CCS0317

To my father, Jack, whose motto
"Never say can't; do it and say it was hard"
has sustained me throughout my life,
and is carried forward by his grandchildren Nathaniel,
Louisa, Benjamin, and Ethan.

—Lori Thein Brody

I would like to dedicate this book to
my three daughters, Caroline, Gabrielle, and Jillian,
who encourage me daily to be my best; my patients, who continuously
teach me about the complexity of the movement system;
my amazing colleagues who challenge me to stay current
and maintain a growth mind-set;
and my mother Carol,
who lived her life with courage and resolve and continues to
serve as my daily inspiration.

—Carrie M. Hall

Preface to the First Edition

Choosing the title of this book was not easy, but once it was decided, the choice seemed obvious. *Therapeutic Exercise: Moving Toward Function* is the title that encapsulates the premise of this book. The emergence of managed care in the United States has altered the delivery of health care. Although value has always been important, its role in today's health care management is even more critical. Value can be defined as patient satisfaction (i.e., functionally meaningful patient outcomes), divided by the financial and social costs of providing care (Kasman GS, Cram JR, Wolk SL. Clinical Applications in Surface Electromyography. Rockville: Aspen, 1998). Physical therapists are challenged daily to provide value to their patients in delivering care to improve function and quality of life. Among the many interventions available to the physical therapist, therapeutic exercise is the cornerstone in providing patients with the means to improve their functional capabilities and, ultimately, their quality of life. Although other interventions can improve these elements, it is the assumption of this book that only through careful therapeutic exercise prescription can an individual make the permanent changes necessary to maintain, optimize, or prevent future loss of function. It is the premise of this book to use therapeutic exercise for patients with musculoskeletal dysfunction for the sole purpose of achieving functionally meaningful patient outcomes.

It was our decision to write this book as a textbook and not a manual of activities and techniques. The latter deals with providing activities and techniques without the theoretic framework to make decisions about what would or could be the best possible course of treatment and the possible alternatives. *Therapeutic Exercise: Moving Toward Function* attempts to provide a conceptual framework for learning how to make clinical decisions regarding the prescription of therapeutic exercise—from deciding which exercise(s) to teach to how to teach them to the dosage required for the best possible outcome. The common thread throughout the text is to treat, with the use of therapeutic exercise and related interventions, the impairments that correlate with functional limitations and disability and to work toward the most optimal function possible.

Because this book was written primarily as a textbook, decisions were made to provide the reader and instructor with a variety of educational features:

- Extensively illustrated. Therapeutic exercise is a visual intervention. This book uses photographs and line drawings to illustrate examples of therapeutic exercises.
- Selected Interventions. Featured at the end of pertinent chapters, these are activities or techniques written for the student and are included to provide examples of application of the therapeutic exercise intervention model presented in Chapter 2. Faculty can use the Selected Interventions as models for the student to develop exercise prescriptions.
- Self-Management boxes. These are activities or techniques written for the patient. These are included as examples to show the student how to write an exercise for a patient so that all the important features of an exercise prescription are clearly understood.
- Patient-Related Instruction boxes. These are similar to Self-Management boxes. The primary difference is that these are not exercises, but rather educational features to assist in the carryover of exercise into functional activities.
- Key Points. This feature summarizes key concepts the author wants to convey in the chapter. A thorough understanding of the Key Points should be realized following the reading of each chapter.
- Critical Thinking Questions. These were provided to stimulate the reader's thinking after studying the chapter. Case Studies are used to create hypothetical situations to which concepts can be applied.
- Lab Activities. These provide examples of applied use of the concepts to practice teaching and execution of selected activities and techniques.
- Case Studies. The final unit of the book provides the reader with a description of 11 cases. These cases are used in Critical Thinking Questions and Lab Activities to provide the student with real-life situations in which to apply concepts learned in the relevant chapter.

The book is organized into seven units. The purpose of each unit is as follows:

- Unit 1 provides the foundations of therapeutic exercise, beginning with a presentation of the disablement model to provide conceptual clarity for the remainder of the book, and ending with concepts of patient management. In the second chapter, a proposed therapeutic exercise intervention model is presented. This model attempts to separate the clinical reasoning process into the individual but cumulative steps to take in order to prescribe an effective therapeutic exercise. Chapter 3 describes two crucial elements of patient management: motor learning and self-management.
- Unit 2 provides the reader with a functional approach to therapeutic exercise for physiologic impairments. Although we attempted to include a somewhat extensive review of the scientific literature on muscle performance, balance, endurance, mobility, posture, movement, and pain, our purpose was not to publish a review of the material. Instead, we have selected pertinent literature to illustrate the concepts needed for a basic knowledge of physiologic impairments as it relates to therapeutic exercise prescription.
- Unit 3 presents special physiologic considerations to heed when prescribing therapeutic exercise. They include soft tissue injury, postoperative issues, arthritis, fibromyalgia

syndrome and chronic fatigue, and obstetrics. Although this list is not comprehensive, we chose these special considerations because of the frequency with which the clinician encounters them.

- Unit 4 provides the reader with selected methods of intervention. Although there are numerous schools of thought regarding the prescription of exercise, we chose these methods to provide the reader with examples of a variety of contrasting methods—each has its own merits. The authors have attempted to illustrate how each method can be incorporated into a cohesive program of therapeutic exercise prescription.
- Units 5 and 6 provide the reader with a regional approach to therapeutic exercise prescription. Each chapter is organized into a brief review of anatomy and kinesiology, examination and evaluation guidelines, therapeutic exercise for common physiologic impairments affecting the region, and therapeutic exercise for common medical diagnoses affecting the region. The anatomy, kinesiology, and examination and evaluation sections set the foundation for prescription of therapeutic exercise for physiologic impairments. Therapeutic exercise for physiologic impairments provides the reader with examples of exercises to improve physiologic capability and, ultimately, function. Therapeutic exercise for common medical diagnoses provides the reader with examples of comprehensive interventions, including therapeutic exercise for common medical conditions affecting the region.
- Unit 7 consists of 11 Case Studies, which are used in Critical Thinking Questions and Lab Activities at the end of selected chapters. Faculty can use these Case Studies for a variety of learning experiences.
- Appendices 1 and 2 give the student a quick reference for red flags of serious pathology or visceral referred symptoms and clinical actions to take in the event of serious signs and symptoms in the exercising patient.

We worked diligently to provide a comprehensive textbook designed to prepare the foundation of knowledge and skills necessary to prescribe therapeutic exercise. We urge our readers to write to us to tell us how well we accomplished our goal. We hope that subsequent editions can address your comments as well as the ever-changing needs of those involved in therapeutic exercise prescription.

Carrie M. Hall
Lori Thein Brody

Preface to the Fourth Edition

Therapeutic exercise remains the primary intervention provided by physical therapists and physical therapist assistants around the world. Although the exercises may appear simple in application, the processes that drive the decisions that ultimately result in an exercise program are complex. Therapeutic exercise is applied at the impairment, activity limitation, and participation restriction levels, and ranges from simple stretching to complex multijoint and system-level integrated activities. Therapeutic exercise is employed in the care of patients ranging from the youngest infants to the oldest seniors, across a broad range of abilities, needs, and goals, in a variety of settings.

This multidimensionality underscores the complexity of successful therapeutic exercise application in the patients we care for. Although determining that a patient with impaired quadriceps muscle performance needs quadriceps strengthening activities, choosing the appropriate type and dosage of therapeutic exercise is far more challenging. Consider the following examples of patients with impaired quadriceps performance: a young athlete post knee ligament reconstruction; an elderly woman recovering from a femur fracture resulting from a fall; a young man with a recent below knee amputation. The starting point, rate of progression, program focus, and goals may be different, and therefore require different exercise programs, all with the goal of improving an impairment. Remediation of the impairment is only one level of consideration; activity limitations (stair descent, rising from a chair, extending the knee during gait) and performance restrictions (return to sport, performing instrumental activities of daily living, return to work) are also part of the therapeutic exercise prescription. In addition, impairments rarely exist in singularity. The complexity of evaluation and therapeutic exercise prescription of the entire movement system, with integrated and interdependent impairments, is a complex, high-level decision-making process requiring skilled intervention to reach the desired outcome of function and participation in society. Choosing and dosing the exercise is only the beginning. The patient then must learn the motor control to carry out the specificity of the prescription, adhere to the dosage, and be progressed appropriately to reach his or her personal desired outcome. We continuously hear that students struggle with the daunting task of the decision-making process, teaching, and developing compliance with therapeutic exercise prescription in their varied patient populations. Although we are unable to fully impart all the skills necessary to prescribe and teach therapeutic exercise in a textbook, the fourth edition of *Therapeutic Exercise: Moving Toward Function* continues to emphasize the *decision-making process* necessary for successful outcomes of therapeutic exercise programs.

Successful outcomes require consideration of the therapeutic exercise prescription (exercise choices, frequency, intensity, duration, progression), motivators and barriers to adherence, adjunctive interventions, and evidence to support choices within the framework of a third-party payer system. The focus of this text is on providing the foundational information, and examples, to help clinicians decide where on the continuum of exercise to start a specific patient and how to progress that patient through rehabilitation to and including wellness. Although wellness has often been considered separate from rehabilitation, it should be considered concurrently with remediation of impairments and activity limitations. Wellness is multidimensional, including physical health, emotional health, spirituality, and social connectivity. Physical therapists who place therapeutic exercise within the context of wellness provide that patient with the opportunity to choose a lifetime of physical activity, which is a cornerstone of public health. Availability and individual preferences notwithstanding, consider the difference between an exercise program prescribed to be performed alone at home and one to be performed at a community center. A therapeutic exercise program that is initiated and/or progressed to an environment that allows a seamless transition to wellness is a successful program and one that is vital to the management and prevention of chronic disease

The World Health Organization (WHO) (www.who.int) and the Centers for Disease Control and Prevention (www.cdc.gov) both emphasize the many facets of wellness including physical activity. The WHO's International Classification of Functioning, Disability, and Health (ICF) includes all people in its classification from a continuum of people with no known disease to those with disease-related impairments, activity limitations, and participation restrictions. All people are served by participating in health and wellness-promoting activities, with some requiring the unique skills of a physical therapist in order to participate successfully. The WHO is currently in the process of developing a companion publication, the International Classification of Health Interventions (ICHI) that categorizes interventions associated with impairments of body structures and functions as well as interventions for activity limitations and participation restrictions. Like the ICF, the ICHI will provide a common language for further research into the effectiveness of different types and dosages of therapeutic exercise in patient groups.

With this backdrop, the changes to this edition of *Therapeutic Exercise: Moving Toward Function* capitalize on initiatives such as the ICF, ICHI, and work by the American Physical Therapy Association (APTA) and other professional organizations. Our goal is to deepen the reader's understanding of the complexities of therapeutic exercise prescription in health care today, and to provide examples and evidence of its application to promote a healthy population.

CHANGES AND ADDITIONS IN THE FOURTH EDITION

The changes and additions to the fourth edition of this text reflect extensive user feedback. These changes and additions are consistent with commitment to improve the delivery of successful, evidence-based therapeutic exercise interventions to patients. Language used throughout the book is consistent with that of the ICF and the APTA's Guide to Physical Therapist Practice. This provides a consistent and common language when discussing physical therapy interventions and evidence.

The therapeutic exercise model has been updated to improve clarity and ease of use. APTA has embraced the concept of the movement system as the primary system treated by physical therapists. The premise of the updated model is that ideal movement can be thought of as the result of a complex interaction of several subsystems (support, passive, active, neural, cognitive/emotional) of the larger encompassing movement system. Organizing impairments into subsystems of the movement system will assist the practitioner in systematizing the complex interaction of impairments and guide prioritization, sequencing, and progression of the therapeutic exercise intervention.

Chapter 3 has been expanded beyond patient-related education to include a broader range of information on improving patient outcomes. Patient education and instruction in home exercise programs are just a couple of the strategies to improve patient outcomes. Listening and the many components of communication are critical to ensure that information is delivered in a manner that respects and motivates patients. This chapter describes several opportunities to engage the patient in the therapeutic exercise decision-making process.

Chapter 14, previously labelled "Closed Kinetic Chain," has been revised to "Kinetic Chain Applications in Functional Movement." This change reflects further development in the body of evidence around the kinetic chain and functional movement assessments and interventions. This chapter includes an in-depth discussion of the rationale for and application of kinetic chain concepts, both open and closed kinetic chain. Integrating open and closed chain activities in functional movements is a foundational concept in therapeutic exercise prescription.

All chapters have expanded references and a new feature, **Evidence and Research (EAR) Boxes.** Each chapter continues to be extensively referenced to provide the best current evidence for the reader. We understand that the reader may want to know more details of some research studies. Rather than embedding extensive details in the body of the text, key research is highlighted in EAR boxes throughout the chapter. In this way, the interested reader can readily access the evidence supporting the chosen intervention. These boxes, along with the citations and reference lists, provide a strong evidence resource for the reader.

The look of the text has changed significantly, with more streamlined writing and bulleted lists for ease of finding information quickly. The easily identifiable boxes such as Patient-Related Instruction, Building Blocks, Case Studies, Self-Management, and Selected Interventions remain as strong pedagogical features designed to integrate therapeutic exercise applications into the many facets of effective patient care. ThePoint website contains videos of selected exercises to view and listen to a practitioner teach exercise. The website also contains supportive anatomy, kinesiology, and examination information that provides background knowledge as an easily accessible refresher for the reader. New to this edition is a change to full color images to provide greater clarity in photos and to better engage the reader.

We hope that these changes and additions will make for better reading and help to provide a comprehensive, effective therapeutic exercise program for patients and clients.

ONLINE INSTRUCTOR RESOURCES

Adopting instructors will be given access to the following resources on thePoint:

- Image Bank
- PowerPoint Presentations
- Test Generator
- Answers to Building Blocks

ONLINE STUDENT RESOURCES

Students who have purchased *Therapeutic Exercise: Moving Toward Function*, Fourth Edition, will have access to the following resources:

- Video clips showing various therapeutic exercise techniques
- Additional chapter material not found in text

Materials for students and instructors can be found online at thePoint.lww.com/BrodyHall4e.

Lori Thein Brody
Carrie M. Hall

Acknowledgments

In addition to all those individuals who helped create the first three editions, we wish to thank many people for their contributions to this revision. This book was made possible through the individual and collective contribution of many individuals.

We are privileged to have had so many knowledgeable and dedicated chapter contributors. We are indebted to their contribution to the original work and revisions to create an outstanding fourth edition. We are also acutely aware that the fourth edition could not have been done without input from the reviewers. We appreciate the insights they offered to finalize the content and design of the text. A special thanks is extended to Jill Thein-Nissenbaum who provided additional expertise and extensive editing crucial to the consistency and structure of the fourth edition. A book of this magnitude with its large numbers of figures, legends, displays, tables, special feature boxes, and references cannot be produced without the cohesive efforts of the talented editorial and production teams. For this we thank the editorial and production staff and the art department at Lippincott, Williams & Wilkins. We would like to extend a special thanks to production manager, John Larkin, who, among many other vital functions, played the critical behind-the-scenes role of keeping us organized and on schedule in a professional, kind, and respectful manner.

We would like to extend our gratitude to our colleagues at the UW Health Research Park Clinic and Movement Systems Physical Therapy, P.S. in Seattle, WA, for the use of their facilities. We are also grateful for the time and energy provided by the models, videographers, and photographer Andy Manis, whose calm and organization helped us manage an extensive photo shoot. Over the course of a person's career, many individuals assist in the development of a person's theories, knowledge, and expertise. In the years between editions, we have continued to learn from the patients, students, and teachers who perpetually challenge our thoughts and decisions, and shape our skills.

Last, but most certainly not least, we would like to especially thank our family, friends, and colleagues who offered their emotional support and gave of their time generously to allow us to complete this project.

Lori Thein Brody
Carrie M. Hall

Each coauthor would like to extend her personal acknowledgments:

As we publish the fourth edition of our book, it is more evident now than ever that I am who I am because of the numerous influential and inspirational researchers, practitioners, instructors, business owners, administrators, and advocates, whom I have had the pleasure to work with over my 30+ year career. I was particularly fortunate to work with some of the best and brightest in our field during my formative years at Washington University in St. Louis. I would particularly like to thank Shirley Sahrmann, PhD, PT, FAPTA, for her incredibly insightful theories and devotion to the field of physical therapy. Her philosophy toward exercise prescription is woven into my thoughts and writing. Dr. Sahrmann has planted seeds that are found in research and clinical practice around the world. She is an icon in the field of physical therapy, and I am immensely indebted to her for teaching me how to view education, clinical practice, business acumen, and even advocacy through a movement system lens. I consider this book a result of the responsibility I feel to pay it forward to the next generation of practitioners whom I am confident will take the field of physical therapy into primary care and demonstrate our critical value to public health. I view therapeutic exercise as a cornerstone of our professional identity, and believe that movement is medicine and that physical therapists are uniquely qualified to integrate the biopsychosocial elements of the movement system into a therapeutic and transformative intervention.

The writing of a textbook takes tremendous time and energy away from work, friends, and family. Words cannot express my appreciation for my colleagues at Movement Systems Physical Therapy and my close friends whose support has been truly remarkable. I especially thank my clinic Administrator, Scott Spradling, who kept my business thriving during the hours I spent on research and writing, my three children whose unconditional love keeps me going every day, and my dog, Winston, who kept me running to maintain my fitness and mental clarity.

Carrie M. Hall

My life has been blessed with exceptional colleagues who have believed in and advocated for me as my career has wound its way through physical education, athletic training, physical therapy, preventive medicine, and adult education. My deepest gratitude goes to Peg Houglam, PT, ATC; Bill Flentje, PT, ATC; Susan Harris, PT, PhD, FAPTA; and Joseph PH Black, MDiv, PhD. These individuals provided examples of exceptional leadership and set the standard for professionalism and integrity. I am deeply grateful to them for their past and continued guidance. My sister, Jill Thein-Nissenbaum, PT, DSc, ATC, played a pivotal role, picking up the pieces Carrie and I left in our wake. She was there to take on just about anything, including moral support and providing that kind but critical "you already know that answer to that question, just do it" advice. I am truly blessed by her presence in my life.

Thanks to my colleagues at University of Wisconsin Research Park Clinic, particularly those who contributed to the writing and editing of chapters, and Carrie Schwoerer, who always had an ear or a box of tissues to lend.

I am also deeply grateful to the doctoral students at Rocky Mountain University of Health Professions. They are a remarkable group of bright, inquisitive current and future leaders who do justice to our profession. I am grateful for the opportunity to learn from each of them.

Foundation of Therapeutic Exercise

UNIT 1

CHAPTER

1 Introduction to Therapeutic Exercise and the Model of Functioning and Ability

LORI THEIN BRODY • CARRIE M. HALL

Among the many interventions available to physical therapists, therapeutic exercise has been shown to be fundamental to improving function and decreasing disability.[1–7] It is the premise of this text that, through carefully prescribed therapeutic exercise intervention, an individual can make significant changes in functional performance and disability, and that physical therapists have the unique educational training to be the preferred clinician for prescribing therapeutic exercise.

DEFINITION OF PHYSICAL THERAPY

The Federation of State Boards of Physical Therapy[8] defines physical therapy practice as (with updated language provided by the authors)

1. Examining, evaluating, and testing individuals with mechanical, physiologic, and developmental impairments; activity limitations and participation restrictions or other health and movement-related conditions in order to determine a diagnosis, prognosis, and plan of treatment and intervention; and assessing the ongoing effects of intervention.
2. Alleviating impairments, activity limitations, and participation restrictions by designing, implementing, and modifying treatment interventions that may include, but are not limited to therapeutic exercise, functional training in self-care and in home community or work integration or reintegration, manual therapy including soft tissue and joint mobilization/manipulation, therapeutic massage, prescription, application, and, as appropriate, fabrication of assistive, adaptive, orthotic, prosthetic, protective, and supportive devices and equipment, airway clearance techniques, integumentary protection and repair techniques, debridement and wound care, physical agents or modalities, mechanical and electrotherapeutic modalities, and patient-related instruction.
3. Reducing the risk of injury, impairment, activity limitation, and participation restriction including the promotion and maintenance of fitness, health, and wellness in populations of all ages.
4. Engaging in administration, consultation, education, and research.

Physical therapists examine, evaluate, diagnose, and intervene at the level of *impairment, activity limitation*, and *participation restriction*. Physical therapists then use their knowledge and clinical skills to prevent, reduce, or eliminate impairments, activity limitations, and participation restrictions and to enable patients and clients to achieve the most optimal quality of life possible.

This chapter focuses on the goals of improving function and reducing disability through the use of therapeutic exercise. The physical therapist must consider what impairments are related to reduced function and disability for *this patient* and which exercises can *improve functional performance* by addressing the appropriate impairments. Therapeutic exercises described throughout this book can remediate both impairments and activity limitations. For example, a squat exercise can address the impairment of quadriceps weakness as well as the activity limitation of difficulty with transfer skills.

To understand the relationships among health conditions, impairments, activity limitations, and participation restrictions, a model using common language put forward by the World Health Organization (WHO) called the International Classification of Functioning, Disability and Health (ICF) will be used throughout this book. The model is an updated version of the International Classification of Impairments, Disabilities, and Handicaps (ICIDH) first published by the WHO in 1980. The reader is encouraged to use this model to think about how disability relates to decisions regarding therapeutic exercise intervention.

THERAPEUTIC EXERCISE INTERVENTION

Therapeutic exercise is a health service intervention provided by physical therapists to patients and clients as part of physical therapist practice.

- **Patients** are persons with diagnosed impairments or activity limitations.
- **Clients** are persons who are not necessarily diagnosed with impairments or activity limitations but who are seeking physical therapist services for prevention or promotion of health, wellness, and fitness.

Interventions for these clients can include any of the following:

- Education regarding body mechanics provided to a group of persons involved in strenuous occupational activity
- Preventative education and exercise prescription for persons diagnosed with a musculoskeletal disease such as rheumatoid arthritis
- Exercise recommended for a group of high-level athletes to prevent injury or enhance performance

Therapeutic exercise is considered a core element in most physical therapist plans of care and is defined as:

> The systematic performance or execution of planned physical movements, postures, or activities intended to enable the patient/client to (1) remediate or prevent impairments, (2) enhance function, (3) reduce risk, (4) optimize overall health, and (5) enhance fitness and well-being.[9]

Therapeutic exercise may include aerobic and endurance conditioning and reconditioning; balance, coordination, and agility training; body mechanics and posture awareness training; muscle lengthening; range of motion techniques; gait and locomotion training; movement pattern training; or strength, power, and endurance training.

Although therapeutic exercise can benefit numerous systems of the body, this text focuses primarily on treatment of the musculoskeletal system. Concepts of therapeutic exercise intervention specifically for the cardiovascular/pulmonary, neurologic, and integumentary systems are not covered in this text, except when they relate to impairments of the musculoskeletal system.

Decisions regarding therapeutic exercise intervention should be based on individual goals that provide patients or clients with the ability to achieve optimal functioning in home, work (job/school/play), and community/leisure activities. To implement goal-oriented treatment, the physical therapist must

- Provide comprehensive and personalized patient management sufficient to meet patient goals
- Rely on clinical decision-making skills
- Implement a variety of therapeutic interventions that are complementary (e.g., active warm-up before joint mobilization, followed by active exercise to use new mobility)
- Promote patient independence whenever possible through the use of home treatment (e.g., home spine traction, heat or cold therapy), self-management exercise programs (e.g., in the home, fitness club, community-sponsored group classes, school-sponsored or community-sponsored athletics), and patient-related instruction
- Avoid extraneous interventions and promote health care cost containment

In some cases, patient independence is not possible, but therapeutic exercise intervention is necessary to improve or maintain health status or prevent complications. In these situations, training and educating family, friends, significant others, or caregivers to deliver appropriate therapeutic exercise intervention in the home can greatly reduce health care costs by limiting in-house physical therapist intervention.

THE LANGUAGE OF HEALTH: ABILITIES AND DISABILITIES

The purpose of defining a model of functioning and disability in a text on therapeutic exercise is to provide the reader with an understanding of the complex relationships of health conditions (i.e., pathology, disease, genetic anomalies), impairments, activity limitations, and participation restrictions and to provide a conceptual basis for organizing elements of patient/client management that are provided by physical therapists. This text will use a biopsychosocial model that provides both the theoretical framework for understanding physical therapist practice and the classification scheme by which physical therapists make diagnoses.

Historically, traditional "medical models" viewed disability as an individual problem caused by disease, genetics, or injury, to be treated by individualized medical care. As a patient-centered perspective with the individual as the focus of intervention, little regard is given to the societal aspects of disability beyond public policy health care guidelines (i.e., vaccinations). This contrasts with "social models" that view disability as a socially created problem where disability is created primarily by the social environment and is *not* an attribute of the individual. Therefore, policies and interventions are directed toward society at large, making environmental modifications necessary to allow persons with disabilities to fully participate in all aspects of social life. The ICF is a "biopsychosocial" model embracing both of these perspectives, addressing factors at both the individual and the social level[10] (**Fig. 1-1**).

Terminology of the Biopsychosocial Model of Functioning and Disability

Although previous models of functioning and disability have focused on disability, ICF model focuses on both the positive and negative aspects of health, viewing health as a continuum. Rather than including only people with "disability," the ICF includes *all* people in its model. The ICF is a model of **both** *functioning* and *disability*.[11,12] The following sections define and describe the components of the ICF model.

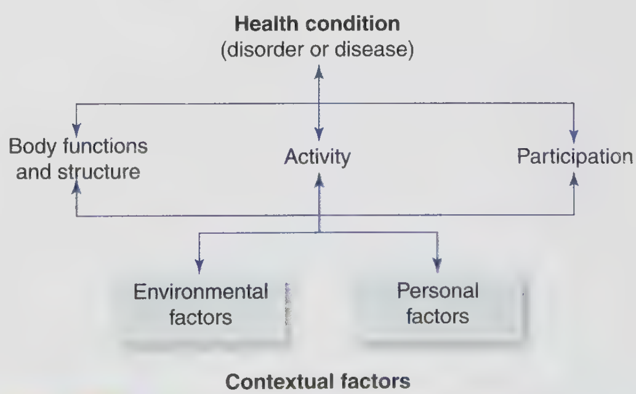

FIGURE 1-1 The WHO model of function and disability.

- **Functioning** is an umbrella term for body structures and function, and activities and participation (Part 1 of the ICF). It represents the *positive* aspects of the interaction between the individual with a health condition and that person's environmental and personal factors (Part 2 of the ICF, "Contextual Factors").
- **Disability** is a parallel umbrella term describing the negative aspects of this same interaction. It is described by terms such as *impairment*, *activity limitation*, and *participation restriction*.

Health Condition

In the medical model, health conditions focused on the negative aspects of health such as infection, trauma, metabolic imbalance, degenerative disease process, or diseases.[13,14] The ICF uses the term *health condition* as an umbrella term for disease, disorder, injury, or trauma, as well as states such as pregnancy, aging, congenital anomalies, or genetic predispositions.[10(p.212)]

Impairment

Impairment refers to a loss or abnormality in a body structure or in a physiologic function at the tissue, organ, or body system level. Impairments frequently treated by physical therapists include impaired range of motion, joint mobility and integrity, or muscle performance. Body function impairments might include pain, mobility or stability of joints, muscle power or endurance functions or gait pattern functions (**Table 1-1**).

TABLE 1-1

Two-Level Classification of Body Functions Related to the Motor System

NEUROMUSCULOSKELETAL AND MOVEMENT-RELATED FUNCTIONS

Functions of the joints and bones (b710–b729)[a]
- b710 Mobility of joint functions
- b715 Stability of joint functions
- b720 Mobility of bone functions
- b729 Functions of the joints and bones, other specified and unspecified

Muscle functions (b730–b749)
- b730 Muscle power functions
- b735 Muscle tone functions
- b740 Muscle endurance functions
- b749 Muscle functions, other specified and unspecified

Movement functions (b750–b799)
- b750 Motor reflex functions
- b755 Involuntary movement reaction functions
- b760 Control of voluntary movement functions
- b765 Involuntary movement functions
- b770 Gait functions
- b780 Sensations related to muscles and movement functions
- b789 Movement functions, other specified and unspecified
- b798 Neuromusculoskeletal and movement-related functions, other specified
- b799 Neuromusculoskeletal and movement-related functions, unspecified

[a]The letter "b" denotes Body Functions.
From World Health Organization. International Classification of Functioning, Disability and Health. Geneva, Switzerland: World Health Organization, 2001.

Activity Limitation

The ICF uses the term *activity limitation* to describe difficulties an individual may have in executing activities. These limitations range from mild to severe and are measured against a population standard. Examples of activity limitations delineated in the ICF model include changing and maintaining body position, carrying, moving and handling objects, walking and moving, moving around using transportation, and self-care.

Participation Restriction

The ICF uses the term *participation restriction* to describe problems an individual may experience in involvement in life situations. Deficits are determined by measuring against societal standards.

Participation restrictions are reserved for social rather than individual functioning and people with similar activity limitations may have very different participation restrictions. For example, two persons with similar levels of impairment and activity limitation may have two different levels of participation restriction. One person may remain very active in all aspects of life (i.e., personal care and social roles), have support from family members in the home, and seek adaptive methods of continuing with occupational tasks, whereas the other individual may choose to limit social contact, depend on others for personal care and household responsibilities, and have a job where no modifications to support ongoing participation are possible. Contextual factors play an important role in these differences.

The distinction between activity limitation and participation restriction is the difference between viewing the individual in isolation (activity limitation) and viewing the individual in relation to the larger world (participation restriction). An activity limitation is primarily a reflection of the characteristics of the individual person. An activity limitation is measured at the level of the individual and compared against a population standard. Participation restriction, however, has a relational characteristic in that it describes the individual's limitation in relation to society and the environment. Persons with similar individual profiles (e.g., disease, impairments, activity limitations) can present with different participation profiles. Factors such as age, general health status, personal goals, motivation, social support, and physical environment influence the level of disability the person experiences (**Evidence and Research 1-1**).

EVIDENCE and RESEARCH 1-1

A total of 100 patients rated as high risk for low back pain because of structural and psychosocial variables were prospectively followed for 4 to 6 years to determine the impact of these variables on disability. Psychosocial variables strongly predicted future disability, whereas the structural variables had no association with future disability and medical care.[15]

INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH

The ICF model is an advancement of previous models in its ability to apply to all people, not just people with disabilities. The ICF describes health and health-related states of all people, and *everyone* can be classified within the ICF system. Identifying the underlying causes of participation restrictions is essential to understanding the complex relationship between the individual with a health condition and that individual's response to that condition. The ICF addresses this in Part 2, "Contextual Factors." Contextual factors include environmental and personal factors.

The language of the ICF reflects a significant change from previous models, recognizing the stigmatizing and potentially negative aspects of the terms "handicap" and "disability." Therefore, the WHO has decided to completely drop the term "handicap" and remove the term "disability" from a component, but retain it as the overall, umbrella term.[10] Moreover, the WHO emphasizes that the ICF is not a classification of *people* but a classification of "people's health characteristics within the context of their individual life situations and environmental impacts. It is the interaction of the health characteristics and the contextual factors that produces disability."[10]

Like the *International Classification of Diseases, Tenth Revision* (*ICD-10*),[11] the ICF uses an alphanumeric system to classify and categorize the levels of functioning and disability.[10] This enhances the system's usefulness for worldwide research and provides a common language. The letters b, s, d, and e are used to denote Body Functions, Body Structures, Activities and Participation, and Environmental Factors, respectively. The letters are followed by a chapter number (e.g., Chapter 7 for Body structures related to movement) followed by three or more numbers with specific descriptors and scales. Because of the complexity of the system, the details of the grading scales will not be covered in this text. For further information on this system, the reader is referred to www.who.org. An example of the two-level classification for *Body Structures* and *Body Functions* can be found in **Tables** 1-1 and **1-2**, respectively.

TABLE 1.2

Two-Level Classification of Body Structures Related to the Motor System

STRUCTURES RELATED TO MOVEMENT

- s710 Structure of head and neck region[a]
- s720 Structure of shoulder region
- s730 Structure of upper extremity
- s740 Structure of pelvic region
- s750 Structure of lower extremity
- s760 Structure of trunk
- s770 Additional musculoskeletal structures related to movement
- s798 Structures related to movement, other specified
- s799 Structures related to movement, unspecified

[a]The letter "s" denotes Body Structures.
From World Health Organization. International Classification of Functioning, Disability and Health. Geneva, Switzerland: World Health Organization, 2001.

The ICF classification has two major *parts*, Part 1 termed "Functioning and Disability" and Part 2 termed "Contextual Factors." *Functioning* indicates the positive aspects of health (including all body functions, activities, and participation), and *disability* indicates the negative aspects of health (impairments, activity limitations, and participation restrictions). The parts are further divided into components, with or without further division into constructs (see **Table 1-3**). A list of definitions for the essential terms can be found in **Table 1-4**.

Part 1: Functioning and Disability

Part 1 of the ICF addresses the majority of issues that physical therapists typically encounter in practice including the body's functions and its structures. Both the body structure and body function components have a positive and a negative aspect. This is one way in which both the "ability" and "disability" aspects of the functioning continuum are incorporated into the ICF.

Component A: Body Functions and Structures

- **Body functions** are the physiologic functions of body systems.
- **Body structures** are the anatomic parts of the body such as organs and limbs.

The body functions and the body structures components are designed to be used in parallel. For example, the body function component includes categories such as "mobility of joint functions" and the related body structures might be "joints of the shoulder region." The ICF would describe a healthy system (positive aspect) as having functional and structural integrity. The negative aspects of body functions and structures are termed impairments.

- **Impairments** are problems in body function or structures that are deviations from generally accepted population standards, such as an anomaly, defect, loss, or other abnormality (**Fig. 1-2A** and **B**).
  - **Physiologic impairment** is an alteration in any physiologic function such as:
    - Aerobic capacity
    - Muscle performance (strength, power, endurance)
    - Joint mobility (i.e., hypomobility/hypermobility)
    - Balance
    - Posture
    - Motor function
    - Mental function

    Physical therapist practice interventions can most significantly modify physiologic impairments. Unit 2 of this text provides a more thorough discussion of each of these physiologic impairments and examples of therapeutic exercise interventions to remediate or prevent these impairments.
  - **Structural impairment** is an abnormality or loss of structure, such as hip anteversion, structural subtalar varus, structural genu varum, or congenital or traumatic loss of a limb.

    Modifications to structural impairments can be made to improve function despite these existing impairments. The physical therapist should be aware of the presence of structural impairments to be able to provide an

TABLE 1-4

Relevant Definitions from the ICF

TERM	DEFINITION
Body functions	Physiologic functions of body systems, including psychological functions. The standard is the statistical norm for humans.
Body structures	The structural or anatomic parts of the body such as organs, limbs, and their components classified accordingly by systems. The standard is the statistical norm for humans.
Impairment	The loss or abnormality in body structure or physiologic function. Abnormality refers to a significant variation from established statistical norms.
Activity	The execution of a task or action by an individual. It is the individual perspective of functioning.
Activity limitations	Difficulties an individual may have in executing activities. The limitations may range from slight to severe in terms of quality or quantity.
Participation	A person's involvement in a life situation. It is the societal perspective of functioning.
Participation restriction	Problems an individual may experience in the involvement in life situations. Participation restrictions are determined by comparing an individual's participation against what is expected of an individual without a disability in that culture or society.
Environmental factors	These make up the physical, social, and attitudinal environment in which people conduct their lives.
Health condition	An umbrella term for disease (acute or chronic), disorder, injury, or trauma. It may also include other situations such as pregnancy, aging, stress, congenital anomaly, or genetic predisposition.
Well-being	A general term encompassing the total universe of human life domains including physical, mental, and social aspects that make up a "good life." Health domains are a subset of the total universe of human life.

appropriate prognosis and determine the best plan of care. Therapeutic exercise intervention in the presence of structural impairments will be discussed in selected chapters in Units 5 and 6.

Impairments are not the same as pathology, but may be expressions of the pathology. However, not all impairments result from pathology. For example, congenital anatomic deformities, immobilization, or faulty movement patterns can result in impairments of body structures and functions, but are not the result of pathology.

Impairments can be considered to be *primary* or *secondary*.

- **Primary impairments** result from pathology, disease, or genetics.
- **Secondary impairments** arise from other impairments.

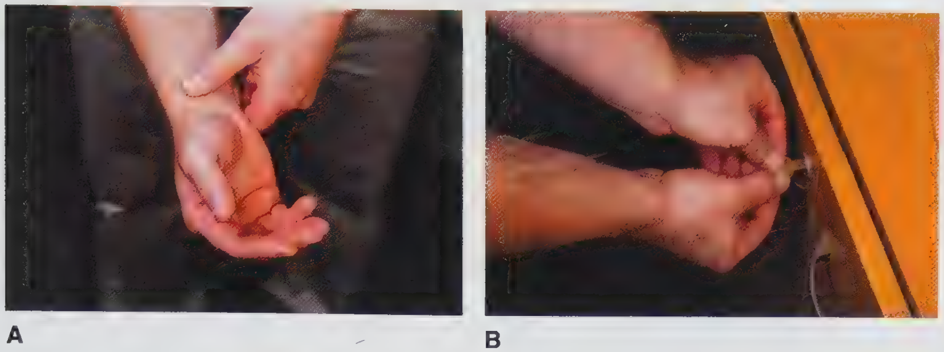

FIGURE 1-2 **(A)** Patient has a loss of forearm supination, a physiologic impairment in range of motion and joint mobility. **(B)** Patient has an activity limitation of inability to turn a key because of this mobility loss.

For example, impairment of the muscles in the lower half of the body (e.g., paraparesis) may result in impairments of the protective functions of the skin (e.g., decubitus ulcers). Likewise, impairment of the control of voluntary movement functions (e.g., from stroke or neurologic disease) may result in impairments of heart functions because of a lack of exercise, or impaired heart functions can lead to impaired respiratory functions. Secondary impairments can also lead to an additional or secondary health condition.

Impairments can be **temporary** or **permanent**, **intermittent** or **continuous**. For example, impaired joint mobility following a total knee replacement is a *temporary* condition, amenable to rehabilitative intervention. A joint that has been fused will have a *permanent* joint function impairment. Impaired joint stability such as occasional episodes of giving way following an anterior cruciate ligament tear is an *intermittent* impairment and may be activity related. An example of a *continuous* body function impairment is a shoulder that remains subluxed following a stroke. Impairments can also be described as progressing, regressing, or static.

Component B: Activities and Participation

The second major component of the ICF Functioning and Disability portion is activities and participation.

- **Activity** is the execution of a task or action by an individual.
- **Participation** is involvement in a life situation.
- **Functioning** is the positive aspect of activities and participation, implying the ability to perform individual activities and to participate in socially appropriate situations.
- **Activity limitations** and **Participation restrictions** are the negative aspects of activities and participation, suggesting that the individual is unable to participate in socially appropriate situations.

The Activities and Participation component has nine domains that encompass all life areas (**Table 1-5**). Each domain has a number associated with it, and within each domain there are several subclassifications. For example, domain 4, Mobility, has four categories, with four to six more specific descriptors. An example of one category can be found in **Table 1-6**.

Both activities and participation have two qualifiers that represent important aspects of assessing abilities. The qualifiers are *performance* and *capacity*.

- **Performance** describes what a person actually does in his or her current environment including all aspects (psychosocial and environmental) of the person's situation. Performance describes what the individual is currently able to do within the context (environmental and personal) of their world.
- **Capacity** is a standardized measure of an individual's ability to execute a task or action. Capacity measures attempt to capture the highest possible level of functioning that a person could attain at a given point in time.

The disparity between performance and capacity provides insight into the environment's contribution to activity limitations and participation restrictions. This information can prove useful in determining how the environment can be modified to improve performance.

WALKING AND MOVING (d450–d469)

- d450 Walking
- d455 Moving around
- d460 Moving around in different locations
- d465 Moving around using equipment
- d469 Walking and moving, other specified and unspecified

Part 2: Contextual Factors

Contextual factors encompass the background of the individual's personal life and environment. The two components are *environmental factors* and *personal factors*. Environmental factors reflect the external influences on functioning and disability, whereas personal factors reflect the internal influences. These factors can have a tremendous impact on a person's health and health status.

- **Environmental factors** are those features that comprise the physical, social, and attitudinal environment in which people live and function and include:
  - Close and personal such as the physical neighborhood in which the person lives, attitudes of coworkers, physical structure of the neighborhood,
  - Broader societal attitudes toward people with differing abilities.

Environmental factors can be positive, helping to improve a person's activity levels and participation, or they can be negative, producing barriers to participation. There are five categories of environmental factors (see **Table 1-7**).

Environmental factors are considered at two major levels, the *individual* and *societal*.

- The **individual** perspective is comprised of environmental settings such as home, school, or the workplace. The physical layout of the home, school, workplace, or environment, or people encountered can support or hinder participation.
- The **societal** perspective includes both formal and informal social structures, community services, community and work organizations, government agencies, communication and transportation services, informal social networks, as well as laws, regulations, and policies, both formal and informal.

Some work or other social structures may be positive, thereby improving a person's functioning, whereas others may be negative, creating barriers.

- **Personal factors** are the elements in an individual's background that are not part of the health condition or health states.

Examples of personal factors include gender, race, age, other health conditions, fitness, lifestyle, personal habits, coping styles, social background, education, profession, individual psychological assets, and life experiences. Like environmental factors, personal factors can have a positive or negative influence.

TABLE 1-7

Domains of Environmental Factors Impacting Functioning and Disability

ENVIRONMENTAL FACTORS	
Chapter 1	Products and technology
Chapter 2	Natural environment and human-made changes to environment
Chapter 3	Support and relationships
Chapter 4	Attitudes
Chapter 5	Services, systems, and policies

These factors can help the person to be resilient or can create barriers to function.

APPLICATION OF THE MODEL TO PHYSICAL THERAPIST PRACTICE

The model put forward by the ICF provides a common language and classification for describing function across a continuum of abilities. An application of this model to physical therapist practice can be found in **Figure 1-3**. The concept of function, disability, and health refers to the "various impact(s) of chronic and acute conditions on the functioning of specific body systems, on basic human performance, and on people's functioning in necessary, usual, expected, and personally desired roles in society."[11,12] Understanding of the factors that influence functioning and disability as well as the timing of the intervention is fundamental to restoring or improving function and reducing disability in the individual seeking physical therapy services (**Evidence and Research 1-2**).

EVIDENCE and RESEARCH 1-2

The timing of intervention may impact psychosocial aspects of the patient's function. A study of patients with low back pain found that those patients randomized to an assess/advise/treat group demonstrated greater improvements in disability, mood, general health, and quality of life than patients in the assess/advise/wait group.[16] The authors felt that the timing of the intervention impacted the development of psychosocial features.

Therapeutic exercise intervention must consider the patient's functional loss and disability in addition to disease or impairments; although a specific therapeutic exercise intervention may be selected to remediate or prevent impairment, it must also improve a functional outcome and the person's role in a specific sociocultural context and physical environment. **Display 1-1** describes a patient with adhesive capsulitis of the shoulder. Physical examination shows impairments of body functions related to mobility and muscle power. A number of activities may be impacted depending upon the severity of the problem, limb dominance, and the patient's work and lifestyle. Display 1-1 lists a number of commonly limited activities, but many more possibilities exist. In this example, physical therapist interventions should be directed not only at the impairments (i.e., loss of mobility, loss of muscle power) but at the activity limitations such as the ability to use both arms to care for one's hair, or the ability to lift and carry loads. If full use of both upper extremities is required for the patient's occupation, then significant participation restrictions can result, especially if environmental factors (i.e., e330 People in positions of authority; e430 Individual attitudes of people in positions of authority; e5902 Labor and employment policies) have a negative impact. The therapist must acknowledge these factors and have a dialogue with the patient about the prognosis at all levels of function. Understanding the relationships among health conditions, impairments, and function for each patient enables the therapist to make sound decisions about therapeutic exercise intervention.

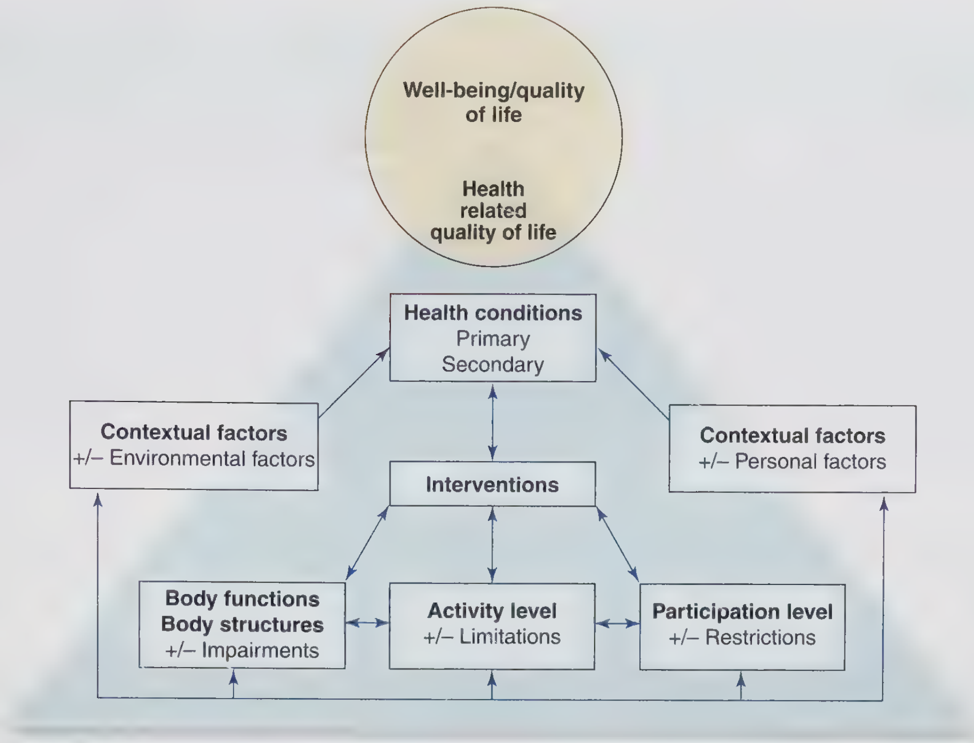

FIGURE 1-3 Modified physical therapy model of function and disability.

Since the publication of the ICF in 2001, a large body of research has been published identifying "core sets" categories specific to certain health conditions or population groups.[17–28] These core sets provide consistency for patient care and policy and research decisions. An example of a core set for low back pain can be found in **Display 1-2**.

DISPLAY 1-2

An Example of a Core Set for Low Back Pain

International Classification of Functioning, Disability and Health (ICF) categories included in the Brief ICF Core Set for low back pain. The categories per component are listed according to the conceded rank order.

ICF Component	Rank Order	ICE Code	ICF Category Title
Body functions	1	b280	Sensation of pain
	2	b152	Emotional functions
	3	b730	Muscle power functions
	4	b710	Mobility of joint functions
	5	b455	Exercise tolerance functions
	6	b134	Sleep functions
	7	b740	Muscle endurance functions
	8	b135	Muscle tone functions
	9	b7l5	Stability of joint functions
	10	b130	Energy and drive functions
Body structures	1	s120	Spinal cord and related structures
	2	s760	Structure of trunk
	3	5770	Additional musculoskeletal structures related to movement
Activities and participation	1	6415	Maintaining a body position
	2	8430	Lifting and carrying objects
	3	8410	Changing basic body position
	4	6450	Walking
	5	6850	Remunerative employment
	6	d859	Work and employment, other specified and unspecified
	7	6640	Doing housework
	8	d540	Dressing
	9	6240	Handling arms and other psychological demands
	10	d760	Family relationships
	11	d530	Toileting
	12	6845	Acquiring, keeping, and terminating a job
Environmental factors	1	e580	Health services, systems, and policies
	2	e570	Social security services, systems, and policies
	3	e355	Health professionals
	4	e450	Individual attitudes of health professionals

Health Conditions

Health conditions (disease, disorder, or condition) refer to an ongoing pathologic/pathophysiologic state that is:

- Characterized by a particular cluster of signs and symptoms
- Recognized by the patient or the practitioner as "abnormal"
- Primarily identified at the cellular, tissue, and organ levels
- Are often the physician's medical diagnosis.

It is, however, within the scope of physical therapist practice to diagnose such conditions at the tissue level using clinical tests and measures such as those outlined by Cyriax (e.g., supraspinatus tendonitis).[29] Furthermore, the complexity of the interrelationships among the ICF components highlights the extensive pathology and pathophysiology knowledge necessary to perform optimal patient management. For example, in the case of a patient referred to a physical therapist with shoulder pain, the physical therapist performs an examination/evaluation to diagnose the condition. The physical therapist's knowledge that different clusters of signs and symptoms are consistent with pathology at the tissue (e.g., tendonitis), organ (e.g., myocardial infarction), or cellular (e.g., lung cancer) level is critical for the diagnosis and management of the patient's condition. If the clinical findings on examination suggest a pathologic or pathophysiologic condition that is not within the scope of physical therapist practice (e.g., myocardial infarction, lung cancer) that has not been addressed by the appropriate practitioner, an immediate referral is necessary (see Appendix 1).

In many instances, the health condition cannot be diagnosed and the physical therapist must rely on clusters of impairments to formulate a diagnosis and intervention. A pathology-based diagnosis does not, by itself, delineate the impairments, activity limitations, or participation restrictions that will guide the physical therapist intervention (see Chapter 2). Therefore, the therapist must collect as much data as possible in each of the ICF components, acknowledge the complex multidirectional and cyclical nature of the biopsychosocial model, and apply interventions in the components of the model that will most efficiently and effectively achieve physical therapy goals.

Additionally, *secondary conditions* may develop as a result of a primary health condition. A secondary condition may be a type of health condition, impairment, activity limitation, or participation restriction. By definition, secondary conditions only occur in the presence of a primary condition. Commonly encountered secondary conditions include pressure sores, contractures, urinary tract infection, cardiovascular deconditioning, and depression. Each of these secondary conditions can lead to additional activity limitations and participation restriction.

Impairments of Body Functions and Structures

Impairments are defined as losses or abnormalities of physiologic, psychological, or anatomic structure or function. Health conditions may result in impairment, but not all impairments originate from a disease, disorder, or health condition. The presence of an impairment does not necessarily mean a loss of function. For example, someone with a congenitally missing fifth finger may live a fully functioning life. In contrast, a person with a fifth metacarpal fracture in their dominant hand may be fully disabled in a job requiring hand power and dexterity. Many physical therapist interventions are directed directly at the measurable body function impairments such as mobility (i.e., range of motion measures), muscle power (i.e., strength testing), pain (i.e., pain scales), or balance (i.e. balance scales). Although it may be easy to measure progress in these impairments of body functions, it is essential to link these impairment improvements to increases in activity limitations and/or participation restrictions (**Fig. 1-4**).

Activity Limitations, Participation Restrictions, and Quality of Life

Activity limitations and participation restrictions are limitations in individual functioning and/or functioning in society. The therapist must look beyond impairments to the activity limitations to design a rehabilitation and therapeutic exercise program to address these limitations. Examples of functional activities include basic mobility (moving around, changing positions,

FIGURE 1-4 **(A)** Patient performing a quadriceps strength test. **(B)** Functional quadriceps strength measured by ability to ascend the stairs.

etc.), carrying and moving objects, walking and moving, and self-care (i.e., BADL, IADL). Examples of important categories of function from the ICF can be found in **Table 1-8**.

Physical therapists utilize therapeutic exercise to improve skills such as walking on different surfaces, moving around within the home, pushing with the lower extremities, throwing and reaching, and transfers. Exercise should focus on remediating impairments linked to activity limitations and to improving functional skills like transferring from supine to sit. Additionally, consideration must be given to the contextual factors that may impact activities and participation.

TABLE 1-8

Expansion of the Categories Within the "Walking and Moving" Category of the Mobility Domain

d450 Walking
- d4500 Walking short distances
- d4501 Walking long distances
- d4502 Walking on different surfaces
- d4503 Walking around obstacles
- d4508 Walking, other specified
- d4509 Walking, unspecified
- d455 Moving around

d4450 Crawling
- d4551 Climbing
- d4552 Running
- d4553 Jumping
- d4554 Swimming
- d4558 Moving around, other specified
- d4559 Moving around, other unspecified

d460 Moving around in different locations
- d4600 Moving around within the home
- d4601 Moving around within buildings other than home
- d4602 Moving around outside the home and other buildings
- d4608 Moving around in different locations, other specified
- d4609 Moving around in different locations, unspecified

d465 Moving around using equipment
d469 Walking and moving, other specified and unspecified

The ultimate goal for people in any health state is to maximize one's health-related quality of life (HRQL). The ICF defines **well-being** as an umbrella term encompassing the total universe of human life. HRQL is a subset of well-being related to health domains. It contains three major components[30,31]:

- *Physical function component*, which includes BADLs and IADLs
- *Psychological component*, which includes the "various cognitive, perceptual, and personality traits of a person" and
- *Social components*, which involves the interaction of the person "within a larger social context or structure."

Assessments of quality of life attempt to capture how limitations in function affect physical, psychological, and social roles as well as perceptions of health status.[32–34] A person may argue that issues related to quality of life are not distinct from disability, but quality of life is considered broader than disability, encompassing more than well-being related to health such as education and employment. Other contextual variables contribute to an individual's sense of well-being and overall quality of life. Such factors include economic status, individual expectations and achievements, personal satisfaction with choices in life, and sense of personal safety. The model (see Fig. 1-3) displays HRQL as a small part of the quality of life or well-being, and general quality of life overlaps with components of the ICF.

Contextual Factors and Interventions

The main pathway from a health condition to disability, including quality of life, can be modified by a host of factors such as age, gender, education, income, comorbidities, health habits, motivation, social support, and physical environment. Proper medical care and timely rehabilitation also can eliminate or reduce the impact of each component's effects on one another. Conversely, improper medical care or rehabilitation along with other aforementioned factors can magnify the impact of an impairment or limitation (**Evidence and Research 1-3**).

EVIDENCE and RESEARCH 1-3

Education, age, gender, disease severity, duration of illness and treatment, and comorbidity modify the functional level in persons diagnosed with rheumatoid arthritis,[34–36] and anxiety, depression, and coping style have been related to activity limitations in individuals with hip or knee osteoarthritis.[37]

Contextual factors can become risk factors if they impede progress toward full functioning in society. There are several types of risk factors:

- Demographic, social, lifestyle, behavioral, psychological, and environmental factors
- Comorbidities (e.g., coexisting conditions)
- Physiologic impairments (e.g., short hamstrings, weak abdominal muscles, lengthened lower trapezius)
- Structural impairments (e.g., congenital scoliosis, shallow glenoid fossa, hip anteversion)
- Functional performance factors (e.g., less than optimal workstation ergonomics resulting in poor posture at the workstation, faulty gait kinetics or kinematics, inappropriate lifting mechanics)

The physical therapist must be aware of how any of these factors might alter the individual's response to the health condition and physical therapy intervention. Many of these factors can directly influence the choice of activities or techniques, dosage, and expected functional outcome. For example, consider two individuals involved in a motor vehicle accident and diagnosed with an acceleration injury to the cervical spine with resultant sprain or strain to the cervical soft tissues. One individual is a sedentary, 54-year-old male smoker with diabetes who has a significant forward head and thoracic kyphosis and must return to a data entry job (which he dislikes) at a poorly designed workstation. The other individual is an active and otherwise healthy, 32-year-old man who enjoys his job as a salesman and is engaged in activities such as sitting, standing, and walking throughout the day. The function and disability profiles of these two individuals are quite different, and the prognoses, therapeutic exercise interventions, and functional outcomes differ accordingly.

In addition to the risk factors present before disability, interventions (see Fig. 1-3) can alter the individual's functional level. Interventions may include extraindividual factors (i.e., outside of the individual) such as medications, surgery, rehabilitation, supportive equipment, and environmental modifications or intraindividual factors (i.e., self-induced) such as changes in health habits, coping mechanisms, and activity modifications.[38] The expected outcome is that interventions modify the functioning and disability profile in a positive manner. However, interventions occasionally serve as exacerbators. Exacerbators may occur in the following ways:

- Interventions may go awry.
- Persons may develop negative behaviors or attitudes.
- Society may place environmental or attitudinal barriers in the path of the individual.

