artificial skin
	Acneiform rash	Cortisone cream, alternative (gel) mask
Oronasal masks	Impede speech and eating	Permit periodic removal if tolerated by patient
	Claustrophobia	Choose clear masks with minimal bulk
	Aspiration	Exclude patients unable to protect airway; nasogastric tubes for patient with nausea and abdominal distention
Mouthpieces/ lip seals	Interference with swallowing, salivary retention	Coaching, adaptation
	Pressure on lips, cheeks	Try different size or type of mask, ensure proper fit, adjust strap
	Dental deformity	Orthodontic consultation
	Aerophagia	Simethicone, coaching
	Allergic reactions	Change prosthetic materials
	Nasal air leaking	Nose clips
	Accidental disconnection	Appropriate alarms in ventilator-dependent patients

Most positive pressure ventilators can be used to provide NIV.[49,50] NIV is normally provided by pressure-targeted ventilation regardless of the cause of ventilatory failure. The newest generation of these ventilators include alarm capabilities and internal battery backup.[50]

The biggest challenge with NIV is not selecting the right ventilator but getting a good, comfortable, minimal-leak interface. Interfaces commonly found in alternative care settings include oronasal (full face) masks; nasal masks; nasal "pillows"; and simple, flanged, or custom mouthpieces. For long-term use, some patients prefer alternating between devices. A patient may prefer a simple mouthpiece for easy accessibility during the day, with a nasal mask providing support at night.[50] Table 57.6 summarizes common problems associated with NIV interfaces and how to correct them.[51]

All positive-pressure ventilators used in alternative settings must have an alarm (pneumatic or electrical) to indicate loss of power. Portable volume-cycled ventilators should also incorporate a high-pressure alarm or cycle override. For patients with conditions in which cessation of ventilation would cause death, a patient-disconnect alarm (low-pressure or low exhaled volume) must be provided.[50,51] In some settings, a remote alarm, secondary disconnect alarm, or both may be needed. A secondary alarm may be based on chest wall impedance and cardiac activity, exhaled volume, end-tidal CO_2, or pulse oximetry with alarm

capabilities. For patients in alternative settings who require only intermittent NIV, a loss-of-power alarm is generally sufficient.[50-52]

RULE OF THUMB All positive-pressure ventilators used in alternative settings must have a loss-of-power alarm. For portable volume-cycled ventilators, alarms for high pressure and loss of pressure (disconnect) are also essential.

OTHER MODES OF RESPIRATORY CARE IN ALTERNATIVE SITES

In addition to O_2 therapy and ventilatory support, other modes of respiratory care are now common in the alternative care setting. These may represent the primary therapy or may be used to supplement other modes of care. Included for discussion here are bland aerosol therapy, aerosol drug administration, airway care and clearance methods, nasal continuous positive airway pressure (CPAP), and apnea monitoring.

Bland Aerosol Therapy

The delivery of bland aerosols has been common in alternative sites for many years. Bland aerosol therapy (see Chapter 39) includes the delivery of sterile water or various concentrations of saline solution in aerosol form. The aerosol can be produced by either an ultrasonic or jet (large volume) nebulizer. If a jet nebulizer is being used, a 50-psi air compressor is also required. Supplemental O_2 is provided by either a concentrator or liquid supply system and must be analyzed with an O_2 analyzer.

Depending on the patient's condition and therapeutic objectives, bland aerosol therapy may be either continuous or intermittent. Although bland aerosol alone may have little effect on the properties of mucus or its clearance, it may be useful as an adjunct to other airway clearance procedures.

The potential problem is infection from contaminated equipment. To reduce the incidence of infection, equipment and patient delivery systems must be cleaned and changed regularly, as noted later in this chapter.[53]

Aerosol Drug Administration

As in the acute care setting, the aerosol route is popular for drug administration to respiratory patients in alternative care settings. As described in Chapter 40, drug categories commonly administered by the aerosol route include beta-adrenergic bronchodilators, anticholinergic agents, and antiinflammatory drugs.

Most pulmonary drugs are available in either metered-dose inhaler or dry-powder inhaler form. Alternatively, the caregiver can use a small-volume nebulizer powered by a low-output diaphragm compressor.[54]

Airway Care and Clearance Methods

Patients in alternative care settings with tracheostomies require both daily stoma care and tracheobronchial secretion clearance. Tracheostomy care can be provided by any trained caregiver, but tube changes should generally be performed only by an RT or a physician.

In most alternative care settings, tracheobronchial clearance (see Chapter 44) is often accomplished by suctioning, using a portable electrically powered suction pump with collection bottle and connection tubing. For suctioning of the patient at home, some patients may be taught to suction themselves. Proper suctioning procedures should also be taught to home caregivers (see Chapter 37). Education and training on proper suctioning methods may begin before patient discharge from the acute care setting, with reinforcement and follow-up as needed.[55] Daily maintenance and cleaning are required.

RULE OF THUMB For portable suction units calibrated in inches of mercury (in Hg), the following vacuum ranges are recommended (adjustment may be needed based on volume and viscosity of secretions):

Patient Category	Vacuum Setting (in Hg)
Infants	5–7
Children	7–12
Adults	12–15

Numerous methods are available for patients in an alternative care setting with an intact upper airway who need help with secretion clearance. These methods include both patient-independent and caregiver-dependent techniques (see Chapter 44).[55] Patients can be taught to apply independently coughing, forced exhalation, active cycle of breathing, and autogenic drainage methods. Caregiver assistance is required with traditional postural drainage, percussion and vibration, and directed or assisted coughing. Additional assistance can be provided by mechanical devices such as a positive expiratory pressure mask, flutter valve, intrapulmonary percussive ventilator, and high-frequency chest compression vest.

Another airway clearance method involves the use of cough-assist devices such as a mechanical **insufflator-exsufflator** or a cough-assist unit. This device, an example of which is included as Fig. 57.4, uses alternating positive and negative pressure to simulate a cough as a form of lung expansion and airway clearance therapy.

These devices can be especially effective with patients receiving NIV. The application of secretion clearance devices or techniques by nonprofessional caregivers must involve good preliminary instruction and ongoing follow-up by the RT working in any alternative site.[55]

Nasal Continuous Positive Airway Pressure Therapy

Nasal CPAP therapy has become an accepted form of home care used to treat sleep apnea–hypopnea syndrome. For Medicare reimbursement of home nasal CPAP equipment, the diagnosis of sleep apnea must be confirmed by polysomnography, also known as a *sleep study*. Private commercial insurances will typically reimburse for a **home sleep test**, also known as an "unattended sleep study" (see Chapter 34). These basic yet accurate studies measure nasal and oral airflow, respiratory effort, and oxygen saturation. With proper application and patient compliance, CPAP therapy can dramatically lessen or resolve the many problems associated with sleep apnea–hypopnea syndrome

Fig. 57.4 CoughAssist device. (Used with permission of Philips Respironics, Murrysville, PA.)

(morning headaches, daytime hypersomnolence, cognitive impairment). The patient's quality of life can be enhanced, and more severe complications, such as systemic and pulmonary hypertension and cor pulmonale, may be reduced.[56,57]

Equipment

A typical nasal CPAP apparatus consists of a flow generator capable of establishing varying levels of PEEP or CPAP, a circuit, and a patient interface (e.g., nasal mask, nasal pillows). One of the most common interfaces in alternative settings is the nasal mask. However, many patients requiring nocturnal CPAP prefer to use a full-face mask instead of a nasal mask. Most systems provide manually adjustable pressures in the range of 4 to 20 cm H_2O. Most units have a ramp feature that gradually increases the pressure to the prescribed level over a time interval to increase comfort and therapy compliance.

RULE OF THUMB For Medicare reimbursement of CPAP equipment, the diagnosis of sleep apnea must be confirmed by polysomnography, also known as a sleep study. Most insurance providers, including Medicare, will cover payment for CPAP accessories including the mask interface, tubing, and filters every 3 months.

Determining Proper Continuous Positive Airway Pressure Level

The proper CPAP level for a patient is determined by one of several methods. The most common method is to conduct the sleep study while titrating different levels of CPAP. Observed changes in the apnea-hypopnea index are correlated with the various CPAP levels. The prescribed level of CPAP is the lowest pressure at which apneic episodes are reduced to an acceptable frequency and duration.

More recently, CPAP units that automatically adjust the pressures to maintain airway patency have been commonly used. These self-titrating or auto-CPAP devices generally result in use of the lowest effective pressures and better patient compliance while also reducing the need for a subsequent sleep study and titration.[58]

Alternatively, CPAP may be titrated against pulse oximetry data. In this case, the goal is to use the lowest CPAP that maintains adequate arterial saturation (SpO_2 <90%). With changes in medical insurance policies, home sleep testing has become the preferred method for screening patients who have suspected sleep apnea. These unattended sleep study devices are used at home and are very portable. They measure nasal and oral airflow, respiratory effort, and oxygen saturations. For patients who have additional comorbidities in addition to obstructive sleep apnea, an in-lab study is recommended.[58]

Sleep Remote Telemonitoring

Technology has dramatically advanced in PAP devices. All new devices have built-in modems where a RT can remotely monitor the patient's compliance. If the patient requires a change to his or her existing parameters, the RT can adjust ramp settings, humidification, and even change the CPAP pressure. These advances in technology have helped to increase compliance by rapid intervention and adjustment to treatment.[59]

Use and Maintenance

Once proper CPAP level is determined, the patient is fitted for a mask and trained in the proper use, cleaning, and maintenance of the equipment. Typical patient instructions for self-administration of nasal or full-face mask CPAP therapy are provided in Box 57.5.

Problem Solving and Troubleshooting

Patient problems associated with nasal or full-face mask CPAP therapy include skin irritation, conjunctivitis, epistaxis, and nasal discomfort (dryness, burning, and congestion). Skin irritation is usually due to tight mask straps or a dirty patient interface. Persistent redness on the face or around the nose is the primary sign. Adjusting the straps (while maintaining a good mask seal) can help prevent irritation. In addition, the patient interface should be cleaned daily to remove dirt and facial oils. Based on medical insurance allotments, masks and nasal pillows are usually replaced every 3 to 6 months or sooner if leakage or discomfort occurs.

Conjunctivitis is probably the result of mask leakage around the bridge of the nose, which is easily corrected by ensuring a good seal in this area. Epistaxis (nosebleeds) and nasal discomfort are associated with drying of the nasal mucosa—a particular problem in cold, dry winter climates. Methods used to overcome excessive drying include in-line humidifiers, chin straps (to decrease loss of upper airway moisture), and saline nasal sprays.[60] Because none of these methods has proved satisfactory for all patients, selection should be based on individual patient acceptance and observed improvement in comfort. However, almost all patients receiving nocturnal CPAP therapy benefit from the addition of an in-line humidifier.

The most common problem with the CPAP apparatus is an inability to reach or maintain the set pressure. This problem is

BOX 57.5 Typical Patient Instructions for Self-Administration of Nasal or Full-Face Mask Continuous Positive Airway Pressure Therapy

Equipment Preparation

1. Place blower unit on a level surface (table or nightstand) close to where you sleep.
2. Ensure that the air exhaust and inlet vents are not obstructed.
3. Plug machine into a standard grounded (three-prong) electrical outlet.
4. Check air inlet filter to make sure that it is in place and free of dust.
5. Connect one end of the tubing to the interface (e.g., mask, nasal pillows).
6. Attach interface to your nose or face.
7. Adjust tightness of headgear strap to seat interface firmly onto your nose or face.
8. Turn on the blower and verify a flow of air.
9. Ensure proper fit and adjustment of mask and headgear. Air should not be leaking out around the bridge of your nose into your eyes or from the mask to your upper lip.
10. Adjust ramp feature and comfort setting if needed.
11. Continuous positive airway pressure therapy is now fully functional, but minor adjustments may be needed with ongoing use.

In the Morning

1. Remove mask by slipping the strap off the back of your head (you may leave the head strap connected between cleanings).
2. Turn off blower.
3. Wash interface every morning with a mild detergent, then rinse it with water.
4. Once dry, store interface in a plastic bag to keep it clean.
5. Empty excess water left in the humidifier.

Weekly

1. Wipe off the blower unit with a clean damp cloth.
2. Wash the head strap and circuit tubing.
3. Service the filters according to the instructions in your patient manual.
4. Wash the humidifier chamber with mild dish detergent and rinse with water.

usually due to either inadequate flow or, more commonly, system leaks. Common causes of leaks include inappropriate patient interface (mask vs. nasal pillows) or pressure loss through an open mouth. As part of their initial training, patients and caregivers should be taught how to recognize and correct these common problems. Box 57.6 outlines the procedures patients or caregivers can use to troubleshoot inadequate flows and system leaks.[61]

Follow-up with patients soon after they begin CPAP therapy is important to resolve complications promptly. If left unresolved, these issues often discourage the patient and result in decreased compliance and a return of original symptoms.[61]

For financial coverage to be provided, most medical insurance policies including CMS require that the patient be compliant with their sleep therapy within the first 90 days of treatment.

Apnea Monitoring

Apnea monitors alert clinicians and caregivers to certain life-threatening events, most notably recurrent apnea, bradycardia, and hypoxemia. At-risk infants are frequently set up on apnea monitors while they are in the hospital. After extensive family

BOX 57.6 Patient and Caregiver Instructions for Troubleshooting Continuous Positive Airway Pressure Equipment

Inadequate Flow

1. Make sure that the unit is plugged into a working electrical outlet.
2. Confirm that the unit is turned on.
3. Make sure that all connections are tight.
4. Confirm that airflow is coming from the blower.
5. Make sure that the intake/exhaust vents are not obstructed.
6. Check the blower inlet filter to confirm that air can easily enter the unit. If the filter appears obstructed, wash or replace it.
7. If there is still no flow, contact your home care provider.

Air Leaks

1. Check interface fit and readjust mask or headgear if necessary.
2. Request a chin strap to help keep patient's mouth closed.
3. If the problem is not resolved, contact the home care provider for adjustments or a different interface such as a nasal pillow.

MINI CLINI

Troubleshooting Nasal Dryness With Continuous Positive Airway Pressure

Problem

A 43-year-old obese man with documented obstructive sleep apnea has been advised by his attending physician that home CPAP therapy at night is needed. The home-care RT makes an appointment with the patient to assess his tolerance of the CPAP unit. During the visit, the patient notes that he has been experiencing nasal discomfort. How can the RT assist in problem solving with this specific complaint, and what are some of the other potential patient problems associated with CPAP therapy that the clinician should be alerted to?

Solution

CPAP devices use some type of patient interface such as a nasal mask, pillows, or full-face mask with supporting headgear. Complaints of nasal discomfort are common and are most likely due to the effects of dry airflow through the CPAP unit blower. However, other factors may aggravate the sensation of nasal irritation. Poor systemic hydration could worsen nasal mucosal drying. In addition, environmental humidity may be a factor. Cold, dry winter climates can aggravate symptoms, as can dry forced-air heating systems. In these cases, the RT might recommend increasing oral intake of fluids (if no restrictions on fluid intake), the installation of a room or heating system humidifier, or the as-needed use of a saline nasal spray. Also, almost all patients receiving nocturnal CPAP therapy benefit from the addition of an in-line humidifier. Additionally, newer CPAP machines have the option, with a physician's prescription, to add climate line tubing that delivers a consistent and comfortable temperature throughout the night, even as the room temperature and humidity levels change.

In addition to the above-mentioned factors, large leaks in the system can significantly increase flows and worsen the drying effect of these devices. Often such leaks originate from a poorly fitting patient interface. Consequently these problems can be remedied by ensuring a proper fit via repositioning the interface or switching to one of the many alternative masks or nasal pillows available today.

instruction in both equipment use and resuscitation, some of these infants may be discharged to the home with this equipment.[62]

Most apnea monitors detect both respirations and heart rate and activate audio and visual alarms when preset high or low limits are reached. Follow-up visits by the RT are usually frequent at first but occur less often as the family becomes skilled with use of the equipment and the monitoring routine. Some models record each alarm event and can be useful in monitoring the patient's progress. The "memory" of such monitors can be monitored continuously via an internet connection or via periodic downloading. Apnea monitors are usually discontinued after an infant has a negative pneumocardiogram (sleep study) or when recorded memory reveals no events during a prescribed time frame—often 2 to 4 months from the initial setup.[62]

PATIENT ASSESSMENT AND DOCUMENTATION

Alternative care sites demand extensive patient assessment and documentation. These requirements are based on both stringent reimbursement criteria and the rehabilitation orientation characterizing these settings.

Institutional Long-Term Care

In institutions providing long-term care, the assessment and documentation process involves four key components: screening, treatment planning, ongoing assessment, and discharge (Fig. 57.5).

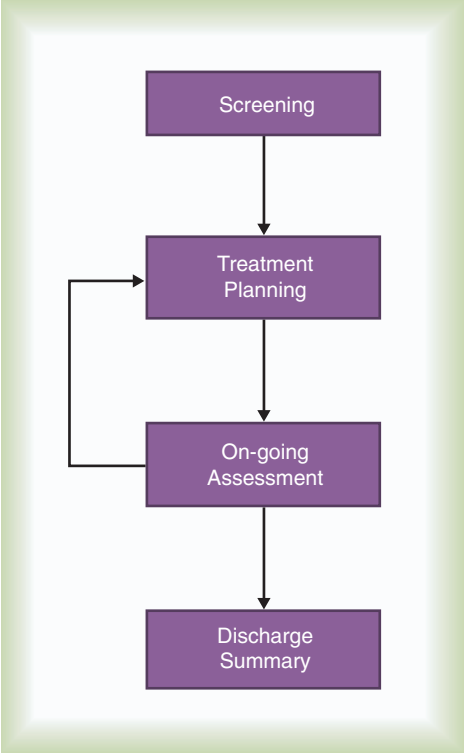

Fig. 57.5 The assessment and documentation process in institutional subacute or long-term care.

Screening

On admission to a long-term care facility, all patients with a respiratory-related admitting diagnosis should be screened by an RT. This screening is often accomplished mainly by a medical record review. During screening, the RT reviews the pertinent respiratory diagnosis, onset and severity of symptoms, current radiograph results, pulmonary function tests, arterial blood gas values, and other nonrespiratory treatment orders (e.g., physical therapy).

If the review indicates the need for a more in-depth assessment, the RT can recommend a more complete evaluation. On receipt of the appropriate orders, the RT interviews the patient and conducts a physical assessment, including inspection, palpation, auscultation, and percussion. Key clinical findings include description of breath sounds; rate, depth, and pattern of respirations; heart rate; signs of dyspnea; cough; sputum production; level of consciousness; and ability of the resident to understand and follow commands. Also noteworthy are the resident's prior respiratory status, use of supplemental O_2, pulse oximetry, skin turgor, and medications.

Treatment Planning and Ongoing Assessment

Based on the information obtained during the initial screening process, the RT and often other members of the patient care team design a specific treatment plan. A typical treatment plan includes patient demographics, assessment information, short-term and long-term goals reflective of overall rehabilitation potential, and measures to be used to achieve such goals. A treatment plan for the resident of a long-term care facility with moderate to severe COPD would likely reflect the treatment goal of correcting hypoxemia through the use of low-flow O_2 and patient monitoring.

After therapy has been initiated, the RT uses several other tools to monitor a patient's progress. In addition to regular treatment documentation, the RT should document a regular summary on each patient. This summary provides a synopsis of progress toward goal attainment, including changes in respiratory status, results of any additional tests, explanation of any patient education, and recommendations for additional therapy. Additionally, treatment plans and progress summaries become part of the resident's permanent record and are often required documentation for third-party reimbursement.

Discharge Summary

When a patient reaches his or her maximum potential, has attained all set goals, or is discharged, the RT should complete a discharge summary. The discharge summary describes the complete course of respiratory therapy, including its success or failure.

Home-Care Plan

A home-care plan must specify not only the types of care provided but also a strategy for patient follow-up. The individual making the follow-up visits is often the visiting nurse, a physical therapist, or an RT. For patients receiving respiratory care at home, follow-up by a home-care team member should occur regularly, particularly for patients on "hi-tech" equipment such as ventilators. Some patients may require more frequent follow-up, especially patients recently discharged or patients requiring

ventilatory support. Factors relevant to the frequency of home visits include the following:

- Patient's condition and therapeutic needs (objectives)
- High risk for hospital readmission
- Level of family or caregiver support available
- Type and complexity of home-care equipment
- Overall home environment
- Ability of the patient to provide self-care
- Third-party reimbursement for such visits

When a visit is made by the RT, numerous functions must be performed, including the following:

- Patient assessment (objective/subjective data and pretreatment/posttreatment data)
- Patient's compliance with prescribed respiratory home care
- Equipment assessment (operation, cleanliness, and need for related supplies)
- Identification of any problem areas or patient concerns
- Statement related to patient goals and therapeutic plan

A standard written report, consistent with the care plan, should be completed by the visiting RT. Copies are often sent to the patient's physician, the nursing agency, the home-care referral source, and any other member of the patient care team requiring this information. The report should become part of the patient's medical record and should be referred to when the patient's course and overall progress is being followed.

EQUIPMENT DISINFECTION AND MAINTENANCE

With many patients receiving respiratory care outside the hospital, the danger of infection caused by direct contact with caregivers and visitors or indirect contact with contaminated articles has grown. To help minimize home-related infection, guidelines for disinfecting home respiratory care equipment have been established. Accepted infection control techniques are based on clinical evidence, such as the evidence outlined in several of the AARC Clinical Practice Guidelines.

Collectively, these guidelines focus on sources of infection, basic principles of infection control, patients at high risk, disinfection methods, equipment processing, and care of solutions and medications. Procedures focus significantly on surveillance, prevention, and control of infection.

In regard to infection control, all guidelines and procedures mandate proper hand hygiene techniques by all caregivers—proper handwashing and use of antiseptic hand lotions. In addition, visits to the patient by friends or relatives with respiratory infections are discouraged. Relating to medical equipment suppliers, the guidelines suggest that all permanent equipment (e.g., ventilator circuits, O_2 delivery equipment, and aerosol systems) be sterilized or receive high-level disinfection before being supplied to another patient. Disposable or single-patient use equipment must be used by one patient only. It is recommended that all equipment be completely disassembled and washed first in water, followed by a soak in warm soapy water for several minutes, with equipment scrubbed as needed to remove any remaining organic material. Following this step, the equipment must be thoroughly rinsed to remove any residual soap and drained of excess water. Air drying on a clean surface or rack is recommended to minimize recontamination.

Additionally, the broad bactericidal activity exhibited by many premanufactured disinfectant solutions makes them the first choice. Other disinfection solutions to be considered include a 1:50 dilution of 5.25% to 6.15% sodium hypochlorite (household bleach) with water for a minimum of 3 minutes.

Regarding the use of water for humidification or nebulization, it is recommended that distilled water be used as a first choice. It is recommended that manufacturers' guidelines for the proper handling of specific medications be strictly followed. Detailed instructions for patients and caregivers on how to clean and disinfect selected respiratory care equipment are generally available from most manufacturers.[63,64]

SUMMARY CHECKLIST

- An increasing number of health services are being provided in alternative care settings.
- Subacute care aims achieve the highest level of patient functioning—ideally self-care.
- Standards for subacute and home health care derive from federal and state laws and private-sector accreditation, mainly TJC.
- Acute and alternative care settings differ in regard to resource availability, supervision and work schedules, documentation and assessment, and professional–patient interaction.
- Effective discharge planning (1) guides the multidisciplinary team in transferring patients to alternative sites of care and (2) ensures the safety and efficacy of the patient's continuing care.
- Alternative site caregivers must have all the competencies required to meet the patient's ventilatory and respiratory needs and provide adequate 24-hour coverage. The selected site must also be safe and suitable for the patient's specific condition.
- O_2 prescriptions for patients in alternative settings must be based on a documented diagnosis, including hypoxemia, as determined by either blood gas analysis or oximetry.
- In most alternative care sites, O_2 is normally most often supplied by concentrators with gaseous cylinders as backup and for portability.
- Most patients in alternative care settings needing O_2 use a nasal cannula; conserving devices such as portable oxygen concentrators and demand-flow O_2 systems can decrease O_2 use and costs and provide greater patient mobility.
- Because problems with long-term O_2 therapy include issues involving both people and equipment, caregivers should be allowed to operate and maintain O_2 delivery devices only after they have been properly instructed by credentialed RTs.
- Key factors needed for successful ventilatory support in alternative sites include (1) careful patient selection, (2) effective discharge planning, (3) an interdisciplinary team approach, (4) effective caregiver and family education, (5) thorough assessment and preparation of the environment, and (6) careful selection of needed equipment and supplies.
- Patients being considered for ventilatory support in alternative settings must be medically and psychologically stable.

- Most patients requiring mechanical ventilation in alternative settings can be supported with NIV if they are alert and cooperative, can maintain acceptable oxygenation without high FiO_2, and have intact airway reflexes and adequate clearance mechanisms.
- Positive-pressure ventilators used in alternative settings should be electrically powered, easy to operate, and portable (run on both AC and DC power). Loss-of-power alarms are essential, high-pressure alarms are needed on volume-cycled ventilators, and patient-disconnect (low-pressure) alarms should be provided.
- A typical nocturnal CPAP system consists of a flow generator or blower, tubing, humidification system, and nasal or full-face mask; some units can increase pressure to the prescribed level over time (ramping); others can autoadjust the CPAP level in response to apnea, hypopnea, airflow limitation, or snoring.
- The proper CPAP level can be determined by polysomnography, continuous monitoring of hemoglobin saturation, or an auto-CPAP system.
- A common problem with nocturnal CPAP systems is the inability to reach or maintain the set pressure, usually because of either inadequate flow or system leaks.
- Remote monitoring is beneficial in providing quick intervention for CPAP patients who are struggling with their therapy.
- Proper caregiver hand hygiene, limiting visits by persons with respiratory infections, providing sterile or disposable clean equipment, and proper equipment processing are the keys to infection control in such settings.

Ethics and the End of Life

Ellen M. Robinson, Frederic Romain, and M. Cornelia Cremens

CHAPTER OBJECTIVES

After reading this chapter you will be able to:

- Describe the elements of the "goals-of-care framework" and state the advantages of its use in contributing to the care of seriously ill patients approaching the end of life
- Describe the ethical and legal significance of the "right to refuse life-sustaining treatment" and how it is applied in the care of seriously ill patients at the end of life
- Articulate the importance and contribution to care of clinicians taking the time to know the patient as person rather than only as a patient
- Discuss the legal and ethical approaches to end-of-life care, including the merits of the concepts of euthanasia, physician-assisted suicide, withdrawing and withholding life-sustaining treatment, and palliative sedation while also considering the distinctions between these concepts
- Describe an ethically defensible approach to the management of pain and other symptoms at the end of life in the setting of withdrawing life-sustaining treatment
- Describe and apply the rule of double effect to a clinical case
- Describe the role of the respiratory therapist as a contributing professional on an interdisciplinary team

CHAPTER OUTLINE

KEY TERMS

advance directive
assisted suicide
best interests
cardiopulmonary resuscitation
ethics consultation
euthanasia
goals of care
health care agent or durable power of attorney for health care
interdisciplinary team
life-sustaining treatment
palliative sedation
prognosis
rule of double effect
substituted judgment
values, beliefs, and preferences
withholding and withdrawing life-sustaining treatment

INTRODUCTION

Advances in life-sustaining medical technology abound, contributing to cures for desperately ill patients with a host of diseases. The field of solid organ and hematologic transplantation has progressed, providing tremendous benefit in both the extension of life and its quality to patients with oncologic diagnoses.[1] Dialysis as a **life-sustaining treatment (LST)** is now available in many forms and at various access points, even for the most critically ill patients, in the form of continuous venovenous hemofiltration (CVVH).[2] Extracorporeal membranous oxygenation (ECMO), once a therapy used only for premature infants, is now available in quaternary care centers for patients with acute cardiac, respiratory, or cardiopulmonary failure as a life-saving therapy. That is, patients with cardiopulmonary collapse, who would have died in the past, can now be offered a lifesaving treatment.[3] This is an incomplete description of the available LSTs, but it presents a snapshot of the latest advances and shows

that seriously ill patients can often have opportunities for cure or the palliation of their disease even if they are returned to a reduced yet acceptable quality of life.

Whenever a patient is seriously ill, "airway and respiration" are of prime concern. Whether the patient is being monitored for threats to the airway and oxygen exchange, receiving advanced respiratory interventions (e.g., nasotracheal suctioning), biphasic positive airway pressure (BIPAP) or other assistive respiratory therapies, being ventilated mechanically, or even receiving ECMO, the respiratory therapist (RT) plays a key role in the patient's care. Although the ability to breathe easily is taken for granted by those who are well, that is not the case for patients whose respiratory status is under threat for any length of time. In such a situation, the respiratory system is arguably the body system that the patient experiences most acutely and chronically, with a sense of anxiety regarding his or her well-being and life itself. When the patient cannot recover and is approaching the end of life, the RT plays his or her professional role by responding with competence, compassion, and knowledge of ethical practice. *To this end, the purpose of this chapter is to educate the RT regarding the key background tenets of ethical practice at the end of life as well as sound ethical approaches and considerations in the care of such patients. The RT plays a key role on the health care team, contributing a body of expertise that is unique and essential to high-quality, compassionate, and ethical patient care.*

"GOALS OF CARE" AS AN ESSENTIAL ORGANIZING FRAMEWORK

As a member of the health care team, the RT should be cognizant of the **"goals of care"** for the patient as an organizing framework in approaching a seriously ill patient's overall care. Developing goals of care requires physician leadership, including input from medical and surgical physician consultants. In addition, nurses and allied health professionals offer important contributions. RTs as allied health professionals are key in bringing forward their assessment, intervention, and the patient's response to the formulation of goals of care. "Breathing," or "taking a breath," is likely the most critical of all physiologic processes that non-comatose patients can directly experience. When a patient's breathing is compromised, his or her perception of this difficulty and its physiologic impact can cause immense distress and anxiety.

The goals-of-care framework has three components:

- The patient's medical and rehabilitative **prognosis**
- The patient's **values, beliefs, and preferences**
- Ethically and legally permissible care options

These three components provide a framework for formulating the goals of a patient's care. Attention to each component allows for a formalized approach to decision making and intervention in a patient's care as opposed to a haphazard based on momentary reactions. RTs play a significant role in this process, given their expertise in assessing and managing a patient's airway and overall oxygenation and observing the patient's response to respiratory interventions. Thus the presence and perspective of the RT on the health care team is essential to formulating goals of care that can become part of a clinically and ethically appropriate plan of care.

RULE OF THUMB A goals-of-care framework can direct purposeful versus haphazard care to seriously ill patients. This framework includes establishing the patient's medical and rehabilitative prognosis; learning the patient's values, beliefs and preferences; and considering the approaches that are ethically and legally permissible.

Medical Prognosis and Rehabilitative Prognosis

The concept of "medical prognosis" in patient care is primary and integral in addressing goals of care for a patient. Medical prognosis is defined by Merriam Webster (https://www.merriam-webster.com/dictionary/prognosis) as the "prospect of recovery as anticipated from the usual course of disease or the peculiarities of the case." In an age of advanced medical-surgical life-sustaining treatment, it is more critical than ever to address the question of medical prognosis on a regular basis within medical and interprofessional teams and with patients and families. An intentional examination of the patient's medical prognosis is the first step in a process of determining the goals of a patient's care. The following questions should be posed by or to the responsible physician:

- What is medically possible for the patient?
- Can the opinions of medical and surgical consultants be brought to bear on the "whole"?
- What is the rehabilitation potential for the patient?
- Are LSTs effective or likely to be effective in restoring the patient's functional status or at least restoring the patient to a reduced yet acceptable functional status and quality of life?

In American health care today, it increasingly seems that only the very ill are hospitalized, with multiple specialties and health professional roles involved in their care. Although the establishment of medical prognosis rests squarely within the domain of the responsible physician, it is imperative that all physicians avail themselves of disciplinary input from medical specialties, highly skilled nurses, and allied health professionals, including RTs, rehabilitation professionals, occupational therapists, physical therapists, speech-language therapists, nutrition specialists, social workers, and chaplains to gain a full picture of a given patient's response to medical/surgical interventions. Families of patients often look to the physician during a family member's prolonged illness and hospital stay for guidance about whether their loved one can get better. Speaking strictly about the "medical prognosis" without accommodating the patient's ability to rehabilitate can fall short for families, who are almost always thinking about whether their loved one can return to an acceptable level of function. Considering a patient's projected functional status as an important adjunct to medical prognosis requires the input of rehabilitation professionals whose expertise lends critical data to the patient's problems. This includes the discipline of respiratory therapy. In this way, the establishment of medical prognosis can reflect not only the patient's pathophysiology as determined by the medical examination, diagnostic tests and response to medical interventions but also how the patient is then able to function. Thus it is essential for the **interdisciplinary team** of nurses, RTs, and other allied health professionals to create a more holistic picture of what is possible for the patient.

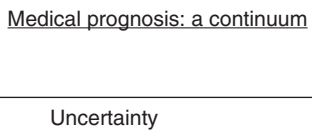

Fig. 58.1 Visual depiction of consideration of medical prognosis. (Courtesy Ellen M. Robinson.)

A patient with a primary respiratory disease process alone as well as patients with respiratory disease along with other body system disease processes may be of concern for the RT's assessment, intervention, and evaluation. It is critical for the RT to understand and appreciate the patient's patient response to intervention as well as his or her pathophysiology, medical and surgical treatment, and nursing and rehabilitation needs. All of these considerations can provide the RT with insight into the full context of the patient's medical problems. Most patients who have life-threatening conditions will have a respiratory component that requires the close attention of an RT.

Honest, transparent assessments for establishing prognosis are the responsibility of the medical and surgical physician staff, who must reevaluate the patient on a regular basis. Medical prognosis can be thought of on a continuum (Fig. 58.1), with clarity at each end: expectation of a clear recovery versus imminent death. Under such circumstances, the collective direction of care in a particular patient's case is generally evident and health professionals, physicians, and families are in agreement.

Uncertainty in medical prognosis is challenging for all involved. Time is needed to ascertain progress and setbacks, to allow interventions to take hold, and to allow the patient to declare himself or herself in a direction of recovery versus the end of life. The RT's input to team discussions is critical in all areas of prognostication, as such a specialist is an expert in airway management as well as ventilator and oxygen therapies and can speak to a patient's response to interventions in terms of benefit or burden.

The input of the RT is both objective and subjective. Objectively, the RT can report on indices that measure oxygenation, tidal volume, airway resistance, secretion management, the patient's passive or active participation, and his or her ability to cough among other important data points. Subjectively, the RT hears directly from the patient, as does the nurse, regarding pain, shortness of breath (SOB), dyspnea, and his or her overall willingness and ability to participate in interventions that are aimed at the restoration of health. The RT assesses, monitors, and responds to diseases and other issues affecting the respiratory system, the most basic functional component of human life. Thus it is critically important that RTs contribute to discussions about patient prognosis. Team huddles and meetings are vehicles designed to impart the RT's assessment and evaluation; however, if such meetings are not possible, the RT has a professional and ethical obligation to impart his disciplinary contribution—both verbally and through excellent documentation—directly to the nurses and physicians caring for the patient.

In cases where the respiratory system is failing and the patient's movement toward recovery or death is directly contingent on how he or she responds to therapy, the RT may play a critical role in team-family meetings. We recall the input of an RT into a team-family meeting when a patient suffered from unrelenting respiratory failure secondary to advanced lung cancer and was unable to be weaned from mechanical ventilation. The family insisted that the patient could be "taught" to breathe again and could "practice" doing so. The RT who was present at the team-family meeting provided a concise and compassionate explanation to the family about the innate drive to breathe, and that persons will instinctively breathe without coaching when they are able to do so. This description gave the family some sudden clarity and led to their understanding that their loved one would not be able to recover.

The practice of observing, listening, discussing, reflecting as a team and together with family can yield insights that contribute to an overall prognostic assessment from both a medical and rehabilitative perspective. Each patient's case is an ongoing narrative, particularly when the prognosis is uncertain.

RULE OF THUMB The patient's medical prognosis is a key piece of information for clinicians to consider in a goals-of-care framework. When a given patient's medical prognosis is being considered, it is also important to think about his or her potential for rehabilitation. Families are concerned mainly with their relative's potential to return to function.

Values, Beliefs, and Preferences

An "ethic of care"[4–6] is one approach that can guide ethical decision making; examples include concepts such as deontology, utilitarianism, principles, rights, virtues, and narrative ethics (see Chapter 5). An ethic of care is invoked as a framework to complement principle-based ethics, recognizing that principles provide a time-honored structure for analyzing difficult ethical problems.[7] In a goals-of-care framework, an ethic of care is made tangible by considering particulars, context, and relationships.

Particulars

It is important for all health professionals who participate in a patient's care to speak to the question, "Who is this person (and family)?" The attending physician, resident staff, and medical/surgical consultants assess and diagnose the patient's medical condition, whereas nurses assess the patient's responses using the 11 functional health patterns described by Gordon (Box 58.1).[8] Social workers assess the psychosocial domains of the patient and family, chaplains the patient's spiritual needs and priorities, rehabilitation therapists the cognitive-functional domains, nutrition specialists the patient's nutritional and metabolic needs, and RTs the patient's primary system of "respiration." All of the team members contribute vital information regarding their assessments of the patient's overall status. Regarding values, beliefs, and preferences, RTs attend to the patient's response to underlying breathing problems and respiratory therapies. The patient's ability to tolerate symptoms can often provide a window into his or her preferences. Thus it is important to consider the patient's responses within the "values, beliefs, and preferences" component of a goals-of-care framework. Questions seeking responses either directly from the patient or from his or her surrogate decision maker in building the goals-of-care framework are as follows:

BOX 58.1 Gordon's Functional Categories for the Assessment of Health Patterns

- Health perception and management
- Nutritional and metabolic issues
- Elimination
- Activity and exercise
- Sleep and rest
- Cognitive/perceptual issues
- Self-perception and self-concept
- Role relationships
- Sexuality/reproductive issues
- Coping and stress tolerance
- Values and beliefs

These issues, with input from all disciplines, are to be considered in the nursing assessment seeking to answer the question, "Who is this person living with this disease?"