Prevention and the Promotion of Health, Wellness, and Fitness

Physical therapists may prevent impairment, activity limitation, and participation restriction as well as improving the HRQL by identifying risk factors during the diagnostic process. Risk factors are typically part of the ICF profile (i.e., other health conditions, impairments, or contextual factors) that place the individual at an increased risk of disability. Identifying these factors allows the therapist to implement a prevention program. Three major types of prevention include[9]

- *Primary prevention*, which is the prevention of disease in a susceptible or potentially susceptible population through specific measures such as general health promotion efforts,
- *Secondary prevention*, which includes efforts to decrease duration of illness, severity of disease, and sequelae through early diagnosis and prompt intervention, and
- *Tertiary prevention*, which includes efforts to decrease the degree of disability and promote rehabilitation and restoration of function in patients with chronic and irreversible diseases.

Therapeutic exercise as an intervention intends to promote primary, secondary, and tertiary prevention as well as health, wellness, and fitness. Prevention, health, wellness, and fitness must be considered critical foundational concepts of therapeutic exercise intervention (see Chapter 4).

SUMMARY

The model of **function and disabilities** (see Fig. 1-3) exhibits the complexity of the relationships among health conditions, impairments, activity limitations, participation restriction, contextual factors, interventions, quality of life, and prevention, wellness, and fitness. A practitioner's understanding of this model is critical to developing a therapeutic exercise program that is effective, efficient, and meaningful for the individual seeking physical therapist services. The amount of data that can be collected during an initial examination or evaluation of an individual can be immense and oftentimes overwhelming. This model allows the physical therapist to organize data pertaining to the patient's impairments, activity limitations, and participation restrictions. It also allows the physical therapist to categorize pertinent aspects of the patient's history, the effect of prior treatment, and the presence of contextual factors. Most important, the clinical presentation can be classified in a way that identifies the impairments impeding the performance of certain functional tasks and activities, thereby focusing the treatment on only those impairments directly related to activity limitation and participation restriction. It also enables the practitioner to clarify contextual factors and interventions that may serve as impediments to improved functional performance, reduced disability, and improved quality of life, thereby serving the role of prevention and promoting health, wellness, and fitness. With this analysis, the practitioner can develop goals that are relevant to the individual's daily life and promote health, wellness, and fitness at any level of ability.

KEY POINTS

- Physical therapists examine patients with impairments, activity limitations, and participation restrictions or other health-related conditions to determine a diagnosis, prognosis, and intervention.
- Physical therapists are involved in alleviating and preventing impairments, activity limitations, and participation restrictions by designing, implementing, and modifying therapeutic interventions.
- Therapeutic exercise intervention engages the individual to become an active participant in the treatment plan.
- Therapeutic exercise should be a core intervention in most physical therapist treatment plans.
- As the health care industry continues to change, the practitioner must recognize that the third-party reimburser for medical care is seeking health care services that are efficient and cost-effective. Prudent use of therapeutic exercise can reduce health care costs by promoting patient independence and self-responsibility.
- A thorough understanding of the process of functioning and disability can assist the practitioner in developing an effective, efficient, and cost-contained therapeutic exercise intervention, meaningful to the person seeking physical therapist services.

CRITICAL THINKING QUESTIONS

Develop a case defining each feature of the physical therapist model of functioning and disability. Given a patient with low back pain, provide a probable history of the condition. Include a brief description of each of the following features:

- Contextual factors
- Health condition
- Impairments (structural, physiologic)
- Activity limitations
- Performance restriction
- Secondary conditions
- Previous interventions (intraindividual, extraindividual, and exacerbators)

How would these elements change if the patient was of a different age, had a different lifestyle, or a different occupation?

CHAPTER

2 Patient Management

CARRIE M. HALL

The physical therapist is responsible for evaluating and managing an individual's movement system across the life span to promote optimal development; diagnose impairments, activity limitations, and participation restrictions; and provide interventions targeted at preventing or ameliorating activity limitations and participation restrictions.[1]

A clear understanding of the International Classification of Functioning, Disability and Health (ICF) system presented in Chapter 1 enables the clinician to provide optimal patient management by understanding the relationships between movement, body function and structure, functional abilities, and activity participation in the expected environments. Knowledge of the ICF system enables the clinician to

- Develop comprehensive yet efficient examinations and evaluations of impairments and activity limitations relating to the patient's unique participation limitations and environmental and personal factors.
- Reach an accurate diagnosis based on logical classification of pathology, impairments, functional abilities, and participation restrictions.
- Develop a prognosis based on the evaluation and the patient's unique profile.
- Create and implement effective and efficient interventions.
- Reach a desirable functional outcome for the patient (patient experience), promoting fitness, health, and wellness (population health), with effective and efficient service delivery (low cost). This is called the "triple aim" in health care[2] (**Fig. 2-1**).

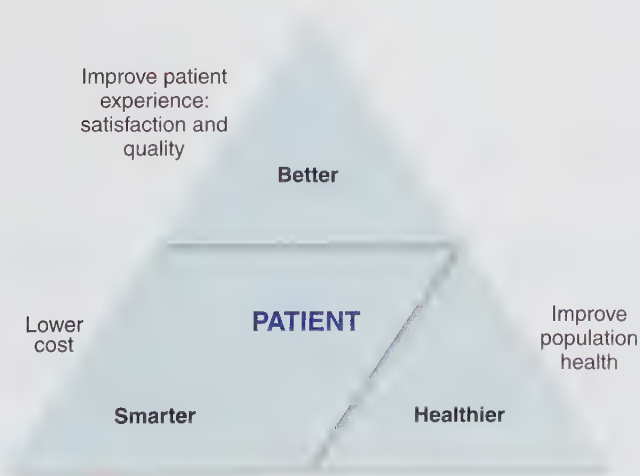

FIGURE 2-1 Triple aim.

Each patient presents with unique anatomic, physiologic, kinesiologic, psychological, and environmental characteristics. Consideration of all these variables is necessary to develop an effective plan of care, but it can be overwhelming, even for the experienced clinician. This chapter presents visual models to assist the clinician in the organization of data and the clinical decision-making process that necessitates development of an effective and efficient therapeutic exercise intervention.

PATIENT MANAGEMENT MODEL

The physical therapist's approach to patient management contains five main elements (**Fig. 2-2**). These five elements of care are integrated in a manner designed to maximize the patient's outcome, which may be conceptualized as patient related (e.g., patient experience) or associated with service delivery (e.g., low cost).

Patient and client management (**Fig. 2-3**) is an ongoing, iterative process that focuses on the evolving needs of each individual. Physical therapists apply the process of patient and client management to rehabilitate, habilitate, maintain health or function, prevent functional decline, and, in healthy individuals, enhance performance.

Examination

Examination is required before the initial intervention and is performed for all patients/clients.

The physical therapist's examination includes:

- **History** (including symptom investigation and review of systems; see **Display 2-1**)
- **Systems review** (a limited examination of the musculoskeletal, neuromuscular, cardiovascular/pulmonary, and integumentary systems)
- **Tests and measures**

Physical therapists conduct a history, perform a systems review, and use tests and measures in order to describe and/or

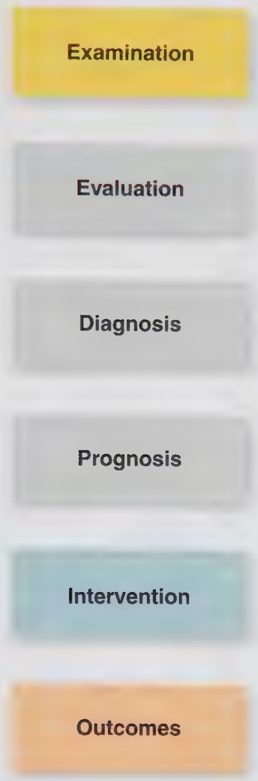

FIGURE 2-2 Patient management model.

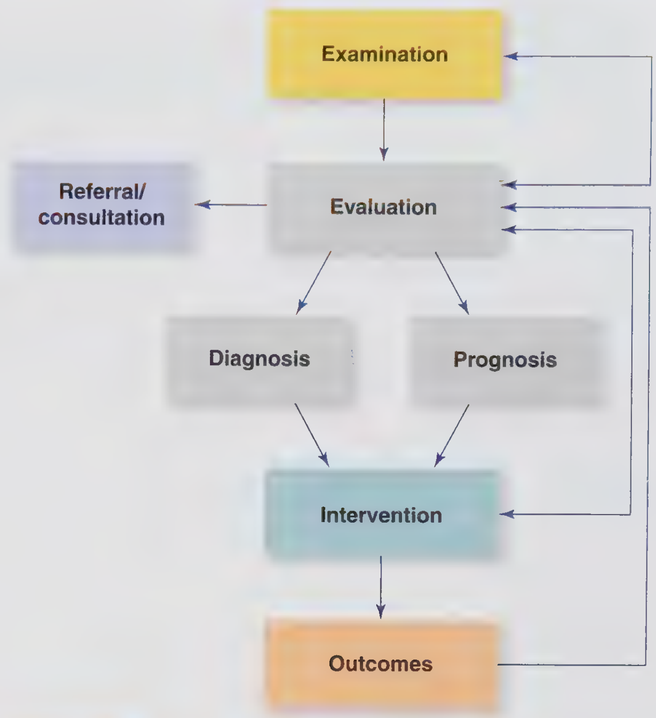

FIGURE 2-3 Process of physical therapy patient and client management.

quantify an individual's need for services. The physical therapist has the responsibility to determine if there is sufficient information to:

- Conclude whether the individual would benefit from physical therapy
- Develop the plan of care
- Progress the plan of care based on the individual's response to intervention

History

The history is a systematic gathering of data—from the past and the present—related to why the individual is seeking the services of the physical therapist. These data can be obtained from the patient, family, significant others, caregivers, and other interested persons through interview or self-report forms, by consulting with other members of the health care team, and by reviewing the medical record. Display 2-1 summarizes the data generated from the history.

Systems Review

During the history-gathering phase, physical therapists also seek information about all major body systems to determine whether there are symptoms that suggest the need for referral for additional medical evaluation. **Display 2-2** summarizes the data generated from a systems review. Reports related to the individual's overall physical (e.g., unexplained weight change, fatigue/lethargy/malaise) and emotional (e.g., anxiety, feelings of hopelessness) well-being are also noted.

Tests and Measures

Tests and measures are the means of gathering data about the individual. Physical therapists use tests and measures to rule in or rule out causes of impairment in body structures and functions, activity limitations, and participation restrictions.

The tests and measures performed as part of an initial examination should be only those that are necessary to (1) confirm or reject a hypothesis about the factors that contribute to making the individual's current level of function less than optimal and (2) support the physical therapist's clinical judgments about the diagnosis, prognosis, and plan of care.

Before, during, and after administering the tests and measures, physical therapists gauge responses, assess physical status, and obtain a more specific understanding of the condition and the diagnostic and therapeutic requirements.

The physical therapist may decide to use one, more than one, or portions of several specific tests and measures as part of the examination, based on the purpose of the visit, the complexity of the condition, and the directions taken in the clinical decision-making process.

Implementation of the examination is based on a prioritized order of tests and measures that depend on medical safety, patient comfort, and medical treatment priorities; the patient's physiologic, emotional, functional, social, and vocational needs; and financial resources. The tests and measures used by physical therapists are organized into 26 categories. Several tests from one category may be performed, whereas the physical therapist may conclude that no tests from another category are indicated (**Table 2-1**).[3]

DISPLAY 2-1

Data Generated from Client History

General Demographics

- Age
- Gender
- Race
- Primary language

Social History

- Cultural beliefs and behaviors
- Family and caregiver resources
- Social interactions, social activities, and support systems

Occupation

- Current or prior work (e.g., job, school, and play) or community activities

Growth and Development

- Hand and foot dominance
- Developmental history

Living Environment

- Living environment and community characteristics
- Projected discharge destination(s)

History of Present Condition

- Concerns that led the individual to seek the services of a physical therapist
- Concerns or needs of the individual requiring the services of a physical therapist
- Onset and pattern of symptoms
- Mechanism(s) of injury or disease, including date of onset and course of events
- Patient's, family's, or caregiver's perceptions of the patient's emotional response to the present clinical situation
- Current and prior therapeutic interventions

Functional Status and Level of Activity

- Prior functional status, and self-care and home management (i.e., activities of daily living [ADLs] and instrumental ADLs)
- Behavioral health risks
- Sleep patterns and positions
- Patient's, family's, or caregiver's functional goals for the therapeutic intervention

Medications

- Current medication list (include dosage information and reason for taking)

Other Tests and Measures

- Review of available records
- Imaging and laboratory test results

Medical or Surgical History

- Endocrine/metabolic
- Gastrointestinal
- Genitourinary
- Pregnancy, delivery, and postpartum
- Prior hospitalizations, surgeries, and preexisting medical and other health-related conditions

Family History

- Familial health risks

Social Habits (Past and Present)

- Level of physical fitness (self-care, home management, community, and work [e.g., job, school, and play] and leisure activities)
- Smoking, alcohol, drug habits

American Physical Therapy Association Board of Directors. Guidelines: Physical Therapy Documentation of Patient/Client Management (BODG03-05-16-41). Accessed 12/01/2016.

DISPLAY 2-2

Systems Review Data[3]

The systems review includes the following:

- Cardiopulmonary: assessment of heart rate, respiratory rate, blood pressure, and edema
- Musculoskeletal: gross symmetry, gross ROM, gross strength, BMI
- Neuromuscular: gross coordinated movement (e.g., balance, locomotion, transfers, transitions)
- Integumentary: skin integrity, skin color, presence of scar formation
- Communication ability, affect, cognition, language, and learning style: includes the assessment of the ability to make needs known, consciousness, orientation × 3 (person, place, and time), expected emotional/behavioral responses, and learning preferences (e.g., learning barriers, educational needs)

Other information may be required to complete the examination process such as clinical findings of other health care professionals, results of diagnostic imaging, clinical laboratory, and electrophysiologic studies or information from the patient's place of work regarding ergonomic, posture, and movement requirements.

The examination is an ongoing process throughout the patient's treatment to determine the patient's response to intervention. Based on reexamination findings (e.g., new clinical symptoms or failure to respond in the expected manner to the intervention), the intervention may be terminated or modified. Exercise modification is discussed later in this chapter.

Evaluation

Evaluation is the process by which physical therapists:

- Make judgments based on data gathered during the examination
- Interpret the individual's response to tests and measures

TABLE 2-1

Physical Therapy Examinations

- Aerobic capacity/endurance
- Anthropometric characteristics
- Assistive technology
- Balance
- Circulation (arterial, venous, lymphatic)
- Community, social, and civic life
- Cranial and peripheral nerve integrity
- Education life
- Environmental factors
- Gait
- Integumentary integrity
- Joint integrity and mobility
- Mental functions
- Mobility (including locomotion)
- Motor function
- Muscle performance (including strength, power, endurance, and length)
- Neuromotor development and sensory processing
- Pain
- Posture
- Range of motion
- Reflex integrity
- Self-care and domestic life
- Sensory integrity
- Skeletal integrity
- Ventilation and respiration
- Work life

- Integrate the test and measure data with other information collected during the history
- Determine a diagnosis amenable to physical therapist management
- Determine a prognosis, including goals for physical therapist management
- Develop a plan of care

Interpretation of the examination findings is one of the most critical stages in clinical decision-making. In interpreting the data to understand the sources (pathoanatomic) or causes (pathomechanic) of the patient's impairments in body structure or function, limitations in activities, restriction in participation, and environmental barriers, all aspects of the examination must be considered and analyzed to determine the following:

- Progression and stage of the signs and symptoms
- Stability of the condition
- Presence of preexisting conditions (i.e., comorbidities)
- Relationships among involved systems and sites

To remain consistent with the language of the ICF and to link the physical therapy patient management model with the ICF model (see Table 1-3), the following sections provide the reader with examples of examinations and evaluations for each element of the ICF model.

Health Condition (Disorder/Disease/Injury/Trauma)

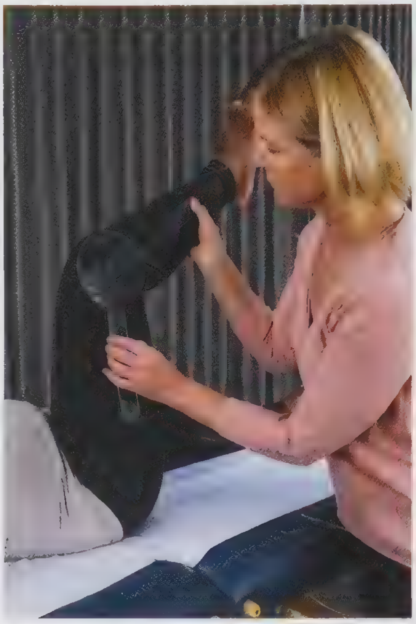
Laboratory tests, imaging studies, and electrophysiologic studies are used to assess the presence and extent of the pathologic process at the organ, tissue, or cellular level. Because some biochemical and physiologic abnormalities may be beyond the scope of medical testing, detection often relies on the examination/evaluation of impairments. One of the frustrations for physical therapists is that underlying pathology associated with the impairments in body function or structure cannot be accurately identified. Imaging, laboratory, or electrophysiologic study results can be negative despite the presence of clinical signs and symptoms (low sensitivity) or positive in the absence of the pathology (low specificity). However, the lack of an identifiable pathology or disease state should not lead the physical therapist to believe that an organic reason for the individual's impairments in body function or structure, activity limitations, or participation restrictions is not present. Even with a diagnosis of pathology or disease, the physical therapist should concentrate on examination and evaluation of impairments in body function and structure, activity and participation levels, and environmental accessibility, because the pathoanatomic or pathophysiologic diagnosis cannot, in and of itself, guide the physical therapist's intervention.

Impairments in Body Function and Structure

Medical procedures to evaluate impairments in body function and structure include clinical examinations, laboratory studies, electrophysiologic studies, imaging procedures, and the patient's medical history and symptom reports. Physical therapy procedures to examine and evaluate impairments should be based on bodily systems most treated by physical therapists including the musculoskeletal, neuromuscular, cardiovascular, pulmonary, and integumentary systems (see **Fig. 2-4**). Many bodily systems are not within the scope of thorough and definitive examination by a physical therapist (e.g., metabolic, renal, and gastrointestinal). However, if pertinent to the physical therapy intervention, this information should be gathered from the patient, other health care professionals, or medical records.

Examinations may reveal a list of impairments that may or may not be amenable to physical therapy treatment. It is tempting to evaluate and treat lists of impairments, but this type of practice may not be the most effective or efficient use of health care dollars. It is therefore prudent to make simultaneous decisions about whether testing or measuring an impairment is pertinent to determining the cause(s) of the activity limitation and participation restriction. To facilitate this decision-making process, ask the following questions:

- **Is the impairment related directly to a limitation in activity level or restriction in participation?** For example, reduced thoracic or hip rotation ROM may be related to low back pain, even though it is not in the region of complaint.
- **Is the impairment a secondary condition of the primary pathology or impairment?** For example, a patient has complaints of shoulder pain and loss of mobility (i.e., physiologic impairments) resulting in reduced function of the upper extremity for ADLs (i.e., activity limitation) and subsequently restriction in sports or recreational activities (i.e., participation restriction). However, the source of the shoulder pain is cervical disk disease (i.e., primary pathology). Loss of mobility of the shoulder is a secondary impairment, and reduced use of the upper extremity during ADLs and sports is a secondary limitation/restriction, both of which developed because of pain in the shoulder originating from the primary condition of cervical degenerative disk disease.



A B

FIGURE 2-4 **(A)** Measurement of ROM and muscle length impairment. The patient shows signs of limited hamstring extensibility. **(B)** Measurement of aerobic capacity impairment. The clinician takes the patient's blood pressure.

- **Can the impairment be related to future limitations in activity or participation restrictions?** Studies have shown that a relationship can exist between current impairment findings and future activity limitations.[4,5] For example, loss of shoulder ROM in the absence of ADL limitation may lead to limitation in the future from exaggeration of the impairment or lead to other impairments, such as neck-related impairments.
- **Is the impairment unrelated to the activity limitation, participation restriction, or environmental barrier and therefore should not be assessed or treated?** For example, a patient complains of shoulder pain and reduced use of the shoulder girdle during ADLs. Hypomobility of the shoulder girdle may be an obvious impairment, but it may not be related to the activity limitation. The patient's pain may occur in the midrange, limiting activity at chest height vs. overhead activity.

In summary, not all impairments result in activity limitation, and not all activity limitations result in participation restriction. In theory, interventions should target only those impairments that will ultimately affect function and reduce the potential for participation restriction. Indeed, it has been suggested that through the examination process, the clinician determines the interactions between impairments, activity limitation, participation restriction, and environmental barriers for a patient with a given diagnosis and that this information then guides treatment.[6] Examples of cervical spine **impairments** include reduced range of cervical spine motion and decreased segmental joint mobility, whereas an **activity limitation** might be inability to rotate the head and neck sufficiently to be able to see behind. A **participation restriction** results when this occurs while driving an automobile in reverse. If an individual is then unable to work because his or her occupation requires automobile use that person has **environmental barriers.**

Activity Limitation and Participation Restriction

Patients ultimately seek the services of a physical therapist typically because impairments and functional limitations result in participation restriction. For example, the patient is probably more concerned about his or her ability to climb the flight of stairs to enter his or her office (i.e., participation) than the adequate knee ROM and quadriceps force or torque production needed to climb the stairs (i.e., physiologic impairment). Furthermore, improved knee ROM and quadriceps torque production may not result in the ability to climb a flight of stairs. The inability to climb stairs may be related to other impairments, such as weak gluteal musculature, lack of ankle mobility, or psychological impairment (e.g., fear, confidence).

One question must be addressed in daily practice and in physical therapy research, "Which and to what degree are impairments in body function and structure linked to activity limitations and participation restriction?" Many studies are attempting to establish the relationships among pathology/disease, impairments, activity limitations, and participation restriction because this question is clinically important to physical therapists (**Evidence and Research 2-1**).

EVIDENCE and RESEARCH 2-1

Information gained from a descriptive study of individuals with arthritis indicates correlations between pathology (i.e., arthritis), impairments (i.e., knee ROM, pain and joint stiffness, and reduced muscle performance), and activity limitations (i.e., performing ADLs including getting down to and up from the floor and ascending/descending stairs).[7] This study indicates that quadriceps muscle performance, joint pain during the activity, perceptions of functional ability, and body weight combined can predict between 39% and 56% of the variance in time to perform four functional tasks in adults with osteoarthritis of the knee. These findings appear to indicate that interventions that improve quadriceps muscle performance, reduce joint pain and body weight, and facilitate perceptions of functional ability may have a positive impact on the ability to get down to and up from the floor and ascend/descend stairs in adults with osteoarthritis of the knee.

In order for investigators to generate meaningful research of disability, valid and reliable measurement tools must be utilized. Measurement of disability requires tests that consider the complexity of variables that affect the person's ability to interact in society. With standardized tests, no single assessment instrument can measure the full range of potential impairments, activity limitations, or participation restrictions. Adequate evaluation usually must rely on a battery of appropriate instruments. It is beyond the scope of this text to discuss the various standardized tests, but a literature search on the specific population you are testing can offer explicit tests and measures for your desired purpose.[8–19]

Tests and measures of function and disability have various formats:

- *Self-reports or proxy reports*
  The standard and most economic procedure for measuring disability is self-reports or proxy reports,[20,21] which include simple ordinal or interval scoring of the degree of difficulty in performing roles within the person's milieu.[18,22–30] Self-reports are increasingly required for third-party reimbursement and are mandated by the Centers for Medicare and Medicaid Services (CMS; available at: http://www.cms.gov/Outreach-and-Education/Medicare-Learning-Network-MLN/MLNMattersArticles/Downloads/SE1307.pdf. Accessed February 10, 2015).
- *Observation and scoring of performance of functional tasks*
  Observation of performance of functional tasks, rating the level of difficulty (e.g., fully able, partially able, and unable), such as measuring distances, weight lifted, number of repetitions, or quality of motion based on kinesiologic standards.[22]
- *Clinical tests of physical mobility*
  Timed walking tests and movement batteries[31–33]
- *Equipment-based evaluation of performance*
  Use of a hand dynamometer to examine grip strength, computer-assisted assessment of balance, use of specialized grids to measure performance of closed chain activities.[23–25,34,35]

Results of a disability measure often reveal aspects of the disability that are beyond physical impairments and activity limitations. In some cases, aspects of an individual's disability are beyond the knowledge, expertise, or experience of the PT, in which case the patient should be referred to the appropriate health care professional. A simultaneous decision must be made as to whether further physical therapy intervention is appropriate or if physical therapy should be deferred until other aspects of disability are adequately managed. For example, a patient with low back pain may have a high level of anxiety or depression associated with the loss of function and the disability. Physical therapy may not be effective until the patient is treated for the anxiety or depression, or physical therapy concurrent with counseling may be determined to be most effective.

Diagnosis

In 1982, the House of Delegates stipulated that physical therapists must establish a diagnosis (American Physical Therapy Association. Diagnosis by physical therapists. Available at: http://www.apta.org.offcampus.lib.washington.edu/uploadedFiles/APTAorg/About_Us/Policies/Practice/Diagnosis.pdf. Updated August 22, 2012, Accessed February 2015). Diagnosis is the process and end result of information obtained in the examination and evaluation. The diagnostic process includes analyzing the information obtained in the examination and evaluation and organizing it into clusters, syndromes, or categories (see **Display 2-3** for definition of terms) to help determine the most appropriate intervention strategy for each patient. The diagnostic process includes the following components[3]:

- Obtaining a relevant history (i.e., examination)
- Performing a systems review (i.e., examination)
- Selecting and administering specific tests and measures (i.e., examination)
- Interpreting all data (i.e., evaluation)
- Organizing all data into a cluster, syndrome, or category (i.e., diagnosis)

The end result of the diagnostic process is establishing a diagnosis. To reach an appropriate diagnosis, additional information may need to be obtained from other health care professionals. In the event that the diagnostic process does not yield an identifiable cluster, syndrome, or category, intervention may be guided by the reduction of impairments and restoring activity and participation levels.

Diagnosis in the physical therapy patient management model is synonymous with the term clinical classification and is not to be confused with the term medical diagnosis.[36] Medical diagnosis is the identification of a patient's pathology or disease by its signs, symptoms, and data collected from tests ordered by the physician. Diagnosis established by a physical therapist is related to the primary dysfunction toward which the physical therapist directs treatment.[36–38] The ability to diagnose clusters, syndromes, or categories can foster the development of efficient treatment interventions and facilitate reliable outcomes research to present to the public, medical community, and third-party payers.

A common medical diagnosis of patients referred to outpatient physical therapy practices is low back pain, which is nothing more than a location of pain. If an outcomes study was performed that included all patients with the diagnosis of low back pain in a given practice, the results would not shed light on the best approach for treating low back pain because of the diverse pathoanatomic sources, pathomechanic causes, stages and severity of the condition, and comorbidities involved. Subclassification of patients based on diagnostic classification paradigms is necessary to provide more efficient patient management strategies and more meaningful outcome data.

DISPLAY 2-3
Definitions of Terms

Cluster: A set of observations or data that frequently occur as a group for a single patient.

Syndrome: An aggregate of signs and symptoms that characterize a given disease or condition.

Diagnosis: A label encompassing a cluster of signs and symptoms commonly associated with a disorder, syndrome, or category of impairment, activity limitation, or disability.

Adapted from American Physical Therapy Association. A guide to physical therapist practice, I: a description of patient management. Phys Ther 1995;75:749–756.

Medical diagnosis (e.g., herniated nucleus pulposus, spondylolisthesis) may not be helpful in directing successful rehabilitation of patients with low back pain.[39] The medical diagnosis, in most cases, does not provide the physical therapist with enough information to proceed with intervention, as the medical diagnosis does not provide any information related to the patient's impairments, limitations in activities, or restriction in participation. The diagnosis made by a physical therapist is reached only after performing a thorough examination and evaluation combined, if necessary, with the results of tests and measures ordered and performed by professionals from other disciplines combined with the medical diagnosis.

While medicine has had hundreds of years to refine diagnostic categories, physical therapy is in the early stages of developing diagnostic classifications. After classifications are developed, much work regarding validity, reliability, and sensitivity of diagnostic classifications needs to be done.

The interaction of these four components results in "diagnostic disablement."[40]

The first step toward agreement regarding diagnostic classifications is to standardize the language that physical therapists use to diagnose conditions within their scope of practice. Leaders in the field of physical therapy are working toward this common language (available at: https://dxdialog.wusm.wustl.edu/Pages/WelcomeDxDialog.aspx. Accessed February 17, 2015). The goal is to be able to one day correlate effective and efficient treatment with the clinical diagnosis made by physical therapists to establish more efficient and cost-effective outcomes.[36–47] Only then can physical therapists promote the efficacy of the profession in today's responsibility-focused health care environment.

Prognosis and Plan of Care

After a diagnosis has been established, the physical therapist determines the prognosis and develops the plan of care. Prognosis is the process of determining the level of optimal improvement that may be obtained from intervention, and the amount of time required to reach that level.[3] For example, an expected short-term outcome for an otherwise healthy 65-year-old person after a hip fracture treated with open reduction and internal fixation may be the ability to walk 300 ft with partial weight-bearing, using a walker, in 3 days; an expected long-term outcome may be the ability to walk independently without a gait deviation in 12 to 16 weeks.

The plan of care consists of statements that specify the interventions to be used and the proposed duration and frequency of the interventions that are required to reach the anticipated goals and expected outcomes.[3] The plan of care is the culmination of the examination, diagnostic, and prognostic processes.

The prognosis and plan of care should be based on the following factors:

- The patient's health status, risk factors, and response to previous interventions
- The patient's safety, needs, and goals
- The natural history and the expected clinical course of the pathology, impairment, or diagnosis
- The results of the examination, evaluation, and diagnostic processes

To ensure that the prognosis and plan of care are based on the patient's safety, needs, and goals, the physical therapist should confer with the patient.[48] During this discussion, the patient must be informed of the diagnosis or prioritized impairment list if a diagnosis cannot be developed. The patient should also be provided with an explanation of the relationship between the diagnosis or impairments and the activity limitations and participation restrictions. This information can assist the patient in developing realistic goals and understanding the purpose of the selected interventions, which may ultimately increase compliance. Agreement between the patient and therapist on the long-term and short-term goals is imperative for successful treatment outcomes. When the physical therapist determines that physical therapy intervention is unlikely to be beneficial, the reasons should be discussed with the patient and other individuals concerned and documented in the medical record.

The prognosis and plan of care are based on the natural history and the expected clinical courses of the pathology, disease, or disorder based on the most current evidence, including literature reviews, research articles, evidence-based clinical practice guidelines, and clinical experience.[49] Following these steps can assist the clinician in developing a sound prognosis and plan of care based on finding the best evidence available in a practical time frame (**Evidence and Research 2-2**).

EVIDENCE and RESEARCH 2-2

Straus succinctly outlined the steps necessary to practice evidence-based patient management in her 1998 article[49]:

- Convert the need for information into clinically relevant, answerable questions
- Find, in the most efficient way, the best evidence with which to answer these questions (whether this evidence comes from clinical examination, published research, medical tests, or other sources)
- Critically appraise the evidence for its validity (closeness to the truth) and usefulness (clinical applicability)
- Integrate the appraisal with clinical expertise and apply the results to clinical practice
- Evaluate your performance

Intervention

Intervention is defined as the purposeful and skilled interaction of the physical therapist with the patient using various methods and techniques to produce changes in the patient's condition consistent with the evaluation, diagnosis, and prognosis.[3] Ongoing decisions regarding intervention are contingent on the timely monitoring of the patient's response to treatment and the progress made toward achieving outcomes. The three major types of intervention are listed in **Display 2-4**. This text focuses on one aspect of direct intervention (i.e., therapeutic exercise) and patient-related instruction as it relates to therapeutic exercise.

The key to a successful intervention and patient outcome is to *do the right things well*.[50] To determine the *right things*, the physical therapist must have a thorough understanding of the patient's activity limitation/participation restriction profile and sound clinical decision-making skills.

DISPLAY 2-4

Types of Physical Therapy Interventions

- Direct intervention (e.g., therapeutic exercise, manual therapy techniques, integumentary repair and protection techniques, motor function training)
- Patient-related instruction (e.g., education provided to the patient and other caregivers involved regarding the patient's condition, treatment plan, information and training in maintenance, and prevention activities)
- Coordination, communication, and documentation (e.g., electronic medical record, patient care conferences)

Clinical Decision-Making for Intervention

The physical therapist is educated and trained to effectively and efficiently treat impairments in body function or structure related to activity limitations and participation restrictions in order to arrive at desirable functional outcomes for the patient. In designing the plan of care, the physical therapist analyzes and integrates the clinical implications of the severity, complexity, and acuity of pathology, disease, or disorder; the extent of the impairment of body function and structure; the types of activities and participations and the environment to which the person wishes to return. Recall that the ultimate functional goal of physical therapy is the achievement of optimal movement and functioning in the activities and participations that are unique to the individual. Physical therapists generally develop treatment interventions with the intention of restoring function and improving participation in desired activities. However, strictly impairment-based interventions often do not achieve functional goals because the focus may not be on the right impairment.

Treating the "Right" Impairments An important clinical decision in the patient management process is to determine the impairment that most closely relates to an activity limitation or participation restriction. Physical therapists are often tempted to include impairments that are not relevant because they assume that the reduction of any or all impairments leads directly to improvement in function.[51] In reality, the treatment of impairments can only lead to improvement in function if the impairments contribute directly to a limitation in activity.

If an impairment seems to be linked to an activity limitation or participation restriction, the therapist must question whether the impairment is amenable to physical therapy intervention. To help determine the answer, the physical therapist should ask several questions:

- Will the patient benefit from the intervention (i.e., can treatment of the impairment improve functioning or prevent functional loss)?
- Are there any possible negative effects of the treatment (contraindications)?
- What is the cost–benefit ratio?

If it is determined that no treatment can be justified, the physical therapist should consider other options such as the following:

- Discussing the decision to decline intervention with the patient to ensure patient agreement and understanding of the decision
- Referring the patient to an appropriate practitioner or resource
- Assisting in modifying the environment in which the individual lives, goes to school, or works to ensure maximal performance despite the impairment, activity limitation, or participation restriction
- Teaching the individual to appropriately compensate for the impairment during activities or participation in more complex social roles

If the impairment is amenable to treatment, decide whether to treat the impairment, activity limitation, or both. **Building Block 2-1** illustrates this point.

BUILDING BLOCK 2-1

Consider a 72-year-old man 4 weeks s/p total knee replacement. He presents with weakness of the quadriceps and reduced flexion ROM of the knee. Would you choose to treat the impairments with specific exercise instruction to increase quadriceps muscle performance and tibiofemoral joint mobility or teach the patient the functional task of sit to stand? Please defend your answer.

Selecting and Justifying Treatment Interventions After a decision has been made to treat a specific impairment or activity limitation, the next step is to select an appropriate intervention or combination of interventions with the proper sequencing (e.g., moist heat before joint mobilization, which is followed by stretching the short or stiff tissue and strengthening the antagonist, ending with a functional task that employs the new mobility).

Physical therapists may select interventions from among the following possibilities[3]:

- Airway clearance techniques
- Assistive technology: prescription, application, and, as appropriate, fabrication or modification
- Biophysical agents
- Functional training in self-care and in domestic, education, work, community, social, and civic life
- Integumentary repair and protection techniques
- Manual therapy techniques
- Motor function training
- Therapeutic exercise

Numerous patient factors must be taken into consideration to determine which of the described interventions are appropriate. This information is obtained from the history and systems review (see Displays 2-1 and 2-2). An awareness of the patient's physical environment for living and/or working, or the recreational activities to which the patient wishes to return is important in developing patient-centered interventions and achieving functional outcomes. For example, a successful outcome may not be reflected in increased strength in the quadriceps measured by a hand-held dynamometer, but may be observed in the use of that strength in a functional manner in the patient's environment, such as walking up a flight of stairs with 20 lb of groceries.

The process of selecting and justifying treatment intervention must be based on the integration of research evidence, clinical expertise, and patient values, called "evidence-based medicine (EBM)."[52] EBM aims to improve health care outcomes by balancing findings from research with clinical experience and patient/family preferences. The Internet has greatly increased the ease with which many clinicians can access and rapidly sort research evidence. Of the numerous databases available, a few are particularly relevant to physical therapy. PubMed is probably the best known database. It is maintained by the National Library of Medicine and is free to the public at www.ncbi.nlm.nih.gov/PubMed. The American Physical Therapy Association's (APTA) PTNow provides access to several databases and health care literature from ProQuest, Joanna Briggs Institute, and the Cochrane Library. More information can be accessed at http://www.apta.org/EvidenceResearch/Tools.

Patient-Related Instruction

Patient-related instruction is the process of imparting information and developing skills to promote independence and to allow care to continue after discharge.[3] It must be an integral part of any physical therapy intervention (**Fig. 2-5**) and will be featured in this text to enhance the therapeutic exercise intervention.

When patient education is not possible (e.g., the patient is an infant, comatose, there is a cognitive deficit or language barrier), educating family members, significant others, friends, or other caregivers is essential. Patient-related instruction offered to a support person, even when educating the patient is possible, can promote compliance by teaching the support person to intervene in an appropriate manner and encouraging the display of appropriate attitudes toward the patient's activity limitations and disabilities.

Patient-related instruction is critical to enhance compliance in following through with interventions and preventing future limitations in activity or restrictions in participation. Imparting your knowledge of the patient's function/disability process enables the patient to gain confidence in your skills, which further enhances compliance. Patient-related instruction may include the following:

- Education pertaining to the
  - Pathologic process and impairments contributing to activity limitation and participation restriction
  - Prognosis
  - Purposes and potential complications of the intervention
- Instruction and assistance in making appropriate decisions about management of the condition during ADLs (e.g., workstation ergonomic modifications, altered movement patterns and body mechanics, and altered sleep postures)
- Instruction and assistance in implementing interventions under the direction of the physical therapist (e.g., training a support person in techniques of therapeutic exercise in the event that cognitive, physical, or resource status of the patient requires assistance to perform a home management program)

FIGURE 2-5 Patient-related instruction is an integral part of physical therapy intervention. By helping the patient understand her impairment and activity limitations, the clinician promotes patient compliance with the therapeutic intervention program. In addition, patient satisfaction is promoted by taking the time to educate the patient regarding the cause(s) of his condition, self-management techniques, and prevention.

Patient-related instruction confers several benefits that promote the triple aim in health care (patient satisfaction, healthy population, low cost):

- Increased patient, significant other, family, and caregiver knowledge about the patient's condition, prognosis, and management
- Acquisition of behaviors that foster healthy habits, wellness, and prevention
- Improved levels of performance in employment, recreational, and sports activities
- Improved physical function, health status, and sense of well-being
- Improved safety for the patient, significant others, family, and caregivers
- Reduced participation restriction, secondary conditions, and recurrence
- Enhanced decision-making about the use of health care resources by the patient, significant others, family, or caregivers
- Decreased service use and improved cost containment

Patient-related instruction represents the first and *most important step* toward directing responsibility for treatment outcome from the physical therapist to the patient. A thorough understanding of the individual's disablement process and the factors that may impede improved functional outcome are necessary to provide comprehensive and personalized patient-related instruction. The successful practitioner is one who is skilful in the delivery of an active treatment approach based on treatment specific to the individual's profile and on education that places the patient (or caregiver) in the position of taking responsibility for the outcome.

Outcome

In the new age of collaborative care with performance-based and bundled payment systems and accountable care organizations and medical homes, physical therapists must consider themselves primary caregivers for the neuromusculoskeletal system. The physical therapist treats patients across their life span, similar to primary care physicians. Although a patient may be discontinued from an episode of care, the patient is not discharged from the care of his/her physical therapist, similar to a dental model where a patient is treated for a cavity, but never discharged from the care of the dentist. The neuromusculoskeletal system is managed with periodic "booster" sessions and the patient's physical therapist is available to manage any new conditions or injuries that occur on a timely basis, again similar to the dental model of preventive care.

As the patient/client reaches the end of the episode of care, the physical therapist measures the global outcomes of the physical therapy services by characterizing or quantifying the impact of the physical therapy interventions on the following domains[3]:

- Health condition (disorder or disease)
- Body functions/structures
- Activities
- Participation
- Risk reduction/prevention
- Health, wellness, and fitness
- Personal/environmental factors
- Patient/client satisfaction

An outcome is considered successful when the following conditions are met:

- Activity and participation is improved or maintained whenever possible.
- Activity limitation or participation restriction is minimized or slowed when the status quo cannot be maintained.
- The patient is satisfied.

At each step of the patient management process, the physical therapist considers the possible patient outcomes. This ongoing measurement of patient outcomes is based on the examination and evaluation of impairments, functional status, and level of participation restriction. To evaluate the effectiveness of the intervention, the physical therapist must select criteria to be tested (e.g., impairments and activity limitations) and interpret the results of the examination. Outcomes can be measured through outcome analysis. This is a systematic examination of patient outcomes in relation to selected patient variables (e.g., age, sex, diagnosis, interventions, and patient satisfaction). It can be part of a quality assurance program, used for economic analysis of a practice, or used to demonstrate efficacy of intervention.

Modification

On January 15, 2014, the CMS issued an update to clarify skilled nursing facility, inpatient rehabilitation facility, home health agencies, and outpatient therapy coverage requirements pursuant to the settlement agreement in the case of *Jimmo v. Sebelius*. This landmark case changed the definition of medical necessity in physical therapy from a purely restorative care to including the skilled care necessary to prevent a slow decline in a condition (available at: http://www.cms.gov/Outreach-and-Education/Medicare-Learning-Network-MLN/MLNMattersArticles/Downloads/MM8458.pdf. Accessed February 17, 2015). Positive outcomes are not synonymous with improved impairment measures, but impairments and functional status should be measured to determine the efficacy of the intervention plan. By measuring both variables, the therapist can determine whether changes in the impairment, or maintenance of status, are associated with improved, or the prevention in the decline of, functional status.[51] If functional status has not improved when expected to, or declines when maintenance was the goal, consider modifying the intervention plan. Modification of intervention is based on the status relative to the expected outcome and the rate of progress. **Display 2-5** illustrates additional factors to consider with respect to modification of an intervention.

Prudent clinical reasoning assists the clinician in determining the need for modification and the best adjustments to implement. In determining and implementing revised goals and interventions, the clinician uses the additional data gathered from the reevaluation. This reevaluation and modification process continues until the completion of the episode of care.

DISPLAY 2-5

Factors to Consider When Modifying an Intervention

- Medical safety
- Patient comfort
- Patient's level of independence with the intervention (especially related to therapeutic exercise intervention)
- Effect of the intervention on the functional activities and participation restrictions
- New or altered symptoms because of intervention by other health care providers
- Patient finances, environment, and schedule constraints

The intervention may be modified by one of the following actions:

- Increasing or decreasing the dosage of the intervention, especially in the case of therapeutic exercise intervention (see the section on "Exercise Modification" in this chapter)
- Treating different impairments
- Changing the focus to activity limitations
- Consulting or referring to a physical therapist with advanced training or certification in a content area
- Referring the patient to another health care provider specializing in a system that is beyond the PT scope of practice
- Improving physical therapy techniques, verbal cues, and teaching skills

In the current health care environment, physical therapists are faced with the challenge of practicing in an increasingly competitive marketplace. As marketplace competition continues to grow, patient satisfaction with physical therapy is emerging as an outcome variable of critical importance. The results of one study show that patient satisfaction with care is most strongly correlated with the quality of patient care–provider interactions.[53] This includes the care provider spending adequate time with the patient, demonstrating strong listening and communication skills, and offering a clear explanation of treatment and prevention strategies.

Complex reimbursement models, greater public scrutiny, and disclosure of clinical quality and patient safety performance standards are demanding a new, more equitable, and effective reimbursement model for hospitals and physician services.

The goal of APTA is to reform payment for outpatient physical therapy services to improve quality of care, recognize and promote the clinical judgment of the physical therapist, and provide policymakers and payers with an accurate payment system that ensures the integrity of medically necessary services.

The association and its collaborators developed a 3-tiered system of CPT evaluation codes to replace the previous single code that covered all physical therapist evaluations. This new system went into effect January 2017. The new CPT evaluation and reevaluation codes are a step in the right direction toward overall payment reform, and APTA continues to work with AMA and other provider groups in seeing value-based payment evolve.

DISPLAY 2-6

Patient Management Concepts

- Develop an examination or evaluation schema pertinent to the patient.
- Diagnose the patient's impairments, activity limitations, and disabilities/participation restrictions.
- Develop a prognosis based on the patient's individual disablement profile.
- Develop a plan of care designed to improve, or prevent the loss of, function (i.e., the right things).
- Apply appropriate judgment and motor treatment skills to provide the proper intervention.
- Continually use clinical reasoning to modify the intervention as needed for a positive outcome.

Now more than ever, successful patient management is vital to the growth of our profession. As discussed in detail, successful patient management entails many aspects of clinician and patient–client interaction. **Display 2-6** succinctly summarizes patient management concepts.

CLINICAL DECISION-MAKING

At each juncture in the patient management model, clinical decisions are made. Appropriate decisions are crucial for a successful outcome. However, the clinical decision-making process involved in patient management presents the greatest challenge to the physical therapist. The following aspects are found to be most difficult in the clinical decision-making process:

- Organization of evaluation findings into a diagnosis
- Development of a prognosis based on the patient's activity limitations and participation restrictions
- Development of realistic patient-based goals
- Development and implementation of an intervention that is effective and efficient

Display 2-7 summarizes clinical decision-making tips in relation to patient management to assist the physical therapist when addressing these challenges. The effectiveness of clinical decision-making is based on obtaining pertinent data. The physical therapist must possess

- Knowledge about what is pertinent
- The skill to obtain the data
- The ability to store, record, evaluate, relate, and interpret the data

These actions require knowledge of the function/disability process; clinical experience and skill in treating impairments and activity limitations; and a disciplined, systematic thought process. Common to those who strive to excel in clinical decision-making are the following characteristics:

- Wide range of knowledge
- Ongoing acquisition of knowledge
- Need for order or a plan of action
- Questioning unproven conventional solutions
- Self-discipline and persistence in work

DISPLAY 2-7

Clinical Decision-Making Tips for Patient Management

Examination: Prioritize the problems to be assessed and the tests and measures to be implemented.

Evaluation: Consider and analyze all examination findings for relationships, including the progression and stages of the symptoms, diagnostic findings by other health care professionals, comorbidities, medical history, and treatment or medications received.

Diagnosis: Segregate findings into clusters of symptoms and signs by common causes, mechanisms, and effects.

Prognosis and Plan of Care: Develop long-term and short-term goals based on patient safety, needs, and goals and on information regarding the natural history and expected clinical courses of the pathology, impairment, or diagnosis.

Intervention: Determine whether impairments correlate with an activity limitation or disability and are amenable to physical therapy treatment. Select and justify a method of intervention. The most credible source of justification is based on relevant research literature.

Outcome: Measure the success of the intervention plan according to functional gain and make appropriate modifications when necessary.

Information regarding the clinical decision-making process warrants its own text. However, this text strives to include theoretic information and pertinent issues related to clinical decision-making. This information empowers the physical therapist with some of the necessary tools to make appropriate clinical decisions regarding the design and application of treatment plans.

THERAPEUTIC EXERCISE INTERVENTION

The revised Vision Statement for APTA is as follows: "The physical therapy profession will define and promote the movement system as the foundation for optimizing movement to improve the health of society. Recognition and validation of the movement system is essential to understand the structure, function, and potential of the human body. The physical therapist will be responsible for evaluating and managing an individual's movement system across the life span to promote optimal development; diagnose impairments, activity limitations, and participation restrictions; and provide interventions targeted at preventing or ameliorating activity limitations and participation restrictions. The movement system is the core of physical therapist practice, education, and research" (available at: http://www.apta.org/Vision/. Accessed February 17, 2015). It is for this reason that therapeutic exercise is the cornerstone intervention for physical therapists.

After completion of the examination and evaluation, the development of a diagnosis and prognosis, and the relationship between the pathology, impairments, activity limitations, and participation restrictions has been established, a plan of care is determined utilizing the clinical decision-making process. Therapeutic exercise may be the basis of the intervention or

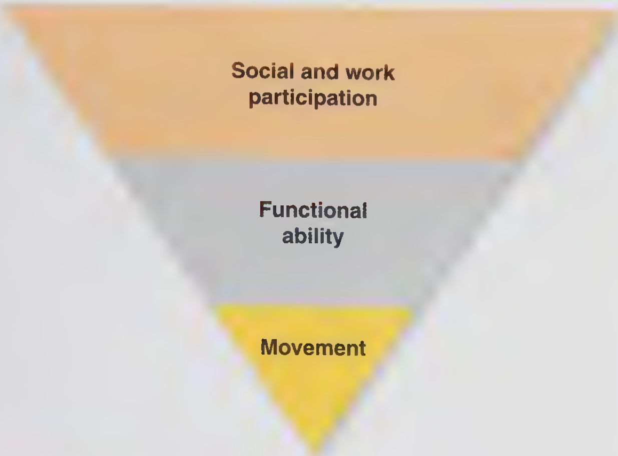


FIGURE 2-6 Movement is the foundation for functional activity and participation in social and work-related roles.

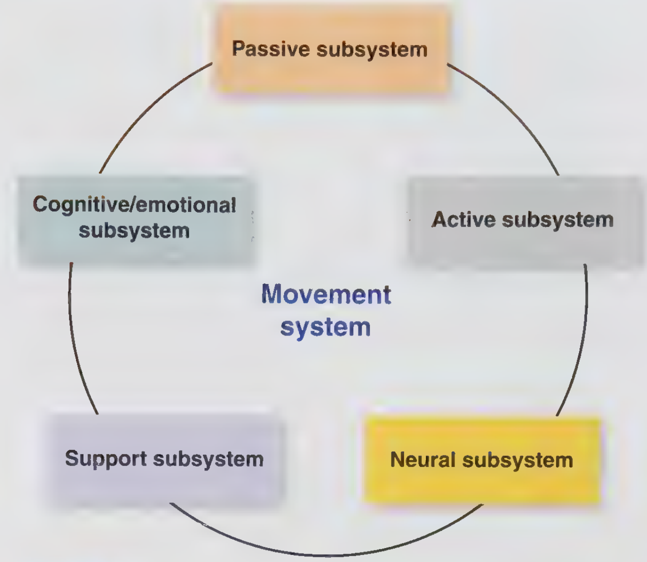

FIGURE 2-7 Model of movement system and component subsystems.

may be one component of the intervention, but it should be included to some extent in all patient care plans. Therapeutic exercise includes activities and techniques to improve physical function and health status resulting from impairments by identifying specific performance goals that allow a patient to achieve a higher functional level. It also incorporates activities to prevent loss of function in individuals where improvement is not expected, and allow well clients to improve or maintain their health or performance status and to prevent or minimize future potential functional loss or health problems.

Therapeutic Exercise Intervention Model

To prescribe the appropriate exercise, factors regarding the patient's activity limitation(s) and participation restriction(s) must be considered. Each exercise prescription has two common goals:

1. To restore functional movement as best as possible
2. To prevent or minimize functional movement loss in the future

Figure 2-6 depicts the relationship between movement, functional abilities, and participation in social and work roles. It is represented as a hierarchy in that movement is the foundation to optimal living and quality of life for all people of all ages. Movement extends beyond health to every person's ability to participate in and contribute to society. The domain of physical therapists is evaluation and treatment of the movement system. For this reason, the foundation of the intervention model is the movement system and its component subsystems.

Subsystems of the Movement System

The **movement system** is defined as:

1. A physiologic system that functions to produce motion of the whole body or of its component parts
2. The functional interaction of structures that contribute to the act of moving (http://medical-dictionary.thefreedictionary.com/movement+system. Accessed March 2015)

Figure 2-7 describes the movement system as made up of several subsystems, each of which has a unique basic function necessary for the production and regulation of movement. The optimal actions and interactions of the multiple anatomic, physiologic, and psychological systems involved in movement must be considered when prescribing therapeutic exercise. The subsystem impacts the stage of motor control, choice of activity, dosage, and specific cuing provided to the patient (see **Fig. 2-8A** and **B**).

The subsystems proposed are a hybrid of theories provided by Sahrmann, Panjabi and Lee and Lee.

The ideal movement can be thought of as the result of a complex interaction of several subsystems of the larger encompassing movement system.

- *Support subsystem:* This subsystem includes the physiologic status of the integumentary, circulatory, lymphatic, respiratory, endocrine, urinary/excretory, reproductive, and digestive systems. These systems play an indirect role in that they do not produce motion of the segments, but provide substrates and metabolic support required to maintain the viability of the other systems. Examples of components included in this element would be respiratory status (including breathing patterns) and hormonal factors.
- *Passive subsystem:* This subsystem includes the structural status of the passive properties of the neuromyofascia and capsuloligamentous, bony, and joint-related tissues (cartilage). Linking back to ICF, this includes impairments such as mobility and stability of joint function and includes tests and measures such as ROM, muscle length, and joint integrity.
- *Active subsystem:* This subsystem includes muscle contractile properties and provides the force/torque requirements for movement. ICF impairments include muscle power, tone, endurance and tests and measures such as strength, power, and endurance.
- *Neural subsystem:* This subsystem is related to motor function. ICF impairments include control over voluntary and involuntary movement functions and gait and tests and measures related to timing of muscle recruitment, muscle cessation patterns, and feed-forward and feedback systems.

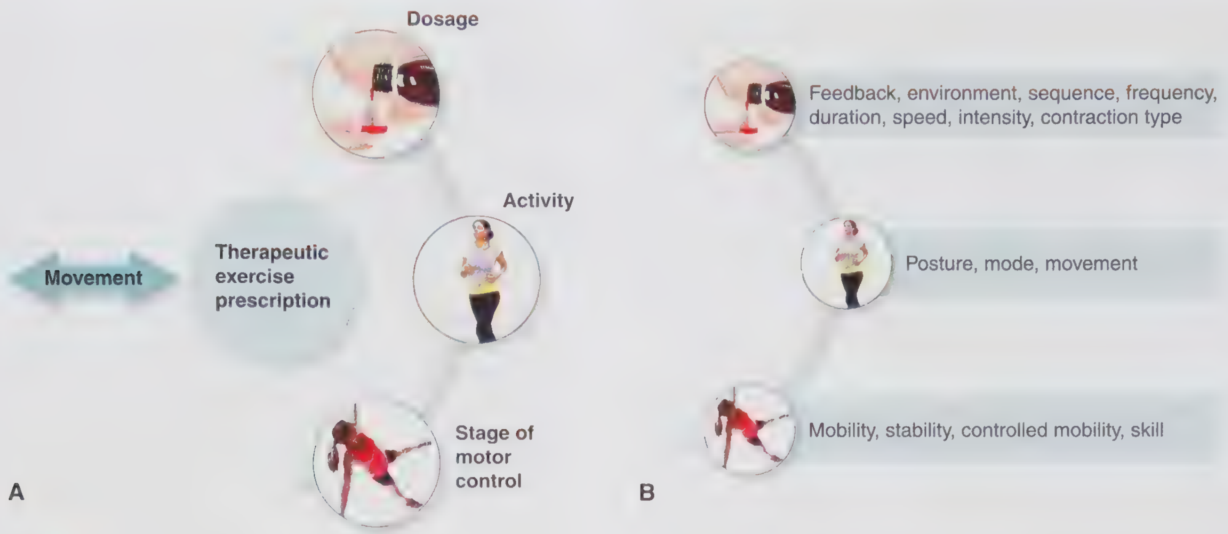

FIGURE 2-8 **(A)** and **(B)** Movement related to stage of motor control, activity, dosage.

- *Cognitive/emotional subsystem:* This subsystem includes functional status of the psychological system as it is related to movement. Components of this element include learning ability, compliance, motivation, emotional status, and processing of nociception and experience of pain.

The diagnostic process can determine the impairments that are related to the patient's activity limitations and participation restriction. To begin planning the therapeutic exercise intervention, the impairments should first be related to a subsystem of the movement system. This process not only illustrates the complex interaction of the subsystems of the movement system, but also guides the clinician toward the most appropriate stage of motor control, activities or techniques, exercise sequence, and dosage. For example, a person with knee pain with a posture impairment of genu valgum may require orthotics to influence the passive subsystem as a first priority. Changing the alignment at the knee is a prerequisite to effective active or neural subsystem training. It may then be decided that muscle performance training (active subsystem) is a prerequisite to motor control training (neural subsystem) because of the fact that the patient's strength, power, and endurance are below functional levels. Muscle performance dosage parameters are different from motor control dosage parameters (see "Dosage" in a subsequent section of this chapter).

After evaluating a patient, it may be apparent that one, a few, or all subsystems of the movement system are related to the activity limitation and participation restriction. Most often, the interaction of the subsystems is critical, but nonetheless must be prioritized. **Building Blocks 2-2** and **2-3** are provided for examples of this clinical decision-making process.

Display 2-8 lists the relationship between impairments and subsystems to the case in Building Block 2-2.

Attempts should be made to prescribe exercise that will address the complex interaction of the subsystems. For example, to restore normal shoulder girdle movement, instruction in diaphragmatic breathing (i.e., support) may be pivotal to reduce the activity (neural) of the pectoralis minor, improve thoracic spine alignment (passive), and increase thoracic spine and rib cage mobility (passive). Another example is to design an exercise that will concurrently

BUILDING BLOCK 2-2

History

A 42-year-old female graphic designer presents with a diagnosis of impingement syndrome of the shoulder. She spends a large part of her day at a monitor creating design documents. She has two children aged 1 and 3. She likes to garden and cook. Activity limitation is an inability to raise the arm to groom her hair.

Evaluation

A pivotal impairment is determined to be a thoracic kyphosis that results in the scapula resting in an excessive anterior tilt (**Fig. 1**).

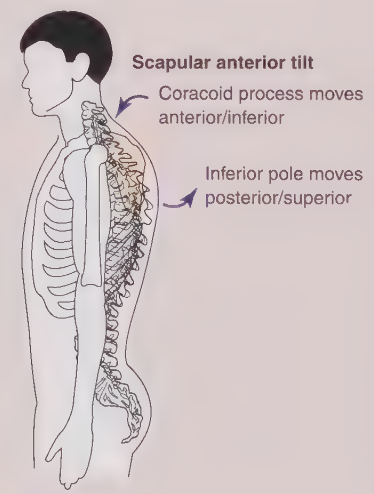

FIGURE 1 Thoracic kyphosis with excessive scapular anterior tilt. With anterior tilt of the scapula, the inferior angle moves posterior/superior and the coracoid process moves anterior/inferior.

The scapula, resting in anterior tilt, fails to adequately tilt posteriorly during upper extremity flexion (**Fig. 2**). As a result, the glenohumeral joint mechanically impinges under the acromion process, and tissues in the subacromial space (e.g., subacromial bursa, biceps tendon, and rotator cuff tendons) undergo microtrauma resulting in pain (i.e., impairment), inflammation (i.e., pathology), and the inability to raise the arm without pain (i.e., activity limitation). List examples of activity limitations and participation restrictions that result from this movement impairment.

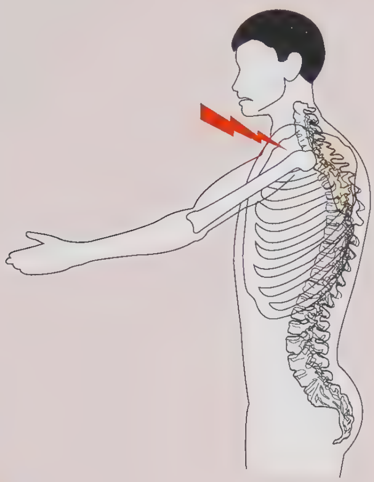

FIGURE 2 Lack of scapular posterior tilt leads to glenohumeral impingement.

BUILDING BLOCK 2-3

Wall slides (Fig. 2-7) are a good choice of exercise for the patient described in Building Block 2-2. This exercise can simultaneously address several impairments. List three impairments that this exercise addresses and indicate the correlating subsystem of the movement system.

DISPLAY 2-8
Subsystems of the Movement System Related to Impairments

- **Support subsystem impairment:** Using accessory muscles of inspiration (pectoralis minor) versus diaphragm for breathing, potentially leading to overuse and shortening of pectoralis minor
- **Passive subsystem impairment:** Short pectoralis minor and short head of biceps pulling coracoid process anterior and inferior, lengthened and weak lower trapezius not providing sufficient counterforce leading to scapular anterior tilt. Thoracic kyphosis contributing to the anterior tilt of the scapula
- **Neural subsystem impairment:** Reduced recruitment of lower trapezius and serratus anterior not counterbalancing the anterior scapular tilt
- **Active subsystem impairment:** Reduced force production from the lower trapezius and serratus anterior
- **Cognitive/emotional subsystem impairment:** Patient is clinically depressed, and the physical manifestation is a slumped posture contributing to the thoracic kyphosis. The depression also contributes to central sensitization and hyperalgesia experience of pain.

FIGURE 2-9 This exercise illustrates a patient performing a wall slide. The patient moves from the position shown here to the end position of the shoulders in full elevation. Note the arms are positioned in the scapular plane (slightly forward of the wall with thumbs touching the wall), the spine and pelvis are in neutral, and the feet are only a few inches away from the wall.

DISPLAY 2-9
Considerations in Clinical Decision-Making Relevant to the Subsystems

- Identify the activity limitations and related impairments to be treated.
- Relate activity limitations and impairments to be treated with the appropriate subsystems of the movement system.
- Prioritize subsystems of the movement system.

stretch the pectoralis minor and strengthen the lower trapezius (active) (**Fig. 2-9**). Optimizing the recruitment strategy (neural) during specific exercise and during functional movement is always necessary to achieve the best functional outcome.

Display 2-9 summarizes the factors to consider before determining the relevant and prioritized list of the subsystems of the movement system (see **Building Block 2-4**).

BUILDING BLOCK 2-4

Given the example of the women with impingement in Building Block 2-2, is there another pivotal subsystem of the movement system that might need to be addressed, prior to any other, for her to achieve a successful outcome? Explain your answer.

Stages of Motor Control

Once the impairments and the relationship to the movement system are defined, the therapist is challenged with determining the appropriate stage of motor control with which to focus. This will further define the activity and dosage parameters.

A person with musculoskeletal dysfunction may exhibit impairments in either or both parameters of mobility. For example, after total knee arthroplasty, a person may experience passive mobility restrictions caused by pain, swelling, and soft-tissue stiffness and have decreased ability to initiate active knee motion as a result of reduced muscle force/torque production or reduced recruitment capability. The cause of the mobility restriction must be determined on a case-by-case basis to determine the most appropriate exercise intervention (see Chapter 7).

A precursor to achieving the stability necessary for movement, or dynamic stability, is optimal posture (see Chapter 9). The individual must be able to maintain optimal posture without a load before optimal posture can be maintained during movement of a limb. Mobility and stability are not mutually exclusive. Achieving mobility before addressing stability is unnecessary; the two stages of motor control can occur concurrently. For example, as mobility after total knee arthroplasty is achieved passively, active motion must be prescribed. For optimal active motion, the knee requires a stable proximal base from which to move (i.e., pelvis and trunk) and distal base for weight-bearing (i.e., foot and ankle). Stability must be achieved at these regions for optimal active motion to take place (**Display 2-10**).

Controlled movement requires proper timing and recruitment of synergists that perform movement concurrent with recruitment of muscles and appropriate length of soft tissues providing a stable foundation for movement. The previous example would progress from exercises improving knee mobility, as well as pelvic-trunk and foot-ankle stability, to functional movement patterns. To walk, the knee must flex and extend at proper stages in the gait cycle. The trunk, pelvis, ankle, and foot must move into proper position at each stage of the gait cycle and provide proximal and distal stability for optimal knee function. The activity may involve the swing phase of gait, which requires a stable pelvis from which to swing the lower limb (**Fig. 2-10A**), or the stance phase of gait (Fig. 2-10B), which requires a stable foot for optimal knee loading.

The final progression in the stages of motor control is skill. Skill implies consistency in performing functional tasks with economy of effort.[54] Skill in the upper extremities most often requires freedom of movement in space in a coordinated manner within and between the hand, wrist, forearm, elbow, shoulder girdle, trunk, and pelvis (e.g., grasping a cabinet door) (**Fig. 2-11**). Occasionally, closed chain (weight-bearing) movements are required in the upper extremity (e.g., gymnast performing a handstand on the balance beam) (**Fig. 2-12**). Skill

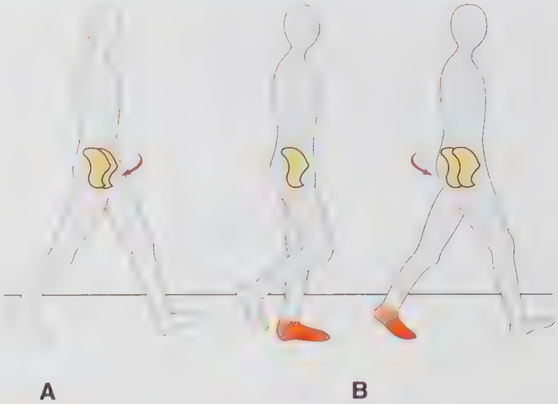

FIGURE 2-10 **(A)** Swing phase of gait requires a stable pelvis. **(B)** Stance phase of gait requires a stable foot.

FIGURE 2-11 Grasping a cabinet door requires freedom of movement in space in a coordinated manner within and between the joints of the upper extremity, trunk, and pelvis.

FIGURE 2-12 A gymnast performing handstand on the balance beam represents an upper extremity closed chain movement.

DISPLAY 2-10

Stages of Movement Control

Mobility: A functional range through which to move and the ability to sustain active movement through the range

Stability: The ability to provide a stable foundation from which to move

Controlled Mobility: The ability to move within joints and between limbs following the optimal PICR

Skill: The ability to maintain consistency in performing functional tasks with economy of effort

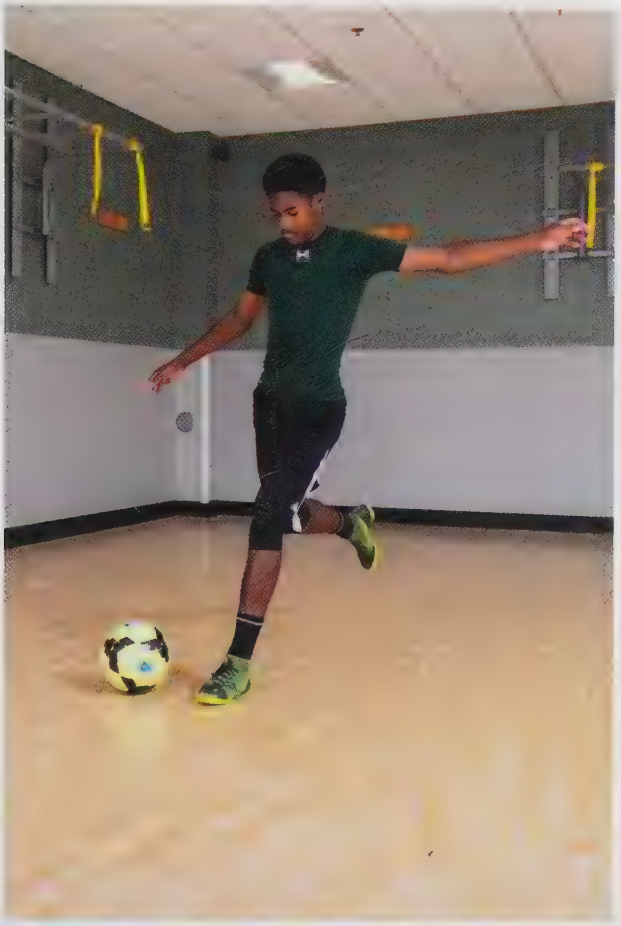

FIGURE 2-13 Skill in lower extremities requires coordination of open and closed chain movement. The swing leg performs an open chain movement as the stance leg performs a closed chain movement.

FIGURE 2-14 A tennis swing represents a total body movement, which is coordinated within and between each segment involved in the movement.

in the lower extremities requires coordination of open chain (nonweight-bearing) movements (e.g., swing leg in kicking a soccer ball) (**Fig. 2-13**) and closed chain movements (e.g., stance leg in kicking a soccer ball) within and between the foot, ankle, knee, hip, and spine for movement on varied surfaces. For total body movement to be optimal, coordinated movement must occur within and between each segment involved in the movement (e.g., tennis swing) (**Fig. 2-14**).

Commonly, patients are asked to perform skill-level activities without first developing the proper foundation for functional motor control. Conversely, patients may be prescribed exercises developing the other stages of motor control without finalizing the intervention with skill-level activities during functional movements. Skill is a necessary stage of motor control despite the prognosis of the patient (e.g., walk 10 ft with a walker versus run a marathon), which must be worked toward by achieving optimal function at each prior stage of motor control.

In summary, an activity can be as simple as performing a dynamic knee extension movement in sitting (i.e., mobility) or as difficult as an integrated movement pattern such as walking on an uneven surface (i.e., skill). An understanding of the level of involvement of the support, base, modulator, and cognitive/affective elements of the movement system helps to determine the complexity of the task and the stage of motor control in which to intervene.

Activity or Technique

To be successful in choosing the proper activity or technique, first determine the subsystem associated with the impairment or activity limitation. Each subsystem is associated with specific therapeutic exercise interventions. **Table 2-2** cross-references the subsystems with the most common therapeutic exercise activities or techniques. Though an argument can be made to prescribe a specific therapeutic activity or technique to address nearly any subsystem of the movement system, this table refers to the most common relationships.

In addition to identifying the subsystems and the stage of motor control, the physiologic status of the body function or structure must be considered. This information assists in determining the activity or technique, posture, movement, and mode parameters. For example, if muscle performance (active subsystem) is pivotal to return to an activity or participation, the chosen activity or technique may depend on the force or torque capability of the affected muscle(s). If the

TABLE 2-2

Therapeutic Activities Cross-Referenced with Subsystems of the Movement System

ACTIVITY	SUPPORT	PASSIVE	ACTIVE	NEURAL	COGNITIVE EMOTIONAL
Stretch (passive/active)		x	x		
ROM (passive, active assisted, active)		x	x		
Strengthening[a]			x	x	
Neuromuscular reeducation			x	x	
Developmental activities			x	x	
Breathing	x				
Gait training	x		x	x	
Aquatic therapy	x	x	x	x	
Balance and coordination training			x	x	
Body mechanic and ergonomic training			x	x	
Movement training			x	x	
Posture awareness training			x	x	
Aerobic or muscular endurance[b]	x		x	x	

[a] Strengthening activities include active assistive, active, and resistive exercise using manual resistance, pulleys, weights, hydraulics, elastics, robotics, mechanical, or electromechanical devices.

[b] Aerobic or muscular endurance activities include use of cycles, treadmills, steppers, pools, manual resistance, pulleys, weights, hydraulics, elastics, robotics, mechanical, or electromechanical devices.

force or torque capability is less than fair muscle strength, as determined by Kendall,[55] a gravity-minimized position active ROM activity or an against-gravity active assisted technique may be chosen. Another related impairment may be related to reduced muscle recruitment from prolonged immobilization (i.e., neural subsystem). If the ability to recruit is poor, a gravity-minimized active ROM activity may be chosen with tactile feedback or against-gravity active ROM with neuromuscular electrical stimulation as an adjunctive intervention (discussed later in this chapter), both of which are chosen to augment muscle reeducation.

Building Block 2-5 challenges you to consider the status of the tissue when determining the activity, posture, movement, and mode of exercise to address reduced muscle performance.

BUILDING BLOCK 2-5

A patient has sustained a grade 2 muscle strain to the hamstrings. It is in the intermediate stage of healing and repair (between 4 and 8 weeks poststrain). Describe two to three therapeutic activities to restore muscle strength with the mode, posture, and movement specifically described.

How would you progress each of your choices as the patient moved toward 8 to 12 weeks of healing?

Display 2-11 summarizes the factors to consider before determining the activity or technique.

DISPLAY 2-11

Considerations Involved in Clinical Decision-Making Related to Choice of Activity or Technique

- Determine the element of the movement system related to the impairment or activity limitation to be treated.
- Consider the physiologic status of the movement system.
- Determine the stage of motor control.

Mode, Posture, and Movement After choosing the activity or technique, further breakdown of the activity is necessary for precise prescription. The mode, which is the method of performing the activity or technique, must be chosen. For example, if aerobic exercise is chosen, the mode can be cycling, swimming, walking, or a similar activity. If strengthening is chosen, the mode can be weights, manual resistance, or active assisted exercise. If balance and coordination training is chosen, the mode can be a balance board, balance beam, or computerized balance device.

The initial and ending postures (e.g., standing, sitting, supine, prone, wide base of support, and narrow base of support) need to be determined. Included in this information is proper hand placement and angle of application of the force or load. When using elastics, pulleys, mechanical or electromechanical devices, proper equipment placement and angle of application of force must be determined. These descriptions must be included in the beginning and ending posture information.

Finally, the movement needs to be specifically defined (e.g., partial squat through a 30-degree arc, unilateral arm raise through full range, proprioceptive neuromuscular facilitation diagonal of the upper extremity to chest height).

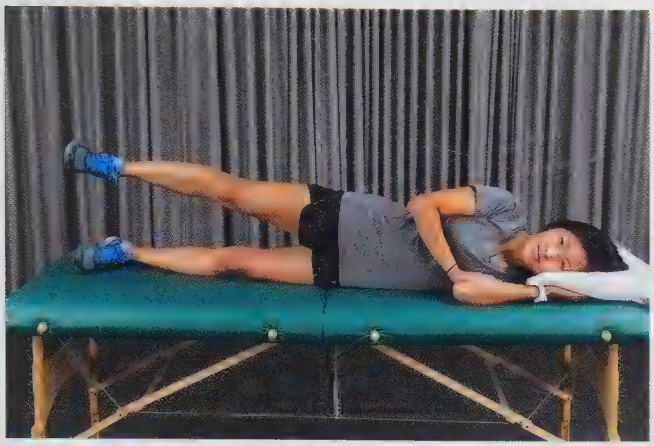

FIGURE 2-15 Hip abduction in the side-lying position. Optimal execution is with the pelvis and femur in the frontal plane and the movement of hip abduction occurring in the frontal plane with a stable pelvis. This requires recruitment of all of the hip abductors and proximal lumbopelvic muscles working in synergy.

DISPLAY 2-12

Variations in Performing Side-Lying Hip Abduction

1. Side-lying with pelvis in frontal plane and abducting the hip with all of hip abductors in synergy (see Fig. 2-11)
2. Side-lying with pelvis rotated backward and femur rotated laterally, causing the movement to move toward the sagittal plane and resulting in recruitment of hip flexors
3. Side-lying with pelvis in frontal plane with femur rotated medially and flexed, resulting in recruitment of tensor fascia lata
4. Side-lying with pelvis in frontal plane, but movement is at the pelvis (hip hike), resulting in recruitment of lateral trunk muscles
5. Side-lying with pelvis in frontal plane, but movement is abduction of opposite hip, resulting in recruitment of opposite hip abductors

The quality of performance of the exercise is critical to the outcome (i.e., neural subsystem). In relation to active or neural subsystems, an obvious but often neglected concept is that a muscle cannot be strengthened if it is not recruited. Even if the correct activity is chosen, and the mode, posture, and movement are carefully selected, proper execution of the exercise is necessary to ensure a successful outcome. For example, side-lying hip abduction can be performed with at least five different recruitment patterns (**Fig. 2-15** and **Display 2-12**).[56] Attention to precision of movement and recruitment patterns is vital and must always be promoted to the best of the individual's capability. If the intent of the exercise is not achieved, the physical therapist must modify the dosage parameters, either more or less challenging, to achieve the desired outcome.

Dosage

When determining dosage, physiologic status of the affected body functions/structures and the patient's learning capability must be considered. The anatomic site comprises the specific tissues involved (e.g., ligament, muscle, tendon, bone, cartilage, skin, and nerve). The physiologic status of the affected body functions/structures includes the severity of the tissue damage (e.g., partial versus complete tear), the irritability of the condition (e.g., easily provoked and difficult to resolve versus difficult to provoke and easy to resolve), the nature of the condition (e.g., chemical versus mechanical mediated pain), and the stage of the condition (e.g., acute, subacute, and chronic). For patients recovering from an injury, the dosage parameters are modified according to the tissues involved and the principles of tissue healing (**Table 2-3**). In the early stages of healing, tissues tolerate low-intensity passive or active activities, but in the later stages, tissues tolerate more aggressive resistive activities (see Chapter 10).

The patient's ability to learn, or learning capability, influences the schedule and the amount of reinforcement, feedback, or sensory input needed to perform the activity successfully. If a patient has difficulty learning a motor task, the dosage may be altered according to the principles of learning (see Chapter 3). For example, various forms of feedback (e.g., verbal, visual, and tactile) combined with numerous low-intensity repetitions may be required initially for optimal performance of an activity. As skill is acquired, feedback and repetitions may be reduced and more complex activities may be prescribed.

TABLE 2-3

Body Function/Structure Impairment Categories

STAGE OF RECOVERY	STAGE 1	STAGE 2	STAGE 3
Onset of injury	Recent		Remote
Symptoms	↑ Severity ↑ Irritability		↓ Severity ↓ Irritability
Activity level	Decreased use of segment/limb in function	Segment/limb used—not optimal	Near-normal use of segment/limb in function
Precautions/restrictions	Yes	Guarded	No
Outcome scores	High-participation restriction		Low-participation restriction

DISPLAY 2-13

Considerations Involved in Clinical Decision-Making Related to Choice of Dosage Parameters

- Determine the anatomic sites involved in the current condition.
- Determine the physiologic status of the tissue(s) involved.
- Consider the patient's learning capability.

After the anatomic and physiologic elements and the learning capabilities are understood, specific dosage parameters can be determined. **Display 2-13** summarizes the factors to consider before determining dosage parameters. Parameters related to dosage include:

- **Type of contraction** (i.e., eccentric, concentric, isometric, dynamic, or isokinetic)
- **Intensity** (i.e., amount of assistance or resistance required)
- **Speed** of the activity or technique
- **Duration** tolerated (i.e., number of repetitions or number of sets, particularly related to endurance and stretching activities)
- **Frequency** of exercise (i.e., number of exercise sessions in a given period)
- **Sequencing** of the exercise prescription (i.e., stretch before strengthen, low-intensity warm-up before moderate or intense aerobic activity, or single joint uniplanar movement before multijoint multiplanar movement)
- **Environment** in which the exercise is performed (i.e., quiet, controlled environment of a private room in a physical therapy clinic versus a loud, chaotic, uncontrolled, and outside environment)
- **Amount of feedback** necessary for optimal performance of the activity

SUMMARY

In summary, numerous variables in this model must be considered in prescribing an exercise, and variables often overlap. For example, learning capabilities under dosage is similar to stages of motor control, which is similar to neural and cognitive/emotional subsystems for the movement system. The task of organizing this data can be overwhelming. This model may help to visualize the relationships among the components of exercise prescription. It is the goal of this text that this model assists in organizing the data necessary to develop an effective, efficient therapeutic exercise intervention.

Exercise Modification

When the desired patient outcome is not met in a reasonable time frame, modification is based on evaluating how the following possibilities affect the lack of progress achieved with the therapeutic exercise intervention:

- The physical therapist may choose the **wrong activity**, dosage of exercise, or both.
- The physical therapist may be **ineffective in teaching** the exercise.
- The patient **may not be able to learn** the exercise well enough or misunderstand or forget the instructions or dosage.
- The patient **may not follow through** with the prescription.

To be most effective and efficient with exercise prescription, constant reexamination and reevaluation of changes in impairments, activity levels, and participations are required. The exercises must be continually modified to increase or decrease the difficulty to ensure continual progress is being made with minimal setbacks. Numerous parameters can be modified to render an exercise more or less difficult. Four general parameters can be varied in an exercise prescription: biomechanical, physiologic, neuromuscular, and cognitive/emotional. **Display 2-14** outlines parameters that can be varied and provides examples for various types of exercise.

If you've paid careful attention to these basic methods and principles, but the patient is not responding to the intervention, you must realize that all has been done within the scope of your therapeutic knowledge, expertise, and experience and that the patient should be discharged if you feel maximum improvement has been attained. If not, the patient should be referred to another practitioner for further treatment.

DISPLAY 2-14

Exercise Modification Parameters

Biomechanical

Stability

- Size of base of support
  Example: It is more difficult to balance with feet close together or in tandem than feet wide apart, and in side-lying rather than supine.
- Height of center of mass
  Example: Sit-ups may be done first with hands at the sides, progressed to forearms folded across the chest, progressed to hands clasped behind the neck. This upward shift of arm weight moves the center of mass toward the head by stages, progressively increasing the difficulty of the exercise.
- Support surface
  Example: The stability of the support surface can be progressed from a static or stable surface to a mobile base, such as foam, a balance board, or a trampoline.

External Load

- Magnitude
  Example: Increased magnitude of resistance alters the weight of the segment and thereby increases the difficulty

DISPLAY 2-14

Exercise Modification Parameters (*continued*)

of movement; however, it may also increase feedback from muscle and joint receptors and enhance the response.

- Gravitational forces
  Example: The force of gravity on a segment is maximal when the part is horizontal and diminishes as it moves toward the vertical. Knee flexion in prone is more difficult at the beginning of the movement and becomes easier as the motion progresses. Hip abduction is gravity reduced in prone and against gravity in side-lying.
- Speed (see Chapter 5)
  Example: A medium rate is usually easier than very rapid or very slow rate.
- Length of lever arm
  Example: In prone exercises for scapular adductors (middle and lower trapezius), raising the arms with the elbows flexed gives less resistance than if the elbows are nearly or completely straight.
- Point and angle of application of manual or mechanical resistance
  Example: A muscle pulling at or near a right angle to the long axis of the segment exerts its force more effectively than when its angle of pull is very small.

Number of Segments Involved

- Fewer segments may not always be easier than more segments, especially as in fine motor control.

Length of Muscle

- A muscle is better able to exert active tension when it is in a lengthened state than after it has undergone considerable shortening. When it is desirable to limit the participation of a given muscle in a movement, it is placed in a shortened position, or "put on slack." The active tension exerted by a muscle spanning more than one joint at a given joint depends on the position of the second joint over which it passes, because this determines the length of the muscle. For instance, the hamstrings are more effective as knee flexors when the hip is flexed and less effective when the hip is extended. Similarly, if the goal is to isolate the gluteus maximus during hip extension, the participation of the hamstrings is reduced if hip extension is done with the knee flexed compared with the knee extended.

Passive Tension of Two-Joint Muscles

- The hip can be flexed to only 70 to 90 degrees with the knee extended but considerably more if the knee is flexed. Similarly, the ankle can dorsiflex more when the knee is flexed than when the knee is extended. These considerations are particularly important in planning effective stretching activities and in analyzing stabilization of body segments in all types of exercise. Altering joint positions or the use of external supports such as pillows can reduce or increase the tension of two-joint muscles based on the goal of the exercise.

Open versus Closed Kinetic Chain

- The kinetic chain is related mostly to specificity of exercise. If the desired activity is in the closed kinetic chain, this position should be used for training whenever possible. However, the closed kinetic chain often cannot isolate muscle function as well as a specific open kinetic chain exercise.

Stabilization (External or Within)

- If stability is required for a movement, use of external support or prepositioning a limb may assist stabilization if the patient is unable to stabilize with proper patterns internally. For example, in supine, the trunk can stabilize with greater ease if the hip and knee are flexed and held in place by the hands while the other limb slides down and back during an abdominal strengthening exercise (Fig. 1). This is an example of prepositioning to offer external stability.

Physiologic

Duration

- Duration of activity in seconds, minutes, or hours
- Number of repetitions or sets performed

Frequency

- Number of exercise sessions in a given time period

Speed

- Slower is not necessarily easier (see earlier)

Intensity of Contraction or External Load

- Percentage of maximum voluntary contraction

Type of Muscle Contraction

- Eccentric, isometric, concentric

Sequence of Exercise

- May require beginning with less complex tasks or less strenuous activity in the early stages of learning or healing and progressing to less need for "warm-up" activities as skill is achieved and tissues are in more advanced stages of healing

Rest Between Repetitions and Sets

- As strength or endurance improves, less rest is necessary between repetitions and sets. But, as intensity of exercise increases, rest between sessions for tissue recovery becomes more important. Be cautious of overtraining, especially in the presence of neuromuscular disease or injury.

Neuromuscular

Sensory input

- Visual, vestibular, and proprioceptive inputs can be manipulated. If the eyes are closed, visual input is eliminated, leaving the vestibular and proprioceptive receptors to detect any disturbance. The proprioceptive input can be varied by standing on soft foam. The vestibular input can be varied with head movement.

Sensory Facilitation or Inhibition

- Techniques such as cutaneous and pressure input, approximation, and traction can alter muscle responses. Prolonged pressure on the long tendons such as the quadriceps, biceps, hamstrings, or finger flexors seems to

(*continued*)

DISPLAY 2-14

Exercise Modification Parameters (*continued*)

A B

FIGURE 1 Leg slide movement for strengthening lumbopelvic stabilizing muscles. The hip and knee are flexed and held close to the chest as the other limb slides down and back. This modification reduces the stabilizing force needed by the trunk muscles because of the amount of hip flexion in the stationary limb. The more proximal the stationary limb is relative to the center of mass, the less difficult the exercise becomes; the more distal the stationary limb is relative to the center of mass, the more difficult the exercise becomes. This photograph illustrates the mid position of the exercise **(A)**. The patient should end with the extremity as close to full extension as the length of the hip flexors will allow **(B)**.

inhibit responses. The placement of manual contacts is critical to facilitate the desired response. Contacts are placed in the direction toward which the segment is to move. Approximation or compression into or through a joint stimulates the joint receptors and may facilitate muscles and stability around a joint. Traction separates the joint surface and is incorporated if increasing ROM around a joint is desired.

Number of Segments Involved

- In weight-bearing postures, joint involvement usually refers to the weight-bearing segments; for example, prone on elbows does not require participation of the forearm and hand or the lower body compared with the quadruped position. The placement of manual contacts or other external forces also influences the number of segments involved. For example, contacts placed on the scapula and pelvis in side-lying involve the entire trunk, whereas contacts positioned on the lumbar spine and pelvis result in more isolated activity of the lower trunk.

Stage of Motor Control

- Mobility, stability, controlled mobility, skill (see Display 2-9 for the definitions of stages of motor control)

Cognitive/Emotional

Frequency and Duration of the Activity

- Increased frequency and duration of the activity increases the practice schedule to enhance learning.

Initial Information Provided

- Care should be taken to provide enough information to perform the activity with the correct strategy, but not to give too much information, which may overwhelm the learner.

Accuracy Provided

- As skill is acquired, increased accuracy of cues is provided to "fine-tune" a movement.

Variability of Environmental Conditions

- Initially reduced number of external distractions is provided with increasing external distractions toward a functional environment as skill is acquired.

Complexity of Activity

- Number of steps involved, as in breaking down components of gait into single tasks and then uniting them into the integrated complex motor task of gait with numerous steps

Anxiety Level

- Initially, greater focus on the activity is combined with the least emotional distractions to enhance early learning.

ADJUNCTIVE INTERVENTIONS

To complete this chapter on patient management, adjunctive interventions were chosen to be included in this section to provide insight into the complementary role they play in therapeutic exercise prescription. The interventions presented in this section are considered adjunctive to therapeutic exercise in that they are not regarded as essential to achieving a functional outcome.

When choosing to use an adjunctive intervention, a decision must be made regarding the benefit of its use in conjunction with therapeutic exercise. The clinician should be reasonably sure that combining the adjunctive intervention with the therapeutic exercise would produce more rapid or optimal functional recovery. Make it clear to the patient that the adjunctive intervention is being used in the short term to augment the exercise and that the exercise and posture and movement habits will ultimately change the impairments and activity limitations for long-term improvement. There are conditions for which physical agents, mechanical and electrotherapeutic modalities, and orthotics are imperative to achieve improved physical function and health status, in which case these interventions are not considered adjunctive (e.g., significant soft tissue inflammation, severe pain disorders, skin conditions, nerve injury, impaired motor function, and structural abnormalities).

Physical agents, mechanical modalities, and electrotherapeutic modalities can play a vital role in the total plan of care for a patient and serve as important adjuncts to therapeutic exercise. Elaboration of the role of each of these therapies can be found on thePoint.lww.com/BrodyHall4e. Additional adjunctive interventions such as taping and orthotic prescription are presented in Units 5 and 6.

KEY POINTS

- The physical therapist integrates five elements of care—examination, evaluation, diagnosis, prognosis, and intervention—in a manner designed to maximize the patient's outcome.
- An understanding of each component of the patient management model assists the clinician in maximizing patient satisfaction and in delivering the most effective and efficient services possible.
- The clinician's knowledge, expertise, experience, and ongoing acquisition of knowledge and experience are the determinants for successful patient management.
- Critical clinical decisions are those involved in determining which impairments from the list generated from the examination are most closely related to activity limitation and participation restriction and therefore warrant intervention.
- Patient-related instruction must be an integral part of any physical therapy intervention.
- The three-dimensional therapeutic exercise intervention model is designed to help organize the data necessary to make clinical decisions regarding therapeutic exercise intervention.
- Exercises must be continually monitored to determine the need for modification to increase or decrease difficulty to ensure continual progress is being made with minimal setbacks. To be most effective with exercise modification, the clinician must possess thorough understanding of the parameters that can be modified.
- Therapeutic exercise can be complemented with adjunctive interventions if the additional intervention can lead to a higher level of functional outcome in a shorter period.

CRITICAL THINKING QUESTIONS

1. Read Case Study No. 2 in Unit 7.
   a. List the physiologic, anatomic, and psychological impairments.
   b. List the activity limitations.
   c. Correlate the impairments to the activity limitations.
   d. Choose the impairments and activity limitations you feel warrant treatment.
   e. Correlate the impairments and activity limitations you have chosen to treat with the subsystems of the movement system.
   f. Prioritize the subsystems of the movement system.
2. Still using Case Study No. 2, you have decided to prescribe exercises to improve knee mobility, because you know the patient requires 70 degrees of knee flexion to perform simple ADLs. You would like to use a sit-to-stand movement to work on knee mobility. Recall that she requires moderate assistance with sit-to-stand transfers.
   a. Describe the posture (beginning and end position), mode, and movement of the activity.
   b. Describe all pertinent parameters of dosage.
3. The patient has progressed to 70 degrees of flexion and no longer requires assistance with sit-to-stand transfers. How would you modify the mobility exercises to make them more difficult? Use the principles of exercise modification listed in Display 2-12.
4. The patient is having difficulty with recruitment of her quadriceps.
   a. What adjunctive intervention would you use?
   b. Describe the posture, mode, and movement of the activity.
   c. Describe all pertinent parameters of dosage.

CHAPTER

3

Strategies for Improving Therapeutic Exercise Outcomes

LORI THEIN BRODY

The best intended therapeutic exercise program will be unsuccessful if the exercises are done incorrectly or not done at all. Teaching patients how to self-manage their condition between appointments is a critical component of patient care. Changes in the structure of the medical system, reimbursement issues, and an increase in the prevalence of chronic problems require educating patients about their conditions and teaching them effective self-management strategies. Teaching in the clinic is an ongoing and ever-changing process. Many clinicians find that they are no longer full-time, hands-on providers of rehabilitation services but rather part-time educators, administrators, and clinicians.[1] Teaching self-management strategies extends the provider's impact beyond the face-to-face visit and arms the patient with tools to recover from their current problem and to prevent a recurrence.

PATIENT EDUCATION: DEFINITION AND SCOPE

Patient-related instruction is the "process of informing, educating, or training patients/clients, families, significant others, and caregivers with the intent to promote and optimize physical therapy services."[2] Instruction includes information on:

- Current condition
- Diagnosis
- Prognosis
- Plan of care
- Health and wellness
- Risk factors

Teaching in the clinic is an ongoing process throughout the evaluation and treatment sessions (**Evidence and Research 3-1**). Therapists typically educate patients about their condition, the prognosis and plan of care, and teach specific activities (i.e., stretching exercises, gait training, postural interventions, etc.). Clinicians also educate their patients on important issues such as the relationship between symptoms and their patients' daily routines and the expected response to the exercise program. Patients' satisfaction with treatment and willingness to adhere are often based on the fulfillment of their expectations. More time spent educating the patient on prognosis and expectations from the rehabilitation program may increase adherence to and satisfaction with the treatment program. However, "educating" and "teaching" are carried out by the provider, whereas "learning" is associated with the patient. Understanding issues related to effective communication skills, teaching, learning, and performance is essential to optimizing outcomes.

Patient learning is categorized as **cognitive**, **affective**, and **psychomotor**.[4] In therapeutic exercise, all three domains are part of the instruction process. The cognitive domain includes information and facts about the patient's condition and the rehabilitation program. This might include descriptions of the anatomy, biomechanics, or pathomechanics of the condition. Educating patients about therapeutic exercise theory and the rationale behind the exercise choices also falls into the cognitive domain (**Evidence and Research 3-2**). Affective domain education addresses the patient's attitude and motivation. Possessing the cognitive information and the psychomotor skill to execute the exercise program is of little use when the patient is unmotivated to participate. The patients' attitudes toward their condition and their attitudes and beliefs about the likelihood of the therapeutic exercise program remediating their symptoms are essential for program adherence. This topic is explored further in the section on "Adherence and Motivation."

Finally, the psychomotor domain is critical for learning the proper motor programs and performing the therapeutic

EVIDENCE and RESEARCH 3-1

A study of the perceptions of physical therapists regarding their involvement in patient education showed that therapists educate 80% to 100% of their patients.[3] Gahimer and Domholdt[1] found that therapists educated their patients primarily in the areas of information about illness, home exercises, and advice and information. Moreover, the patients reported attitudinal or behavioral changes ranging from 83.8% to 86.5% as a result of this education. Health education and stress counseling were addressed less frequently during the treatment session.

EVIDENCE and RESEARCH 3-2

A study of patients with a mean 10-year history of low back pain found that 51% of these patients had noticeable improvement in their pain 1 week after being provided with an individualized biomechanical treatment booklet. At both the 9- and the 18-month follow-up assessments, statistically and clinically significant improvements were reported in pain management, number of episodes of care, and perceived benefit.[5]

exercises correctly. The nuances of muscle activation and control during therapeutic exercise distinguish this type of rehabilitative exercise from recreational exercise. The psychomotor domain is explored in further detail in the "Motor Learning" section.

KEY COMPONENTS OF PATIENT-RELATED INSTRUCTION

Effective patient-related instruction for successful patient outcomes is a complex process with many interrelated components. For example, how the diagnosis, prognosis, and plan of care are communicated to the patient will impact the patient's confidence in the provider and adherence to the plan of care. Poor instruction in the psychomotor aspects of an exercise can cause symptom exacerbation rather than remediation. Some of the key components of patient-related instruction include communication skills, cognitive aspects of instruction, affective domain considerations, and psychomotor factors.

Patient–Clinician Communication

Communication is a two-way conversation, not a one-way provision of factual information. Good communication requires understanding both the verbal and the nonverbal components of communication. Communication has many nuances and components, each requiring appropriate interpretation and responses. Body language and posture, eye contact, physical contact, tone of voice, type of questioning, and listening ability all impact rapport and trust. Clinicians must recognize their own verbal and nonverbal communication and also similar cues from the patient. They must then respond appropriately from these patient cues, reflecting back the patient's concerns and providing support.[4]

Communication is most effectively accomplished when the clinician has established rapport with the patient. **Rapport** is a quality of interaction that is difficult to define but is comprised of an ability to make patients feel cared for and respected.[4] The patient must trust the care provider, and the care provider must be able to accept and empathize with the patient's situation. This does not mean that the provider should support poor health behavior choices but that he or she should acknowledge the challenges the patient may be facing. This acknowledgment is followed by active problem solving to eliminate barriers to good choices and to design a support system that will facilitate and reward positive choices.

Individual differences significantly affect the patient–clinician relationship. Fundamental personality differences, values, and teaching and learning styles influence communication and may ultimately affect adherence and outcome. Possessing important skills to assess the patient's willingness and style of communication and learning can enhance the rehabilitation program. These skills include the ability to actively listen to and reflect on the patient's reports and to provide appropriate feedback[6,7] (**Evidence and Research 3-3**).

EVIDENCE and RESEARCH 3-3

Sluijs et al.[8] found lack of positive feedback to be one of the primary factors related to lack of adherence to a rehabilitation exercise program. Cameron[9] suggests improving the quality of the interaction by showing sensitivity to the patient's verbal and nonverbal communications and understanding of and empathy with the patient's feelings.

Patient communication implies a willingness to participate by the patient and the clinician. The patient's readiness to learn depends on many factors, including the relationship with the health care provider. The relationship is affected by how the patient is coping with the particular situation. Schwenk and Whitman[7] describe a control scale in which the control level of the patient and that of the clinician are inversely related. As the clinician uses less controlling or assertive behaviors, the patient's control of the situation increases. The converse is also true: the active and assertive clinician is likely to push the patient into a more passive role. If the patient is unwilling to be in such a role, conflict will ensue or the clinician will become more passive, relinquishing some control to the patient.

The clinician's attention to the patient's needs can guide the appropriate communication style. In the initial visits, a more active listener role gives the patient an opportunity to explain his or her needs. The clinician can then hear the patient's concerns, expectations, and goals. Fundamental skills necessary for active listening include close observation of the patient's words, intonation, and body language. Judicious use of eye contact, along with affirmation and reflection of the patient report, can clarify what the clinician heard and validate the patient report (**Fig. 3-1**). This gives the clinician an opportunity to discuss the

An effective communicator:
- Observes body language
- Listens for intonation
- Establishes rapport
- Establishes trust
- Actively listens
- Reflects and rephrases
- Affirms and restates
- Provides realistic expectations
- Understands and integrates cultural factors

FIGURE 3-1 Key factors in effective communication.

recovery prognosis given the adherence to the treatment program, which, along with discussion of the clinician's expectations of the patient, can enhance communication and the rehabilitation process. Several studies have shown the "Pygmalion effect" in a variety of settings in which the instructors' expectations were matched by students' achievements.[10–13]

Although communicating the expectations of all involved participants is important, it is equally important to provide realistic expectations in the form of short-term and long-term goals. Setting reasonable and achievable goals that address the patient's impairments and that are linked to activity limitations and participation restrictions can provide one form of positive feedback for the patient. Occasionally, the patient's motivation can be improved by education about reasonable goals. The ability to perform the same level of exercise or activity at a lower level of pain is a reasonable short-term goal. The patient may only see that he or she is performing at the same level and perceive this as a lack of progress. Clarification on how progress is defined and reasonable expectations regarding progress can improve patient adherence and satisfaction (see **Building Block 3-1**). Some advocate a contract approach in which the specific obligations of each party in the attainment of the therapy goals are set forth and a timeline is determined.[9]

BUILDING BLOCK 3-1

Kathy is a 53-year-old high-level recreational tennis player. She sustained an acute rotator cuff tear during a fall 8 months ago, and 2 months later underwent rotator cuff repair. Physical therapy was initiated 2 weeks post-op, and Kathy has been making steady progress on her ROM and strength. However, at 3 months post-op, she is frustrated at the rate of her progress and feels as though she should be farther along in her recovery than she currently is. She is worried that she will not be able to play tennis again. She has been performing her land-based rehabilitation program faithfully.

Her physician performed an ultrasound to assess healing and felt that her rate of healing was as expected given her age and tissue quality. She remains frustrated at what she perceives to be a lack of progress despite improvement in impairments and increased functional use of the arm. How would you counsel the patient?

Patient-Related Instruction in Home Exercise Prescription

The home exercise program is an increasing component of the overall treatment program for most patients. In some cases, patients perform the exercises independently, whereas in other cases, a family member or other health care provider assists in the exercise program. In either situation, clarity in goals and exercise procedures is essential to ensure an optimal outcome.

One of the fundamental steps in ensuring a positive outcome is the therapist's ability to communicate instructions effectively. The best-designed rehabilitation program may fail because it has not been carried out well. Variables such as language or cultural barriers, reading or comprehension levels, hearing or visual impairment, and clarity of instructions can affect understanding. Do everything possible to ensure that your instructions are clear and easy to understand. Although affective domain issues may be relevant here, many of the learning issues are related to the cognitive domain.

Cultural Barriers

Identify any cultural barriers to understanding early in the rehabilitation course. Language differences may hinder the use of even the simplest terminology. Although an individual may appear to understand many words in English, communicating thoughts about medically related issues is often difficult. Use of an interpreter can minimize communication difficulties in this area.

Other cultural barriers to adherence may exist and should be identified to the best of your ability. Religious or other cultural customs may prevent individuals from exercising on certain days or from wearing clothing that allows a body part to be visualized or palpated during exercise. In major metropolitan areas, a multitude of cultures exist, making it difficult to know the intricacies of all cultures and customs. Culturally competent providers will:

- Do their best to know the times and meanings of the patient's ethnic or religious holidays
- Seek information on cultural or religious customs related to:
  - Eye contact (avoiding eye contact is a sign of respect in some cultures)
  - Physical contact
  - How the patient is addressed
  - Appropriate type of greeting[14]
- Ask for permission to perform examination procedures in advance
- Explain what needs to be done and ensure patient comfort with procedures

Although these specific instances are difficult to know ahead of time, be alert to signs during the appointment that the patient is unwilling or hesitant to participate. In many cases, the patient feels most comfortable being examined by a therapist of the same sex. To the best of your ability, these issues should be addressed when scheduling the patient.

Clarity of Instruction

Simple aspects of the exercise program such as clear descriptions and legible writing are also important for adherence. Although written exercise programs may provide a personalized touch to the program, it may have detrimental results if the patient is unable to read the writing. Some key issues are:

- Specific exercise descriptions may make perfect sense to the clinician but confuse the patient.
- Baseline knowledge assumed by the therapist may be too much for the patient and may result in incorrect exercise performance.
- Clarity about which direction is "forward" or "up" is necessary.

Providers may find it useful to ask patients what they would name the exercise or how they would describe a certain movement. Using the key words identified by the patient helps to personalize the home program and increases the patient's understanding of it. This is in contrast to an authoritarian position where the provider gives the patient a routine exercise handout that seems highly impersonal. Directions should be lengthy enough to be comprehensive without overburdening the patient with details. Full sentences are unnecessary, but key phrases or bulleted points can improve clarity.

Include pictures of the exercises and show the exercise in the start and finish positions. Communicating a three-dimensional movement on a single sheet of paper at a stationary point in time is difficult. Show starting and ending positions or show pictures from different angles to clarify the three-dimensional nature of the movement. Arrows showing the direction of movement with marks clearly indicating the start and end positions are helpful. Often, exercise pictures show positions midway through the exercise, and the patient is unclear as to the full excursion of the movement. Throughout this book, Self-Management boxes present examples of exercise instructions.

Many clinics provide picture files or computer-generated exercises with pictures, descriptions, and exercise prescriptions included. These are helpful for the clinician, but use caution and be alert to these considerations:

- The therapist frequently needs to modify the exercise in some way to adapt it to the specific patient needs.
- These modifications should be made on the patient's exercise record, not just verbalized.
- Do not assume that because an exercise is provided in one of these formats, it is the best or the only way to perform the exercise.
- The exercise prescription should be individualized based on the patient's needs and ability to self-manage the problem, not necessarily prescribed as a certain number of sets and repetitions per day.

This type of prescription may conflict with the goal of teaching the patient self-management skills. Exercises that appear to be "canned" or the standard sheet of exercises that is given to every patient with a certain diagnosis minimizes the individuality of the exercise program. Lack of individualization minimizes the skills of the therapist and may affect adherence if the patient feels his or her needs are not being met.

Communication with the patient regarding the exercise program should be written, verbal, and, with increasing frequency, visual using video. Using the patient's own phone to video exercises can provide easy access to correct performance at their fingertips. Research has shown similar performance in patients receiving written handouts compared with video programs.[15,16] However, simply handing a patient the exercise program without demonstrating or having the patient perform each of the exercises increases the likelihood of nonadherence and incorrect performance[17] (**Evidence and Research 3-4**). Although patients may say they can remember their exercises, it is best to document the exercises with a written description that is reinforced with verbal cueing as the exercises are performed.

Organize the exercises in a logical sequence. An exercise program requiring frequent position changes is time consuming and burdensome for the patient. Cluster exercises of a similar nature for ease of understanding and ease of performance. For example, when possible, cluster all exercises performed in a supine position to minimize position changes, and group together shoulder rotation exercises because of their similar nature. Be sure to organize the exercises to simplify their performance and minimize the impact on the patient's lifestyle.

> **EVIDENCE and RESEARCH 3-4**
>
> A study by Friedrich et al.[18] found that patients who received a brochure of exercises rather than a supervised instruction had a lower rating of "correctness" of exercise performance. A strong correlation between the quality of exercise performance and a decrease in pain was found.

Cognitive Domain: Informing and Educating

Patient education is critical for a number of reasons including understanding the diagnosis, prognosis, plan of care, intervention techniques/dosage, and expected outcomes; improving program adherence; and teaching self-management. Clinical teaching, particularly teaching home exercise programs, is very important, because in-house supervised physical therapy services are often inadequate to achieve the patient's goals. Frequently, rehabilitation services are limited to a few visits. In this situation, the patient may be carrying out the rehabilitation program at home or at a local health club with intermittent rechecks for reexamination and program progression. To ensure safety during exercise and improvement in the patient's symptoms, the exercise program must be executed properly. Poor technique can slow or stop improvement and potentially worsen the symptoms. Therapists also teach patients which signs and symptoms predict an exacerbation so that they can modify the exercise program appropriately. This education can prevent a setback or potential reinjury (**Building Block 3-2**).

> **BUILDING BLOCK 3-2**
>
> Kathy returned to physical therapy for a follow-up visit. Review of Kathy's land-based program reveals that she has been performing exercises correctly and she has added aquatic rehabilitation exercises as well. However, in her zest to hasten her progress, she was overexercising, performing her exercises more frequently than prescribed, which resulted in an increase in pain and a slowing in her progress. Given this information, what are key aspects of education for this patient?

When prescribing a rehabilitation program, therapists must educate patients about the expected effects of the therapeutic exercise program on specific symptoms. This will provide patients with the necessary information to self-manage the situation. The more clearly patients understand the relationships among various activities (including the exercise program) and their symptoms, the better able they will be to regulate their activity levels. This makes the patient a partner in the rehabilitation program (**Evidence and Research 3-5**). The patient

> **EVIDENCE and RESEARCH 3-5**
>
> A recent study examined the impact of patient education and counseling regarding pain management, physical activity, and exercise in patients with low back pain and high levels of fear avoidance behavior.[19] While both groups improved with standard physical therapy intervention, those who received additional education and counseling had significantly fewer days off work than those without this education. This finding reinforces the importance of educating patients about their condition and strategies to effectively manage their symptoms.

still looks to the clinician for guidance and education regarding the physical problem, but the clinician gives the patient some responsibility in decision-making. This approach gently guides the patient in the self-management process.

Self-management has become increasingly important as people are living longer with chronic health conditions such as arthritis, heart disease, stroke, and diabetes. Patients must learn how to manage their symptoms, prevent a decline in their health status, maintain their overall level of health and well-being, and prevent complications of the disease process. In summary, patient must learn to self-manage conditions to avoid activity limitations and participation restrictions. An individual seeing a physical therapist for knee osteoarthritis may need education to understand the role of therapeutic exercise in maintaining knee function and total body health. Extensive patient education may be necessary to help that patient achieve optimal function. Additionally, patients who are hospitalized for various conditions are being discharged earlier. This results in a greater demand for outpatient services and the need for patient and family/caregiver education to manage impairments to avoid activity limitations and participation restrictions (**Evidence and Research 3-6**).

EVIDENCE and RESEARCH 3-6

Holmes et al.[20] successfully used a self-management approach in the treatment of a woman with impingement syndrome and adhesive capsulitis. She was seen for 6 visits over 10 weeks and followed up for 1 year. The authors felt that the intensive patient education allowed the patient to develop an internal sense of control and prevented the development of an external focus in which the patient depends on the therapist for the management of the condition. Motivation exhibited by patients may be a manifestation of their locus of control beliefs.[8]

Affective Domain: Adherence and Motivation

Patient compliance with a treatment regimen is a subject of a great deal of research. The terms *compliance*, *adherence*, and *therapeutic alliance* are often used to discuss the extent to which a patient's behavior coincides with medical advice.[9] Some feel that the term compliance is too dictatorial on the part of the caregiver and seems to neglect the philosophy of "patient as partner" in determining the plan of care. The term adherence is used throughout this chapter. The best-designed rehabilitation program achieves little if the patient is not compelled to participate (**Evidence and Research 3-7**). Strategies to improve adherence follow from an understanding of health behaviors.

EVIDENCE and RESEARCH 3-7

A study by Sluijs et al.[8] demonstrated a complete adherence rate of only 35%, with 76% of the patients "partly" compliant with their rehabilitation program. The factors related to nonadherence were patient-perceived barriers, a lack of positive feedback, and the degree of helplessness.

Health Behavior Models

Clinicians spend a great deal of time designing what they believe to be the best plan of care for their patients. However, even the best intervention plans will fail in the absence of patient participation. The factors associated with adherence to medical professional recommendations have been well studied. Some studies focus on eliminating unhealthy behaviors (smoking, excessive alcohol use), whereas others focus on initiating healthy behaviors (good eating habits, exercise, compliance with medication schedules).[8,9,21] A number of behavior change models have been put forth. For example, the Health Belief model stresses a reduction of environmental barriers to healthy behaviors including perceived barriers, benefits, self-efficacy, and severity.[22,23] Other models include the Health Locus of Control, Self-Efficacy, and Transtheoretical, or Stages of Change model.[22,24] Of these models, the Transtheoretical model has been applied to many aspects of exercise behaviors.

The Transtheoretical model emphasizes the temporal aspect of a behavior change, underscoring the ability to change a behavior over a variable length of time. Individuals may spend varying lengths of time in different stages as they slowly make changes, or they may get stuck in one stage. Additionally, the patient may move through some of the stages several times before completing the behavior change.[24] The stages identified in this model include *precontemplation*, *contemplation*, *preparation*, *action*, and *maintenance* (**Table 3-1**).

In the precontemplation stage, the individual states that he or she has no intention of changing in the next 6 months.[25] A person in this stage will be reluctant to begin any rehabilitation program and generally does not see the need or benefit of it. The individual may feel forced to come for rehabilitation by an outside party (physician, family member, employer), and no amount of explanation or information will improve adherence.

Individuals in the contemplation phase state that they are planning to make a change within the next 6 months. Those in the preparation stage indicate that they are planning to change in the next month or had made some changes but had not fully achieved the change. Individuals in the action stage have reached some criterion level of change (such as quitting smoking or exercising three times per week) within the past 6 months. Those in the maintenance stage had reached the criterion level of behavioral change more than 6 months earlier.[25]

Improving Adherence

Improve adherence by giving attention to the patient's readiness to begin such a program.[21,24,26] The first step is active listening to identify clues as to the patient's state of readiness for change. This can be done by using open-ended questions to explore issues related to adherence and to facilitate the patient's personal involvement. Help the patient identify potential barriers to participation and request input as to how these barriers can be removed or minimized. Patients need to believe that the pros of participation outweigh the cons and that they are capable of achieving the expected outcomes if they participate.[25,27,28] Build rapport through regular appointments and reflective conversation.[28] Purposefully link the exercise to the patient's impairments, activity limitations, and participation restrictions. For example, a patient may be more likely to perform a quadriceps strengthening exercise when they understand this intervention directly affects their reduced function of the lower extremity for activities of daily living (ADL) (i.e., activity limitation) and their inability to play tennis (i.e., participation restriction). Activity limitations and participation restrictions are often the primary reasons the patient sought medical attention initially. Friedrich et al.[18] found

TABLE 3-1

Transtheoretical Model of Behavior Change

STAGE	DESCRIPTION OF STAGE	PHYSICAL THERAPIST ROLE
Precontemplation	No intention of changing Does not see the need to change	Help identify goals that might be achieved by participation in the rehabilitation program
Contemplation	Seriously considering change but have not initiated it	Build motivation by providing information and encouragement
Preparation	Have plans to change in the next month Started to make changes but not complete	Educate the patient on the relationship between his or her own goals, the treatment program, and expected outcomes
Action	Have reached some level of change in the past 6 months	Actively engage in the plan of care development and provide support for the plan
Maintenance	Have reached the behavior goal more than 6 months ago	Provide positive reinforcement to continue participation

that compliance with exercise was increased through patient education in a group of patients with rheumatoid arthritis. The therapist must identify and address barriers to implementation in the treatment plan while encouraging ongoing participation and relapse prevention.

Use caution when using standardized "exercise files." Patients may have difficulty adhering to an exercise program that seems nonspecific or unrelated to the patient's functional needs. In the early rehabilitation phases, some exercises may not appear "functional" to the patient, but are important foundational components of the treatment program, as they oftentimes address impairments. Explaining the importance of the exercise educates the patient about the condition, assures the patient of the clinician's understanding of the problem and the potential solution, and treats the patient as an educated participant in the rehabilitation process. Further explanation of how the exercises will progress to more functional activities that address activity limitations and participation restrictions validates the importance of that activity and verifies that this is important to the patient.