Adapted from Gordon M: *Manual of nursing diagnoses*, Sudbury, MA, 2010, Jones & Bartlett Publishers.

- Who is this person (and family)?
- What is important to her/him/them?
- What would a "good day" look like for the patient and family?
- What would "intolerable days" be like for the patient?
- Quality of life—can it be projected for the patient?
- What religious, spiritual, and cultural beliefs influence end-of-life decision making?

Often a patient will come into an emergency department (ED) and then be urgently admitted to an intensive care unit (ICU), but he or she may be lacking in decision-making capacity. Under such circumstances, physicians, nurses, and health professionals seek to identify a surrogate decision maker, preferably an appointed health care agent (HCA) noted through a health care proxy or durable power of attorney for health care document or, in some cases, a legal guardian. In most states, when a power of attorney for health care does not exist or legal guardian has not been appointed, clinical teams will turn to family members. In some but not all states, a "rank order" of family members as decision makers is written into the state statute. (https://www.americanbar.org/content/dam/aba/administrative/law_aging/2014_default_surrogate_consent_statutes.authcheckdam.pdf)

Families at Massachusetts General Hospital are invited to complete a "Get to Know Me" poster (Fig. 58.2) for their loved ones who are unable to communicate. This can help familiarize clinicians with the patient, what she or he enjoyed doing, who were his or her family and friends, and also favorite movies, books, and other information of interest describing the patient. Photographs of the patient are also included on the poster. Information on this poster alone would be an insufficient contribution to the values, beliefs, and preferences component; however, it can provide bedside clinicians, including RTs, with a sense of the person who is now a critically ill patient. For the family of such a patient who is unable to communicate, hearing statements from a professional caregiver that signify familiarity with "patient as person" can be comforting. RTs who manage the patient's most vital body system, respiration, can make the patient feel safe and at ease while contributing to the decisions being made daily by the medical team.

MINI CLINI

Problem: Consider the Case of Mrs. Lake and the Concept of "Context"

Mrs. Lake, age 63, who had a recurrent glioblastoma, was raising her 12-year-old grandson. The neurology team asked for an ethics consult because Mrs. Lake was requesting or demanding additional chemotherapy, which was not indicated given her advanced disease and poor functional status. Mrs. Lake refused to assent to DNR/DNI, interventions that her physicians and the team recommended. The ethics consultant learned that Mr. and Mrs. Lake's daughter had died in a motor vehicle accident (MVA) 10 years earlier and that they had been caring for their grandson ever since. The boy loved his grandparents and was thriving in their care. One can understand how desperate Mrs. Lake and her spouse were, yet physicians and health professionals were caught in the ethical bind of wanting to protect her from harm while not breaking her spirit of self-determination. The patient was very ill, and her respiratory status was tenuous. The RT, nurse, and physicians were unsure in how to proceed.

Discussion

An urgent team meeting with a neurologist, nurses, the RT, social work, chaplaincy, and ethics consultant was held to explore approaches to the patient. It was agreed that the neurologist, nurse, RT, and social worker should meet with the patient and her spouse to compassionately explain the clinical situation and explore the best alternatives. Mrs. Lake was teary, as was her spouse, but they agreed to DNR/DNI and expressed understanding that additional chemotherapy would not be helpful. Mrs. Lake died peacefully 2 days later, at the hospital, in the presence of her spouse and grandson. In summary, the context of this patient's life and advanced disease, when understood, provided an opening for clinicians to intervene.

Context

Considering the patient's overall context as a dimension of an ethic of care can yield insight for health professionals at the end of life, and RTs, given their area of concern, must be actively involved. Where does this patient find herself or himself at this time—what is immediately confronting the patient in terms of utmost concern? What led the patient to this disease process, hospitalization, and now end-of-life situation? How is the patient responding to all of it? How is the family responding? What is the patient primarily concerned about at this time, either expressed or unexpressed? How are the patient's immediate concerns affecting the airway and the experience of respiration? To intervene appropriately and with compassion, health professionals and RTs must consider the context from which the patient comes and what is directly being experienced in order to understand patients and their concerns.

Relationships

Although the principles of biomedical ethics, specifically autonomy, represent ethical ideals, the reality is that almost all persons, particularly when ill and at the end of life, look to the relationships that are important in their lives. Otherwise, if they are not able to engage, their destiny may be affected by the relationships that they had with others in earlier times. Being bound in, enriched by, and sometimes injured by relationships is opposed to self-determination in isolation with "relational autonomy."[9,10] Patients may have significant family and friends that they care about and that care about them. It is important for health professionals to

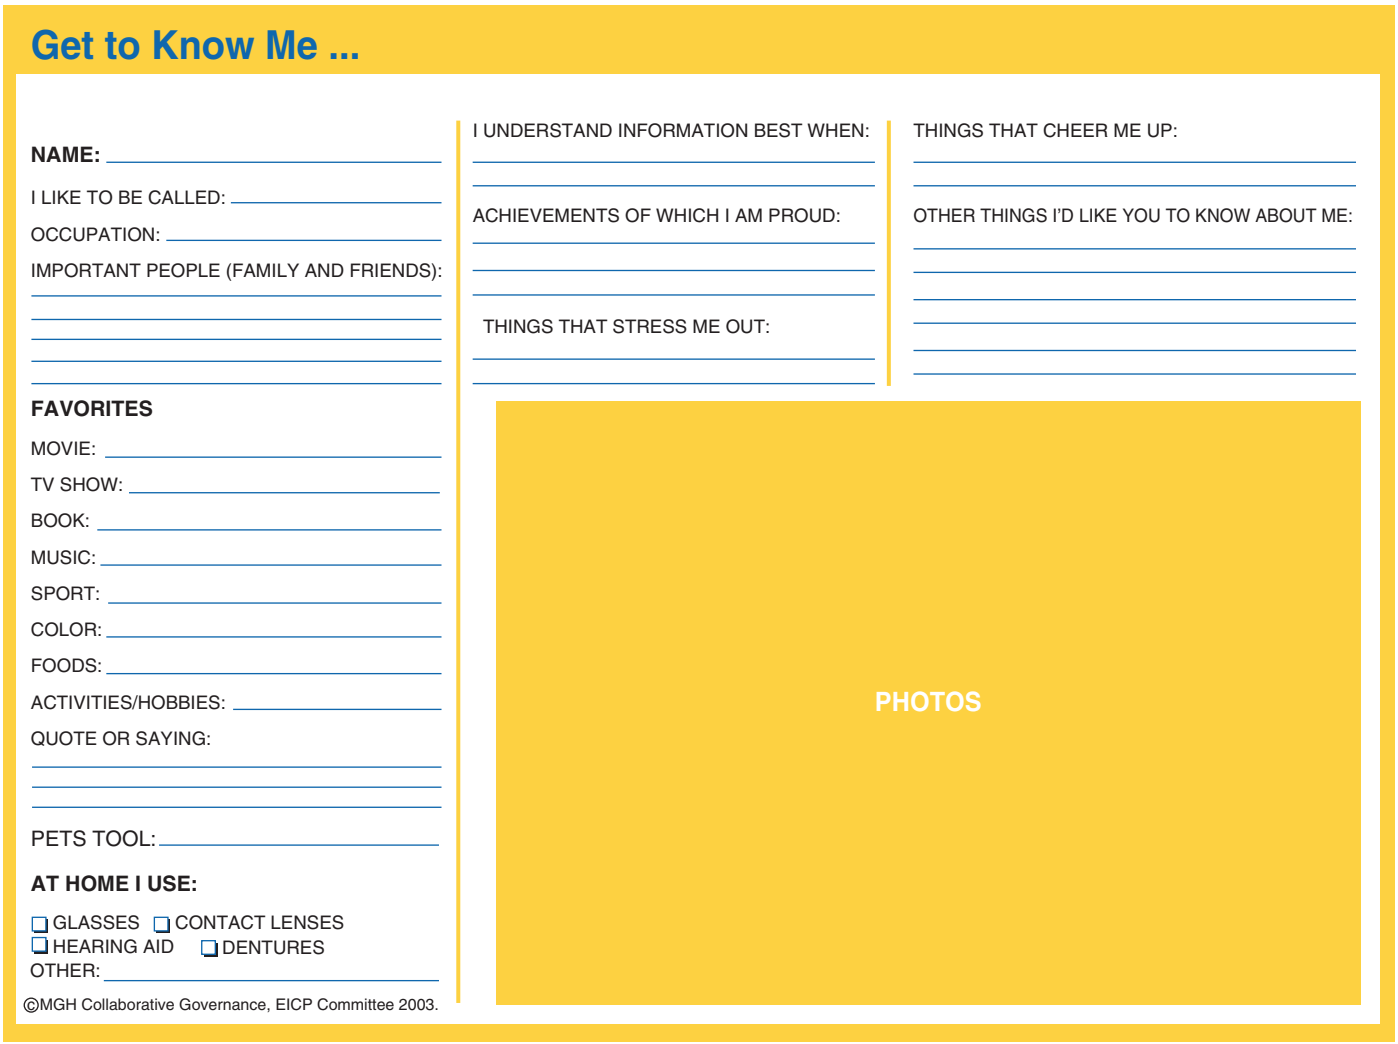

Fig. 58.2 "Get to Know Me" Poster. (Courtesy Ellen M. Robinson.)

recognize that significant family and friends may be in conflict with the patient but are still important to him or her. When health care professionals, including RTs, recognize this reality of the human condition, they can assist in working effectively with family as defined by the patient on behalf of the patient. Hopefully, in most situations, a patient's relationships can flourish even during a difficult time, serving the patient's **best interest.** There are times when relationships that are significant to the patient may not contribute to the patient's best interest and overall well-being or may authentically represent the patient's voice through "**substituted judgment,**" where the patient still loves and values these persons.

RULE OF THUMB The patient's values, beliefs, and preferences near the end of life care can be systematically uncovered in seeking to answer the question: Who is this person living with this disease? Aiming to know the patient's earlier context as well as learning about relationships that are important to the patient can also aid in this interdisciplinary assessment process.

Ethical and Legal Parameters

Refusal of Life-Sustaining Treatment

It is critical for tRTs to know what is ethically and legally permissible in the United States and their state of practice related to end-of-life care. Decision making around LST and respiratory therapies for critically ill patients is a fast-moving process that has immediate implications for the patient's life or death. As licensed health care professionals, RTs are the recipients of physician orders to be carried out on the patient's behalf; however, the RT must be aware of the ethical and legal appropriateness of a physician's orders in general as well as in terms of the specific patient case. The RT is ethically and professionally bound to question any orders that are not congruent with acceptable ethical and legal practices as well as hospital policy, which should be in synchrony with sound ethical and legal practices. One's intuition in difficult circumstances, along with a sound knowledge base, should be trusted and can lead to "speaking up" for the patient's benefit. Familiarity with hospital LST policies as well as consulting with colleagues or the RT supervisor are suggested

MINI CLINI

Problems: Complexities of Lifelong Relationships at the End of Life

The case of Mrs. Smith, an elderly woman, and Marilyn, her adult daughter, serves as an example of the complexities of lifelong relationships at the end of life. Marilyn—one of four adult children, three of whom were estranged—cared for her mother for many years. Mrs. Smith's advance directive stated her wishes against medically supplied nutrition and hydration. She had expressive aphasia due to an old stroke, was in the final weeks of life, and was refusing oral feedings. Her daughter insisted on "force feeding her," and Mrs. Smith was aspirating. Marilyn was angry and emotional, realizing that her mother was dying.

Discussion

When Marilyn left the room for a short break, the nurse said to Mrs. Smith, "I think you are both embarrassed by Marilyn's behavior, and also worried about Marilyn; please do not worry, as we understand and will take care of her." Mrs. Smith's eyes filled with tears, which streamed down her face. The nurse demonstrated to Mrs. Smith her realization that regardless of Marilyn's difficulty in accepting her mother's wishes, she knew that Mrs. Smith still loved Marilyn; it was a difficult yet important relationship that they shared. Recognition by a health care professional of this human dynamic can serve patients in protecting them from harm while also preserving family relationships at the end of life.[11]

resources, enabling the RT to talk through uncertainties and approaches in difficult situations.

A right to refuse LST exists in the United States, and this right is considered to be a bedrock of American law and ethics.[12,13] Prior to the 1960s and 1970s, medical and surgical interventions could bring a desperately ill patient only so far in terms of recovery, and death would come when the best therapies of the time were not effective. As medical technology advanced, LSTs became available to stave off death, with the intention of allowing a desperately ill patient to heal and recover. Although these can be lifesaving in many regards, there were also situations where patients would languish on life support with no hope of recovery. When LST was initiated, it was, and still often is, unclear which patients would benefit and which would merely be burdened by the treatment, with no benefit. During the early days of these LSTs, including mechanical ventilators, physicians were concerned that if the LST were terminated, it would be tantamount to murder.[14] It was often the families who requested that the LST be removed, realizing over time that their loved one was not recovering. Such was one of the major factors leading to the laws that established the legal right to refuse LST.

Several court cases initiated by family members ensued between the 1970s and 1990s, leading to the "right to refuse LST."[12,13] Themes that then emerged made explicit the parameters around refusal of LST; these are presented in Box 58.2. The case of Nancy Cruzan[15] led to the establishment of the Patient Self-Determination Act (PSDA) and the Omnibus Reconciliation Act.[16] These were the final bookend to this period of change in health law and ethics, which clearly and unequivocally established the right to refuse LST. The PSDA provides a statutory mechanism for patients to sign **advance directives** allowing their voices to be heard when they no longer have capacity to make health

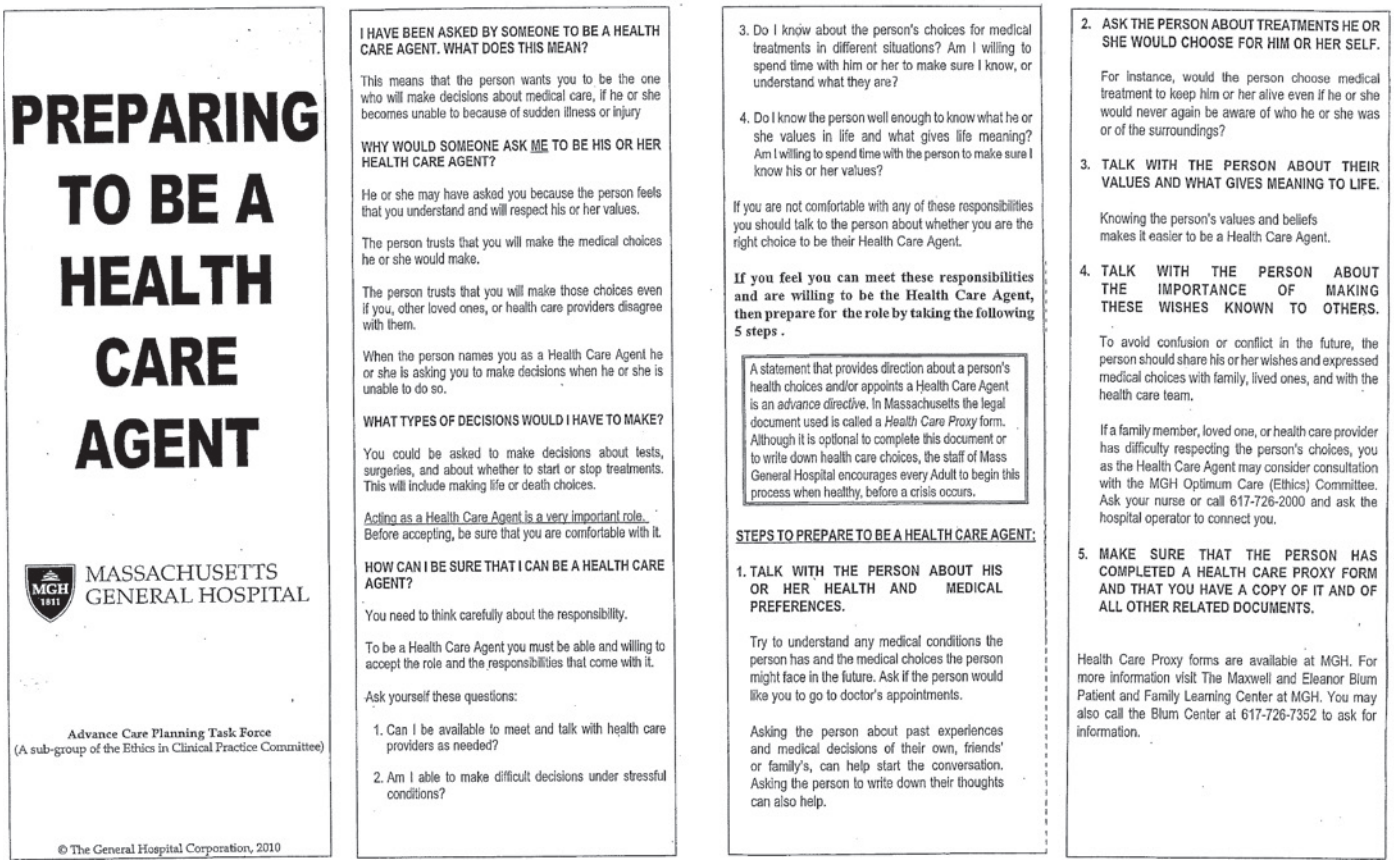
BOX 58.2 Ethics and Law at the End of Life: What Is Permissible?

- In the United States, patients have the right to refuse life-sustaining treatment.
- This right extends to the competent, once competent, and never competent person.
- The type of treatment is not determinative: analysis is necessary in terms of the benefits and burdens of life-sustaining treatment to the patient.
- Withholding and withdrawing life sustaining treatment are ethically equivalent.
- Good palliative care is supported by the US Supreme Court.
- Advance directives provide a mechanism whereby the right to refuse life-sustaining treatment can be actualized.

Data from Emanuel EJ: A review of the ethical and legal aspects of terminating medical care. *Am J Med* 84:291–301, 1988 and Cantor N: Twenty-five years after Quinlan: a review of the jurisprudence of death and dying. *J Law Med Ethics* 29:182–196, 2001.

care decisions. Individual states have specific advance directive forms, such as the Massachusetts Health Care Proxy (https://malegislature.gov/Laws/GeneralLaws/PartII/TitleII/Chapter201D). But suffice it to say that all 50 states recognize the person's right to appoint an HCA. The PSDA requires health care systems that are receiving federal monies through the Centers for Medicare and Medicaid to ask all patients upon admission if they have an advance directive; if not, they must offer to assist patients with education, counseling, and forms to complete (https://www.cms.gov/Regulations-and-Guidance/Guidance/Transmittals/downloads/R75SOMA.pdf; 2011). A patient, of course, can refuse to complete an advance directive. Overall compliance with advance directives is generally only about 33%.[17]

The history of the case law culminating in the Nancy Cruzan case, leading to the creation of the PSDA, has cemented the right to refuse LST in the American health care system. With the opportunity to identify a legally recognized surrogate decision maker through state laws, designating **an HCA or durable power of attorney for health care** decisions, persons can use their agency to name a person to speak on their behalf if a time comes when the person can no longer speak on his or her own behalf. There will be times when a patient does not have an HCA available, and physicians and health professionals will turn to close family or friends. Some states have a "rank ordering" of position in the family to turn to in such situations, as previously stated.[18] Other states, such as Massachusetts, do not have a rank ordering and seek to identify close family members and domestic partners who seem committed to the patient's care. For patients who have never had capacity (profound intellectual disability), or who do not yet have capacity (such as children), health professionals turn to court-appointed guardians or parents to make health care decisions based on the best interest of the patient. Decision making by the "best interest standard" was specified in the President's Commission Report[19] to include consideration of relief of suffering, preservation or restoration of functioning and quality, as well as extent of life sustained. Thus the right to refuse LST extends to persons with full decision-making capacity or former decision-making capacity as well as those who have never had decision-making capacity.



PREPARING TO BE A HEALTH CARE AGENT

MASSACHUSETTS GENERAL HOSPITAL

Advance Care Planning Task Force
(A sub-group of the Ethics in Clinical Practice Committee)

I HAVE BEEN ASKED BY SOMEONE TO BE A HEALTH CARE AGENT. WHAT DOES THIS MEAN?

This means that the person wants you to be the one who will make decisions about medical care, if he or she becomes unable to because of sudden illness or injury

WHY WOULD SOMEONE ASK ME TO BE HIS OR HER HEALTH CARE AGENT?

He or she may have asked you because the person feels that you understand and will respect his or her values.

The person trusts that you will make the medical choices he or she would make.

The person trusts that you will make those choices even if you, other loved ones, or health care providers disagree with them.

When the person names you as a Health Care Agent he or she is asking you to make decisions when he or she is unable to do so.

WHAT TYPES OF DECISIONS WOULD I HAVE TO MAKE?

You could be asked to make decisions about tests, surgeries, and about whether to start or stop treatments. This will include making life or death choices.

Acting as a Health Care Agent is a very important role. Before accepting, be sure that you are comfortable with it.

HOW CAN I BE SURE THAT I CAN BE A HEALTH CARE AGENT?

You need to think carefully about the responsibility.

To be a Health Care Agent you must be able and willing to accept the role and the responsibilities that come with it.

Ask yourself these questions:

1. Can I be available to meet and talk with health care providers as needed?
2. Am I able to make difficult decisions under stressful conditions?
3. Do I know about the person's choices for medical treatments in different situations? Am I willing to spend time with him or her to make sure I know, or understand what they are?
4. Do I know the person well enough to know what he or she values in life and what gives life meaning? Am I willing to spend time with the person to make sure I know his or her values?

If you are not comfortable with any of these responsibilities you should talk to the person about whether you are the right choice to be their Health Care Agent.

If you feel you can meet these responsibilities and are willing to be the Health Care Agent, then prepare for the role by taking the following 5 steps .

A statement that provides direction about a person's health choices and/or appoints a Health Care Agent is an *advance directive*. In Massachusetts the legal document used is called a *Health Care Proxy* form. Although it is optional to complete this document or to write down health care choices, the staff of Mass General Hospital encourages every Adult to begin this process when healthy, before a crisis occurs.

STEPS TO PREPARE TO BE A HEALTH CARE AGENT:

1. TALK WITH THE PERSON ABOUT HIS OR HER HEALTH AND MEDICAL PREFERENCES.

   Try to understand any medical conditions the person has and the medical choices the person might face in the future. Ask if the person would like you to go to doctor's appointments.

   Asking the person about past experiences and medical decisions of their own, friends' or family's, can help start the conversation. Asking the person to write down their thoughts can also help.

2. ASK THE PERSON ABOUT TREATMENTS HE OR SHE WOULD CHOOSE FOR HIM OR HER SELF.

   For instance, would the person choose medical treatment to keep him or her alive even if he or she would never again be aware of who he or she was or of the surroundings?

3. TALK WITH THE PERSON ABOUT THEIR VALUES AND WHAT GIVES MEANING TO LIFE.

   Knowing the person's values and beliefs makes it easier to be a Health Care Agent.

4. TALK WITH THE PERSON ABOUT THE IMPORTANCE OF MAKING THESE WISHES KNOWN TO OTHERS.

   To avoid confusion or conflict in the future, the person should share his or her wishes and expressed medical choices with family, lived ones, and with the health care team.

   If a family member, loved one, or health care provider has difficulty respecting the person's choices, you as the Health Care Agent may consider consultation with the MGH Optimum Care (Ethics) Committee. Ask your nurse or call 617-726-2000 and ask the hospital operator to connect you.

5. MAKE SURE THAT THE PERSON HAS COMPLETED A HEALTH CARE PROXY FORM AND THAT YOU HAVE A COPY OF IT AND OF ALL OTHER RELATED DOCUMENTS.

Health Care Proxy forms are available at MGH. For more information visit The Maxwell and Eleanor Blum Patient and Family Learning Center at MGH. You may also call the Blum Center at 617-726-7352 to ask for information.

Fig. 58.3 "Preparing to Be A Health Care Agent" poster. (Courtesy Ellen M. Robinson.)

When a patient has an advance directive and is unable to speak on his or her own behalf, the responsible physician is required to "invoke" the advance directive through documentation in the patient's medical record, stating that the patient does not have decision-making capacity. The HCA for the patient is ethically bound to provide the patient's voice, through the standard of "substituted judgment," which answers the question, "What would the patient say if he or she could participate in this decision-making process on behalf of himself?" Whatever the patient has discussed with the HCA that can be brought to bear in such a medical situation.[20] Substituted judgment can be thought of on a continuum, with greater and lesser degrees of knowing a patient's wishes about a specific health/illness circumstance that can be known by the HCA. Research has demonstrated that there are challenges in the surrogate decision maker role, namely that surrogates will often not be able to predict a loved one's preferences accurately or enact the intent of the role in sharing the patient's wishes versus their own wishes for the patient.[21–23] Health professionals will often be in the position to instruct a HCA in this important obligation. Hospitals can provide information to guide the HCA. Massachusetts General Hospital has an educational tool that assists in this educational process (Fig. 58.3).

The type of LST is not determinative; rather, it is the right of the patient to refuse LST regardless of the treatment in question. Treatments are not ordinary or extraordinary across the board; the treatment is analyzed within the context of what is a benefit versus a burden to the patient. Numerous LSTs are available, and they have recently multiplied. The question of whether the LST can advance a patient toward his or her goals in light of the medical prognosis is the relevant question to ask.

Within the framework of the right to refuse LST, withholding and withdrawing LSTs are rendered as ethically and legally equivalent. The concept of "time-limited trials" is useful; a treatment can be trialed, and, if deemed to be ineffective, can be discontinued.[24] From a qualitative standpoint, clinicians and families may find withdrawing LSTs, particularly medically supplied nutrition and hydration, to be emotionally challenging. However, ethical and legal equivalence in both withholding and withdrawing life support exists as a steadfast principle.

RULE OF THUMB In the United States, it is legally and ethically permissible to refuse LSTs.[12,13]

Summary

The goals-of-care framework brings to bear attention to the patient's medical and rehabilitative prognosis, then combining it with the patient's values, beliefs, and preferences within the context of ethically and legally acceptable practice. The synthesis

of prognosis, values, beliefs, and preferences and that which is ethically and legally permissible can lead to setting "goals of care" that are personalized for the patient's overall situation. Once goals are established, a plan for the patient's care is devised. As the continuum of care can range from aiming toward cure to palliation and the end of life, goals and plans may be dynamic, as a patient's condition may fluctuate. The goals-of-care framework is valuable in that it leads to purposeful and appropriate care at any given time in the patient's trajectory.

RULE OF THUMB A goals-of-care framework brings to bear attention to the patient's medical and rehabilitative prognosis, values, beliefs, and preferences within the context of ethically and legally acceptable practice.

MANAGEMENT OF PAIN AND OTHER SYMPTOMS AT THE END OF LIFE: LEGAL AND ETHICAL CONSIDERATIONS

The provision of palliative and comfort-oriented care is also both ethically and legally permissible and ought to be provided to patients in their end-of-life time when goals of care define such a pathway. The RT can develop a sound understanding and ethically defensible practice of pain and symptom management at end of life after mastering a variety of concepts, some of which define an ethically/legally defensible practice and others that are not ethically or legally defensible. Understanding definitions and distinctions between **euthanasia**, **physician-assisted suicide (PAS)**, palliative and comfort-oriented care can guide the RT in the care of patients at the end of life (Box 58.3).[25] Developing an ethically and legally defensible position is quite relevant for the RT, given that the RT's professional craft is front and center relative to decisions related to the withdrawal of LSTs such as mechanical ventilation, BIPAP, high-flow oxygen, and ECMO. When such LSTs are withdrawn, medications are rightfully ordered to ensure the patient's comfort.

BOX 58.3 Definitions of End-of-Life Concepts

Euthanasia: The act of putting to death someone suffering from a painful or prolonged illness or injury. Someone other than the patient commits the action to end the patient's life, usually by the injection of medicine.

Assisted Suicide: The means to end a patient's life is provided to the patient with knowledge of the patient's intention to use it. Physician-assisted suicide connotes that a physician will provide such means.

Palliative Sedation: The controlled and monitored use of nonopioid medications intended to lower the patient's level of consciousness to the extend necessary for relief of awareness of refractory and unendurable symptoms.

Withholding, Withdrawing, and Refusal of Life-Sustaining Treatment: Life-sustaining treatments include but are not limited to mechanical ventilation, cardiopulmonary resuscitation, chemotherapy, dialysis, antibiotics, medically supplied nutrition, and hydration.

Palliative Care: An approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness through the prevention and relief of suffering by means of the early identification and careful assessment and treatment of pain and other problems, physical, psychosocial, and spiritual.

Hospice Care: Care of patients and families at the end of life and during the last few weeks or months of life that builds on the palliative care model to minimize suffering by providing appropriate symptom management and emotional support.

Physician-Assisted Suicide

PAS was introduced into professional discourse in American medicine through some published cases in the medical literature, including the case of Diane,[26] and an anonymous piece in the Journal of the American Medical Association.[27] In Diane's case, Dr. Timothy Quill provided his patient, who had terminal cancer, with a prescription for barbiturates sufficient to end her life when she believed it was time to do so, given her fear of suffering at the end. In the anonymous piece, a resident physician described his intentional act of overmedicating a 20-year-old female patient on the night shift, who was suffering profoundly with the pain and symptoms associated with advanced gynecologic cancer. The anonymous case, arguably, could be categorized as euthanasia. The unendorsed and illegal practices of Jack Kevorkian also raised public attention to this debate; Kevorkian was ultimately arrested and convicted.[28] Thus when the US Supreme Court heard two state cases, *Vacco v. Quill*[29] and *Washington v. Glucksberg*,[30] many wondered if the court would come out in favor of "a constitutional right to die" through PAS. The court in fact did not support a constitutional right to PAS; however, it did, in an opinion authored by Justice Sandra Day O'Connor in 1997, articulate clear support for palliative care:

> *Patients near death have a right to avoid great suffering. No state laws should exist to prevent a patient who is experiencing pain from obtaining medications from qualified physicians to alleviate their suffering, even to the point of causing unconsciousness and hastening death.*
>
> ***Justice Sandra Day O'Connor (1997)***

It was stated in court opinion that the idea and practices of PAS should return to the states. In fact, as of early 2019, states that have legalized PAS include Oregon (1994), Washington (2008), Montana (2009), Vermont (2013), the District of Columbia (2016), Colorado (2016), California (2015), and Hawaii (2018). Oregon was the first state to legalize the practice, setting the model for eligibility criteria and restrictions on the practice to which other states have largely adhered (Box 58.4). Those persons who meet the criteria and request PAS may use the medication provided, and almost all patients, users or not, die under traditional hospice care.[31] Primary reasons for requesting PAS are generally not the fear of poorly managed pain; rather, it is the fear of loss of autonomy and dignity, inability to participate in the activities that made life enjoyable, existential suffering, and the unwillingness to become a burden to others.[31–34]

BOX 58.4 Requirements of the Death With Dignity Act[a]

The Death with Dignity Act (DWDA) allows terminally ill residents of Oregon to obtain and use prescriptions from their physicians for self-administered lethal medications.

Under the act, ending one's life in accordance with the law does not constitute suicide. The DWDA specifically prohibits euthanasia, where a physician or some other person directly administers a medication to end another's life.

To request a prescription for lethal medications, the DWDA requires that a patient must be

- An adult (18 years of age or older)
- A resident of Oregon
- Capable (defined as able to make and communicate health care decisions)
- Diagnosed with a terminal illness that would lead to death within 6 months

Patients meeting these requirements are eligible to request a prescription for lethal medication from a licensed Oregon physician. To receive a prescription for lethal medication, the following steps must be fulfilled:

- The patient must make two oral requests, separated by at least 15 days, to his or her physician.
- The patient must provide to his or her physician a written request signed in the presence of two witnesses.
- The prescribing physician and a consulting physician must confirm the diagnosis and prognosis.
- The prescribing physician and a consulting physician must determine whether the patient is capable.
- If either physician believes the patient's judgment to be impaired by a psychiatric or psychological disorder, the patient must be referred for a psychological examination.
- The prescribing physician must inform the patient of feasible alternatives to DWDA, including comfort care, hospice care, and pain control.
- The prescribing physician must request but may not require the patient to notify his or her next of kin of the prescription request.

To comply with the law, physicians must report to the Oregon Health Authority (OHA) all prescriptions for lethal medications. Reporting is not required if patients begin the request process but never receive a prescription. In 1999, the Oregon legislature added a requirement that pharmacists must be informed of the prescribed medication's intended use. Physicians and patients who adhere to the requirements of the Act are protected from criminal prosecution, and the choice of DWDA cannot affect the status of a patient's health care or life insurance policies. Physicians, pharmacists, and health care systems are under no obligation to participate in the DWDA.

Reporting requirements

Within **7** calendar days of writing prescription:	Patient's written request for medication/consent form Attending physician compliance form Consulting physician compliance form Psychiatric/psychological consultant compliance form (if applicable)
Within **10** calendar days of the pharmacy dispensing the lethal medications:	Pharmacy dispensing record form
Within **10** calendar days of the patient's death and/or ingestion of lethal medications:	Attending physician's follow-up form

From The Oregon Revised Statutes specify that action taken in accordance with the DWDA does not constitute suicide, mercy killing, or homicide under the law.

[a]Links to statutes can be found at https://public.health.oregon.gov/ProviderPartnerResources/EvaluationResearch/DeathwithDignityAct/Pages/ors.aspx.

Arguments and professional positions against PAS, in the opinion of some authors,[35] carry ethical weight and include erosion of trust in the medical profession, given its commitment to human dignity and care. Patients are vulnerable, given their illnesses; therefore it is imperative that health professionals can be trusted to cure when possible and, when not possible, to care for them well until death. In addition, the tools of palliative care have expanded, and teaching models and the literature are replete with strategies, even accessible for health professionals in more remote areas. given internet access and emerging telemedicine technology.

The practice of PAS will likely grow in the United States, as we have seen the expansion of it into nine states as of early 2019. Considering where the practice rests for any individual philosophically is important, especially for RTs and all health professionals, as patients and lay persons will likely ask about the arguments for and against it. Therefore all RTs should be prepared if and when PAS is legalized in their states.

Euthanasia

PAS is different from euthanasia, which is not legal in the United States. Euthanasia is defined as the active act, on the part of a health care professional, to intentionally end the life of a patient due to intolerable pain and suffering. Although euthanasia is legal in some countries such as Belgium,[36] it is not supported in the United States and is considered a criminal act punishable by law.[25]

RULE OF THUMB Euthanasia is illegal in the United States; PAS is illegal in most US states; RTs should be able to describe these practices and to distinguish between them.[25,35]

Ethically Defensible Comfort-Oriented Care

Doctrine or Rule of Double Effect

A palliative approach to care at the end of life has been a positive addition in the care of acutely and chronically ill patients when it has been determined—based on the patient's prognosis, values, beliefs, and preferences—that continuing LST in the hope for recovery is no longer an appropriate goal. The ethical approach to pain and symptom management at the end of life is best guided by the **rule of double effect**,[37,38] derived from the ethical principle of nonmaleficence and recognizing that an act can have both a good and bad effect, and that to achieve the good effect, the bad effect must be tolerated. When a well-considered decision to redirect the patient's goals of care to "comfort measures" is made and it has been decided that the burden of LST ought to be withdrawn, the responsible physician in collaboration with the interprofessional team can consider the optimal end-of-life approach given the unique specifics of the patient's condition.

The rule of double effect[37,38] provides an ethical guideline to care well for the patient (realizing that life support is no longer benefiting the patient) while also avoiding harms (pain and discomfort that may accompany the termination of life support). The rule of double effect also provides support for the ethical administration of pain and symptom management at end of life

when LSTs are not being utilized. In either clinical ethical scenario, where it is acknowledged that a patient will require pain and symptom management to ensure a peaceful death, this rule provides an ethical framework to guide practice around pain and symptom management within a sound and defensible ethical practice. Sulmasy[39] states that this moral rule has played an important role in the care of the dying, in that it allows clinicians who are opposed to euthanasia (illegal in all US states) and PAS (illegal in the majority of US states) to provide pain and symptom management while fulfilling their professional goals as health professionals and not violating their consciences. This rule should be in the "ethical parlance" of all clinicians who have professional responsibilities in caring for dying patients, as it permits the physician, pharmacist, nurse, and RT to defend their clinical actions to colleagues as well as families.

The rule of double effect provides language and reasoning that recognizes when a clinician cannot avoid all harm but can still achieve important good. The rule of double effect is invoked to justify claims that a single act (medicating a patient at the end of life) can have two foreseen effects, one good (preventing and alleviating pain and untoward symptoms) and one harmful (hastening death) is not always morally prohibited if the harmful effect is not intended. The rule of double effect has four conditions that must be satisfied in the practice of medicating a patient at the end of life. Each condition is reviewed next, integrating a tangible example of medicating a patient whose ventilator is to be withdrawn. See also Box 58.5.

1. The "nature of the act" must be good, or at least morally neutral—the act of medicating a patient at the end of life is not immoral. For example, if a "goals of care process" has led to a well-considered decision to withdraw mechanical ventilation, the patient's comfort in the process of ventilator withdrawal must be ensured. Thus the idea of providing medication to provide comfort and symptom alleviation is a good and moral act.
2. The second and perhaps most important condition is the "intention of the health professional" in the clinical situation. The goal is to "intend the good effect" while foreseeing the potential "bad effect," which must be tolerated. The good intent is to prevent or alleviate pain or untoward symptoms, such as SOB or manifestations of air hunger that might go along with the termination of ventilatory support. The intention is *not* to "kill the patient" but only to provide a dose of medicine that is clinically sound, given the patient's history with narcotics. Some may ask, "How can you really know another person's intentions?" If a physician orders 30 mg morphine IV push immediately prior to extubation in a "narcotic-naive patient," then a good intention would be questionable, as such a dose would likely go beyond anticipating the patient's discomfort and would obfuscate the patient's attempts to breathe. The RT—along with nurses, physicians, and pharmacists—can collaborate in planning how to dose a patient in such situation so as to satisfy the condition of "intention."
3. The third condition of the rule of double effect is the distinction between means and effects. Simply stated, the bad effect must not be the means to the good effect, in that the patient doesn't have to die to be free of pain and symptoms; medications can be provided that will accomplish this goal of good effect (pain and symptom relief) without the patient's immediate death from the medications.
4. The fourth condition to be met is consideration of "proportionality between good and bad effect," meaning that anticipation and treatment of a patient's distress is an ethically important value when withdrawal of LST has been agreed on as the right thing to do. Therefore there is a proportionately good reason (humane goal and value for comfort at end of life) to tolerate the "bad effect" (potential for hastening death can be foreseen) in hopes that the good effect may be realized.