Exercise program progressions should more closely reflect the identified activity limitations and participation restrictions. For example, for the individual recovering from shoulder surgery who is unable to reach a top shelf repeatedly (activity limitation), transferring dishes or groceries of increasing weight from the counter to the shelf for progressively longer periods is more motivating and interesting than lifting a 1-lb weight (**Fig. 3-2**). This type of activity has the added benefit of requiring distal muscle function that more closely replicates the actual functional activity. Weights and tubing are useful adjuncts to the rehabilitation program and, when possible, should be used in a way that duplicates the functional activity. Rather than performing a series of cardinal plane shoulder exercises, mimicking activities such as a tennis swing, raking, sawing, or throwing a ball (participation restriction) can increase strength and reinforce important motor programs (see **Building Block 3-3**).

A therapeutic exercise program requiring the fewest lifestyle changes increases the patient's adherence to it. Rather than trying to add more activities to the patient's day (often asking that exercise be performed several times per day), choose exercises that can be incorporated into his or her day. If an exercise program requires 15- or 30-minute time blocks carved out of a person's busy day, adherence is difficult despite the patient's desire to participate. If the exercises can be blended into activities that the patient already does during the day, adherence becomes much easier (**Evidence and Research 3-8**). An example of an exercise program for a patient with adhesive capsulitis can be found in **Display 3-1**.

FIGURE 3-2 Choose home exercises reflective of the patient's usual activities such as lifting cans up onto a shelf.

BUILDING BLOCK 3-3

Kathy returns to physical therapy and is pleased with the progress but is anxious to return to tennis. She can see how she is getting stronger and her ROM is nearly full. She is concerned that she will not be able to make the arm movements necessary to play tennis. Her exercise program has focused on cardinal plane strengthening from 0 to 90 degrees on land and on overhead swimming strokes and diagonal patterns in the pool. How might you modify her exercise program to address her concerns?

Fitting exercise into the patient's daily routine establishes a conditioned response that may carry over after therapy is concluded. For example, if a patient needs to increase the length of the gastrocnemius-soleus complex by stretching several times each day, instructing that person to stretch for 20 to 30 seconds each time he or she ascends the stairs is less burdensome than doing this as part of an exercise routine at

EVIDENCE and RESEARCH 3-8

A study by Fields et al.[29] examined the relationships among self-motivation or apathy, perceived exertion, social support, scheduling concerns, clinical environment, and pain tolerance to adherence to sport injury rehabilitation in college-age recreational athletes. Of the variables under consideration, significant differences were seen between adherers and nonadherers in self-motivation, scheduling concerns, and pain tolerance; of these factors, scheduling concerns contributed most to the overall group difference. In another study, Sluijs et al.[8] found that the strongest factor in nonadherence was that the exercises did not fit into the patient's daily routine.

the day's end. For the individual needing to increase shoulder flexion ROM, leaning ahead with his or her arm forward and flexed on the desk or kitchen counter before making a phone call is a productive use of time. This may become a conditioned response, and whenever the phone rings, the individual associates that activity with stretching his or her shoulder, or whenever the patient climbs the stairs, he or she thinks of calf stretching. This technique works particularly well with postural reeducation exercises (**Fig. 3-3**).

DISPLAY 3-1

Home Exercise Program for an Office Worker with Adhesive Capsulitis

Impairments

1. Decreased ROM in all directions in a capsular pattern
2. Decreased strength tested by manual muscle tests in all major shoulder muscle groups
3. Resting pain at 4 on 0 to 10 (0 = least; 10 = most pain); activity pain at 8 and 0 to 10.

Activity Limitations

1. Unable to use the arm for activities of daily living
2. Unable to lift weight with the arm held away from the body
3. Unable to get the arm over the head for work and daily activities

Participation Restrictions

1. Unable to fulfill all roles at work, such as filing heavy documents
2. Unable to participate in leisure activities, such as bowling

Home Exercises

1. Stretching for shoulder elevation while in warm shower
2. Active use of the arm for personal hygiene, including showering, combing hair, dressing, eating, and pendulum exercises during dressing
3. Scapular retraction exercise with abduction in front of the mirror during grooming three times per day, looking in the mirror each time
4. Shoulder flexion or abduction stretch on the desk when talking on the phone
5. Passive shoulder external rotation stretch at the file cabinet every time
6. Isometric exercise while reading morning mail
7. Walk with large arm swings during lunch hour
8. Supine overhead stretches on the couch during the evening news
9. Use the arm as much as possible for cooking, dishwashing, housework, and yard work
10. Resistive tubing exercises sometime during the day—patient's choice

FIGURE 3-3 Prescribe exercises that can be performed during other home or work activities.

Psychomotor Domain: Motor Learning

Patient education and instruction in a clinic or home exercise program require more than the simple transfer of information from the provider to the client. While some aspects are clearly cognitive, many are psychomotor. Exercise program design and exercise execution can impact the client's participation and eventual success. A successful program is designed to maximize learning a skill and to facilitate carryover of that skill to other environments, contexts, or situations. Factors for success extend beyond cognitive and affective to include psychomotor. How the exercises are ordered and how feedback is provided affects the motor learning process. Thus, another important focus of exercise program design and patient education is motor learning.

Models of Motor Learning

- Opportunities to enhance motor learning exist within the exercise program design. **Motor learning** is defined as the acquisition and/or modification of movement.[30] Some issues affecting the acquisition and learning of motor skills include the organization of practice conditions, the type and frequency of feedback, and the use of observational practice.

These factors influence the patient's ability to learn, apply, and retain motor programs. Learning is different from performance:

TABLE 3-2

Two Major Models of Motor Programming

	FITTS AND POSNER		SYSTEMS MODEL		EXAMPLE
	STAGE NAME	CHARACTERISTICS	STAGE NAME	CHARACTERISTICS	LUMBAR STABILIZATION
First stage	Cognitive	Gross motor strategies developed	Novice	Cocontraction restrains degrees of freedom	Learner overconstrains, tightening all pelvic muscles in order to control movement
Second stage	Associative	Motor strategies further refined	Advanced	Constraint reduced and degrees of freedom increased	Muscle activation and cocontraction are decreased as appropriate pelvic control is learned
Third stage	Autonomous	Motor tasks performed with little cognitive input	Expert	All degrees of freedom are released	Learner activates core muscles in the right sequence and right level for task at hand in a variety of situations

learning is more permanent, reflecting a true change in a person's ability to perform a skill whereas *performance* can be temporary, affected by the immediate testing conditions.[31]

Researchers and clinicians have attempted to characterize the process of learning a new motor skill. Visualize the last time you learned or watched someone else learn a new motor skill such as snowboarding, skating, or playing a musical instrument. Various theories related to the stages of motor learning exist; two three-stage theories will be summarized (**Table 3-2**).

The **Fitts and Posner[32] model** labels the first stage as *cognitive*. In the cognitive stage, attention to the task is necessary to master the fundamental components of the skill. During this phase, gross motor strategies are developed. Overcorrection and exaggerated movements are typical in this phase. The second phase, or *associative* phase, is characterized by further refinement of these gross strategies. Movements are becoming more efficient with less overcorrection and more refined muscle activation. The third and final phase is the *autonomous* phase where the motor program is activated and implemented with little cognitive input.

Another model, the **systems three-stage model**, is based on controlling the movement and degrees of freedom as the central tenet of motor learning.[30] In the first, or *novice* phase, the learner uses muscle agonist–antagonist cocontraction to restrain movement and control the degrees of freedom.[33] Here, the learner simplifies movement by constraining or coupling some joints, thereby stabilizing or fixating these joints, decreasing the degrees of freedom to be managed. This is a relatively inflexible and inefficient movement pattern. The second phase, or *advanced stage*, is characterized by reducing constraint and increasing the degrees of freedom to be managed. This allows more coordinated movement without the constraint of agonist–antagonist cocontraction. Movement becomes more efficient and less rigid. The final phase, called the *expert phase,* sees the individual now releasing all degrees of freedom, and movement is allowed to proceed in the most efficient and coordinated manner. Movement is adaptable to multiple environments.

Varying Practice Conditions: Contextual Interference

Theories of motor learning have been tested using a variety of practice conditions. Therapists strive to teach patients effective and efficient motor programs that they hope will transfer to a variety of situations. When a motor learning does not generalize to other environments or situations, it is termed *interference*.[34] Contextual interference is the process of using various forms of interference during a practice session in order to improve retention and carryover.[35,36] Contextual interference[35,36] and its ability to enhance motor skill acquisition appear to be affected by many variables including practice schedule (random, blocked, serial, combined), focus of attention, previous experience, feedback, age, and the task difficulty[37–41] (**Evidence and Research 3-9**).

EVIDENCE and RESEARCH 3-9

In an example of a motor programming trial, Herbert et al.[42] examined the effectiveness of different feedback schedules on the performance and learning of a lumbar multifidus muscle activity. Those subjects who had a variable practice schedule performed better 3 to 4 months later than did those with a constant practice schedule.

Practice Schedule

In general, it appears as though random practice conditions (where the patient practices several different tasks in random order) result in superior transfer skill performance compared with blocked practice conditions (practicing one task and then moving on to the next) or serial practice conditions (the practice schedule is ordered and predictable).[43] However, blocked practice seems to be more effective when learning a new skill[44] (**Evidence and Research 3-10**). Thus, the stage of motor learning as well as the individual's capacity for learning must be considered when choosing random, blocked, serial, or combination

EVIDENCE and RESEARCH 3-10

Bertollo et al.[46] taught a group of adolescent girls a rhythmic dance sequence in either blocked or random sequence, testing after 6 training sessions and testing retention 21 days later. The blocked group performed better than the random group immediately after the training sessions. The random group showed fewer performance decrements over the 21-day interval, resulting in similar performance to the blocked group in the retention trial.

practice conditions. Porter et al.[45] found that increasing contextual interference (starting with blocked, then serial, and finally random schedules) showed superior performance, retention, and transfer to other generalized motor programs compared with either blocked or random only schedules. It may be more appropriate to use a blocked practice schedule during the acquisition phase or with lower-skilled individuals, progressing to random practice conditions once the skill is acquired.

The application of practice schedules also varies by other population variables. It appears that children, perhaps because of less life experience and practice at many tasks, respond more robustly to a varied practice schedule than do adults.[47,48] Subjects with Parkinson disease performed better with a blocked order practice schedule.[49] However, while varying practice conditions may intuitively seem superior, most importantly, the training should mimic functional activity and trend toward a constant practice schedule.[50–52] At this point, varying other components of the practice situation, such as focus of attention, may be more appropriate.

Feedback: Focus of Attention

Attentional focus, or the act of directing attention to information sources or objects, is another variable impacting motor learning.[39] Attentional focus has been divided into *external focus of attention*, where the learner focuses on the action results, and *internal focus of attention*, where the learner attends to the body movements. For example, when learning to kick a ball, cues for an external focus ask the learner to attend to the movement of the ball and its position relative to the target. An internal focus would ask the learner to attend to the movements of the hip, knee, and foot while kicking.

Although numerous studies have found that groups trained with an external focus performed better on both immediate and transfer trials, other studies suggest that preference for an external or an internal focus may be skill and/or age dependent[53–56] (**Evidence and Research 3-11**). In adults, it has been hypothesized that an internal focus constrains the motor system, altering the usual automatic control processes.[53,54] A large body of research suggests that instructions that promote an internal focus or draw attention to the patient's bodily movements disrupt the automatic processes that produce efficient movement patterns.[57–61] The internal focus also requires more cognitive input, potentially limiting available space for additional information processing, such as other players, ball movement, environmental conditions.[62] Therefore, in adults, particularly those of some skill level, an external focus of control will likely produce optimal results. These findings have been reproduced in a number of populations and conditions including elderly women,[63] low-skilled sprinters,[64] patients post ankle sprain,[65] patients following a stroke,[66] in patients with Parkinson disease,[67,68] and in agility[69] and plyometric training. Moreover, increasing the distance of the external focus of attention led to further improvements in activities such as the standing long jump.[70,71] Focus preferences in children are less clear, and whereas some research supports a preference for an internal focus of control, others have found external or combined attentional focus producing better outcomes, suggesting a need for further study.[39,47,72]

EVIDENCE and RESEARCH 3-11

A study of highly skilled and lesser skilled golfers found that the highly skilled golfers performed better with an external focus of control, while the lesser skilled golfers performed better with an internal focus.[53]

Feedback Frequency

The type and schedule of feedback impacts motor program development. The timing of performance feedback can vary from during performance to immediately after or can be delayed. Feedback frequency can vary, with feedback given randomly, scheduled, or with every trial; importantly, the feedback schedule can be self-controlled. Research on optimal feedback schedule is often confounded by the type of feedback given. For example, a high frequency of feedback that has an internal focus can compromise motor learning[73] (**Evidence and Research 3-12**).

EVIDENCE and RESEARCH 3-12

Wulf et al.[73] studied the effects of feedback frequency (100% vs. 33%) and type of feedback (internal vs. external) in a group of experienced soccer players. Accuracy was increased in the external focus group, and frequency of feedback did not affect accuracy in this group. However, the internal focus group performed better under conditions of reduced feedback, suggesting that frequent internal focus feedback may have negative effects on performance.

Research into the motivational aspects of feedback has suggested that feedback provided after "good" trials results in more effective learning than feedback provided after "poor" trials.[31,74] Many individuals have a relatively accurate sense of their own performance, rendering corrections after a poor trial redundant. This can increase the self-focus, constraining the body's automatic processes and further compromising motor learning.[58]

Self-control over the practice session and feedback schedule has emerged as an important motor learning factor.[75–78] In most clinics, the therapist determines the patient training schedule including the activity choices and their frequency, intensity, duration, and sequence. However, subjects who were allowed to choose when they received feedback showed greater improvements in motor learning (measured by a delayed transfer task) than those who received scheduled feedback. Both groups preferred receiving feedback after "good" trials.[76] Additionally, subjects who were allowed to choose whether or not to receive feedback after their trial showed greater motor learning effects than those who had to choose before their trial.[77]

Visual Feedback: Observation and Mental Practice

Feedback extends beyond verbal feedback to include an ever expanding variety of feedback techniques to enhance motor learning. Movement observation, either alone or combined with physical practice, has been shown to improve motor learning.[79–81]

Brain imaging has identified a network of several regions of the brain that are activated when observing a physical activity.[82–84] These networks are activated similarly when an individual performs as well as observes a task.[85] Additionally, the model

EVIDENCE and RESEARCH 3-13

Research suggests that observing either a correct model or a peer model (someone also in the process of learning the skill) is equally effective in learning a motor skill.[86,87] Peer observation may allow the observer to observe movement deficits and devise motor strategies to correct these deficits without the dual demand of the cognitive load and physical performance.

observed does not have to be an expert at the task in order for learning to take place (**Evidence and Research 3-13**). Observing a peer provides the observer with an opportunity to problem solve deficits without the simultaneous physical demand (**Fig. 3-4**).

Many high-level athletes use mental practice to augment their physical training. Research has shown improved performance when mental practice was combined with physical practice.[88] In general, mental rehearsal and imagery can be a useful adjunct to physical practice.[89–92] However, mental practice alone is not a sufficient substitute for physical practice.

Combined observational and physical practice can be easily achieved using dyad training. Dyad training uses pairs of individuals alternately performing and observing a task. Dyad training research has shown that this type of training provides efficient use of resources, possible competitive motivation, and improved performance and learning.[57,62,93–95] Dyad training using alternate practicing with a partner can be more effective than individual training even when retention trials are performed individually.[93] However, dyad training outcomes can be specific to the environment and task at hand[96,97] (**Fig. 3-5**).

An alternate form of observational training is the use of video feedback or video overlay of a movement pattern. A video overlay uses a video model of the approximate same size and proportions as the individual performing the task correctly. This provides a target for the individual who can see a video overlay of his or her own movement pattern to observe how closely it matches the correct model's pattern.[62] The goal is to achieve full overlap of the individual and the correct model during the movement being trained. This type of training provides real time external attentional focus feedback of motor performance.

APPLICATIONS: HOME EXERCISE PRESCRIPTION

Prescribing exercises for a home program is challenging. These exercises are performed without supervision, and patient education is critical for success. Frequently, limited patient visit time further challenges the clinician to teach the patient all the necessary components of the self-management program. Providing a short, safe home exercise program is better than being too broad and overwhelming the patient with information on the first visit.

Considerations in Exercise Prescription

Exercise prescription can be difficult for several reasons. We know less about exercise prescription in those with impairment, injury, or disease, making proper exercise dosage determination challenging. Too little exercise may not produce the desired result, whereas too much exercise may overwork the patient, resulting in a decline in progress. Many factors influence choices regarding the exercise prescription:

- Stage of healing
- Tissue irritability and symptom stability
- Daily activities
- Time between physical therapy visits
- Ensuring proper exercise execution
- Equipment and environment
- Patient's time and willingness to participate

A B

FIGURE 3-4 Athlete watching another athlete jump off **(A)** and **(B)** land from a box. Observation of another person performing an activity can improve learning.

FIGURE 3-5 Athletes watching each other **(A)** jump, and **(B)** land in dyad training. Dyad training is another effective strategy for motor learning and works well in partner activities.

Stages of Healing

The acuity or chronicity of the injury affects the exercise prescription, including the regularity of supervised physical therapy and the time between visits. In the early stages, give the patient a few things to do at home between closely scheduled supervised visits. In this phase, appointments may be more frequent because of the rapidity with which the patient's symptoms and impairments are changing. The exercise program changes more frequently as goals are met and new goals established. In the early stage, the symptoms may be new to the patient, making determination of the appropriate exercise level difficult. Closely following the response to treatment is necessary to ensure forward progress. Conversely, in the intermediate to later stages, changes in the patient's symptoms and function occur more slowly, and the exercise program may be more extensive. At that point, the patient is often instructed in self-progression of activities.

Tissue Irritability and Symptom Stability

Tissue irritability has a significant effect on intervention choices. This factor is somewhat subjective and is determined through a complete subjective examination. Questions regarding the patient's symptoms provide the clinician with the best information on this issue (**Display 3-2**).

Before deciding on the content of the home program, understand what kinds of activities or positions worsen the patient's symptoms. These activities or positions may or may not need to be avoided. If the patient can tolerate the activity or position for some time, is able to detect the prodromal signs that the symptoms are going to worsen, and understands that stopping the activity or changing position can alleviate the symptoms, use these activities or positions therapeutically. For example, if a patient with carpal tunnel syndrome enjoys knitting but knitting is currently compromised (participation restriction), knitting may be used as part of the rehabilitation program. The patient must be able to recognize the onset of symptoms and be able to alleviate them by taking a rest period or discontinuing the knitting. Similarly, if a patient with back pain enjoys and is able to tolerate some walking, this activity can be a component of the exercise program. The patient must be able to detect the onset of symptoms and relieve them by discontinuation, stretching, icing, or some other self-management intervention. Conversely, if the patient reports an unmanageable, inevitable worsening of symptoms once irritated, the exercise program should expressly avoid any position or activity that may exacerbate symptoms.

DISPLAY 3-2

Questions Assessing Tissue Irritability

1. What activities or positions increase your symptoms?
2. How much time can you spend in that activity or position before your symptoms begin?
3. When you start feeling these symptoms, will they continue to progress despite discontinuing the activity or changing positions? Will changing the activity or position alleviate the symptoms?
4. After you begin experiencing your symptoms, how long do they last? How long until you return to "baseline?"
5. Is there anything you can do to relieve your symptoms?

Be sure to consider the *stability* of the patient's symptoms as a component of tissue irritability. Individuals may have significant unpredictable fluctuations in their symptoms over the course of the day or week. If symptom changes cannot be associated with the time of day, position, or any specific activity, the exercise prescription can be difficult. If the patient is unable to determine what kinds of things make him or her better or worse, assessing the effects of the exercise program becomes yet another variable in the symptomatology. Deciding whether a specific exercise prescription is beneficial or deleterious is challenging if the patient's symptoms fluctuate randomly. When possible, it is best to proceed with fewer exercise interventions until a stable baseline of symptoms is achieved. This baseline then serves as a gauge of the effect of the exercise program.

Daily Activities

The patient's other daily activities affect the exercise prescription. Understanding the behavior of a patient's symptoms over a 24-hour period and how his or her normal daily routine affects the symptoms helps the clinician to gauge appropriate exercise levels. The patient may be unaware of the impact of certain routine activities on his or her problem, or the patient must perform some activities that worsen his or her symptoms (such as sitting or walking). For example, counsel the individual with patellofemoral pain about the importance of good shoes, particularly if standing for a large portion of the day. Despite the fact that standing behind a cash register for 8 hours may exacerbate the patient's symptoms, this work may be financially necessary. The individual with back pain may need to lift a child out of a crib several times each day, despite the fact that this activity is painful. Educate the patient about the impact of these activities on symptoms and provide suggestions to minimize their negative effects. Educate the patient regarding modification of the exercise program based on the symptoms related to participation in these activities. On days when the patient's symptoms may be increased because of excessive standing, working, or lifting, he or she may need to decrease the rehabilitation exercise level. Failure to recognize the impact of daily activities on symptoms may cause the clinician to erroneously assume that a change in the patient's symptoms was caused by the exercise program alone.

Time Between Physical Therapy Visits

The time between follow-up visits affects the exercise prescription. For the patient attending supervised physical therapy one or more times per week, the clinician may give the patient more challenging home exercises, knowing that the patient will be monitored more closely in the clinic. For those patients who live some distance away or who have longer intervals between supervised visits for other reasons, provide exercises that are less likely to overwork the patient. Supplement this program with instructions on how to progress exercises if they become too easy (e.g., increase time, repetitions, intensity), or schedule an intermediate phone follow-up. In many cases, interim contact with the patient via a phone call or electronic communication can assess the patient's progress. The therapist can make suggestions on how to modify the home program until the patient's next clinic appointment, thereby avoiding any plateaus in the rehabilitation process.

Proper Exercise Execution

Although patients may appear to follow the exercise instructions, they may still perform the exercise incorrectly. Patients may understand the instructions, but:

- The instructions may be incomplete or unclear
- Patients may read things into the instructions
- Patients may simply be unaware that they are doing the exercises incorrectly

For example, the patient may think he or she is performing a trunk curl but is actually doing a full sit-up or performing a straight leg raise without the necessary quadriceps set first.

Ensure proper performance by:

- Having the patient perform each of the exercises under your direction and guidance
- Providing verbal and tactile cueing for proper performance
- Encouraging the patient to take notes during these sessions
- Incorporating evidence on the psychomotor aspects of motor learning

Although written and verbal instructions help ensure proper performance, more instruction is occasionally necessary. Other options include having a family member observe the clinician instructing the patient, so that this individual may guide the patient's home exercise performance. Videoing the exercise session allows the patient to see him or herself performing the exercise, along with hearing the clinician's verbal cues and observing tactile cues for proper performance. The patient can replay this video at home if a question regarding the exercise program exists.

When the patient returns for follow-up, ask him or her to demonstrate the home exercise program. In most cases, if the patient has been performing the exercises on a daily basis, the exercises should nearly be committed to memory. The ability of the patient to quickly recall the exercises with or without the assistance of the handout may provide insight into adherence. Moreover, this shows precisely how the patient has been executing the exercise. Frequently, the exercise has been changed somewhat from the clinician's original intended performance, and this may affect the patient's progress since the last visit. Occasionally, the incorrect exercise performance can have negative consequences, such as increasing the patient's symptoms or hindering progress (**Fig. 3-6A** and **B**).

A B

FIGURE 3-6 Review the exercise program at follow-up visits to ensure correct performance. **(A)** Incorrect position—straight leg raise without appropriate quadriceps set. **(B)** Correct performance—clinician cues the patient for correct exercise performance.

Equipment and Environment

Along with determining what motivates the patient, determine the motivation derived from the use of exercise equipment. Performing exercises using body weight, objects in the home or office, or work tools may be more functional; however, the patient may feel like this is not really exercise if it does not involve weights or resistive bands. Patient education is necessary to ensure the patient knows the importance of these activities. However, preconceived ideas about exercise are frequently difficult to overcome, and adherence may be improved by use of some equipment. The financial cost of purchasing some equipment for home use may increase or decrease adherence. If money must be spent to carry out the exercise program, the patient may decline participation. However, some patients feel obligated to use equipment that they have purchased. Assess the patient's position on this issue before issuing or recommending purchase of equipment.

When designing an exercise program with some specific equipment, ensure that the patient has a place to use the equipment (**Fig. 3-7**). For example, the patient's home may or may not have stairs. Accommodations may be necessary if exercises require the use of a step. When prescribing exercises to be performed in a supine or prone position, a surface of the appropriate height and firmness must be available. Exercises often are easy to perform on the plinth in the clinic, but the quality or the ability to perform the exercise is negated at home because of the patient's environment. The patient must be able to comfortably transition positions to and from that surface. If the only available firm surface to carry out the exercise program is the floor, the patient must be able to easily get up and down from the floor. If not, the exercise program should be modified to increase the ease of participation in the program.

FIGURE 3-7 Choose equipment that can be easily used by the patient at home.

A final aspect of the environment that the clinician has little control over but should consider is the presence of a supportive family. Social support is an important factor in patient adherence to a treatment regimen. Social support includes both the medical community and the patient's family and immediate community. Social isolation has been determined to be a major factor in nonadherence to a medication regimen. Lack of social support has contributed to dropping out of treatment in a number of studies.[98] Social support is particularly important when managing chronic disease, owing to the ongoing nature of the problem.

Be sure to evaluate the role of the family and other support systems in the patient's immediate community. The family or work community can either provide support or potentially have a negative effect. A supportive family can maximize the patient's opportunity to participate in medical care by being physically and emotionally supportive. Family members who take over duties normally carried out by the patient and advocate participation in the exercise program can enhance the patient's opportunity for improvement. Nonsupportive family members who criticize the patient for being injured or unable to carry out expected roles can create barriers to improvement.

If possible, involve the family members in the patient's care to ensure an understanding of the plan of care and prognosis. This will help them understand how the impairments, activity limitations, and participation restrictions are relative to the patient's goals and the plan to achieve the goals. If family members are nonsupportive, do your best to minimize their negative impact by providing additional support to your patient. Always be alert to signs of this situation and make referrals as necessary to ensure optimal participation in the rehabilitation program.

Patient's Time and Willingness

The amount of time the patient has available to exercise is an important factor affecting exercise prescription. If the patient claims to have little time available for the home exercise program, be sure to respect the patient's position on this issue. Educate the patient about the importance of the program in a nonjudgmental fashion, followed by conscious choices about priority exercises. Make an effort to select exercises considered to be the most important for the exercise program. More is not always better, and giving thoughtful consideration to the core exercises is beneficial for the clinician and the patient. Choosing exercises that have the greatest impact for the least time commitment can minimize the time requirement and maximize the benefits. The patient will probably appreciate your concern and attention to his or her needs. Couple this approach with education regarding the importance of the home exercise program to address activity limitations and participation restrictions in as expedient and efficient a time frame as possible. Emphasize

TABLE 3-3

Curwin and Stanish Classification for Determining the Appropriate Level of Discomfort Associated with Home Exercise Prescription

LEVEL	DESCRIPTION OF PAIN	LEVEL OF SPORTS PERFORMANCE OR ACTIVITY
1	No pain	Normal
2	Pain only with extreme exertion	Normal
3	Pain with extreme exertion and 1–2 hr afterward	Normal or slightly decreased
4	Pain during and after any vigorous activities	Somewhat decreased
5	Pain during activity and forcing termination	Markedly decreased
6	Pain during daily activities	Unable to perform

From Curwin S, Stanish WD. Tendinitis: Its Etiology and Treatment. Lexington, MA: DC Heath, 1984:64

your own and the patient's responsibilities in achieving those mutually defined goals.

Determining Exercise Levels

Determining the appropriate level of exercise can be difficult, particularly when the patient has had little or no experience with the specific problem or with exercise. Although many individuals exercise regularly, many others have little experience with exercise. Knowing how to respond to different sensations felt during the rehabilitation exercises can prove frustrating to the patient. Many patients ask whether to continue exercising if the exercise produces pain. Despite the fact that pain is a subjective symptom, acknowledge this sensation. Consider pain in the context of change from the patient's baseline symptom level and how the symptoms behave over the subsequent 24-hour period.

Curwin and Stanish[99] provide guidelines originally designed to help determine readiness to return to a sport. However, these same guidelines are nicely adapted to evaluate the patient's exercise program (**Table 3-3**). The column in Table 3-3 entitled "Description of Pain" refers to the level of pain during performance of the rehabilitation program, and the category "Level of Sports Performance or Activity" could be retitled "Level of Exercise Program Performance." Activity levels that keep the patient within his or her optimal loading zone are generally levels 1 through 3. Occasionally, some patients may be able to tolerate exercise at level 4 without any residual effects. For example, patients with adhesive capsulitis often experience pain at level 4, but this level of pain does not interfere with their overall function or progress. These guidelines provide the patient and the clinician with common criteria by which the exercise program prescription is evaluated.

Despite the clinician's best efforts, some patients experience an exacerbation of their symptoms, which may or may not be related to the exercise program. Although the first response of the clinician and the patient may be some level of distress, an exacerbation is not always a negative experience. An exacerbation can be a "teachable moment" with valuable lessons learned. At some point, whether days, weeks, months, or years later, most patients experience some type of symptoms related to the current problem. The patient with patellofemoral pain may experience a milder level of pain after a hiking vacation, or the individual with low back pain may notice some back discomfort after a long plane flight. Some patients experience a complete exacerbation of their symptoms at some future point, and patients must learn how to manage exacerbation of symptoms.

Therapist-guided self-management instruction can teach the patient how to intervene immediately in future cases of an exacerbation. Too often the patient experiencing a recurrence of symptoms delays obtaining medical attention or has difficulty obtaining a timely appointment. The optimal time for intervention has passed, and the patient may be struggling with secondary problems resulting from compensation, movement changes, or other impairments. One of the best services the clinician can offer the patient is instruction on how to manage the acute return of symptoms. Instruction may include the use of modalities such as ice, activity modifications including relative rest, changes in the maintenance exercise program, and education regarding when to seek medical attention.

In addition to possibly preventing reentry to the medical system through immediate, appropriate symptom management, self-management has the added benefit of enhancing patients' confidence in their ability to resolve the symptoms. The exacerbation experience coupled with instruction in appropriate management under the clinician's guidance can greatly decrease the patient's anxiety. Patients are often fearful about participating in activities that may provoke their symptoms, afraid that they will be "back where they started" in the early stages of their injury. Learning that an exacerbation does not necessarily send them back to the initial phase and that they can successfully manage the problem independently empowers patients to make appropriate activity choices. Eventually, patients may choose to participate in activities they enjoy at the expense of getting a little sore, knowing that they can successfully manage the symptoms independently (see **Building Block 3-4**).

BUILDING BLOCK 3-4

Kathy had been performing racquet swings without a ball for 15 minutes per day as part of her rehabilitation program. On a warm sunny day, she decided that she wanted to start hitting a ball, so she joined her usual tennis partner for 40 minutes of light hitting on the court. She returned to physical therapy 3 days later with increased pain throughout the shoulder girdle. She reported that the pain was different from the pain she experienced when she injured her rotator cuff. She is again highly concerned that she will not be able to return to tennis. What are some possible educational strategies and recommendations?

Formulating the Program

When possible, **formulate the exercise program after the patient's baseline level of symptoms has stabilized** and the previously mentioned factors (e.g., tissue irritability) have been determined. Ensuring the patient's understanding of what the "baseline" feels like allows better communication between the clinician and the patient regarding the behavior of his or her symptoms and the effects of the exercise program. Symptoms that are unstable or fluctuating without determinable cause make assessing the effects of intervention difficult. Ask the patient to articulate his or her "normal" level of symptoms to assist in determining the stability of symptoms. If patients have difficulty determining the stability of their symptoms, slow progression is necessary. When the patient is able to perform the same exercise program for three consecutive sessions without an increase in symptoms, progression is appropriate.

If intervention needs to be implemented before establishing a stable baseline, **give the patient as few exercises as possible**. This minimizes the impact of the exercise program, thereby lowering the possibility of exacerbating the symptoms. If the patient's symptoms do worsen, you will have an easier time determining the cause, and changes can be made more appropriately. As symptoms resolve and the baseline stabilizes, increase activities systematically and gradually. Do this by increasing the time and repetitions or by adding new exercises slowly.

Vary the exercise program progression based upon each person's stage of injury, specific goals, and stability of symptoms. For the individual who is in the intermediate to late healing stages and has demonstrated stable symptoms, several exercises can be progressed simultaneously. For those with unstable symptoms and frequent exacerbations, keep rehabilitation program changes to a minimum. In this way, any positive or negative response to the change can be more easily identified and remedied.

Teach patients how to modify their exercise program based on their activity level on any given day. Put exercises in the context of their daily routine. On days when the patient is more active (e.g., working overtime, child care, shopping, yard work), modify the home exercise program to prevent overload. On days when the patient is more sedentary (e.g., bad weather, day off from work), increase the exercise program. In this way, the patient begins to understand the impact of his or her overall activity level on his or her symptoms. This assists the patient in the self-management of symptoms in the future.

Choose exercises that can be incorporated into activities already performed during the day. This type of exercise prescription results in short bouts of exercise performed several times throughout the day, thus improving adherence. In this case, the patient is unlikely to overwork in any single session, resulting in a lower chance of an exacerbation of symptoms. Moreover, the likelihood of exacerbation is decreased despite a greater volume of exercise that can be performed in any single session. For example, the individual with Achilles tendinitis may tolerate only two repetitions of 30 seconds of calf stretching at a time. If that individual performs those two repetitions six times spread out over the course of his or her day, the stretch has been performed 12 times. By contrast, if the patient tried to carry out the home exercise program in the evening, chances are that only two repetitions would be performed that day.

Finally, teach the patient that some exercise is better than none, and if time limitations exist, a couple of key exercises identified by the therapist should be performed. Occasionally, other life events prevent completion of the full home exercise program despite the patient's willingness to adhere. Prioritize the exercises, highlighting those that are most important to complete if time does not permit completion of the entire program. Emphasize the importance of finishing all of the exercises when time permits, while suggesting that some exercise is better than none.

KEY POINTS

- Patient education and self-management have become increasingly important with greater life expectancy.
- Patient safety is the first consideration when designing a home exercise prescription.
- Exercises requiring the fewest lifestyle changes can increase adherence.
- Patient–clinician communication is enhanced by determining the patient's willingness to learn and listening actively to the patient's needs.
- Written and verbal instructions should be included in a home exercise program. Written exercises should include beginning and ending positions and any precautions. Use video when possible.

Incorporate evidence regarding the psychomotor aspects of exercise performance in order to facilitate motor learning.

- At follow-up visits, have the patient demonstrate the home exercise program to ensure correct performance of all exercises.
- Home exercise choices are affected by the acuity of the injury, tissue irritability, stability of symptoms, patient's daily activity level, time available for exercise, and factors affecting the length of time between follow-ups.
- A symptom exacerbation can be a learning experience for the patient if the patient is educated properly on symptom management.
- Patients must be encouraged to take control of their exercise program and taught how to modify their home exercise program based on other daily activities and symptoms.
- Understanding the typical behavior of their symptoms allows patients to more easily recognize an exacerbation and be able to guide activity choice and intensity.
- Any cultural, language, education, visual, or hearing barriers should be identified early and appropriate accommodations made.
- Prioritize exercises so that the patient may perform at least some of his or her exercises on busy days.

CRITICAL THINKING QUESTIONS

1. How would your home exercise instruction differ for patients who are
   a. Visual learners
   b. Auditory learners
   c. Kinesthetic learners

2. Consider the patient in Lab Activities. How would you provide this patient with a home exercise program if he or she were blind?
3. A patient returns to see you and reports that the home exercise was not done because of a lack of time. How would you respond? What would be your strategy and rationale?
4. A patient returns to see you and reports that the home exercise program was not done because the exercises hurt. How would you respond? What would be your strategy and rationale?

LAB ACTIVITIES

1. Refer to Case Study No. 6 in Unit 7. Design a home program for this patient. Include written instructions and diagrams for all exercises. Teach your patient this home program while relaying the following emotions:
   a. Empathy
   b. Disinterest
   c. Hurry
   d. Insecurity
2. Using the exercises developed for the first question, modify each exercise to be performed throughout the day, incorporating the exercises into the patient's daily routine.
3. Using the exercises developed for the first question, prioritize the exercises for the patient and explain your rationale for the prioritization to the patient. Use language the patient can understand.
4. Your patient desires to return to several sporting activities. Choose two of the exercises you have given the patient, and modify them to mimic a sporting activity to which the patient would like to return.
5. Teach someone else in the class who does not know how to tie a necktie how to do this without looking at each other and without using the words yes or no.
6. Pick several physical activities such as squats, lunges, side lunges, jumps, etc. Pair up in dyads and have one student perform an activity while the second attempts to match the movement pattern. Make corrections using an external focus of control.

CHAPTER 4

Prevention and the Promotion of Health, Wellness, and Fitness

JANET R. BEZNER

The function of protecting and developing health must rank even above that of restoring it when it is impaired.
—*Hippocrates*

Interventions aimed at preventing injury and illness are among the many tools physical therapists use on a daily basis to address the health needs of patients and clients they serve. Indeed, prevention, health promotion, fitness, and wellness efforts have recently garnered increased attention as the nation struggles to control escalating health care costs and to stop the progression of chronic diseases that have reached epidemic proportions.[1,2] It has been estimated that 50% of premature deaths in the United States are related to modifiable lifestyle factors,[3] so there is clearly a need for effective prevention programs and efforts aimed at reducing risk factors and improving health and wellness.

Traditionally, the physical therapist's role in prevention and wellness has been narrowly focused on preventing a recurrence of the injury or illness a patient already has experienced or identifying risk factors and preventing escalation into disease. For example, when treating a patient recovering from an ankle sprain, some rehabilitation activities are directed toward preventing a recurrence of that injury. The approach may include direct interventions such as balance exercises or indirect interventions such as patient education. Physical therapists may perform biomechanical analyses such as running gait analysis or ergonomic workstation analysis to identify risk factors predisposing clients to injury. Although appropriate and worthwhile, these efforts do not produce the significant outcomes that primary prevention programs might, because they are applied after the onset of risk, illness, or injury. Contemporary physical therapist practice is consistent with the American Physical Therapy Association's (APTA) Vision Statement for the Profession—transforming society by optimizing movement to improve human experience.[4] There is a role for the physical therapist in addressing all barriers and limitations to movement—that is, interacting with patients and clients to promote health and improve wellness, thereby minimizing participation restriction.

Physical therapists' efforts in health and wellness promotion require an expanded view of health beyond the biomedical or disablement models. Additionally, it is important to recognize that clients may not be motivated to participate in health-causing behaviors until they become symptomatic or ill. In addition, patients may not be motivated to address health behaviors that may seem unrelated to the primary diagnosis for which they are seeking physical therapy. The purpose of this chapter is to explore the concepts of prevention, health promotion, fitness, and wellness. Because the remainder of this book discusses interventions aimed at injured or ill patients, this chapter focuses on primary prevention and the services that physical therapists can provide to clients before they become patients and to current patients to address health behaviors.

THE CONTEXT FOR PRIMARY PREVENTION

Numerous physical therapy professional references support a role for the physical therapist in health promotion and wellness. *The Guide to Physical Therapist Practice*, which defines the physical therapist's scope of practice, discusses the physical therapist's role in prevention and the promotion of health, wellness, and fitness.[5] The APTA vision statement, goals, and objectives and several policy statements reference the role of the physical therapist in the provision of health and wellness services.[4,6] Numerous state licensing acts include language permitting licensees to promote and maintain fitness, health, or wellness in all age groups.[6] The accreditation criteria for physical therapist educational programs state that graduates of accredited programs are prepared to provide physical therapy services that address primary, secondary, and tertiary prevention; health promotion; and wellness to individuals, groups, and communities.[7]

Thus, the expectation that physical therapists participate actively in health and wellness practice exists in many professional documents. To provide such services, the physical therapist must first understand and differentiate the many terms used to describe these concepts.

DEFINITIONS

Prevention, Health Promotion, and Health Education

There are many terms used within the context of "prevention" within the US health care system. Differentiating these terms

FIGURE 4-1 Differentiation of primary, secondary, and tertiary prevention.

Prepathogenesis Period			Period of Pathogenesis		
Health promotion	Health protection	Preventive health services	Early diagnosis and prompt treatment	Disability limitation	Rehabilitation
Primary prevention			Secondary prevention		Tertiary

provides a valuable perspective for the delivery of appropriate services by physical therapists. **Figure 4-1** illustrates the prevention to intervention continuum, ranging from health promotion services to rehabilitation. The associated pathologic state of the patient/client at each stage of prevention is shown across the top of the diagram. Definitions and examples for terms in the figure are provided in **Table 4-1**. Prevention is divided into primary and secondary prevention services. Also referred to as public health, primary prevention includes health promotion, health protection, and preventive health services. Primary prevention takes place in the "prepathogenesis" period before the onset of disease. Secondary prevention services take place after the onset of illness or injury, in the presence of pathology, and include screening for the purpose of early diagnosis and treatment of disease, as well as disability limitation. Secondary prevention includes efforts to identify disease early by recognizing either the physiologic changes that precede illness or signs of subclinical illness. Examples include breast and prostate cancer screening, osteoporosis screening, medical preplacement evaluations, and accident reporting.[8] Also included within secondary prevention are efforts to limit disability for those with chronic diseases such as diabetes (i.e., a foot care educational program) or spinal cord injury (i.e., a program to prevent skin breakdown). Tertiary care, or rehabilitation, is the category that encompasses most traditional physical therapist services. Although the physical therapist may use health education methods to provide information in the case of a secondary prevention effort, the health status of the patient/client determines whether this information falls under primary, secondary, or tertiary care. For example, providing information about how to be physically active for a

TABLE 4-1

Definitions and Examples of Prevention, Health Promotion, and Related Terms

TERM	DEFINITION	EXAMPLE
Prevention[5]	The avoidance, minimization, or delay of the onset of impairment, activity limitations, and/or participation restrictions. Includes primary, secondary, and tertiary prevention initiatives for individuals as well as selective intervention initiatives for subsets of the population at risk for impairments, activity limitations, and/or participation restrictions	
Primary prevention[5]	Efforts that prevent a target condition in a susceptible or potentially susceptible population through specific measures such as a general health promotion effort	Messages to the general population to be physically active; messages to teenagers to not smoke
Secondary prevention[5]	Efforts that decrease duration of illness, severity of disease, and number of sequelae through early diagnosis and prompt intervention	Breast cancer screening (early diagnosis and prompt treatment) Education for patients with diabetes to perform regular foot inspection (disability limitation)
Tertiary prevention[5]	Efforts that limit the degree of disability and promote rehabilitation and restoration of function in patients with chronic and irreversible diseases	Traditional rehabilitation services
Health promotion[62]	The process of enabling people to increase control over, and to improve, their health	Messages to eat 5–7 fruits and vegetables per day; walking trails in communities; no smoking laws
Health education[63]	Any combination of learning experiences designed to help individuals and communities improve their health, by increasing their knowledge or influencing their attitudes	Educational classes on nutrition, diabetes prevention, prenatal care
Health protection	Strategies related to engineering the physical environment	Water fluoridation
Preventive health services	Traditional medical system efforts to prevent injury and illness	Immunizations

client without injury or illness might be classified as primary prevention, whereas providing the same information to a client with diabetes would be considered secondary prevention, and including physical activity in an intervention plan for a diabetic client who is receiving rehabilitation for an amputation would be considered tertiary care.

In terms of primary prevention, health promotion is the most significant component for the physical therapist to understand (see Table 4-1).

It is critical to recognize that health promotion is broad and includes both individual and social/regulatory activities. For example, a physical therapist working for a large manufacturing company may want to begin a smoking cessation program to improve overall worker health. However, if the employer does not have a nonsmoking policy, efforts to stop smoking at the individual level will most likely be ineffective. Other illustrations of the broad net of health promotion include programs to increase the activity levels of adolescents or the elderly, corporate policies that provide release time to exercise, and funding to support or build public parks and trails. In addition to supporting individual patients/clients to improve their health, physical therapists can and should play a role in societal efforts to remove barriers to physical activity and thus to health.[9,10] For example, physical therapists can advocate for sidewalks, public transportation, and lit walkways in communities and serve on local health boards, city councils, and other community groups where decisions that impact the health of members of the community are made.

Based on these definitions, it is apparent that the term health education falls under the umbrella of health promotion, and often the activities that would define each are overlapping.[11]

Health education activities are planned out (e.g., designed), rather than incidental experiences, and facilitate behavioral changes without coercion (e.g., voluntary). Examples of health education initiatives include counseling a patient on the risks of smoking, providing an osteoporosis prevention class for a corporate wellness program, and teaching children how to carry and load their backpacks safely.

Both health promotion and health education refer to the "broad and varied set of strategies to influence both individuals and their social environments, in order to improve health behavior and enhance health and quality of life."[11(p.11)]

Physical Fitness, Exercise, and Physical Activity

Within the context of therapeutic exercise as discussed in this book, the physical therapist has a primary and important role in all types of prevention to keep people active. Several terms are used to describe what laypersons commonly refer to as "exercise." Physical activity has been defined as any bodily movement produced by skeletal muscles that results in energy expenditure.[12] Examples of physical activity include walking, performing yard or housework, and playing catch. Similarly, exercise is a type of physical activity that is planned, structured, repetitive, and is purposely aimed at improving physical fitness. Consistent with this definition, exercise is typically prescribed in terms of frequency, intensity, and duration in a dose adequate to improve physical fitness (discussed in greater detail in Chapter 6). Physical fitness is a set of attributes that people have or achieve and includes components of health-related (cardiorespiratory endurance, body composition, muscular

CASE STUDY 4-1

A 36-year-old male (Derek Prager) has come to your practice following a left ACL reconstruction performed 3 days ago. He tore his ACL 1 week ago sliding into second base during a company softball game. He had arthroscopic surgery to reconstruct the ACL. He arrives to your office with his knee wrapped in an elastic bandage and using crutches. During your subjective history you obtain the following information from Derek:

- He is married and has two children; a 12-year-old daughter and a 10-year-old son. His wife works full-time outside of the home.
- He works approximately 60 hours per week as a construction foreman. He spends about 2 hours per day in his office and the rest of the day he is traveling between residential construction sites supervising his crew. He tells you that his job has become much more stressful the past couple of years because of conflicts with his supervisor.
- Derek smokes a pack of cigarettes per day and has smoked for 16 years.
- He tells you that he was diagnosed with high cholesterol about a year ago. He is currently taking Lipitor (cholesterol-lowering medication) once a day.
- His father died of a massive heart attack at age 60. He has an older brother who he describes as "a health nut." His brother participates in triathlons and eats "rabbit food."
- Derek's hobbies include watching sports on television, watching his children's sporting activities, and playing on the company softball team one night per week.
- Derek tells you that he has gained weight over the past 5 years but doesn't weigh himself and because his wife buys his clothes he doesn't pay much attention to changes in his clothing sizes.

In addition to the physical findings that you obtained regarding Mr. Prager's left ACL reconstruction, you also obtain the following information:

- Height = 5′11″
- Weight = 208 lb
- Body mass index (BMI) = 29
- Relationship of BMI to weight status according to the Centers for Disease Control and Prevention
  - Below 18.5 = Underweight
  - 18.5 to 24.9 = Normal weight
  - 25.0 to 29.9 = Overweight
  - 30.0 and above = Obese
- Resting HR = 70 bpm
- Resting BP = 128/84

endurance, muscular strength, flexibility) and athletic-related skills. Assessment of physical fitness is used to measure the impact of exercise or physical activity on the components of fitness, such as a 12-minute walk test to assess cardiorespiratory endurance. Based on decades of research on a wide variety of age groups, inclusive of both sexes and individuals with all types of chronic and acute disease, physical activity has been shown to be an extremely powerful resource to keep people healthy and to improve impairments, activity level, and participation level in those with health conditions.[13]

Wellness, Lifestyle, and Quality of Life

Wellness is defined in the *Guide to Physical Therapist Practice*, 3.0, as "A state of being that incorporates all facets and dimensions of human existence, including physical health, emotional health, spirituality, and social connectivity."[5] Because Dunn[14] conceptualized wellness in 1961 and offered the first formal definition of the term ("an integrated method of functioning which is oriented toward maximizing the potential of which the individual is capable"), wellness has been explained by various models and approaches.[15–22] Although the literature is full of definitions of, references to, and information about wellness, a universally accepted definition has failed to emerge. Several conclusions can be drawn, however, from the abundance of literature about wellness (see **Building Block 4-1**).

BUILDING BLOCK 4-1

Consider the Patient in Case Study 4-1

1. Given the patient's history and examination findings, what health education and/or health promotion interventions might be indicated during the patient care episode?
2. Does Mr. Prager perform regular exercise?

For many people, including the public, health and wellness are synonymous with physical health or well-being, and commonly consists of physical activity, efforts to eat nutritiously, and adequate sleep. Research has indicated that when the public is asked to rate their general health, they narrowly focus on their physical health status, and do not consider their emotional, social, or spiritual health.[23] Referring back to the definitions introduced earlier, it is obvious that wellness includes more than just physical parameters. Wellness and fitness are not synonyms; as indicated in Chapter 1, well-being or wellness is a broad term, like quality of life, that the ICF defines as encompassing the total universe of human life.

The common themes that emerge from the various models and definitions of wellness suggest that wellness is multidimensi onal,[14,16–22,24,25] salutogenic or health causing,[14,16,19,20,22,26,27] and consistent with a systems view of persons and their environments.[14,28–30] Each of these characteristics will be explored.

First, as a multidimensional concept, wellness is more than simply physical health. Among the dimensions included in wellness are physical, spiritual, intellectual, psychological, social, emotional, occupational, and community or environmental.[31] Adams et al.[31] proposed six dimensions of wellness based on the strength and quality of the theoretical support in the literature.

TABLE 4-2

Definitions of the Dimensions of Wellness

Physical	Positive perceptions and expectancies of physical health
Psychological	A general perception that one will experience positive outcomes to the events and circumstances of life
Social	The perception that family or friends are available in times of need, and the perception that one is a valued support provider
Emotional	The possession of a secure sense of self-identity and a positive sense of self-regard
Spiritual	A positive sense of meaning and purpose in life
Intellectual	The perception that one is internally energized by the appropriate amount of intellectually stimulating activity

Adams T, Bezner J, Steinhardt M. The conceptualization and measurement of perceived wellness: integrating balance across and within dimensions. Am J Health Promot 1997;11:208–218.

The six dimensions and their corresponding definitions are shown in **Table 4-2**.

The second characteristic of wellness is that it has a salutogenic (e.g., health-causing) focus in contrast to a pathogenic focus in an illness model.[27] Emphasizing that which causes health is consistent with Dunn's original definition.[14] It suggests that wellness involves maximizing an individual's potential, not just preventing an injury or maintaining the status quo. Wellness involves choices and behaviors that emphasize optimal health and well-being beyond the status quo.

Third, wellness approaches use a systems perspective. In systems theory, each element of a system is independent and contains its own subelements, in addition to being a subelement of a larger system.[24,28,29] Further, the elements in a system are reciprocally interrelated, indicating that a disruption of homeostasis at any level of the system affects the entire system and all of its subelements.[28,29] Therefore, overall wellness is a reflection of the state of being within each dimension and a result of the interaction among and between the dimensions of wellness. **Figure 4-2** illustrates a model of wellness reflecting this concept. Vertical movement in the model occurs between the wellness and illness poles as the magnitude of wellness in each dimension changes (see "black arrow" in Fig. 4-2). The top of the model represents wellness because it is expanded maximally, whereas the bottom of the model represents illness.

The size of each dimension (a subelement in systems theory) represents how much wellness an individual possesses in that dimension. As wellness fluctuates in each dimension, an effect is generated on all of the other dimensions, resulting in the reciprocal interrelation (Fig. 4-2). According to systems theory, movement in every dimension influences and is influenced by movement in the other dimensions.[31] As an example, an individual who experiences a shoulder injury and undergoes surgery to repair the rotator cuff will probably experience at least short-term decreased physical wellness (the size of the physical dimension on the diagram will decrease). Applying systems theory and

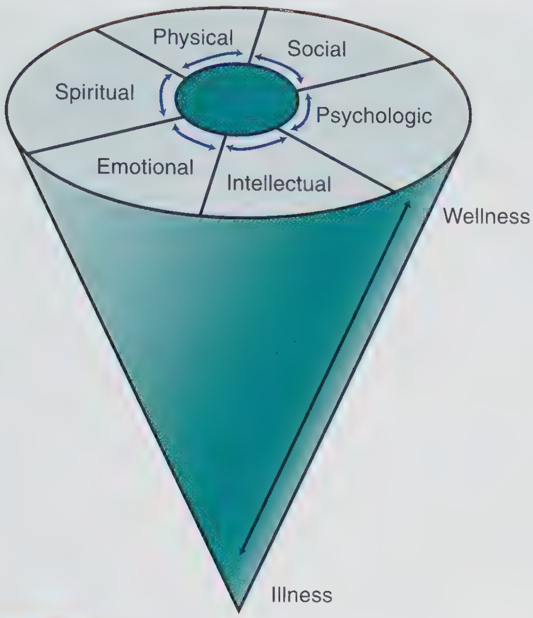

FIGURE 4-2 The wellness model.

according to the model, this individual may also experience a decrease in other dimensions, such as emotional, social, or psychological wellness, in the postoperative period resulting from the interrelatedness of all of the dimensions. The overall effect of the changes in these dimensions will be a decrease in overall wellness, which has anecdotally been shown to occur in patients when they experience a physical illness or injury. In other words, the individual also experiences a change in his or her emotional, social, or psychological states as a result of an unexpected injury; this may significantly impact body image, self-confidence, energy level, comfort, personal finances, work, etc. Further applying the model in terms of an intervention plan, focus on a nonphysical state, such as the emotional or social dimension, can positively affect the physical dimension and result in improved wellness during recovery from a health condition.

The term health-related quality of life has already been defined in the context of the ICF model in Chapter 1. A similar term, quality of life, is "an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns. It is a broad concept affected in a complex way by the person's physical health, psychological state, level of independence, social relationships, personal beliefs and their relationship to salient features of their environment."[32]

The word lifestyle differs from wellness and thus is also important to consider, because many significant causes of disease, such as obesity and diabetes, involve lifestyle choices.[33] The term "lifestyle" is defined as "the habits and customs influenced by the lifelong process of socialization, including social use of alcohol and tobacco, dietary habits, and exercise, all of which have important implications for health."[34] The complex notion of lifestyle recognizes that personal behaviors are significantly influenced by social and cultural circumstances, indicating that behavioral choices may not be entirely under volitional control. For example, there is a great deal of controversy over obesity and how much responsibility for obesity is the individual's versus a response to an obesogenic environment.[35] Consideration, therefore, of an individual's behaviors related to health and wellness is most appropriately done within the context of social and cultural influences, and, more importantly, interventions designed to change behaviors should recognize the important influence of the environment in which the patient loves, works, and plays. This understanding of lifestyle is congruent with definitions of wellness, because it acknowledges that there are multiple influences on behavior.

In summary, the terms wellness and well-being can be used interchangeably and refer to an individual's perception of self in a broad sense. Quality of life is also a broad term that refers to an individual's perception of life in a broad sense. Finally, lifestyle is a term that describes personal behaviors that impact health.

MEASUREMENT OF WELLNESS

As a result of the varied way that wellness has been defined and understood, a variety of wellness measures exist. A good wellness measure should reflect the multidimensionality and systems orientation of the concept and have a salutogenic focus. In the literature and in daily practice, clinical, physiologic, behavioral, and perceptual indicators are all touted as wellness measures.

- Clinical measure: blood lipid levels and blood pressure
- Physiologic indicators: include skinfold measurements and maximum oxygen uptake
- Behavioral measures: smoking status and physical activity frequency
- Perceptual measures: patient/client self-assessment tools such as global indicators of health status ("compared to other people of your age, would you say your health is excellent, good, fair, or poor?")[36] and the SF-36 Health Status Questionnaire[37]

Although clinical, physiologic, and behavioral variables are useful indicators of bodily wellness and are commonly used to plan individual and community interventions, they are incomplete measures of wellness.[38] Clinical and physiologic measures assess the status of a single system, most commonly within the physical domain of wellness. Overall, behavioral measures are a better reflection of multiple systems because of the influence of motivation and self-efficacy on the adoption of behaviors, but they do not describe the wellness of the mind. On the other hand, perceptual measures are capable of assessing all systems and have been shown to predict effectively a variety of health outcomes.[31,36,39–41] Perceptual measures can complement the information provided by body-centered measures.[38]

Although some perceptual measures assess only single-system status (e.g., psychological well-being, mental well-being), numerous multidimensional perceptual measures exist and can serve as wellness measures. Perceptual constructs that have been used as wellness measures include general health status,[37] subjective well-being,[42,43] general well-being,[44,45] morale,[46,47] happiness,[48,49] life satisfaction,[50–52] hardiness,[53,54] and perceived wellness.[31,55,56] Example questions from a few of these perceptual tools are listed in **Table 4-3**.

The influence of perceptions on health and wellness has been demonstrated repeatedly in a variety of patient/client populations and a variety of settings. Mossey and Shapiro[36]

TABLE 4-3

Sample Items from Perceptual Measurement Tools

INSTRUMENT	PERCEPTUAL CONSTRUCT	SAMPLE ITEMS (RESPONSES)
Short-Form 36 (SF-36)[37]	General health perceptions	"In general, would you say your health is" (excellent, very good, good, fair, or poor) "Compared to 1 y ago, how would you rate your health in general now?" (much better than 1 y ago, somewhat better, about the same, somewhat worse, much worse)
Satisfaction with Life Scale[64]	Life satisfaction	"In most ways my life is close to my ideal" "I am satisfied with my life" (7-point Likert scale from strongly disagree [1] to strongly agree [7])
Perceived Wellness Survey[31]	Perceived wellness	"I am always optimistic about my future" "I avoid activities that require me to concentrate" (6-point Likert scale from very strongly disagree [1] to very strongly agree [6])
NCHS[a] General Well-Being Schedule[42]	General well-being	"How have you been feeling in general?" (During the past month) (In excellent spirits, In very good spirits, In good spirits mostly, I have been up and down in spirits a lot, In low spirits mostly, In very low spirits) "Has your daily life been full of things that were interesting to you?" (During the past month) (All the time, Most of the time, A good bit of the time, Some of the time, A little of the time, None of the time)
Philadelphia Geriatric Center Morale Scale[65]	Morale	"Things keep getting worse as I get older" "I am as happy now as when I was younger" (yes, no)
Memorial University of Newfoundland Scale of Happiness[49]	Happiness	"In the past months have you been feeling on top of the world?" "As I look back on my life, I am fairly well satisfied" (yes, no, don't know)

demonstrated more than 25 years ago that self-rated health was the second strongest predictor of mortality in the elderly, with age being the strongest predictor. Numerous other researchers have replicated these findings in other populations, lending support to the value of perceptions in understanding health and wellness and indicating that how well you *think* you are may be more important than how well you *actually* are. Patient's perceptions are critical in understanding and explaining quality of life.[38] Health perceptions provide an important link between the biomedical model with its focus on "etiological agents, pathological processes, and biological, physiologic, and clinical outcomes" and the quality of life model, with its focus on "dimensions of functioning and overall well-being"[38] (**Fig. 4-3**). Health perceptions "are among the best predictors of general medical and mental health services as well as strong predictors of mortality, even after controlling clinical factors."[36,38]

Physical therapists assess perceptions as a part of the patient/client history, as recommended in the *Guide to Physical Therapist Practice*.[5] Some of the kinds of perceptions that can be assessed include perceptions of general health status, social support systems, role and social functioning, functional status in self-care and home management activities, and work, community,

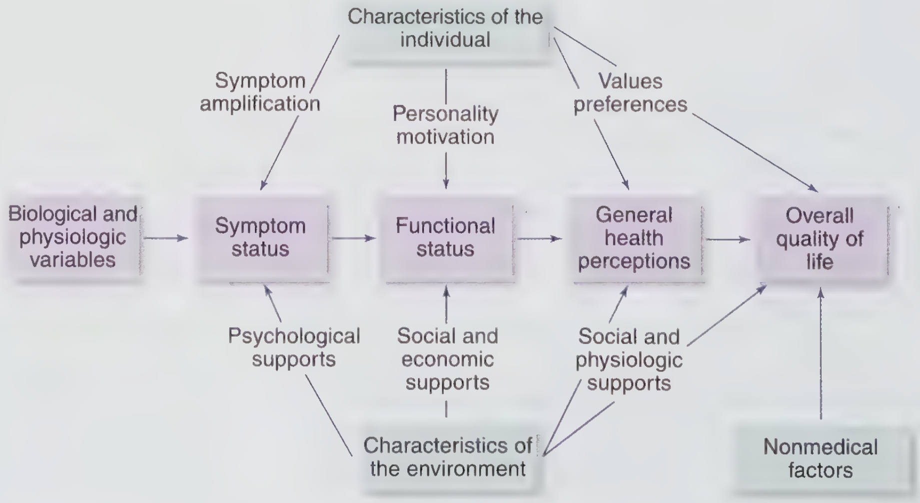

FIGURE 4-3 Health-related quality of life conceptual model. (Reprinted with permission from Mokdad AH, Ford ES, Bowman BA, et al. Prevalence of obesity, diabetes, and obesity-related health risk factors, 2001. JAMA 2003;289:76–79.)

and leisure activities. Although a few of these categories are included in overall wellness, such as general health status and social and role functioning, measuring wellness perceptions specifically can provide additional and more complete information about the patient that the physical therapist can use to formulate a plan of care unique to the patient/client. Therefore, perceptual tools should be included when measuring wellness within a primary prevention context and when examining patients/clients within a secondary or tertiary prevention context (see **Building Block 4-2**).

BUILDING BLOCK 4-2

Consider the Patient in Case Study 4-1

1. How do you think Mr. Prager's perceived wellness will be impacted by his knee injury?
2. How would you describe Mr. Prager's lifestyle?
3. What assessment tool would you use to measure perceptions?
4. Why use one of these perceptual instruments?

HEALTH PROMOTION AND WELLNESS-BASED PRACTICES

Establishing a wellness-based practice or offering health promotion and wellness services requires that the physical therapist modify the traditional approach used to treat patients. Creating a successful wellness-based practice has many unique features:

- Changing the focus from illness to wellness
- Being a role model of wellness
- Incorporating wellness measures into the examination
- Considering the client within his or her lifestyle or "system"
- Offering services beyond the traditional patient–provider relationship

From Illness to Wellness

The types of services provided in a physical therapist wellness-based practice can be varied and are influenced by the population served, the skills and expertise of the physical therapist, and the setting in which the services are provided. Based on the definition and characteristics of wellness provided earlier in this chapter, wellness services can be provided in any setting and to any population—it simply requires changing the approach to consider patients as clients who have the potential and opportunity to be more well.

The most common wellness-based practices are integrated within a traditional physical therapist practice in which patients convert to "members" after discharge for a specific diagnosis.[57] These patients/clients use the clinic or fitness facility to continue their exercise program. In this case, the client would have access to the facility to perform an individually or group prescribed exercise program and to the physical therapist who would be available to answer questions and progress the client's program. Additionally, to truly address "wellness," the provider must consider offering services beyond the physical domain. In other words, providing the "nonpatient" with the opportunity to continue an exercise program under the supervision of the physical therapist addresses the physical component of wellness, and although exercise can impact the other dimensions of wellness as described earlier, specific interventions aimed at the other dimensions of wellness would provide a holistic approach to wellness, as described below.

Establishing a wellness-based practice within an existing physical therapist practice requires several features. The facility should be available and staffed at convenient hours for clients; the staff should have expertise in exercise prescription as well as awareness and knowledge of wellness. For example, opportunities can be created to acknowledge the influence of social connections on wellness by offering group classes and group interaction among clients. The intellectual aspect of wellness can be tapped by providing educational resources and challenges for clients. For example, offering an educational class on topics such as progressing an exercise program or nutrition, followed by a test of understanding of the class topic are activities that would use and challenge the intellectual dimension. Additional staff with expertise in mental and spiritual health can be retained as consultants to provide services in these dimensions when indicated or requested by clients. Some facilities provide an integrated experience, with mental and spiritual health as a component of the wellness program.

Establishing a wellness-based practice also requires that the provider assume the role of a facilitator or partner rather than that of an authority figure.[58] When a patient is ill, it is often appropriate for the health care provider to act as the expert when the patient has limited ability to provide self-care and is relying on the provider for information and skills to recover and improve. In a wellness setting, the best approach is to believe that the client knows best in terms of maximizing his or her potential, therefore assuming a partner or facilitator role is more appropriate and will create a relationship in which the client feels empowered to take control. Rather than "making" the client well, the provider can view the client as a whole person within a biopsychosocial context and consider teaching the client how to achieve wellness. Being a role model and fulfilling the role of facilitator will establish a relationship and environment in which clients can attain greater wellness.

The Use of Screening as an Examination Tool Within a Wellness-Based Practice

Screening, or determining the need for further examination or consultation by a physical therapist or for referral to another health professional, is important and applicable in a health promotion context because it enables identification of the health status, personal goals, and available resources of the client. Within a physical therapist's scope of practice and a health promotion/wellness context, clients can be screened in numerous ways. Physical therapists routinely screen for osteoporosis, physical activity level, balance/risk for falls, muscle strength and endurance, and flexibility. Physical therapists can also screen perceptions, including perceived wellness and quality of life, and motivation to change health-related behaviors or adopt new behaviors. A number of tools have been developed and are available in the literature for use in screening clients. Example perceptual screening tools that can be used in a wellness or primary prevention context and their uses are listed in **Table 4-4**.

Screening tools can be used to identify whether or not a client has risks that should be investigated before participating in an

TABLE 4-4

Perceptual Screening Tools

PERCEPTUAL SCREENING TOOL	USE	RESOURCE/REFERENCE	PHYSICAL THERAPY APPLICATION
Physical Activity Readiness Questionnaire	General activity screen for ages 15–69	Canadian Society for Exercise Physiology http://www.csep.ca/en/publications	Indicates whether or not an individual should seek further medical consultation before beginning an aerobic exercise program
Self-efficacy for Exercise Questionnaire	Assesses the beliefs one has regarding success with physical activity	Marcus et al.[66]	Provides the physical therapist with information about perceptions of success with physical activity, which can be a barrier to adopting an activity habit if not addressed
Physical Activity Enjoyment Scale	Assesses how enjoyable a client finds exercise	Kendzierski and DeCarlo[67]	Provides information about how enjoyable a client finds exercise. Researchers have found that enjoyment is related to adherence to physical activity, so when enjoyment is low it should be addressed in the exercise prescription
Motivational Readiness for Change Scale (Transtheoretical Model)	Assesses a client's readiness to change for any behavior (exercise, smoking, etc.)	Marcus and Simkim[68]; Prochaska and DiClemente[69]	Provides information from which the physical therapist can tailor the intervention for a specific behavior. For example, if a client is not ready to change, the intervention will be very different compared to a client who is ready to make a change
Short Form 36 (SF-36)	General perceptual health status and outcomes questionnaire	Medical Outcomes Trust www.outcomes-trust.org	Provides information about perceptions in eight health concepts, including physical functioning, role limitations resulting from physical health problems, bodily pain, social functioning, general mental health, role limitations resulting from emotional problems, vitality (energy/fatigue), and general health perceptions. Can be used to determine the relative burden of an injury or illness and to document the relative benefits/outcomes of an intervention or interventions
Perceived Wellness Survey	General perceptual wellness survey	Adams et al.[31]	Provides information about general wellness perceptions in six dimensions, including physical, emotional, social, psychological, spiritual, and intellectual. Can be used to determine the relative burden of an injury or illness and to document the effect of an intervention on overall wellness
Risk for Falls	Assesses a client's risk for falling	Balance Self-Test www.balanceandmobility.com/patient_info/printout.aspx	Indicates an individual's risk for falling and thus the need for further examination and intervention
Computer Workstation Checklist	Identifies clients at risk for injury as a result of computer use	www.osha.gov/SLTC/etools/computerworkstations/checklist.html	Identifies specific areas within a computer workstation where problems may exist that would benefit the worker to be addressed. Includes the areas of posture, seating, keyboard/input device, monitor, work area, accessories, and general issues

intervention program. The physical therapist can also use the screening information to identify who should perform further examination and intervention, and the conditions under which the intervention should be performed (e.g., with or without supervision, the need for a medical diagnostic test). Screening tools can also identify a baseline from which progress can be assessed and documented. Depending on specific state law, screens may be performed on existing clients or can be used to identify those who would benefit from services.

Starting a Wellness-Based Practice

The mechanics of starting a specific wellness-based practice do not differ from starting or expanding any type of practice.

The first step should include verifying that "wellness" or "health promotion" is included within the definition and description of physical therapy in the state practice act.[59] Second, the liability policy should be checked to ensure coverage for wellness-type activities. As with any new endeavor, physical therapists should spend time identifying and understanding the potential risks involved in the provision of wellness services.

Although great strides have been made in the area of insurance coverage for health promotion and wellness services, most insurers do not reimburse health care providers for these services. However, the public understands the value of these services and is becoming more and more willing to pay directly for them.[60] Although there isn't a specific formula for determining the mechanics of charging for health promotion services and integrating these services into a physical therapist practice, following the same practice management and business principles used in creating any physical therapist practice, as well as knowing what other providers charge for health promoting services, will result in a service that will be competitive in the market as well as provide a valuable service for clients. A rich section of resources can be found on the APTA website (www.apta.org/PatientCare) in the Prevention, Wellness, and Disease Management section of the Patient Care page. In the case of populations that are unable to afford these types of services, consider providing more affordable group and community programs, applying for state and federal grants to support programs, or providing pro bono services that offer recognition through positive public relations.

Other activities that should be well thought out and planned include marketing and advertising the program and evaluating the program's success. Although specifics of these activities are outside the scope of this chapter, they are key to overall program effectiveness. Whether you are starting a specific wellness-based practice or program or are adopting a wellness approach within an existing health care setting, shifting from a medical to a biopsychosocial focus, recognizing that, as important as they may be, there is more to wellness than physical parameters. As such, adding the assessment of perceptions to your examination toolbox is a critical approach that will provide a strong basis for a wellness program.

PHYSICAL WELL-BEING: PHYSICAL ACTIVITY PROGRAMS

Transitioning a patient within a physical therapist practice from an intervention program addressing specific impairments to a general physical activity program addressing overall physical fitness and/or quality of life, and keeping in mind the impairments the physical therapist was addressing, is an approach physical therapists can and should consider. Physical therapists are uniquely qualified to create physical activity programs that enhance overall fitness and quality of life, while concurrently addressing specific neuromusculoskeletal impairments that require the expertise of the physical therapist. The 2008 Physical Activity Guideline recommendations include that adults accumulate 150 minutes per week of moderate physical activity or 75 minutes per week of vigorous activity and perform muscle strengthening activities that are of moderate or high intensity and involve all major muscle groups twice per week.[13] Physical therapists within the context of primary prevention can assist clients to achieve this goal safely and effectively by routinely inquiring about patient/client physical activity habits, conducting physical fitness assessments, prescribing physical activity to improve general health and well-being, and encouraging clients to adopt an active lifestyle.

Conducting Health-Related Physical Fitness Assessments

Clients who desire a physical activity program for improvement of overall physical fitness and/or quality of life should receive a physical therapist examination and evaluation similar to any other patient/client seen by a physical therapist. Parts of the examination may be abbreviated or taken from the patient/client's existing medical record in the case of a patient/client who was treated by the physical therapist for a specific impairment or health condition in the recent past. Prior to engaging in a physical activity or exercise program, clients should be screened to determine their readiness and appropriateness for exercise. For individuals who do not require medical evaluation as described in Chapter 6, preparticipation screening can be performed using a self-report questionnaire, such as the Physical Activity Readiness Questionnaire or PAR-Q[60,61] (see Appendix 3). Based on the answers to the seven questions on the PAR-Q, individuals between the ages of 15 and 69 can either appropriately participate in exercise or be referred to a physician for further evaluation before beginning an exercise program. All individuals who fall outside of the boundaries described should be referred to a physician for medical evaluation before participating in exercise training.

Depending on the client's goals for an exercise program, the five elements of physical fitness should be assessed to create a baseline and from which to prescribe exercise. **Table 4-5** provides examples of the types of tests that can be used to assess each of the five elements of physical fitness. For example, for a client who desires to lose weight through physical activity and nutrition modification, body composition and cardiorespiratory endurance should be assessed at a minimum to establish a baseline of weight, body fat, and cardiorespiratory fitness and to establish goals and assess progress. If a general systems screen indicates impairments in musculoskeletal areas that might be impacted by physical activity, tests of muscular endurance, strength, and flexibility should also be performed. In general, a personalized physical activity prescription should be prescribed based on the patient/client's specific physical characteristics, which will prevent injury, enhance participation and adherence, and promote overall physical fitness.

Establishing Physical Activity Interventions

Armed with the results of a patient/client history, including goals for physical activity, systems review, and physical fitness testing, the physical therapist can establish a physical activity program for a client. Specific aspects of the history that may be useful when prescribing exercise include past experience with exercise or physical activity, dietary habits, social situation, and current medications. This information can be useful and necessary to ensure safety, enjoyment, adherence, and effectiveness when creating an exercise program for a client.

TABLE 4-5

Health-Related Physical Fitness Tests

PHYSICAL FITNESS PARAMETER	TEST NAMES	TEST DESCRIPTION	REFERENCE/RESOURCE
Body composition	1. Body mass index 2. Waist to hip ratio 3. Skin fold measurements	1. Ratio of weight to height (weight in kg/height in m) 2. Circumference of waist at smallest point/circumference of hips at largest point 3. Uses skin fold calipers to assess amount of fat using standardized equations	American College of Sports Medicine[61,70]
Cardiorespiratory endurance	1. Cooper 12-min test 2. 1.5 mile test 3. 3-min YMCA step test 4. Astrand-Rhyming cycle ergometer test	1. Participant walks or runs to cover the greatest distance in 12 min. 2. Participant runs or walks the distance in the shortest period of time. 3. Using a 12-inch-high step, the participant steps up and down at a rate of 24 steps/min for 3 min. Heart rate is measured immediately for 1 min and used to estimate VO_2. 4. Participant cycles on a stationary cycle ergometer for 6 min at a standard resistance, pedaling at a rate of 50 rpm. Heart rate is taken twice and used to estimate VO_2.	American College of Sports Medicine[70]
Flexibility	1. Sit and reach test 2. Standard flexibility tests	1. Test to assess low back and hip joint flexibility; client in long sitting, reaches with both hands between outstretched legs as far as possible and tester measures distance reached 2. Tests to determine joint range of motion specific to each joint	American College of Sports Medicine[61,70]
Muscular endurance	1. Total number of repetitions at a given amount of resistance 2. Total number of repetitions at a % of 1 repetition maximum (RM) 3. Curl up 4. Push-up	1. Participant performs as many repetitions of a specific movement as possible at a submaximal level of resistance to fatigue. 2. Same as no. 1 using a percentage of 1 RM 3. Participant is supine with knees at 90 degrees, arms at side, palms facing up. Client performs slow controlled curl ups at a rate of 25 per minute. Tester counts the number per minute. 4. Male participants use standard "down" position and females "knee push-up" position. Participant raises body by straightening elbows and returns to down position keeping back straight. Tester counts the number per minute.	American College of Sports Medicine[61,70]
Muscular strength	1. Manual muscle testing 2. 1 RM	1. Manually applied resistance to specific muscle groups based on established norms and using standard scales 2. The greatest resistance that can be moved through the full range of motion in a controlled manner with good posture	American College of Sports Medicine[70]

There are numerous ways clients can become more physically active, including but not limited to walking, cycling, climbing stairs, doing yardwork and housework, and dancing. Clients who have been appropriately screened can engage in any type of physical activity that appeals to them and that they enjoy and will perform consistently. Setting a goal of 30 minutes of physical activity, 5 days per week for an inactive client, consistent with government guidelines, provides great latitude in terms of activity, and yet is achievable for most people. To achieve health-related benefits, physical activity can be performed in smaller bouts and does not need to be continuous or performed all at one time. For example, three 10-minute walks per day satisfy the goal of 30 minutes of moderate physical activity per day and perhaps can be incorporated more easily into the busy and demanding lifestyle of an individual who struggles to find time for physical activity (see **Building Block 4-3**).

BUILDING BLOCK 4-3

Consider the Patient in Case Study 4-1

1. Near the end of his episode of care for his knee rehabilitation, Mr. Prager indicates that he is worried and has gained weight over the past 6 weeks while rehabilitating his knee. What might you suggest for Mr. Prager?
2. You administer the PAR-Q to Mr. Prager. What does the PAR-Q indicate?
3. What assessment tool would you use to assess body composition?
4. How would you address stress with Mr. Prager?
5. Create a physical activity program involving walking that incorporates physical activity into Mr. Prager's lifestyle.

Some clients may have specific goals that require more than the minimum amount of physical activity for health-related well-being, like running a marathon, playing recreational soccer, or losing weight. In these situations, specific exercise prescriptions should be established including well-defined and tailored doses of exercise in order to accomplish the specific client goal. The information in Chapter 6 is designed to assist in creating these types of exercise prescriptions.

KEY POINTS

- Prevention is classified as primary, secondary, or tertiary
- Health promotion and wellness fall into the realm of primary prevention, whereas most rehabilitation is secondary or tertiary prevention
- The terms health promotion and health education are often used interchangeably
- Physical activity is any bodily movement produced by skeletal muscles resulting in energy expenditure, whereas exercise is planned, structured, and repetitive and is a type of physical activity
- Wellness is multidimensional, salutogenic, and requires a systems perspective and can be used interchangeably with the term well-being
- Wellness extends beyond only the physical domain to include many other dimensions such as spiritual, intellectual, psychosocial, and emotional well-being
- Perceptual measures are often better predictors of general well-being than physiologic measures
- Wellness requires a vision beyond just the physical domain and the biomedical model
- Physical therapists should assess the physical activity level of their patients/clients and encourage patients/clients to become more physically active, including establishing physical activity programs to enhance health-related quality of life and well-being

Impairments of Body Functions and Therapeutic Exercise

UNIT 2

CHAPTER

5

Impaired Muscle Performance

LORI THEIN BRODY • CARRIE M. HALL

Muscular performance is an essential component of a person's life. Every human activity from breathing to walking to the bathroom to running a marathon requires muscle activity. Physiologic, anatomic, psychological, and biomechanical factors affect muscle performance. Pathology and disease affecting the cardiovascular, endocrine, integumentary, musculoskeletal, neuromuscular, or pulmonary systems can also affect muscle performance; strength training can improve the function of these systems. Muscle performance impairments can be considered as impairments in muscle *strength, power,* or *endurance*. These impairments must be related to an activity limitation or participation restriction, or promote prevention, health, wellness, and fitness, in order to justify therapeutic exercise intervention. For example, an individual lacking the muscular ability to carry a bag of groceries into the house requires intervention to achieve this instrumental activity of daily living. A worker lacking the muscle endurance to maintain efficient posture and safe movement patterns throughout the workday requires intervention to prevent work disability. A person with osteoarthritis of the knee and poor quadriceps muscle performance requires quadriceps muscle training to prevent further knee joint deterioration.

Although not all scientific and clinical information on strength, power, and endurance production can be covered in this text, this chapter provides a strong foundation for this element of therapeutic exercise intervention. Fundamental terms and concepts are defined, the essential morphology and physiology of skeletal muscle relative to muscle performance are reviewed, and clinical applications are presented.

DEFINITIONS

Definitions of key terms vary from one researcher, text, or profession to another. The following definitions are presented to clarify how these terms will be used throughout this text.

Strength

Impaired muscle performance is commonly treated by clinicians and is usually described as a strength deficit. However, strength is only one of the three components of muscle performance (i.e., strength, power, and endurance).

Strength is defined as the maximum force that a muscle can develop during a single contraction, and is the result of complex interactions of neurologic, muscular, biomechanical, and cognitive systems. Strength can be assessed in terms of force, torque, work, and power. If appropriate decisions are to be made regarding these impairments, operational definitions are necessary.

Force is an agent that produces or tends to produce a change in the state of rest or motion of an object.[1] For example, a ball sitting stationary on a playing field remains in that position unless it is acted upon by a force. Force, described in metric units of newtons (N) or British units of lb, is displayed algebraically in the following equation:

$$\text{Force} = \text{mass} \times \text{acceleration}$$

Kinetics is the study of forces applied to the body. Some of the factors influencing muscular force production include the neural input, mechanical arrangement of the muscle, cross-sectional area, fiber-type composition, age, and gender.[1]

Torque is the ability of a force to produce rotation. All human motion involves rotation of body segments about their joint axes. These actions are produced by the interaction of forces from external loads and muscle activity. Torque represents the rotational effect of a force with respect to an axis:

$$\text{Torque} = \text{force} \times \text{moment arm}$$

The *moment arm* is the perpendicular distance from the line of action of the force to the axis of rotation. The metric unit of torque is newton-meter (Nm); the foot-pound (ft lb) is used in the older British system of units.

Clinically, the word *strength* is often used synonymously with torque. Large amounts of torque are produced by the musculoskeletal system during everyday functional activities such as walking, lifting, and getting out of bed. Torque can be altered in biomechanics through three strategies:

1. Changing the force magnitude
2. Changing the moment arm length
3. Changing the angle between the direction of force and momentum

In the human musculoskeletal system, changing the force magnitude (i.e., tension-producing capability of muscle) can be altered by training. The moment arm can be decreased by positioning a load closer to the body, and the angle between the force and moment arm may be changed by altering joint alignment through postural education (see **Building Block 5-1**).

BUILDING BLOCK 5-1

A patient with thoracic spine and neck pain works at a research laboratory where the work stations are positioned such that it requires the patient to either (a) bend over a table top or (b) work with her arms extended well in front of his or her at shoulder height. Please apply the three principles of altering torque just discussed to minimize thoracic and cervical spine pain for this patient.

Power and Work

Power is the rate of performing work. *Work* is the magnitude of a force acting on an object multiplied by the distance through which the force acts. The unit used to describe work is the joule (J), which is equivalent to 1 Nm (the foot-pound unit is used in the British system). Work is algebraically expressed in this equation:

$$\text{Work} = \text{force} \times \text{distance}$$

The unit of power in the metric system is watt, which is equal to 1 J per second (foot-pound per second in the British system). Power can be determined for a single body movement, a series of movements, or for a large number of repetitive movements, as in the case of aerobic exercise. Power is algebraically expressed as:

$$\text{Power} = \text{work/time}$$

For the simple movement of lifting or lowering a weight, the muscle must overcome the weight of the limb and the weight (force), acting some distance from the axis of rotation (torque) through a range of motion (ROM) (work) during a specific time frame (power). This example summarizes the practical aspects of force, torque, work, and power in resistance training.

Endurance

Endurance is the ability of muscle to sustain forces repeatedly or to generate forces over a certain period of time. It is often measured as the ratio of the peak force that can be generated by a muscle at a given point in time, relative to the peak force that was possible during a single maximum contraction. Muscle endurance is the ability of a muscle group to perform repeated contractions against a load. This load can be applied externally or as a result of posture, such as when someone is working over a desk, counter, or work station all day (**Fig. 5-1**). Muscle endurance can be examined by isometric contractions, repeated dynamic contractions, or repeated contractions on an isokinetic dynamometer.

Muscle Actions

Poorly defined muscle actions can be a source of confusion and inaccuracy. Resistive exercise uses various types of muscle contraction to improve impaired muscle performance. Muscle actions can be divided into two general categories: static and dynamic. A static muscle action, traditionally referred to as *isometric*, is a contraction in which force is developed without any motion about an axis, so no work is performed. The amount of force generated by the muscle matches the external resistance applied.

All other muscle actions involve movement and are called *dynamic* or *isotonic*. An **isotonic exercise** suggests a uniform

A B

FIGURE 5-1 Individual standing at a computer workstation using **(A)** poor posture or **(B)** good posture.

force throughout a dynamic muscle action. No dynamic muscle action uses constant force because of changes in mechanical advantage and muscle length. *Isotonic* is therefore an inappropriate term to describe human exercise performance, and the term *dynamic* is preferred.

Dynamic muscle action is further described as concentric or eccentric action. The term *concentric* describes a shortening muscle contraction, and the term *eccentric* describes a lengthening muscle contraction. A concentric contraction happens when the internal force generated by the muscle exceeds the external load, whereas an eccentric contraction occurs when the external load exceeds the muscle force and the muscle lengthens while still developing tension.[2] Eccentric contractions differ from concentric and isometric contractions in several important ways. Per contractile unit, compared to concentric contractions, eccentric contractions:

- Can generate more tension and at a lower metabolic cost (i.e., less use of ATP-derived energy)[3]
- Are an important component of a functional movement pattern (e.g., required to decelerate limbs during movement)
- Are the most energy-efficient form
- Can develop the greatest tension of the various types of muscle actions

The term *isokinetic* refers to a concentric or eccentric muscle contraction in which a constant velocity is maintained throughout the muscle action. A person can exert a continuous force by using an isokinetic device, which provides a resistive surface that restricts movement to a preset, constant velocity. Some acceleration and deceleration occurs as the individual accelerates the limb from a resting position to the preset velocity and decelerates the limb to change directions. By constraining the speed of the isokinetic device, the limb moves at a constant velocity. Because the device cannot be accelerated beyond the preset speed, any unbalanced force exerted against it is resisted by an equal and opposite force. This muscular force may be measured, displayed, recorded, or used as concurrent visual feedback. Although the isokinetic device may be moving at a constant velocity, it does not guarantee that the user's muscle activation is at a constant velocity. Despite this inaccuracy, the terms *isokinetic* and *isotonic* to describe muscle action are likely to be employed for pragmatic reasons.

During functional movement patterns, combinations of static and dynamic contractions occur. Trunk muscles contract isometrically to stabilize the spine and pelvis during movements of the extremities such as reaching or walking. Lower extremity muscles are subjected to impact forces requiring combinations of concentric and eccentric contractions, sometimes within the same muscle acting at two different joints. Muscles commonly perform eccentric contractions against gravity, as in slowly lowering the arm from an overhead position.

Muscles often act eccentrically and then contract concentrically. The combination of eccentric and concentric actions forms a natural type of muscle action called a *stretch-shortening cycle* (SSC).[4,5] The SSC results in a final action (i.e., concentric phase) that is more powerful than a concentric action alone. This phenomenon is called *elastic potentiation*.[5] The SSC is discussed in more detail later in this chapter.

PHYSICAL FACTORS AFFECTING MUSCLE PERFORMANCE

The total force a muscle can produce is influenced by numerous factors. Knowledge of muscle morphology, physiology, and biomechanics is critical for successful therapeutic exercise prescription. The following section discusses the primary factors influencing force production and, hence, muscle performance. A brief review of the structure of muscle and the physiology of muscle contraction can be found on thePoint.lww.com/BrodyHall4e.

Fiber Type

Sedentary men and women and young children possess 45% to 55% slow-twitch fibers.[6] Persons who achieve high levels of sport proficiency have the fiber predominance and distributions characteristic of their sport. For example, those who train for endurance sports have a higher distribution of slow-twitch fibers in the significant muscles, and sprint athletes have a predominance of fast-twitch fibers. Other studies show that men and women who perform in middle-distance events have an approximately equal percentage of the two types of muscle fibers.[7] Any resistive rehabilitation program should be based on the probable distribution of fiber type of the individual.

Clear-cut distinctions between fiber-type composition and athletic performance are true for elite athletes. A person's fiber composition is not the sole determinant of performance. Performance capacity is the end result of many physiologic, biochemical, and neurologic components, not simply the result of a single factor such as muscle fiber type.[6]

Fiber Diameter

Although the different fiber types show clear differences in contraction speed, the force developed in a maximal static action is independent of the fiber type but is related to the fiber's cross-sectional diameter. Because type I (slow-twitch) fibers tend to have smaller diameters than type II (fast-twitch) fibers, a high percentage of type I fibers is believed to be associated with a smaller muscle diameter and therefore lower force development capabilities.[8]

Muscle Size

When adult muscles are trained at intensities that exceed 60% to 70% of their maximum force-generating capacity, the muscle increases in cross-sectional area and force production capability. The increase in muscle size may result from increases in fiber size (i.e., hypertrophy), fiber number (i.e., hyperplasia), interstitial connective tissue, or some combination of these factors.[9,10]

Although the major mechanism for increased muscle size in adults is hypertrophy, ongoing controversy surrounds evidence of hyperplasia. Mammalian skeletal muscle does possess a population of reserve or satellite cells that, when activated, can replace damaged fibers with new fibers.[11,12] The mechanisms for fiber hyperplasia probably are the result of satellite cell proliferation and longitudinal fiber splitting.[9]

Despite few investigations of the effect of strength training on interstitial connective tissue, it appears that, because interstitial connective tissue occupies a relatively small proportion of the total muscle volume, its potential to contribute substantial changes in muscle size is limited.[13]

Force–Velocity Relationship

Muscle can adjust its active force to precisely match the applied load. This property is based on the fact that active force continuously adjusts to the speed at which the contractile system moves. When the load is small, the active force can be made correspondingly small by increasing the speed of shortening appropriately. When the load is high, the muscle increases its active force to the same level by slowing the speed of shortening (**Fig. 5-2**).[14]

Slowing the speed of contraction allows a patient time to develop more tension during concentric contractions. This principle is evident during resistive exercise in water, where the water's viscosity slows limb movement, allowing more time for tension development. However, during eccentric contractions, increased speed of lengthening produces more tension. This appears to provide a safety mechanism for limbs excessively loaded. Increasing the speed of a concentric contraction significantly lowers the amount of concentric torque developed. In contrast, increasing the speed of an eccentric contraction increases the amount of torque developed until a plateau speed is reached.

Length–Tension Relationship

A muscle's capacity to produce force depends on the length at which the muscle is held with maximum force delivered near the muscle's normal resting length (**Fig. 5-3**). The relationship between strength and length is called the length–tension property of muscle. The number of sarcomeres in series determines the distance through which the muscle can shorten and the length at which the muscle produces maximum force. Sarcomere number is not fixed, and in adult muscle, this number can increase or decrease (**Fig. 5-4**).[15] Regulation of sarcomere number is an adaptation to changes in the functional length of a muscle.

Length-associated changes can be induced by postural malalignment or immobilization.[16,17] In muscles chronically maintained in a shortened range because of faulty posture or immobilization, sarcomeres are lost, and the remaining sarcomeres adapt to a length that restores homeostasis; the new length enables maximum tension development at the new immobilized, shortened position.[18] For example, people who spend most of the day sitting can develop adaptive shortening of their hip flexor muscles. These muscles need to be stretched to avoid chronic shortening. In muscles immobilized or posturally held in a lengthened position, sarcomeres are added, and maximum tension is developed at the new increased length. This may be true of people at workstations where the scapular retractor muscles are lengthened due to thoracic kyphosis and a chronically protracted scapula. When a cast is removed or posture restored, the sarcomere number returns to normal. The stimulus for sarcomere length changes may be the amount of tension along the myofibril or the myotendon junction, with high tension leading to an addition of sarcomeres and low tension to a subtraction of sarcomeres.[19]

The clinical implication of the length–tension relationship is that the evaluation of muscle "strength" must be reconsidered. Muscles that tend to be shortened (e.g., hip flexors) may test as strong as normal-length muscles, because the manual muscle test position is a shortened position.[20] Conversely, the lengthened

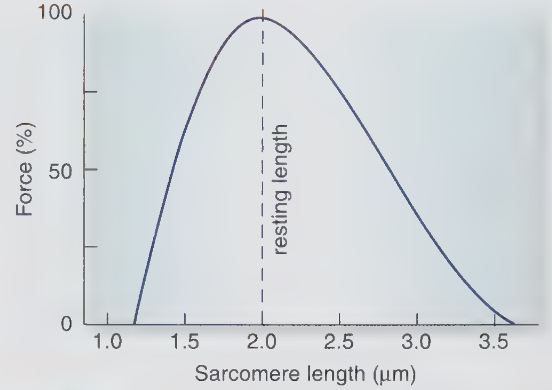

FIGURE 5-3 The length–tension curve depicts the relationship between muscle length and force development.

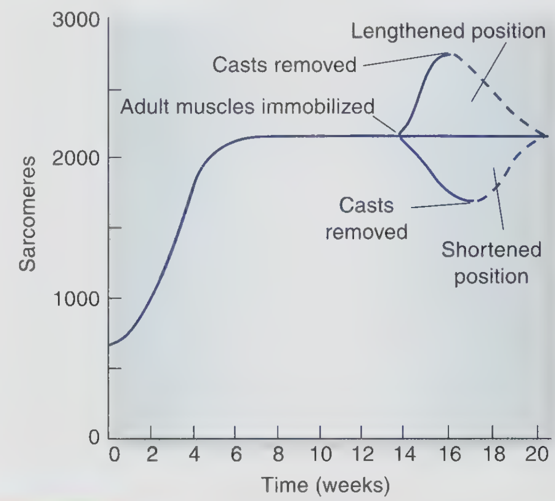

FIGURE 5-4 Changes in the number of sarcomeres in various conditions.

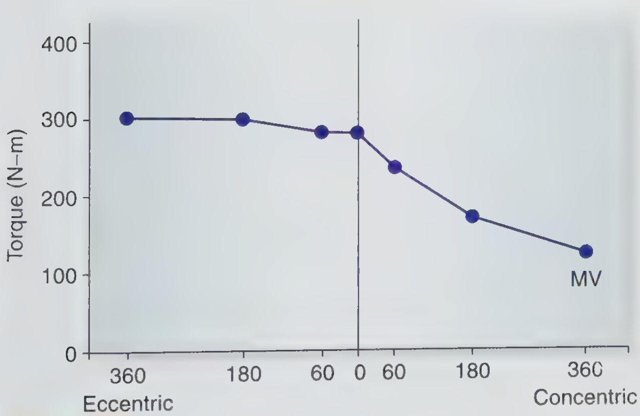

FIGURE 5-2 Relationship between the force and velocity of eccentric muscle contractions. (Adapted from Herzog W, Ait-Haddou R. Mechanical muscle models and their application for force and power production. In: Komi PV, ed. Strength and Power in Sport. 2nd Ed. Malden, MA: Blackwell Scientific Publications, 2003:176.)

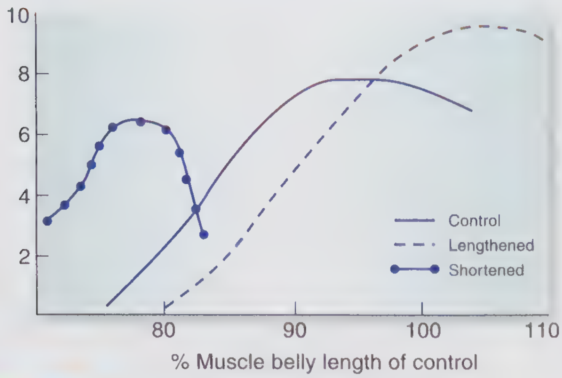

FIGURE 5-5 Changes in the length–tension relationship caused by length changes associated with immobilization. (Modified from Gossman, Sahrmann SA, Rose SJ. Review of length-associated changes in muscle. Experimental evidence and clinical implications. Phys Ther 1982;62:1799.)

muscle (e.g., the lower trapezius in the patient with protracted scapula) tests weak, because the manual muscle test occurs at a relatively shortened range, which is an insufficient position. According to animal studies,[21,22] the short muscles should develop the least peak tension, followed by the normal-length muscle and the lengthened muscle, which develops the greatest peak tension (**Fig. 5-5**). This finding directly reflects the number of sarcomeres in series. The lengthened muscle may be interpreted as weak although it is capable of producing substantial tension at the appropriate point in the range. This phenomena is called *positional strength*. Clinically, this is why a muscle should be tested at multiple points in the range. It is imperative that the physical therapist determine whether the muscle is positionally weak or weak throughout the range, as these findings will affect the selection of interventions (see **Building Block 5-2**).

BUILDING BLOCK 5-2

Think of some other muscle groups that might not test "normal" when testing at mid-range position due to positional weakness (shortening or lengthening of the muscle).

The emphasis of therapeutic exercise intervention should be on restoring normal length and tension development capability at the appropriate point in the range, rather than just strengthening the muscle. The positionally weak muscle should be strengthened in the shortened range, and the weak muscle should be strengthened dynamically throughout the range.

Muscle Architecture

The arrangement of the contractile components affects the contractile properties of the muscle dramatically. The more sarcomeres lie in series, the longer the muscle will be, the more sarcomeres lie in parallel, the larger the cross-sectional area of the muscle will be. These two basic architectural patterns affect the contractile properties of the muscles in the following ways:

- The force the muscle can produce is directly proportional to the cross-sectional area.
- The velocity and working excursion of the muscle are proportional to the length of the muscle.

Generally, muscles with shorter fibers and a larger cross-sectional area are designed to produce force, whereas muscles with long fibers are designed to produce excursion and velocity.[22] For example, the quadriceps muscle contains shorter myofibrils and appears to be specialized for force production, whereas the sartorius muscle has longer fibers and a smaller cross-sectional area and is better suited for high excursion (see **Building Block 5-3**).

BUILDING BLOCK 5-3

How might the rehabilitation of someone with a quadriceps muscle strain differ from someone with a hamstring muscle strain based upon the muscle architecture?

CLINICAL CONSIDERATIONS

Many factors impact the effectiveness of resistive exercise program. Issues such as medication use, physical health, age, and program design can impact a person's ability to participate in and successfully respond to a training stimulus.

Dosage

Exercise is described in terms of **dosage**. The components of the exercise dose include the exercise frequency, intensity, duration, volume, and rest interval. The exercise **frequency** is how often the exercise is performed, usually described as the number of days per week. The *intensity* is the amount of force necessary to achieve the activity, usually described as mass (in kilograms) or weight (in lb). The intensity is often described as a percentage of a **repetition maximum (RM),** or the maximum amount of weight that can be lifted for a certain number of repetitions. For example, a 10 RM is the maximum amount of weight that can be lifted 10 times and a 1 RM is the maximum amount of weight that can be lifted once.

The *duration* is the number of repetitions or time the exercise is performed. Often, a certain number of repetitions are performed in a **set,** and several sets of an exercise might be performed in a single session. The exercise *volume* is the total amount of exercise performed in a single session. Volume has been defined in different ways for different purposes. In weight training, volume is often defined as the product of the number of sets and repetitions and the weight. For example, the volume for 3 sets of 10 repetitions at 15 lb would be 3 × 10 × 15 lb = 450 lb. It has also been defined as the total number of repetitions performed in a training session.[23]

The *rest interval* is the amount of time between each set and/or between each exercise. The rest interval can be passive or active, where *passive rest* is simply resting before the next exercise bout, whereas *active rest* is rest where the person performs a light activity such as walking or stretching between resistive exercise bouts. In order for resistive training to improve muscle performance, the muscle must be overloaded. *Overload* means exercising or applying resistance above the loads currently or normally encountered.

The exercise dosage can be altered in a variety of ways. Some examples include:

- Increasing the intensity or amount of weight
- Changing the relationship to gravity

- Increasing the lever arm length
- Increasing sets and repetitions
- Decreasing the rest interval
- Increasing the frequency

The dosage parameters of intensity, duration, and frequency are related and together are considered the training *volume*; all must be considered when designing a resistive exercise program. Choose appropriate dosage parameters based on the needs of the patient (**Display 5-1**). Be aware of patients with fair or lower muscle grades who cannot perform resistive exercise against gravity with proper recruitment and movement patterns. In this situation, the patient may be forced to train a faulty movement pattern (see **Building Block 5-4**). Determine whether the goal is to develop muscular strength, power, endurance, or some combination of these muscle performance parameters. Subsequently, progress the resistive exercise to a functional activity to transition intervention at the impairment level to the activity limitation level (**Fig. 5-6**).

BUILDING BLOCK 5-4

A patient complains that he or she is unable to lift her arm overhead without pain. The patient is evaluated and is found to have a physiologic impairment of a muscle strength grade of fair for the lower trapezius and serratus anterior. How do these muscles function in arm elevation to an overhead position? Given her strength grade, what approach or approaches might be appropriate for initiating the rehabilitation program? Provide several options in different positions.

DISPLAY 5-1

Dosage Options for Individuals with Muscles of Various Strength Grades

Muscles Fair or Below Progressing to Muscles Above Fair:

1. Work in a gravity-lessened position or against gravity with other modification
2. Use active assistive, active, or resisted muscle contractions as available
3. Modify the working ROM, using resistance when possible, and assistance at other time
4. Progress from a shorter lever arm to a longer lever arm

Muscles Above Fair Strength Grade:

1. Vary the type of contraction (e.g., isometric, concentric, eccentric, isokinetic, plyometric)
2. Increase the amount of weight or resistance
3. Increase the number of sets or repetitions
4. Increase the frequency of training sessions (be cautious of overtraining)
5. Modify the speed of movement (slower speed increases amount of force or torque generated during concentric exercise)
6. Increase the distance (e.g., running, jumping, throwing)
7. Decrease the rest interval between sets

Dosage parameters can be manipulated for maximum gains in strength, power, and endurance through a system of training called *periodization*. Periodization systematically varies the training dosage to prevent "plateaus" in training gains, to maintain interest, and to provide a well-balanced program. Varying the training program is essential to making long-term gains in training. Periodization breaks the training program down into cycles of a specific length and goals (i.e., hypertrophy, basic strength, power, and endurance). The cycles can vary from "minicycles" of 1 week to mesocycles of several months. Often a training program comprises a variety of cycles of variable

A B

FIGURE 5-6 Progression of exercise: **(A)** Lifting free weights overhead to **(B)** placing a box up on a shelf.

lengths. Further discussion of periodization is presented later in this chapter in relation to training the advanced or elite athlete.

Intensity

Extensive strength training research has been performed on individuals without injury. Dosage parameters to increase strength began with DeLorme's classic paper in 1945.[24] He proposed a 10-RM, 10-set regimen. Later, DeLorme and Watkins[25] modified this regimen to a 10-RM, three-set regimen with loads increasing progressively for each set from one half to three fourths to a full 10-RM set. DeLorme called this regimen *progressive resistance exercise* (PRE), a term still used today (**Table 5-1**). DeLorme's three-set progressive resistance program has served as a control condition by which the effectiveness of other methods has been judged.

In 1951, an alternative to the DeLorme regimen was proposed by Zinovieff[26] at Oxford. He suggested adjusting the intensity of the load to allow for progressive fatigue. This was achieved by selecting an initial load that was just enough to permit each set to be completed. This regimen was called the Oxford technique. McMorris and Elkins[27] compared the DeLorme and Oxford techniques and found the Oxford technique to be slightly better, but the differences were not statistically significant.

The daily adjustable progressive resistive exercise (DAPRE) technique has been proposed as a more adaptable progressive exercise program than the Oxford or DeLorme approaches (see Table 5-1).[28] This program eliminates arbitrary decisions about the frequency and amount of weight increase. The DAPRE program can be used with free weights or with weight machines. A 6 RM is used to establish the initial working weight. Thereafter, weight increases are based on the performance during the previous training session.

These guidelines have been based on studies of uninjured subjects. When treating a patient with specific impairments, the resistive exercise dosage varies.[29] Exercise should be performed to substitution or form fatigue, the point at which substitution or alterations in form occur.

Duration/Volume

Duration or volume of resistive training can be considered the number of sets, repetitions, or time of a specific exercise session. Most exercises are performed for a given number of repetitions and sets that can be considered the exercise duration or volume. In rehabilitation, resistive exercises might also be prescribed for a certain time interval such as 15, 30, or 60 seconds depending on the goal of the exercise.

In weight training for fitness, *volume* is often defined as the total number of repetitions performed during a training session multiplied by the resistance used. Intensity and volume are inversely related. The greater the intensity, the fewer are

TABLE 5-1

Common Strength Training Dosages and DAPRE Program and Adjustments

TECHNIQUE	BASE REPETITION MAXIMUM (RM)	SETS	NUMBER OF REPETITIONS
DeLorme	10	1. 50% of 10 RM	10
		2. 75% of 10 RM	10
		3. 100% of 10 RM	10
Oxford	10	1. 100% of 10 RM	10
		2. 75% of 10 RM	10
		3. 50% of 10 RM	10
DAPRE	6	1. 50% of 6 RM	10
		2. 75% of 6 RM	6
		3. 100% of 6 RM	As many as possible
		4. Adjusted weight based on number of reps performed in set 3[a]	As many as possible; this number of reps is used to determine the working weight for the next day[a]

NUMBER OF REPETITIONS	ADJUSTED WORKING	ADJUSTED WORKING
Performed in set 3[a]	Weight for set 4[a]	Weight for next day[a]
0–2	Decrease 5–10 lb	Decrease 5–10 lb
3–4	Decrease 0–5 lb	Same weight
5–6	Keep weight the same	Increase 5–10 lb
7–10	Increase 5–10 lb	Increase 5–15 lb
11	Increase 10–15 lb	Increase 10–20 lb

[a]Adjustments for the DAPRE program.

the repetitions performed. When training at a low RM (near 1 RM or maximum amount of weight that can be lifted), very few repetitions are performed, and strength gains are the chief goal. When training at 10 RM or higher, many repetitions are performed, and the goals are endurance and other aspects of muscle performance.

Very little stimulus is necessary to make strength gains in the beginner. In untrained individuals, one set of 10 RM, two to four times per week, may be adequate. In advanced or elite athletes, multiple set routines, three times per week, will be necessary to achieve strength and power gains. For this group, performing one set of an exercise is less effective for increasing strength than performing two or three sets, and there is evidence that three sets are more effective than two sets.[30] However, multiple sets pose higher risk for injury; therefore, careful technique must be employed to avoid injury.

For most individuals, a moderate training volume is sufficient to achieve strength gains and these gains can be made via any resistive training mode.[31,32] A review of meta-analyses concluded that:

- In untrained subjects, a dosage of 60% of 1 RM, 3 days per week with a mean training volume of four sets per muscle group produced optimal strength gains.[33]
- For recreationally trained nonathletes, an intensity of 80% of 1 RM, 2 days per week with a mean training volume of four sets per muscle group was best.
- For athletes, a training of 85% of 1 RM, 2 days per week with a mean training volume of eight sets per muscle group was necessary for optimal strength gains.

The rest interval between sets is another important variable to consider. Much research has been performed to determine the optimal rest interval to achieve different resistive training goals. Some controversy exists regarding single versus multiple sets and the length of the rest interval between sets.[34,35] Strength results might change when training at different rest intervals. Rest intervals will vary from <1 minute to 3 to 5 minutes depending on the intensity of the lift and the purpose of the training. The higher intensity required for strength training will necessitate longer rest intervals.

- For loads near 1 RM, a rest interval of 3 to 5 minutes allows for more recovery and the ability to train at a higher intensity for more repetitions.[34]
- For power training, a minimum of 3 minutes rest between activities, such as plyometric jumps, will retain the necessary intensity.
- When training for muscle endurance, a circuit program with approximately 30 seconds between sets is sufficient.
- Muscles can be overloaded by decreasing the rest interval between sets.

Frequency

Training frequency depends on the rehabilitation goals. Isometric exercise is performed several times per day, and heavy dynamic exercise may be performed every other day. Frequency of an exercise is related to the exercise goal, intensity, duration, and other exercises in the patient's rehabilitation program. Individuals training for power lifting or body building lift daily or twice daily, whereas individuals in rehabilitation programs may perform resistive exercise 3 days per week, cardiovascular exercise on alternate days and certain exercises daily. Be sure to allow adequate time for recovery between training sessions. Shortening the recovery period between training sessions can produce persistent fatigue.[36]

Studies provide a variety of frequency recommendations, and these need to be balanced with intensity, duration, initial training status, and the goals of the training. PRE training one time weekly with 1 RM for one set increases strength significantly after the first week of training and each week up to at least the sixth week.[30] Significant increases have occurred for beginners training 1 to 5 days per week.

Sequence

The sequence of training muscles can affect the development of strength. In general, multijoint exercises are advocated for strength and power gains. However, specific isolated muscle training is often necessary when rehabilitating individuals with impaired muscle performance. In this case, the single-joint exercises should be performed first, before the patient gets fatigued. Follow these exercises with multijoint functional movement patterns. When designing the sequence of rehabilitation exercises, consider whether the exercises are **stacked** (several exercises in a row that train the same muscle group) or **unstacked** (exercises are organized to alternate between different muscle groups, allowing rest intervals). In the early rehabilitation phases, unstacking exercises to allow for an active rest interval for the muscle group being trained may prevent overwork of that muscle. As rehabilitation progresses, the exercises can be rearranged to include a sequence of two or more exercises in a row working the same muscle group. For training novice, intermediate, and advanced individuals who do not have an injury who want to increase strength, the American College of Sports Medicine (ACSM) provides the following recommendations[37]:

- Exercise large muscle groups before small and perform multijoint before single-joint activities.
- When training all major muscle groups in one training session, alternate upper body and lower body activities.
- When training upper body and lower body muscles on different days, alternate agonist and antagonist exercises.
- When training individual muscle groups, perform higher-intensity exercises before lower intensity exercises.

Program Design

Program design simply means looking at the overall training session. This includes the sequence of the exercises discussed in the previous section as well as overarching issues like interval training and circuit training. *Interval training* is a type of training that is predominantly used to build anaerobic metabolic systems; although depending on the work:relief ratio, it can be used to train aerobic systems as well. Interval training prescription includes the exercise intensity and duration as well as the duration and activity for the relief interval.[2,23]

- The relief interval can be either passive (rest-relief) or active (work-relief).
- Examples of work-relief interval activities include active movement without resistance, stretching, or another light activity.

- The relationship of work:relief can vary from 1:1 or 1:1.5 when training the aerobic system and to 1:12 to 1:20 when training the phosphagen system (the system used for all-out exercise in the first 10 seconds).
- The combination of high intensity and short duration places greater loads on the phosphagen system and requires a longer relief interval.
- A longer work interval (3 minutes or more) works the aerobic system, minimizing the necessity of a long relief interval.

Interval training methods can be applied to resistance training by using weight equipment (free weights, variable resistance machines, elastic resistance) to obtain a certain number of repetitions within a given time frame. The relief interval can again be a passive rest interval or an active work interval. Interval training will be discussed in greater depth in Chapter 6 relative to the cardiopulmonary system.

Circuit training usually includes 8 to 15 exercise stations that are completed in a sequence or circuit. The stations can be general training for the major muscle groups, serving as a general fitness routine or can be specific. For example, a swim team might perform circuit training 3 days per week with exercises focused on preventing injuries specific to swimmers. Exercises can be one mode (i.e., variable resistance machines) or they can be a combination of stations such as variable resistance machines, free weights, elastic resistance, and functional skills such as jumping. Participants complete two or three circuits at a given intensity depending on goals with a prespecified relief interval of 15 to 30 seconds between stations. When designing the circuit, keep in mind the sequence considerations discussed previously.

Training Specificity

Training specificity suggests that "you get what you train for." The SAID (**S**pecific **A**daptations to **I**mposed **D**emands) principle extends the idea first put forth in Wolff's law. Wolff's law states that bone will adapt to the loads placed upon it. The soft-tissue corollary is called Davis' law and states that soft tissues will remodel according to the loads placed upon them.[38] This specificity is particularly significant in terms of training range, mode, contraction type, posture and velocity[39–41] (**Evidence and Research 5-1**).

EVIDENCE and RESEARCH 5-1

The effects of posture on the specificity of training were assessed using squat and bench press lifts as the training tool. A variety of tests followed an 8-week training session that included skills such as vertical jump, 40-m sprint, isokinetic tests, and a 6-second bout on a power bicycle. The authors found results to support the concept of posture specificity, because the exercise postures similar to the training postures enabled the greatest improvements.[42]

The greatest training effects are evident when the same exercise type is used for testing and training, although this principle varies by muscle contraction types (**Evidence and Research 5-2**). A muscle trained isometrically will show the greatest strength improvement when tested isometrically and a muscle trained dynamically will test stronger when evaluated dynamically. However, a study of concentric and eccentric quadriceps training found that specificity was related to eccentric training but not concentric training.[44] Concentric training showed increases only in concentric and isometric strength.[43] Studies have shown bilateral transfer; training one limb resulted in strength gains in the contralateral limb.[39,45,46] Further studies of bilateral versus unilateral training have shown improved bilateral scores when training bilaterally and improved unilateral scores when training unilaterally. These findings were consistent for upper extremity and lower extremity training.[47]

EVIDENCE and RESEARCH 5-2

A group of 12 men was trained in a traditional isotonic strength program for knee flexor and extensor muscles.[43] They were tested isokinetically before and after the 12-week program. Their isotonic strength increased nearly 227%, whereas their isokinetic strength at 60 degrees per second increased only 10%.