BOX 58.5 Application of the Rule of Double Effect

Morphine in the treatment of dying patients in pain is generally used in a manner that satisfies the criteria for the double effect, which includes the following criteria:

1. (Nature of the act): The use of morphine is not in itself immoral.
2. (Intention of health professional): The administration of morphine is undertaken only with the intention of relieving pain, not of causing death through respiratory depression.
3. (Means vs effects): If it first kills the patient, morphine does not only relieve pain.
4. (Proportionality): The relief of pain is a proportionally grave reason for accepting the risk of hastening death.

Data from Beauchamp TL, Childress JF: *Principles of biomedical ethics*, ed 7, New York, 2013, Oxford University Press; Sulmasy DP, Pellegrino ED: The rule of double effect: clearing up the double talk. *Arch Inter Med* 159:545–550, 1999.

RULE OF THUMB The rule of double effect provides a framework for health professionals to both implement and defend their actions in the provision of pain and symptom management at the end of life.[37–39]

Pain and Symptoms at the End of Life: Clarifying the Roles of the Physician and Health Care Agent

There are times when the family member of a patient at the end of life, who may even be a legally designated surrogate, will resist the administration of pain medicines for a loved one that, per health care professional assessment, is in pain or experiencing untoward symptoms. Some families express concern that the medicine will make their loved one sleepy, and that they want the patient to be awake. In other instances, there may be a belief that suffering is redemptive and ought to be endured.[40] In such situations, a hospital chaplain may assist in exploring the origin, breadth, and depth of such religious beliefs and may discourage such a practice. In other instances, family members may not notice the objective signs of pain and symptoms or hear the patient's complaint of discomfort. In many situations, clinicians can gently inquire to better understand if there are fears or misconceptions on the part of the family and then help the family observe and understand the signs and symptoms that they, as health professionals, are noticing, and are using as the basis to

conclude that the patient, even if not conscious, might be experiencing as pain and discomfort. Clinicians have an obligation to treat a patient's pain and symptoms, and in many of the advance directives statutes, it is made clear that pain and symptom management is within the domain of the physician, not the HCA. Consider as example the section from Massachusetts General Laws Chapter 201D (Health Care Proxy Statute), Section 13: Pain Alleviation, Comfort Care Procedures states:

> *Nothing in this chapter shall preclude any medical procedure deemed necessary by the attending physician to provide comfort care or pain alleviation. Such procedures shall include but not be limited to treatment with sedatives and pain killing drugs, non-artificial oral feeding, suction and hygienic care.*

With a compassionate inquiry to the family members, clinicians can better understand their concerns and misconceptions and correct them. In rare circumstances, it may be necessary to let the family member know that the clinician's practice in assessing and medicating their loved one at end of life is, in fact, the law.

Palliative Sedation

There are times when a patient's pain and symptoms are not alleviated by the usual repertoire of medicines used at the end of life. This scenario can come up with advanced cancer or conditions such as terminal liver disease, where pain, agitation, and discomfort are unrelenting. In such situations, the practice of "palliative sedation" is permitted and its use is ethically permissible.[41,42] At Massachusetts General Hospital, a palliative care consult is required prior to instituting **palliative sedation.** As in the case of traditional end-of-life practices that are ethically defensible by meeting the criteria of the doctrine of double effect, palliative sedation, too, is an ethically defensible practice used in rare circumstances, but it is an essential tool when needed to provide comfort for a patient dying of a terminal illness with intractable pain and symptoms.

MINI CLINI

Problem: Patient Dying of a Terminal Illness With Intractable Pain and Symptoms

Louise was in her early forties, with advanced cervical cancer that had metastasized along the nerve pathways and bones of her pelvis. She had excruciating pain, for which she was treated as an outpatient for several months by palliative care physicians, who had tried every advance in pain medication and procedures that was available—including nerve blocks, injections, and other therapies—to no avail. Finally, the patient was admitted to the hospital, where the chronic pain service and acute pain service were consulted, joining palliative care to collaborate in treating Louise's pain, again to no avail.

Discussion

Palliative sedation was proposed to Louise and her spouse, and they accepted it, along with declining medically supplied nutrition and hydration. Her cancer was advanced and could not be cured. Louise was treated with midazolam (Versed), ketamine, fentanyl, methadone, and haloperidol (Haldol) in the ICU, where she was sedated to the point of sleep. She died 48 hours later.

Withdrawal of Life-Sustaining Treatment

The discussion about the right to refuse LST and the parameters that surround it can create a pathway to a peaceful death for a patient at the end of life, even in the ICU setting. One prospective study in France revealed that 50% of ICU deaths involved withholding or withdrawing LSTs.[43] The RT is therefore in a key role in the process, given that mechanical ventilation and other aggressive respiratory therapies are very often part of, if not central, in terms of withdrawal. Different approaches to terminating mechanical ventilation are ethically defensible and can be tailored to the individual patient and family's needs. It is important to ask the family of their past experiences with deaths of loved ones, as past experiences may explain current fears. Some families may fear that their loved ones will experience great distress as LST is withdrawn.

Once consensus is reached that withdrawal of LSTs is the right action plan given the patient's goals of care, the physician, nurse, and RT can collaborate on the best approach given the specific patient's condition and family situation. A comprehensive narrative review of practices[44] reveals practice variations in the withdrawal of LSTs, although consensus exists regarding the domains to address in planning and executing withdrawal of LST in each case, including planning for withdrawal, assessment of distress, consideration of pharmacologic management of distress, and the approach to discontinuation of treatment and monitoring.[45]

Campbell[46] reviewed eight published accounts of ventilator withdrawal, citing terminal weaning and extubation as common practices; she and others argue for extubation whenever possible to promote comfort and clear visualization of the patient's face for the family's benefit, often after a long ordeal of critical illness.[47] In general, the physician, RT, and nurse should make a recommendation regarding the specific approach to terminating LST. The RT is well positioned to contribute assessment information regarding respiratory mechanics, tidal volumes, respiratory rate, minute ventilator, negative inspiratory force (NFI), P0.1. An rapid shallow breaths index (RSBI) rapid shallow breathing index can also be determined from the patient's spontaneous exhaled tidal volumes, respiratory rate, and use of accessory muscles; such data may contribute to a best prediction of how the patient might fare in the ventilator withdrawal process.[48] Long and colleagues[49] conducted an observational analysis to determine time to death after terminal withdrawal of mechanical ventilation and found, in their study of 330 patients, that predictors to shorter time to death included higher positive end-expiratory pressure, extubation prior to death, and presence of diabetes, whereas higher mean arterial pressure predicted a longer time to death. The median time to death in their cohort was 0.58 hours, with an interquartile range of 0.22 to 2.25 hours.

Some families prefer to see all tubes and lines removed so that they can see their loved one's face as intact. In this instance, the patient's endotracheal tube along with nasogastric and orogastric tubes are removed and the patient's face, upper and lower airways, and nasal passages are cleared of secretions to enhance the patient's appearance, recognizing these will likely be the family's final moments with their loved one. Families are most often

asked to step out of the room while the actual extubation process is performed. Some families, however, may prefer not to have their loved one extubated, opting rather that the patient's sedating medications be titrated to ensure comfort without any sign of respiratory distress or struggle until the patient expires with the endotracheal tube in place. Some families prefer not to have the ventilator removed from the patient until there are no detectable signs of spontaneous respirations. In such instances, it is acceptable to allow the patient to remain connected to the ventilator until cardiac arrest occurs. This requires that the RT be present throughout the entire process, as the ventilator will undoubtedly sound an alarm once assist/control ventilator modes are no longer in use and the patient's respiratory efforts become fewer and more distant during the dying process.

In some cases, family members may feel torn between the need to alleviate respiratory distress and a belief that assenting to ventilator withdrawal will precipitate the death of their loved one.

Communication with members of the family is essential in preparing them for the withdrawal process. Much care is taken to avoid using terms such as *agonal respirations*, as the family may conclude that *agonal* may imply that their loved one is truly suffering. The family must be reassured that when palliation is appropriately applied, this breathing pattern is a reflexive and normal part of the dying process rather than indicative of respiratory distress.[50]

Although the sudden discontinuation of LSTs such as CVVH, ECMO, vasocopressors, and antibiotics may not cause patient distress and discomfort, a sudden or abrupt discontinuation of mechanical ventilator support and a significant decrease in oxygen even with anticipatory medication provided can sometimes lead to patient discomfort, and the appearance of such can be quite distressing, especially to family members who have an emotional bond with the patient or inexperience with the ICU setting. Therefore it may be of benefit to the patient that a gradual ventilator wean and removal of oxygen and mechanical ventilation be considered. However, gradual and prolonged mechanical ventilator wean should be considered only in situations where the patient is clearly dyspneic and the mechanical ventilatory support is maintained as a temporizing measure to relieve the patient's dyspnea while palliation is optimized to allow for a less turbulent ventilator withdrawal process where the patient's distress can be managed more effectively. An overall guiding principle is that the sequence and process for terminal ventilator wean should be as rapid as the patient's respiratory status and anxiety level will allow. Prolonging the process of withdrawal can contribute to patient distress and family anxiety, especially if the family had been anticipating a quick end to the process.[50]

Generally, exubation to room air is standard. There are, however, times when it seems important to the family that oxygen be administered, such as by nasal cannula or face mask. Quinn-Lee and associates[51] surveyed attitudes, beliefs, and practices of oxygen use at the end of life and found that 96% of the respondents' facilities had a standard comfort-care protocol for the end of life that offered oxygen regardless of the patient's respiratory status. Over 40% of respondents in this survey stated a belief that the use of oxygen prolongs the dying process. Reasons that study participants cited to not provide oxygen included the belief that oxygen administration could be a possible irritant, could prolong death, and was not a factor in providing comfort to patient, family, or clinicians. It remains unclear whether oxygen administration prolongs death; however, it is clear that for some patients who do not exhibit breathing difficulty, it may not be beneficial to administer oxygen near the end of life.[52] For some families, providing oxygen may be reassuring, and if it is not causing the patient undue distress, it seems that responding to the family's request would be reasonable.

Noninvasive positive pressure ventilation (NPPV) can sometimes be applied following extubation or for patients who use continuous positive airway pressure (CPAP) or BIPAP to alleviate SOB.[53] Health care professionals may be apprehensive about the use of NPPV on patients whose goals of care are focused on comfort measures only.[54] However, as long as it is acknowledged that NPPV is being employed for comfort as opposed to a bridge to recovery, all can better understand its utility. NPPV can be a source of comfort for many patients as their respirations may be labored at the end of life and NPPV can relieve them of the burden of having to do all the work of breathing. NPPV is also utilized to help patients maintain some level of alertness and afford them some ability to communicate in the waning moments of life, a priority for patients and families in some situations.[55] The RT needs to adjust BIPAP or CPAP settings to patient's comfort so that NPPV does not become a burden. Whatever approach is utilized to terminally wean a patient from a mechanical ventilator, clear and constant communication with the family before, during, and after the procedure with the family is imperative.

RULE OF THUMB Providing end-of-life care when the management of pain and symptoms is required and LSTs will be withdrawn requires RTs, physicians, and nurses to be in close communication with one another as well as with the patient, if able, and family. Personalization of a plan for ventilator withdrawal should take into consideration ethically and legally acceptable standards of care.

Special Situations

Status Epilepticus

The ventilator-dependent patient who is in status epilepticus—often after a devastating brain injury requiring seizure-suppressive medications, some of which may depress respiratory effort—presents a unique challenge in end-of-life care. The ethical dilemma of stopping seizure suppressive medicines to give the patient an opportunity for respiratory effort versus continuing seizure suppressive medications, realizing that respiratory effort will be subdued, must be addressed. Most critical care physicians believe that allowing a patient, albeit comatose, to be unmedicated with status epilepticus is a harm to the patient and inhumane. Such patients on seizure-suppressive medicines that can also suppress respiratory drive at the time of ventilator withdrawal could theoretically experience a sensation of air hunger but be unable to initiate a breath. Such patients should therefore have these medicines continued, with the addition of narcotics to alleviate any potential air hunger or anxiety.[56–58] Palliative care services should be consulted in such cases.

MINI CLINI

Problem: Withdrawal of Lifesaving Treatment in a Patient With Anoxic Brain Injury

Jane had a pulseless electrical activity (PEA) arrest after massive hemoptysis leading to anoxic brain damage. She was in the ICU for 8 days, receiving high doses of sedative medications and multiple antiepileptic infusions to achieve burst suppression, given her myoclonic status and persistent electroencephalographic signatures of marked and irreversible cortical injury. The medical and neurology teams, in collaboration with interprofessional clinicians and Jane's HCA, agreed that the most appropriate goals of care would be to withdraw LST and allow Jane to die, given her very poor neurologic prognosis and prior wishes. Jane required high-dose continuous infusions of propofol, pentobarbital, and midazolam to control her ongoing abnormal electroencephalographic and myoclonic activity. When these medications were slightly reduced, she would manifest seizure activity.

Discussion

The physicians, nurse, and RT asked if it was ethically permissible to continue these antiepileptic medications while withdrawing the ventilator, as such medications could further suppress the patient's respiratory drive and ultimately hasten her death. Based on the principle of nonmaleficence, from which the doctrine of double effect is derived, it was determined to be ethically defensible, compassionate, and good medical practice at the end of life to continue the antiepileptic medications. The doctrine of double effect specifies the principle of nonmaleficence when a clinician (physician, nurse, pharmacist, and RT) cannot avoid all harms and still achieve important good.[37,39] The rule of double effect was invoked to justify claims that a single act having two foreseen effects, one good and one harmful, it is not morally prohibited if the harmful effect is not intended.

Four criteria of double effect offer a pathway for analysis in Jane's case:

The nature of the act must be good or morally neutral: For Jane, who is in a state of severe irreversible cortical injury manifesting as abnormal high-frequency electroencephalographic activity and intermittent myoclonic activity that can only be suppressed with multiple medication infusions, there is both a humane desire and professional obligation to alleviate this state. Although she may not "experience or appreciate" this state, given her devastating and irreversible brain injury, physicians, in their obligation "to do no harm," must alleviate it as best they can—thus the "nature of the act" to alleviate the condition of epileptiform activity is morally good.

Presence of good intention: The physician's intention is to eradicate seizure activity for the patient's benefit. The physician's intention is not to directly end the patient's life. The bad effect, that the patient's death may be hastened, is foreseen but not intended.

Distinction between means and effects: The provision of high-dose seizure-suppressive medication is required only if a patient's seizures are not responsive to lesser doses/types of medicine. However, the titration of such medications and addition of other medications are justified in pursuit of the good effect (seizure eradication) and not as a means to the patient's death.

Proportionality between the good effect and the bad effect must exist: The good effect (seizure suppression) must outweigh the bad effect (hastening death). The bad effect is permissible only if a proportionate reason is present that compensates for this foreseen bad effect. Allowing Jane to be in a state of myoclonus as she is dying is inappropriate and against the standards of humane end-of-life care.

Therefore continuing Jane's antiepileptic medications even when ventilator support is withdrawn meets the four criteria specified in the doctrine of double effect and is thus not only ethically permissible but also recommended as compassionate, competent end-of-life care. The intention of her physicians is to control her seizures and minimize her suffering, not to hasten her death. Discontinuation of antiepileptic medications that have been required to suppress Jane's seizures has great potential to further her suffering; thus it would be an action that cannot be tolerated.

Patient Receiving Paralytics

Some patients require paralytic medicines to promote concordance with mechanical ventilation, which allows the patient to obtain the maximal benefit from mechanical ventilation toward recovery. In time, for some patients, when progress is absent and recovery does not seem possible, the goals of care change and decisions to withdraw mechanical ventilation and other LSTs are appropriate. The ethical ideal is to wean the individual from paralytic agents before proceeding with the withdrawal of mechanical ventilation to both allow the patient the opportunity to initiate respiration postwithdrawal and to ensure that the patient does not experience air hunger without the ability to initiate a breath. There may be *rare instances*, however, when the patient's overall condition precludes tolerating the time to wean paralytics; in such *rare circumstances*, as when a patient's hemodynamic status is deteriorating rapidly, the patient's comfort should be assured with adequate sedating medicines in the process of ventilator withdrawal.[50,59] Similar reasoning by the rule of double effect applies in the earlier section titled "Status Epilepticus."

RULE OF THUMB Careful ethical consideration must be given to patients at the end of life who have intractable pain and symptoms requiring palliative sedation, patients in status epilepticus, and those who have been receiving paralytics. RTs must know ethically and legally acceptable practices in these circumstances.[42,50,56–59]

ETHICAL CONFLICT AT THE END OF LIFE

Many end-of-life decisions are reached daily at bedside and in a hospital's family meeting rooms. For the vast majority, a consensus can be reached without issue or disagreement. A patient's medical prognosis formulated by physicians and an interprofessional team is most often accepted by family. Once presented with all the facts, most families and patients concur with the physician's recommendation and the plan is adapted to accommodate unique family, religious and cultural practices. In a small percentage of cases the differences are often the result of incongruence in the family's wishes and what the clinicians deem medically appropriate.

Although case law and ethical standards have settled the right to refuse LST, there remain many reasons for ethical conflict

over LST when patients are approaching the end of life. Conflict can be present within families, within the health care team, or between families and the health care team. Some conflicts can be addressed through therapeutic use of the interprofessional team, particularly when there is good medical and nursing leadership in an ICU setting. At times, however, the conflict is such that bona fide ethics expertise, via an "ethics consult," may be sought to facilitate resolution of the conflict. It should be noted that any professional, patient, or family member can request an ethics consult. The goal of an ethics consult is to mitigate conflict by hearing the views of all stakeholders, assessing values, and helping build compromise or consensus on behalf of the patient.[60,61] The RT, as a member of the health care team, is a stakeholder in any case where ethical conflict exists and therefore has a rightful place at the table of negotiations and consensus building.

In the setting of difficult conflict at the end of life, **ethics consultation** is beneficial to health professionals, patients, and families. As of 1992, The Joint Commission on Accreditation of Hospitals and Organizations (JCAHO)[62] has required that health care organizations have a mechanism for clinicians, patients, and/or families to convey their ethical concerns.[63] When ethical concerns are related to patient care, most hospitals look toward the clinical ethics consultation service and committee. Although membership on ethics committees varies, in general there are at minimum one or more persons on the committee who have recognized expertise in ethics.[64] Ethics committees that are multidisciplinary—including community members—offer patients, families, and clinicians the "best practice" model for ethics consultation.[65] Increasingly, ethics consultation is a recognized professionalized activity, with the American Society of Bioethics and Humanities (ASBH) having recently defined criteria for health care ethics consultation.[66]

Ethics consultants are charged with responding to requests by clinicians, patients, and/or families when there is conflict. In our institution, requests are primarily about conflict at the end of life. Ethics consultants review the medical record and obtain the views of stakeholders in the case, which usually includes physicians, nurses, allied health professionals, and patients and their families. Ethics consultants may request to meet with the health care team and then with the team and family as well as the patient if able to participate. In our review of 7 years of ethics consultation, three main reasons for requests included moral support or affirmation of a plan, a surrogate decision maker's continued request for LST, and clarification of patient values and preferences.[67] Overall, the goal is to mitigate conflict, build consensus, honor patient wishes when possible, and protecting a patient from harm.

Ethics consultants possess a body of knowledge that assists them in their application of ethical theory and approaches; they are familiar with medical diagnoses and treatments, communication techniques and skills; can tolerate complex emotions; and have overall compassion for others.[61,68] In addition, ethics consultants are knowledgeable about case law, federal and state statutes, professional position statements, hospital policy, and empirical data that can contribute to an ethical analysis and recommendations.

Particular attention to the experiences of patients and families in nondominant cultures is also very important in the ethics consultation process. Persons of nondominant cultures may begin with a preconceived notion that clinicians cannot be trusted to look after their loved one's best interest. They often ask questions such as, "Can I trust them to do all they can for my loved one?" As Romain and Courtwright[69] explain, distrust in health care is manifest in different ways, and one area that has not been extensively explored is in decision making over continuing or withdrawing life-sustaining treatment. When health professionals make recommendations to stop LST or assert that there are no additional treatment options, long-standing distrust in the medical system may manifest as disbelief and refusal to accept the recommendations. Patients and families of all backgrounds should be treated respectfully, translated as equally without prejudice. Respect for human dignity and attention to the goals of the professions serves as the foundational pillars of ethics in health care.[70]

RULE OF THUMB The JCAHO mandates that health care organizations have a mechanism available to patients, families, and clinicians who encounter ethical problems. Interdisciplinary collaboration with excellent team-patient-family communication prevents many ethical conflicts; however, ethics committees and ethics consultation services exist to assist in the mitigation of ethical conflict.[60–62]

Professional Position Statements, Empirical Data, and Hospital Policy Provide Support in Ethical Conflict

There are tools available that assist clinicians and ethics consultants in formulating recommendations in practice and in situations of conflict. Professional position statements and empirical data provide evidence that can guide actions in clinical/ethical conflicts and speak to the fact that researchers and ethicists have considered the kinds of ethical problems that emerge. Clinicians and ethics consultants who draw on empirical evidence and professional position statements can demonstrate to patients and families that the end-of-life recommendations they make have a basis in evidence-based practice and professional thought beyond the institution at hand. Many institutions, such as Massachusetts General Hospital, have utilized empirical evidence and professional positions on topics in end-of-life care into hospital policy, which guides such care in the institution. Some examples follow.

The Heart Rhythm Society's[71] has issued a statement titled Expert Consensus Statement on Management of Cardiovascular Implantable Electronic Devices (CIEDs) in patients nearing end-of-life; it states that these devices—which include pacemakers, automatic implantable cardiac defibrillators (AICD), and in principle, mechanical cardiac support (MCS)—can be turned off or withdrawn when the burden of these therapies is greater than the benefit. Guided by and consistent with established case law in end-of-life care that defines the right to refuse LST [12,13] or the termination of these devices after an analysis of "goals of care" for a patient is bedrock of ethical and legal practice. Clinicians can "conscientiously object" to carrying out this "legally

BOX 58.6 Massachusetts General Hospital's Life-Sustaining Treatment Policy

Doing No Harm: The responsible physician always has an overriding responsibility to protect the patient from harm. In some clinical situations, the responsible physician may determine, after exploring and documenting a patient's values and beliefs and in conjunction with clinicians involved in the patient's care, that attempting cardiopulmonary resuscitation (CPR) would be more harmful than beneficial for the patient. In such situations, the responsible physician may decide not to offer CPR. In two such situations, the responsible physician may follow guidelines for entering appropriate code status orders, which may include do not resuscitate (DNR), do not intubate (DNI), or both.

Situation 1: The responsible physician should consider protecting a patient who is imminently dying from CPR's potential harms by not offering CPR and entering the appropriate orders. In this situation, the responsible physician may decide but is not required to obtain a second opinion about not offering CPR from another senior or experienced physician or from the optimal core committee (OCC) and also may request advice from the Office of General Counsel (OGC).

Situation 2: The responsible physician may also consider not offering CPR to a patient who is not imminently dying but has no reasonable chance of surviving CPR to the point of leaving the hospital. In this case if, after careful discussion with the patient or surrogate, the patient or surrogate does not assent to the plan, orders to withhold CPR should be entered only if another senior or experienced physician and a consultant from the OCC concur with the plan and only if this concurrence has been documented in the medical record.

In either circumstance, the responsible physician who decides not to offer CPR should inform the patient or surrogate of this decision and its rationale and ensure that the patient will continue to receive the highest possible quality of care.

Courtesy Ellen M. Robinson.

and ethically permissible procedure to terminate these devices" but must not abandon the patient and thus are obligated to identify a clinician who can do it for the patient. The RT will find it useful to be aware of this position statement, as a knowledge deficit regarding the termination of these devices persists among physicians and health care professionals in practice.

ECMO is utilized for adults with cardiac and respiratory failure due to conditions such as acute, serious influenza; acute respiratory distress syndrome (ARDS); interstitial lung disease; and cardiogenic shock as well as other life-threatening illnesses leading to cardiopulmonary collapse.[72] Although outcomes vary, given the patient's index condition and accompanying comorbidities, for some patients the provision of ECMO can clearly be lifesaving. At our institution, an ethics consult is placed for each patient receiving ECMO for the purposes of identifying any ethical conflict early.[73] RTs are key professionals in ECMO therapy in that they are responsible for administering the therapy and being present at the patient's bedside. Therefore their engagement with emerging ethical issues in these cases is essential.

The Renal Physicians' Association has published a document titled "Shared Decision Making in Appropriate Initiation and Withdrawal from Dialysis."[74] It identifies 10 recommendations that guide practice in goals of care for the patient in consideration of ethically appropriate use of dialysis and withholding or withdrawing dialysis.

The question of administration of **cardiopulmonary resuscitation** (CPR) often comes up at the end of life. Clinicians become increasingly concerned when a patient is imminently dying and DNR has not yet been agreed on by the family. Empirical evidence provides a framework for the ineffectiveness of CPR for the seriously ill.[75,76] Hospitals have adopted policies to limit offering CPR to patients who are clearly at the end of life based on this empirical evidence, showing that CPR in such instances has largely had poor outcomes. When the physician believes that the patient cannot benefit from CPR, she or he should consider not offering it as a LST.[77] At our institution, experience in using a "Do no harm, or medically indicated DNR/DNI policy" has been largely positive, and in most cases the family appreciates that they have been relieved of the burden of decision making. The case of Ms. Yates demonstrates the benefits that the policy can have.

At times there are situations when conflict about withdrawing LST is intractable and ethics consultation is not able to bring about resolution. To address such conflicts, some quaternary care institutions have written or adopted "resolving intractable conflict" policies that are due process approaches to attempt to resolve issues involving the continued use of LST. These policies are guided by or adhere to principles in a five-society position statement entitled "Responding to Requests for Potentially Inappropriate Treatments in ICUs." Those who collaboratively wrote this statement included the American Thoracic Society, the American Association of Critical Care Nurses, the American College of Chest Physicians, the European Society of Critical Care Medicine, and the Society of Critical Care Medicine.[78]

Empirical evidence can also guide ethics consultation analyses and recommendations in situations of feeding options for patients with advanced dementia, cases in which RTs may well be involved due to aspiration risk and sequelae. When a person with dementia struggles with dysphagia and aspiration, family members may believe that medically supplied nutrition and hydration can help their loved one meet his or her nutritional needs. In fact, the evidence suggests otherwise, in that patients with feeding tubes are also at risk for aspiration, along with a host of other complications including aspiration pneumonia, esophageal perforation, infection, tube blockages and dislodgements, physical or pharmacologic restraint due to agitation/attempts to remove a feeding tube, and deprivation of the pleasure of food and social interaction of feeding.[79–81] Such evidence leads to a general recommendation against tube feeding for persons with advanced dementia, a position supported by the American Geriatrics Society.[82] For such patients, ethics consultation can often provide much-needed empirical data to support both medical teams and families in their decision making against medically supplied nutrition and hydration.

RULE OF THUMB Empirical data, professional position statements, and hospital policy are resources that help patients, families. and clinicians make sound clinical/ethical decisions. Ethics consultants are experts; they know the relevant sources of information and when such might be applicable.[71,74–82]

MINI CLINI

Problem: Cardiopulmonary Resuscitation in a Patient at the End of Life

Ms. Yates, a 60-year-old Asian woman of Buddhist tradition, had metastatic breast cancer that had been diagnosed 6 years earlier. Ms. Yates had been cared for at a premier care cancer center and had benefited from cancer treatments; however, her oncologist informed her and her son, Kyle, who was also her HCA, that no further treatment could be offered given her advanced disease. Primarily driven by her son, Mrs. Yates was taken to yet another quaternary care institution, seeking treatment. She was hospitalized and her disease was found to be similarly advanced, metastatic, and no longer responsive to cancer treatment. Ms. Yates was oxygen-dependent, her functional status had declined significantly, and she had recently endured pathologic fractures of bones in her left arm and right leg.

Kyle and his sister, Lee, were almost always present in their mother's hospital room. Lee sat quietly and did not speak often. Ms. Yates had demonstrated to health professionals signs of acceptance that she was in her end-of-life time; however, when Kyle was present, she would nod in agreement to what he said about continuing treatment. Kyle had a job as a computer programmer but gave it up 6 years earlier to care for his mother. Lee shared with a social worker that although Kyle was very good at programming, he did have difficulty getting along with his supervisor and coworkers.

Discussion

Kyle was struggling with the fact that his mother had a terminal condition and a very limited life expectancy. Reportedly, Kyle was unable to accept that further life-sustaining measures, including CPR, would be both nonbeneficial and burdensome interventions for his mother. Furthermore, Ms. Yates was often uncomfortable, had difficulty breathing, and grimaced and moaned with basic nursing care. Morphine would be the most effective treatment for her symptoms; however, in the setting of a full code, nurses were hesitant to give her medication that could depress her breathing. The attending physician heard the nurses' concerns and requested an ethics consult for the question regarding limiting CPR in the setting of advanced metastatic breast cancer, nonresponsiveness to treatment, and declining functional status.

Given that Ms. Yates was at the end of life, the ethics consultants, based on a hospital policy, recommended the following: physicians are bound by the first ethical principle of their roles as doctors, which is to do no harm. In a situation such as this, CPR should not be offered, with the explicit goal of protecting the patient from harm (Box 58.6).

Kyle was angry when the attending physician told him of the medically indicated DNR/DNI—he resisted it and began talking about wanting to transfer his mother to yet another hospital. Physicians and nurses persuaded him to "stay the course." In a day or so, Kyle seemed accepting of the DNR/DNI and stopped requesting transfer. His mother's status deteriorated further, and she was transitioned to comfort measures, receiving morphine for difficult breathing and a generalized appearance of discomfort. Within a few days, the nurse suggested to Kyle and Lee that their mother was getting closer to death, and given Ms. Yates's Buddhist faith, that the Buddhist chaplain be called. The chaplain led a chanting service at Ms. Yates's bedside, and Kyle and Lee seemed comforted by it. They prayed together that Ms. Yates might have a peaceful transition and that all her family members be well.

The nurse attending the patient's death documented the following:

Kyle reported that he was so happy that his mother passed peacefully and that he now understands and appreciates what the staff who had cared for her were trying to tell him. He reports that he now realizes how much she had been suffering for so many months.

THE RESPIRATORY THERAPIST AS ETHICAL PRACTITIONER

Respiratory therapists should not make assumptions about a patient's or family's wish or preferences and how their unique cultural backgrounds may shape how they arrive at certain decisions. In such cases an RT will be present throughout and will be well positioned to show understanding, empathy, and respect to all patients and families. In times of serious illness, RTs can comfort patients and families as they imagine walking in their patient's and families' shoes, bearing in mind the vulnerability of both patient and family. A patient on a gurney who is critically ill or at the end of life can lose all sense of dignity, being surrounded by strangers who are providing care. It is therefore important for practitioners to learn who the person being treated is and thus responding to that person as an individual rather than simply a patient. The way a therapist explains the ability or failure to wean from mechanical ventilation can either calm a family member's anxiety or cause distress. Distress may ensue if the explanation is void of compassion even when it is correct. A family can more easily accept that their relative cannot be liberated from the ventilator if the explanation is communicated with empathy. Health professionals including RTs do not communicate only with words but also with their body language and attitude. The RT can convey a genuine sense of compassion by using terms that a layperson can understand, as opposed to medical jargon. While interacting with patients and families, the RT must strive to not appear rushed and preoccupied and not seem eager to be somewhere else.

When faced with a critical illness and with end-of-life decisions, patients and families do not want technically precise answers to their questions; rather, they want explanations that will bring clarity to their understanding delivered in an empathic manner—a manner that leaves the door open for continued conversation. Like physicians, nurses, and social workers, the RT is in a unique position to comfort families in times of grief. The RT is attending the patient's most vital function, respiration. RTs, whose disciplinary expertise is unique, essential, and highly valued, can also demonstrate compassion as they administer their professional craft to seriously ill patients and their families. Practicing within an ethical comportment of virtue[83] (see Chapter 5) calls the RT to be discerning, compassionate, trustworthy, manifesting a sense of integrity, having the "good of the patient" always in mind.

Dr. Edmund Pellegrino[83] cautioned health professionals that virtuous practice can be under threat, as physicians and health professionals respond to increasing economic pressures confronting health care, among other factors that can, unabated, compete with ethical and quality patient care. A health professional must bear in mind, in training and practice, what, in fact, called her or him to the vocation of the health professions. Being cognizant of the mission and objectives of the health care institution of your practice and asking, "is this organization's mission in concert with my professional-philosophical beliefs about patient care?" is a place to begin when interviewing for positions. As a licensed RT in practice, intentionally observing the care delivered and ethical climate in the organization as well as experiencing how the RT role is supported in the delivery of care, allows the RT

to reflect on his or her own professional philosophy of care and how it can or cannot be enacted in the practice setting. Are there opportunities to ask questions in patient cases? Are the health professionals collaborative and inclusive of the RT? Are practice and legal and ethical standards upheld in usual care aimed toward recovery and in end-of-life care? Health professionals who are rooted in character ethics are needed in moral transactions between professionals as well as the patients and families they serve. Sick persons are vulnerable and therefore must rely on and trust their physicians, nurses, and allied health professionals in setting goals and providing goal-appropriate, competent, and compassionate care. It is important to know that the physician, the nurse, and the RT as providers of intimate care to vital body systems are expected to be intrinsically predisposed to do the right thing for the patients they serve.[84]

RULE OF THUMB RTs are bound to practice ethically, always placing patient well-being above all and respecting the dignity of each patient they serve.

Finally, as an RT practicing in health care organizations—be they ICUs, general units, or long-term care facilities—it is essential to be a participating member of an interprofessional team.[85] Health professionals cannot practice in isolation—doing so can harm the patient, denying the patient of the multiple benefits that collaborative teamwork can provide, not to even speak of the benefits it affords each professional on a team. Seeking to know the patient in the context of her or his medical and rehabilitative prognosis as well as ethically and legally permissible strategies in end-of-life care can enhance the RT's role and professional satisfaction in providing high-quality, ethical, collaborative care.

SUMMARY CHECKLIST

- The approach to a seriously ill patient's care should be goal directed and intentional and should include consideration of the patient's prognosis and values, beliefs, and preferences within the context of what is legally and ethically permissible in the jurisdiction in which the patient is receiving treatment and care.
- In the United States, case law has accrued, building the right to refuse LST as a legal right and ethically permissible action. This right applies to the person with decision-making capacity, former decision-making capacity, or never having had decision-making capacity. LST may be withheld or withdrawn within the framework of legal and ethical permissibility. This right applies to any LST; it is analyzed in terms of benefits and burdens to the patient considering his or her goals of care.
- Good pain and symptom management at the end of life is both legally and ethically permissible. The rule of double effect provides an ethical and time-honored framework for analyzing the ethics of pain and symptom management at the end of life.
- Withdrawal of LST, in particular mechanical ventilation, requires a careful interdisciplinary process of assessment, intervention, and evaluation. The RT is a key professional in this process, given his or her expertise in the assessment and management of the patient's airway. The unique characteristics of the patient's condition should be considered as physicians, nurses, and RTs make plans for withdrawing the patient's mechanical ventilation.
- Special situations at the end of life include patients with status epilepticus, those with intractable pain and symptoms in need of palliative sedation, and those on paralytics; all such patients require careful ethical analysis with an interdisciplinary team collaboration.
- Physician and nursing leadership and interdisciplinary team collaboration can often assist in mitigating ethical conflict at the end of life. However, when conflict is challenging, ethics consultation can assist interdisciplinary teams, patients, and families in navigating to an ethical consensus.
- Professional position statements, empirical data regarding clinical-ethical decision making, and hospital LST policies can guide clinicians in sound decision making with patients and families at the end of life.
- RTs are key members of the interdisciplinary health care team with expertise that is not duplicated by other professional disciplines. Thus their disciplinary perspective into clinical/ethical decision making with and on behalf of seriously ill patients approaching the end of life is essential.