ROM specificity also exists; strength improvements are greatest at the joint angles exercised.[40] A study of eccentric training showed isometric strength gains that were joint-angle specific; a similar study of concentric training showed improvements throughout the range.[46] The importance of training specificity is highlighted by the many variables affecting strength development. If the muscular system were the only system involved, then strength development would be predictable and linear. However, functional strength development is a complex relationship between the muscle tissue and the neural system dedicated to that tissue. This includes local and central nervous system mechanisms.

This specificity of exercise is evident to anyone who has trained for one activity (i.e., running) and subsequently discovered little transfer to another activity (i.e., tennis). Even resistive training, while providing a good strength base, does not transfer to other activities, even activities using the same muscle group. Therefore, it is important that resistive training serve as the training base upon which functional training is imposed.

Neurologic Adaptation

Muscle performance is determined by the type and size of the involved muscles and by the ability of the nervous system to appropriately activate muscles. When an unfamiliar exercise is introduced into the resistive exercise program, the early increase in strength partially results from adaptive changes in the nervous system control. Inappropriate instruction or failure to monitor the exercise and ensure appropriate nervous system control can render it ineffective or detrimental to the expected outcome. In order to achieve efficient and effective muscle performance, the following must occur:

- The agonists (muscles responsible for producing the large force in the intended direction) must be fully activated.
- The synergists (muscles that assist in coordinating the movement) must be appropriately activated to ensure precision.
- The antagonists (muscles producing force in the opposite direction of the agonists) must be appropriately activated or relaxed.

DeLorme and Watkins[25] hypothesize that the initial increase in strength after PRE occurs at a rate greater than can be accounted for by muscle morphologic changes. The initial rapid increases in strength probably result from motor learning. When a new exercise is introduced, neural adaptation predominates in the first several weeks of training as the individual masters the coordination necessary to perform the exercise efficiently. Eventually, hypertrophic factors gradually dominate over neural factors in the gain in muscle performance.[43] Although neurologic adaptations were once thought to dominate in the first few weeks of training, Staron et al.[48] found that morphologic changes begin to occur in the second week of training.

Other adaptations, such as the ability to fire motor units at very high rates to develop power, may require a longer period of training to attain and be lost more rapidly during detraining.[49] In the long term, further improvement in performance critically depends on the way the muscles are activated by the nervous system during training.[50]

Muscle Fatigue

Muscle fatigue may be defined as a reversible decrease in contractile strength that occurs after long-lasting or repeated muscular activity.[51] Human fatigue is a complex phenomenon that includes failure at more than one site along the chain of events that leads to muscle fiber stimulation. Fatigue involves a central component, which puts an upper limit to the number of command signals that are sent to the muscles, and a peripheral component. Peripheral changes in cross-bridge function associated with fatigue include a slight decrease in number of interacting cross-bridges, reduced force output of the individual cross-bridge, and reduced speed of cycling of the bridges during muscle shortening (**Table 5-2**).

When the patient is performing resistive training, be alert for signs of fatigue. Fatigue can lead to substitution or injury. The dosage for resistive exercise is often limited to *form fatigue*, the point at which the individual must discontinue the exercise or sacrifice technique. Quality of motion is necessary to ensure that the muscles of interest are being recruited. Synergists can readily dominate a movement pattern when muscle fatigue causes form fatigue. Changes in activation and optimum length for torque activation have been found following fatiguing exercise.[52,53] The patient should be instructed to stop the exercise once form is compromised (i.e., form fatigue). Continuing to exercise with poor technique compromises the outcome and may be detrimental. It is not good enough to perform the exercise; it must be performed correctly and with the appropriate recruitment pattern (**Fig. 5-7 A** and **B**). *A person cannot strengthen a muscle that is not being recruited.*

Muscle Soreness

During resistive training, especially in an untrained state, minor lesions of the muscle structure and inflammation can result in muscle soreness.[54] Most people who initiate a resistive exercise program will feel some stiffness and soreness in the exercised muscles following activity. Soreness may be caused by myofibrillar damage, membrane damage, or inflammatory processes. The serum or plasma level of creatine kinase, an enzyme found almost exclusively in muscle tissue, may be elevated, indicating muscle damage.[55–57] This muscle damage extends beyond just the local muscle environment, but it leads to systemic inflammation as well as increased arterial stiffening, negatively impacting central macrovascular function.[58,59]

TABLE 5-2

Chain of Events Leading to a Muscle Contraction

CHAIN OF EVENTS LEADING TO A MUSCLE CONTRACTION (ANATOMIC SITES OF FATIGUE)		MECHANISMS INVOLVED IN PROCESSING INFORMATION THROUGH THE CHAIN OF EVENTS (PHYSIOLOGIC PROCESSES RESPONSIBLE FOR FATIGUE)	
Central fatigue	Limbic, premotor, and association cortices ↓	Insufficient motivation or incentive	Processes involved in delivery of sufficient electrical excitation from CNS to muscle
	Sensorimotor cortex ↓	Insufficient cortical motoneuron activation	
	Spinal cord ↓	Depressed alpha motoneuron excitability	
Peripheral fatigue	Peripheral motor neurons ↓	Failure in neural transmission	
	Neuromuscular junction ↓	Failure in neuromuscular transmission	
	Sarcolema ↓	Depressed muscle membrane excitability	
	Transverse tubules ↓	Failure of muscle action potential propagation	
	Sacroplasmic reticulum ↓	Insufficient release and/or reuptake of Ca^{3+}	Metabolic and enzymatic processes involved in providing sufficient energy for contraction
	Formation of actin–myosin cross-bridges	Failure in excitation–contraction coupling, insufficient energy supplies, inadequate energy supply replenishment, metabolic accumulation	
	Muscle contraction

FIGURE 5-7 Ensuring proper exercise mechanics: **(A)** Inappropriate shoulder elevation during arm raising and **(B)** appropriate scapular stabilization during arm raising.

A specific type of muscle soreness referred to as **delayed-onset muscle soreness** (DOMS) is common following eccentric exercises, especially when the exercises are performed at a high velocity.[60] DOMS usually peaks about 2 days after exertion and can last for up to 7 days. During this time, muscle function deteriorates, and muscle strength may be reduced for a week or more after intensive eccentric exercise. Additionally, there is a shift of the optimal angle of peak torque production to longer lengths.[52,53] However, an adaptive process reduces the soreness after repeated eccentric training sessions.[52] Soreness following eccentric training can also be attenuated by preconditioning the muscle groups, performing isometric muscle contractions in a lengthened position.[61,62]

The unaccustomed eccentric exercise and associated high muscle forces damage aboth the muscle contractile and noncontractile structures, and abnormal metabolite accumulation in the muscle cell produces additional damage. Because eccentric contractions utilize a smaller number of motor units than concentric contractions, the excess stress on these motor units appears to be the source of tissue damage and associated inflammation.[63,58] The inflammation initiates the healing process, resulting in an adaptive process, protecting the muscle from similar damage in subsequent exercise bouts.[52]

Even during the soreness period, moderate activity is advised, because the adaptation response occurs before full recovery and restoration of muscle function. A single session of eccentric exercise provides a protective effect against DOMS in subsequent exercise bouts for up to 6 weeks.[52] Therefore when initiating a resistive training program that includes eccentrics, it is best to begin with a light exercise session to protect against significant DOMS.[62]

Patients should be cautioned that eccentric training may lead to muscle soreness 24 to 48 hours after exercise, but that moderate exercise should continue during the recovery period. However, some research has shown attenuation of position sense and joint reaction angle following a bout of eccentric exercise (**Evidence and Research 5-3**). Therefore, use caution when treating populations who are training or working in at-risk environments (i.e., steel workers, roofers).[67,68,69]

EVIDENCE and RESEARCH 5-3

Position sense and reaction angle were tested in the upper extremity by fatiguing the elbow flexors and in the lower extremity by fatiguing knee flexors via repeated eccentric muscle contractions. Although the exercise induced greater muscle damage and loss of position sense in the elbow flexors than in the knee flexors, the elbow flexors remained faster and more accurate than the knee flexors at all measured time points post exercise.[64] Errors were biased toward a more lengthened position.[64,65] A repeated bout of exercise resulted in less muscle damage and improved position sense of the knee flexors.[66]

Life Span Considerations

Newborn Through Preadolescence

Only about 20% of a newborn child's body mass is muscle tissue. The infant is weak, and muscular strengthening in the first months takes place by spontaneous movements. These movements should not be limited by tight clothes or constant bundling of the newborn. However, the infant and toddler should not be burdened with systematic resistive training; normal developmental progression provides an appropriate stimulus for the development of an optimal amount of muscular strength.

In the preadolescent phase (up to age 11 in girls and 13 in boys; approximately Tanner stages 1 and 2), muscle mass increases parallel to body mass. Children are able to make strength gains above and beyond growth and maturation. Benefits of exercise and specifically resistive training in this age group include[70]:

- Improved muscle performance
- Increased motor performance
- Improved body composition
- Increased bone strength
- An enhanced sense of well-being
- A positive attitude toward fitness

During preadolescence, there are no differences between girls and boys with respect to the ability for strength training. Boys have a small genetic advantage, which is completely compensated by the developmental advantage of girls.[71] There is no biologic basis for a sex-dependent difference in strength performance. Most improvements in performance are the result of neurologic changes, such as increased motor unit activation, coordination, and motor learning.[70]

Moderate strength training is acceptable. Resistive training at this age should focus on the neurologic aspects of training (**Fig. 5-8**). See **Table 5-3** for recommendations for programs at the pre-adolescent level.[72,73]

Muscle performance training should always be supervised by knowledgeable staff to avoid risk of injury. Although it has been suggested that resistance training in pre-adolescent children leads to increased musculoskeletal injuries, this appears to be anecdotal. Controlled studies have not found an increase in muscle, bone or joint injuries in resistance training in this population when the program is run by experienced professionals.[74,75]

FIGURE 5-8 Child performing a squat exercise.

Adolescence

Adolescence refers to the time period between childhood and adulthood encompassing young girls aged 12 to 18 years and boys aged 14 to 18 years (Tanner stages 3 and 4).[72] The ability to improve strength increases rapidly during adolescence, particularly in boys. The increase in male sexual hormones is significant because of their anabolic (i.e., protein-incorporating) component. During maturation, the proportion of muscle in boys increases from 27% to 40% of body mass.[71] With the onset of adolescence, the strength of girls compared with boys diverges markedly. On average, the strength of girls is 90% that of boys at 11 to 12 years, 85% at 13 to 14 years, and 75% at 15 to 16 years.[71] Although this gender difference has a biologic basis, biology does not completely account for the differences seen, suggesting continued societal influences.

General strength training is recommended during this phase (**Table 5-4**). Optimal strength and muscular balance are critical for the quickly growing skeleton. Like preadolescence, evidence does not support increased musculoskeletal injuries in adolescents involved in appropriately supervised resistance training programs.[70,74] Low back or other musculoskeletal injuries in resistance training often occur in unsupervised settings where appropriate instruction may be absent.

Guidelines for resistance training in adolescents are similar to that of preadolescents with the most important factors being proper instruction, supervision, and safe progression. Additionally, participants must have the ability to listen and directions to ensure safety. As youth progress through a resistive training program, they progress with activities from isolated muscle exercises to complex multijoint activities that require more coordination. They progress with varies speeds, including higher-speed activities to develop power, and include activities that challenge balance as well (**Table 5-5**). For specific guidelines, see Behm et al.[70] and Faigenbaum et al.[72]

Early Adulthood

Strength potential is at its highest in the 18- to 30-year period.[75] The competent biologic structures show a state of good adaptability, and the joints tolerate high loads. Most individuals are actively involved in physical activity without the responsibility of working long hours. During this period, emphasis should be placed on a balanced fitness program comprised of cardiopulmonary fitness, muscle performance, and flexibility.

Middle Age

The decrement of strength during this phase of life must be differentiated according to training activities, gender, and body area. Training for as little as 2 hours or more each week is sufficient to positively influence strength. A small amount of training increases the difference between active and inactive persons as age increases. As obligations increase in middle age, exercise may become secondary to other responsibilities. Continuing a resistive exercise program can help maintain

TABLE 5-3

General Youth Resistance Training Guidelines

- Provide qualified instruction and supervision
- Ensure the exercise environment is safe and free of hazards
- Start each training session with a 5–10-min dynamic warm-up period
- Begin with relatively light loads and always focus on the correct exercise technique
- Perform 1–3 sets of 6–15 repetitions on a variety of upper- and lower-body strength exercises
- Include specific exercises that strengthen the abdominal and lower-back region
- Focus on symmetrical muscular development and appropriate muscle balance around joints
- Perform 1–3 sets of 3–6 repetitions on a variety of upper- and lower-body power exercises
- Sensibly progress the training program depending on needs, goals, and abilities
- Increase the resistance gradually (5%–10%) as strength improves
- Cool down with less-intense calisthenics and static stretching
- Listen to individual needs and concerns throughout each session
- Begin resistance training 2–3 times/week on nonconsecutive days
- Use individualized workout logs to monitor progress
- Keep the program fresh and challenging by systematically varying the training program
- Optimize performance and recovery with healthy nutrition, proper hydration, and adequate sleep
- Support and encouragement from instructors and parents will help maintain interest

strength and function, bone density, and appropriate body composition.

Advanced Age

The body can adapt to strengthening exercise throughout the life span. It is possible to reverse existing muscular weakness in old age.[76] Strength increases can result from relatively low stimuli in detrained elderly individuals. Like younger individuals, these strength increases result from both muscular hypertrophy and neural factors.[77,78] Cross-sectional area of trained muscles in older individuals show increases after several weeks of resistive training[79] (**Evidence and Research 5-4**). In general, fatigability increases with advancing age, and older muscles require a longer period of recovery after strenuous exertion. There is also a significant increase in the collagen content of muscle with advancing age. This is associated with thickening of the connective tissue and increased muscle stiffness.

EVIDENCE and RESEARCH 5-4

Fourteen elderly subjects were randomly assigned to a resistive training (RT) or control group. The RT trained BIW for 4 sets of 10 repetitions of a leg press at 70% to 80% of 1 RM. The leg press 1 RM increased by 42% after 10 weeks of training, whereas significant increases in vastus lateralis muscle cross-sectional area were seen only after 9 weeks.[22] Walker et al.[80] compared the changes in neuromuscular performance and muscle hypertrophy between young and older men who performed 10 weeks of a high-volume, medium load resistance training program two times per week. Although both groups improved their muscle performance, only the young men showed significantly increased lean mass, and only the older men showed increased muscle activation. This program did not result in increases in muscle power measured by concentric rapid force production.[81]

The decrease in muscle performance with advancing age affects men and women differently. The absolute decline in strength is less steep in women than in men. Parts of the body are also affected differently. The arms are more affected than the trunk and legs, probably because of less use of the upper extremities in strength-related activities. Active elderly women surpass inactive men with respect to trunk muscle strength.

Adequate muscle strength helps to prevent or moderate the symptoms of degenerative changes of the joints. Resistive exercise by the elderly should be directed toward the muscles susceptible to atrophic changes, especially the deep neck flexors, scapular stabilizers, abdominal and gluteal muscles, and quadriceps. Unjustifiably, little attention is paid to strength of the ventilatory muscles (i.e., diaphragm) and pelvic floor muscles. Training should include both multijoint and single-joint exercises.

Additionally, the elderly should consider training for power, not just strength. Leg power has been shown to significantly influence the physical performance of mobility-limited elderly people.[82,83,84] In some cases, power training has been found to be more effective at improving physical function than traditional strength training.[81,83,85,86] Ankle dorsiflexor and plantarflexor peak power is predictive of chair rise and stair climb performance.[87] Elderly with low power have a two to three times greater risk of significant mobility limitations compared with elderly with low strength.[88] Most strength programs are performed at a slow velocity, whereas power training typically occurs at a higher velocity.

High-velocity resistance training has been shown to increase muscle power more effectively than low-velocity training in older women.[89] High-velocity power training at both high resistance (70% of 1 RM) and low resistance (40% of 1 RM) yielded improvements in muscle power and performance in mobility-limited elderly[90,91] (**Evidence and Research 5-5**). High-velocity power training has also improved braking speed in the elderly, an important factor in fall prevention.[92] As such, high-velocity training may be a preferred resistance training strategy in the elderly.[93] Power training in this group should include light to moderate loads performed for 6 to 10 repetitions with high velocity. See Chapters 17 through 26 for resistive exercises for the spine, shoulder, arm, hip, knee, and pelvic floor (**Fig. 5-9**).

EVIDENCE and RESEARCH 5-5

Researchers studied the effects of power training at different velocities on functional activities such as habitual gait velocity (HGV), stair climb (SC), and chair rise (CR) and compared these to strength training in older men and women. .Power training at 70% and 40% 1 RM showed greater associations with HCV and SC than did strength training at 1 RM. Additionally, power training at 40% 1 RM accounted for more of the variability in HCV than did power training at 70% 1 RM, supporting the use of higher-velocity training in older men and women with mobility limitations.[91]

With advancing age, the social needs and individual motivation for strength demands lessen; the atrophy reflects the effects of disuse, not mere age-related changes. The voluntary and deliberate use of the motor system in daily life activities and intentional resistive training are able to counteract the

FIGURE 5-9 Power training in the elderly using a leg press machine.

loss of muscle mass with increasing age. The vigorous use of muscles, particularly among old persons, improves their health and sense of well-being.

Cognitive Aspects of Performance

The cognitive or mental aspects of strength and performance are most easily seen in elite athletes. Sport psychologists and athletes support using mental imagery techniques such as visualization and positive self-talk. Positive cognitive strategies can enhance strength and performance, and negative strategies may have a negative or negligible impact (**Evidence and Research 5-6**).

EVIDENCE and RESEARCH 5-6

A study of different mental preparation techniques (i.e., arousal, attention, imagery, self-efficacy, and control-read conditions) showed that these techniques and other self-efficacy techniques produced greater posttest strength performance than a group of controls who did not use any mental preparation techniques.[94] Jump height was improved following stating or reading specific action verbs, after specific kinesthetic imagery activities, and after performing mathematical operations, suggesting a link between cognition and performance.[95]

Different kinds of imagery and their impacts on power and endurance activities (i.e., seated shot of endurance activities put and push-ups to exhaustion) have been studied. Results show that these imagery techniques have a positive impact and that using metaphors is particularly effective in improving power and endurance measures.[96] A study of the impact of imagery, preparatory arousal, and counting backward on hand grip strength found imagery to enhance grip strength in both older and younger subjects.[97] Gould et al.[98] found that imagery and preparatory arousal improved strength performance. Verbal encouragement and head-to-head competition enhance performance of endurance activities, whereas mental fatigue has a negative impact.[99]

Effects of Alcohol

The deleterious effects of alcohol abuse on muscle have been well documented.[100] The myopathic changes seen in patients abusing alcohol have at times been attributed to malnutrition or disuse. Experiments have demonstrated that, even with nutritional support and prophylactic exercise, normal subjects can develop alcoholic myopathy if they ingest large amounts of ethanol.[101]

Alcoholic myopathy has two clinical phases:

1. An acutely painful presentation that follows "binges"
2. A chronic phase that consists of morphologic and functional alterations in muscle[102]

Acute alcoholic myopathy has morphologic features, such as fiber necrosis, intracellular edema, hemorrhage, and inflammatory changes. Binges by chronic alcoholics can result in an acute myopathy characterized by muscle cramps, muscle weakness, tenderness, myoglobinuria, reduced muscle phosphorylase activity, and decreased lactate response to ischemic exercise. Exercise is contraindicated for persons with acute myopathy and those with myoglobinuria, because it may stress an already compromised system.

Changes seen with chronic alcoholic abuse include type II fiber atrophy, suggesting that alcoholic patients may exhibit an inability to generate tension rapidly and to produce power.[103] For many patients, abstinence leads to full recovery of muscle function, but for others, the injury may be more severe and resistant to treatment, and this must be considered as a comorbidity when projecting the prognosis.

Effects of Medications

The widespread use of oral corticosteroid agents as anti-inflammatory and immunosuppressant agents has led to cases of steroid atrophy.[104,105] Corticosteroids are a potent catabolic stimuli, and the atrophy caused by prolonged corticosteroid use occurs as protein degradation exceeds protein synthesis. In patients with chronic lung disease, the adverse effects appear to be dose related with increased muscle weakness, back pain, and bruising associated with higher-corticosteroid dosages.[106] The primary biopsy finding in patients treated with prednisone-like steroids (e.g., prednisone, prednisolone, methylprednisolone) is type II fiber atrophy, specifically in type IIB fibers[105,107]; it is believed to occur more often in women than men.[108] Goldberg and Goodman[109] believe that the constant use of the type I fibers during normal voluntary movement provides these fibers with a protective mechanism. Exercises recruiting type II muscle fibers may protect them from steroid-induced atrophy. Normal function can be expected to return within 1 year or, more often, within several months after steroid use has stopped.[108]

Myositis and more severe cases of rhabdomyolysis (requiring hospitalization) have been associated with statins, one of the most commonly prescribed cholesterol-reducing medications, statin[110–113] Although the benefits of cholesterol lowering are clear, side effects such as muscle fatigue, weakness, and pain can be debilitating for patients.[114] Muscle cell apoptosis has been suggested as a potential mechanism for statin-induced myopathy.[114] Myopathy may be caused by the drug itself, by interactions with other drugs, or by capitalizing on individual genetic, immunologic, or metabolic factors.[115] A few of the risk factors include polypharmacy, age >80 years, female sex, diabetes, immunocompromised, high-activity levels, or vitamin D deficiency.[116,117]

Patients with statin-induced myopathy will complain of muscle aching, pain, cramping, stiffness, and fatigue, often symmetrical, but not always. Creatine kinase levels may or may not be elevated.[117] Significant individual variability and lack of a gold standard test have made diagnosing this condition challenging. Physical therapists are uniquely positioned to use muscle performance measures to evaluate patients for statin-induced myopathy.[118] Additionally, close monitoring of patient activity levels can detect and prevent worsening conditions such as rhabdomyolysis.[119–121] Use caution when prescribing therapeutic exercise in patients who are on statin medications, particularly those patients with additional risk factors for statin-induced myopathy. Weight-bearing exercise and eccentric muscle contractions will place patients at additional risk of myopathy.[122] Additionally, statin use can blunt the usual response to aerobic and strength training.[123]

CAUSES OF DECREASE MUSCLE PERFORMANCE

Muscle performance can be impaired for a variety of reasons. Some of these include central or peripheral neurologic pathology; injury to the muscle from a strain or contusion; injury or inflammation to the tendon or its attachment to bone (see Chapter 11); certain medications (see previous section); and disuse or deconditioning for any reason. The goal of examination/evaluation of muscle performance is to determine the *cause* of the impairment in order to develop the most efficient and comprehensive intervention plan. The following section discusses the potential factors that can cause impaired muscle performance, examination/evaluation results of each potential cause, and general intervention concepts for each specific cause.

Neurologic Pathology

Neurologic pathology can affect the contractile capacity of muscle as a result of pathology in the central or peripheral nervous system. The peripheral nervous system can be affected at the nerve root or peripheral nerve level.

Individuals with nerve root pathology may present with muscle performance impairments in the nerve root distribution. For example, nerve root compression at the L4–L5 spinal level can produce quadriceps femoris weakness, whereas nerve root compression at the C5–C6 spinal level can result in deltoid and biceps weakness. Therapeutic exercise intervention depends on the prognosis for the nerve root involvement. If the changes are relatively recent and resolution of the nerve root compression is expected through conservative or surgical management, preventive and protective measures are taken. The goal of therapeutic exercise intervention is not only to promote optimal muscle performance of the muscles innervated by the affected spinal segment (pending prognosis) but also to promote spine stability and optimal movement patterns to alleviate any mechanical cause of nerve root pathology incurred by the spinal segment(s) (see Chapters 17 and 23).

Peripherally, use resistive exercise to maintain or improve current strength levels, while training deep lumbar or deep cervical flexor muscles to provide proximal stability. Centrally, use resistive exercise to train inner core muscles (i.e., longus coli, transversus abdominis, lumbar multifidus, pelvic floor; see Chapters 18, 19, and 24 for detailed muscle performance training) to effectively stabilize the spine and relieve mechanical nerve root irritants. After the mechanical or chemical cause of nerve root injury is remediated, use specific, localized resistive exercise of the involved musculature to restore precise recruitment patterns.

Neurologic weakness may also result from a peripheral nerve injury (i.e., median nerve at the carpal tunnel, the ulnar nerve at the cubital tunnel, or the common peroneal nerve at the fibular head). The pattern of sensory loss and weakness depends on which nerve and where along the nerve's course the insult occurs. Therapeutic exercise should be focused on remediating the mechanical cause of the peripheral nerve injury. For example, a depressed shoulder girdle may contribute to traction on the long thoracic nerve, causing motor changes in the serratus anterior. Exercise and posture education to elevate the shoulder girdle may alleviate the traction on the long thoracic nerve and ultimately restore normal innervation to the serratus anterior. Exercise should try to maintain muscle balance and efficient movement patterns without developing a dominant muscle group. Splinting, bracing, taping, or other supportive measures may be necessary to maintain balance, especially in the short term.

Other neurologic conditions include neuromuscular disease such as multiple sclerosis, postpolio syndrome, Guillain–Barré syndrome, and muscular paralysis or paresis resulting from spinal cord injury or stroke. Resistive exercise programs must consider the prognosis and tailor the exercises appropriately. In situations such as Guillain–Barré syndrome, certain cases of spinal cord injury and stroke and progressive stages of multiple sclerosis, some recovery is expected. Exercise programs focus on improving muscle performance in intact musculature and gently strengthening weakened muscles as recovery and remission advances. Avoid fatiguing weakened muscles during strengthening exercises. Dosage parameters generally include several short exercise sessions of a few repetitions interspersed throughout the day.

During quiescent periods of diseases such as multiple sclerosis, a general conditioning program of balanced strengthening and mobility exercises is appropriate. When recovery is not expected, resistive exercise programs emphasize functional strength of remaining musculature. This includes strength for functional activities such as self-care, transfers, and mobility. Take care to avoid overworking these muscles. Unlike persons with full innervation who use their muscles efficiently, the individual with paralysis uses the few innervated muscles they have for nearly all their activities. The potential for overuse injuries is very high.

Muscle Strain

Muscle strain occurs along a continuum from acute macrotraumatic injury to chronic microtraumatic overuse injuries and can be caused by traumatic strain, eccentric loading, chronic overuse, muscle dominance overuse, or continuous overstretching (see Chapter 11). Resistive exercise in the treatment of muscle strain injuries depends on where along this continuum the injury occurs. Resistive exercise that neither overloads nor underloads the tissue is optimal. Determining this resistance dosage is the challenge.

Acute traumatic injuries occur when a muscle is rapidly overloaded or overstretched, and the tension generated exceeds the tensile capability of the musculotendinous unit.[124] The hamstring muscle is a common site of muscle strain injury. A combination of insufficient strength, reduced extensibility, inadequate warm-up, and fatigue has been implicated in hamstring injuries[125] (see **Patient-Related Instruction 5-1**). Strength, extensibility, and fatigue resistance protect a muscle from strain injury.

Eccentric loading is a common mechanism of muscle strain injury, but a muscle prepared for eccentric loading is less likely to sustain an injury. Eccentric loading should be an integral part of any resistance training program (see **Selected Intervention 5-1**, for an example of eccentric loading). A program to prevent muscle strain injuries should include dynamic resistive exercises with a strong eccentric component, flexibility exercises, appropriate warm-up before activity, and attention to fatigue levels. The rehabilitation program after injury should also focus on these factors.

Muscles may also be strained from chronic overuse. For example, extensor digitorum longus (EDL) strain is common in workers performing continuous repetitive elbow, wrist, and hand activities as a result of using the EDL for wrist extension and elbow flexion. Training the individual to use the biceps for elbow flexion whenever possible (i.e., keep the hand supinated vs. pronated during elbow flexion) can alleviate the overuse strain to the EDL. A thorough evaluation can determine the cause of the overuse problem. Ergonomic assessment and appropriate work site modification are also necessary to prevent a recurrence of the strain if ergonomics is at the root of undesirable posture or movement patterns. If left untreated, this impairment can quickly lead to participation restrictions.

Strain resulting from muscle dominance overuse is managed by reducing the loads imposed on the strained muscle. When the tensor fasciae latae dominates over the iliopsoas during hip flexion and over the gluteus medius during abduction, the tensor fasciae latae is at risk for an overuse strain. Improving the strength and recruitment patterns of the iliopsoas and gluteus medius can reduce the load on the tensor fasciae latae and allow it to recover. Postural habits (e.g., standing in medial rotation) and movement patterns (e.g., hip flexion or abduction with medial rotation) must also be modified to improve recruitment of the underused synergists.

A potential risk factor of muscle strain is gradual, continuous overstretching, which occurs when a muscle is continuously placed in a relatively lengthened, tension-producing position. For example, the lower trapezius in a person with protracted scapulae is subjected to continuous tension and has adapted to a lengthened state. It may not take much force to produce a strain injury in a muscle that is already overstretched. This type of strain puts the muscle at risk for two forms of muscle weakness; (1) from length–tension changes and (2) from overstretch strain.

Patient education is a key component of the rehabilitation program in the case of muscle strain associated with continuous overstretch. In the lower trapezius example, educate the patient about optimal postural habits to reduce tension on the lower trapezius. Improving postural habits and reducing tension on the lower trapezius with bracing or taping (see Chapter 25) will allow the muscle to heal more rapidly. In addition, it will promote adaptive shortening and therefore ultimately achieve a more optimal length–tension relationship and reduce the risk for future reinjury.

Patient-Related Instruction 5-1

Preventing Muscle Strain

Although some muscle strains are not preventable, precautions can reduce your risk of injury.

1. Warm up before a vigorous activity; 5 to 7 minutes of a large muscle group activity such as walking, jogging, or cycling should suffice. This should be enough activity to break a sweat.
2. Stretch stiff and short muscles after your general warm-up. Stretching can be static or dynamic depending on your activity. Stretch each muscle for 15 to 30 seconds for 4 repetitions at the conclusion of your exercise session.
3. Balance your sports or other leisure activities with strengthening exercises. Your clinician can help you focus on muscles susceptible to injury.
4. Avoid fatigue during the activity. Fatigue can increase your risk of injury.
5. Strengthen underused muscles to prevent overuse to susceptible muscles. Your clinician can help you determine which muscles these are and what specific exercises you need to perform to maintain muscle balance.

SELECTED INTERVENTION 5-1

Lateral Kicks

See Case Study No. 1

Although this patient requires comprehensive intervention as described in other chapters, only one exercise related to resistive training is described. This exercise would be used in the late phase of this patient's rehabilitation.

ACTIVITY: Resisted hip abduction and ankle eversion.

PURPOSE: To increase the muscle performance of the ankle evertor and hip abductor muscles.

STAGE OF MOTOR CONTROL: Controlled mobility.

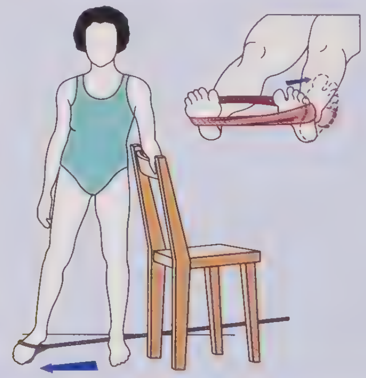
MODE: Resistive band.

POSTURE: Standing with one foot on the resistive band and the band around the other foot. A support should be readily available for balance as needed.

MOVEMENT: Standing on the uninjured leg, abduct the hip in the frontal plane, and evert (pronate) the ankle. Raise the leg to the side slowly and controlled (concentric phase) and lower to the starting position more quickly (eccentric phase), but controlled. Maintain good spinal posture throughout the exercise. Do not hike pelvis; move only at the hip joint. Maintain frontal plane movement; moving toward flexion results in the motion performed by the flexor abductor group. Repeat.

DOSAGE: Two to three sets per day to form fatigue. If patient does not fatigue by 20 repetitions, increase the resistance of the band.

EXPLANATION OF PURPOSE OF EXERCISE: This exercise increases muscle performance in the hip abductors and ankle evertors in a synergistic fashion. Abductors are strengthened in both concentric and eccentric modes. It may be progressed to a higher speed to increase the eccentric loading. Remove the support to challenge stability.



Disuse and Deconditioning

Muscle performance may be impaired because of disuse or deconditioning for a variety of reasons. Illness, surgery, specific physical conditions (e.g., pregnancy with twins), or injury may necessitate a period of decreased activity. Subtle muscle imbalances can lead to overuse of one muscle and to disuse and deconditioning of another.

Illness and injury are common causes of deconditioning. For example, illness such as pneumonia or an injury such as a herniated disk can result in a period of decreased activity and subsequent deconditioning. In these situations, total-body deconditioning occurs, and general conditioning is necessary, whereas specific exercises may be necessary to improve muscle performance and prevent secondary impairments. For example, an elderly individual may have relatively asymptomatic osteoarthritis until a bout with pneumonia produces general deconditioning. Subsequently, knee osteoarthritis becomes symptomatic because of impaired muscle performance in the lower extremity muscles involved in gait and other functional activities. Specific resistive exercises to address the impairment of muscle weakness are necessary to restore proper biomechanics and prevent activity limitations and participation restrictions.

Reduced activity levels can impair muscle performance in a similar manner. Multiparous pregnancies, exacerbation of a musculoskeletal injury, an episode of colitis, or social factors such as major life changes (e.g., job, school, divorce, family illness) can reduce activity levels and result in impaired muscle performance. For example, regular exercise may keep a woman's patellofemoral malalignment from becoming symptomatic. When her activity level decreases in the late stages of pregnancy, the combination of decreased activity, weight gain, and hormonal changes produces symptoms at the patellofemoral joint. Selective resistive exercises combined with patient education can prevent this exacerbation. Resistive exercises in the case of overall decreased activity must consider the muscles most likely to be affected, the patient's desired activity level and preference, and any underlying or residual medical conditions.

An overlooked source of deconditioning or disuse is a subtle muscle imbalance. When activating muscles for a functional movement, the body chooses the most efficient muscular and motor unit activation pattern. Certain motor units in a muscle may be preferentially recruited when a muscle is engaged in a particular task.[126] For example, motor units in the lateral portion of the long head of the biceps are preferentially activated when this muscle is engaged in elbow flexion, whereas motor units in the medial portion are preferentially activated in forearm supination.

The recruitment thresholds of motor units in a muscle are also influenced by the type of muscle actions associated with a movement. In elbow flexion, biceps motor units have a lower threshold in slow concentric and eccentric actions than isometric actions; the reverse is true for the brachialis.[127] The recruitment thresholds of motor units of a muscle active in a movement may also be affected by changes in joint angle.[128] Some muscles or portions of a muscle may be overused, whereas other muscles or portions are disused, and the resistive rehabilitation program must acknowledge this imbalance. In the previous example, instruction in general resisted elbow flexion may exacerbate the imbalance whereas specific training of the weaker recruitment pattern can restore muscle balance.

Length-Associated Changes

The principle of the length–tension curve affects muscle performance when a muscle is adaptively lengthened from prolonged posture and repetitive movement patterns with the muscle in that lengthened state. Positional weakness can result. Postural examination findings of a depressed shoulder suggest length weakness in the rhomboids and trapezius muscles, whereas findings of an adducted and medially rotated hip suggest length weakness in the gluteus medius muscle. Muscles will test weak in the short range when compared with synergists (i.e., posterior gluteus and tensor fasciae latae), paired muscle of the other extremity (i.e., right and left posterior gluteus medius), or other half of the axial skeleton (i.e., right and left external oblique muscles). Intervention should focus on strengthening the muscle in the shortened range, optimizing posture to reduce lengthening tension on the muscle, and altering movement patterns to recruit the muscle in the shortened range.

PHYSIOLOGIC ADAPTATIONS TO TRAINING

Strength and Power

The benefits of resistive exercise extend beyond the obvious improvements in muscle performance to include positive effects on the cardiovascular system, connective tissue, and bone. Moreover, these effects translate into function. Individuals perform their daily activities with more ease because they are functioning at a lower percentage of their maximum capacity. Functional activities such as gait velocity, stair climbing, and ease of transfers are all improved with resistive training.[90,129] Improved functioning also enhances the patient's sense of well-being and independence. Additionally, strength training has shown crossover effects, where training one limb translates into muscle performance improvements in the contralateral limb.[39,130]

Muscle

The most obvious benefits of resistive training are for the muscular system. Regular resistive exercise is associated with several positive adaptations, most of which are dosage dependent (**Table 5-6**). The cross-sectional area of the muscle increases as a result of an increase in the myofibril volume of individual muscle fibers, fiber splitting, and potentially an increase in the number of muscle fibers. These changes have been seen in a variety of age groups, and when using different resistance training modes and dosages.[131–135] Changes in the muscle depend on fiber type and the stimulus.[136,137] Hypertrophy of fast-twitch fibers occurs when all or most of the fibers are being recruited and is considered an adaptation for increased power output. Slow-twitch fibers hypertrophy in response to frequent recruitment. In repetitive, low-intensity activity, fast-twitch fibers are rarely recruited, and these fibers may atrophy while the slow-twitch fibers hypertrophy. Staron et al.[138] examined the differences in the proportion of muscle fiber types between distance runners, weight lifters, and sedentary controls. The weight lifters had a greater proportion of type IIA fibers than the controls or distance runners.[138] This exemplifies the need for specificity of resistive training when designing a training program.

On the cellular level, capillary density is unchanged or decreases, and the mitochondrial density decreases.[132,133] Although protein volume and cross-sectional area increase, some of the cellular or systemic factors may remain unchanged, resulting in a perceived decrease, although the decrease is only relative.

TABLE 5-6

Physiologic Adaptations to Resistance Training

VARIABLE	RESULT AFTER RESISTANCE TRAINING
Performance	
Muscle strength	Increases
Muscle endurance	Increases for high-power output
Aerobic capacity	No change or increases slightly
Maximal rate of force production	Increases
Vertical jump	Increases
Anaerobic power	Increases
Sprint speed	Improves
Muscle Fibers	
Fiber size	Increases
Capillary density	No change or decreases
Mitochondrial density	Decreases
Enzyme Activity	
Creatine phosphokinase	Increases
Myokinase	Increases
Phosphofructokinase	Increases
Lactate dehydrogenase	No change or variable
Metabolic Energy Stores	
Stored ATP	Increases
Stored creatine phosphate	Increases
Stored glycogen	Increases
Stored triglycerides	May increase
Connective Tissue	
Ligament strength	May increase
Tendon strength	May increase
Collagen content	May increase
Bone density	Increase
Body Composition	
Percentage of body fat	Decreases
Fat-free mass	Increases

Adapted from Falkel JE, Cipriani DJ. Physiological principles of resistance training and rehabilitation. In: Zachazewski JE, Magee DJ, Quillen WS, eds. Athletic Injuries and Rehabilitation. Philadelphia, PA: WB Saunders, 1996.

Energy sources that fuel muscle contraction increase after resistive training. In general, levels of creatine phosphate, ATP, myokinase, and phosphofructokinase increase in response to a resistive exercise program.[139–142] Lactate dehydrogenase is variably changed.[140]

Neural adaptations occur with resistive training. Studies have shown increases in the muscle's ability to produce torque and increased neural activation, as measured by electromyography (EMG).[49] Increased EMG values associated with greater power and maximal contraction were attributed to a combination of increased motor unit recruitment and increased firing rate of each unit.[143]

Connective Tissue

Although disuse and inactivity cause atrophy and weakening of connective tissues such as tendon and ligament, physical training can increase the maximum tensile strength and the amount of energy absorbed before failure.[144] Physical activity returns damaged tendons and ligaments to normal tensile strength values faster than complete rest.[145] Physical training, particularly resistive exercise, may alter tendon and ligament structures to make them larger, stronger, and more resistant to injury. Additionally, resistive training can increase the loading capabilities of the tendon-bone and ligament-bone interfaces.[146]

Bone

Weightlessness[147] and immobilization[148] can cause profound loss of bone density and mass. Weight-bearing activities that recruit antigravity muscles can maintain or enhance bone density and mass.[149] Individuals in sports requiring repeated high-force movements such as weight lifting and throwing events have higher-bone densities than distance runners, soccer players, or swimmers.[150] Those who play tennis regularly have higher-bone density in their dominant forearms, and professional pitchers have greater bone density in the dominant humerus.[151] A 5-month study of weight training compared with jogging found that weight training produced significantly better increases in lumbar bone density than the aerobic exercise.[152]

Resistive training to improve bone density is important for people of all ages, and particularly for women who are prone to osteoporosis[153] (**Evidence and Research 5-7**). In adolescents, resistive training and weight-bearing exercise consistently show improvements in bone density compared with sedentary peers.[157–159] Impact activities that include jumping and landing are particularly effective in building bone mass and strength, especially when combined with proper nutrition in the pre- and peri-pubertal periods.[160] Research into bone mass and exercise dosage found that daily loading regimens broken down into four sessions with recovery time in between improved bone mass significantly over a loading schedule that performed the training in a single, uninterrupted session.[161] Thus smaller exercise sessions separated by recovery periods may be a better prescription when increased bone mass is the goal.

EVIDENCE and RESEARCH 5-7

A study of adolescent female athletes found runners to have higher total body and site-specific bone mineral density than swimmers or cyclists, and that knee extension strength was an independent predictor of bone mineral density in this population.[154] Adolescent female swimmers did not show increases in bone mineral density compared with a control group, highlighting the importance of weight-bearing or impact activities for adolescent females.[155] Female athletes participating in high impact or odd impact (i.e., soccer, racket sports) demonstrated thicker cortices and denser bones than controls or swimmers.[156]

Cardiovascular System

Resistive training benefits the cardiovascular system. The idea that strength training causes hypertension is erroneous. Most reports show that highly strength-trained athletes have average or lower than average systolic and diastolic blood pressures.[162] When performed properly and heeding the proper precautions, strength training can have a positive effect on the cardiovascular system.

Increased intrathoracic or intra-abdominal pressures may affect cardiac output and blood pressure during resistive exercise. In the classic model, increased intrathoracic pressures are thought to decrease venous return, decrease cardiac output, and cause an increase in blood pressure. Performing resistive exercises with a Valsalva maneuver, which elevates intrathoracic pressure, leads to a greater blood pressure response than performance of the exercise without a Valsalva maneuver.[163] Instructing the patient to breathe properly during exercise may reduce the increase in blood pressure sometimes seen during exercise.

Increased intramuscular pressure during resistive exercise may result in increased total peripheral resistance and increased blood pressure. Mechanically induced increases in peripheral resistance probably are the cause of higher blood pressures during isometric and concentric exercise compared with pressures during eccentric exercise.[164] Isometric or concentric exercise combined with a Valsalva maneuver can produce the greatest increase in blood pressure. This combination should be avoided, especially by individuals at risk for elevated blood pressure (see Section "Precautions and Contraindications").

Resistive exercise does result in a pressor response that affects the cardiovascular system by causing hypertension through exciting the vasoconstrictor center, which leads to increased peripheral resistance. If precautions are taken to ensure proper breathing and avoid isometric contractions in persons at risk for a pressor response, resistive exercise's benefits outweigh the risks. Long-term performance of resistive exercise can result in positive adaptations of the cardiovascular system at rest and during work. Cardiovascular adaptations to resistive training are summarized in **Display 5-2**.

Endurance

As expected, the muscle's response to endurance training is different from its response to strength or power training. Muscular endurance depends on oxidative capacity, and training increases the muscle's metabolic capacity. During prolonged activities, depletion of intramuscular glycogen reserves may contribute to impaired muscular endurance.

Muscles trained for endurance demonstrate cells with increased mitochondrial size, number, and enzymatic activity,[166] allowing the muscle to better use the oxygen delivered. In addition, endurance-trained muscle demonstrates increased local fuel storage; they increase fatty acid use and decrease the use of glycogen as a fuel, allowing more exercise before fatigue. Lastly, endurance muscle training improves the oxygen delivery system by increasing the local capillary network, producing more capillaries per muscle fiber.[166] Increased perfusion slows the accumulation of lactate in the working muscles.

DISPLAY 5-2

Benefits of Strength Training on the Cardiovascular System[165]

- Decreased resting heart rate
- Decreased or unchanged systolic blood pressure
- Decreased or unchanged diastolic blood pressure
- Increased or unchanged cardiac output
- Increased or unchanged stroke volume
- Increased or unchanged maximal oxygen consumption
- Decreased or unchanged total cholesterol

EXAMINATION AND EVALUATION OF MUSCLE PERFORMANCE

Decreases in muscle performance may occur for a number of reasons. The physical therapist must perform a thorough examination to determine the cause of impaired muscle performance and the link between impaired muscle performance and activity limitations or participation restrictions. After that relationship is established, therapist must then match the intervention to the cause of impaired muscle performance. The muscle test is only one small part of the examination process and must be used with additional information (e.g., ROM, joint mobility, balance, sensory, and reflex integrity) to determine the specific cause of impaired muscle performance.

The tests and measures recommended by the *Guide to Physical Therapist Practice*[167] ensure comprehensive assessment of the patient's impairments, activity limitations, and participation restrictions. Various muscle performance tests include manual muscle tests, dynamometry, electrophysiologic testing, and an analysis of functional muscle strength, power, or endurance. Of these, manual muscle testing is the most fundamental of all strength tests. Consider length–tension relationships, muscle imbalance, and positional weakness when choosing manual muscle test positions. Minimize the chance of erroneous results by paying close attention to substitution patterns and by testing in a variety of positions. When used reliably, hand-held dynamometers can provide muscle performance information that is more reliable than that of tests using the traditional criteria of 0 through 5.

Isokinetic dynamometers are commonly used to assess muscle performance. Computerized systems provide tremendous data reduction capabilities. Tests can be performed at a variety of speeds and comparisons made with antagonists, the contralateral limb, normative standards, or previous test results. These tools provide reliable data that can be used to assess progress, as a motivator, or as criteria for progression to more advanced rehabilitation phases. A variety of muscle actions can be assessed using this equipment.

Dynamic strength can also be determined using the RM method. For example, a 10 RM is the maximum amount of weight that can be lifted 10 times, and a 1 RM is the maximum amount of weight that can be lifted once. The amount of weight that can be lifted for a given number of repetitions can be determined and compared with that for the antagonist, the opposite limb, or to a previous test result.

The magnitude of measured increases in force or torque depends on how similar the test is to the training exercise.[168] For example, if athletes train their legs by doing the squat exercise, the increase in strength measured as maximal squatting is much greater than the strength increase measured in isometric leg press or open kinetic chain knee extension tests. This specificity of movement pattern in strength training probably reflects the role of learning and coordination.[169] Improved coordination takes the form of the most efficient activation of all of the involved muscles and the most efficient activation of motor units within each muscle involved. Testing force production in the manner in which the muscle has been trained reflects the morphologic and neurologic adaptations.

CLASSIFICATION OF RESISTANCE EXERCISE

Resistive exercise can be broadly classified into categories comparing the force generated by a muscle or muscle group relative to an external load. This external load can be applied by numerous mechanisms such as a machine, a resistive band, hand-held equipment, a person (manual resistance), a stationary object or body weight. Exercises where the internal force generated matches the externally applied load are considered to be **isometric** exercises. In isometric exercise, no joint motion takes place, although muscle activation occurs. All other activities are **dynamic** involving joint motion. When the external load is less than the force generated by the muscle **concentric** contractions result, whereas when external loads exceed the internally generated force, **eccentric** contractions are produced. Resistance applied at a constant velocity is termed *isokinetic*.

Isometric Exercise

Isometric exercise is commonly used to increase muscle performance. Although no joint movement occurs and technically no work is performed (work = force × distance and distance = 0), isometric exercise is considered functional because it provides a strength base for dynamic exercise and because many postural muscles work primarily in an isometric fashion (see **Self-Management 5-1**, for an example of isometric exercise for postural muscles). Before an eccentric muscle contraction, a concentric or an isometric contraction must occur first, presetting tension in the muscle. For example, the quadriceps muscles isometrically preset tension to stabilize the knee in full extension before initial contact during the gait cycle; the same happens when the knee is in near full extension prior to landing from a jump. These isometric contractions allow a subsequent quadriceps eccentric contraction to decelerate the flexing knee to absorb shock. Therefore, isometric contractions are an essential component of many functional activities.

Indications

Isometric exercise is a valuable rehabilitation tool in many situations. For example, isometrics are:

- A foundational exercise, an isometric training often precedes dynamic muscle training
- Used to pretension muscles before any eccentric muscle contraction
- Preferred over dynamic exercise when joint motion is uncomfortable or contraindicated, such as postoperatively or with an unstable joint
- Essential to maintain muscle strength and prevent significant declines during immobilization
- Combined with dynamic exercise to focus strengthening at a weak point in the ROM
- Frequently used for muscle reeducation purposes
- An important component of stabilization programs

One of the benefits of isometric exercise is the ability to perform repetitive submaximal contractions as "reminder" or reeducation exercises. Following lower extremity injury or surgery, recruiting and activating the quadriceps muscles can be difficult; similarly, recruiting and activating the rotator cuff musculature following shoulder surgery or injury can be equally challenging. Quadriceps setting and rotator cuff isometric exercises at a low, submaximal level can maintain connective tissue mobility (i.e., patellar mobility, ligament, tendon, and fascial mobility), and muscle mobility and function. Quadriceps and gluteal sets are also used to enhance circulation and maintain mobility and muscle performance throughout the lower extremity during periods of bed rest.

Isometric setting exercises area prerequisite for more advanced dynamic exercises, particularly those requiring eccentric muscle contractions. This is a more complex neuromuscular activity than one might think. *Neuromuscularly, isometric tension is set at an appropriate and predetermined level before commencing an eccentric muscle contraction*. For example, if one were to catch an object being tossed at them, or to jump down from a given height, the brain must first signal the necessary muscles to preset isometric tension in order to decelerate the object upon catching, or the body upon landing, *respectively*. The brain determines how much isometric tension to preset based upon previous experience and estimates of the object weight or distance to landing (**Fig. 5-10**). One of the significant challenges is teaching the patient *how* much tension to preset to accomplish a given task. In this case, isometric training at different percentages of maximal activation is useful.

Isometric exercise also functions as a component of dynamic exercise when weakness exists at a specific point in the ROM. Proprioceptive neuromuscular facilitation (PNF) techniques include isometric contractions as part of a dynamic program to enhance stability and to strengthen muscles in a weak portion of the range (see Chapter 15). For example, while performing a diagonal pattern, the therapist may stop and apply an isometric contraction at a weaker portion of the ROM.

A B

FIGURE 5-10 Landing from a jump requires presetting isometric quadriceps muscle contraction **(A)** prior to landing **(B)**.

Isometric contractions are also an important component of stabilization programs. **Stabilization** programs are a progressive series of exercises and activities designed to increase a patient's ability to dynamically control movement at a joint or series of joints. Stabilization exercises are an important component of treatment programs for shoulder, knee, and ankle instability, as well as the basis of treatment for many spinal problems (**Fig. 5-11**). For example, PNF techniques such as alternating isometrics and rhythmic stabilization use isometric contractions as the basis for stability training.

This resistive mode is easy to understand and perform correctly, requires no equipment, and can be performed in almost any setting. Isometric exercise is most effective when individuals are in a low state of training, because the benefits of isometric exercise decrease as the state of training increases. Most gains are made within the first 5 weeks of the onset of training.[170]

FIGURE 5-11 Plank on elbows and knees is a common isometric stabilization exercise.

Considerations in Isometric Training

Some factors are important in choosing isometric exercise for rehabilitation. Isometric strength is specific to the joint angle. Studies have demonstrated isometric joint angle specificity, noting that strength gained at one joint angle did not predictably carry over to other joint angles.[171] Neuromuscular changes accounted for the joint-angle–dependent effects, and obtaining generalized strength gains required multiangle training programs. Whitley[172] found significantly increased strength at all joint angles after 10 weeks of training at specific joint angles. Others have found this general transfer, although only after training was well advanced.[173] In the beginning training phase, the strength gains were transferred only when the muscle was at shorter than resting length.

Dosage

Like most resistive exercise programs, dosing the exercise is the most challenging aspect. Dosing for strength differs from dosing for muscle reeducation, and this differs from dosing for stabilization. Isometric exercise for these different therapeutic goals requires a specific approach for each.

Dosing for strength training has two important variables: intensity and ROM. Because of the angle specificity, multiangle isometric training is recommended whenever possible. Muscle contraction should be maximal or nearly maximal and should be performed to fatigue. Exercise may be performed at a low frequency. Sample dosage parameters for isometric exercise prescription for strength are as follows:

- Perform isometric contractions every 15 to 20 degrees throughout the ROM.

- Hold each contraction approximately 6 seconds, which is long enough to fully activate all motor units. The first few seconds of the first maximum contraction appears to trigger the major training effect—after the first few seconds, the ability to maintain a maximal contraction drops off dramatically.[23]
- Repeat frequently throughout the day.
- Have their greatest effect near maximal contraction, although this may not be possible in many clinical situations.

Dosing for muscle reeducation requires a different prescription. Contraction intensity is submaximal and can vary from very low intensity (<20% maximum voluntary contraction or MVC) to >50% MVC depending on the situation:

- Exercise at the lowest intensity immediately after injury or surgery serves as a reminder to contract the muscle.
- Following back surgery, perform abdominal muscle contractions at a very low level.
- Following a patellar dislocation, perform low level quadriceps contractions.
- A patient who needs improved thoracic and cervical posture might perform scapular retraction isometrics at 50% or more of MVC throughout the day.

  Because intensity and volume are inversely related, isometric contractions for muscle reeducation are performed at a high volume. Activities that are performed for postural awareness may be put "on cue" asking the patient to perform a set of isometrics on cue, such as every time the phone rings, or every time a new e-mail message arrives. Progress these exercises to dynamic strengthening, isometrics at a higher percentage of MVC, and/or isometric exercise with external resistance, such as holding a position against elastic resistance or with a free weight.

Isometric dosage for stabilization will vary depending on the patient's current strength, injury or pathology and current pain levels. Stabilization exercises are like muscle reeducation in that one of the goals is to train the muscles to dynamically maintain a joint or series of joints within a small range of optimal postures. An additional goal is to simultaneously strengthen the muscles required to do this. Thus the dosage is more flexible and is specific to each patient situation. For stabilization activities, a common pattern would be initial training for muscle reeducation, where the emphasis is on contracting the right muscle group and avoiding the "overflow" phenomenon where the patient globally activates all muscles in the region. For example, in attempting to perform a quadriceps set, the patient may "overflow" activating the hamstring and gluteal muscles in addition to the quadriceps. In the core, the patient may activate all abdominal muscles when trying to activate only the deep trunk stabilizers. Once the correct activation has been achieved, progress the program to strengthening followed again by a muscle reeducation program to teach the patient to activate just enough motor units to accomplish the functional task safely. Thus, the program might look like this:

1. Teach patient how to activate the muscle(s) of interest without overflow.
2. Once isolated, strengthen the muscle(s) of interest.
3. Reeducate to activate only to the level necessary to accomplish the task at hand.

Precautions

Use caution when prescribing isometric exercise for patients with hypertension or known cardiac disease. Isometric exercise can produce a pressor response, increasing blood pressure. Perform isometric exercise without breath holding or a Valsalva maneuver. Individuals with hypertension may benefit from simple, repeated contractions held only 1 to 2 seconds. Encourage the patient to "count aloud while exhaling" to avoid breath holding.

Dynamic Exercise

Dynamic resistive exercise can be performed in a variety of modes, postures, and dosages, as well as with a variety of contraction types (i.e., concentric, eccentric). Dynamic exercise implies joint motion and a shortening or lengthening contraction of the working muscle. Dynamic exercises have been called *isotonic exercises* in the past and the term is still in common usage today despite the technical shortcomings of the term.

Body weight, elastic bands, free weights, pulleys, manual resistance, and weight machines are a few modes of dynamic resistive exercise (see **Patient-Related Instruction 5-2**). Concentric and eccentric contractions can be used in different combinations depending on the mode of exercise chosen (i.e., most weight machines use concentric and eccentric contraction of the same muscle groups whereas manual resisted exercise can use concentric and/or eccentric contractions of opposing or same muscle groups). As with isometric exercise, each type of dynamic exercise has risks and benefits, and the training mode should match the identified activity limitations and participation restrictions. The ACSM recommends that for novice and intermediate training, both free weights and machines be used, whereas the advanced and elite athletes' emphasis should be primarily with free weights.[37]

Although isokinetic exercise is a type of dynamic exercise, it is often considered in a different category from isotonic exercise. Although isotonic exercise can be performed at a constant velocity, it is performed against a constant load. Isokinetic

Patient-Related Instruction 5-2

Purchasing Resistive Equipment

Before purchasing resistive equipment for home use, the following information should be considered:

1. Is the equipment safe? Is it approved by a reputable organization?
2. How easy is the equipment to use? How long will it take to learn how to use it?
3. Is the equipment versatile? Can it be used to train a number of different muscle groups?
4. Will the equipment suit your needs as your training progresses?