GLOSSARY

A

***a* waves** occur when the atria contract, causing a slight increase in both atrial and ventricular pressures within 0.1 second. (Chapter 10)

AARC abbreviation for the *American Association for Respiratory Care (AARC),* the primary voluntary professional association for respiratory therapists. (Chapters 1 and 2)

abdominal compartment syndrome arises when the abdomen has become a fixed compartment, with increased pressure resulting in ischemia and organ dysfunction. (Chapter 16)

abdominal paradox abnormal breathing pattern seen as a sinking inward motion of the abdomen with each inspiratory effort; a sign of diaphragm fatigue. (Chapter 16)

abdominal thrust external pressure forcefully exerted on the abdomen, under the diaphragm, to expel obstructing objects from the upper airway. (Chapter 37)

absolute humidity actual mass or content of water in a measured volume of air, usually expressed in grams per cubic meter or pounds. (Chapters 6 and 39)

accessory muscles of breathing occurs when muscles of the neck, back, and abdomen assist the diaphragm and the internal and external intercostal muscles in respiration, especially in some breathing disorders or during exercise. (Chapter 9)

accountable care organizations (ACOs) groups of doctors, hospitals, and healthcare providers who voluntarily come together to deliver coordinated patient care. (Chapter 3)

accreditation a process of review that allows healthcare organizations to demonstrate their ability to meet regulatory requirements and standards established by a recognized accreditation organization such as The Joint Commission. (Chapter 2)

accuracy determined by how precisely a measuring instrument indicates a known reference value. (Chapter 20)

acid a compound that yields hydrogen ions (H^+) when it is dissolved in an aqueous solution. (Chapters 13 and 14)

acidemia a state in which arterial blood is more acidic than normal (pH < 7.35). (Chapter 14)

acid-fast bacterium type of bacteria that resists decolorizing by acid after accepting a stain. (Chapter 17)

acinus any small, sac-like structure, particularly one found in a gland. (Chapter 9)

activated clotting time the amount of time it takes blood to form a clot. (Chapter 51)

active compression decompression (ACD) uses a hand-held suction device, applied mid-sternum, to compress the chest then actively decompress the chest after each compression during CPR. (Chapter 38)

active compression decompression device a hand-held suction device, applied mid-sternum, which compresses the chest then actively decompress the chest after each compression during CPR. (Chapter 38)

active cycle of breathing technique (ACBT) the use of repeated cycles of breathing control, thoracic expansion, and forced expiration technique. (Chapter 44)

active transport the movement of molecules across membranes in a direction opposite to that expected because of diffusion or osmotic pressure. (Chapter 13)

acute chest syndrome a syndrome that develops in patients with sickle cell disease. The chief complaints are acute chest pain, cough, and shortness of breath caused by the sickling of red blood cells. (Chapter 12)

acute coronary syndrome (ACS) a term comprising three types of coronary artery diseases associated with gradual and/or sudden obstruction of the coronary arteries.

acute exacerbation of COPD state of worsening of chronic obstructive pulmonary disease, often defined by the need to increase medication or escalate care. (Chapter 25)

acute hypoxemic respiratory failure (AHRF) respiratory compromise characterized by severely decreased oxygenation that develops over a relatively short period of time. (Chapter 29)

acute lung injury (ALI) a condition characterized by alveolar flooding caused by an acute insult (e.g., sepsis). Normally a rapidly developing bilateral pulmonary process of noncardiac origin with ratio of a PaO_2 to FiO_2 greater than 200 mm Hg but less than 300 mm Hg. (Chapter 29)

acute respiratory distress syndrome (ARDS) a respiratory disorder characterized by respiratory insufficiency and hypoxemia; triggers include gram-negative sepsis, O_2 toxicity, trauma, pneumonia, and systemic inflammatory responses. (Chapter 29)

adaptive support ventilation (ASV) a mode of ventilation guided by evaluation of the patient's lung mechanics; the ventilator tries to impose a ventilatory pattern that results in the least amount of patient work. (Chapter 53)

adenocarcinoma a type of cancer characterized by glandular structures. (Chapter 32)

adenosine triphosphate (ATP) The most common "energy currency" of cells; a molecule that stores a lot of energy in its phosphate bonds. These bonds are broken to release the energy needed to drive all the physiological mechanisms that maintain life. (Chapter 23)

adhesion a band of scar tissue binding anatomic surfaces that are normally separate from each other. Adhesions most commonly form in the abdomen after abdominal surgery, inflammation, or injury. (Chapter 6)

adiabatic a process in which no heat is gained or lost by the system. (Chapter 6)

adrenergic of or pertaining to the sympathetic nerve fibers of the autonomic nervous system that use epinephrine or epinephrine-like substances as neurotransmitters; any chemical or drug that mimics the effect of these neurotransmitters. Also called a *sympathomimetic drug; catecholamine*. (Chapter 36)

Advanced Cardiac Life Support (ACLS) emergency medical procedures beyond basic life support; they include the establishment of an intravenous fluid line, defibrillation, drug administration, control of cardiac arrhythmias, and use of ventilatory equipment. ACLS usually requires direct or indirect supervision by a physician. (Chapter 38)

advanced directive a document in which an individual specifies what medical care he or she wishes to receive in the future should he or she no longer be able to make such decisions. It may be in the form of a living will or a durable power of attorney. (Chapters 5, 16 and 58)

adventitious lung sounds abnormal lung sounds. (Chapter 16)

aerobic exercise any physical activity that requires increased cardiac output and ventilation to meet the increased O_2 demands of the skeletal muscles. (Chapter 56)

aerophagia the swallowing of air. (Chapter 47)

aerosol a suspension of solid or liquid particles in a gas. (Chapter 40)

aerosol output the weight or mass of aerosol particles produced by a nebulizer per unit time or volume. (Chapter 40)

affective domain a learning domain addressing the area of emotion, mood, or feeling. (Chapter 55)

afterload the load against which an activated muscle must try to shorten; greater afterloads result in lower velocities. (Chapters 10, 51, and 52)

aging growing older. (Chapter 40)

agonal breathing irregular, gasping breaths often seen during cardiac arrest. (Chapter 16)

agonist a chemical substance or drug that has affinity for a receptor and exerts a desired or expected effect (as opposed to an antagonist). (Chapter 36)

air bronchograms lucent tubular shadows running through areas of consolidation. (Chapter 21)

airway hyperresponsiveness a state of the airways that causes them to constrict abnormally in response to stress or insults (e.g., exercise, inhaled materials such as dust or allergens). (Chapter 25)

airway inflammation a localized protective response to pathogens occurring within the routes for passage of air into and out of the lungs and involving the release of mediators including mast cells, eosinophils, macrophages, epithelial cells, and T lymphocytes. (Chapter 25)

airway obstruction a state of abnormally slowed expiration characterized most commonly by a decrease in FEV_1. (Chapter 25)

airway occlusion pressure inspiratory pressure generated 100 msec after airway occlusion; P0.1 (the negative airway pressure generated during the first 100 msec of an occluded inspiration) is effort independent and is thought to be a good measure of central respiratory drive. (Chapter 53)

airway pressure release ventilation (APRV) a form of pressure ventilation that uses two levels of continuous positive airway pressure in an intermittent mandatory ventilation breathing pattern. (Chapter 29)

airway resistance a measure of the impedance to ventilation caused by the movement of gas through the airways; abbreviated as Raw, airway resistance is computed as the change in pressure along a tube divided by the flow. (Chapter 11)

airway stents devices designed for internal splinting of the airway lumen to help reduce airway obstruction from malignant or benign processes that compress the airway from the outside. (Chapter 22)

alae the lateral surfaces of the external nose; the alae may flare out during respiratory distress. (Chapter 9)

albumin the largest constituent protein in plasma. (Chapter 23)

alkalemia a decreased hydrogen ion concentration in the blood; as applied to arterial blood, denotes pH greater than 7.45. (Chapter 14)

alpha-1 antitrypsin deficiency an inherited disorder that may cause emphysema and liver disease. (Chapter 25)

alternative (nonacute) care a site in which healthcare is provided to patients outside of acute care hospitals. It includes skilled nursing, long-term and rehabilitation facilities, as well as homecare. (Chapter 57)

alveolar-arterial oxygen tension difference ($P[A-a]O_2$) the difference between the alveolar and arterial PO_2, usually about 5 to 10 mm Hg when a person is breathing room air. (Chapter 52)

alveolar-capillary membrane a thin tissue barrier through which gases are exchanged between the alveolar air and the blood in the pulmonary capillaries. (Chapter 9)

alveolar dead space alveoli that are ventilated but not perfused. The condition may exist when pulmonary circulation is obstructed, as by a thromboembolus. (Chapters 11 and 12)

alveolar period the development of mature alveoli accompanied by capillary proliferation around their outside walls. (Chapter 9)

alveolar shunt alveolar units that are closed to ventilation but still perfused. (Chapter 12)

alveoli small outpouching of walls of alveolar space through which gas exchange between alveolar air and pulmonary capillary blood occurs. (Chapter 9)

alveolopleural fistula an abnormal communication between the alveoli and the pleura, often associated with pneumothorax. (Chapter 27)

ambulation the process of helping a bedridden patient begin to sit up, stand, and walk around independently. (Chapter 3)

American Academy of Sleep Medicine a professional society for the subspecialty of sleep medicine which accredits sleep medicine facilities in the United States. (Chapter 2)

American Association for Respiratory Care (AARC) a professional association of RTs. (Chapters 1 and 2)

American Respiratory Care Foundation (ARCF) a nonprofit organization formed to support research, education, and charitable activities in respiratory care. (Chapter 1)

American Society for Testing and Materials (ASTM) A nongovernment agency that establishes performance standards for various types equipment and materials. (Chapter 39)

American Society of Anesthesiologists (ASA) an educational, research, and scientific association of physicians organized to maintain the standards of the medical practice of anesthesiology. (Chapter 2)

American Standard Safety System (ASSS) specifications adopted in the United States and Canada for threaded high-pressure connections between compressed gas cylinders and their attachments. (Chapter 41)

American Thoracic Society (ATS) a nonprofit organization focused on improving care for pulmonary diseases, critical illnesses and sleep-related breathing disorders. (Chapter 2)

ampere the basic unit of electrical energy current; equivalent to the amount of electrons flowing when 1 volt of electromotive force is applied to a circuit with 1 ohm of resistance. (Chapter 3)

amyotrophic lateral sclerosis (ALS) a degenerative disease of the motor neurons often characterized by atrophy of the muscles of the hands, forearms, and legs, eventually involving most of the body including the muscles of respiration. (Chapter 33)

analyte a chemical substance that is being measured as in a broad test. (Chapters 17 and 19)

analyzer a person or device that evaluates some submitted material (e.g., a machine that measures blood chemistry components). (Chapter 19)

anatomic dead space airways and lung tissue which does not participate in gas exchange. (Chapter 9)

anemia an abnormal condition characterized by a reduction in the number of circulating red blood cells or the amount of normal hemoglobin available to carry O_2. (Chapters 17 and 23)

anergy lack of activity; an immunodeficient condition characterized by a lack of or diminished reaction to an antigen or group of antigens. This state may be seen in advanced tuberculosis and other serious infections, AIDS, and some malignancies. (Chapter 23)

angina a spasmodic, cramp-like choking feeling. (Chapter 16)

angina pectoris severe chest pain, often also spreading to the shoulders, arms, and neck, caused by an inadequate blood supply to the heart. (Chapter 10)

angle of Louis a slightly oblique angle where the manubrium articulates with the body of the sternum. (Chapter 9)

anion gap a measurement that provides a quick way of determining whether a decrease in HCO_3^- is caused by a disruption of normal anion balance or the presence of an abnormal acid anion. (Chapter 17)

anions negative ions that migrate to the anode (positive electrode) in an electrolyte solution; negative ions. (Chapter 13)

ankylosing spondylitis a chronic inflammatory disease of unknown origin, first affecting the spine and adjacent structures and commonly leading to eventual fusion (ankylosis) of the involved joints. (Chapter 33)

antagonist in pharmacology, a drug that has affinity but produces no effect; an antagonist can be competitive (forms reversible bond with receptor) or noncompetitive (forms irreversible bond). (Chapter 36)

anterior nares openings to the nose; nostrils. (Chapter 9)

anthropometrics the science of measuring the human body—height, weight, and size of component parts, including skin folds—to study and compare the relative proportions under normal and abnormal conditions. Also called *anthropometric measurement*. (Chapter 23)

antiadrenergic pertaining to blocking of the effects of impulses transmitted by the adrenergic postganglionic fibers of the sympathetic nervous system. (Chapter 36)

antibiotic therapy treatment of infections with antimicrobial agents, such as the penicillins. (Chapter 24)

anticholinergic of or pertaining to the blockade of acetylcholine receptors resulting in the inhibition of transmission of parasympathetic nerve impulses. (Chapter 36)

antiseptic a substance that tends to inhibit the growth and reproduction of microorganisms. (Chapter 4)

APACHE scoring system the *Acute Physiology and Chronic Health Evaluation* scoring system; used to assess the severity of illness in critically ill patients. (Chapter 52)

apexes uppermost regions. (Chapter 9)

Apgar score A score evaluating an infant's physical condition, usually performed 1 minute and 5 minutes after birth. It is based on a rating of five factors that reflect the infant's ability to adjust to extrauterine life. (Chapter 54)

apnea absence of spontaneous breathing. (Chapter 15)

apnea of prematurity a disorder in preterm infants, probably of central nervous system origin, characterized by frequent apneic pauses lasting longer than 20 seconds and often associated with cyanosis, pallor, hypotonia, or bradycardia. (Chapter 34)

apneustic breathing a pattern of respiration characterized by a prolonged inspiratory phase followed by expiratory apnea. (Chapters 15 and 16)

apneustic center a localized collection of neurons in the pons located at the level of the vestibular area that moderates the rhythmic activity of the medullary respiratory centers. (Chapter 15)

appropriate for gestational age (AGA) a term describing newborn—whether delivered prematurely, at term, or later than term—whose size, growth, and maturation are normal for gestational age. (Chapter 54)

argon plasma coagulation a medical endoscopic procedure used to stop bleeding or remove tumor tissue. (Chapter 22)

arterial blood pressure the force exerted by the heart against the systemic arteries as the blood moves through them. (Chapter 16)

arterialized blood blood that resembles the blood in arteries (e.g., from the finger or earlobe capillaries). (Chapter 19)

arteriovenous anastomosis a communication between an artery and a vein, either as a congenital anomaly or as a surgically produced link between vessels. (Chapter 10)

artifact an aberration resulting from interference or technical failure. An artifact does not represent a normal or so-called physiologic change. (Chapter 52)

asbestosis a restrictive lung disease caused by prolonged exposure to asbestos fibers; it is associated with a high incidence of malignant lung tumors and pleural abnormalities. (Chapter 26)

assault any conduct that creates a reasonable apprehension of being touched in an injurious manner; no actual touching is required to prove assault. (Chapter 5)

assist/control (A/C or ACV) volume ventilation continuous mandatory ventilation in which the minimum breathing rate is predetermined but the patient can initiate mechanical ventilation at an increased rate. (Chapter 49)

assisted breath a breath whose delivery is aided by a mechanical device. (Chapter 46)

assisted suicide a situation in which the means to end a patient's life is provided to the patient with knowledge of the patient's intention to use it. Physician-assisted suicide connotes that a physician provides such means. (Chapter 58)

Association for the Advancement of Medical Instrumentation (AAMI) a nonprofit organization founded in 1967 by a diverse community of approximately 7000 professionals. (Chapter 2)

asthma a respiratory disorder characterized by recurring episodes of paroxysmal dyspnea, including wheezing on expiration or inspiration, caused by constriction of the bronchi, coughing, and viscous mucoid bronchial secretions. The episodes may be precipitated by the inhalation of allergens or pollutants, infection, cold air, vigorous exercise, or emotional stress. Also called *bronchial asthma*. (Chapter 25)

asthma-COPD overlap syndrome a condition in which a patient has symptoms of both asthma and chronic obstructive pulmonary disease (COPD). (Chapter 25)

atelectasis collapse of the distal lung parenchyma. (Chapters 21 and 43)

atelectrauma lung injury as a result of alveolar collapse secondary to inappropriate positive end-expiratory pressure settings. (Chapter 47)

atmospheric pressure absolute (ATA) a measure of pressure used in hyperbaric medicine; 1 ATA equals 760 mm Hg or 101.32 kPa. (Chapter 42)

atomizer a device that produces an aerosol suspension of liquid particles without using baffles to control particle size. (Chapter 40)

atria the upper two of the heart's four chambers; the right atrium received deoxygenated blood from the inferior and supervior vena cava, and the left atrium receives oxygenated blood from the pulmonary veins. (Chapter 10)

atrial kick the propulsion of blood resulting from contraction of the atrium. (Chapters 10 and 18)

atrioventricular (AV) rings the right and left fibrous rings of heart (anuli fibrosi cordis) which surround the atrioventricular and arterial openings. (Chapter 10)

atrioventricular (AV) valves thin structures that are composed of endocardium and connective tissue, which are located between the atria and the ventricles of the heart. (Chapter 10)

atrophy the loss of muscle mass as a result of disuse. (Chapter 48)

ATPS abbreviation for *ambient temperature, ambient pressure, saturated* (with water vapor). (Chapter 6)

attending title applied to the responsible most senior physician caring for the patient in an academic medical center. (Chapter 3)

atypical pathogens select organisms in *Legionella* species, *Chlamydophila pneumoniae,* and *Mycoplasma pneumoniae* that cause pneumonia. (Chapter 24)

auditory pertaining to the sense of hearing. (Chapter 3)

autogenic drainage (AD) modification of directed coughing, beginning with low lung volume breathing, inspiratory breath holds, and controlled exhalation and progressing to increased inspired volumes and expiratory flows. (Chapter 44)

automatic external defibrillator (AED) a portable automatic device designed to perform defibrillation on patients outside of a hospital. (Chapter 38)

automatic tube compensation (ATC) a mode of ventilation that attempts to maintain tracheal pressure equal to end-expiratory pressure during both inspiration and expiration. (Chapter 53)

automaticity the heart's ability to generate its own intrinsic electrical rhythm. (Chapters 10 and 18)

autonomy the ability or tendency to function independently. (Chapter 5)

auto-PEEP pressure above atmospheric remaining in the alveoli at end-exhalation due to air trapping. Also called *intrinsic PEEP*. (Chapter 45)

autoregulation automatic control of a mechanical or physiologic system; necessitates both a sensing mechanism (to measure what is regulated) and a feedback loop (to respond to changes). (Chapter 47)

autotriggering triggering of a ventilator by any phenomenon that is not a result of the patient making an inspiratory effort. Most commonly a result of a small circuit leak. (Chapter 48)

Avogadro constant the number of constituent particles (usually molecules, atoms or ions) that are contained in one mole, the international (SI) unit of amount of substance. (Chapter 6)

Avogadro's law law in physics stating that equal volumes of all gases at a given temperature and pressure contain the identical number of molecules. (Chapter 6)

azotemia the buildup of excess nitrogenous waste products in the blood, usually secondary to renal failure. (Chapter 23)

B

bactericidal term describing substances with the ability to kill microorganisms. (Chapter 4)

bacteriostatic term describing substances with the ability to restrain the growth of microorganisms. (Chapter 4)

baffle a surface in a nebulizer designed specifically to cause impaction of large aerosol particles, leading either to further fragmentation or removal from the suspension via condensation back into the reservoir. (Chapter 40)

baffling the process of removing large water particles from suspension in a jet nebulizer so that the particles entering the patient's airways are of a uniform therapeutic size. (Chapter 39)

bands bundles of fibers, as seen in striated muscle that encircle a structure or bind one part of the body to another. (Chapter 17)

baroreceptor one of the pressure-sensitive nerve endings in the walls of the atria of the heart, the vena cava, the aortic arch, and the carotid sinus. (Chapter 10)

barotrauma physical injury sustained as a result of exposure to ambient pressures above normal, most commonly secondary to positive-pressure ventilation (e.g., pneumothorax, pneumomediastinum). (Chapters 29 and 45)

barrel chest an abnormal increase in the anteroposterior diameter of the chest caused by hyperinflation of the lungs. (Chapter 16)

basal metabolic rate (BMR) the amount of energy used in a unit of time by a fasting, resting subject. BMR, determined by the amount of O_2 used, is expressed in calories consumed per hour per square meter of body surface area or per kilogram of body weight. Also called *basal energy expenditure (BEE)*. (Chapter 23)

base a compound that yields hydroxyl ions [OH^-] when it is dissolved in an aqueous solution. (Chapters 13 and 14)

base excess (BE) the difference between the normal buffer base (NBB) and the actual buffer base (BB) in a whole-blood sample, expressed in mEq/L; a normal BE is +2 mEq/L. (Chapter 14)

basic chemistry panel (BCP) or basic metabolic panel a panel including the predominant electrolytes sodium (Na^+), potassium (K^+), chloride (Cl^-), and total CO_2/bicarbonate (CO_2) as well as glucose. (Chapter 17)

basic life support (BLS) cardiopulmonary resuscitation designed to reinstitute either circulatory or respiratory function without the use of equipment or drugs. (Chapter 38)

battery (legal) unconsented touching of an individual that causes injury. (Chapter 5)

benchmarking establishing the relationship between an organization's ability to perform at a given level to that of other comparable organizations. (Chapter 7)

beneficence the principle requiring that health providers go beyond doing no harm and actively contribute to the health and well-being of their patients. (Chapter 5)

benevolent deception actions in which the truth is withheld from the patient for his or her own good. (Chapter 5)

Bernoulli principle a principle stating that as flow increases, the pressure in the fluid will decrease along with its potential energy. (Chapter 6)

best interests UN Convention on the Rights of the Child, "…all actions concerning children, whether undertaken by public or private social welfare institutions, courts of law, administrative authorities or legislative bodies, the best interests of the child shall be a primary consideration". (Chapter 58)

bibliographic database a collection of reference sources often used in research. (Chapter 8)

bilevel positive airway pressure (bilevel PAP) spontaneous breath mode of ventilatory support that allows separate regulation of the inspiratory and expiratory pressures. (Chapter 34)

Biot respiration breathing characterized by irregular periods of apnea alternating with periods in which four or five breaths of identical depth are taken. (Chapter 16)

biotrauma inflammation of the lungs in response to inappropriate mechanical ventilation that promotes alveolar overdistention in inspiration and derecruitment on exhalation. (Chapter 47)

biovariable targeting scheme a ventilation mode that continuously monitors and makes changes based on patient and ventilator variables to mimic the natural variability of breathing. (Chapter 46)

biphasic automated external defibrillation a treatment to correct a potentially lethal heart rhythm by delivering a shock to the heart in two directions, via changing the polarity of the electrodes in the latter part of the shock delivery. (Chapter 38)

bladder pressure pressure established in the bladder. (Chapter 52)

blood-brain barrier the anatomic-physiologic feature of the brain thought to consist of walls of capillaries in the central nervous system that surround astrocytic glial membranes. This barrier separates the parenchyma of the central nervous system from blood. The blood-brain barrier prevents or slows the passage of some drugs and other chemical compounds, radioactive ions, and disease-causing organisms such as viruses from the blood into the central nervous system. (Chapter 15)

blunt trauma nonpenetrating trauma that may result in pulmonary contusion. (Chapter 30)

Board of Directors a board of directors is a group of people who jointly supervise the activities of an organization, such as the American Association for Respiratory Care (AARC). (Chapter 2)

Board of Medical Advisors (BOMA) the medical advisory group for the American Association for Respiratory Care. (Chapters 1 and 2)

body humidity absolute humidity in a volume of gas saturated at a body temperature of 37°C; equivalent to 43.8 mg/L of water in the air. (Chapter 39)

body mass index (BMI) formula for determining obesity, calculated by dividing a person's weight in kilograms by the square of the person's height in meters. (Chapter 23)

Bohr effect effect of variations in blood pH on the affinity of hemoglobin for O_2. (Chapter 12)

boiling point temperature at which the vapor pressure of a liquid exceeds atmospheric pressure. (Chapter 6)

Bourdon gauge fixed-orifice variable-pressure flowmeter. (Chapter 41)

Boyle's law law stating that with constant temperature, volume and pressure are indirectly proportional. That is, as the pressure is increased, the volume will decrease. (Chapter 6)

brachytherapy a method to deliver short-distance radiation therapy to a tumor via a bronchoscope. (Chapter 22)

bradycardia an abnormal decrease in heart rate. (Chapter 16)

bradypnea an abnormal decrease in breathing rate. (Chapter 16)

breach of contract failure, without legal excuse, to carry out the terms of a legal agreement. (Chapter 5)

breath-actuated nebulizer aerosol device responsive to the patient's inspiratory effort that reduces or eliminates aerosol generation during exhalation. (Chapter 40)

breath-enhanced nebulizer nebulizer that entrains room air in direct relation to the patient's inspiratory flow. (Chapter 40)

breathlessness distressful sensation of uncomfortable breathing that may be caused by certain heart conditions, strenuous exercise, or anxiety. (Chapter 16)

bronchial washings and brushings material sampled during bronchoscopy, specifically from instilling and withdrawing saline into the lung (washings) or inserting a brush into the lung. (Chapter 22)

Bronchial thermoplasty (BT) a nonpharmacologic treatment modality for asthma. (Chapter 22)

bronchiectasis abnormal condition of the bronchial tree characterized by irreversible dilation and destruction of the bronchial walls. (Chapters 25 and 44)

bronchiolitis acute infection of the lower respiratory tract causing expiratory wheezing, respiratory distress, inflammation, and obstruction of the bronchioles; bronchiolitis is usually caused by respiratory syncytial virus (RSV) and is most common in infants less than 2 years old. (Chapter 35)

bronchoalveolar lavage (BAL) technique used to obtain specimens from the alveolar level of the lung. BAL is performed by instilling a small volume (up to 50 mL) of normal saline solution deep into the airways and then suctioning it back. (Chapter 22)

bronchodilator a substance, especially a drug, that relaxes contractions of the smooth muscle of the bronchioles to improve ventilation to the lungs. Pharmacologic bronchodilators are prescribed to improve aeration in asthma, bronchiectasis, bronchitis, and emphysema. (Chapter 25)

bronchophony abnormal voice sounds heard over lung consolidation. (Chapter 16)

bronchopleural fistula any air communication from the lung to the pleural space. (Chapter 27)

bronchopneumonia acute inflammation of the lungs and bronchioles characterized by chills, fever, high pulse and respirator rates, bronchial breathing, cough with purulent bloody sputum, and chest pain. (Chapter 41)

bronchopulmonary dysplasia (BPD) a chronic respiratory disorder characterized by scarring of lung tissue, thickened pulmonary arterial walls, and mismatch between lung ventilation and perfusion. It often occurs in infants who have been dependent on long-term mechanical ventilation. (Chapters 35 and 42)

bronchoscopy the process of passing a bronchoscope into the airways for diagnostic testing or therapeutic purposes. (Chapter 22)

bronchospasm abnormal contraction of the smooth muscle of the bronchi, resulting in acute narrowing and obstruction. (Chapter 25)

brownian diffusion primary mechanism for deposition of small particles (<3 µm), mainly in the respiratory region where bulk gas flow ceases and most aerosol particles reach the alveoli by diffusion. (Chapter 12)

BTPS abbreviation for *body temperature, ambient pressure, saturated* (with water vapor). (Chapter 6)

buffer base total blood buffer capable of binding hydrogen ions; normal buffer base ranges from 48 to 52 mEq/L. (Chapter 14)

buffering the process of removing H^+ or OH^- in solution to minimize change in pH. (Chapter 13)

bulbar palsy a disease affecting the glossopharyngeal, vagus, accessory and hypoglossal nerves and is due to lower motor neuron pathology. (Chapter 33)

buoyancy the property that enables certain objects to float in water. (Chapter 6)

business intelligence (BI) a set of tools that permit the capture, storage, and transformation of data into useful and actionable information. (Chapter 7)

C

c wave upward bulging of the arteriovenous valves during this phase causes a slight upswing in atrial pressure graphs. (Chapter 10)

cachexia general ill health and malnutrition characterized by weakness and emaciation. (Chapter 16)

cachexic the state of being of general ill health and suffering from malnutrition. (Chapter 23)

calibration media types of equipment used to test and ensure that the output of an analyzer (blood gas) is both accurate and linear across the range of measured values. (Chapter 19)

canalicular stage in fetal development, this is the stage beginning at week 16 and continuing until week 26. (Chapter 9)

canals of Lambert openings that connect alveoli with secondary respiratory bronchioles. (Chapter 9)

cannulation the process of placing a catheter in an artery or vein. (Chapters 51)

capacity the range or limit of how much can be measured or stored in a space; it can also mean the combination of two or more lung volumes. (Chapter 20)

capillary action the basis for blood samples obtained by using a capillary tube. (Chapter 6)

capnography the process of obtaining a tracing of the proportion of CO_2 in expired air using a capnograph. (Chapters 19, 22, and 52)

capnometry measurement of CO_2 in a volume of gas, usually by methods of infrared absorption or mass spectrometry. (Chapters 19 and 52)

carbon monoxide poisoning poisoning as a result of exposure to carbon monoxide that allows the attachment of carbon monoxide to hemoglobin, preventing the attachment of O_2 to hemoglobin. (Chapter 30)

carboxyhemoglobin the compound produced by the chemical combination of hemoglobin with carbon monoxide. (Chapter 12)

cardiac output the volume of blood pumped per minute by the heart. (Chapters 10, 51 and 52)

cardiac tamponade compression of the heart caused by the collection of blood, fluid, or gas under pressure in the pericardium. (Chapter 10)

cardiopulmonary exercise evaluation (CPX) exercise-based assessment of a patient before pulmonary rehabilitation designed to determine the patient's exercise capacity and risk for desaturation. (Chapter 56)

cardiopulmonary resuscitation (CPR) basic emergency procedure for life support consisting of artificial respiration and manual external cardiac massage. (Chapters 38 and 58)

cardiorenal syndrome the combination of kidney failure resulting from a cardiac condition, frequently poor cardiac output. (Chapter 31)

cardioversion the use of electrical energy to bring an abnormal heart rhythm back to normal. (Chapter 38)

carina bifurcation of the trachea into the right and left main stem bronchi. (Chapter 9)

case report a detailed report of the symptoms, signs, diagnosis, treatment, and follow-up of an individual patient or an individual subject in clinical research. (Chapter 8)

catabolism a form of metabolism involving the breakdown of complex molecules in living organisms to form simpler ones to release of energy. (Chapter 23)

catecholamine any one of a group of sympathomimetic compounds composed of a catechol molecule and the aliphatic portion of an amine. (Chapter 36)

cation a positively charged ion. (Chapter 13)

cellular respiration the process whereby cells convert chemical energy in the three energy-yielding nutrients (CHO, protein, lipids) to the high-energy phosphorylated nucleotides comprising the currency of life. (Chapter 23)

Centers for Disease Control and Prevention (CDC) the federal agency under the U.S. Department of Health and Human Services whose main purpose is to protect public health and safety through the control and prevention of disease, injury, and disability in the United States and internationally. (Chapter 4)

Centers for Medicare and Medicaid Services (CMS) a federal agency within the US Department of Health and Human Services that administers the Medicare program and works in partnership with state governments to administer Medicaid. (Chapters 2 and 57)

central cyanosis abnormal discoloration of the skin distributed in central structures like the nose and lips. (Chapter 16)

central line–associated bloodstream infection a serious infection that occurs when microns enter the bloodstream through the central line. (Chapter 7)

central neurogenic hyperventilation breathing characterized by persistent hyperventilation driven by abnormal neural stimuli. (Chapter 16)

central neurogenic hypoventilation condition in which the respiratory centers do not respond appropriately to ventilatory stimuli, such as CO_2. It also is associated with head trauma and brain hypoxia as well as narcotic suppression of the respiratory center.

central sleep apnea absence of breathing as the result of medullary depression that inhibits respiratory movement, which becomes more pronounced during sleep. (Chapter 34)

central venous pressure (CVP) right atrial pressure. (Chapter 10)

cephalization increased visualization of pulmonary blood vessels on a chest radiograph in the nondependent regions of the lung; often a sign of left heart failure. (Chapter 21)

channel a passageway or groove that conveys fluid, such as the central channels that connect the arterioles with the venules. (Chapter 3)

Charles law a law stating that with pressure constant, the volume of a gas is directly proportional to its temperature. (Chapter 6)

chemoreceptor a sensory nerve cell activated by changes in the chemical environment surrounding it; the chemoreceptors in the carotid artery are sensitive to PCO_2 in the blood, signaling the respiratory center in the brain to increase or decrease ventilation. (Chapters 10 and 15)

chemotherapy treatment of infections and other diseases with chemical agents. (Chapter 32)

chest cuirass a device that fits over the thorax that is designed to deliver negative-pressure ventilation. (Chapter 50)

chest physical therapy (CPT) a group of therapeutic techniques designed to aid in the clearance of secretions, improve ventilation, and enhance the conditioning of the respiratory muscles; includes positioning techniques, chest percussion and vibration, directed coughing, and various breathing and conditioning exercises. (Chapter 44)

chest radiograph an x-ray image of the chest; a posteroanterior view and a lateral, or side, view are routinely obtained. (Chapter 21)

chest tube a tube inserted to monitor the rate of bleeding and determine whether the source is arterial or venous. (Chapter 27)

chest x-ray an image produced by passing x-rays through the chest to a photographic film or detector. (Chapter 21)

Cheyne-Stokes respiration an abnormal breathing pattern with periods of progressively deeper breaths alternating with periods of shallow breathing and apnea. (Chapter 16)

CHF abbreviation for *congestive heart failure;* an abnormal condition that reflects impaired cardiac output caused by myocardial infarction, ischemic heart disease, or cardiomyopathy. (Chapters 10 and 29)

chlorofluorocarbons (CFCs) gaseous chemical compounds that were originally used to power metered-dose inhalers; they are now no longer used. (Chapter 40)

cholinergic of or pertaining to nerve fibers that elaborate acetylcholine at the myoneural junctions. (Chapter 36)

chordae tendineae cordis are fibrous cords of connective tissue that connect the papillary muscles to the tricuspid valve and the bicuspid valve in the heart. (Chapter 10)

chorionic villi vascular projections arise from the chorion of the embryo and penetrate the uterine endometrium. (Chapter 9)

chronic bronchitis a common debilitating pulmonary disease characterized by a greatly increased production of mucus by the glands of the trachea and bronchi that results in a cough with expectoration for at least 3 months of the year for more than 2 consecutive years. (Chapter 25)

chronic care medical care which addresses pre-existing or long-term illness. (Chapter 55)

chronic cough a cough that lasts approximately eight weeks or longer in adults, or four weeks in children. (Chapter 16)

chyle a cloudy liquid product of digestion taken up by the small intestine. Consisting mainly of emulsified fats, chyle passes through finger-like projections in the small intestine, called *lacteals,* and into the lymphatic system for transport to the venous circulation at the thoracic duct in the neck. (Chapter 27)

chylothorax pleural fluid collection that is high in triglycerides, usually from disruption of the thoracic duct. (Chapter 27)

cilia tiny hair-like projections that line mucus-producing structures. Generally they operate in a wave-like motion to move mucus along the structure. (Chapter 9)

ciliary dyskinetic syndromes conditions in which respiratory tract cilia do not function properly. (Chapter 40)

Clara cells nonciliated cuboidal cells with apical granules. (Chapter 9)

clinical decision support (CDS) health information technology that builds on the foundation of an electronic health record to provide specific information, intelligently filtered and organized, at appropriate times to enhance health and healthcare. (Chapter 7)

clinical simulation the simulation of an actual clinical scenario using actors, manikins, and paper and pencil. (Chapter 7)

clinical staff first-line providers of respiratory care but also responders to rapid response alerts, codes, and disaster/fire emergencies. (Chapter 2)

closed buffer system a buffer system in which all components of acid-base reactions remain in the system. Products accumulate and reach equilibrium with reactants, and chemical activity ceases (no further buffering activity can take place). Closed buffer systems in the body include nonbicarbonate buffers, such as those involving plasma proteins, hemoglobin, and phosphates. (Chapter 14)

closed-loop ventilation limited, proprietary, computerized closed-loop weaning software packages that automate weaning according to set physiologic parameters. (Chapter 7)

clubbing bulbous swelling of the terminal phalanges of the fingers and toes, often associated with certain chronic lung diseases. (Chapter 16)

Coanda effect a phenomenon in hydrodynamics whereby a fluid in motion may be attracted or held to a wall. (Chapter 6)

CoBGRTE group a nationally based organization that supports the advancement of Respiratory Care education at the bachelor's and graduate degree level. (Chapter 2)

cognitive domain level of the mind comprising the processes of comprehension, judgment, memory, and reasoning. (Chapter 55)

cohesion attractive force between like molecules. (Chapter 6)

cohorting the grouping of individuals who share a common characteristic, such as the same age or sex or a common infection. (Chapter 4)

coinvestigators individuals who have a range of roles spanning screening/entering subjects into the study (including obtaining informed consent, if applicable), collecting and analyzing data, and finally assisting with writing the abstract and manuscript for publication. (Chapter 8)

cold shock cardiorespiratory reflexes reflexes activated by water temperatures below 25°C. A breathing pattern characterized by gasping followed by hyperventilation and shallow breathing at total lung capacity. (Chapter 30)

collateral circulation redundant circulation in an area of tissue or an organ that supplies blood to the tissue by more than one path. (Chapter 19)

colloids substances containing large molecules that attract and hold water; also a dispersion or gel. (Chapter 13)

Committee on Accreditation for Respiratory Care (CoARC) the committee that establishes standards and oversees approval of educational programs in respiratory care. (Chapter 1)

competencies measurable or observable skills, knowledge, behaviors, or abilities to perform a job or task. (Chapter 3)

community-acquired pneumonia an acute inflammation of the lungs contracted from the environment (as distinguished from nosocomial, or hospital-acquired, pneumonia). (Chapter 24)

compensatory justice calls for the recovery of damages resulting from the harmful action of others. (Chapter 5)

complete blood count a determination of the number of red and white blood cells per cubic millimeter of blood. A complete blood count is one of the most routinely performed tests in a clinical laboratory and one of the most valuable screening and diagnostic techniques. (Chapter 17)

compliance the volume change per unit of applied pressure. (Chapters 11 and 20)

Comprehensive Outpatient Rehabilitation Facility (CORF) a Medicare-approved facility that provides a broad scope of ambulatory rehabilitation services as defined in section 933 of Public Law 96-499. (Chapter 55)

compression atelectasis collapse of a part of the lung as a result of an external force compressing the lung. (Chapter 43)

computed tomography (CT) radiographic technique that produces a film that represents a detailed cross section of tissue structure. (Chapters 21 and 32)

computerized physician order entry (CPOE) a system by which medical orders can be electronically transmitted to the electronic health record saving time and reducing transcription errors resulting from illegible handwriting. (Chapter 7)

condensation change of state from gas to liquid, as with the condensation of water vapor. (Chapter 6)

conditions of coverage/participation a certificate awarded to institutions that meet specific standards of quality and safety as determined by the Centers for Medicare and Medicaid Services. (Chapter 57)

conduction transfer of heat by the direct interaction of atoms or molecules in a hot area that contact atoms or molecules in a cooler area. (Chapter 6)

confidentiality nondisclosure of certain information except to another authorized person. (Chapter 5)

congestive heart failure (CHF) an abnormal condition that reflects impaired cardiac pumping; caused by myocardial infarction, ischemic heart disease, or cardiomyopathy that results in either pulmonary or systemic edema. (Chapters 10 and 29)

conjugate base the base associated with the weak acid in a buffer system. (Chapter 14)

connective tissue disease a group of acquired disorders that have in common diffuse immunologic and inflammatory changes in small blood vessels and connective tissue. The causes of most of these diseases are unknown. Also called *collagen vascular disease*. (Chapter 26)

consequentialism the idea of judging an act to be right; an ethical viewpoint in which decisions are based on the assessment of consequences. (Chapter 5)

conservative fluid management a strategy of administering fluids that attempt to minimize fluid excess over output. (Chapter 29)

consultant a person who may give advice before, during, or after a study. (Chapter 8)

contact precautions safeguards designed to reduce the risk for transmission of epidemiologically important microorganisms by direct or indirect contact. (Chapter 4)

continuing respiratory care education education sought by respiratory therapists after graduation. (Chapter 7)

continuous mandatory ventilation (CMV) a system of mechanical ventilation in which the patient is allowed to initiate breathing but the ventilator delivers a set volume or pressure with each breath. The ventilator can also be programmed to initiate breathing if the patient's breathing slows beyond a certain point or stops entirely. (Chapter 46)

continuous positive airway pressure (CPAP) a method of ventilatory support whereby the patient breathes spontaneously without mechanical assistance against threshold resistance, with pressure above atmospheric maintained at the airway throughout breathing. (Chapters 34, 43, 50, 53, and 54)

continuous quality improvement (CQI) a process-based, data-driven approach that attempts to enhance the quality of care and patient safety. (Chapter 7)

continuous spontaneous ventilation (CSV) a method of delivering ventilatory support in which the patient determines when a breath is initiated and when it is terminated. (Chapter 46)

contractility the property of muscle tissue to shorten in response to a stimulus, usually electrical. (Chapters 10 and 52)

control system the system used to determine how a mechanical ventilator delivers gas (e.g., targeting schemes). (Chapter 46)

controlled ventilation the use of an intermittent positive-pressure breathing unit or other respirator that has an automatic cycling device that replaces spontaneous respiration. (Chapter 48)

convection heat transfer through the mixing of fluid molecules at different temperature states via thermal currents. (Chapter 6)

convection currents Fluid movements carrying heat energy. (Chapter 6)

coronary artery diseases (CAD) a condition in which the arteries that supply blood to heart muscle become hardened and narrowed. (Chapter 10)

coronary circulation the heart's circulatory system. (Chapter 10)

coronary sinus a large vessel wherein veins gather together which passes left to right across the posterior surface of the heart. (Chapter 10)

corticosteroid any one of the natural or synthetic hormones associated with the adrenal cortex that influence or control key processes of the body, such as carbohydrate and protein metabolism, electrolyte and water balance, and function of the cardiovascular system and kidneys. (Chapter 26)

costal cartilage fibrous tissues that connect the ribs to the sternum and to each other anteriorly. (Chapter 9)

costal groove a channel containing the thoracic artery, vein, and nerve and supplying blood flow and innervation to that region of the chest wall. (Chapter 9)

costophrenic angle an acute angle where the costal pleura meets the diaphragm. (Chapter 9)

cough a forceful expiratory effort designed to expel mucus and other foreign material from the upper airway. (Chapter 16)

crackles a discontinuous type of adventitious lung sound. (Chapter 16)

creatine phosphate a molecule that serves as a rapidly mobilizable reserve of high-energy phosphates in skeletal muscle and the brain to recycle adenosine triphosphate, the energy currency of the cell. (Chapter 23)

creatine phosphokinase (CPK) an enzyme found in your heart, brain, and skeletal muscles which leaks into the blood when muscle tissue is damaged. (Chapter 17)

creatinine a chemical waste product that's produced by your muscle metabolism and which is filtered by the kidneys. High levels are suggestive of kidney insufficiency or failure. (Chapter 23)

creatinine-height index (CHI) a method of estimating the amount of skeletal muscle mass. (Chapter 23)

credentialing the process of obtaining a recognized designation from the National Board of Respiratory Care (NBRC) which permits individuals obtaining it to apply for licensure and practice respiratory care and/or be recognized for expertise in a clinical specialty. (Chapter 2)

credentials the recognized designations from the National Board of Respiratory Care (NBRC) which permits individuals to apply for licensure and practice respiratory care and/or be recognized for expertise in a specialty area. (Chapter 2)

cricoid cartilage a ring of cartilage forming the lower border of the larynx. (Chapter 9)

critical temperature the highest temperature at which a substance can exist as a liquid, regardless of pressure. (Chapter 6)

critical test value a test result that requires its immediate communication to a physician. (Chapter 17)

croup an infectious disorder of the upper airway occurring chiefly in infants and children; it normally results in subglottic swelling and obstruction. (Chapters 41 and 42)

cryogenic related to a very low temperature. (Chapter 41)

cryotherapy treatment using the application of cold temperatures, as for airway lesions during bronchoscopy. (Chapter 22)

culture behaviors, values, and patterns of beliefs shared by a group. (Chapter 55)

current a flowing or streaming movement; a flow of electrons along a conductor in a closed circuit; an electrical current. (Chapter 3)

cuvette a small transparent tube or container with specific optical properties. The chemical composition of the container determines the vessel's use, such as Pyrex glass for examining materials in the visible spectrum or silica for examining materials in the ultraviolet range. (Chapter 19)

cyanide toxicity a result of the inhalation of gas produced by the burning of nitrogenous material. Cyanide combines with cytochrome oxide, the last receptor of the electron transport chain, which prevents the utilization of O_2. (Chapter 30)

cyanosis a bluish discoloration, especially of the skin and mucous membranes, due to excessive concentration of deoxyhemoglobin in the blood caused by deoxygenation. (Chapter 16)

cyanocobalamin chemical that reduces the half-life of the toxic compound that results from the reaction of cyanide with cytochrome oxide. (Chapter 30)

cycle asynchrony a lack of coordination of the ending of a patient's inspiration with the ending of the ventilator inspiration. (Chapter 48)

cystic fibrosis an autosomal recessive disease characterized by pancreatic insufficiency, abnormally thick secretions from the exocrine glands, and increased concentration of sodium and chloride in the sweat glands; known in Europe as *mucoviscidosis*. (Chapters 25 and 35)

cytochrome oxidase an oxidizing enzyme that contains iron and a porphyrin and is found in the mitochondrial membrane. (Chapter 30)

D

Dalton's law in physics, law stating that the total pressure exerted by a mixture of gases is equal to the sum of the pressures exerted by the individual gases if they were present alone in the container. (Chapter 6)

D-dimer small protein fragment found in the blood when fibrin clots are dissolving. (Chapter 17)

dead space respired gas volume that does not participate in gas exchange; may be anatomic, alveolar, or mechanical. (Chapter 12)

dead space/tidal volume ratio (V_D/V_T) percentage of tidal volume that does not participate in gas exchange, usually approximately 30% to 35%. (Chapter 52)

decannulation removal of a cannula or tube that may have been inserted during a therapeutic or surgical procedure. (Chapters 37 and 51)

decremental positive end-expiratory pressure (PEEP) trial progressively decreasing the amount of PEEP to assess oxygenation and hemodynamic status immediately following a recruitment maneuver. (Chapter 30)

deep breathing/directed cough movements used to improve pulmonary gas exchange or to maintain respiratory function, especially after prolonged inactivity or general anesthesia. (Chapter 43)

deep venous thrombosis (DVT) a blood clot that forms in the deep veins, usually of the legs. (Chapter 28)

defendant a person denying the party against whom relief or recovery is sought in an action or suit; also, the accused in a criminal case. (Chapter 5)

defibrillation termination of ventricular fibrillation by delivering a direct electrical countershock to the patient's precordium. (Chapter 38)

density mass per unit volume. (Chapter 6)

departmental director in respiratory therapy, this must be a highly skilled respiratory therapist; an energetic, forward-thinking, innovative individual who has as his or her primary goal high-quality patient care and the continued development of the department and the profession of respiratory care. (Chapter 2)

depolarization reduction of a membrane potential to a less negative value; in cardiac fibers, this results in the release of calcium ions into the myofibrils and activates the contractile process. (Chapter 18)

deposition testimony of a witness taken on interrogatories, either oral or in writing. (Chapter 40)

dermatomyositis a condition characterized by inflammation of the muscles and/or skin. (Chapter 33)

dewpoint temperature at which water vapor condenses back to its liquid form. (Chapter 6)

diagnosis the process of identifying the underlying cause for signs and symptoms, as in naming a patient's disease. (Chapter 16)

diameter-indexed safety system (DISS) specifications established to prevent accidental interchange of low-pressure (<200 psig) medical gas connectors. DISS is used in respiratory care to connect equipment to a low-pressure gas source. (Chapter 41)

diaphoresis secretion of sweat, especially profuse secretion associated with an elevated body temperature, physical exertion, exposure to heat, and mental or emotional stress. (Chapter 16)

diaphragm a large dome-shaped muscle that separates the thorax from the abdomen; the primary muscle of ventilation. (Chapter 9)

diaphragm dysfunction inability of the diaphragm to contract normally. (Chapter 48)

diaphragm electrical activity (EAdi) a minimally invasive bedside technology to detect diaphragmatic activity to facilitate the neurally adjusted ventilatory assist (NAVA) mode of mechanical ventilation. (Chapter 53)

diaphragm ultrasound a relatively new and promising method of evaluating and monitoring the function of the diaphragm. (Chapter 52)

diastolic pressure baseline blood pressure in the arteries during ventricular relaxation. (Chapter 16)

dicrotic notch a phenomenon caused by the elastic recoil of the arteries. (Chapter 16)

diet-induced thermogenesis the increase in energy expenditure above basal fasting level divided by the energy content of the food ingested and which is commonly expressed as a percentage. (Chapter 23)

differential diagnosis distinguishing among several diseases which share the similar signs and symptoms. (Chapter 16)

diffusing capacity of the lung (DL) the number of milliliters of gas that transfer from the lungs to the pulmonary blood per minute for each 1 mm Hg partial pressure difference between the alveoli and pulmonary capillary blood. (Chapter 20)

diffusing capacity of the lung to alveolar volume ratio ($DLCO/V_A$) index of the diffusing capacity for each 1 L of lung volume and an index of the functional alveolar surface area available for diffusion. (Chapter 20)

diffusing capacity of the lung-to–effective total lung capacity ratio index of the diffusing capacity normalized to the total lung capacity, useful to distinguish between interstitial lung disease and extrathoracic causes of restriction. (Chapter 20)

diffusion the process whereby molecules move from areas of high concentration to areas of lower concentration. (Chapter 6)

diluent a substance, generally a fluid, that makes a solution or mixture less concentrated, less viscous, or more liquid. (Chapter 13)

dilute solution a solution that contains a small amount of solute in relation to solvent. (Chapter 13)

dilution equation an equation used to determine the final concentration of a solution in which the original volume multiplied by the original concentration are equal to the final volume multiplied by the final concentration. (Chapter 13)

disease management an integrated process for the care of patients with a particular chronic disease. Generally, a multidisciplinary group of practitioners, most of whom are nonphysicians, provides this care. (Chapters 3 and 55)

disinfection the process of destroying at least the vegetative phase of pathogenic microorganisms by physical or chemical means. (Chapter 4)

distributive justice the just and proper allotment of the benefits and burdens in a society, such as taxes and subsidies. (Chapter 5)

Donnan effect of increasing osmotic pressure within the capillary. (Chapter 13)

dorsal respiratory groups (DRGs) groupings of cells in the medulla oblongata that are active in controlling inspiration. (Chapter 15)

double effect the idea that many good actions have both good and bad effects. (Chapter 5)

double triggering the activation of a second ventilator-delivered breath without exhalation after the first breath. This normally occurs when tidal volume is too small and inspiratory time is too short. (Chapter 48)

downstream reference to a point more distal from the source in a stream of flowing fluid. (Chapter 41)

driving pressure the pressure driving a fluid from one point to another. During mechanical ventilation, this is the difference between plateau pressure and positive end-expiratory pressure. (Chapters 29, 46, 47, and 52)

droplet nuclei residue of evaporated water droplets; owing to their small size (0.5 to 12 mm), droplet nuclei can remain suspended in the air for long periods. (Chapter 4)

droplet precautions safeguards designed to reduce the risk for the droplet transmission of infectious agents. (Chapter 4)

drug signaling the mechanism by which a drug exerts its effect on receptors. (Chapter 36)

dry drowning drowning that occurs without water entry into the lungs as a result of reflex laryngeal spasm. (Chapter 30)

dual targeting scheme a classification of ventilatory modes that allows the ventilator to switch between volume control and pressure control during each breath cycle. (Chapter 46)

Duchenne muscular dystrophy (DMD) an abnormal congenital condition characterized by progressive symmetric wasting of the leg and pelvic muscles; it predominantly affects males and accounts for 50% of all muscular dystrophy diseases. (Chapter 33)

ductus arteriosus a vascular channel in the fetus that joins the pulmonary artery directly to the descending aorta; it normally closes after birth. (Chapters 9 and 35)

ductus venosus a vascular channel in the fetus passing through the liver and joining the umbilical vein with the inferior vena cava; before birth, it carries highly oxygenated blood from the placenta to the fetal circulation. (Chapter 9)

durable medical equipment (DME) supplier a company that provides medical equipment to patients in the home. (Chapter 57)

durable medical equipment, prosthetics, orthotics, and supplies (DMEPOS) the collection of medical devices bundled together and designated to satisfy quality standards by the Centers for Medicare and Medicaid Services. (Chapter 57)

dynamic compression collapse of airways caused by a pressure gradient that occurs normally in diseased airways with breathing or forced breathing. (Chapter 11)

dynamic hyperinflation an increase in functional residual capacity above the elastic equilibrium volume of the respiratory system; causes include increased flow resistance, short inspiratory time, and increased postinspiratory muscle activity; see also *auto-PEEP*. (Chapters 11 and 45)

dysoxia abnormal metabolic state in which the tissues are unable to properly use the O_2 made available to them. (Chapter 12)

dyspnea difficult or labored breathing as perceived by the patient. (Chapter 16)

dysrhythmias abnormal heart rhythms. (Chapter 18)

E

ECLS extracorporeal lung support, the same process as extracorporeal membrane oxygenation. (Chapter 29)

ECMO extracorporeal membrane oxygenation is the process whereby blood is removed from the body, pumped through a membrane to exchange CO_2 for O_2, and then returned to the body. (Chapter 29)

ectopic beat impulse that originates in the heart at a site other than the sinus node. (Chapter 18)

ectopic foci origination of a heartbeat from some place in the heart other than the sinoatrial node. (Chapter 18)

educational coordinator a person tasked with individually assessing the educational needs of the respiratory therapists within the department and assigning resources to help reduce educational deficiencies. (Chapter 2)

effective total lung capacity single-breath technique distributes a gas mixture through unobstructed airways to an alveolar volume. (Chapter 20)

egophony physical examination finding of increased resonance of voice sounds when auscultating the chest (e.g., due to lung consolidation). (Chapter 43)

ejection fraction the percentage of blood that is pumped (or ejected) from the ventricles of the heart with each contraction, often separated into the right (ventricular) and left (ventricular) ejection fractions. (Chapter 10)

elastance the tendency of matter to resist a stretching force and recoil or return to its original size or form after deformation or expansion; the reciprocal of compliance. Also called *elasticity*. (Chapters 11 and 46)

elasticity ability of tissue to regain its original shape and size after being stretched, squeezed, or otherwise deformed. Muscle tissue is generally regarded as elastic because it is able to change size and shape and return to its original condition. (Chapter 11)

electrical impedance tomography (EIT) the process by which mapping of the lung is obtained by a series of electrodes placed around the chest that sequentially emit low level current. The variability among the impedance to the current between electrodes is used to map lung volume. (Chapter 52)

electrocardiogram (ECG) an important diagnostic tool used to measure the electrical activity of the heart. (Chapter 18)

electrochemical refers to processes where electrical changes drive chemical processes. (Chapter 19)

electrolyte solution a solution in which this dissociation occurs. (Chapter 13)

electromagnetic navigational bronchoscopy a bronchioscopic technique that facilitates accurate navigation to sample peripheral pulmonary target lesions. (Chapter 22)

electronic health record (EHR) the sum of all medical records produced for a patient during the different encounters with various healthcare entities throughout his or her lifetime and which are available across the continuum of care in all geographic locations. These data are stored in an electronic system. (Chapter 7)

electronic medical record (EMR) a system whereby the medical record is stored in a computer (rather than on paper records). (Chapter 7)

embryonic period the first 8 weeks of pregnancy. (Chapter 9)

E-medicine the use of computerized or digital technology to enhance efficiency and effectiveness of healthcare in general and more specifically patient care. (Chapter 7)

emitted dose the mass of drug leaving the mouthpiece of a nebulizer or inhaler as aerosol. (Chapter 40)

emphysema a destructive process of the lung parenchyma leading to permanent enlargement of the distal air spaces; classified as either centrilobular (CLE), which mainly involves the respiratory bronchioles, or panlobular (PLE), which can involve the entire terminal respiratory unit. (Chapter 25)

empyema pus within the pleural space. A Gram stain of the pleural fluid will show bacteria. (Chapters 21, 27)

end-diastolic volume (EDV) the volume of blood remaining in the ventricles just prior to contraction. (Chapter 10)

endobronchial biopsy sampling of an abnormality seen within the bronchus on bronchoscopy. (Chapter 22)

endobronchial intubation the purposeful or accidental placement of an endotracheal tube into a main stem bronchus, usually the right main stem bronchus. (Chapter 48)

endotracheal tubes artificial airways that pass through the oropharynx or nasopharynx into the trachea. (Chapter 37)

end-systolic volume (ESV) the volume of blood in the ventricles at the end of contraction, or systole. (Chapter 10)

enterprise software packages computer software used by a whole health system. (Chapter 7)

epicardium tissue that covers the outer surface of the heart and great vessels. (Chapter 10)

epiglottis flat cartilage that extends from the base of the tongue backward and upward. (Chapter 9)

epiglottitis acute, often life-threatening infection of the upper airway, which leads to severe obstruction secondary to supraglottic swelling; caused primarily by *Haemophilus influenzae* type B and affecting mainly children under 5 years of age. (Chapter 35)

epistaxis to bleed from the nose. (Chapter 9)

equal pressure point (EPP) during forced exhalation, the point along an airway where the pressure inside its wall equals the intrapleural pressure; upstream beyond this point, the pleural pressure exceeds the pressure inside the airway, tending to promote bronchiolar collapse. (Chapter 11)

equilibrium constant a constant determined by the amount of a buffer that dissociates in solution. It identifies the pH at which the buffer is most effective. (Chapter 14)

equivalent weight weight of an element in any given unit (e.g., grams) that displaces a unit weight of hydrogen from a compound or combines with or replaces a unit weight of hydrogen. (Chapter 13)

erythema reddish discoloration of a tissue, usually referring to the skin and one of the features of inflammation. (Chapter 50)

erythrocytes red blood cells. (Chapter 17)

esophageal balloon a catheter with an elongated balloon placed in the esophagus used to measure pressure change that is reflective of pleural pressure change. (Chapter 52)

esophageal pressure pressure measured inside the esophagus, often with a catheter. (Chapter 53) –

essential nutrients nutrients required for normal body functioning that cannot be synthesized by the body. (Chapter 23)

ethics consultation consultation with a group often consisting of ethicists and others regarding difficult management decisions, frequently regarding end-of-life issues. (Chapter 58) consultation with a group often consisting of ethicists and others regarding difficult management decisions, frequently regarding end-of-life issues

eustachian tubes bilateral tubes that connect the nasopharynx to the middle ear and mastoid sinus. (Chapter 9)

euthanasia the act of putting to death a person (or animal) suffering from a painful or prolonged illness or injury. Someone other than the patient commits the action to end the patient's life, usually by the injection of medicine. (Chapter 58)

evaporation change in state of a substance from a liquid to a gaseous form occurring below its boiling point. (Chapter 6)

evidence-based medicine an approach to medical practice intended to optimize decision making by emphasizing the use of evidence from well-designed research projects. (Chapter 8)

excessive daytime sleepiness sleepiness during the day to an abnormal extent, sometimes associated with narcolepsy. (Chapter 34)

excitability the ability of cells to respond to electrical, chemical, or mechanical stimulation. (Chapter 10)

expiratory cycling criteria the criteria employed by the ventilator to transition from inspiration to exhalation. In pressure support ventilation, this is usually flow. (Chapter 48)

expiratory positive airway pressure (EPAP) the application of positive pressure to the airway during exhalation. Compare with *inspiratory positive airway pressure*. (Chapter 50)

expiratory reserve volume the total amount of gas that can be exhaled from the lung after a quiet exhalation. (Chapter 20)

external nares the external openings of the nasal passages. (Chapter 9)

external respiration the part of the respiratory process that involves the exchange of gases in the alveoli of the lungs. (Chapter 9)

extracellular outside of the cell. (Chapter 13)

extracorporeal carbon dioxide removal ($ECCO_2R$) the procedure whereby blood is passed from the patient through an external membrane, which filters CO_2 to support ventilation. (Chapter 29, 51)

extracorporeal life support (ECLS) several forms of mechanical support, all of which involve circulating blood from a patient to outside the body through a mechanical gas exchanger and returning it back to the patient. (Chapter 51)

extracorporeal membrane oxygenation (ECMO) the procedure whereby venous blood is pumped outside the body to a heart-lung machine for oxygenation and returned to the body. (Chapters 29 and 51)

extrapolated volume The volume exhaled before the zero time point. (Chapter 20)

extremely low birth weight (ELBW) describes a neonate weighing less than 1 kg at birth. (Chapter 54)

extubation the process of withdrawing a tube from an orifice or cavity of the body. (Chapter 37)

exudate fluid oozing from cells and tissues. (Chapter 30)

exudative relating to the oozing of fluid and other materials from cells and tissues, usually as a result of inflammation or injury. (Chapter 42)

exudative pleural effusion any pleural effusion high in protein or lactate dehydrogenase, which implies inflammation or vascular injury on the pleural surface. (Chapter 27)

F

factitious events values that are real but "out of range" and often temporary, such as the elevation in airway pressure during a cough. (Chapter 52)

false ribs of the 12 pairs of ribs forming a large part of the thoracic skeleton, the first 7 are called *true ribs* and the next 5 are called *false ribs;* the first 3 attach to the ribs above and the last 2 are free. (Chapter 9)

fasciotomy a surgical procedure that cuts away the fascia to relieve tension or pressure. Used to treat burn patients with severe scar formation. (Chapter 30)

fatigue the inability of a muscle to carry its normal load. (Chapter 48)

febrile describing a person who has a fever. (Chapter 16)

feedback in communication theory, information produced by a receiver and perceived by a sender that informs the sender of the receiver's reaction to the message. Feedback is a cyclic part of the process of communication that regulates and modifies the content of messages. (Chapter 3)

Fellow of the American Association for Respiratory Care (FAARC) a person who has been recognized for the AARC for sustained and substantial contributions to the field of respiratory care. (Chapter 1)

fenestrated an opening into a structure; from the Latin *fenestra,* meaning "window." (Chapter 37)

fetal hemoglobin (HbF) hemoglobin variant that has a greater affinity for O_2 than adult hemoglobin; HbF is gradually replaced over the first year of life by HbA. (Chapter 12)

fetal lung fluid a unique combination of plasma ultrafiltrate from the fetal pulmonary microcirculation, components of pulmonary surfactant, and other fluids from pulmonary epithelial cells and the developing fetus. (Chapter 9)

fetal period the remaining 32 weeks of pregnancy. (Chapter 9)

fetid foul smelling. (Chapter 16)

fever abnormal elevation of body temperature owing to disease. (Chapter 16)

fiberoptic bundles individual coated fibers (or fibers formed into ribbons or bundles) that have a tough resin buffer layer; they are used to transmit light from a light source to view the airways through a bronchoscope. (Chapter 22)

fibrous pericardium a tough, loose-fitting, inelastic sac surrounding the heart. (Chapter 10)

Fick equation an equation for computing cardiac output based on knowledge of O_2 consumption and the arteriovenous O_2 content difference. (Chapters 12 and 52)

Fick's first law of diffusion law for determining the rate of gaseous diffusion across biologic membranes. (Chapter 12)

filling density ratio between the weight of liquid gas put into a cylinder and the weight of water the cylinder could contain if full. (Chapter 41)

fine-particle fraction particles that are small enough to reach the lower respiratory tract. (Chapter 40)

fissures narrow clefts or slits; the lines that divide or separate the lobes of the lung glottis. (Chapter 9)

fixed (nonvolatile) acid titratable, nonvolatile acid representing the by-product of protein catabolism; examples include phosphoric acid and sulfuric acid. (Chapter 14)

flammable the ability of a substance to burn or ignite, causing fire or combustion. (Chapter 41)

flexible bronchoscopy a bronchoscopy that is flexible in structure, allowing it to be placed deep into the respiratory tract. (Chapter 32)

floating ribs last two rib pairs that are free at their ventral extremities. (Chapter 9)

flow asynchrony asynchrony as a result of the ventilator not providing sufficient flow to meet the patient's inspiratory demand. Most commonly occurs in volume ventilation. (Chapter 47)

flowmeter device operated by a needle valve that controls and measures gas flow according to the principles of viscosity and density. (Chapter 41)
flow resistance the difference in pressure between the two points along a tube, divided by the actual flow. (Chapter 6)
fluvial or brackishwater sea water used in reference to drowning. (Chapter 30)
fomites nonliving material, such as bed linens or equipment, which may transmit pathogenic organisms to a person who comes into contact with the object. (Chapters 4 and 24)
foramen ovale opening in the septum between the right and the left atria in the fetal heart. This opening provides a bypass for blood that would otherwise flow to the fetal lungs. After birth, the foramen ovale closes. (Chapters 9 and 10)
forced expiratory technique (FET) modification of the normal cough sequence designed to facilitate clearance of bronchial secretions while minimizing the likelihood of bronchiolar collapse. (Chapter 44)
forced expiratory volume in 1 second (FEV_1) the maximum volume of gas that the patient can exhale during the first second of the forced vital capacity maneuver. (Chapter 20)
forced expiratory volume in 1 second–to–vital capacity ratio (FEV_1/FVC) the percent of the measured forced vital capacity that can be exhaled in 1 second. (Chapter 20)
forced expiratory volume in 1/2 second ($FEV_{0.5}$) the maximum volume of gas that the patient can exhale during the first half-second of a forced vital capacity maneuver. (Chapter 20)
forced vital capacity (FVC) the maximum volume of gas that the subject can exhale as forcefully and as quickly as possible. (Chapter 20)
formalism ethical viewpoint that relies on rules and principles. (Chapter 5)
fractional distillation the process of separating the components of a liquid mixture according to their boiling points via the application of heat; the primary commercial process used to produce O_2. (Chapter 41)
Frank-Starling principle rule stating that the more a muscle fiber is stretched, the greater the tension the fiber generates when contracted. (Chapter 10)
frequency/tidal volume ratio (f/V_T) ratio of the tidal volume in milliliters divided by the respiratory rate. (Chapter 52)
full ventilatory support ventilatory support modes in which the ventilator provides all of the patient's minute ventilation requirements. (Chapter 49)
functional residual capacity (FRC) the total amount of gas left in the lungs after a resting expiration. (Chapter 20)

G

gallop rhythm an abnormal heart sound that resembles the gallop of a horse; it most often indicates heart failure. (Chapter 16)
gas absorption atelectasis collapse of airways due to hyperoxygenation and nitrogen washout. (Chapter 43)
gaseous diffusion the process whereby gas molecules move from an area of high partial pressure to an area of low partial pressure. (Chapter 12)
gastric inflation the introduction of air into the stomach and intestines. (Chapter 38)
gastroesophageal reflux disease (GERD) a condition characterized by the abnormal movement of stomach contents into the esophagus or mouth; acid from the stomach may be aspirated into the lung and cause asthma-like symptoms. (Chapter 35)
geometric standard deviation (GSD) describes the variability of particle size in an aerosol distribution set at 1 standard deviation above and below the median. (Chapter 40)
gladiolus the body of the sternum. (Chapter 9)
Glasgow Coma Scale (GCS) scale used to score the level of conscious awareness in patients suspected of having an acute brain injury. (Chapters 30 and 52)
glomerular filtration rate the volume of water filtered out of the plasma through glomerular capillary walls into Bowman's capsule in the kidney per unit of time. (Chapter 30)
glottis the variable opening between the vocal cords. (Chapter 9)
gluconeogenesis the process of converting liver glycogen stores into glucose. (Chapter 23)
glucose a simple sugar which is an important energy source in living organisms and is a component of many carbohydrates. (Chapter 17)
goals of care an organizing framework for a seriously ill patient's overall care. (Chapter 58)
Graham's law law stating that the rate of diffusion of a gas through a liquid (or the alveolar-capillary membrane) is directly proportional to its solubility coefficient and inversely proportional to the square root of its density. (Chapter 6)
ground the connection between the electrical circuit and the ground, which becomes a part of the circuit. (Chapter 3)
grunting an expiratory sound caused by the sudden closure of the glottis during exhalation to maintain functional residual capacity and prevent alveolar atelectasis. (Chapter 9)
grunting, flaring, and retracting (GFR) the respiratory pattern observed in infants in marked respiratory distress. The neonate makes a grunting sound during breathing with flaring of the nostrils. (Chapter 54)
Guillain-Barré syndrome idiopathic, peripheral polyneuritis characterized by lower extremity weakness that progresses to the upper extremities and face; may lead to flaccid paraplegia and marked respiratory muscle weakness. (Chapter 33)

H

Haldane effect influence of hemoglobin saturation with O_2 on CO_2 dissociation. (Chapter 12)
Hamburger phenomenon the shifting of Cl ions out of the red blood cell as HCO ion is formed in the cell by hydrolysis (combination of CO_2 with H_2O). (Chapter 12)
hard palate the anterior roof of the oral cavity. (Chapter 9)
Harris-Benedict equation equation used to estimate the caloric expenditure in normal individuals under conditions of minimal activity. (Chapter 52)
healthcare agent and durable power of attorney for healthcare a named individual who has been given authority by another person to make decisions regarding her/his healthcare when the individual is not competent to make those decisions. (Chapter 58)
healthcare-associated infection (HAI) an infection that develops from a hospital or other healthcare environment. (Chapter 4)
health education the process of planned learning opportunities designed to enable individuals to make informed decisions about and act to promote their own health. (Chapter 55)
health informatics the systematic application of information and computer science and technology to clinical or public health practice. (Chapter 7)
Health Information Technology for Economic and Clinical Health Act (HITECH Act) part of a national strategy for building a national health information infrastructure that, among other things, began providing incentives to hospitals, physicians, and other health service providers who demonstrate that they are meaningfully using their electronic health records by meeting predefined standards. (Chapter 7)
health literacy the degree to which individuals can obtain, process, and understand basic health information to make appropriate health decisions and recommendations. (Chapter 55)
health promotion the combination of educational, organizational, economic, and environmental support necessary for behavior conducive to health; includes both disease prevention and wellness activities. (Chapter 55)
Healthcare Infection Control Practices Advisory Committee a federal advisory committee appointed to provide advice and guidance to government agencies regarding the practice of infection control and strategies for surveillance, prevention, and control of healthcare-associated infections, antimicrobial resistance and related events in United States healthcare settings. (Chapter 4)
heart failure the condition that occurs when a person's heart is weakened and not able to pump blood the way it should, causing the ejection fraction (EF) to fall below normal, healthy levels. (Chapter 10)
heart rate (HR) the number of heartbeats per unit of time, usually expressed as beats per minute. (Chapter 10)
heat and moisture exchanger (HME) a device that recirculates moisture from exhaled gas to humidify the next inhaled breath. (Chapter 39)
heave a precordial impulse that may be felt (palpated) in patients with cardiac or respiratory disease. (Chapter 16)
heliox a low-density therapeutic mixture of helium with at least 20% O_2; used in some centers to treat large airway obstruction. (Chapter 41)

heliox therapy a treatment used to reduce the work of breathing, especially in patients with severe acute asthma or upper airway obstructions, until the primary problem can be resolved. (Chapter 42)

hematemesis the vomiting of blood. (Chapter 16)

hematocrit the packed red blood cell volume in relation to total blood volume, expressed as a percentage. (Chapter 17)

hematology the branch of medicine involved in the study of blood morphology, physiology, and pathology. (Chapter 17)

hemolysis rupture of red blood cells. (Chapter 17)

hemoptysis the coughing up of blood from the lungs. (Chapter 16)

hemothorax accumulation of blood in the pleural cavity. (Chapter 27)

Henderson-Hasselbalch (H-H) equation an equation enabling the determination of pH as a measure of acidity (using pK_a, the negative log of the acid dissociation constant) in biological and chemical systems. (Chapter 14)

Henry's law in physics, a law stating that the solubility of a gas in a liquid is proportional to the pressure of the gas if the temperature is constant and if the gas does not chemically react with the liquid. (Chapter 6)

hepatomegaly abnormal enlargement of the liver; usually a sign of disease. (Chapter 16)

Hering-Breuer inflation reflex a parasympathetic inflation reflex mediated via the lung's stretch receptors that appears to influence the duration of the expiratory pause occurring between breaths. (Chapter 15)

Hertz (Hz) a unit derived from time which measures frequency in the International System of Units (SI). A frequency of 1 hertz means that something happens once a second. (Chapter 44)

heterodispersing referring to an aerosol consisting of particles of varying diameters and sizes. (Chapter 40)

high-flow nasal cannula (HFNC) a variation of the standard nasal cannula that can deliver both FiO_2 and relative humidity greater than 90% by using heated, humidified O_2 with flows up to 50 L/min. These systems have been shown to successfully treat moderate hypoxemia through a combination of a high FiO_2, distending PAP, and meeting or exceeding the patient's minute ventilation. (Chapters 42 and 43)

high-efficiency particulate air/aerosol filters a filter which is capable of filtration to a standard. Specifically, HEPA is an acronym for "High Efficiency Particulate Air" or "High Efficiency Particulate … the filter to capture 99.97% of the 0.3-micron (0.000012-inch) particles in the air. (Chapter 4)

high-flow system O_2 therapy equipment that supplies inspired gases at a consistent preset O_2 concentration. (Chapter 42)

high-frequency chest wall compression (HFCWC) a mechanical technique for augmenting secretion clearance; small gas volumes are alternately injected into and withdrawn from a vest by an air-pulse generator at a fast rate, creating an oscillatory motion against the patient's thorax. (Chapter 44)

high-frequency oscillatory ventilation (HFOV) a type of mechanical ventilation which utilizes a respiratory rate greater than four times the normal value and very small tidal volumes. (Chapters 49)

high-frequency ventilation (HFV) ventilatory support provided at rates significantly higher than normal breathing frequencies. (Chapters 29 and 54)

hilum vertical opening on either side of the mediastinum through which all the airways and pulmonary vessels pass. (Chapter 9)

home sleep test (HST) a test done in the patient's home (vs. in a sleep laboratory) to assess for sleep-disordered breathing, e.g., simplified with monitoring oxygen and breathing effort. (Chapter 57)

homeostasis relative constancy in the internal environment of the body, naturally maintained by adaptive responses that promote healthy survival. (Chapter 17)

Hoover sign inward movement of the lower lateral margins of the chest wall with each inspiratory effort owing to a low, flat diaphragm as seen in emphysema. (Chapter 16)