Before purchasing equipment, consider joining a health club for a month or two to see:

1. Which equipment you tend to use regularly
2. What features you like about some equipment
3. What features you dislike or seem to be lacking

exercise is performed at a constant velocity with accommodating resistance; that is, the isokinetic device "matches" the resistance applied by the subject. Specific indications and dosage for each type of dynamic exercise will be considered in the next section.

METHODS OF RESISTANCE TRAINING

The specific activities and dosage chosen to improve muscle performance depend on many factors, including the individual's age and medical condition, muscles involved, activity level, current level of training, goals (i.e., strength, power, and endurance), and cause of decreased muscle performance. The following sections describe the activities used to increase muscle performance and their relative risks and benefits. Be sure to match the appropriate training mode to the patient's impairments, activity limitations, and participation restrictions.

Manual Resistance

Manual resistance can be applied by the clinician, the patient, or a family member. It is one of the most longstanding forms of resistance training in the rehabilitation profession. This is likely due to its ease of application and its versatility. Manual resistance can be applied at a variety of intensities, speeds, ranges, and contraction types. The speed, intensity, contraction type, and movement pattern can be varied during a given exercise. Several well-known techniques such as PNF are applied predominantly with manual resistance.

Indications

Manual resistance can be performed in almost any situation where resistance for rehabilitation is required. However, it becomes challenging in situations requiring high force levels, as in training for fitness, wellness, or sports. Manual resistance is especially effective when strength varies throughout the ROM. A patient may have a portion of the ROM that is either weak or painful; the therapist can modulate the resistance more easily with manual techniques than with resistive equipment. The therapist can also apply specific tactile cues to facilitate recruitment at a weak portion of the ROM. Similarly, manual techniques work well if a patient needs assistance through a portion of the ROM, followed by resistance at other positions.

Manual techniques are quite useful when teaching proper movement patterns, as manual assistance/resistance can facilitate proper firing patterns. For example, a PNF technique called *rhythmic initiation* teaches proper movement patterns before the addition of resistance. Manual resistance is indicated when manual contacts are necessary to ensure the proper muscle activation. For example, in some situations synergists may substitute for the desired primary muscle action. Palpation, combined with manual contacts and tactile cues, can facilitate the proper muscle activation and stabilization. Manual cues with one hand can facilitate isometric stabilization contractions while the other hand facilitates and resists a dynamic contraction. PNF techniques, such as alternating isometrics or rhythmic stabilization, are very effective for enhancing specific muscle activation patterns. With these techniques, the agonist and antagonist are alternately activated within a small ROM and at progressively higher speeds until cocontraction provides stability. The alternating aspect of this activity makes manual techniques the optimal form of resistance. Finally, when a variety of speeds is necessary, manual resistance offers the flexibility to change rapidly, enhancing motor learning opportunities.

Considerations

Manual resistance has the benefit of being readily available in the clinic and does not require specific positioning against gravity to achieve resistance. Benefits include the following:

- The amount of resistance can be modified as the exercise session progresses, with decreasing resistance as the patient fatigues. The resistance can be more finely adjusted through the ROM and with every repetition to ensure maximum resistance through the exercise.
- The therapist is able to feel the change in force offered by the patient and can adjust the applied resistance appropriately. That way the patient can obtain the maximum resistance tolerated through the entire exercise set.
- The therapist's hand position is also easily modified to change the lever arm and resistance offered.
- Manual resistance also allows manual contact between the therapist and patient. For many patients, this tactile contact provides comfort and increases ease.

Although there are a number of benefits to manual resistance techniques, there are also some drawbacks including:

- The labor intensive nature of manual resistance
- Its impracticality for many home programs
- Difficulties measuring and quantifying manual resistance

Manual resistance requires the time, energy, and physical strength of a therapy provider. Depending on the body part being exercised and the relative strengths, manual resistance can be physically taxing. Performing PNF diagonal patterns for the lower extremity can be physically difficult and could potentially result in injury to the therapist using poor body mechanics. Be sure to use proper body mechanics, maximizing hand positioning, base of support, and lever arms to minimize the stress and risk of injury.

Manual resistance is not practical for many home programs. Caregiver assistance is required and may place the caregiver at risk of injury. For all but the lightest of manual resistance applications (i.e., hand, wrist, foot) the resistance is too great and the body mechanics challenging. Few homes have sufficient tables or supports at the right height and firmness to allow the caregiver to use good body mechanics.

Measuring and defining manual resistance is difficult. Therapists use terms like *minimum*, *moderate*, and *maximal* but these are poorly defined and vary from one person to another. For situations where documentation needs to be precise, verifying the dosage of manual resistance can be difficult.

Techniques

Techniques for performing manual resistance require attention to patient positioning, therapist positions, manual contact, grading of resistance, and verbal cues. Attention to these details provides the safest experience for both the patient and therapist. Consider the following points, essential to manual resistance:

- Make sure that the patient's clothing allows you to see the muscles or joints associated with the exercise.
- Position the patient so that full excursion of the movement is possible without restrictions.
- Make sure that the patient is comfortable and as stable as necessary as dictated by the exercise goal.
- Position yourself in the plane of the movement, using a wide base of support; shift your weight and step as necessary with the movement to maintain good body mechanics.
- Use as wide a contact area as possible to prevent discomfort at the point of resistance or stabilization application.
- Using a wide, gentle grip, take the patient's limb through the exercise ROM to teach them the movement pattern (PNF rhythmic initiation).
- While continuing to move through the range, tell your patient that you will be gradually applying some resistance to the movement.
- Be sure to gradually apply and slowly release the resistance to avoid sudden muscle contractions that might cause injury or pain.

Video clips of some commonly used manual resistance patterns can be found on thePoint.lww.com/BrodyHall4e.

Dosage

Dosing manual resistance can be challenging due to the inability to quantify the intensity of the exercise. The therapist is able to document sets and repetitions as well as a nominal description of the amount of resistance (i.e., minimum resistance, maximum resistance). Like all forms of resistance, manual resistance is applied with a specific goal in mind (i.e., strength, endurance, stabilization), and the sets, repetitions, and relevant rest intervals are derived from the goal. Stop the exercise when form fatigue becomes evident. Exercises can be varied by speed, muscle contraction type (concentric, eccentric, isometric) ROM, and resistance. Manually resisted exercises can be performed in an open chain or a closed chain (see **Fig. 5-12A** and **B**).

A

B

FIGURE 5-12 **(A)** Manually resisted open-chain leg press and **(B)** manually resisted rise from a chair.

Pulley System

Many pieces of exercise equipment are based on a pulley system where a weight plate is attached via a cable and pulley to a handle or lever that is controlled by the patient. In a standard pulley system, the cable attaches over a single or double round pulley. In other situations, the pulley or cam itself is elliptical, thereby providing variable resistance as they rotate through the cable's excursion. These are called *variable resistance* machines and will be considered in the next section. This section will focus on traditional pulley devices without an elliptical cam.

Most pulley systems consist of a simple cable and pulley attached to a weight stack of variable weight increments (i.e., 2.5, 5, or 10 lb). Most pulley systems are a single stack of weights that are freestanding or attached to a wall (**Fig. 5-13**). The other end of the pulley typically contains a clip or hook to which a number of different implements can be attached. These attachments may include a straight bar, cuff, handgrips, or various sizes and grips of implements designed to allow a wide range of exercises. Activities such as triceps pulls, biceps curls, latissimus pull-downs, rows, shoulder rotations, shoulder press, leg lifts, and abdominal crunches are some of the many activities that can be performed with a pulley. Thus, a pulley is a versatile piece of equipment that allows someone to perform a large variety of activities with a single piece of equipment.

A pulley system is indicated anytime resistive exercise though a ROM is necessary. Pulleys are prescribed after baseline strength is established, as most pulley systems start with a minimum of 2.5 lb of resistance. Few pulley systems provide stabilization such as chairs or benches. Therefore, most exercises require dynamic stabilization from the person performing the exercise. Chairs or benches can be set up to provide support or stabilization for specific exercises. For example, someone with

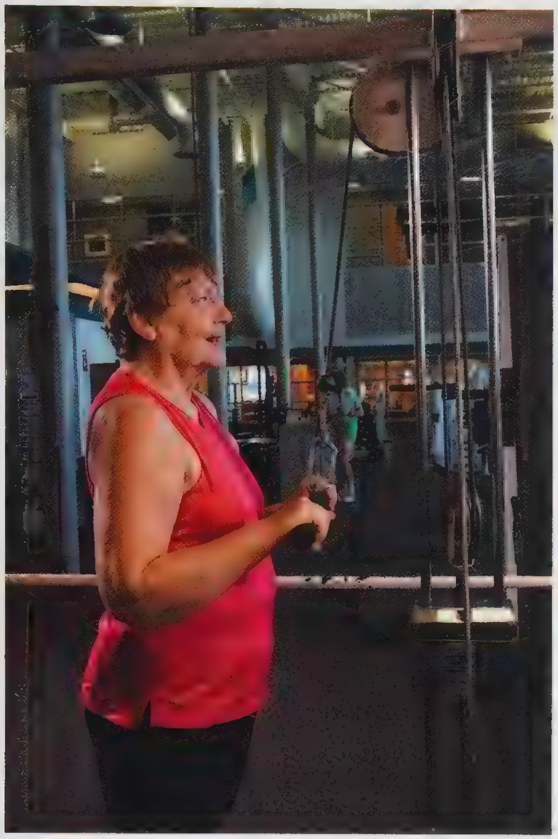

FIGURE 5-13 A standard pulley system.

FIGURE 5-14 Variable resistance machine.

limited standing tolerance or balance may be safer performing biceps curls seated rather than standing.

The most fundamental disadvantage of this type of system is the constant load provided by the equipment. When performing an exercise through a full ROM, the muscle will be maximally loaded only in the weakest portion of the range. The remaining portion of the ROM will be underloaded, failing to achieve the criteria necessary for strengthening. One technique to accommodate for this shortcoming is to train different portions of the ROM at different intensities. For example, the patient may train through the full ROM at a lower intensity, then perform an additional set at a higher intensity in the mid-portion of the ROM, where the muscle requires higher resistance to overload.

Variable Resistance Machines

Resistive exercise machines are commonly found in rehabilitation clinics and health clubs. Historically, most weight machines were designed to isolate a specific muscle group such as the quadriceps femoris or biceps brachii. Some equipment trains multiple muscle groups in combination patterns such as a leg press or pull-up machine. Those machines using weight stacks have plates weighing 5 to 20 lb each. The weight stack configuration varies with the specific muscle action trained. A pin placed in the weight stack selects the amount of weight to be lifted. The muscle contraction type is concentric during the lifting phase and eccentric during the lowering phase (**Fig. 5-14**).

The type of system—either the pulley or cam—is an important component of the weight machine. In contrast to a simple pulley system that provides a constant load through the ROM, a variable resistance machine contains an elliptical cam and pulley system that varies the resistance through the ROM. The kidney-shaped cam is an attempt to account for changes caused by varying length–tension relationships through the ROM. Variable resistance devices provide less resistance at the beginning and end of the ROM, and more resistance midrange.

Other machines use hydraulics to provide variable resistance through the range. Again, the machine is designed to provide more resistance in the mid-ROM, replicating "typical" length–tension ratios. In contrast to pulleys which provide alternating concentric–eccentric contractions of the same muscle groups, the hydraulic resistance machines typically provide reciprocal concentric contractions of opposing muscle groups (i.e., biceps–triceps). This is an important distinction to consider when designing a rehabilitation program; hydraulic machines provide only concentric resistance.

Weight machines also differ in their adjustability. Lever arms and seat positions should be adjustable for a variety of body sizes. This ensures the ability to align the joint axis with the axis of the machine and prevent injury from poor posture or exercise mechanics. Stops and range-limiting devices should be available and easily adjustable.

An **advantage** of weight machines over other types of resistance is safety. Patients are stabilized effectively by the equipment, and the risk of falls or injury resulting from instability is minimized. It takes less time to learn weight machine exercises. After the adjustments are learned, the equipment is relatively easy to use, and novice weight lifters are less intimidated by the equipment. Weight machines are also relatively time efficient because the machines are already setup. Only a few simple adjustments are necessary, and the patient is ready to begin. These machines frequently isolate a specific muscle group to be trained, and the variable resistance accommodates for changing length–tension relationships better than other types of resistance.

One of the **disadvantages** of weight machines is their expense and ability to perform only a single exercise. For example, an expensive machine may train only biceps, whereas this could be done inexpensively with a couple of free weights and a bar. Another disadvantage is that weight increases are restricted to fixed increments (i.e., weight plates) on weight machines. Smaller changes of 1 or 2 lb are not possible on most machines. Despite the many size adjustments on weight machines, they still do not fit everyone. Most also have a fixed, two-dimensional movement pattern. Because the machine guides the patient through the ROM, little proprioception, balance, or coordination is learned from the experience. The stabilization helps with isolation but limits the patient from learning self-stabilization. Most machines are designed to perform bilateral exercise. In some cases, performing unilateral exercise is difficult, if not impossible.

Elastic Resistance

Elastic resistance in a form of elastic bands or tubing, improved greatly from its origins, as "dental dam" used in dental procedures. Use of elastic resistance has increased significantly since its first appearance. It is relatively inexpensive, easy to use, small and light making it ideal for home and travel use and can be used in an infinite variety of exercises. However, the trade-off for ease of use is the difficulty in quantifying and dosing an exercise program. Research suggests that the amount of resistance varies with the band thickness, attachment technique, and the specific exercise performed.[174,175–177]

Elastic resistance is a dynamic exercise but cannot be classified as isotonic or isokinetic. The variability in load through the ROM does not allow it to be classified as isotonic and the variability in speed does not allow classification as isokinetic. It has unique characteristics that require it to be considered independent of other types of resistance. Elastic resistance is often compared with an isotonic pulley system. However, the unique characteristics of elastic do not allow a direct comparison with a pulley system.[178]

Unlike a pulley system which has a fixed load, the resistance provided by an elastic band varies with the thickness of the band and the elongation.[173,179,180] Any elastic material's resistance to stretch is proportional to its original cross-sectional area.[178] Therefore, doubling the cross-sectional area by folding (effectively doubling) the elastic doubles the resistance. Additionally, elastic resistance has unique force-elongation characteristics. The force increases as the elastic is stretched from 0% to 250% of its resting length. The force-elongation curve of Thera-Band (The Hygenic Corporation, Akron, OH, USA) elastic bands as well as the force in lb can be found in **Figure 5-15** and **Table 5-7**, *respectively*.

This force development is distinct from the torque created when functionally using elastic bands through a ROM with changing moment arms. Like all elastic materials, the force developed when pulling that material in a linear fashion will increase as the material is lengthened until failure is reached. However, the actual amount

of torque developed when using elastic bands through a ROM (such as shoulder abduction) follows an ascending–descending pattern. That is, the torque increases from 0 to 90 degrees abduction as the moment arm increases, then decreases again as the moment arm decreases as the shoulder approaches 180 degrees. An example of strength curves can be found in **Figure 5-16**.

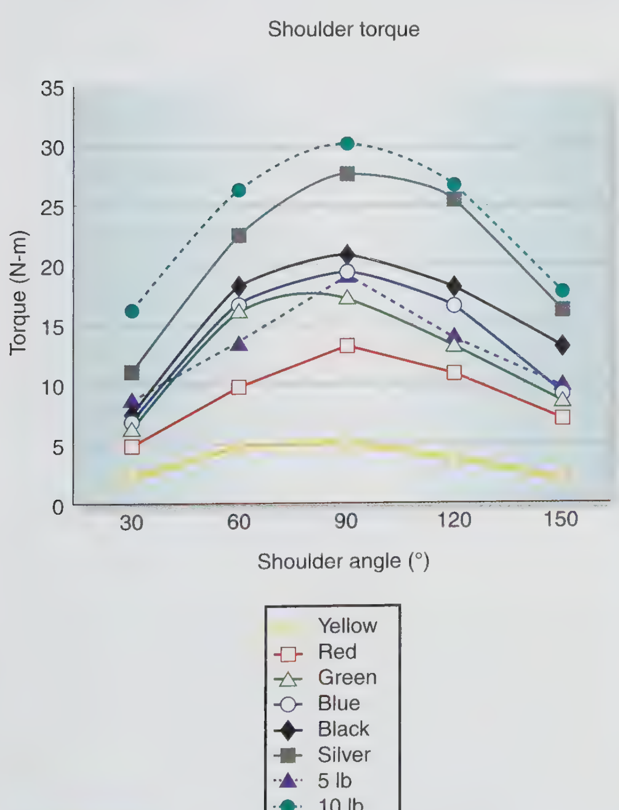

FIGURE 5-16 Strength curves of Thera-Band elastic tubing compared to free weights. (Used with permission of The Hygenic Corporation. Data from Page P, Labbe A, Topp R. Clinical force production of Thera-Band elastic bands [Abstract]. J Orthop Sports Phys Ther 2000;30(1):A47–A48.)

Indications

Elastic bands are indicated anytime strengthening but an external resistance is required. Elastic resistance can be used in the clinic under a therapist's supervision. It also works well for home programs utilized in conjunction with in-house rehabilitation. Because it is lightweight and easily transported, elastic resistance works well for those needing to perform exercise while at work or traveling. Resistive bands can be used for fitness or wellness training, providing challenges to muscle strength, power, endurance, as well as plyometric training, balance, and stabilization (**Evidence and Research 5-8**). Bands can be integrated into a practice or training session to provide additional activity-specific, open, or closed chain training. Resistive bands work well for individuals who have limited mobility, as the resistance can be applied in a variety of positions or postures. The resistance variation provides people with low physical capacity the opportunity to train and improve strength and function.[189–192]

EVIDENCE and RESEARCH 5-8

The effects and outcomes of elastic band training compared with other forms of strength training have supported the use of elastic bands in a variety of situations. Plasma creatine kinase levels, muscle soreness, and magnetic resonance imaging demonstrated equivalent responses when comparing elastic band resistance to Nautilus machine training.[181] Elastic band training has shown equivalent results when compared with dumbbell training,[182] free weights, and variable resistance devices.[183,184] Improvements in strength and power following elastic band training have been shown in adults with and without musculoskeletal pain,[185] in patients with COPD[186] females with knee osteoarthritis,[187] and in women performing squat activities.[188]

Considerations

There are some issues to be considered when prescribing elastic band resistive exercises. First, although there is some data about the amount of resistance provided from different colors of elastic bands, patient implementation variables render it an inexact quantity. The amount of resistance varies with the elongation, so if the patient grasps the band at a different location, or initiates the exercise at a greater percent elongation, the torque may vary from one session to the next. The patient may not understand why the exercise seems easier 1 day and harder the next.

Although the reproducibility of testing or exercise with elastic bands may be questioned due to issues of cross-sectional area, length, and origin/stabilization, the reliability and validity of elastic band use has been established under controlled conditions. Researchers found a 30-second elastic band elbow flexion test to be significantly correlated with a 30-second elbow flexion test using dumbbells ($r = 0.62$) and maximal isokinetic testing ($r = 0.46$). The test–retest reliability was high as well ($ICC = 0.89$).[179]

Another consideration is the impact of cyclic loading. Like any other elastic medium, loading the material results in changes such as creep. Additionally, cyclic loading (repeatedly stretching and relaxing the bands or tubing) can result in fatigue to the material. Over time, this fatigue can decrease the performance of the elastic and can eventually lead to failure. Research has shown that elastic bands stretch to 100% elongation for 500 cycles, resulting in a 5% to 12% decrease in force.[177] More importantly, the majority of the change occurred within the first 50 cycles. If patients are performing sets of 30 or more repetitions, the elastic can fatigue quickly. Therefore, it is important to replace elastic bands frequently.

Like pulleys, elastic resistance exercises can be performed with or without external stabilization. If no stabilization is provided, be sure the patient is performing the exercise without substitution.

Dosage

Like any resistive exercise, the proper dosage is necessary to ensure achievement of rehabilitation goals. Dosage is more difficult with elastic resistance because of the number of variables associated with this resistance mode. The length of the band, the percentage elongation, the color of band, and the origin of the elastic resistance all impact the torque developed.

Elastic resistance typically comes in a variety of colors and each color provides a different amount of resistance. Research on Thera-Band elastic bands showed a 20% to 30% increase in force production between colors.[176] Increases in intensity should be accomplished by moving to the next higher level of resistance rather than doubling the elastic band. Doubling the elastic band will double the resistance, whereas increasing to the next higher level will provide only a 20% to 30% increase, a safer intensity increase.

Another important variable in dosing elastic band exercise is the **length of the band** or tubing. The band should be elongated to no more than 250% of its original length.[178] To maintain the optimal ascending–descending torque curve, the length of the elastic should be equal to the length of the lever arm. In the case of exercise at the shoulder (i.e., abduction or flexion), the tubing should be equal to the length of the arm. This way, the elongation through the full ROM will be twice the length of the lever (a 200% elongation) resulting in an optimal torque curve for the shoulder musculature.

The **angle of the origin** of the tubing also impacts the torque curve and the subsequent resistance. An angle that is too acute will shift the torque curve to the left, increasing torque earlier in the ROM. An angle that is too obtuse will shift the torque curve to the right, increasing torque later in the ROM. This may be desirable in specific rehabilitation situations, but in general does not reproduce the torque curve of a normal muscle–joint interaction. The therapist should be aware of the impact of this angle on torque production. The origin of the elastic should be in the plane of the axis of rotation and in the direction of the desired motion.[178]

Finally, the **resistance arm angle** should be considered during exercise prescription. The resistance arm angle is the angle produced by the band or tubing and the lever arm (i.e., the hand and the band in the shoulder abduction example). The band and the limb should be aligned to ensure a normal physiologic ascending–descending torque curve. If this alignment is incorrect, excessive torque may be produced at end range, where the least amount is available. It is recommended that the band or tubing be aligned with the ending lever arm at a resistive arm angle of 15 degrees to 0 degree.[178] For example, in shoulder flexion, the band should be placed under the foot so that in the full 180 degrees overhead position, the band pulls nearly straight down, with the wrist:band angle at <15 degrees. A higher angle would place excessive load on the wrist extensor muscles.

Once the patient is properly positioned and the band or tubing color (resistance) and length determined, the number of sets and repetitions should be determined. The patient should start with slight tension on the band (approximately 25% elongation) and perform the exercise through the desired ROM. Depending on the patient's goals (strength, power, endurance, etc.) an increase or decrease in the band color might be indicated. Like free weights or weight machines, the resistance and number of repetitions depend on the goal. For traditional strength or endurance training, repetitions at approximately 6 to 10 RM would be appropriate. For those doing power training, the intensity would be greater, with intensity at 90% of a 3 RM.[178]

As with any resistive exercise, substitution, form fatigue, and stabilization are factors to be considered. Do not sacrifice form for additional resistance or repetitions. Training programs can be designed similar to those with traditional weights. As the patient fatigues, consider performing additional sets at a lower elastic band resistance, just as one might to a decreasing training schedule with free weights.

Free Weights

Free-weight training is the resistive exercise technique of choice for body builders and power lifters. Free weights and cuff weights are also commonly used in rehabilitation. Free-weight training is usually performed with hand-held weights that range from 0.5 to 75 lb or more. Free weights can also be combined on a bar with weight plates. Cuff weights typically range from 0.5 to 25 lb.

Free-weight training allows more discrete increases in resistance, and resistance can differ from one side to the other (see **Self-Management 5-2**). For example, reciprocal biceps curls can be performed with 10 lb on the injured side and 15 lb on the uninjured side. Incremental increases of 1 to 2 lb or less are available, allowing a more gradual overload. Free-weight equipment is affordable, and a multitude of exercises can be performed with the same free weights. These exercises can include simple strengthening and endurance activities or power training techniques.

Free-weight exercises can be performed in a multitude of different ways that meet the needs of individual patients or clients. For example, a variety of positions are available and are not restricted by the design of the machine. Biceps curls can be performed in standing, sitting, supine or even prone. They can be performed symmetrically or reciprocally and the patient may have different weights in each hand. The exercise can be performed at a variety of different speeds and the working ROM can be altered. Changing the position and/or ROM can alter the relationship with gravity, affecting the working muscle group and contraction type. For example, a hamstring curl performed in standing provides concentric resistance during shortening and eccentric resistance while lengthening, both to the hamstring muscle group. This same exercise performed in prone provides concentric resistance with a decreasing moment arm against gravity until the knee approaches the 90-degree angle. At this position, there is no moment arm against gravity and no significant resistance. Continuing into further flexion produces an eccentric contraction of the quadriceps as they are lengthened while trying to slow the flexing knee (**Fig. 5-17A** and **B**). Free-weight exercises provide a multitude of possibilities to match the exercise with the patient's goals.

One of the biggest advantages of free-weight training is the neural component of balance. Compared with the external stabilization provided by a weight machine, the free weight usually has little external stabilization. These exercises require postural muscle stabilization beyond the work required to

SELF-MANAGEMENT 5-2
Standing Biceps Curls

Purpose: To strengthen the biceps muscles.

Position: Standing position, with shoulder girdles, spine, and pelvis in neutral. Hold a weight in each hand, palms facing toward your thighs.

Movement Technique: Level 1: Alternately bend your elbows, turning your palms upward as the weights clear your hips; bend your elbows so your hands come within 4 inches of your shoulder; slowly straighten your elbows, turning your palms sideways again as you move lower your forearms. Maintain your neutral shoulder, spine, and pelvic position as you lift and lower the weight.
Level 2: Bend and straighten your elbows simultaneously.

Hold _____ lb in each hand.

Dosage:

Repetitions: ______________________________
per set, ______________________________ sets

Frequency: ______________________________
sessions per day, ____________________ sessions per week

FIGURE 5-17 **(A)** Hamstring curl in standing and **(B)** hamstring curl in prone.

move the weight. The individual lifting with free weights must understand proper posture and spinal stabilization to prevent injury to the back. If balance is a rehabilitation goal, free-weight exercise may be indicated.

The neural demands of free-weight exercise are a disadvantage for some. It takes longer to learn free-weight exercise, because the free-weight tasks usually are more complex than those with weight machines. Novice lifters may be at greater risk for injury because of poor technique (**Fig. 5-18A** and **B**). Spotters are necessary for many of the free-weight lifts, increasing the personnel demands of this resistive technique. Because of the time required to load and unload bars, free-weight training can be less time efficient. However, for those using smaller hand-held weights, these can be more time efficient than weight machines, due to the lack of setup time.

Safety for individuals training with free weights includes working with a knowledgeable partner who can spot safely. Collars should always be used to lock the weights on the bar and prevent movement of the plates on the bar. Correct form and technique, including proper breathing, should be mastered before performing the exercise with load.

Free weights are used in a similar fashion to elastic bands, tubing, and pulleys. However unlike bands and pulleys, free-weight exercises still need to be positioned with regard to gravity (see **Self-Management 5-3**). Free weights, resistive bands, and pulleys have the advantage of movement in a variety of three-dimensional patterns without fixed movement patterns. This allows highly specific training that matches individual needs. For example, resisted lunging patterns forward, backward, laterally, or diagonally can be performed with elastic bands, pulleys, or free weights. These movement patterns can be performed in whatever range is necessary for the individual, rather than in ranges dictated by a weight machine.

SELF-MANAGEMENT 5-3
Supine Shoulder Flexion

Purpose: To increase the strength of the shoulder muscles, especially serratus anterior.

Position: Lying on your back with the band tied around your foot. Hold the band in the ipsilateral hand with the arm next to your side and elbow bent to 90 degrees.

Movement Technique: Level 1: Keeping your elbow bent, punch your hand toward the ceiling until your elbow is straight, then move your straight arm upward toward your head. Press backward into the surface you are lying on or pillow(s) as needed to support you at the end of your ROM. Push back with an isometric contraction for 10 seconds. Return arm in reverse movement pattern. Repeat as prescribed.
Level 2: Perform level 1 with a straight arm.

Dosage:

Isokinetic Devices

Isokinetic dynamometers are designed to provide maximum resistance through the entire ROM. The resistance provided by these devices is termed *accommodating*, because once the preset speed is achieved, the dynamometer "matches" the force applied by the patient. The dynamometer provides a counterforce equal to the force applied by the patient. Therefore, the patient can obtain the maximum amount of resistance tolerated throughout the ROM. If a patient has pain or weakness in a specific portion of the ROM, the remaining portion can still be fully challenged. Additionally, patients can train at a variety of speeds.

Currently, isokinetic devices are active computerized training and testing devices that are capable of actively moving the patient's limb for him or her. These dynamometers provide reciprocal concentric resistance at fixed speeds, and they provide multiangle isometric resistance, fixed resistance concentric and eccentric contractions, passive motion, and fixed speed concentric and eccentric contractions. Because these dynamometers now function in a variety of modes, they have become multipurpose testing and training devices. Although many dynamometers are capable of providing isometric and isotonic resistance, most providers still refer to these devices as isokinetic dynamometers and emphasize the isokinetic capabilities of these devices.

Indications

The isokinetic mode is used most frequently for muscle performance testing and training. The dynamometers are capable of testing and training muscle groups around most major joints of the body. Muscles around the shoulder, elbow, forearm, and wrist in the upper extremity and the hip, knee, and ankle in the lower extremity are all readily tested and trained using an isokinetic dynamometer. Adaptive attachments allow training for pediatric patients, industrial medicine (i.e., lifting and work simulation attachments) and closed chain exercise and testing. Isokinetic testing is frequently performed as an alternative to 1-RM testing due to the computerized capabilities of the devices and safety issues. The dynamometer matches the patient's force output, thereby minimizing the chance of injury that may be found when performing 1-RM testing, particularly in the presence of an injury. Tests can be performed in a limited ROM and at a fixed speed to assess muscle strength or endurance. Test results are stored in the computer and can be compared with the results of future tests or to population-based norms.

Isokinetic testing is performed to assess muscle performance against some standard. The standard may be the contralateral side, a population norm, or a percentage of the antagonist muscle performance. Testing is performed to assess progress after injury or surgery and to determine readiness to advance the rehabilitation program or to return to activity. In some situations, testing is performed pre-season to provide guidance for the training program or to provide a baseline measure in the case of a future injury.

Testing is typically performed at two or three different speeds to capture speed-specific muscle impairments. Each company that produces dynamometers has specific testing protocols and standards to follow to ensure validity and test–retest reliability. The data are captured in a computer file and can be examined and manipulated in a variety of different ways (**Fig. 5-19**). Several important terms are used to describe isokinetic data results.

- *Peak torque* is the most common variable measured and is the maximum torque generated regardless of where in the ROM it is achieved.
- *Work* is the total amount of work performed under the torque curve, regardless of ROM, time, or speed.
- *Average power* is the amount of work (total work under the curve) performed per time unit ($P = W/T$).
- *Time to peak torque* is the amount of time it takes to achieve peak torque.
- *Peak torque angle* is the joint angle at which peak torque occurred.

Other important and common comparisons are bilateral comparisons and agonist–antagonist ratios. In bilateral comparisons, one extremity is compared with the other to determine the absolute and/or relative difference from side to side. In agonist–antagonist ratios, the opposing muscle groups (i.e., quadriceps and hamstrings) are compared with the antagonist given as a proportion of the agonist (i.e., the hamstrings are 70% of the quadriceps). Normative standards for some agonist–antagonist ratios exist.

Isokinetic training is indicated any time the patient needs muscle activation throughout the ROM. Isokinetics works well when there are fluctuations in torque production due to changes in the length–tension relationships or due to pain or pathology causing significant variation in torque production through the range. Unlike a fixed, constant load (i.e., isotonic), there is no minimum load to lift to complete the activity. If the patient is unable to continue the exercise, he or she can simply stop without worrying about dropping a weight. Isokinetic training also works well when a variety of speeds need to be trained. Velocity spectrum training (VSRP, velocity spectrum rehabilitation program), or training through a variety of speeds, is a commonly used training regimen. Patients may start at a slow velocity (i.e., 60 degrees per second) and increase speed by 30 degrees per second up to a maximum velocity (i.e., 300 degrees per second), and then decrease speed incrementally until the starting speed is reached. A variety of training programs can be designed using this technique.

The passive mode on an isokinetic dynamometer can be used to train isokinetically as well. The passive mode does precisely what the name implies: it passively moves the limb at a preselected velocity. The patient can use this mode in a variety of different ways. The patient might be instructed to relax and let the machine move and mobilize the joint. Alternatively, the patient might be asked to assist the machine in the direction it is moving (a concentric contraction) or to resist against it (an eccentric contraction). Why choose resisting against the passive movement rather than the active isokinetic or isotonic concentric and eccentric contractions? In the active modes, the patient must still generate enough torque to actively move the dynamometer arm and match the preset speed of the machine. In some cases, such as a postoperative surgery or an acute injury, this amount of force may still exceed the muscle's capacity. In the passive mode, the machine moves continuously, and the patient can provide resistance at the level and in the appropriate ROM given the current injury status.

Comments:

PEAK TORQUE:	Highest muscular force output at any moment during a repetition. Indicative of a muscle's strength capabilities.
PEAK TQ/BW:	Represented as a percentage normalized to bodyweight and compared to an established goal
MAX REP TOT WORK:	Total muscular force output for the repetition with greatest amount of work. Work is indicative of a muscle's capability to produce force throughout the range of motion
AVG POWER:	Total work divided by time. Power represents how quickly a muscle can produce force
ACCELERATION TIME:	Total time to reach Isokinetic speed. Indicative of a muscle's neuromuscular capabilities to move the limb at the beginning of the range of motion.
DECELERATION TIME:	Total time to go from Isokinetic speed to zero speed. Indicative of a muscle's neuromuscular capability to eccentrically control the limb at the end of the range of motion.
AGON/ANTAG RATIO:	The Reciprocol muscle group ratio. Excessive imbalances may predispose a joint to injury
DEFICITS:	1 to 10% No significant difference between extremities 11 to 25% Rehabilitation recommended to improve muscle performance balance.

Biodex Rev 4.18b Sep 25 2006

FIGURE 5-19 Isokinetic test data analysis.

Considerations

The major advantage of isokinetic resistive training is its ability to fully activate more muscle fibers for longer periods. Because the machine matches the torque provided by the patient, it "accommodates" the patient's changing abilities throughout the ROM. In contrast, free weights (i.e., fixed resistance training) overload only the weakest portion of the range, but the stronger portion (usually the middle third) is not overloaded. For testing purposes, isokinetic dynamometers allow individuals to be tested at a variety of speeds, potentially identifying deficits at more functional speeds. Compared to a 1-RM strength measure, the isokinetic dynamometer produces a force curve through the ROM rather than a single measure. This allows more detailed evaluation of muscle function characteristics (i.e., time to peak torque, total work performed, etc.).

Isokinetic devices allow training at a variety of speeds. The positive effect of fast-speed training on performance is highlighted with isokinetic training. Training at faster speeds can assist the return to functional activities that require less muscle torque development but faster speeds of contraction. Speeds that more closely match the patient's function can be chosen to match functional velocities. Higher speeds can decrease joint compression forces in areas such as the patellofemoral joint, decreasing the pain and discomfort often seen with heavy resistance exercises. Although less torque is generated at high speeds, the decrease in pain and more functional speeds may produce better results.

Studies assessing the speed variable favor slow-speed isokinetic training over fast-speed training for the development of strength.[193] High muscular tension is necessary for generating strength gains and is achieved when the isokinetic speed is slow enough to allow full recruitment and generation of a high resisting force.

Isokinetic dynamometers with computer interface also provide feedback for training purposes. This feedback can take many forms, such as visual when trying to reproduce a torque curve or producing enough force to raise a bar to a preset level. Feedback can be auditory with bells when a preset goal is met. Isokinetics can also provide neuromuscular training by requiring the patient to resist at a specific level that is submaximal, a relatively challenging task. Although it may be easy for patients to push as hard as they can to achieve maximum torque production, it is often harder to regulate torque production at lower levels.

Isokinetic resistive training also has disadvantages. These devices are expensive to purchase and maintain. They require trained personnel for setting up patient training programs, testing, and data interpretation. From a biomechanical perspective, most training is done in a single plane, with a fixed axis at a constant velocity in an open kinetic chain. Testing and training in a single plane improve test reproducibility but do not necessarily carry over to function. We rarely move at a constant velocity in functional activities, although this feature provides for maximal loading through the ROM. Some isokinetic devices offer closed-chain components, which have the advantage of testing a functional movement pattern but the disadvantage of being unable to tell where the muscle performance impairment lies.

Dosage

Isokinetic exercise is dosed similarly to other types of quantitative resistive training. Isokinetic devices have the advantage of computerized data reduction, which helps to see and manage resistive exercise volume and intensity. The computerized system allows for storage of exercise training programs, which can be programmed and executed with minimal setup. This data can then be tracked over time. Like any resistive exercise program, the volume of activity must be balanced with intensity and viewed within the context of the patient's daily activities.

Body Weight

Body weight can be effectively used as resistance. Resistive exercises for the lower extremity are the most obvious application of body weight as resistance, due to the high number of functional activities that require the lower extremity muscles to move body weight. Walking, running, sports, stair climbing, and transfers of all sorts are examples of activities requiring the movement of body weight. Examples of upper extremity exercises using body weight include push-ups, planks, pushing or pulling oneself out of bed or a chair, suspension exercises, or sporting activities such as gymnastics. Many exercises using body weight as the primary resistance are classified as **closed chain** exercises. Closed chain exercises are those activities where the distal segment is fixed on a rigid or semi-rigid surface. Squats, lunges, step-ups, or push-ups are considered closed chain exercises. **Open chain** exercises are those where the distal segment is free, as in performing a straight leg raise, resistive knee extension, or biceps curl.

Body weight can be decreased by altering the position of the body (i.e., push-ups from the knees rather than the feet), using a harness unweighting system, or using a pool. An advantage of using body weight as resistance is that it is always available and rarely requires equipment. A disadvantage is that it is difficult to isolate specific muscles that need strengthening, and the multijoint nature of closed chain exercises lends itself to subtle substitution. See more on closed and open chain exercise in Chapter 14.

THERAPEUTIC EXERCISE INTERVENTION FOR IMPAIRED MUSCLE PERFORMANCE

Therapeutic activities to enhance muscle performance are at the core of the intervention program for many patients. The clinician is faced with a multitude of variables to consider when designing this program. These variables are found in the intervention model in Chapter 2. Prioritizing and balancing all these variables to achieve the best patient outcome requires both knowledge and experience. The following sections will highlight the key variables to consider when designing a resistive exercise program for patients with impairments.

Program Initiation

One of the first variables to consider is the initial physical or training status of the patient. Realize that recommendations about the intervention model variables will change with the training status of the individual patient. Two patients with identical impairments related to an inflammatory shoulder condition may present very differently: one who is a regular exerciser, lifting weights 5 days per week and working construction, whereas the other is a sedentary individual, working at a desk job. The initial exercise prescription and progression plan will differ based on the difference in their initial physical condition and training status. The initial examination and evaluation is used to determine the starting point for the therapeutic exercise program. Once the starting point is determined, progress the rehabilitation program based upon the goals established and the gains made. Based upon the initial examination, the following questions should guide the therapist in determining the appropriate starting point for the program:

- What muscle or muscle group(s) need training? What type of muscle contraction does that muscle utilize to perform the functional activities that are limited?
- What type of training is required (i.e., strength, endurance, power, etc.) at this stage of the rehabilitation program? Should the muscle be isolated or worked as a synergist?
- What activity will best accomplish this goal? What range should be exercised?
- What is their current performance/training/strength status? Is strength above or below fair? Are the manual muscle tests normal? Approximately what resistance do you think they will tolerate and for how many repetitions?
- Given the patient's strength, what is the best mode to perform the exercise (i.e., manual resistance, free weights, body weight, isokinetics, etc.)?
- Are there any precautions necessary (i.e., blood pressure, diabetes, joint instability)?
- What is the injury, pathology, and stage of healing? Other medical comorbidities?

Answering these questions will provide the therapist with a starting place for the rehabilitation program (**Table 5-8**). If the patient reports increased symptoms or is unable to perform the exercise at the level chosen based upon the initial evaluation, a number of opportunities to decrease the exercise challenge exist. Many of these possibilities can be found in Chapter 2 and in Display 2-13. In general, decreasing the intensity, volume, complexity, or environment/stabilization can increase exercise tolerance. Once a set of exercises that do not exacerbate symptoms is developed, then the therapist can consider how to progress the exercise program.

Oftentimes, using palpation combined with manual resistance in the clinic for 1 to 2 sets of 10 to 12 repetitions can help the therapist appropriately dose the exercise. The therapist can monitor for improper muscle recruitment and assess how the muscle(s) of interest are recruited throughout the range of movement, and it assists the therapist determine the appropriate resistance to provide the patient for their home program.

TABLE 5-8

Template for Determining Initial Therapeutic Exercise Prescription

EXAMINATION QUESTION	THERAPEUTIC EXERCISE INTERVENTION MODEL DIMENSION	THERAEPEUTIC EXERCISE PRESCRIPTION OBTAINED
What muscle is impaired?	Muscle or muscle group	Muscle group to be trained
How does this muscle function primarily in this patient's activities? Is this the appropriate contraction type to begin with?	Movement	Type of muscle contraction for initial rehabilitation program, as well as contraction type to be progressed toward (if different)
In what range does the muscle function and does it need to be trained through that full range?	Movement	Working ROM
What is the best mode for applying the resistance?	Mode	Exercise mode such as manual, pulley, elastic band, variable resistance equipment, etc.
What posture or position is this muscle used in functionally for this patient? Is this the best position to initiate training?	Posture	Beginning exercise posture as well as postural goal (if different)
At what speed does this muscle typically function? Is this the best speed to initiate training?	Speed	Beginning exercise speed as well as speed goal (if different)
What is the patient's baseline strength? What are the functional strength demands?	Intensity	Initial training resistance and resistance goals
What muscle function is the primary requirement? (i.e., power, strength, endurance) and at what frequency?	Frequency/duration	Initial training sets and repetitions and sets and repetition goal
What other associated muscle or muscle groups need training? How do they work with the muscle group of interest? (i.e., synergist)	Sequence	Other supportive muscle groups to be trained and sequence for training
Are there any medical precautions or contraindications?	Overarching	Precautions and contraindications to exercise
What is the stage of healing?	Overarching	Volume and intensity limitations

Program Progression

Once the rehabilitation goals and the initial rehabilitation program are determined, the next step is determining the appropriate exercise progression. Exercises can be progressed in a multitude of different ways, ranging from the most obvious of increasing the exercise intensity to changing the exercise to a more complex activity. It is possible to achieve continual advancement toward rehabilitation goals with the appropriate manipulation of program variables. Advancing an exercise program in a healthy individual training for health and wellness follows a more predictable pattern. However, progression in the presence of pathology or deficits is much more challenging.

The goal inpatient progression is to narrow or eliminate the gap between the patient's current status and the desired functional status. How the therapist guides the patient to bridge that gap will likely vary from one individual to the next. The progression from program initiation to discharge requires a balance between exercise load and the loads applied with daily activities.

- *Exercise load* is the amount of stress and strain applied to the tissue of interest as a result of the rehabilitation program.
- *Daily activity load* is the stress and strain applied to the same tissue as a result of daily activities.

The daily activity load may change from 1 day to the next depending on the patient's activities on a given day. The therapist must teach the patient how to modify the exercise load based upon that activity level. This will ensure that the total load placed on the tissue stays within the tissue tolerance. If not, then the likely result is an increase in symptoms.

Display 2-13 (Chapter 2) describes exercise modification parameters that can be used to increase or progress the program. Similarly, if a patient reports an increase in symptoms following program initiation, or the patient is not tolerating the activities at the level they were initiated, the display provides suggested modifications that can decrease the exercise challenge. The overarching goal is to continuously challenge the patient and to expand the training volume to bridge the gap between current and desired functional status. **Figure 5-20** shows the relationship between progression variables/opportunities and expanding exercise volume. By systematically alternating expanding volume and increasing intensity, patients can continue progressing toward their goals.

How much the volume is increased depends on the discrepancy between current and desired function. If a patient is functioning at a very low level due to injury, surgery, or pathology, then the increase in their total quantity of activity may be substantial. For others who may be very physically

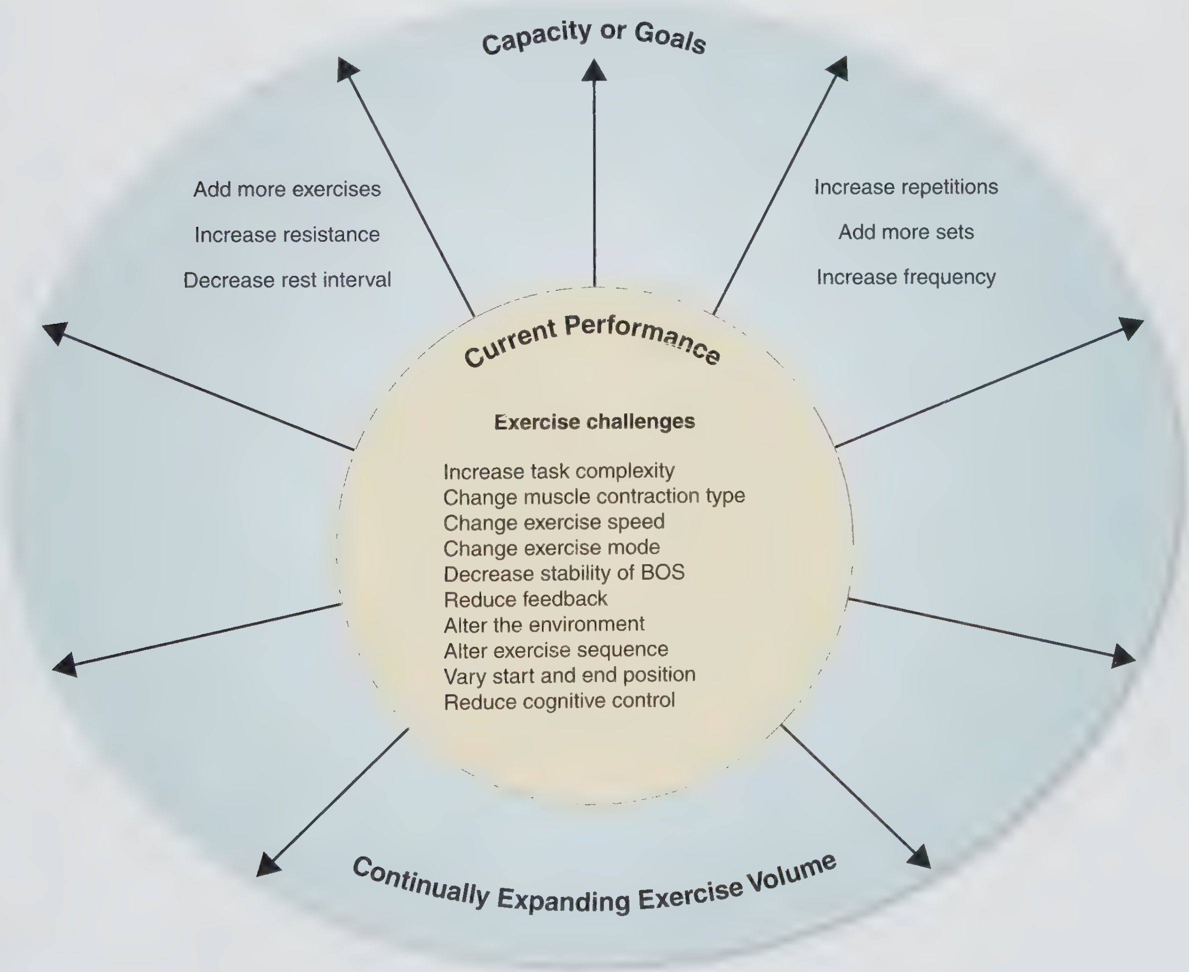

FIGURE 5-20 Exercise progression model.

active but who still have pain, changing the exercise parameters within the same exercise volume may be preferable. For most patients trying to restore a previous level or to obtain a higher level of function, program progression likely follows a variable course with volume increases balanced with exercise parameter changes. For example, a patient recovering from rotator cuff tendinosis may alternate exercise volume increases with changes from isometric or concentric contractions to eccentric, changes from slow speed to fast, and mode changes from free weights to elastic resistance and variable resistance machines (see **Building Block 5-5**). A variety of options exist depending on patient goals and preferences. The therapist must use solid clinical decision-making skills to best fit the appropriate type of exercise progression to the patient's goals.

BUILDING BLOCK 5-5

A 22-year-old marathon runner has had Achilles tendinitis for 6 weeks. She is currently able to run only 3 miles per day every other day before the symptoms prevent her from running any further. Describe how you might progress her strength program to prepare her to return to marathon training. The patient is unwilling to decrease her running at this point.

Another consideration during program progression is the difference between current performance and current capacity. Although a higher capacity or level of function is the long-term goal, the program should be viewed in phases, each with a short-term goal. For example, a patient who sustained a second degree ankle sprain 2 weeks previously may desire to return to long-distance running. However, at this stage of healing, she is doing a series of rehabilitative exercises, deep water running and walking and standing intermittently as part of her job. She is experiencing some increased pain and swelling at the end of the day. It resolves by morning, and overall is making steady improvement. At this point, she is likely performing close to her current physical capacity given the stage of healing. Therefore, increasing her exercise volume might be inappropriate at this point as it may overwork the healing tissue. Rehabilitative exercise changes within the same working volume may be more appropriate at this stage of healing. Looking at the model in Figure 5-20, consider alternative changes to progress her program that do not include increasing exercise volume.

Options to increase the total volume are relatively clear; adding new exercises, resistance, sets, or repetitions are obvious ways to expand the exercise volume. Within a given volume, exercise parameter changes allow exercise progression toward a specific goal without (or with, if that is preferred) a change in total volume. **Increasing task complexity** can be accomplished in a number of different ways. Increasing the number of body segments, the cognitive challenge, or the number of steps are examples of increasing task complexity. For example, increased coordination might be a patient goal. Rather than performing several exercises independently of several repetitions (blocked exercise), different exercises might be combined into a single task (i.e., rise out of a chair, walk across the room around a series of cones, reach up five times, then turn and sit down).

Changing **muscle contraction type** is another way to change and progress the exercise challenge. For someone recovering from knee surgery, changing from isometric quadriceps sets to straight leg raises and knee extension exercises is an exercise progression. For someone recovering from tendinosis, progressing from isometric contractions to eccentric contractions is another way to progress the exercise program without increasing the exercise volume. For general training purposes, it is important to train both concentric and eccentric muscle actions unless one type of action is preferred based on the pathology, impairments, or activity limitations. For example, patients who have difficulty descending stairs because of poor quadriceps control, but no trouble ascending stairs, should emphasize eccentric muscle contractions.

Altering **exercise speed** can change the exercise impact. For many exercises, resistance varies with speed. For example, in the pool, increasing the speed increases resistance, whereas with isokinetic concentric exercise, decreasing the speed increases the resistance. When treating tendinosis, the rehabilitation program often progresses from exercises performed slowly to higher speeds.

Changing the **exercise mode** can alter the exercise challenge. Moving from isotonic resistance to isokinetic can provide more challenge through the ROM. Changing from variable resistance machines to free weights can encourage more balance and stability. Likewise, decreasing stabilization in any way (with or without changing the mode) will place more challenge on the patient as he or she must provide internal stabilization to maintain balance and control in the exercise. Similarly, decreasing feedback requires the patient to rely on internal memory trace of correct motor performance rather than on external feedback provided by the therapist.

Changing the **environment** can provide numerous differing challenges to the patient. One important environmental change is moving from performing exercises in the pool in a minimally or unweighted environment to performing similar exercises on land, or vice versa. Another example is progressing from the structured environment of the clinic where the patient is used to focusing solely on the exercises at hand to a community environment where there are many competing stimuli. Similarly, changing the exercise sequence can be a form of progression. **Sequence** preferences were discussed earlier in this chapter. A sample sequence progression might be performing two exercises training the same muscle group back to back rather than alternating the exercises with a different activity. For example, the patient might perform resisted knee extension immediately followed by resisted straight leg lifts rather than performing a hamstring curl or an upper body exercise in between.

For many individuals, changing the **movement pattern or posture** can significantly alter the activity. For example, patients with spinal stenosis may need to perform exercises in slight flexion in the early stages. As symptoms improve, progression might include performing the same exercises closer to neutral or neutral toward an extended position. The movement for trunk stabilization exercises might progress from performing an exercise bilaterally (where the bilateral nature of the exercise provides balance and some stability) to performing the same movement unilaterally with the contralateral limb held close to the side. This asymmetric pattern would provide increase trunk stability challenge.

Finally, removing **cognitive control** asks the patient to progress the exercise from the cognitive motor control stage to the autonomous stage (see Chapter 3). This is simply done by engaging the patient cognitively while asking him or her to perform a motor skill. Thus the same task becomes more challenging as the patient is no longer allowed to cognitively focus on the exercise demands.

Finding the right balance of expanding volume and program changes within the same volume is no easy task. However, taking smaller incremental steps to progress the patient will minimize any significant regression should the program changes be too challenging. Ongoing communication and close monitoring either face to face or by other means can help ensure continuous forward progress toward goals. This communication should include patient education on the expected response to the exercise program and instructions for modification should symptoms increase.

THERAPEUTIC EXERCISE INTERVENTION FOR PREVENTION, HEALTH PROMOTION, AND WELLNESS

Patients who successfully complete a rehabilitation program may want to continue a resistive exercise program to further the gains they have made and/or to prevent a recurrence of their injury. These individuals can transition into a fitness exercise program. Exercise progression following a rehabilitation program, or designing a program for injury prevention or wellness, must consider the current training level of the individual.

The ACSM defines a *novice* as someone with no training experience, *intermediate* as someone with 6 months of consistent resistance training experience, and *advanced* as someone with years of resistive training experience.[37] *Elite* individuals are highly competitive athletes. Strength gains vary considerably among these training groups. You can expect muscle strength gains of approximately 40% in untrained individuals, 16% to 20% gains in intermediate, 10% in advanced, and 2% in elite athletes.[37] These gains can be expected over the course of 4 weeks to 2 years, with the majority of gains (especially in the untrained) occurring in the first 4 to 8 weeks. For untrained individuals, the responses to just about any training program will be profound, whereas making gains in intermediate, advanced, or elite athletes is much more difficult. Exercise prescription will need to be more creative and variable in these individuals.

Although strength gains in the short-term (4 to 8 weeks) can be encouraging for the participant, this rate of progress will level off after an initial period of training. At this point, program changes must be considered to continue progression toward exercise goals. The ACSM defines **progression** as the continued improvement in a desired variable (i.e., strength, power, endurance, muscle hypertrophy, etc.) over time until the individual goal has been achieved.[30] Continuing the initial training program for several months following program initiation is unlikely to sustain forward progress. Changes to the resistive training program are necessary to minimize training plateaus and to sustain forward progress. Like resistive training for rehabilitation, progressive overload can occur by increasing the exercise load, repetitions, or volume, or by changing the exercise speed, decreasing rest intervals, or by any combination of these variables. A periodized program to systematically vary exercise volume and intensity has been shown to be most effective for long-term progression.[37,194,195]

Dosage for Strength Training

For strength development, the ACSM recommends that novice and intermediate lifters train at an intensity of 60% to 70% of 1 RM for 8 to 12 repetitions.[37] All lifters should use both concentric and eccentric contractions. Untrained individuals require very little load to improve strength. Loads as little as 45% to 50% of 1 RM and less have been shown to increase strength in previously untrained individuals.[195,196] Novices should train the entire body 2 to 3 days per week whereas intermediate lifters should train similarly, unless desiring to progress to split workouts (upper body 1 day and lower another). In this case, the frequency should be 3 to 4 days per week, allowing training of each muscle group 1 to 2 days per week. The volume prescription should include either single or multiple sets initially (such as the DeLorme or DAPRE) and progressed to periodized training using multiple sets. Advanced lifters should train at 80% to 100% of 1 RM in a periodized plan.[37] Apply an approximately 2% to 10% increase in load when the individual can perform the current intensity for one to two repetitions over the desired number on two consecutive training sessions.[37] Base the intensity progression on the muscle group and activity.