Hospital Readmission Reduction Program (HRRP) a Medicare value-based purchasing program that reduces payments to hospitals with excess readmissions. (Chapter 24)

hospital-acquired or nosocomial infection infection acquired at least 72 hours after hospitalization, often caused by *Candida albicans, Escherichia coli,* hepatitis viruses, herpes zoster virus, *Pseudomonas,* or *Staphylococcus.* (Chapter 4)

hospital-acquired pneumonia (HAP) a lower respiratory tract infection that develops in hospitalized patients more than 48 hours after admission and excludes community-acquired infections that are incubating at the time of admission. (Chapter 24)

huff coughing a type of forced expiration with an open glottis to replace coughing when pain limits normal coughing. (Chapter 44)

humidifier a device that adds molecular water to gas. (Chapter 39)

humidity deficit a condition associated with a BH less than 100% that represents the amount of water vapor the body must add to the inspired gas to achieve saturation at body temperature (37°C). (Chapter 6)

hydrofluoroalkane (HFA) the current gaseous chemical compound used to power metered-dose inhalers. (Chapter 40)

hydrophilic having a tendency to mix with, dissolve in, or be wetted by water. (Chapter 13)

hydrophilic drugs drugs with strongly polar groups that readily interact with water. (Chapter 30)

hydrophobic pertaining to the property of repelling water molecules, a quality possessed by nonpolar radicals or molecules that are more soluble in organic solvents than in water. (Chapter 39)

hydropneumothorax a pneumothorax that is partially filled with fluid. (Chapter 21)

hydrostatic relating to the pressure of fluids or to their properties when in equilibrium. (Chapter 27)

hydrostatic pressure pressure caused by the weight of fluid; related to the volume of fluid in a container and the effects of gravity. (Chapter 13)

hydrostatic pulmonary edema pulmonary edema caused by an increase in hydrostatic (water) pressure. (Chapter 29)

hygrometer an instrument that directly measures the relative humidity of the atmosphere or the proportion of water in a specific gas or gas mixture without extracting the moisture. (Chapters 6 and 39)

hygroscopic attracting or absorbing moisture from the air. (Chapters 39 and 40)

hyperbaric oxygen (HBO) therapy therapeutic application of O_2 at pressures greater than 1 atm (or 760 mm Hg). Also called *hyperbaric oxygenation.* (Chapter 42)

hypercalcemia greater than normal amounts of calcium in the blood, most often resulting from excessive bone resorption and release of calcium, as occurs in hyperparathyroidism, metastatic tumors of bone, Paget disease, and osteoporosis. (Chapter 13)

hypercapnia the abnormal presence of excess amounts of CO_2 in the blood (in arterial blood, PCO_2 >45 mm Hg). (Chapter 14)

hypercapnic respiratory failure inability to breathe characterized by the abnormal accumulation of carbon dioxide in the blood. (Chapter 50)

hypercapnic respiratory failure (type II) the inability to maintain normal removal of CO_2 from the tissues; may be indicated by $PaCO_2$ greater than 50 mm Hg in an otherwise healthy individual. See *ventilatory failure.* (Chapter 45)

hyperglycemia an abnormally elevated blood glucose level most often resulting from either diabetes or severe sepsis. (Chapter 17)

hyperkalemia greater than normal amounts of potassium in the blood. (Chapters 13 and 17)

hypernatremia a greater than normal concentration of sodium in the blood caused by excessive loss of water and electrolytes secondary to polyuria, diarrhea, excessive sweating, or inadequate water intake. (Chapter 17)

hyperoxemia higher than normal levels of oxygen in the blood. (Chapter 42)

hyperoxic acute lung injury the condition formerly known as oxygen toxicity. (Chapter 42)

hyperphosphatemia elevated serum levels of phosphate. (Chapter 13)

hypersensitivity pneumonitis an inflammatory form of interstitial pneumonia resulting from an immunologic reaction in a hypersensitive person. The reaction may be provoked by various inhaled organic dusts, often containing fungal spores. The disease can be prevented by avoiding contact with the causative agents. Also called *extrinsic allergic alveolitis.* (Chapter 26)

hypertension high blood pressure. (Chapter 16)

hypertonic solutions with more tonicity (more oncotic pressure and higher concentration as a result of less water). (Chapter 13)

hyperventilation ventilation greater than necessary to meet metabolic needs; signified by PCO_2 less than 35 mm Hg in the arterial blood. (Chapter 11)

hypocalcemia low serum levels of Ca^{2+}. (Chapter 13)

hypocapnia the presence of lower than normal amounts of CO_2 in the blood (in arterial blood, PCO_2 <35 mm Hg). (Chapter 14)

hypoglycemia a lower than normal amount of glucose in the blood, usually caused by administration of too much insulin, excessive secretion of insulin by the islet cells of the pancreas, or dietary deficiency (normal blood glucose levels range from 70 to 105 mg/dL). (Chapter 17)
hypokalemia a condition in which an inadequate amount of potassium, the major intracellular cation, is found in the circulating bloodstream. (Chapters 13 and 17)
hyponatremia a lower than normal concentration of sodium in the blood, caused by inadequate excretion of water or by excessive water in the circulating bloodstream. (Chapter 17)
hypoperfusion decreased pumping of the heart resulting in inadequate organ perfusion. (Chapter 31)
hypopharynx the lower portion of the upper airway between the oropharynx and the larynx. (Chapter 9)
hypoplastic lungs underdeveloped lungs. (Chapter 9)
hypotension an abnormal condition in which the blood pressure is inadequate for normal perfusion and oxygenation of the tissues. (Chapter 16)
hypothermia an abnormal and dangerous condition in which the temperature of the body is less than 32°C, usually caused by prolonged exposure to cold. (Chapters 16 and 39)
hypothesis a proposed explanation for a phenomenon to be proven or disproven through well-founded research. (Chapter 8)
hypotonic having a tonicity less than that of normal saline (0.9% NaCl). (Chapter 13)
hypoventilation ventilation less than necessary to meet metabolic needs; signified by PCO_2 greater than 45 mm Hg in the arterial blood. (Chapter 11)
hypovolemia an abnormally low circulating blood volume. (Chapter 16)
hypoxemia an abnormal deficiency of O_2 in the arterial blood. (Chapters 12 and 42)
hypoxemic respiratory failure the inability to maintain normal oxygenation in the arterial blood. (Chapter 50)
hypoxemic respiratory failure (type I) inability to breathe characterized by lower than normal blood oxygen levels. (Chapter 45)
hypoxia an abnormal condition in which the O_2 available to the body cells is inadequate to meet metabolic needs. (Chapter 12)
hysteresis the failure of two associated phenomena to coincide, as in the observed difference between the inflation and deflation volume-pressure curves of the lung. (Chapter 11)

I

ideal body weight the optimal weight associated with maximum life expectancy for a given height. (Chapter 23)
idiopathic pulmonary fibrosis the formation of scar tissue in the connective tissue of the lungs without known cause resulting in severe chronic restrictive lung disease. (Chapter 26)
impedance threshold device a valve used in cardiopulmonary resuscitation (CPR) to decrease intrathoracic pressure and improve venous return to the heart. (Chapter 38)
impulse-conducting system Purkinje fibers within the heart muscle that conduct impulses controlling the contractions of the atria and ventricles. (Chapter 18)
incentive spirometry the process of encouraging a bedridden patient to take deep breaths to avoid atelectasis; most often done with the use of an incentive spirometer that provides feedback to the patient when a predetermined lung volume is reached during inspiration. (Chapter 43)
indirect calorimetry measurement of the amount of energy a body consumes (in kcal) by determining the consumption of O_2 and production of CO_2. (Chapter 23)
inertial impaction the deposition of particles by collision with a surface; primary mechanism for pulmonary deposition of particles greater than 5 mm in diameter. (Chapter 40)
infiltrates fluids that pass through body tissues into a space or virtual space, as seen in the lung. (Chapter 21)
information retrieval gathering information, often from an electronic medical record. (Chapter 7)
informed consent permission granted based on full knowledge of the possible consequences of participating, often used in the context of participating in a research study. (Chapter 5)
inhaled mass the mass of the particles inhaled from an aerosol. (Chapter 40)
inhaled nitric oxide (INO) gas that is administered to decrease pulmonary hypertension. (Chapter 54)
innominate artery rupture a rupture of the innominate artery usually as a result of a tracheostomy tube eroding the tissue leading to the artery and eventually causing the artery to rupture. (Chapter 48)
inotropic support a way of enhancing cardiac output, either by medication or mechanically. (Chapter 31)
insensible nonmeasurable. (Chapter 13)
inspiratory capacity (IC) the maximum amount of air that can be inhaled from the resting end-expiratory level or functional residual capacity; sum of the tidal volume and inspiratory reserve volume. (Chapter 20)
inspiratory positive airway pressure (IPAP) application of positive pressure to the airway during inspiration. (Chapter 50)
inspiratory reserve volume (IRV) maximum volume of air that can be inhaled after a normal quiet inspiration. (Chapter 20)
inspiratory-to-expiratory ratio (I/E) the relationship between the time involved in inhalation versus that related to the exhalation portion of the breathing cycle, expressed as a proportion. (Chapter 29)
inspissated describing a fluid that is thickened or hardened through the absorption or evaporation of the liquid portion, as can occur with respiratory secretions when the upper airway is bypassed. (Chapters 39)
inspissation the process of becoming thickened, often referring to mucus. (Chapter 44)
Institutional Review Board an administrative body established to protect the rights and welfare of human research subjects recruited to participate in research activities conducted under the auspices of the **institution** with which it is affiliated. (Chapter 8)
insufflator-exsufflator a mechanical device that provides an artificial cough by alternately applying positive pressure and negative pressure to the airway. (Chapter 57)
intelligent targeting scheme a ventilator control system that uses artificial intelligence programs such as fuzzy logic, rule-based expert systems, and artificial neural networks. (Chapter 46)
intellivention the ability of a mechanical ventilator to utilize programmed algorithms to either make or recommend setting changes, including those related to weaning and discontinuance. (Chapter 53)
interatrial septum the wall separating the two atria in the heart. (Chapter 10)
intercostal nerves the nerves serving the intercostal muscles. (Chapter 9)
interdisciplinary collaboration working together by individuals in different medical disciplines, e.g., respiratory therapists with nurses and/or doctors. (Chapter 58)
intermittent mandatory ventilation (IMV) mode of mechanical ventilatory support in which the patient receives a preset number of machine breaths per minute set by time. The patient is allowed to breathe spontaneously as often as desired in between machine breaths. Depending on the base rate, IMV can provide partial or full ventilatory support. (Chapter 46)
intermittent positive-pressure breathing (IPPB) the application of positive-pressure breaths to a patient for a relatively short period (10 to 20 minutes). (Chapter 43)
internal respiration the exchange of O_2 and CO_2 at the tissue level. (Chapter 9)
International Council for Respiratory Care (ICRC) a diverse group of worldwide health professionals addressing issues affecting educational, medical, and professional trends in the global respiratory care community. (Chapters 1 and 2)
International Organization for Standardization an international standard-setting body composed of representatives from various national standards organizations. (Chapter 39)
interstitial fluid fluid between cells but outside of the vascular spaces. (Chapter 13)
interstitial lung disease (ILD) respiratory disorder characterized by a dry, unproductive cough and dyspnea on exertion. X-ray films usually show fibrotic infiltrates in the lung tissue, usually in the lower lobes. (Chapters 21 and 26)
interventricular septum the wall in the heart separating the right and left lower chambers (ventricles). (Chapter 10)
intervillous spaces an embryologic term describing the space between the structures (villi)containing the vessels of the mother and the embryo. (Chapter 9)

intracellular fluid fluid within cells. (Chapter 13)
intrapulmonary percussive ventilation (IPV) airway clearance technique that uses a pneumatic device to deliver a series of pressurized small volume breaths at high rates (1.6 to 3.75 Hz) to the respiratory tract, usually via a mouthpiece; usually combined with aerosolized bronchodilator therapy. (Chapter 44)
intubation passage of a tube into a body aperture; commonly refers to the insertion of an endotracheal tube within the trachea. (Chapter 37)
intuitionism an ethical viewpoint that holds that there are certain self-evident truths, usually based on moral maxims such as "treat others fairly." (Chapter 5)
invasive characterized by a tendency to spread or infiltrate; also refers to the use of diagnostic or therapeutic methods requiring access to the inside of the body. (Chapter 19)
ionic electrovalent; relating to or containing matter in the form of charged atoms or groups of atoms. (Chapter 13)
iron lung full-body negative-pressure ventilator. (Chapter 50)
ischemia decreased oxygen supply. (Chapter 10)
isohydric buffering a buffering process where the H ion produced by one buffer system is immediately buffered by another, such as the buffering of H ion by hemoglobin when H ion is formed by the combination of CO_2 and H_2O in the red blood cell. (Chapter 14)
isothermic saturation boundary (ISB) the point at which inspired gas becomes fully saturated to 100% relative humidity at body temperature. (Chapter 39)
isotonic describing a solution having the same concentration of solute as another solution and exerting the same amount of osmotic pressure as that solution, such as an isotonic saline solution that contains an amount of salt equal to that found in the extracellular fluid. (Chapter 13)

J

jet entrainment the design principle used in simple O_2 masks with variable FiO_2 settings. (Chapter 6)
Jidoka a joining of automation and human intelligence that results in a higher level of quality control. (Chapter 3)
Joint Commission a private nongovernment agency that establishes guidelines for the operation of hospitals and other healthcare facilities, conducts accreditation programs and surveys, and encourages the attainment of high standards of institutional medical care in the United States; formerly Joint Commission on Accreditation of Healthcare Organizations (JCAHO). (Chapter 2)
Joule-Thompson phenomenon effect phenomenon of expansion cooling. (Chapter 6)
J receptors C fibers in the lung parenchyma near the pulmonary capillaries, also called juxtacapillary receptors. (Chapter 15)
jugular venous distention abnormal distention of the jugular veins, most often caused by heart failure. (Chapter 16)
justice principle of fair and equal treatment for all, with due reward and honor. (Chapter 5)

K

Karvonen formula a simple formula used to set a target heart rate for patients during exercise. (Chapter 56)
Kerley B lines thin lines seen near the pleural edge on a chest film as a result of increased pulmonary capillary pressures. (Chapter 21)
key performance indicators specific measures which are used to determine the level of quality outcomes within a healthcare setting. (Chapter 7)
kilocalorie a unit of energy equal to 1000 calories. (Chapter 23)
kinetic energy energy a body possesses by virtue of its motion. (Chapter 6)
Krebs cycle (tricarboxylic acid [TCA] cycle) the sequence of reactions occurring inside the mitochondrion by which most living cells generate energy during the process of aerobic respiration. (Chapter 23)
Kussmaul breathing type of breathing observed during severe metabolic acidosis whereby patients breathe rapidly and deeply, similar to the breathing of a normal person during strenuous exercise. (Chapter 16)
Kussmaul sign paradoxical increase in venous pressure with distention of the jugular veins during inspiration, as seen in constrictive pericarditis or mediastinal tumor. (Chapter 16)
kwashiorkor a disease involving protein-energy malnutrition due to the stress of disease and the resulting increase in catabolic rate. (Chapter 23)
kyphoscoliosis abnormal condition characterized by anteroposterior and lateral curvature of the spine. (Chapter 33)

L

L/S ratio the ratio of lecithin to sphingomyelin in amniotic fluid, a test of fetal amniotic fluid to assess for fetal lung immaturity. (Chapter 9)
lactate anion of lactic acid. (Chapter 17)
Lambert-Eaton syndrome a disorder of neuromuscular conduction commonly associated with an underlying malignancy that leads to muscle weakness, frequently with sensory deficits that can often be improved by repetitive muscle contraction against pressure. (Chapter 33)
laminar flow a pattern of flow consisting of concentric layers of fluid flowing parallel to the tube wall at linear velocities that increase toward the center. (Chapter 6)
Laplace law principle of physics that the tension on the wall of a sphere is the product of the pressure times the radius of the chamber and that the tension is inversely related to the thickness of the wall. (Chapter 6)
large cell carcinoma type of lung cancer characterized by large cells. (Chapter 32)
large for gestational age (LGA) refers to an infant whose fetal growth was accelerated and whose size and weight at birth are above the 90th percentile of appropriate-for-gestational-age infants, whether delivered prematurely, at term, or later than term. (Chapter 54)
laryngectomy the surgical removal of the larynx. (Chapter 37)
laryngopharynx one of the three regions of the throat, extending from the hyoid bone to the esophagus. (Chapter 9)
larynx organ of the voice that is part of the upper air passage connecting the pharynx with the trachea. It accounts for a large bump in the neck called the *Adam's apple* and is larger in men than in women, although it remains the same size in boys and girls until puberty. (Chapter 9)
laser photocoagulation a means of using a laser with a bronchoscope to stop the bleeding in the airway. (Chapter 22)
latent heat of fusion the amount of heat at a substance's melting point required to change 1 g of the substance from a solid to a liquid. (Chapter 6)
latent heat of vaporization the amount of heat at a substance's boiling point required to change 1 g of the substance from a liquid to a gas. (Chapter 6)
law of continuity law saying that the velocity of a fluid moving through a tube varies inversely with the available cross-sectional area. (Chapter 6)
laws of thermodynamics laws that describe the relation between temperature and the kinetics of matter changing its state. (Chapter 6)
lean management a business management philosophy that focuses on eliminating waste or non–value-added activities. (Chapter 3)
learning management systems computerized web-based platforms that are used to offer courses and other learning resources. (Chapter 7)
left ventricular aid a mechanical pump that is implanted in patients with heart failure to help the heart pump blood. (Chapter 10)
left ventricular heart failure poor pumping of the heart involving the left ventricle. (Chapter 31)
leukocytes white blood cells. (Chapter 17)
leukocytosis abnormal increase in the number of circulating white blood cells. (Chapter 17)
leukopenia a low white blood cell count. (Chapter 17)
leukotriene class of biologically active compounds that occur naturally in leukocytes and produce allergic and inflammatory reactions similar to histamine. They are thought to play a role in the development of allergic and autoallergic diseases such as asthma, rheumatoid arthritis, inflammatory bowel disease, and psoriasis. (Chapter 36)
libel false accusation written, printed, or typewritten or presented in a picture or a sign that is made with malicious intent to defame the reputation of a person who is living or the memory of a person who is dead, resulting in public embarrassment, contempt, ridicule, or hatred. (Chapter 5)
licensure the granting or regulation of licenses, as for professionals. (Chapter 2)
life-sustaining treatment treatment that is preventing imminent death, such as mechanical ventilation, blood pressure-sustaining medications, cardiopulmonary resuscitation. (Chapter 58)

linearity refers to the accuracy of the instrument over its entire range of measurement, or its capacity. (Chapter 20)
lipophilic drugs drugs that can readily dissolve in lipid substances. (Chapter 30)
living will advance declaration by a patient that indicates agreement between a patient and physician to withhold heroic measures if the patient's condition is found to be irreversible. (Chapter 5)
loaded breathing breathing under conditions where breathing is challenged, as by a superimposed resistance to inspiration. (Chapter 46)
lobar atelectasis a collapsing of the airways and or alveoli limited to one lung segment. (Chapter 43)
long-term subacute care hospitals (LTACHs) facilities that provide highly focused care to patients with complex medical conditions outside of traditional acute care hospitals, including patients who have been ventilator-dependent and are difficult to wean. (Chapter 57)
loud P-2 abnormally loud closure of the pulmonic valve as part of S_2; usually caused by pulmonary hypertension. (Chapter 16)
lower confidence a statistical concept defining the lower range of normal. (Chapter 3)
lower respiratory tract infection any infectious disease of the left and right bronchi and the alveoli. (Chapter 24)
low-flow system a variable performance O_2 therapy device that delivers O_2 at a flow that provides only a portion of the patient's inspired gas needs. Also called *variable performance system*. (Chapter 42)
L/T ratio the lung availability of an aerosol divided by the total system availability of the aerosol. (Chapter 35)
lung protective ventilation (LPV) the use of low tidal volumes to help prevent ventilator-induced lung injury. (Chapter 29)
lung-protective ventilatory strategy an approach to mechanical ventilation that attempts to avoid overdistention of the lung and recruitment and derecruitment of unstable lung units with each breath. (Chapter 49)
lung stress and strain the force applied per unit area. As applied to the respiratory system it is equal to transpulmonary pressure. (Chapter 52)
lung ultrasonography the use of ultrasound technology to view lung structures. (Chapter 52)
lymphadenopathy of or pertaining to a disease of the lymph nodes; refers also to the visualization of enlarged lymph nodes on radiographs. (Chapter 16)
lymphangioleiomyomatosis rare disorder of abnormal smooth muscle tissue proliferating around small airways and leading to severe obstruction and destruction of alveoli with resultant thin-walled cyst formation. (Chapter 26)

M

machine-cycled a breath that is turned off by the ventilator. (Chapter 46)
machine-triggered a breath that is initiated by the ventilator. (Chapter 46)
macroshock shock from an electrical current of 1 mA or greater that is applied externally to the skin. (Chapter 3)
magnetic resonance imaging (MRI) an imaging technique using the magnetic disturbance of tissue to obtain images. (Chapter 32)
Mallampati classification one of the most commonly used methods to identify the ability to visualize the vocal cords and glottis and therefore assess the degree of difficulty clinicians may encounter during intubation. (Chapter 22)
malpractice in law, professional negligence that is the proximate cause of injury or harm to a patient, resulting from a lack of professional knowledge, experience, or skill that can be expected in others in the profession or from a failure to exercise reasonable care or judgment in the application of professional knowledge, experience, or skill. (Chapter 5)
mandatory ventilatory support breath either initiated or ended by the machine. (Chapter 46)
mandatory minute volume ventilation (MMV) variation of the intermittent mandatory ventilation mode of ventilatory support in which the ventilator keeps the total minute volume constant. (Chapter 52)
manifold a pipe with many connections; in medical gas storage, a collection of gas cylinders linked together for purposes of bulk storage and usually including at least one reserve bank and other safety systems, such as low-pressure alarms. (Chapter 41)
manubrium the upper triangular portion of the sternum. (Chapter 9)
marasmus protein-energy malnutrition caused by starvation. (Chapter 23)
mass the physical property of matter that gives it weight and inertia; an aggregate of cells clumped together, such as a tumor. (Chapter 32)
mass median aerodynamic diameter (MMAD) measure of central tendency that describes the particle diameter in micrometers in medical aerosols and pertains to cascade impaction. (Chapter 40)
maximal voluntary ventilation measure of maximum spontaneous breathing capabilities. Measures over 15 sec converted to minute ventilation/minute. (Chapter 20)
maximum expiratory pressure (MEP) measure of the output of the expiratory muscles against a maximum stimulus measured in cm H_2O positive pressure. (Chapter 45)
maximum inspiratory pressure (MIP) measure of the output of the inspiratory muscles against a maximum stimulus, measured in cm H_2O negative pressure. Also known as *negative inspiratory force (NIF)* or *maximum inspiratory force (MIF)*. (Chapter 45)
maximum voluntary ventilation (MVV) maximum volume of air in liters per minute that a patient can breathe during a 12- to 15-second period. It is a very patient-dependent test. Formerly called the *maximum breathing capacity (MBC)*. (Chapters 45 and 52)
mean airway pressure (MAP) the average pressure applied to the airway. (Chapters 47 and 52)
mechanical insufflation-exsufflation a mechanical device that provides an artificial cough by alternately applying positive pressure and negative pressure to the airway, also referred to as an *in-exsufflator*. (Chapter 44)
mechanical support enhancement of cardiac output using a device, e.g., an intraaortic balloon pump. (Chapter 31)
meconium material that collects in the intestines of a fetus and forms the first stools of a newborn. (Chapter 54)
meconium aspiration syndrome inhalation of meconium by a fetus or newborn; this can block the air passages and cause failure of the lungs to expand. (Chapter 35)
mediastinum the portion of the thoracic cavity lying in the middle of the thorax (between the two pleural cavities); extends from the vertebral column to the sternum and contains the trachea, esophagus, heart, and great vessels of the circulatory system. (Chapters 9 and 21)
medical director responsible for assisting and advising the department director on the management of the respiratory therapy department. (Chapter 2)
medical instrumentation devices/instruments designed specifically for use in medicine. (Chapter 2)
melting point characteristic temperature at which the solid and liquid forms of a substance are in equilibrium. (Chapter 6)
membrane pressures the pressure across an oxygenator used in an extracorporeal membrane oxygenation circuit. (Chapter 51)
meniscus the top part of a liquid where its edges form a curved surface. (Chapter 6)
Merit-based Incentive Payment System (MIPS) a salary raise program based on performance of the employee not longevity. (Chapter 7)
meta-analysis a systematic review of the available literature. (Chapter 8)
metabolic acidosis nonrespiratory processes resulting in acidemia. (Chapter 14)
metabolic alkalosis nonrespiratory processes resulting in alkalemia. (Chapter 14)
metabolic cart a specific device desing to evaluate metabolic function, frequently used to dedermine daily caloric needs. (Chapter 23)
metabolism systemic inflammatory response syndrome characterized by increased total caloric requirements, hyperglycemia, triglyceride intolerance, increased net protein catabolism, and increased macronutrient and micronutrient requirements. (Chapter 23)
methemoglobin abnormal form of hemoglobin in which the iron component has been oxidized from the ferrous to the ferric state. (Chapter 12)
methemoglobinemia abnormal condition characterized by high levels of methemoglobin in the blood and reduction in O_2-carrying capacity; may be caused by nitrite poisoning or ingestion of a certain oxidizing agent or a genetic defect in the enzyme NADH methemoglobin reductase (an autosomal dominant trait). (Chapters 12 and 22)
m-health a system focused on incurring overall medical health, not just the management of acute incidents. (Chapter 7)
micronutrients nutrients that appear in the body in very small quantities. (Chapter 23)
microshock shock from a usually imperceptible electrical current (<1 mA) that is allowed to bypass the skin and follow a direct, low-resistance pathway into the body. (Chapter 3)

minute ventilation total lung ventilation per minute, the product of tidal volume and respiration rate. It is measured by expired gas collection for a period of 1 to 3 minutes; normal rate is 5 to 10 L/min. (Chapters 11 and 20)

missed triggering the inability of a patient to trigger the ventilator during a particular inspiratory effort—usually a result of auto-PEEP or too large a tidal volume with a rapid respiratory rate. (Chapter 48)

mitral valve the heart valve between the left atria and left ventricle. (Chapter 10)

mode any one of many categories of mechanical ventilation that are determined by a number of characteristics, including how the breath is initiated and how the inhalation ceases and exhalation starts. (Chapter 46)

mode asynchrony the selection of a mode of ventilation that does not synchronously interact with the patient's inspiratory efforts. (Chapter 48)

moderate sedation a form of sedation used for certain procedures such a bronchoscopy, whereby patients can respond to verbal stimuli and maintain protective airway reflexes. (Chapter 22)

modified Allen test the most common technique to determine the adequacy of ulnar circulation. (Chapter 19)

molal solution a solution containing 1 mole of solute per kilogram of solvent or 1 mmol/g solvent. (Chapter 13)

molar solution 1 mole of solute per liter of solution or 1 mmol/mL of solution. (Chapter 13)

molar volume the volume of solvent needed to establish a 1 molar solution. (Chapter 13)

monitor to observe and evaluate a function of the body closely and constantly; a mechanical device that provides a visual or audible signal or a graphic record of a particular function, such as a cardiac monitor or a fetal monitor. (Chapter 19)

monodispersing referring to an aerosol in which particles are of uniform size. (Chapter 40)

morbid obesity a state of having a body mass index greater than 45 kg/m^2. (Chapter 30)

mucociliary escalator a term used to define the process in which the cilia of the airways continually move mucus from the lower respiratory tract to the oral cavity. (Chapter 9)

mucoid resembling mucus. (Chapter 16)

mucous plugging the partial or complete occlusion of the airway by thick mucus. (Chapter 44)

multiple organ dysfunction syndrome (MODS) a condition in which dysfunction of many different organs occurs, usually accompanying ALI. (Chapter 29)

murmur an abnormal heart sound created by turbulent blood flow through a narrowed or incompetent heart valve. (Chapter 16)

Murray lung injury score a score used to define the severity of injury in patients with acute respiratory distress syndrome (ARDS). (Chapter 52)

muscarinic stimulating the postganglionic parasympathetic receptor; pertaining to the poisonous activity of muscarine. (Chapter 36)

muscle fatigue a condition involving loss of the capacity to develop force or velocity of a muscle resulting from muscle activity overload, which is reversible by rest. (Chapter 44)

myasthenia gravis a disorder of neuromuscular conduction that leads to muscle weakness of the skeletal muscles, particularly the muscles of the face, throat, and respiratory system. Weakness and respiratory failure can occur rapidly as muscle strength decreases with repetitive contraction against a load. (Chapter 33)

myocardial infarction (MI) damage to the heart caused by a lack of blood flow to the myocardial tissue. (Chapter 10)

myogenic control the relationship between vascular smooth-muscle tone and perfusion pressure. (Chapter 10)

myotonic dystrophy a type of muscular dystrophy. (Chapter 33)

N

nanomole a quantity equal to 10^{-9} of a mole. (Chapter 13)

narrow-band imaging an imaging technique used in conjunction with bronchoscopy, where light of specific blue and green wavelengths is used to enhance the detail of certain aspects of the surface of the mucosa. (Chapter 22)

nasal flaring dilation of the alae nasi on inspiration; an early sign of an increase in ventilatory demands and the work of breathing, especially in infants. (Chapter 35)

nasopharynx the upper portion of the airway behind the nasal and oral cavities. (Chapter 9)

National Association for Medical Direction of Respiratory Care A medical association focused on the provision of respiratory care. Medical directorship of a respiratory care program required for membership. (Chapter 2)

National Asthma Educator Individual who has been certificeid to provide asthma education, requires passing a test. (Chapter 2)

National Board for Respiratory Care (NBRC) the national credentialing agency for respiratory care practitioners and pulmonary function technologists. (Chapters 1 and 2)

nebulizer a device that produces an aerosol suspension of liquid particles in a gaseous medium using baffling to control particle size. (Chapters 39 and 40)

needle capping device a safety device used to prevent or minimize needlestick injuries when capping a syringe needle (as required after blood gas sampling). (Chapter 19)

negative feedback loop exists when the output of a system acts to oppose changes to the input of the system, with the result that the changes are attenuated and output is balanced. (Chapter 10)

negative inotropism indicator of a decrease in the contractility of the heart. (Chapter 10)

negative-pressure ventilation approach to ventilation in which negative pressure is intermittently applied to the chest surface in an effort to cause inflation of the lungs. (Chapter 50)

negligence omission to do something that a reasonable person, guided by ordinary considerations, would do. (Chapter 5)

neovascularization formation of new capillary beds. (Chapter 42)

neurally adjusted ventilatory assist (NAVA) an approach to ventilation based on the electromyelographic (EMG) activity of the diaphragm. Airway pressure is increased proportional to the change in EMG activity. No control variable is set. (Chapters 48 and 49)

neutropenia an abnormal decrease in the number of neutrophils in the blood. (Chapters 17 and 36)

neutrophilia an absolute elevation in neutrophils. (Chapter 17)

nitric oxide (NO) an inhaled gas used to reduce pulmonary artery pressure and improve arterial oxygenation. (Chapter 42)

nitrogen balance the appropriate amount of nitrogen in the body, the balance between nitrogen and other nutrients. (Chapter 23)

nocturnal hypoventilation elevated $PaCO_2$ and accompanying decline in O_2 saturation that occurs in response to a progressive decrease in minute ventilation occurring during sleep, most often in the rapid-eye-movement stage. (Chapter 50)

nodule small node; small node-like structure. (Chapter 32)

nonflammable unable to support combustion. (Chapter 41)

nonhydrostatic pulmonary edema pulmonary edema that is caused by something other than an increase in blood pressure. (Chapter 29)

noninvasive pertaining to a diagnostic or therapeutic technique that does not require the skin to be broken or a cavity or organ of the body to be entered, such as obtaining a blood pressure reading by auscultation with a stethoscope and sphygmomanometer. (Chapter 19)

noninvasive positive-pressure ventilation (NPPV) positive-pressure ventilation without endotracheal intubation or tracheotomy, usually via a form-fitting mask (also referred to as noninvasive ventilation or NIV). (Chapters 50)

noninvasive ventilation mechanical ventilation performed without intubation or tracheostomy, usually using a mask. (Chapters 25, 43, 45, 50, and 57)

nonmaleficence principle that obligates healthcare providers to avoid harming patients and actively to prevent harm where possible. (Chapter 5)

nonpolar covalent a bond between molecule that does not have polarity. (Chapter 13)

non–small cell carcinoma a major category of histologic types of lung carcinomas, including adenocarcinoma of the lung, large cell carcinoma, and squamous cell carcinoma. Treatment depends on the stage of development of the cancer at the time of initial presentation. The treatme nt of choice for otherwise physically fit patients with early stages of disease is resection. (Chapter 32)

Non–ST-segment-elevation myocardial infarction (NSTEMI) a myocardial infarction that does not show the normal ECG changes, specifically no elevation is the ST segment of the ECG. (Chapter 10)

normal solution a solution that contains the gram-equivalent weight of a reagent per liter; denoted by the symbols N/I or N. (Chapter 13)

normometabolic the normal level of metabolic function in a healthy individual. (Chapter 23)
nosocomial acquired in the hospital (often defined as more than 48 hours after hospital admission), often referring to infections. (Chapter 4)
nosocomial pneumonia an infectious inflammatory process of the lung parenchyma contracted in the hospital. (Chapter 24)
null hypothesis that the probability of two events are equal. (Chapter 8)

O

O_2-conserving device an O_2 delivery system that minimizes the amount of O_2 actually delivered to a patient while also maintaining the FiO_2. (Chapter 57)
obesity hypoventilation a general syndrome involving chronic hypercapnia and hypoxemia, sleep apnea, and decreased respiratory center responsiveness to CO_2. Complications, primarily owing to chronic hypoxemia, include polycythemia, pulmonary hypertension, and cor pulmonale. (Chapter 34)
obesity hypoventilation syndrome a common underdiagnosed condition in hospitalized extremely obese patients. (Chapter 30 and 50)
observational cohort study a study in which there is just observation of the subjects with no specific intervention. (Chapter 8)
obstructive pulmonary disease any respiratory disease characterized by decreased airway size and increased airway secretions. (Chapter 20)
obstructive sleep apnea (OSA) a condition in which five or more apneic periods (lasting at least 10 seconds each) occur per hour of sleep and characterized by occlusion of the oropharyngeal airway with continued efforts to breathe. (Chapters 30, 33 and 34)
obturator device used to block a passage or a canal or to fill in a space, such as the obturator used to insert a tracheostomy tube. (Chapter 37)
occupational interstitial lung disease (ILD) ILD resulting from an occupational exposure; asbestosis is a common example. (Chapter 26)
Occupational Safety and Health Administration (OSHA) a federal agency of the United States that regulates workplace safety and health. (Chapter 4)
ohm a unit of measurement indicating the degree of resistance to the flow of electricity. (Chapter 3)
oligohydramnios conditions that lead to inadequate fetal breathing and low amounts of amniotic fluid formation. (Chapter 9)
onset of blood lactate accumulation (OBLA) the point at which blood lactate levels increase above normal when the body cannot deliver sufficient O_2 to meet the demands of energy metabolism; a term used in exercise physiology. (Chapter 56)
open buffer system the bicarbonate buffer system is an open system because H_2CO_3 can be removed as CO_2 is broken down into H_2O and CO_2 as long as ventilation removes CO_2. (Chapter 14)
optical fluorescence the use of fluorescent dyes illuminated with light of a specific wavelength for the measurement of respiratory gases. (Chapter 19)
optimal targeting scheme a scheme for mechanical ventilator gas delivery that targets an optimal approach to delivering ventilation to the patient based on predetermined variables. (Chapter 46)
optode fluorescent chemosensor useful in measuring pH or gas tensions in arterial or mixed venous blood. (Chapter 19)
organizing pneumonia (OP) the new term for bronchiolitis obliterans organizing pneumonia, which generally occurs in the setting of connective tissue disease. (Chapter 26)
oropharynx the portion of the pharynx located closest to the mouth. (Chapter 9)
orthodeoxia a decrease in PaO_2 owing to changes in position. (Chapters 16 and 45)
orthopnea labored breathing in the reclining position. (Chapter 16)
oscillation back-and-forth motion; vibration or the effects of mechanical or electrical vibration. (Chapter 44)
osmolality a measure of the concentration of a solute in a solution. (Chapter 13)
osmotic pressure a force produced by solvent particles across semipermeable membranes. (Chapter 13)
output the specific measurements made or computed by an instrument. (Chapter 20)
oxidizing the process of combining or causing to combine with O_2 to remove hydrogen or to increase the valence of an element through the loss of electrons. (Chapter 41)
oximetry a noninvasive method for monitoring how saturated a person's hemoglobin is with oxygen and other gases. (Chapter 19)
oxygen consumption (VO_2) the amount of O_2 consumed per minute; the normal value is 200 mL/min. (Chapter 52)
oxygen content the amount of oxygen carried in the blood. (Chapter 51)
oxygen delivery the amount of oxygen actually available for delivery to the tissues. (Chapter 51)
oxyhemoglobin a chemical combination resulting from the covalent bonding of O_2 to the ferrous iron pigment in hemoglobin. (Chapter 12)

P

P wave the wave of depolarization that occurs in the atria, the wave just preceding the QRS complex. (Chapter 18)
P_{100}or $P_{0.1}$ the amount of negative pressure a patient generates in the first 100 milliseconds of inspiration. (Chapter 48)
P_{50} a symbol quantifying variations in the affinity of Hb for O_2. It is the partial pressure of O_2 at which the Hb is 50% saturated, standardized to a pH level of 7.40. (Chapter 9)
pack-years a method of determining the number of cigarettes a patient has smoked over time. The number of packs of cigarettes a person smoked is divided by the number of years during which he or she has smoked. (Chapter 16)
palate a bony plate that separates the nasal cavity from the oral cavity. (Chapter 9)
palatine folds a double web on each side of the oral cavity. (Chapter 9)
palliative care care only designed to relieve suffering, usually instituted in patients with DNI medical states. (Chapter 50)
palliative sedation the controlled and monitored use of nonopioid medication intended to lower the patient's level of consciousness to the extend necessary for relief of awareness of refractory and unendurable symptoms. (Chapter 58)
Pancoast syndrome a combination of signs associated with a tumor in the apex of the lung; these signs include neuritic pain in the arm, atrophy of the muscles of the arm and the hand, and Horner syndrome they are caused by the damaging effects of the tumor on the brachial plexus and sympathetic ganglia. (Chapter 32)
PaO_2/FiO_2 ratio the PaO_2 divided by the FiO_2, indicative of the severity of lung injury. (Chapter 52)
paradoxical breathing motions a breathing pattern in which the chest wall expands first followed by the abdomen. (Chapter 33)
paraneoplastic syndrome effect of tumors remote from the tumor site and often mediated by reactions to tumor products or immune response to the tumor. (Chapter 32)
parenteral patient feeding that involves directly delivering food into the venous circulation. (Chapter 23)
parenteral nutrition (PN) a way of nourishing a patient when all other attempts at feeding are unsuccessful or not recommended. (Chapter 23)
paresthesia a subjective sensation experienced as numbness, tingling, or a "pins and needles" feeling. (Chapter 14)
parietal pleura a thin membrane covering the surface of the chest wall, mediastinum, and diaphragm that is continuous with the visceral pleura around the lung hilum. (Chapters 9 and 27)
partial pressure the pressure exerted by a single gas in a mixture. (Chapter 6)
partial ventilatory support modes of ventilatory support in which the patient must contribute to the total minute volume with spontaneous breathing. (Chapter 49)
Pascal's principle law stating that a confined liquid transmits pressure equally in all directions. (Chapter 6)
PASS an acronym for Pull the pin, Aim the nozzle, Squeeze the handle, Sweep the nozzle across the base of the fire. (Chapter 3)
passive refers to the delivery of medical care that the patient is not directly involved with. Controlled mechanical ventilation is passive ventilation. (Chapter 47)
patent ductus arteriosus (PDA) a common cardiovascular anomaly of infants in which the ductus arteriosus either fails to close or reopens after birth. (Chapter 9 and 54)
patient-cycled cycling of the mechanical ventilator in which the patient determines the end of the breath. (Chapter 46)
Patient Protection and Affordable Care Act (PPACA) legislation that changed many aspects of the American healthcare system by expanding healthcare coverage to many uninsured people, prohibiting the exclusion of

preexisting conditions, creating an exchange for purchasing health insurance coverage, increasing the scope of coverage for certain types of preventive care, and many other provisions. (Chapter 56)

patient-triggered the initiation of a mechanical breath as a result of patient effort. (Chapter 46)

patient-centered care care that is always focused on what is best for the patient not the caregiver. (Chapter 25)

patient-ventilator asynchrony lack of coordinated gas delivery between the patient and the ventilator. (Chapters 47 and 48)

peak expiratory flow rate (PEFR) maximum expiratory flow rate in liters per second. (Chapter 20)

pedal edema swelling of the ankles, usually secondary to heart failure. (Chapter 16)

Pediatric Advanced Life Support (PALS) advanced resuscitation beyond the ABC's of basic resuscitation delivered to pediatric patients. (Chapter 38)

peer review the articles published in journals. (Chapter 8)

peer review organization (PRO) an elaborate system to evaluate the quality and appropriateness of care given to Medicare beneficiaries. (Chapter 3)

penetrating trauma chest trauma that is caused by a bullet, knife, or other weapon which makes a singular entry into the chest. Normally pulmonary contusion does not occur with penetrating trauma. (Chapter 30)

percent body humidity the ratio of a saturated gas's actual water vapor content to its capacity for same at body temperature (37°C). (Chapter 6)

percent solution the weight of solute per weight of solution. (Chapter 13)

percent total body surface area (%TBSA) the percent of the body surface that is affected. Normally used to identify the extent of body surface burns. (Chapter 30)

performance improvement a measurement of the results of a process and then changing it to enhance future results. (Chapter 3)

pericardial effusion an abnormal amount of fluid between the layers. (Chapter 10)

pericardial fluid a thin layer of fluid. (Chapter 10)

pericarditis inflammation of the pericardium that results in a clinical condition. (Chapter 10)

pericardium fibrous, serous sac that surrounds the heart and roots of the great vessels. (Chapter 10)

peripheral cyanosis a bluish tinge of the extremities often caused by low arterial blood oxygen content or poor circulation. (Chapter 16)

permissive hypercapnia the purposeful increase in $PaCO_2$ to insure lung protection. (Chapter 29)

persistent pulmonary hypertension of the newborn (PPHN) a clinical syndrome seen in infants soon after birth and characterized by abnormally increased pulmonary vascular resistance. (Chapter 35)

pharmacodynamic phase mechanisms of drug action that cause effects on the body. (Chapter 36)

pharmacokinetic phase time, course, and disposition of a drug in the body. (Chapter 36)

pharyngeal airways devices that maintain the patency of the pharyngeal structure. (Chapter 37)

pharynx the throat—a tubular structure approximately 13 cm long that extends from the base of the skull to the esophagus and is situated immediately in front of the cervical vertebrae. The pharynx serves as a passageway for the respiratory and digestive tracts and changes shape to allow the formation of various vowel sounds. (Chapter 9)

phlegm mucus from the tracheobronchial tree. (Chapter 16)

photoplethysmography light-emitting technology used to detect changes in blood flow. (Chapter 19)

phrenic nerves paired nerves that originate as branches of spinal nerves C3-5, pass down along the mediastinum, and innervate the diaphragm. (Chapter 9)

physician assistant (PA) an individual academically and clinically prepared to practice medicine under the supervision of a licensed doctor of medicine or osteopathy. Within the physician-PA relationship, PAs exercise autonomy in medical decisions and provide a wide range of diagnostic and therapeutic services. Training programs average 25 to 27 months. National certification is available to graduates of approved training programs. (Chapter 1)

physiologic dead space an area of the respiratory system that includes the anatomic dead space together with the space in the alveoli occupied by air that does not contribute to the O_2-CO_2 exchange. (Chapter 11)

picture archiving and communication systems a medical imaging technology that permits storage and convenient access to images. (Chapter 7)

piezoelectric crystal a transducer capable of converting electrical energy into the physical energy of high-frequency vibrations. (Chapter 39)

pin-indexed safety system (PISS) part of the American standard safety system, this system's specifications apply only to the valve outlets of small cylinders, up to and including size E, that use a yoke-type connection. (Chapter 41)

plaintiff a person who brings an action; a person who seeks remedial relief for an injury to his or her rights. (Chapter 5)

plan-do-study-act cycle (PDSA) part of a continuous quality improvement program. (Chapter 3)

plasma colloid osmotic pressure (oncotic pressure) the osmotic pressure exerted by proteins that remain in the intravascular compartment, which draws water and small solute molecules back into the capillaries. (Chapter 13)

plateau pressure (P_{plat}) pressure in the patient's airway during mechanical ventilation resulting from the application of an end-inspiratory hold. This is equal to the average peak alveolar pressure. (Chapters 47 and 49)

platypnea the opposite of orthopnea; an abnormal condition characterized by difficult breathing in the standing position that is relieved in the lying or recumbent position. (Chapters 16 and 45)

plethysmograph a device for measuring pressure; in pulmonary physiology, a chamber in which the subject sits while lung pressures and volumes are being measured. (Chapter 11)

pleural effusion an abnormal collection of fluid in the pleural space. (Chapters 21 and 27)

pleural fluid a clear fluid with a pH of 7.60 to 7.65 that has few cells, a small amount of protein (about 1 g/dL), and glucose and electrolytes in concentrations that approximate those of plasma. (Chapter 9)

pleural friction rub friction during breathing that produces a creaking or grating sound. (Chapter 16)

pleural space the space between the parietal and pleural membranes. (Chapter 9)

pleurisy pain that comes from the pleural surface, usually as a direct result of a viral infection, but the term has been generalized to any condition (e.g., pulmonary embolism) causing pleural pain. Synonymous with *pleurodynia*. (Chapters 9 and 27)

pleurodesis a procedure of fusing the parietal and visceral pleura to prevent the formation of pleural fluid or the recurrence of pneumothorax. (Chapter 27)

pneumobelt a ventilatory assist device that applies positive pressure to the abdominal contents during expiration. (Chapter 50)

pneumomediastinum the presence of air or gas in the mediastinal tissues, which may lead to pneumothorax or pneumopericardium. (Chapter 21)

pneumonia an inflammatory process of the lung parenchyma, usually infectious in origin. (Chapter 24)

pneumotachometer any device for measuring gas flow. (Chapters 11 and 20)

pneumotaxic center a center in the upper part of the pons that rhythmically inhibits inspiration independently of the vagi. (Chapter 15)

pneumothorax the presence of air or gas in the pleural space of the thorax; if this air or gas is trapped under pressure, tension pneumothorax exists. (Chapters 16, 21 and 27)

point-of-care testing the analysis of body fluids at the bedside as opposed to conventional laboratory testing. (Chapters 7 and 19)

Poiseuille's law the physical law describing the difference in pressure required to produce a given flow under conditions of laminar flow through a smooth tube of a fixed size. (Chapter 6)

polar covalent molecular compounds dissolved in water or other solvents to produce ions (ionization); electrolytes may be weak or strong, depending on degree of ionization; polar covalent solutions are weak electrolytes or conductors ~~polarize and are good conductors~~. (Chapter 13)

polycythemia an abnormal increase in the number of erythrocytes in the blood; termed *secondary* if attributable to defined causes other than direct stimulation of the bone marrow, as occurs in chronic hypoxemia. (Chapters 6 and 17)

polymyositis a condition characterized by the inflammation of many muscles. (Chapter 33)

population health the health outcomes of a group of individuals, including the distribution of such outcomes within a group. (Chapter 55)

pores of Kohn small openings between adjacent alveoli. (Chapter 9)
portable oxygen concentrator (POC) a portable device that produces oxygen by the removal of nitrogen form room air. Used by many patients requiring continuous home oxygen therapy. (Chapter 57)
portals a means by which authorized users can gain access to computerized medical records and health resources. (Chapter 8)
positive end-expiratory pressure (PEEP) the application and maintenance of pressure above atmospheric at the airway throughout the expiratory phase of positive-pressure mechanical ventilation. (Chapters 29 and 45)
positive expiratory pressure (PEP) an airway clearance technique in which the patient exhales against a fixed-orifice flow resistor to help move secretions into the larger airways for expectoration via coughing or swallowing. (Chapters 43 and 44)
positive inotropism an increase in the contractility of muscle tissue. (Chapter 10)
positron emission tomography (PET) a computerized radiographic technique that uses radioactive substances to examine the metabolic activity of various body structures. The patient either inhales or is injected with a metabolically important substance such as glucose, which is carrying a radioactive element that emits positively charged particles, or positrons. When the positrons combine with electrons normally found in the cells of the body, gamma rays are emitted. The electronic circuitry and computers of the PET device detect the gamma rays and construct color-coded images that indicate the intensity of metabolic activity throughout the organ involved. (Chapter 32)
postural hypotension a sudden decrease in arterial blood pressure caused by a change in position; it most often occurs when a hypovolemic patient moves from the reclining position to the upright position. (Chapter 16)
potential energy energy contained in a body as a result of its position in space, its internal structure, and stresses imposed on it. (Chapter 6)
preanalytic error an error that occurs outside of the actual testing procedure. (Chapter 19)
precision the accuracy of an instrument during the measurement of a particular substance. (Chapters 19 and 20)
precordium the region of the thorax immediately in front of the heart. (Chapter 16)
preexperimental an evaluation designed to refine the actual protocol for an experiment. (Chapter 8)
preload pressure stretching the ventricular walls at the onset of ventricular contraction. (Chapters 10, 51, and 52)
pressure the amount of force applied to a specific area. (Chapter 6)
pressure-controlled ventilation (PCV) a mode of ventilatory support in which mandatory support breaths are delivered to the patient at a set inspiratory pressure. (Chapters 46 and 49)
pressure gradient the pressure difference between two points in a system. (Chapter 11)
pressure support ventilation (PSV) a mode of ventilatory support designed to augment spontaneous breathing; patient-triggered, pressure-limited, flow-cycled ventilation. (Chapters 49 and 53)
pressure-regulated volume control (PRVC) pressure-limited ventilation in which inspiratory time and a backup rate are set and a tidal volume is targeted. (Chapter 49)
pressure-time index the product of pressure generated during inspiration and the time that it is applied, an index of patient effort. (Chapter 45)
pressure-time product (PTP) product of pressure over a time interval, usually pleural pressure times inspiratory time during breathing. (Chapter 52)
primary lobule the terminal bronchiole and the cluster of respiratory bronchioles that it supplies. (Chapter 9)
primary pulmonary hypertension of the newborn (PPHN) a form of pulmonary hypertension that occurs in the absence of other heart or lung diseases and is characterized by diffuse narrowing of the pulmonary arterioles without obvious reason. (Chapter 54)
primary spontaneous pneumothorax pneumothorax occurring without underlying lung disease. (Chapter 27)
principal investigator the one who is ultimately responsible for completing a study in compliance with all applicable rules and regulations and for adhering to the protocol approved by the institutional review board (IRB). (Chapter 8)
process control a method of quality control that uses detailed information about a process to optimize outcomes. (Chapter 3)
prodrug inactive or partially active drug that is metabolically changed in the body to an active drug. (Chapter 36)
proficiency testing (PT) process of comparing measurements of a known value from different sources to establish a level of accuracy. (Chapter 19)
prognosis an estimation of a patient's outcome based on the severity of illness and the ability to treat the problem. (Chapter 58)
progressive mobility the process of increasingly mobilizing intensive care unit patients, including those on mechanical ventilation. (Chapter 53)
progressive resistance a method of increasing the strength of a weak or injured muscle by gradually increasing the resistance against which the muscle works, as by using graduated weights over a period of time. Also called *graduated resistance*. (Chapter 56)
prolonged mechanical ventilation (PMV) a lengthy process of mechanical ventilatory support. No precise length has been determined but most would consider longer than 3 weeks prolonged ventilatory support. (Chapter 53)
prone positioning the face-down position, often used during mechanical ventilation to help improve ventilation and oxygenation. (Chapter 29)
propellant something that propels or provides thrust, such as the propellant in a metered-dose inhaler. (Chapter 40)
proportional assist ventilation (PAV) a mode of ventilation without any control variable that delivers gas in proportion to the patient's actual inspiratory effort. (Chapters 48 and 49)
protein-energy malnutrition (PEM) a wasting condition resulting from a diet deficient in protein, energy (calories) or both. (Chapter 23)
protocol-based oxygen therapy oxygen therapy based on a predefined guideline that directs therapy without specific physician orders. (Chapter 42)
pseudoglandular stage an early stage of development of the lungs or any organ before the actual development of glands. (Chapter 9)
pseudorestriction an abnormality that appears at first to be a result of a restriction but is not even though its presentation is similar to a restriction. (Chapter 20)
psig abbreviation for pounds per square inch-gauge—the pressure above atmospheric registered on a meter or gauge. (Chapter 41)
psychomotor domain the area of observable performance of skills that require some degree of neuromuscular coordination. (Chapter 55)
psychosocial support needs of or pertaining to the mental, emotional, and social aspects of human existence or development. (Chapter 56)
PubMed a free computerized search engine that facilitates access to peer-reviewed articles, abstracts, and references related to the life sciences. (Chapter 8)
pulmonary arterial hypertension (PAH) an increase above normal levels in blood pressure in the pulmonary vasculature. (Chapter 28)
pulmonary artery (PA) catheter a catheter placed in the pulmonary artery designed to measure pressures reflective heart function. (Chapter 19)
pulmonary contusion the internal pulmonary bleeding and edema resulting from blunt trauma, generally localized to the area adjacent to the trauma. (Chapter 30)
pulmonary edema a condition in which excessive amounts of plasma enter the pulmonary interstitium and alveoli, usually accompanied by severe respiratory distress, tachypnea, and hypoxemia. (Chapter 29)
pulmonary embolism (PE) blockage of a pulmonary artery by foreign matter. The obstruction may be fat, air, tumor tissue, or a thrombus usually arising from a peripheral vein (most frequently from the deep veins of the legs). A pulmonary embolism is detected by chest x-ray, pulmonary angiography, and radioscanning of the lung fields. (Chapter 28)
pulmonary hypertension (PH) a condition characterized by abnormally high pulmonary artery pressures (i.e., mean pulmonary artery pressures >22 mm Hg). (Chapter 28)
pulmonary Langerhans cell histiocytosis (PLCH) a condition characterized by an abnormal proliferation of Langerhans cells accompanied by interstitial markings on the chest film and dyspnea. (Chapter 26)
pulmonary rehabilitation an organized multidisciplinary approach to improving the functional status of patients with chronic obstructive pulmonary disease, usually including education, exercise, aerosolized medication, and O_2 therapy. (Chapter 56)
pulmonary surfactant a surface-active lipoprotein formed by type II cells, which reduces surface tension and facilitates alveolar expansion during inhalation. (Chapter 9)

pulmonary vascular resistance (PVR) the resistance of blood flow through the pulmonary vascular system. (Chapter 10)
pulse co-oximetry a pulse oximetry that is capable of measuring carboxyhemoglobin and methemoglobin. (Chapter 19)
pulse pressure the difference between the systolic and diastolic pressures, which is normally 30 to 40 mm Hg. (Chapter 16)
pulseless electrical activity (PEA) a serious condition characterized by a disassociation between the electrical and mechanical activity of the heart. In essence, the electrical ECG pattern on the monitor generates neither mechanical activity of the heart nor a pulse. (Chapter 10)
pulsus alternans a pulse alternating between strong and weak heartbeats. (Chapter 16)
pulsus paradoxus an abnormal decrease in pulse pressure with each inspiratory effort. (Chapter 16)
pump flow the flow of blood pumped through on an extracorporeal membrane oxygenation system in liters per minute. (Chapter 51)
purulent consisting of or containing pus. (Chapter 16)
***P* value** a statistical value the indicates the difference between two variables or outcomes, a $p < 0.05$ indicates that the probability of the two variables being equal in less than 5%. (Chapter 8)

Q

quality assurance any evaluation of services provided and the results achieved compared with accepted standards. (Chapter 3)
quality control a planned, systematic approach to designing, measuring, assessing, and improving performance. (Chapter 19)
quality improvement the enhancement of a process, structure, product and/or organization to more closely adhere to best practices, reduce errors, and achieve intended outcomes. (Chapter 3)
quasi-experimental research designs that lack full control of all variables but where there is an effort to compensate with other controls. (Chapter 8)
qui tam Latin for suing for one's self. (Chapter 5)

R

RACE acronym for Rescue patients in the immediate area of the fire. Alert other personnel about the fire so they can assist in the rescue and can relay the location of the fire to officials. Contain the fire. Evacuate other patients and personnel in the areas around the fire who may be in danger if the fire spreads. (Chapter 3)
radiation treatment of neoplastic disease by using x-rays or gamma rays, usually from a cobalt source, to deter the proliferation of malignant cells by decreasing the rate of mitosis or impairing the synthesis of deoxyribonucleic acid. (Chapter 6)
radiograph x-ray image. (Chapter 21)
radiolucent of or pertaining to a substance or tissue that readily permits the passage of x-rays or other radiant energy. Compare with *radiopaque*. (Chapter 21)
radiopaque of or pertaining to a substance or tissue that does not readily permit the passage of x- rays or other radiant energy. Compare with *radiolucent*. (Chapters 21 and 37)
radiotherapy treatment with radiation. (Chapter 32)
rales an abnormal breath sound also known as "crackles," which is discontinuous and can be further characterized as "fine rales" associated with congestive heart failure or "coarse rales" most often associated with air moving through secretions in the airways. (Chapter 16)
random error variability of a measurement outside of accepted limits that occurs in a nonreproducible fashion. (Chapter 19)
randomized controlled trial a clinical trial where the new treatment is received by one group and a second comparative group receives the standard approach to care. (Chapter 8)
rapid shallow breathing index (f/V_T) a patient's spontaneous respiratory rate (f) in breaths per minute divided by the spontaneous tidal volume in liters. Values greater than 100 are associated with poor weaning outcomes. (Chapter 53)
ratio solution the amount of solute to solvent expressed as a proportion (e.g., 1:100). (Chapter 13)
reabsorption the active or passive transport of filtrate substances that moves them from the tubule lumen back into the tubule cell and into the blood of nearby capillaries (Chapter 14). The rebound effect withdrawal of NO resulted in the development of hypoxemia and pulmonary hypertension, perhaps worse than they were before therapy was started. (Chapter 42)
recidivism a circumstance where the same behavior is repeated and repeated in spite of attempts to correct the problem. (Chapter 58)
recirculation the movement of blood from one cannula to another in an extracorporeal membrane oxygenation (ECMO) circuit—specifically, blood being infused into a patient by a venous return catheter that is immediately removed from the patient by the venous drainage catheter during venovenous ECMO. (Chapter 51)
reconditioning physical activity to strengthen essential muscle groups, improve overall O_2 use, and enhance the body's cardiovascular response to physical activity. (Chapter 56)
recruitment maneuvers an intermittent intervention used on mechanically ventilated patients involving the very brief but repeated use of high ventilation pressures to expand previously collapsed alveoli. (Chapter 30)
reducing valve a valve that reduces gas pressure. (Chapter 41)
reexpansion pulmonary edema a type of pulmonary edema that forms after the rapid reexpansion of a lung that has been compressed with pleural fluid or pneumothorax. (Chapter 27)
reference range the acceptable range for a laboratory value measured during calibration or validation of an operation. (Chapter 17)
refractory period the period during which the myocardium cannot be stimulated. (Chapter 10)
regulator a device that controls both pressure and flow. (Chapter 41)
regurgitation the backward flow of blood through an incompetent valve of the heart. (Chapter 10)
reimbursement criteria the specific criteria required for reimbursement. (Chapter 56)
relative humidity (RH) the amount of moisture in the air compared with the maximum amount that the air could contain at the same temperature. (Chapter 6)
reliability how likely a particular tests is to have the same outcome if repeated. (Chapter 20)
repolarization a process by which the cell is restored to its resting potential. (Chapter 18)
research a scientific and systematic exploration of new knowledge. (Chapter 8)
reservoir system an O_2 delivery system providing a reservoir O_2 volume that the patient taps into when the patient's inspiratory flow exceeds the device flow. (Chapter 42)
residual drug volume medication that remains in a small-volume nebulizer after the device is no longer producing mist. (Chapter 40)
residual volume (RV) the volume of gas remaining in the lungs after a complete exhalation. (Chapter 20)
res ipsa loquitur "the thing speaks for itself"; a rule of evidence whereby the negligence of an alleged wrongdoer may be inferred from the fact that an event actually occurred. (Chapter 5)
resistance impedance to flow in a tube or conduit; quantified as ratio of the difference in pressure between the two points. (Chapters 3 and 46)
respirable mass proportion of aerosolized drug of the proper particle size to reach the lower respiratory tract. (Chapter 40)
respiratory acidosis hypoventilation resulting in acidemia. (Chapter 14)
respiratory alkalosis exists when low $PaCO_2$ decreases dissolved CO_2, raising the pH and leading to alkalemia. (Chapter 14)
respiratory alternans alternation between use of the diaphragm for short periods and use of the accessory muscles to breathe, indicative of end-stage respiratory muscle fatigue. (Chapters 16 and 45)
respiratory bronchioles bronchioles approximately 0.4 mm in diameter that have walls formed largely from flattened squamous epithelia and a thin outer layer of connective tissue. (Chapter 9)
respiratory care the healthcare discipline that specializes in the promotion of optimal cardiopulmonary function and health. Also called *respiratory therapy*. (Chapter 1)
***Respiratory Care* journal** a professional journal with an editorial board and editor in chief who are researchers and either respiratory therapists or physicians. (Chapter 2)
respiratory care practitioner a health professional with special training and experience in the treatment and rehabilitation of patients with

respiratory disorders. The respiratory care practitioner typically does not diagnose but must be able to assess patients in various clinical settings. (Chapter 1)

respiratory distress syndrome (RDS) a condition of respiratory distress in newborns, usually caused by the inadequate production (owing to immaturity) of surfactant. (Chapter 33)

respiratory hygiene/cough etiquette a state in which the respiratory tract is kept as free as possible from contaminants such as bacteria and other microbes. (Chapter 4)

respiratory inductive plethysmograph a device that, by measuring changes in the diameter of the chest and abdomen, can estimate inhaled and exhaled tidal volume. (Chapter 52)

respiratory quotient (RQ) the relationship between oxygen utilization and carbon dioxide production, normally equal to 0.8. (Chapter 23)

respiratory therapist (RT) a graduate of a Council on Accreditation of Allied Health Education Programs/Committee on Accreditation for Respiratory Care (CAAHEP/CoARC) accredited school designed to qualify the graduate for the registry examination of the National Board for Respiratory Care (NBRC). (Chapter 1)

respiratory therapy any treatment that maintains or improves the function of the respiratory tract. (Chapter 1)

resting energy expenditure (REE) caloric needs of the body estimated from O_2 consumption and CO_2 production, usually expressed in kcal/24 hour. (Chapter 23)

restrictive pulmonary disease **a pulmonary disease that primarily causes a** restriction of lung expansion. (Chapter 20)

retinol-binding protein a protein that is responsible for transporting vitamin A from the liver to other tissue. (Chapter 23)

retinopathy of prematurity (ROP) an abnormal ocular condition that occurs in some premature or low-birth-weight infants who receive O_2. Previously called *retrolental fibroplasias*. (Chapters 42 and 54)

retractions repetitive sinking inward of the skin around the chest cage with each inspiratory effort. (Chapter 16)

reverse triggering stimulation of the respiratory center to inspire after the delivery of a controlled positive e

Reynolds number a calculated valve that helps to determine if gas flow will be laminar or turbulent. (Chapter 6)

right-to-left shunt anatomic bypass in which blood flows from the venous to the arterial side of the circulation, bypassing the lungs; this lowers both the O_2 content and PO_2 of the arterial blood. (Chapter 12)

right ventricular heart failure poor pumping of the heart involving the right ventricle. (Chapter 31)

rise time the time it takes for the ventilator flow to reach its maximum flow. Rise time is a control variable available in all pressure-targeted modes. Functionally it changes the slope of the flow increase from baseline to maximum. (Chapter 48)

rocking bed a bed that rocks back and forth, moving the abdominal contents up and down facilitating inspiration and expiration. (Chapter 50)

root-cause analysis a process by which the underlying primary, secondary, and other notable causes of a medical error or other safety issue are identified, followed by the creation and implementation of an action plan. (Chapter 7)

rule of double effect a rule derived from the ethical principle of nonmaleficence, recognizing that an act can have both good and bad effects, and that to achieve the good effect, the bad effect must be tolerated. (Chapter 58)

rule utilitarianism moral reasoning approach based not on which act has the greatest utility, but on which rule would promote the greatest good if it were generally followed. (Chapter 5)

S

saccular stage the stage at which more terminal bronchioles and their associated acini form and develop from 26 weeks to birth. (Chapter 9)

sarcoidosis a chronic disorder of unknown origin characterized by the formation of tubercles of nonnecrotizing epithelioid tissue. (Chapter 26)

saturated solution a solution in which the solvent contains the maximum amount of solute it can take up. (Chapter 13)

scholarship the sharing of methods and findings of existing research and knowledge through presentations at professional events as well as publication in textbooks and journal articles. (Chapter 8)

scientific experiment a systematic evaluation of a specific substance, process or treatment that determines if the substance, process or treatment is legitimate. (Chapter 8)

scientific method usually thought of as a series of steps that lead from question to answer (and then usually to more questions). (Chapter 8)

scintigraph a photograph showing the distribution and intensity of radioactivity in various tissues and organs after administration of a radiopharmaceutical. (Chapter 40)

scope of practice the application of technology and the use of protocols across all care sites including but not limited to the hospital, clinic, physician's office, rehabilitation facility, skilled nursing facility and patient's home. (Chapter 2)

screening preliminary procedure, such as a test or examination, to detect the most characteristic sign or signs of a disorder that may require further investigation. (Chapter 32)

secondary spontaneous pneumothorax pneumothorax that occurs because of underlying lung disease. (Chapter 27)

sedimentation primary mechanism for the deposition of particles 1 to 5 mm in diameter in the central airways, when particles slow and settle out of suspension. (Chapter 40)

segs segmented neutrophils, the mature form of circulating neutrophils. (Chapter 17)

semilunar valves valves that separate the ventricles from their arterial outflow tracts, the pulmonary artery, and the aorta. (Chapter 10)

sensible measurable, as of water loss (e.g., losses from urine and the gastrointestinal tract). (Chapter 13)

sensitivity a test's ability to detect disease or its absence. (Chapter 20)

sensorium general term referring to the locus of a patient's consciousness. (Chapter 16)

serous pericardium the inner serous portion of the myocardium consisting of 2 layers the visceral and parietal layers. (Chapter 10)

servo targeting scheme a ventilator controlling scheme that continually evaluates the ventilator response and readjusts operation until it is on target. (Chapter 46)

servo-controlled heating system in a humidifier, heating unit that monitors the temperature of gas delivered to the patient, adjusting the power to the heater based on the difference between the temperature setting and the temperature monitored by a thermistor probe placed downstream from the humidifier at or near the patient airway connection. (Chapter 39)

severe obesity the state of having a body mass index greater than 40 kg/m^2. (Chapter 30)

shock a condition in which perfusion to vital organs is inadequate to meet metabolic needs; includes hypovolemic, cardiogenic, septic, anaphylactic, and neurogenic forms. (Chapter 16)

sickle cell hemoglobin the presence of hemoglobin S, causing the hemoglobin cell to form a sickle shape. (Chapter 12)

signs objective manifestations of illness, such as an increased respiratory rate and heartbeat. (Chapter 16)

silhouette in imaging, a sign obscuring of the margins of adjacent structures because they have the same density. (Chapter 21)

silicosis a lung disorder caused by continued long-term exposure to the dust of an inorganic compound, silicon dioxide, which is found in sands, quartzes, and many other stones; chronic silicosis is marked by widespread fibrotic nodular lesions in both lungs. (Chapter 26)

situs inversus a condition in which a patient's chest or abdominal contents are reversed. (Chapter 21)

Six Sigma a set of management techniques intended to improve business processes by reducing the probability of errors or defects. (Chapter 3)

six or twelve-minute walk a test that involves walking and an established protocol to assess a patient's level of physical conditioning. (Chapter 56)

skilled nursing facility (SNF) an institution or part of an institution that meets the criteria for accreditation established by the sections of the Social Security Act that determine the basis for Medicaid and Medicare reimbursement for skilled nursing care. Such care includes rehabilitation and various medical and nursing procedures. (Chapter 57)

skinfold measurement a measurement used to determine the percent body fat. (Chapter 23)

slander any words spoken with malice that are untrue and prejudicial to the reputation, professional practice, commercial trade, office, or business of another person. (Chapter 5)

sleep-disordered breathing periods of an absence of attempts to breathe during sleep. (Chapter 34)

sleep-related hypoventilation a syndrome in which CO_2 increases during sleep. (Chapter 33)

small cell cancer a malignant, usually bronchogenic epithelial neoplasm consisting of small, tightly packed round, oval, or spindle-shaped epithelial cells that stain darkly and contain neurosecretory granules and little or no cytoplasm. Many malignant tumors of the lung are of this type. Also called oat cell carcinoma or small cell carcinoma. (Chapter 32)

small for gestational age (SGA) a new born infant whose weight is low for his/her gestational age. (Chapter 54)

sniff nasal inspiratory pressure the amount of inspiratory pressure a patient can generate during the process of sniffing. (Chapter 45)

Society of Critical Care Medicine the primary American professional organization promoting critical care medicine. (Chapter 2)

soft palate structure composed of mucous membrane, muscular fibers, and mucous glands suspended from the posterior border of the hard palate forming the roof of the mouth. (Chapter 9)

sol layer the inner layer of mucus, which is much more fluid-like. (Chapter 9)

solitary pulmonary nodule (SPN) a pulmonary parenchymal opacity smaller than 3 cm in diameter that is totally surrounded by aerated lung. (Chapter 21)

solubility coefficient (gas) volume of gas that can be dissolved in 1 mL of a given liquid at standard pressure and specified temperature. (Chapter 6)

solute substance dissolved in a solution. (Chapter 13)

solution mixture of one or more substances dissolved in another substance. The molecules of each of the substances disperse homogeneously and do not change chemically. A solution may be a gas, a liquid, or a solid. (Chapter 13)

solvent any liquid in which another substance can be dissolved. (Chapter 13)

specific gravity ratio of the density of a substance to the density of another substance accepted as a standard. The usual standard for liquids and solids is water. A liquid or solid with a specific gravity four times the density of water at the same temperature. Hydrogen is the usual standard for gases. (Chapter 6)

specificity addresses a test's ability to detect disease or the absence of it. (Chapter 20)

spectrophotometry procedure for the measurement of color in a solution by determining the amount of light absorbed in the ultraviolet, infrared, or visible spectrum, widely used in clinical chemistry to calculate the concentration of substances in solution. (Chapter 19)

spiral arteries small arteries that temporality supply blood to the endometrium of the uterus during the luteal phase of the menstrual cycle. (Chapter 9)

spirometer sometimes used as a generic term for all volume-measuring and flow-measuring devices. (Chapter 20)

spirometry the measurement of air entering and leaving the lungs—includes measurement of several values of forced airflow and volume during inspiration and expiration. (Chapter 20)

splinting the process of immobilizing, restraining, or supporting a body part. (Chapter 44)

spontaneous awaking trial a trial of sedation removal or reduction performed prior to a spontaneous breathing trial. (Chapter 53)

spontaneous breath ventilatory support breaths initiated and ended by the patient. (Chapter 46)

spontaneous breathing trial (SBT) a trial of spontaneous breathing independent of the ventilator. (Chapter 53)

sporicidal a substance that is destructive to the spore form of bacteria. (Chapter 4)

sputum mucus from the respiratory tract that has passed through the mouth. (Chapter 16)

squamous cell carcinoma a type of lung cancer characterized by cells that appear plate-like. (Chapter 32)

ST-segment elevation myocardial infarction (STEMI) a myocardial infarction demonstrating ECG changes, specifically an elevation of the ST-segment of the ECG. (Chapter 18)

staging system See *TNM staging*. (Chapter 32)

standard bicarbonate plasma concentration of HCO_3^- measured in milli-equivalents per liter that would exist if PCO_2 were normal (40 mm Hg). (Chapter 14)

standard precautions guidelines recommended by the US Centers for Disease Control and Prevention to reduce the risk of transmission of blood-borne and other pathogens in hospitals. Standard precautions apply to (1) blood; (2) all body fluids, secretions, and excretions excluding sweat regardless of whether they contain blood; (3) nonintact skin; and (4) mucous membranes. (Chapter 4)

Starling equilibrium the filtration of fluid across a membrane as a result of equilibration of osmotic and hydrostatic forces across the membrane. (Chapter 13)

stenosis narrowing of a valve or vessel. (Chapters 10 and 37)

sterilization complete destruction of all microorganisms, usually by heat or chemical means. (Chapter 4)

sternal angle the fused connection between the manubrium and the body of the sternum, also known as the angle of Louis. (Chapter 9)

sternum elongated flattened bone forming the middle portion of the anterior thorax. (Chapter 9)

stomata small holes within the parietal pleura that are the main route whereby pleural fluid can exit. (Chapter 27)

STOP-BANG Assessment Tool a quick bedside process to evaluate the presence of sleep apnea. (Chapter 34)

STPD standard temperature and pressure dry; condition of a volume of gas at 0°C and 760 mm Hg and containing no water vapor (dry). It should contain a calculable number of moles of a particular gas. (Chapter 6)

strain-gauge pressure transducers a pressure-measuring device that records pressures by the expansion and contraction of a flexible metal diaphragm connected to electrical wires. (Chapter 6)

stress index an index used to determine whether, during mechanical controlled inhalation, there is overdistention or recruitment of collapsed lung. This is determined by the slope change in the airway pressure curve during volume-controlled square-wave ventilation. (Chapter 52)

strict liability a theory in tort law that can be used to impose liability without fault, even in situations where injury occurs under conditions of reasonable care. The most common cases of strict liability involve the use of dangerous products or techniques. (Chapter 5)

stridor a high-pitched, continuous type of adventitious lung sound heard from the upper airway. (Chapter 16)

stroke a condition characterized by the sudden onset of a neurologic deficit. (Chapter 33)

stroke volume the volume of blood ejected by the left ventricle during each contraction. (Chapter 10)

study subjects people (or animals or even inanimate objects) that meet the entry criteria and are enrolled in the study. (Chapter 8)

subatmospheric pressure pressure below ambient. (Chapter 11)

subcutaneous emphysema an accumulation of air in the subcutaneous tissues owing to leakage from the lung. (Chapter 16)

sublimation term describing the phase transition from a solid to a vapor without becoming a liquid as an intermediary form. (Chapter 6)

substituted judgment judgements or decision made by a third party based on that individuals knowledge of the desires of the patient. (Chapter 58)

suctioning process of mechanically aspirating airway secretions. (Chapter 37)

sudden infant death syndrome (SIDS) the leading cause of death in infants less than 1 year old in the United States. Commonly called *crib death*. (Chapter 35)

sulci surface grooves at the boundaries of the heart chambers. (Chapter 10)

superobesity the state of having a body mass index of greater than 50 kg/m^2. (Chapter 30)

supervisors/lead therapists often more experienced, more highly credentialed therapists who are more highly educated. (Chapter 2)

supplemental oxygen O_2 delivered at concentrations exceeding 21% to increase the amount of O_2 circulating in the blood. (Chapter 25)

suprasternal notch a shallow depression that forms from the superior edge of the manubrium. (Chapter 9)

surface tension the tendency of a liquid to minimize the area of its surface by contracting. This property causes liquids to rise in a capillary tube; it also affects the exchange of gases in the pulmonary alveoli and alters the ability of various liquids to wet another surface. (Chapters 6 and 11)

surfactant a surface-acting agent that forms a monomolecular layer over pulmonary alveolar surfaces. These agents prevent alveolar collapse at lower lung volumes by reducing alveolar surface tension. (Chapter 54)

surgical resection the partial removal of an organ or tissues by surgical means. (Chapter 32)

surveillance a (bacteriologic) ongoing process designed to ensure that infection control procedures are working; generally involves equipment, microbiologic identification, and epidemiologic investigation. (Chapter 4)
suspension dispersion of large particles suspended in a fluid medium; without physical agitation, the particles eventually settle out. (Chapter 13)
Swan-Ganz catheter a catheter that is positioned in the pulmonary artery to measure pressures in the heart and pulmonary circulation and can be used to determine the patient's circulatory status. (Chapter 52)
sweat chloride an analysis of the sodium chloride content of sweat used in the diagnosis of cystic fibrosis. (Chapter 17)
sweep flow the flow of gas in a direction opposite the flow of blood through an extracorporeal membrane oxygenation oxygenator to remove CO_2 and add O_2. Normally the gas is O_2 but on occasion small amounts of CO_2 are added. (Chapter 51)
symptoms the sensations or subjective experiences of some aspect of an illness, such as breathlessness. (Chapter 16)
synchronized cardioversion the delivery of countershock synchronized with the heart's electrical activity. (Chapter 38)
synchronous intermittent mandatory ventilation (SIMV) a mode of ventilatory support using periodic assisted ventilation with spontaneous breathing in between. Assisted breaths are responsive to patient demand. (Chapters 49 and 53)
syncope temporary unconsciousness; fainting. (Chapter 16)
systematic error nonrandom statistical error that affects the mean of a population of data and defines the bias between the means of two populations. (Chapters 19 and 52)
systolic pressure peak blood pressure occurring in the arteries during ventricular contraction. (Chapter 16)
systemic vasodilation relaxation of the arterial blood vessels in the systemic circulation. (Chapter 31)

T

T wave a wave following the QRS complex on an ECG that donates repolarization of the ventricles of the heart. (Chapter 10)
tachycardia an abnormally elevated heart rate. (Chapter 16)
tachyphylaxis a phenomenon in which the repeated administration of some drugs results in a marked decrease in effectiveness. (Chapter 36)
tachypnea an abnormal elevation of breathing rate. (Chapter 16)
tamponade (cardiac) the accumulation of blood in the pericardial sac, increasing pericardial pressure and reducing cardiac output. (Chapter 51)
target heart rate the heart rate achieved at 65% of a patient's maximum O_2 consumption during an exercise evaluation, used for aerobic conditioning. (Chapter 56)
targeting scheme the approach used by a particular mode to achieve the various targets active during ventilation. (Chapter 46)
telemedicine the use of electronic and telecommunication technologies to support healthcare at a geographically different location from that of the patient, thus increasing access to specialty patient care. (Chapter 7)
telemonitoring the monitoring of a patient's clinical condition through a computerized connection to a healthcare facility. (Chapter 7)
telerehabilitation the use a combination of a personal computer or device, a reliable internet connection, a patient monitoring module, and relatively low-cost exercise equipment to allow patients to participate in pulmonary rehabilitation. (Chapter 56)
tension the pressure exerted by gases dissolved in liquids. (Chapter 6)
tension pneumothorax air in the pleural space that exceeds atmospheric pressure, causing outward expansion of the ribs, downward depression of the diaphragm, mediastinal shift, and hypotension. (Chapters 27, 30 and 48)
terminal bronchioles the smallest conducting airways that supply gas to the respiratory zone of the lung. (Chapter 9)
tetralogy of Fallot a congenital cardiac anomaly that consists of four defects: pulmonic stenosis, ventricular septal defect, malposition of the aorta so that it arises from the septal defect or the right ventricle, and right ventricular hypertrophy. (Chapter 35)
thebesian veins veins in the thoracic in which flow through them is part of the normal anatomic shunting of blood past the heart. (Chapter 10)
therapeutic index difference between the minimum therapeutic and minimum toxic concentrations of a drug. (Chapter 40)
thermal conductivity a measure of gas concentrations in a sample calculated by detecting the rate at which different gases conduct heat. (Chapter 6)
thermodynamics the science of the interconversion of heat and work. (Chapter 6)
thiosulfate a compound ($S_2O_3^{2-}$) that is an oxyanion of sulfur used in treating carbon monoxide poisoning. (Chapter 30)
thoracentesis surgical perforation of the chest wall and pleural space with a needle for diagnostic or therapeutic purposes or for the removal of a specimen for biopsy. (Chapter 27)
thoracic flap or flail chest two or more ribs broken in two or more places, creating an unstable segment of the chest wall. (Chapter 30)
thoracic gas volume (TGV) a technique that measures lung volume. (Chapter 20)
thoracic inlet the opening into the thorax formed by first ribs and the upper sternum. (Chapter 9)
thoracic pump a term used to describe the negative and positive intrathoracic pressure changes during breathing that assist venous return of blood to the heart. (Chapter 10)
Thorpe tube a variable- orifice constant-pressure flowmeter. (Chapter 41)
thrill a fine palpable vibration felt accompanying a cardiac or vascular murmur. (Chapter 16)
thrombocytes the smallest cells in the blood; they are formed in the red bone marrow and some are stored in the spleen. Platelets are disc shaped, contain no hemoglobin, and are essential for the coagulation of blood and in maintenance of hemostasis. (Chapter 17)
thrombocytopenia an abnormal condition in which the number of blood platelets is reduced, usually associated with neoplastic diseases or an immune response to a drug. (Chapter 17)
thyroid cartilage a cartilage forming most of the upper portion of the larynx, generally referred to
as the Adam's apple a common term for the larynx. (Chapter 9)
tidal pressure tidal volume scaled by elastance or compliance. (Chapter 46)
tidal volume (V_T) volume of air that is inhaled or exhaled from the lungs during effortless breath. (Chapters 11, 20)
time constant mathematical expression describing the relative efficacy of lung unit filling and emptying and computed as the product of compliance times resistance (measured in seconds). (Chapters 11, 46 and 47)
tissue oxygen sensing the monitoring of the O_2 saturation or PO_2 at the tissue level. (Chapter 52)
tonsillectomy removal of the tonsils. (Chapter 9)
tort a legal wrong committed on a person or property independent of contract. (Chapter 5)
total bilirubin a substance produced by the liver from the breakdown of destroyed red blood cells (RBCs). (Chapter 17)
total lung capacity (TLC) the total amount of gas in the lungs after a maximum inspiration. (Chapter 20)
trachea the large main intrathoracic airway. (Chapter 9)
tracheal malacia softening of the tracheal cartilages. (Chapters 48)
tracheal stenosis a narrowing of the tracheal diameter. (Chapter 48)
tracheal tugging the effect of an aortic aneurysm in which the trachea is pulled downward with each heart contraction. (Chapter 16)
tracheoesophageal fistula a congenital malformation or an abnormality associated with disease in which there is an abnormal tube-like passage between the trachea and the esophagus. (Chapters 37 and 48)
tracheoinnominate artery fistula a fistula (connection between the trachea and the innominate artery). (Chapter 37)
tracheomalacia softening of the cartilaginous rings, which causes collapse of the trachea during inspiration and expiration. (Chapter 37)
tracheostomy an opening through the neck into the trachea, through which an indwelling tube may be inserted. (Chapter 37)
tracheostomy tubes artificial airways that are surgically placed directly into the trachea. (Chapter 37)
tracheotomy procedure by which an incision is made into the trachea through the neck below the larynx to gain access to the lower airways. (Chapter 37)
transairway pressure the difference between airway pressure and alveolar pressure. (Chapters 11 and 47)
transairway pressure gradient the pressure gradient between the mouth and alveoli that moves air into and out of the lung. (Chapter 11)

transalveolar pressure the difference between alveolar pressure and pleural pressure. (Chapter11)

transbronchial biopsy a lung tissue specimen obtained through a needle insertion, bronchoscopy, or surgery. (Chapter 22)

transbronchial needle aspiration the technique of sampling lung tissue through a bronchoscope that involves passing a thin needle through a bronchus. (Chapters 22 and 32)

transcellular fluid fluid that normally moves from the extravascular space into the cells. (Chapter 13)

trans–chest wall pressure the difference between the pleural space and the body surface. Also called transthoracic pressure. (Chapters 11 and 47)

transdiaphragmatic pressure (P_{di}) the pressure change across the diaphragm associated with breathing. (Chapter 47)

transient tachypnea of the newborn (TTN) the periodic increase in respiratory rate that is commonly observed in low-birth-weight infants. (Chapter 35)

transposition of the great arteries a congenital cardiac condition characterized by an anatomic abnormality in which the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle. (Chapter 35)

transpulmonary of or pertaining to the difference in a parameter (e.g., pressure) between the alveoli and pleural space. (Chapter 10)

transpulmonary pressure the difference between the alveolar pressure and intrapleural pressure of the lungs. (Chapters 47, 49 and 52)

transpulmonary pressure difference the difference between intraalveolar and intrapleural pressure, or the pressure acting across the ling from the pleural space to the alveoli. (Chapter 11)

transpulmonary pressure gradient the pressure gradient between the mouth and the pleural space that allows inspiration and expiration. Normally positive at end expiration and negative at end inspiration. (Chapter 11)

transrespiratory pressure the difference between the alveolar pressure and pressure on the body surface. (Chapters 11 and 47)

transthoracic needle biopsy the technique of obtaining a biopsy specimen of lung tissue by passing a needle into the chest, often guided by imaging. (Chapter 32)

transthoracic pressure of or pertaining to the difference in a parameter (such as pressure) between the pleural space and body surface. (Chapter 47)

transthoracic pressure difference (P_{TT}) the difference between the pleural space and the body surface. Also called trans–chest wall pressure. (Chapter 11)

transthyretin a transport protein in the serum and cerebrospinal fluid that carries the thyroid hormone (T4) and retinal binding protein bound to retinal. (Chapter 23)

transtracheal oxygen therapy (T_{TOT}) the administration of O_2 via a low-flow catheter inserted directly into the trachea. (Chapter 57)

transudate the fluid that moves out of a cell or tissue as a result of a concentration/pressure gradient. (Chapter 30)

transudative pleural effusion a pleural effusion low in protein and lactate dehydrogenase, usually caused by congestive heart failure, nephrosis, or cirrhosis. (Chapter 27)

traumatic brain injury a general term referring to any class of either focal or diffuse lesions that can result from head trauma; these lesions include injury to the nerve body (axon), hypoxic brain damage, swelling, hemorrhage, contusions, laceration, and infection. (Chapter 33)

Trendelenburg position the position in which the head is low and the body and legs are on an inclined plane. (Chapter 50)

trepopnea shortness of breath experienced by a patient while side lying. (Chapter 16)

tricuspid valve the valve on the right side of the heart. (Chapter 10)

trigger the inspiratory force a patient must generate to initiate a breath on a mechanical ventilator. (Chapter 46)

trigger asynchrony a lack of coordination between the patient's inspiratory effort and the response of the mechanical ventilator. (Chapter 48)

trigger delay a delay in ventilator response to a patient's inspiratory effort. (Chapter 48)

tripod sign the use of the elbows on a hard surface to support the movement of the chest wall and lung during breathing. This position gives a mechanical advantage to the accessory breathing muscles of the upper chest and neck. (Chapter 16)

troponin a protein in the striated cell ultrastructure that modulates the interaction between actin and myosin molecules. It is believed to be part of the calcium-binding complex of the thin myofilaments. The level of blood troponin is used to identify the presence of a myocardial infarction. (Chapter 17)

troponin I a protein similar to CPK-2; troponin I levels peak 12 to 16 hours after a myocardial infarction. It is associated with cardiac muscle damage. (Chapter 17)

true ribs the first seven ribs on each side of the thorax, called true ribs. (Chapter 9)

true-experimental experiment that attempts to prove the null hypothesis incorrect, that is that there is a difference between two treatments, substances, or devices. (Chapter 8)

tuberculosis a chronic granulomatous infection caused by an acid-fast bacillus, *Mycobacterium tuberculosis*. It is generally transmitted by the inhalation or ingestion of infected droplets and usually affects the lungs, although infection of multiple organ systems occurs. (Chapter 24)

tumor, node, metastasis (TNM) staging staging system based on a size of the tumor *(T)*, the presence and position of abnormal lymph nodes *(N)*, and the presence or absence of metastasis (or spread beyond the primary tumor site) *(M)*. (Chapter 32)

turbinates bony structures that extend from the lateral walls of the interior nasal passages. (Chapter 9)

turbulent flow flow of a fluid that does not occur in a straight line; flow in which molecules tumble over each other. (Chapter 6)

type I pneumocyte cuboidal, secretory epithelia that line the blind tubules of the acinus cells. (Chapter 9)

type II pneumocyte pneumocyte granular cells that are highly active and form part of the lining of the alveoli. These cells secrete surfactant and other substances. (Chapter 9)

U

ultrasonic nebulizer (USN) an aerosol generator in which an electrical signal is used to produce high-frequency vibrations in a container of fluid. The vibrations break up the fluid into aerosol particles. (Chapter 39)

ultrasound, diaphragm the actual diaphragm of an ultrasonic nebulizer that transmits ultrasonic waves to a liquid to form an aerosol. (Chapter 53)

ultrathin bronchoscopy a bronchoscope that has a smaller than usual diameter and circumference to permit insertion into small airways. (Chapter 22)

upper airway stimulation a newer way of treating obstructive sleep apnea which involves implantation of a nerve stimulator to maintain upper airway patency. (Chapter 34)

upper confidence a term used to define upper acceptable limit of a value during a statistical analysis. (Chapter 3)

upstream reference to a point closer to the source in a stream of flowing fluid. (Chapter 41)

uvula a small cone-shaped process suspended in the mouth from the middle of the posterior border of the soft palate. (Chapter 9)

uvulopalatopharyngoplasty (UVPPP) a surgical procedure used in treating severe obstructive sleep apnea, which involves shortening of the soft palate and removal of the uvula and tonsils. (Chapter 34)

V

v wave a rapid decrease in atrial pressures. (Chapter 10)

vagovagal reflexes reflexes caused by the stimulation of parasympathetic receptors in the airways that can result in laryngospasm, bronchoconstriction, hyperpnea, and bradycardia; often associated with mechanical stimulation, as during procedures such as tracheobronchial aspiration, intubation, or bronchoscopy. (Chapter 15)

validity meaningfulness, or the ability to accurately measure what an instrument or procedure was intended to measure. (Chapter 20)

vallecula the anatomic depression immediately beyond the base of the tongue. (Chapter 9)

value-based purchasing (VBP) a system of reimbursement by the government Centers for Medicare and Medicaid Services to hospitals and healthcare providers that is partially based on their ability to meet a predefined set of standards. (Chapter 7)

values, beliefs, and preferences what an individual considers an acceptable ethical standard based on their prior experiences, knowledge and cultural beliefs. (Chapter 58)

van der Waals forces forces that maintain a solid's shape because their atoms are kept in place by strong mutual attraction. (Chapter 6)

vaporization a process whereby matter in its liquid form is changed into its vapor or gaseous form. (Chapter 6)

vasoconstriction narrowing of the blood vessels. (Chapter 10)

vasodilation widening or distention of blood vessels, particularly arterioles, usually caused by nerve impulses or certain drugs that relax smooth muscle in the walls of the blood vessels. (Chapter 10)

vasopressor a medication that causes constriction of the blood vessels, generally used to increase blood pressure. (Chapter 36)

VCV acronym for *volume-controlled ventilation,* a mode of ventilatory support in which volume (or flow × time) serves as the cycle variable. (Chapters 46 and 49)

venoarterial (VA) an approach to ECMO in which blood is removed from the body on the venous side of circulation and returned on the arterial side, used to support heart function. (Chapter 51)

venous admixture mixing of venous blood with arterial blood, resulting in a decrease in the O_2 content of the latter; occurs in anatomic and physiologic shunting. (Chapters 12 and 52)

venous reservoir the capacity of the venous system to pool large volumes of blood. (Chapter 51)

venous thromboembolism (VTE) a clot that spreads from one venous bed to another, such as from the leg veins to the lung. (Chapter 28)

venovenous (VV) approach to ECMO in which blood is removed from the venous circulation but also returned to the venous circulation used to manage lung disease. (Chapter 51)

ventilation/perfusion (V/Q) ratio ratio of pulmonary alveolar ventilation to pulmonary capillary perfusion, both measured quantities being expressed in the same units. (Chapter 12)

ventilation/perfusion (V/Q) scan a scan of the lungs and pulmonary circulation, thus distribution of ventilation is identified but also distribution of perfusion providing the relationship between ventilation and perfusion of the whole lung and regions of the lung. (Chapter 28)

ventilator-associated events a method of determining the quality of mechanical ventilation by evaluating changes associated with the management of hypoxemia. (Chapter 24)

ventilator-associated pneumonia a lower respiratory tract infection that develops more than 48 to 72 hours after endotracheal intubation. (Chapter 24)

ventilator-induced diaphragmatic dysfunction a very common condition among critically ill patients that results in weaning failure and long-term respiratory impairment. (Chapter 33)

ventilator-induced lung injury (VILI) lung injury that occurs as a result of excessive pressure and/or volume during mechanical ventilation. (Chapter 29)

ventilatory threshold during exercise, the point at which increased levels of lactic acid result in increased CO_2 production and minute ventilation; the respiratory quotient (RQ) equals or exceeds 1.0, indicating that CO_2 production equals or exceeds O_2 consumption; at this point, metabolism becomes anaerobic, decreasing energy production and increasing muscle fatigue. (Chapter 56)

ventral respiratory groups (VRGs) groupings of cells in the medulla oblongata that are active in controlling both inspiration and expiration. (Chapter 15)

Venturi effect the flow of a gas through a constriction and the subsequent drop in pressure at the constriction. (Chapter 6)

veracity a principle that binds the healthcare provider and the patient to tell the truth, creating an environment of trust and the mutual sharing of information. (Chapter 5)

very low birth weight (VLBW) describing a newborn who weighs less than the 95% percentile of weight for newborns. (Chapter 54)

virtue ethics the viewpoint that asks what a virtuous person would do in a similar circumstance; it is based on personal attributes of character or virtue rather than on rules or consequences. (Chapter 5)

virucidal an agent that destroys or inactivates viruses. (Chapter 4)

visceral pleura a thin membrane covered by mesothelial cells that covers the entire surface of the lung, dipping into the lobar fissures. (Chapters 9 and 27)

viscosity internal force that opposes flow of a fluid, either a liquid or a gas. (Chapter 6)

vital capacity (VC) the total amount of air that can be exhaled after a maximum inspiration; the sum of the inspiratory reserve volume, tidal volume, and expiratory reserve volume. (Chapters 20 and 52)

volatile acid an acid that can be excreted in its gaseous form; physiologically, carbonic acid is a volatile acid; approximately 24,000 mmol/L CO_2 is eliminated from the body daily via normal ventilation. (Chapter 14)

voltage the expression of electromotive force in terms of volts. (Chapter 3)

volume-median diameter (VMD) the median diameter of an aerosol particle measured in units of volume. (Chapter 40)

volume support pressure-limited ventilation in which tidal volume is targeted. (Chapter 49)

volumetric capnography a way of measuring the volume of exhaled carbon dioxide to assess a patient's ventilatory status. (Chapter 19)

volutrauma alveolar overdistention and damage caused by ventilation with high peak inflation pressures. (Chapters 29 and 47)

W

water vapor pressure the pressure exerted by water in its gaseous state. (Chapter 6)

weight-per-volume (W/V) solution defined as the weight of solute per volume of solution. (Chapter 13)

wet drowning drowning due to the entry into the lungs of a large amount of water. (Chapter 30)

wheezes high-pitched, continuous type of adventitious lung sound. (Chapter 16)

withholding and withdrawing life-sustaining treatment based on the patient's wishes either discontinuing or not initiating treatment that is considered life-sustaining. (Chapter 58)

work of breathing (WOB) the amount of force needed to move a given volume into the lung with a relaxed chest wall; mathematically, work is the integral of pressure × volume. (Chapter 45)

X

xiphoid process the pointed lower portion of the sternum. (Chapter 9)

Z

zone valve on/off piping valve that controls medical gas distribution to a prespecified zone of a building. (Chapter 41)

ABBREVIATIONS

Δ	change in
μ	micro-
μg	microgram
μm	micrometer
μV	microvolt
A	alveolar
a	arterial
AARC	American Association for Respiratory Care
ABG(s)	arterial blood gas(es)
A/C	assist/control
ACBT	active cycle of breathing technique
ADH	antidiuretic hormone
AIDS	acquired immunodeficiency syndrome
AII	airborne infection isolation
ALI	acute lung injury
ALV	adaptive lung ventilation
ANP	atrial natriuretic peptide
AOP	apnea of prematurity
APRV	airway pressure release ventilation
ARDS	acute respiratory distress syndrome
ARF	acute respiratory failure
ASV	adaptive support ventilation
ATC	automatic tube compensation
ATM	atmospheric pressure
ATPD	ambient temperature and pressure, dry
ATPS	ambient temperature and pressure, saturated with water vapor
auto-PEEP	unintended positive end expiratory pressure
AV	arteriovenous
AVP	arginine vasopressin
B	barometric
BAC	blood alcohol content
BE	base excess
bilevel PAP	bilevel positive airway pressure
BiPAP	registered trade name for bilevel PAP device
BP	blood pressure
BPD	bronchopulmonary dysplasia
BSA	body surface area
BTPS	body temperature and pressure, saturated with water vapor
BUN	blood urea nitrogen
C	compliance
c	capillary
C′	pulmonary-end capillary
°C	degrees of Celsius
C_aO_2	arterial content of oxygen
$C(a-\bar{v})O_2$	arterial-to-mixed venous oxygen content difference
CC	closing capacity
cc	cubic centimeter
$Cc'O_2$	content of oxygen of the ideal alveolar capillary
C_D	dynamic characteristic or dynamic compliance
CDC	U.S. Centers for Disease Control and Prevention
CDH	congenital diaphragmatic hernia
CDS	clinical decision support
CHF	congestive heart failure
CI	cardiac index
CINAHL	Cumulative Index to Nursing and Allied Health Literature
C_L	lung compliance (also C_{Lung})
cm	centimeters
cm H_2O	centimeters of water pressure
CMS	Centers for Medicare and Medicaid Services
CMV	controlled (continuous) mandatory or mechanical ventilation
CNS	central nervous system
CO	carbon monoxide
CO_2	carbon dioxide
CoARC	Committee on Accreditation for Respiratory Care
COHb	carboxyhemoglobin
COLD	chronic obstructive lung disease
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CPG	Clinical Practice Guideline
CPOE	computerized physician order entry
CPP	cerebral perfusion pressure
CPPB	continuous positive pressure breathing
CPPV	continuous positive pressure ventilation
CPR	cardiopulmonary resuscitation
CPT	chest physical therapy
CPU	central processing unit
CQI	continuous quality improvement
CRCE	continuing respiratory care education
C_s	static compliance
CSF	cerebrospinal fluid
CSV	continuous spontaneous ventilation
CT	computed tomography
C_T	tubing compliance (also C_{tubing})
CV	closing volume
CvO_2	venous oxygen content
$C\bar{v}O_2$	mixed venous oxygen content
CVP	central venous pressure
D	diffusing capacity
d	diameter
DC	discharges, discontinue
DC-CMV	dual controlled–continuous mandatory ventilation
DC-CSV	dual controlled–continuous spontaneous ventilation
DIC	disseminated intravascular coagulation
DLCO	diffusing capacity of the lung
Dm	diffusing capacity of the alveolocapillary membrane
DO_2	oxygen delivery
DPAP	demand positive airway pressure
DPPC	dipalmitoyl phosphatidylcholine
DVT	deep venous thrombosis
E	elastance
EAdi	electrical activity of the diaphragm
$ECCO_2R$	extracorporeal carbon dioxide removal
ECG	electrocardiogram
ECLS	extracorporeal life support
ECMO	extracorporeal membrane oxygenation
EDV	end-diastolic volume
EE	energy expenditure
EEP	end expiratory pressure
EHR	electronic health record
EIB	exercise-induced bronchospasm
EMR	electronic medical record
EPAP	end positive airway pressure
ERV	expiratory reserve volume
ET	endotracheal tube
E_TCO_2 or $etCO_2$	end-tidal CO_2
F	fractional concentration of a gas
°F	degrees Fahrenheit
f	respiratory frequency, respiratory rate
FDA	U.S. Food and Drug Administration
FEF	forced expiratory flow

FEF_{max}	maximal forced expiratory flow achieved during FVC
FEF_X	forced expiratory flow, related to some portion of FVC curve
FET_X	forced expiratory time for a specified portion of FVC
FEV_1	forced expiratory volume at 1 second
$FiCO_2$	fractional inspired carbon dioxide
FIF	forced inspiratory flow
F_iO_2	fractional inspired oxygen
FIVC	forced inspiratory vital capacity
FRC	functional residual capacity
FVC	forced vital capacity
FVS	full ventilatory support
f/V_T	rapid shallow breathing index (frequency divided by tidal volume)
G_{aw}	airway conductance
GCS	Glasgow Coma Scale
g/dl	grams per deciliter
GERD	gastroesophageal reflux disease
$[H^+]$	hydrogen ion concentration
HAI	health care–associated infection
HAP	hospital-acquired pneumonia
Hb	hemoglobin
HBO	hyperbaric oxygen (therapy)
HCAP	health care–associated pneumonia
HCH	hygroscopic condenser humidifier
HCO_3^-	bicarbonate
H_2CO_3	carbonic acid
H_2O	water
He	helium
He/O_2	helium/oxygen mixture; heliox
HFFI	high-frequency flow interrupter
HFJV	high-frequency jet ventilation
HFNC	high-flow nasal cannula
HFO	high-frequency oscillation
HFOV	high-frequency oscillatory ventilation
HFPPV	high-frequency positive pressure ventilation
HFPV	high-frequency percussive ventilation
HFV	high-frequency ventilation
HHb	reduced or deoxygenated hemoglobin
HMD	hyaline membrane disease
HME	heat and moisture exchanger
HMEF	heat and moisture exchange filter
HR	heart rate
HRRP	Hospital Readmission Reduction Program
ht	height
Hz	hertz
I	inspired
IBW	ideal body weight
IC	inspiratory capacity
ICP	intracranial pressure
ICU	intensive care unit
ID	inner diameter
I:E	inspiratory-to-expiratory ratio
ILD	interstitial lung disease
IMPRV	intermittent mandatory pressure release ventilation
IMV	intermittent mandatory ventilation
INO	inhaled nitric oxide
IPAP	inspiratory positive airway pressure
IPPB	intermittent positive pressure breathing
IPPV	intermittent positive pressure ventilation
IPV	intrapulmonary percussive ventilation
IR	infrared
IRB	institutional review board
IRDS	infant respiratory distress syndrome
IRV	inspiratory reserve volume
IRV	inverse ratio ventilation
IV	intravenous
IVC	inspiratory vital capacity
IVH	intraventricular hemorrhage
IVOX	intravascular oxygenator
kcal	kilocalorie
kg	kilogram
kg-m	kilogram-meters
kPa	kilopascal
KPI	key performance indicator
L	liter
LAP	left atrial pressure
lb	pound
LBW	low birth weight
LED	light-emitting diode
LFPPV-$ECCO_2R$	low-frequency positive pressure ventilation with extracorporeal carbon dioxide removal
LMS	learning management system
LPV	lung protective ventilation
LTACH	long-term acute care hospital
LV	left ventricle
LVEDP	left ventricular end-diastolic pressure
LVEDV	left ventricular end-diastolic volume
LVSW	left ventricular stroke work
m^2	meters squared
MABP	mean arterial blood pressure
MAlvP	mean alveolar pressure
MAP	mean arterial pressure or mean airway pressure
MAS	meconium aspiration syndrome
max	maximal
MDI	metered dose inhaler
MDR	multidrug resistant
MEP	maximum expiratory pressure
mEq/L	milliequivalents per liter
metHb	methemoglobin
mg	milligram
mg%	milligram percent
mg/dl	milligrams per deciliter
MI	myocardial infarction
MICP	mobile intensive care paramedic
MI-E	mechanical insufflation-exsufflation
MIF	maximum inspiratory force
MIGET	multiple inert gas elimination technique
min	minute
MIP	maximum inspiratory pressure
MIPS	Merit-based Incentive Payment System
mL	milliliter
mm	millimeter
mm Hg	millimeters of mercury
MMAD	median mass aerodynamic diameter
mmol	millimole
MMV	mandatory minute ventilation
mo	month
MODS	multiple organ dysfunction syndrome
MOV	minimal occluding volume
$mP_{aw} - P_{\overline{aw}}$	mean airway pressure
MRI	magnetic resonance imaging
msec	millisecond
MV	mechanical ventilation
MVV	maximum voluntary ventilation

NaBr	sodium bromide
NaCl	sodium chloride
NAVA	neurally adjusted ventilatory assist
NBRC	National Board of Respiratory Care
NEEP	negative end expiratory pressure
nHFOV	nasal high-frequency oscillatory ventilation
NICU	neonatal intensive care unit
NIF	negative inspiratory force (also see MIP and MIF)
NIH	National Institutes of Health
NIV	noninvasive ventilation
nM	nanomole
nm	nanometer
NMBA	neuromuscular blocking agent
nM/L	nanomole per liter
NO	nitric oxide
NO_2	nitrous oxide
NP	nasopharyngeal
NPO	nothing by mouth
NPPV	noninvasive positive pressure ventilation
NPV	negative pressure ventilation
NSAIDs	nonsteroidal antiinflammatory drugs
nSIMV	nasal synchronized intermittent mandatory ventilation
N-SiPAP	nasal positive airway pressure with periodic (sigh) bilevel positive airway pressure breaths or bilevel nasal continuous positive airway pressure
NTE	neutral thermal environment
O_2	oxygen
O_2Hb	oxygenated hemoglobin
OH^-	hydroxide ions
OHDC	oxyhemoglobin dissociation curve
OSA	obstructive sleep apnea
OSHA	Occupational Safety and Health Administration
ΔP	change in pressure
P	pressure
P_{50}	PO_2 at which 50% saturation of hemoglobin occurs
P_{100}	pressure on inspiration measured at 100 msec
Pa	arterial pressure
PA	pulmonary artery
$P(A\text{-}a)O_2$	alveolar-to-arterial partial pressure of oxygen
P(A-awo)	pressure gradient from alveolus to airway opening
$PACO_2$	partial pressure of carbon dioxide in the alveoli
$PaCO_2$	partial pressure of carbon dioxide in the arteries
$P(a\text{-}et)CO_2$	arterial-to-end-tidal partial pressure of carbon dioxide
PAGE	perfluorocarbon associated gas exchange
PAH	pulmonary arterial hypertension
P_{al}	alveolar pressure
PAO_2	partial pressure of oxygen in the alveoli
PaO_2	partial pressure of oxygen in the arteries
PaO_2/FiO_2	ratio of arterial PO_2 to FiO_2
PaO_2/PAO_2	ratio of arterial PO_2 to alveolar PO_2
PAOP	pulmonary artery occlusion pressure (Also known as pulmonary capillary wedge pressure [PCWP])
PAP	mean pulmonary artery pressure
$\underline{PAP}$	pulmonary artery pressure
P_{aug}	pressure augmentation
PAV	proportional assist ventilation
P_{aw}	airway pressure
$\overline{P}_{aw}$	mean airway pressure
P_{awo}	airway opening pressure
PAWP	pulmonary artery wedge pressure
PB	barometric pressure
PBW	predicted body weight
P_{bs}	pressure at the body's surface
PC-CMV	pressure-controlled continuous mandatory ventilation
PCEF	peak cough expiratory flow
PC-IMV	pressure-controlled intermittent mandatory ventilation
PCIRV	pressure control inverse ratio ventilation
PCO_2	partial pressure of carbon dioxide
PC-SIMV	pressure-controlled synchronized intermittent mandatory ventilation
PCV	pressure-controlled ventilation
PCWP	pulmonary capillary wedge pressure
$PCWP_{tm}$	transmural pulmonary capillary wedge pressure
PDA	patent ductus arteriosus
PE	pulmonary embolism
PE_{max}	maximal expiratory pressure
PEA	pulseless electrical activity
P_ECO_2	partial pressure of mixed expired carbon dioxide
PEEP	positive end expiratory pressure
$PEEP_E$	extrinsic PEEP (set-PEEP)
$PEEP_I$	intrinsic PEEP (auto-PEEP)
$PEEP_{total}$	total PEEP (sum of intrinsic and extrinsic PEEP)
PEFR	peak expiratory flow rate
P_{es}	esophageal pressure
PET	positron emission tomography
$PetCO_2$	partial pressure of end-tidal carbon dioxide
P_{flex}	pressure at the inflection point of a pressure/volume curve
PFT	pulmonary function test(ing)
P_{ga}	gastric pressure
pH	relative acidity or alkalinity of a solution
P_{high}	high pressure during APRV
PHY	permissive hypercapnia
PIE	pulmonary interstitial edema
PIF	pulmonary interstitial fibrosis
PI_{max}	maximum inspiratory pressure (also MIP, MIF, NIF)
P_{inside}	inside pressure
$P_{intrapleural}$	intrapleural pressure (also Ppl)
PiO_2	partial pressure of inspired oxygen
PIP	peak inspiratory pressure (also P_{peak})
PISS	pin-indexed safety system
P_L	transpulmonary pressure
P_{low}	low pressure during APRV
PLV	partial liquid ventilation
P_M	mouth pressure
pMDI	pressurized metered dose inhaler
P_{mus}	muscle pressure
PO_2	partial pressure of oxygen
POCT	point of care testing
$P_{outside}$	pressure outside
PPACA	Patient Protection and Affordable Care Act
P_{peak}	peak inspiratory pressure (also PIP)
PPHN	primary pulmonary hypertension of the neonate
P_{pl}	intrapleural pressure
$P_{plateau}$	plateau pressure
ppm	parts per million
PPST	premature pressure support termination
PPV	positive pressure ventilation
PRA	plasma renin activity
PRVC	pressure regulated volume control
PS	pressure support
PSB	protected specimen brush
P_{set}	set pressure
psi	pounds per square inch
psig	pounds per square inch gauge

PS_{max}	maximum pressure support
P_{st}	static transpulmonary pressure at a specified lung volume
PSV	pressure support ventilation
P_{TA}	transairway pressure
$PtcCO_2$	transcutaneous PCO_2
$PtcO_2$	transcutaneous PO_2
P_{tm}	transmural pressure
P_{TR}	transrespiratory pressure
PTSD	posttraumatic stress disorder
P_{TT}	transthoracic pressure (also Pw)
P-V	pressure-volume
PV	pressure ventilation
PVC(s)	premature ventricular contraction(s)
$P\bar{v}O_2$	partial pressure of oxygen in mixed venous blood
PVR	pulmonary vascular resistance
PVS	partial ventilatory support
P_w	transthoracic pressure (also P_{TT})
Q	blood volume
$\dot{Q}$	blood flow
$\dot{Q}_{c'}$	pulmonary capillary blood flow
q2h	every 2 hours
$\dot{Q}_T$	cardiac output
$\frac{\dot{Q}_s}{\dot{Q}_t}$	shunt
$\dot{Q}sp$	physiologic shunt flow (total venous admixture)
R	resistance (i.e., pressure per unit flow)
$\bar{R}$	mean total resistance
RAM	random access memory
RAP	right atrial pressure
R_{aw}	airway resistance
rb	rebreathing
RCP	respiratory care practitioner
RDS	respiratory distress syndrome
Re	Reynolds number
R_E	total expiratory resistance
REE	resting energy expenditure
RH	relative humidity
R_I	total inspiratory resistance
RICU	respiratory intensive care unit
R_L	total pulmonary resistance
RM	lung recruitment maneuver
ROM	read-only memory
ROP	retinopathy of prematurity
RQ	respiratory quotient
RSS	really simple syndication
RSV	respiratory syncytial virus
RT	respiratory therapist
Rti	tissue resistance
RV	residual volume
RV/TLC%	ratio of residual volume to total lung capacity
RVEDP	right ventricular end-diastolic pressure
RVEDV	right ventricular end-diastolic volume
RVP	right ventricular pressure
RVSW	right ventricular stroke work
S	saturation in the blood phase
SA	sinoatrial
SaO_2	arterial oxygen saturation
$SBCO_2$	single breath carbon dioxide curve
SCCM	Society for Critical Care Medicine
SFIM	sporadic fatal infectious mononucleosis
S.I.	Système International d'Unités
SI	stroke index
SIDS	sudden infant death syndrome
SIMV	synchronized intermittent mandatory ventilation
Sine	sinusoidal
SNF	skilled nursing facility
sp.	species
sPEEP	spontaneous positive end expiratory pressure
SpO_2	oxygen saturation measured by pulse oximeter
STPD	standard temperature, pressure saturated; 0° Celsius, 760 mm Hg, dry
SV	stroke volume
SVC	slow vital capacity
$S\bar{v}O_2$	mixed venous oxygen saturation
SVN	small volume nebulizer
SVR	systemic vascular resistance
t	time
T	temperature
TAAA	thoracoabdominal aortic aneurysm
Tc	time constant
$tcCO_2$	transcutaneous CO_2
TCPL	time-cycled, pressure-limited ventilation
TCPL/IMV	time-cycled, pressure-limited intermittent mandatory ventilation
TCT	total cycle time
T_E	expiratory time
TGI	tracheal gas insufflation
TGV	thoracic gas volume
T_{high}	time for high-pressure delivery in APRV
T_I	inspiratory time
T_I%	inspiratory time percent
tid	three times per day
TI/TCT	duty cycle
TJC	The Joint Commission (formerly The Joint Commission on Accreditation of Healthcare Organizations [JCAHO])
TLC	total lung capacity
T_{low}	time for low-pressure delivery in APRV
TLV	total liquid ventilation
TOF	tetralogy of Fallot
torr	measurement of pressure that is equivalent to mm Hg
TTN	transient tachypnea of the neonate
TTOT	transtracheal oxygen therapy
TV	tidal volume
U	unit
UN	urinary nitrogen
USN	ultrasonic nebulizer
V	gas volume
v	venous
$\bar{v}$	mixed venous
$\dot{V}$	flow
$\dot{V}_E$	expired minute ventilation
$\dot{V}_A$	alveolar ventilation per minute
V_A	alveolar gas volume
VAI	ventilator-assisted individual
VALI	ventilator-associated lung injury
VAP	ventilator-associated pneumonia
VAPS	volume-assured pressure support
VBP	value-based purchasing
VC	vital capacity
V_C	volume lost to tubing compressibility
VC-CMV	volume-controlled continuous mandatory ventilation
VC-IMV	volume-controlled intermittent mandatory ventilation

VCIRV	volume-controlled inverse ratio ventilation
$\dot{V}CO_2$	carbon dioxide production per minute
V_D	volume of dead space
$\dot{V}_D$	physiologic dead space ventilation per minute
V_{Dalv}	alveolar dead space
$\dot{V}_{Dan}$	anatomic dead space ventilation per minute
V_{DAN}	volume of anatomic dead space
V_{Dmech}	mechanical dead space
V_D/V_T	dead space-to-tidal volume ratio
V_{Dbr}	rebreathing volume
$\dot{V}_{Dbr}$	rebreathing ventilation per minute
$\dot{V}_E$	expired volume per minute
VEDV	ventricular end-diastolic volume
VF	ventricular fibrillation
$\dot{V}_I$	inspired volume per minute
VILI	ventilator-induced lung injury
$\dot{V}_L$	actual lung volume (including conducting airways)
VLBW	very low birth weight
VM	vestibular membrane
$\dot{V}O_2$	oxygen consumption per minute
VS	volume support
VT	ventricular tachycardia
V_T	tidal volume
V_TA	alveolar tidal volume
V_{Texp}	expired tiadal volume
V_{Tinsp}	inspired tidal volume
vol%	volume per 100 ml of blood
$\frac{\dot{V}}{\bar{Q}}$	ventilation/perfusion ratio
VSV	volume support ventilation
VV	venovenous
W	work
WOB	work of breathing
WOBi	imposed work of breathing
wye	"wye" or Y connector
X	any variable
$\bar{X}$	mean value
Y	connects patient endotracheal tube to patient circuit
yr	year
ZEEP	zero end expiratory pressure