The total training volume should be varied and progressed to continue strength gains. The training volume can be varied by changing the number of exercises performed in a session, by changing the number of repetitions performed in a set or the number of sets of exercise. Training volume dose–response recommendations for different populations have been made.[33] For untrained individuals, maximum strength gains were achieved at an intensity of 60% of 1 RM, 3 days per week with a mean training of four sets per muscle group. Recreationally trained athletes showed maximum strength gains at a dosage of 80% of 1 RM, 2 days per week also training four sets per muscle group. For athletes, maximal strength gains were made when training at 85% of 1 RM, 2 days per week at a mean training volume of eight sets per muscle group.[33,196]

Some ongoing debate surrounds the question of single- versus multiple-set resistance training programs.[197–201] Many gen exercisers, either single- or eral strength training programs include a single exercise set of 8 to 12 repetitions.[102] For novice exercisers, either single- or multiple-set resistance programs will achieve strength gains, although multiple sets produced superior gains in some research.[37,200,201] However, for trained individuals, multiple sets are more effective for strength building.[37,198,199]

Slow to moderate velocities are recommended for novice trainers unless the patient has difficulty generating torque or controlling movement at a specific functional speed. The ACSM recommends moderate velocities for intermediate training, and a spectrum of velocities from unintentionally slow to fast to maximize training gains in the advanced and elite athlete.[37] Unintentionally slow velocities are those where the load is so high that it requires the individual to lift slowly due to loading and/or fatigue. This type of training produces overload and a training response, whereas intentionally slow lifting, or submaximal lifting performed at a slow velocity (i.e., 5- to 10-second concentric, 5-second eccentric), do not produce sufficient overload.[203,204]

For novice, intermediate, or advanced training, the ACSM recommends rest intervals of 2 to 3 minutes for multijoint exercises using heavy loads.[37] For other exercises (including weight machines), they recommend a shorter rest interval of 1 to 2 minutes. This recommendation is the same for developing both strength and power.

Dosage for Power Training

Power requires a combination of strength, speed, and skill and the training program should reflect these variables. Effective use of power requires baseline strength at both fast and slow speeds, the ability to generate force quickly, efficient use of the SSC, and good neuromuscular coordination.

For power development, one to three sets of 30% to 60% of 1 RM for three to six repetitions should be incorporated into the intermediate training program.[37] Progression should use various loads planned in a periodized fashion. Advanced training should include a three- to six-set (one to six repetitions per set) power program incorporated into the strength program. Progression of power training requires both heavy loading (85% to 100% of 1 RM) for force development, and light to moderate loading (30% to 60% of 1 RM) performed at high velocity for increasing fast force production.[37] Focus only on heavy loading may actually decrease power output if not accompanied by quick, explosive-type exercises such as the loaded jump squat.[94] Rest period recommendations are the same as for strength training (see **Building Block 5-6**).

BUILDING BLOCK 5-6

A sprint athlete would like advice on how to increase performance for the 220-yard hurdles. Please provide some suggested strategies.

Plyometric Exercise

Functional activity seldom involves pure forms of isolated isometric, concentric, or eccentric actions, because the body is subjected to impact forces (**Fig. 5-21**), as in running or jumping, or because some external force, such as gravity, lengthens the muscle. In these movement patterns, the muscles are acting eccentrically and then concentrically. By definition of eccentric action, the muscle must be active during the lengthening phase. The SSC is the combination of an eccentric action followed by a concentric action. Training techniques that employ the SSC are called *plyometrics*. Examples of plyometric exercises include hopping, skipping, bounding, and jumping drills for the lower extremity, and plyometric ball or elastic resistive exercises for the upper extremity. However, not all jumping or resistive band exercises are plyometric. Plyometrics are done with a specific goal in mind: to increase power and speed.

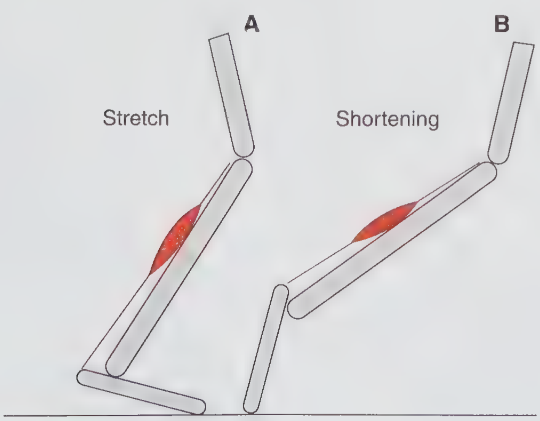

FIGURE 5-21 The SSC cycle in daily activities. At contact, the muscle is stretched and contracts in a lengthening action (eccentric) **(A)**. The stretch phase is followed by a shortening (concentric) action **(B)**. The figure demonstrates the SSC, which is the natural form of the muscle function.

Plyometrics are quick, powerful movements that are used to increase the reactivity of the nervous system. Plyometrics enhance work performance by storing elastic energy in the muscle–tendon unit during the stretch phase and reusing it as mechanical work during the concentric phase. Bosco et al.[205] found that the amount of elastic energy stored in a muscle during eccentric work determines the recoil of elastic energy during positive work. Part of the developed tension during the stretching phase is taken up by the elastic elements arranged in series with sarcomeres (i.e., series elastic component or tendon). This mechanical work is stored in the sarcomere cross-bridges and can be reused during the following positive work if the muscle is contracted immediately after the stretch. The muscle's ability to use the stored energy is determined by the timing of the eccentric and concentric contractions and by the velocity and magnitude of stretch. A quick transition from eccentric to concentric (i.e., undamped landings) along with a high-velocity stretch of high magnitude produces the greatest benefits. The transition time between the eccentric and concentric contractions is called the amortization phase, and the distinction between plyometrics and other impact activities is the goal of decreasing this phase as much as possible.

Plyometrics are high-level activities. Because of the stored energy in the series elastic component, the tendon is susceptible to overuse injury when performing plyometric exercises. The individual should be in an advanced training stage before these techniques are employed. In an advanced exercise program, these techniques develop power and speed, the key muscle performance elements of athletics. Jumping from or to different heights, bounding (i.e., jumping for distance), progressive throwing programs, and throwing for speed or distance are methods of using SSC for enhancing speed or power performance. Before performing lower-extremity plyometrics, the individual must be able to squat his or her body weight, perform a standing long jump equal to his or her height, and balance on a single leg with eyes closed. Programs should be well planned and progressed slowly and appropriately for the individual and the goals. An example of a plyometric program can be found in **Display 5-3**. See Additional Reading for more plyometric materials.

DISPLAY 5-3

Sample Plyometric Activities

Easy

- Ankle bounces in place
- Ankle bounces side to side
- Ankle bounces with 90-degree turn
- Ankle bounces in stride
- Single leg push offs from box
- Lateral hopping over cones
- Forward hopping over cones

Intermediate

- Jump ups on box
- Side jumps on to box

DISPLAY 5-3

Sample Plyometric Activities (*continued*)

- Tuck jump
- Multiple jumps forward
- Multiple jumps sideways
- Split squat jump
- Cone hops with turn
- Cone hops with land and sprint

Advanced

- Multiple box jumps with single leg land
- Squat jumps to multiple boxes
- Depth jumps with ball catch
- Standing long jump with 90-degree turn and sprint
- Depth jump with 90-degree turn and sprint
- Single leg bounding
- Bounding and vertical jump combination

Dosage for Endurance Training

Muscle endurance is necessary for a variety of activities and muscle groups. For example, postural muscles must provide sustained or repetitive contractions for long periods during prolonged standing, walking, or work activities. Many lower extremity muscles need endurance distance running, tennis, or other sports and leisure activities. Repetitive work activities such as carpentry, factory work, or other manual labor require local muscle endurance to fulfill job requirements during 8- to 12-hour work shifts.

For development of muscular endurance in novice and intermediate training, the ACSM recommends relatively light loads with moderate to high volume (10 to 15 repetitions). For advanced training, various loading strategies should be used for multiple sets per exercise (10 to 25 repetitions) using a periodization scheme.[37]

Use shorter rest periods such as 1 to 2 minutes for high repetition (15 to 20 repetitions) and <1 minute for moderate (10 to 15 repetitions) sets.[37] The training frequency is the same as for strength training, and the training velocity should be slow when doing a moderate (10 to 15) number of repetitions, and moderate or fast velocities when performing higher numbers of repetitions (15 to 25 or more).

Dosage for the Advanced or Elite Athlete

The following techniques are used by those who train competitive athletes. These techniques can be used to provide variety, increase resistance, or maximize the workout time in daily workouts. These specific techniques provide the recommended variability necessary for training the advanced or elite athlete. They are introduced to familiarize the therapist with the terminology used in training these athletes. Use good judgment based on scientific principles when using these techniques.

A **superset** consists of two sets of exercise involving opposing muscles that are performed in sequence without a rest between sets (e.g., a biceps curl followed by a triceps extension, without rest, proceeding to the remaining sets). Supersets can reduce workout time or allow more exercise to be performed during the same period.

A **triset** is a group of three exercises, each done after the other with little rest between muscle groups. Trisets can be used to exercise three different muscle groups or three angles of a complex muscle (e.g., flat, incline, decline bench press for the different fiber directions of the pectoralis major).

Pyramid training is a modification of the DeLorme training program. The regimen starts with a high number of repetitions and low weight (to warm up), but instead of maintaining the repetitions constant and increasing the weight, the repetitions are reduced and weight is increased. After the series is completed, the individual works backward, taking off weight and adding repetitions. The number of repetitions and sets is arbitrarily established as long as the high-repetition, low-weight progression to a heavier-weight, low-repetition regimen is followed (**Table 5-9**).

A typical **split routine** consists of a series of exercises that usually emphasize two or three major muscle groups or body parts. This allows the individual to train on two consecutive days without overtraining muscle groups, because one muscle group is resting, whereas the other is exercising. Body builders often follow a double-split routine, in which two sessions are performed on each day (**Table 5-10**).

Matveyev[206] described the basic ideas of periodized training programs for these athletes. A program is periodized when it is divided into phases, each of which has primary and secondary goals. The program is based on the premise that maximum strength gains are not made by constant heavy training but are made possible by different training cycles or periods. These

TABLE 5-10

Example of a Split Routine for Total-Body Resistive Training

FOUR-DAY PROGRAM[a]	SIX-DAY, TWO SESSIONS PER DAY PROGRAM[a]
Monday: upper body	Monday AM: chest
Tuesday: lower body	Monday PM: back
Wednesday: rest	Tuesday AM: shoulders
Thursday: upper body	Tuesday AM: upper legs
Friday: lower body	Wednesday AM: triceps
Saturday: rest	Wednesday PM: biceps
Sunday: repeat sequence	Thursday AM: chest
	Thursday PM: back

[a]Abdominal and calf muscles are exercised each day.

cycles allow the athlete to reach maximum performance level at a predesignated time, usually the day of competition.

In his original model, Matveyev[206] suggested that the initial phase of a strength-power program should contain a high volume (i.e., many repetitions) with lower intensity (i.e., low average weight lifted relative to maximum possible in each movement). Typical high-volume phases for weight lifters contain more training sessions per week (6 to 15), more exercises per session (3 to 6), more sets per exercise (4 to 8), and more repetitions per set (4 to 6). As weeks pass, the volume decreases and intensity increases. The resulting higher intensity and lower volume represent the characteristics of a basic strength phase of training. Typical high-intensity phases for weight lifters contain fewer training sessions per week (5 to 12), fewer exercises per workout session (1 to 4), fewer sets per exercise (3 to 5), and fewer repetitions per set (1 to 3). A third, optional phase may include low volume (low repetitions) with high intensity (heavy weights) to work on power. The final phase is considered an active rest phase with very low volume and very low intensity.

Each phase may be several weeks to several months long. Two or more complete cycles may fit into a training year.

Stone et al.[207] proposed and successfully tested a periodized model of strength-power training with sequential phases that change rather drastically. An example is a phase to increase muscle size (5 sets of 10 RM in core exercises), a phase to improve specific strength (3 to 5 sets of 3 RM), and a phase to "peak" for competition (1 to 3 sets of 1 to 3 repetitions). The use of 10 RM is higher than typically recommended in the early preparation phase but has proved to be successful in a number of studies.[207]

PRECAUTIONS AND CONTRAINDICATIONS

Be sure to consider certain precautions and contraindications when prescribing resistive exercise. Avoid using the Valsalva maneuver during resistive training, especially by patients with cardiopulmonary disease or after recent abdominal, intervertebral disk, or eye surgery. Educate patients to breathe properly during exercise, typically exhaling on exertion. Use isometric exercise with caution by persons at risk for pressor response effects (e.g., high blood pressure after an aneurysm).

Overwork phenomena may exist even at moderate training regimens over an extended period. Overtraining may lead to mood disturbances and reduce the effect of training by a decrease in performance. Avoid fatigue and overtraining by patients with metabolic diseases (e.g., diabetes, alcoholism), neurologic diseases, or severe degenerative joint diseases because of the risk of further joint damage. Overtraining may be the reason for a lack of progress, decreased performance, or development of joint pain and swelling.

Use thoughtful consideration when developing resistive exercise programs for prepubertal and pubertal children and adolescents. Emphasize correct form and technique over weight lifted and develop comprehensive exercise programs to avoid muscle imbalances and overtraining specific tissues.

An absolute contraindication to resistive exercise is acute or chronic myopathy, as occurs in some forms of neuromuscular disease or in acute alcohol myopathy. Resistive exercise in the presence of myopathy may stress and permanently damage an already compromised muscular system.

Scientific knowledge and common sense should be applied in prescribing resistive exercise. Caution should be taken with exercise in the presence of pain, inflammation, and infection. Although resistive exercise may be indicated, the mode and dosage should be carefully chosen.

KEY POINTS

- The term *muscle performance* includes strength, power, and endurance.
- The term *strength* should be clarified in terms of force, torque, and work.
- Muscle actions are static and dynamic. Static muscle actions are called *isometric*.
- A thorough knowledge of muscle morphology is necessary for effective/efficient therapeutic exercise prescription to improve muscle performance.
- *Dynamic action* is the preferred term over *isotonic*. Dynamic actions can be further divided into concentric and eccentric actions.
- Overload training produces changes in the size of the muscle primarily through hypertrophy but also through hyperplasia.
- Muscle strength must be evaluated relative to the muscle's length because of length–tension relationships.
- Muscle architecture can significantly affect muscle force production.
- Specificity of training exists, especially relative to training velocity.
- Eccentric muscle contractions are the most energy-efficient contraction type and can develop the greatest tension of any muscle contraction type.
- Adaptations to resistive training are partially neurologic in that changes in performance often precede morphologic changes.
- *Form fatigue* is the point at which the individual must discontinue the exercise or sacrifice technique.
- Although dosage and goals differ, resistive training is beneficial from late childhood through old age.
- Impaired muscle performance can result from neurologic pathology, muscle strain, muscle disuse, or length-associated changes.
- Adaptations to resistive training extend beyond the muscle to include connective tissues, the cardiovascular system, and bone.
- Activities to improve muscle performance include isometric, dynamic, plyometric, and isokinetic exercise.
- Dynamic exercise can be performed with a variety of modes, including free weight, resistive bands, pulleys, weight machines, or body weight, including various combinations of concentric and eccentric contractions.
- Plyometric activities use the SSC to enhance muscle performance.
- The dosage of exercise to improve muscle performance depends on the goal (i.e., strength, power, and endurance) as well as the initial fitness level of the individual (i.e., novice, intermediate, advanced, and elite).
- Precautions and contraindications to resistive exercise must be known to ensure safety to the patient/client.

LAB ACTIVITIES

1. A series of musculoskeletal conditions is listed from i to viii. For each condition, perform the following:
   a. Determine which muscles are involved. Include possible underused synergists that may lead to overuse of the muscle involved. List each muscle and describe its specific action.
   b. Design and perform one exercise for each muscle (group) given the manual muscle test grade of fair minus (3–/5). Include complete dosage parameters.
   c. Design and perform two exercises for each muscle (group) given the manual muscle test grade of good (4/5). Use an elastic band for one and a free weight for the other, and include complete dosage parameters.
   d. Progress the exercises in question 1c to two functional activities.

Musculoskeletal and Neuromuscular Conditions

i. Achilles tendinopathy
ii. Iliotibial band fascitis
iii. Patellar tendinopathy
iv. Hamstring strain
v. Peroneal nerve palsy (i.e., common peroneal nerve; list muscles innervated)
vi. Supraspinatus tendinopathy
vii. Middle trapezius strain resulting from overstretch
viii. Lateral epicondylitis

2. Using free weights or a weight machine, determine the 1, 6, and 10 RM for a bench press and leg extension. Determine the dosage for Oxford, DeLorme, and DAPRE programs.
3. Pick three muscle groups throughout your body (one upper quarter, one lower quarter, and one trunk). Design two different resistive exercises for each muscle group using a variety of equipment, including elastic bands, free weights, and pulleys and weight machines if available. Determine the dosage for a DeLorme program.

CRITICAL THINKING QUESTIONS

1. Consider each of the questions in the Lab Activities in the next section. How would your dosage differ if you were training for:
   a. strength
   b. power
   c. muscle endurance

   How would your training differ for:
   d. an adolescent cross-country runner who wanted to improve performance
   e. a preadolescent: gymnast, dancer, football player, soccer player
   f. an elderly man who was training for a 10-day hike in the mountains
2. Design a muscle performance program for a woman confined to bed rest for 3 weeks after an acute lumbar fracture without neurologic involvement. Include dosage parameters for strength and endurance.
3. Consider Case Study No. 5 in Unit 7. List muscles with impaired muscle performance. Determine whether the muscle requires strength, endurance, or power training. Decide on one activity for each muscle and determine the dosage relative to the goal (i.e., strength, power, and endurance) and initial fitness level for this patient. Develop the sequence of exercise for each session and include the frequency in the dosage parameters.

CHAPTER

6

Impaired Aerobic Capacity/Endurance

JANET R. BEZNER

Cardiovascular endurance is the ability of the cardiovascular system (i.e., heart, lungs, and vascular system) to take in, extract, deliver, and use oxygen and to remove waste products. Cardiovascular endurance, or aerobic capacity, supports the performance of repetitive activities using large muscle groups for extended periods. All patients and clients require adequate aerobic capacity, especially those who work at home or on the job; participate in athletic endeavors of all levels, skill, and type; and perform physical activity for fun or leisure. Concurrently, these activities also improve impairments in aerobic capacity, and are thus useful therapeutically in a rehabilitation setting.

The literature contains strong evidence that the regular performance of cardiorespiratory endurance activities reduces the risk of developing disease, such as cardiorespiratory disease, metabolic disease (diabetes and metabolic syndrome), and breast and colon cancer, as well as decreases risk of depression and cognitive decline, and is associated with lower mortality rates in both older and younger adults.[1–3] Despite this evidence, recent surveys of exercise trends among inhabitants of the United States illustrate that approximately 51.6% of US adults perform 150 minutes of aerobic physical activity per week.[4] Adolescents and young adults (ages 12 to 21) were found to be similarly inactive, with approximately 47.3% performing 60 minutes per day of physical activity 5 days per week.[4] Since the Surgeon General's report on physical activity and health was published in 1996,[5] numerous efforts have been undertaken to monitor the prevalence of physical activity in the population. Based on Behavioral Risk Factor Surveillance System data collected between 2001 and 2005, the prevalence of regular physical activity (either vigorous or sustained as defined above) increased significantly by 8.6% (from 43.0% to 46.7%) among women overall and by 3.5% (from 48.0% to 49.7%) among men. Except for women between the ages of 18 and 24 years, significant increases in regular activity were reported in all racial/ethnic, age, and education-level categories examined. For men, significant increases in regular physical activity were found among 45- to 64-year-old respondents, non-Hispanic white males, non-Hispanic black males, high school graduates, and college graduates.[5]

Because of the widespread prevalence of physical inactivity among the US population, the US Public Health Service has created goals for exercise participation in the *Healthy People 2020*, *Healthy People 2010*, and *Healthy People 2000* documents, aimed at improving the quality and increasing the years of healthy life.[6,7] In the mid-1990s, the US Department of Health and Human Services, the Centers for Disease Control and Prevention, the National Center for Chronic Disease Prevention and Health Promotion, the President's Council on Physical Fitness and Sports, and the American College of Sports Medicine (ACSM) recommended that all adults should accumulate 30 minutes or more of moderate-intensity physical activity on most, and preferably all, days of the week.[8] In 2007, the recommendation was updated by the ACSM and the American Heart Association (AHA) for adults between 18 and 65 years of age, including adults in this age range with chronic conditions not related to physical activity.[9] The recommendation for adults to promote and maintain health was to perform moderate-intensity aerobic physical activity for a minimum of 30 minutes on 5 days each week or vigorous-intensity aerobic activity for a minimum of 20 minutes on 3 days each week. Also, a combination of moderate- and vigorous-intensity activity could be performed to achieve the recommendation.[9] The US Department of Health and Human Services, Office of Disease Prevention and Health Promotion published yet another guideline in 2008 called the 2008 Physical Activity Guidelines for Americans that compiled all of the research about the impact of physical activity on health and well-being.[10] These guidelines include a recommendation for:

- All adults 18 to 65 to accumulate:
  - 150 minutes per week of moderate aerobic physical activity
  - 75 minutes of vigorous aerobic physical activity
  - or an equivalent combination, plus 2 days of muscle strengthening activities per week[10]
- Children and adolescents should accumulate:
  - 60 minutes a day of moderate or vigorous physical activity including vigorous activity 3 days per week[10]
- Adults over the age of 65 should follow the same guidelines as adults and add balance actvivities.[10]

Toward this end, health care professionals have an opportunity to contribute to the overall well-being of the patients and clients we serve by prescribing meaningful physical activity programs based on the most contemporary scientific evidence. In order to adequately address the plethora of chronic diseases that are prevalent in individuals we serve, it is our responsibility to ensure that every patient/client is assessed and educated about the importance and power of regular physical activity related to the treatment and prevention of disease. In this chapter, the scientific basis of aerobic training will be presented along with guidelines for prescribing and supervising aerobic exercise and physical activity.

AEROBIC CAPACITY AND ENDURANCE

Definitions

There are many terms used in relationship to aerobic capacity and exercise that require clarification. Common terms are defined in **Table 6-1** and examples are provided.

Normal and Abnormal Responses to Acute Aerobic Exercise

The performance of aerobic exercise can be easily assessed using commonly measured parameters, such as heart rate (HR), blood pressure (BP), and respiratory rate (RR). It is important for the clinician to know and recognize the normal and abnormal response to acute aerobic exercise so that a judgment can be made about the patient/client's response and exercise stopped prior to the development of a situation that could put the patient/client in danger. Moreover, patient/clients typically have several comorbidities that may lead to abnormal responses, and therefore a safe environment for exercising can be created with careful monitoring of responses and application of the knowledge about what the responses indicate.

Normal Responses to Acute Aerobic Exercise

To assess an individual's response to exercise, it is important to understand the normal physiologic changes that occur as a result of the performance of physical activity. The ability to sustain aerobic exercise depends on numerous cardiovascular and respiratory mechanisms aimed at delivering oxygen to the tissues. The following changes would be expected *during* aerobic exercise and would be considered normal responses.[12–16]

Heart Rate There is a linear relationship between HR, measured in beats per minute (bpm), and intensity of exercise, indicating that as workload or intensity increases, HR increases proportionally. The magnitude of increase in HR is influenced by many factors, including age, fitness level, type of activity being performed, presence of disease, medications, blood volume, and environmental factors such as temperature and humidity.

Stroke Volume The volume or amount of blood ejected from the left ventricle per heart beat is termed the stroke volume (SV), measured in mL per beat. As workload increases, SV increases linearly up to approximately 50% of aerobic capacity, after which it increases only slightly. Factors that influence the magnitude of change in SV include ventricular function, body position, and exercise intensity.

Cardiac Output The product of HR and SV is cardiac output (Q), or the amount of blood ejected from the left ventricle per minute (L per minute), ($Q = HR \times SV$). Cardiac output (CO) increases linearly with workload because of the increases in HR and SV in response to increasing exercise intensity. Changes in Q depend on age, posture, body size, presence of disease, and level of physical conditioning.

TABLE 6-1

Definitions and Examples of Common Terms Associated with Aerobic Capacity/Endurance Training

TERM	DEFINITION	EXAMPLES
Physical activity	Any bodily movement produced by skeletal muscles that results in energy expenditure.[11]	Walking a dog House work such as sweeping, vacuuming Mowing the lawn
Exercise	A type of physical activity that is planned, structured, repetitive, and is purposely aimed at improving physical fitness.[11]	Jogging to prepare to run a 5K race Walking 60 min/d to lose weight Resistance training to build muscle mass
Physical fitness	A set of attributes that people have or achieve including components of health-related (cardiorespiratory endurance, body composition, muscular endurance, muscular strength, flexibility) and athletic-related skills.[11] Being physically fit enables an individual to perform daily tasks without undue fatigue and with sufficient energy to enjoy leisure-time activities and to respond in an emergency situation, if one arises.	VO_2 max of 35 mL/kg/min Body fat = 27% Ability to perform 55 sit-ups in 1 min Ability to bench press 150 lb 10 repetitions 6 inches on the sit and reach test of flexibility
Cardiorespiratory endurance training (aerobic training)	Repetitive movements of large muscle groups fueled by an adequate response from the circulatory and respiratory systems to sustain physical activity and eliminate fatigue; designed to achieve physical fitness.[1] The ability of the whole body to sustain prolonged exercise.	Jogging 10 min or longer Walking 10 min or longer Bicycle riding 10 min or longer Playing basketball 10 min or longer
Anaerobic training	Exercise performed in short bursts that does not require an ongoing supply of oxygen.[12]	Strength or resistance training
VO_2 max (aerobic capacity, maximal oxygen uptake)	The highest rate of oxygen that the body can consume during maximal exercise.[12]	35 mL/kg/min

Arterial-Venous Oxygen Difference The amount of oxygen extracted by the tissues from the blood represents the difference between arterial blood oxygen content and venous blood oxygen content and is referred to as the arterial-venous oxygen difference (a-vo_2 diff), measured in mL per dL. As exercise intensity increases, a-vo_2 diff increases linearly, indicating that the tissues are extracting more oxygen from the blood, decreasing venous oxygen content as exercise progresses.

Blood Flow The distribution of blood flow (mL) to the body changes dramatically during acute exercise. Whereas at rest, approximately 15% to 20% of the CO goes to muscle, during exercise approximately 80% to 85% is distributed to working muscle and shunted away from the viscera. During heavy exercise, or when the body starts to overheat, increased blood flow is delivered to the skin to conduct heat away from the body's core, leaving less blood for working muscles.

Blood Pressure The two components of BP, systolic (SBP) and diastolic (DBP) pressure, respond differently during acute bouts of exercise. To facilitate blood and oxygen delivery to the tissues, SBP increases linearly with workload. Because DBP represents the pressure in the arteries when the heart is at rest, it changes little during aerobic exercise, regardless of intensity. A change in DBP of <15 mm Hg from the resting value is considered a normal response. Both SBP and DBP are higher during upper extremity aerobic activity, compared to lower extremity aerobic activity. This increase is thought to be because of increased resistance to blood flow and a resulting increase in BP to overcome the increased resistance as a result of the smaller muscle mass and vasculature of the upper extremities compared to the lower extremities.[10]

Pulmonary Ventilation The respiratory system responds during exercise by increasing the rate and depth of breathing in order to increase the amount of air exchanged per minute (L per minute). An immediate increase in rate and depth occurs in response to exercise and is thought to be facilitated by the nervous system, initiated by the movement of the body. A second, more gradual, increase occurs in response to body temperature and blood chemical changes as a result of the increased oxygen use by the tissues. Thus both tidal volume, or the amount of air moved into and out of the lungs during regular breathing, and RR, the number of breaths per minute, increase in proportion to the intensity of exercise.

Abnormal Responses to Acute Aerobic Exercise

Individuals with suspected cardiovascular disease or any other type of disease that may produce an abnormal response to exercise should be appropriately screened and tested before the initiation of an exercise program. This topic will be discussed in greater detail later in this chapter. However, abnormal responses may occur in individuals without known or documented disease and thus routine monitoring of exercise response is important and can be used to evaluate the appropriateness of the exercise prescription and as an indication that further diagnostic testing may be indicated.

In general, responses that are inconsistent with the normal response guidelines described previously are considered abnormal responses. Of the parameters described, HR and BP are most commonly assessed during exercise. The failure of HR to rise in proportion to exercise intensity, a failure of SBP to rise or a decrease in SBP ≥ 20 mm Hg during exercise, and an increase in DBP ≥ 15 mm Hg would all be examples of abnormal responses to aerobic exercise.[15]

Signs and symptoms of exercise intolerance should also be recognized and include those listed in **Display 6-1**. Abnormal exercise responses, such as failure of HR to rise, often occur with patient-related signs and symptoms; however, they can occur independently, so the clinician should be familiar with both. Knowledge of the normal and abnormal physiologic and symptom responses to exercise will enable the clinician to prescribe and monitor exercise safely and confidently and to minimize the occurrence of untoward events during exercise. Regular exposure to aerobic exercise results in changes to the cardiovascular and respiratory systems that can also be assessed by monitoring basic physiologic variables during rest and exercise. These adaptations will be discussed next.[16]

DISPLAY 6-1

Major Signs and Symptoms of Cardiovascular, Pulmonary, and Metabolic Disease

- Pain, discomfort (or other anginal equivalent) in the chest, neck, jaw, arms, or other areas that may result from ischemia
- Shortness of breath at rest or with mild exertion
- Dizziness or syncope
- Orthopnea or paroxysmal nocturnal dyspnea
- Ankle edema
- Palpitations or tachycardia
- Intermittent claudication
- Known heart murmur
- Unusual fatigue or shortness of breath with usual activities

American College of Sports Medicine. Resource Manual for Guidelines for Exercise Testing and Prescription. 6th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010:540.

Physiologic and Psychological Adaptations to Cardiorespiratory Endurance Training

In healthy individuals, cardiovascular training produces profound changes throughout the cardiorespiratory and vascular systems. The documented benefits of aerobic exercise are a result of the adaptations the oxygen delivery system undergoes secondary to the performance of regular activity. These adaptations, considered chronic changes, enable more efficient performance of exercise and thus affect cardiorespiratory endurance and fitness level. These chronic adaptations occur in the cardiovascular and respiratory systems and affect the values of both VO_2 max and body composition (see **Display 6-2**).

Cardiovascular Adaptations

Factors involving the heart that adapt in response to a regular exercise stimulus include heart size, HR, SV, and CO. The weight and volume of the heart and the thickness and chamber size of the left ventricle increase in trained individuals. As a result,

DISPLAY 6-2

Benefits of Regular Physical Activity and/or Exercise

Improvement in Cardiovascular and Respiratory Function

- Increased maximal oxygen uptake resulting from both central and peripheral adaptations
- Decreased minute ventilation at a given absolute submaximal intensity
- Decreased myocardial oxygen cost for a given absolute submaximal intensity
- Decreased HR and BP at a given submaximal intensity
- Increased capillary density in skeletal muscle
- Increased exercise threshold for the accumulation of lactate in the blood
- Increased exercise threshold for the onset of disease signs or symptoms (e.g., angina pectoris, ischemic ST-segment depression, claudication)

Reduction in Coronary Artery Disease Risk Factors

- Reduced resting systolic/diastolic pressures
- Increased serum high-density lipoprotein cholesterol and decreased serum triglycerides
- Reduced total body fat, reduced intra-abdominal fat
- Reduced insulin needs, improved glucose tolerance
- Reduced blood platelet adhesiveness and aggregation

Decreased Morbidity and Mortality

- Primary prevention
  - Higher activity and/or fitness levels are associated with lower death rates from coronary artery disease
  - Higher activity and/or fitness levels are associated with lower incidence rates for combined cardiovascular diseases, coronary artery disease (CAD), stroke, type 2 diabetes, osteoporotic fractures, cancer of the colon and breast, and gallbladder disease
- Secondary prevention
  - Based on meta-analyses, cardiovascular and all-cause mortality are reduced in postmyocardial infarction patients who participate in cardiac rehabilitation exercise training, especially as a component of multifactorial risk factor reduction
  - Randomized controlled trials of cardiac rehabilitation exercise training involving postmyocardial infarction patients do not support a reduction in the rate of nonfatal reinfarction

Other Benefits

- Decreased anxiety and depression
- Enhanced physical function and independent living in older persons
- Enhanced feelings of well-being
- Enhanced performance of work, recreational, and sport activities
- Reduced risk of falls and injuries from falls in older persons
- Prevention or mitigation of functional limitations in older adults
- Effective therapy for many chronic diseases in older adults

American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010.

the heart pumps more blood out per beat (SV) and the force of each contraction is stronger. SV is thus increased at rest, as well as during submaximal and maximal exercise, because of more complete filling of the left ventricle during diastole compared with an untrained heart and an increase in plasma blood volume, discussed in the following section. Changes to HR include a decreased resting HR and a decreased HR at submaximal exercise levels, indicating that the individual can perform the same amount of work with less effort after training. Maximal HR typically does not change as a result of training. The amount of time it takes for HR to return to resting after exercise decreases as a result of training and is a useful indicator of progress toward better fitness. Because Q is the product of HR and SV ($Q = HR \times SV$), it does not change much at rest or during submaximal exercise because HR decreases and SV increases. However, because of the increase in maximal SV, maximal Q increases considerably.[12,15,16]

Adaptations also occur in the vascular system and include blood volume, BP, and blood flow changes. Aerobic training increases overall blood volume, primarily because of an increase in plasma volume. The increase in blood plasma results from an increased release of hormones (antidiuretic and aldosterone) that promote water retention by the kidney and an increase in the amount of plasma proteins, namely albumin. A small increase in the number of red blood cells may also contribute to the increase in blood volume. The net effect of greater blood volume is the delivery of more oxygen to the tissues. Resting BP changes with training are most noteworthy in hypertensive or borderline hypertensive individuals, in whom aerobic training can decrease both SBP and DBP up to 10 mm Hg. During the performance of submaximal and maximal exercise, there is little change, if any, in BP as a result of training. Several adaptations are responsible for the increase in blood flow to muscle in a trained individual, including greater capillarization in the trained muscle(s), greater opening of existing capillaries in trained muscle(s), and more efficient distribution of blood flow to active muscles.[12,15,16]

Respiratory Adaptations

The capacity of the respiratory system to deliver oxygen to the body typically surpasses the ability of the body to use oxygen, thus the respiratory component of performance is not a limiting factor in the development of cardiorespiratory endurance. Nevertheless, adaptations in the respiratory system do occur in response to aerobic training. The amount of air in the lungs, represented by lung volume measures, is unchanged at rest and during submaximal exercise in trained individuals. However, tidal volume, the amount of air breathed in and out during normal respiration, increases during maximal exercise. RR is lower at rest and during submaximal exercise and increases at maximal levels of exercise. The combined increases in tidal volume and RR during maximal exercise of trained individuals produce a substantial increase in pulmonary ventilation, or the process of movement of air into and out of the lungs. Pulmonary ventilation at rest is either unchanged or slightly reduced and during submaximal exercise is slightly reduced following training. The process of gas exchange in the alveoli, or pulmonary diffusion, is unchanged at rest and at submaximal exercise levels, but increases during maximal exercise because of the increased blood flow to the lungs and the increased ventilation as discussed previously.

These two factors create a situation that enables more alveoli to participate in gas exchange, and thus the perfusion of oxygen into the arterial system is enhanced during maximal exercise. Finally, a-vo_2 diff increases at maximal exercise in response to training as a result of increased oxygen distraction by the tissues and greater blood flow to the tissues because of more effective blood distribution.[12,15,16]

One net effect of these cardiovascular and respiratory adaptations on aerobic capacity is an increased VO_2 max after endurance training. A typical training program consisting of three times per week, 30 minutes per session exercise at 75% of VO_2 max, as discussed in a later section of this chapter, over the course of 6 months can improve VO_2 max 5% to 30% in a previously sedentary individual. Resting VO_2 max is either unchanged or slightly increased following training, and submaximal VO_2 is either unchanged or slightly reduced, representing greater efficiency.[12] The second net effect relates to body composition changes that have been documented as a result of aerobic exercise training. Whether caloric intake stays the same during training or is decreased, individuals lose fat mass as a result of training. Several mechanisms have been postulated to produce a loss of body fat secondary to training, including appetite suppression, an increase in the resting metabolic rate, and an increase in lipid mobilization from adipose tissue and thus the burning of fat for energy.[12]

Psychological Benefits of Training

In addition to the myriad of cardiovascular, respiratory, and metabolic improvements that occur after aerobic training, *psychological* benefits have also been documented, although they are less well understood. An overall assessment of the literature in this area indicates that depression, mood, anxiety, psychological well-being, and perceptions of physical function and overall well-being improve in response to the performance of physical activity.[1,15] The finding that exercise can decrease symptoms of depression and anxiety is consistent with the fact that individuals who are inactive are more likely to have depressive symptoms compared to active persons. Improvements in depression and mood have been found in populations with and without clinically diagnosed psychological impairment, as well as in those with good psychological health, although the literature is less conclusive in this specific area.

A number of factors have been postulated to explain the beneficial effects of aerobic training on psychological function, including changes in neurotransmitter concentrations, body temperature, hormones, cardiorespiratory function, and metabolic processes, as well as improvements in psychosocial factors such as social support, self-efficacy, and stress relief. Further research is needed to verify the potential contribution of changes in these factors resulting from aerobic training to improvement in psychological function.

Despite the inability to explain why psychological parameters improve in response to training, the effect on overall quality of life is positive.[17,18] Improvement in quality of life as a result of physical activity has been demonstrated in individuals without[19–23] and with disease, including coronary heart disease patients who are obese,[24] coronary heart disease patients who are elderly,[25] patients with chronic heart failure,[26,27] patients after coronary bypass graft surgery,[28] and patients with multiple sclerosis[29] and cancer.[30] For individuals with disabilities, physical activity has many important benefits beyond psychological function. Because those with disabilities are especially at risk of being sedentary, physical activity is a valuable intervention tool that should be prescribed to match individual levels of ability.[1,31]

Dose–Response Relationship

The amount of physical activity associated with decreased risk for cardiovascular disease and death has been the topic of numerous studies.[32–36] Authors agree that an inverse linear dose–response exists between the amount of physical activity performed and all-cause mortality.[32–34] The 2008 Physical Activity Guidelines clarify that a dose–response relationship exists between physical activity and health benefits, with 500 to 1,000 MET-minutes of activity per week providing considerable health benefits, recognizing that 150 minutes of moderate-activity per week is roughly equivalent to 500 MET-minutes per week.[1] The higher range (1,000 MET-minutes per week) provides more health benefits than the lower range, and activity amounts above 1,000 MET-minutes per week provide even more health benefits.[1] For adults, therefore, at least 150 minutes of moderate-intensity (3.0 to 5.9 METs) activity per week will produce meaningful health benefits.

The dose–response relationship relative to improvements in quality of life has also been examined. The observed improvement in quality of life in individuals who participate in regular exercise is achieved from quantities of exercise considered to produce health-related (versus fitness-related) benefits. Fitness-related benefits include those resulting in significant changes in physical fitness level, as measured by cardiorespiratory endurance and body composition changes. Specific recommendations for fitness-related changes usually include vigorous, continuous activities with a focus on the specific parameters of exercise (intensity, mode, duration, and frequency). Health-related benefits can be achieved through the performance of moderate-intensity, intermittent activity wherein the focus is on the accumulated amount of activity performed.[1,8] The documented health-related benefits from the performance of regular exercise are shown in Display 6-2.

Although improvement in fitness level is a worthwhile goal and also results in the health-related benefits listed previously, exercise to achieve health-related benefits appears to be easier for most people to incorporate into their lifestyle and thus provides a valuable exercise option.[37–39] The specific parameters necessary to achieve both fitness-related and health-related benefits of aerobic exercise are presented later in this chapter.

CAUSES OF IMPAIRED AEROBIC CAPACITY/REHABILITATION INDICATIONS

The ability of the body to use oxygen can be limited by disease and is affected by aging and inactivity. A systems review, conducted as a part of the examination, discussed in the next section, can identify the presence of or risk for pathology/pathophysiology, impairments, functional limitations, or disabilities that impact aerobic capacity.[40] Although injury to or diseases of the heart, lungs, and vascular system—the primary tissues involved in cardiovascular endurance—are the most obvious causes of impairment or functional limitation, diseases and conditions of other body systems also affect aerobic capacity.

There are three categories of diseases that directly affect the heart, including conditions of the heart muscle, diseases affecting the heart valves, and cardiac nervous system conditions.[41] Heart muscle conditions include CAD, myocardial infarction, pericarditis, congestive heart failure, and aneurysms.[41] The pathologic processes involved in the impairment of aerobic capacity in these heart muscle conditions involve obstruction or restriction of blood flow, inflammation, or dilation or distention of one or more heart chambers.[41] Aerobic capacity is impaired because the heart is weakened as a result of the disease or condition or blood flow is impaired, resulting in ischemia and necrosis of heart muscle and an inability to pump enough blood in response to increased demand from activity.

The heart valves can become diseased by rheumatic fever, endocarditis, mitral valve prolapse, and various congenital deformities. Valve defects increase the workload of the heart, as the heart must work harder to pump blood through a malfunctioning valve, resulting in impaired aerobic capacity.[41] The nervous system that controls cardiac muscle contraction, when diseased, produces arrhythmias such as tachycardia and bradycardia. Arrhythmias impair aerobic capacity by causing changes in circulatory dynamics because the heart is beating too slow or too fast, or skipping beats.[41]

There are numerous types of peripheral vascular disease, including arterial, venous, and lymphatic disorders, such as atherosclerosis, embolism, Buerger disease, Raynaud disease, deep venous thrombosis, venous stasis, and lymphedema.[41] Because aerobic capacity is determined by the condition and capacity of both the heart and the peripheral circulation, these conditions also produce impairments. The vascular system is used to transport oxygen to exercising muscles so that diseases of the peripheral vascular system disrupt circulation to peripheral muscles, producing a loss of function at rest and during exercise, impairing aerobic capacity. The most common disease of the vascular system is hypertension, considered a major risk factor for myocardial infarction, stroke, and cardiovascular death.

Conditions affecting the pulmonary system influence the ability of the lungs to bring in and absorb oxygen and expel carbon dioxide from cells in the body. These processes are of primary importance to cardiorespiratory endurance; therefore, diseases affecting ventilation and respiration impact aerobic capacity. Diseases affecting the lungs include lung tumors, chronic obstructive pulmonary disease (including bronchitis, bronchiectasis, emphysema), asthma, pneumonia, tuberculosis, cystic fibrosis, and various occupational lung diseases (pneumoconiosis).[41]

Disease of the neurologic, musculoskeletal, endocrine/metabolic, and integumentary systems may also negatively affect aerobic capacity. Conditions such as cancer, neuromuscular disease, cerebrovascular attacks, traumatic brain injury, spinal cord injury, osteoporosis, arthritis, and AIDS either directly or indirectly impair aerobic capacity and thus limit cardiovascular endurance.

Any medical condition necessitating hospitalization or bed rest can result in deconditioning of the cardiovascular system. Surgical procedures for the gallbladder, appendix, uterus, or other internal organs require a period of decreased activity. Accidents resulting in multiple system injuries can limit activity for long periods of time, resulting in deconditioning.

The effects of aging on the cardiovascular and respiratory systems are numerous, resulting in an overall decrease in aerobic capacity. Some of the factors that have been attributed to the decline in aerobic capacity documented with age include decrements in central and peripheral circulation including a decrease in maximal HR, SV, and a-vO_2 diff; increases in body fat and decreases in lean body mass; and lung function decline including a decrease in vital capacity and forced expiratory volume, an increase in residual volume, and a loss of elasticity in the lung tissue and chest wall.[10] Because the elderly respond to cardiovascular training with impressive improvements in aerobic capacity, it is difficult to differentiate between biologic aging and physical inactivity as the primary cause of the decline in aerobic capacity that occurs with age.

A sedentary lifestyle, or physical inactivity, impairs aerobic capacity and is considered a modifiable risk factor for cardiovascular disease (**Display 6-3**). Considering that more than 25.3% of the US adult population report engaging in no physical activity or exercise other than their regular job in the last 30 days, physical inactivity is more prevalent than the diseases discussed previously that cause impairment in aerobic capacity, and thus is a major public health concern.[1,42] On the positive side, as a modifiable risk factor, physical inactivity is mutable and can and should be addressed when identified during the examination of a patient.

DISPLAY 6-3

Risk Factors for Coronary Heart Disease

Major Risk Factors—Nonmodifiable

Increasing age
Male gender
Family history

Major Risk Factors—Modifiable

High blood cholesterol and triglyceride levels
High BP
Diabetes and prediabetes
Smoking
Overweight and obesity
Lack of physical activity
Unhealthy diet
Stress

US Department of Health & Human Services, National Institutes of Health, National Heart, Lung, and Blood Institute, What are coronary heart disease risk factors? Available at: http://www.nhlbi.nih.gov/health/health-topics/topics/hd#slide-2-field_video_items-924. Accessed September 25, 2015.

EXAMINATION/EVALUATION OF AEROBIC CAPACITY

With the exception of clients with cardiovascular and pulmonary diseases, most clients who are referred to physical therapy do not have as their primary diagnosis impaired aerobic capacity. Because aerobic capacity influences any exercise a client may perform as part of an intervention, and thus the outcomes that client will achieve, it is important that examination and evaluation of the cardiovascular and respiratory systems be included as a part of the examination and evaluation of all clients. The tests and measures described in this section are aimed at identifying the presence of disease, describing baseline aerobic capacity, and measuring change in aerobic capacity as a result of intervention(s). The clinician is assumed to have the knowledge and skill to perform the *basic* tests necessary to diagnose impairments and functional limitations in aerobic capacity; however, detailed information will be provided for the more *advanced* tests of aerobic capacity because many clinicians may not have experience performing these tests on a regular basis. Additional information may be obtained from the ACSM text[43] on exercise testing and prescription.

Patient/Client History

Specific portions of the general data generated from a patient/client history as defined in Chapter 2 are important to note when attempting to identify the presence of an impairment in aerobic capacity that either should be directly addressed in the intervention or may influence the clinician's ability to set and achieve goals related to other impairments. Knowledge of the risk factors for coronary heart disease provides a basis for collecting the most relevant information regarding impaired aerobic capacity. As shown in Display 6-3, general demographic information such as age, gender, and ethnicity is very important to consider. Social/health habits such as smoking, physical activity, and nutrition are important behaviors to inquire about during the history. Assessment of general health status in terms of general health perceptions, mental functions, and physical function can provide additional indication of limitations in cardiovascular endurance. Clinical tests of blood cholesterol are useful to identify clients at risk for coronary heart disease. Other factors that should be noted from the history include medical/surgical history, family history, social history, personality/behavior, pregnancy, and breast-feeding status, factors that may also modify the exercise prescription.[15,40] A review of systems, also part of the history, includes a review of major body systems (endocrine, gastrointestinal, genitourinary, hematologic, etc.) to determine if there are symptoms that require further medical evaluation.[40]

Medication history is of primary importance to review, especially for clients with documented cardiovascular and pulmonary disease, but also for those with risk factors for disease. Many cardiac and pulmonary system drugs affect aerobic capacity, and thus clients using these drugs should be carefully monitored during any intervention that affects the cardiovascular and pulmonary systems, including therapeutic exercise, functional training, airway clearance techniques, integumentary repair techniques, electrotherapeutic modalities, and physical agents and mechanical modalities.

Specific questions that should be posed during the patient/client history to identify the presence of cardiovascular and pulmonary disease and the relevant aspects of the client's overall status that may affect aerobic capacity as discussed above can be found in Goodman and Snyder's text[41] on differential diagnosis.

Systems Review

After, and based on, the patient/client history, a systems review is conducted as a brief or limited examination of the status of the other major body systems (integumentary, musculoskeletal, neuromuscular), and the communication ability, affect, cognition, language, and learning style of the patient.[40] The systems review helps to identify impairments in other areas that may affect the performance of an activity or task within the plan of care. Further, the systems review may identify potential problems that require referral to another provider.

Because the primary intervention used to address aerobic capacity impairments, therapeutic exercise, requires adequate musculoskeletal, neuromuscular, and integumentary function, it is especially important to perform a thorough systems review in clients with cardiovascular and pulmonary impairments. Failure to do so could result in prescribing an intervention that the patient either cannot perform or that compromises the safety of the patient. At a minimum, skin integrity, muscle strength, joint range of motion, balance, gait function, and assessment of the ability to make needs known should be assessed.

Screening Examination

Before the initiation of an exercise program, individuals should be assessed to ensure safety and minimize risks.[15] Preparticipation screening can be performed using a self-report questionnaire, such as the Physical Activity Readiness Questionnaire or PAR-Q[15,43] (see Appendix 3). Based on the answers to the seven questions on the PAR-Q, individuals between the ages of 15 and 69 can either appropriately participate in exercise or be referred to a physician for further evaluation before beginning an exercise program. All individuals who fall outside of the boundaries described should be referred to a physician for medical evaluation before participating in exercise training.

The ACSM[43] has created guidelines delineating who should be medically evaluated, including maximal or submaximal exercise testing, before participation in vigorous exercise (defined as intensity >60% VO_2 max). Those who do not require medical evaluation include those who meet the definition of low risk as per the ACSM Risk Stratification Categories (**Display 6-4**).[43]

For those meeting the criteria for moderate risk in Display 6-4, it is recommended that medical examination and exercise testing be performed prior to the initiation of vigorous exercise training. In addition, for those in the moderate risk category, it is recommended that medical supervision (a physician should be in proximity and readily available should there be an emergent need) occur for maximal exercise testing.

Finally, for those in the high-risk category, medical examination prior to moderate or vigorous exercise and medical supervision for maximal or submaximal exercise testing is recommended.

DISPLAY 6-4

ACSM Risk Stratification Categories for Atherosclerotic Cardiovascular Disease

Low risk = Asymptomatic men and women who have ≤1 CVD risk factor from **Display 6-5**

Moderate risk = Asymptomatic men and women who have ≥2 risk factors from Display 6-5

High risk = Individuals who have known cardiovascular, pulmonary, or metabolic disease or one or more signs and symptoms listed in **Display 6-6**

American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010.

DISPLAY 6-5

Atherosclerotic Cardiovascular Disease (CVD) Risk Factor Thresholds for Use with ACSM Risk Stratification

Positive Risk Factors and Defining Criteria

1. Age—men ≥ 45 years, women ≥ 55 years
2. Family history—myocardial infarction, coronary revascularization, or sudden death before 55 years of age in father or other male first-degree relative, or before 65 years of age in mother or other female first-degree relative
3. Cigarette smoking—current cigarette smoker or those who quit within the previous 6 months or exposure to environmental tobacco smoke
4. Sedentary lifestyle—not participating in at least 30 minutes of moderate intensity (40% to 60% VO_2) physical activity on at least 3 days of the week for at least 3 months
5. Obesity—BMI ≥ 30 kg per m^2 or waist girth >102 cm (40 inches) for men and >88 cm (35 inches) for women
6. Hypertension—SBP ≥ 140 mm Hg and/or DBP ≥ 90 mm Hg, confirmed by measurements on at least two separate occasions, or on antihypertensive medication
7. Dyslipidemia—low-density lipoprotein cholesterol (LDL-C) ≥130 mg per dL or high-density lipoprotein cholesterol (HDL-C) <40 mg per dL or on lipid-lowering medication. If total serum cholesterol is all that is available use ≥200 mg per dL
8. Prediabetes—impaired fasting glucose = fasting plasma glucose ≥100 mg per dL but <126 mg per dL or impaired glucose tolerance = 2-hour values in oral glucose tolerance test ≥140 mg per dL but <200 mg per dL confirmed by measurements on at least two separate occasions

Negative Risk Factor and Defining Criteria

1. High-serum HDL cholesterol ≥60 mg per dL

American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010.

Tests and Measures

The examination categories directly relevant for the client with aerobic capacity impairment include tests and measures of aerobic capacity/endurance, anthropometric characteristics, and circulation and environmental factors.[40] There are numerous tests and measures in each of these categories, and often the most difficult task for the clinician is selecting the most appropriate test. Tests and measures should be selected based on data collected from the history, systems review, and screening; the means the client has available for following through with a program of aerobic exercise; client goals; and the equipment and monitoring equipment available (see **Building Block 6-1**).

DISPLAY 6-6

Major Signs or Symptoms Suggestive of Cardiovascular, Pulmonary, or Metabolic Disease

Signs or Symptoms

- Pain, discomfort (or other anginal equivalent) in the chest, neck, jaw, arms, or other areas that may result from ischemia
- Shortness of breath at rest or with mild exertion
- Dizziness or syncope
- Orthopnea or paroxysmal nocturnal dyspnea
- Ankle edema
- Palpitations or tachycardia
- Intermittent claudication
- Known heart murmur
- Unusual fatigue or shortness of breath with usual activities

American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010.

BUILDING BLOCK 6-1

Patient/Client History and General Information

Susan is a 47-year-old nurse who consulted a physical therapist for primary complaints of posterolateral right (R) thigh pain. Past medical history was unremarkable. The pain was worse with weight-bearing first thing in the morning, got better with limited activity, but worsened by the end of the day—especially if she had been on her feet quite a bit during the day. Secondary complaints included intermittent, dull low back pain and occasional bouts of sharp pain in the arch of her R foot. She was diagnosed and treated by the physical therapist for iliotibial band fasciitis and intermittent plantar fasciitis. The short- and long-term goals set for her were aimed at decreasing disability and returning the patient to a pain-free level of functioning. Susan met the goals established with regular treatment and requested that the physical therapist assist her with establishing a regular physical activity habit.

Based on the information provided, does the patient/client require medical evaluation prior to participating in aerobic exercise?

Aerobic Capacity/Endurance

The development of an appropriate and useful exercise prescription for cardiorespiratory endurance depends on an accurate assessment of VO_2 max, which is most commonly achieved through the performance of a graded exercise test (GXT). Exercise tests can be maximal, in which an individual performs to his or her physiologic or symptom limit, or submaximal, in which an arbitrary stopping or limiting criterion is used.

Maximal Graded Exercise Tests The most important characteristics of a maximal GXT are that it has a variable or graded workload that increases gradually and that the total test time equal approximately 8 to 12 minutes.[43] In addition, individuals undergoing maximal GXT testing are usually electrocardiogram (ECG)-monitored. The direct measurement of VO_2 max requires the analysis of expired gases, which requires special equipment and personnel and is thus costly and time-consuming.[43] VO_2 max can be estimated from prediction equations after the individual exercises to the point of volitional fatigue, or it can be estimated from submaximal tests. For most clinicians, maximal exercise testing is not feasible because of the special equipment required and the ECG monitoring, although it is the most accurate test of aerobic capacity. Additionally, it is recommended that maximal GXT be reserved for research purposes, testing of diseased individuals, and athletic populations.[15] Thus submaximal testing is most commonly used, especially with low-risk, apparently healthy individuals, and will be further described in this section. Individuals who wish to conduct maximal GXT are referred to the ACSM Guidelines for Exercise Testing[43] or the ACSM Resource Manual[15] for more detailed information.

Submaximal Graded Exercise Tests Submaximal exercise tests can be used to estimate VO_2 max because of the linear relationship between HR and VO_2, and HR and workload.[15] That is, as workload or VO_2 increases, HR increases in a linear, predictable fashion. Therefore, the clinician can estimate VO_2 max by plotting HR against workload for at least two exercise workloads and extrapolating to age-predicted maximal HR (220 – age) to estimate VO_2 max (**Fig. 6-1**).[43] Submaximal exercise testing is based on several assumptions, as shown in **Display 6-7**. Failure to meet these assumptions fully, which is usually the case, results in errors in the prediction of VO_2 max. Therefore, submaximal testing typically results in less accurate VO_2 max estimations. However, submaximal tests are appropriately used to document change over time in response to aerobic training and, given the time and money saved, are very useful clinically.

The ACSM[43] provides recommendations for physician supervision during GXT. For those individuals at low risk (Displays 6-4 and 6-5), physician supervision is not deemed necessary during maximal or submaximal testing. Individuals at moderate risk who have two or more risk factors but no symptoms or disease can undergo submaximal testing without physician supervision. Physician supervision during maximal testing is recommended for those at moderate risk.[43] Physician supervision during submaximal and maximal testing is recommended for any individual with CAD or with symptoms of CAD. Therefore, submaximal testing can be performed safely by physical therapists with any age individual who is symptom or disease free, as defined by the ACSM.[43]

Numerous testing protocols have been published and are available for submaximal exercise testing.[43] Because of the requirement of reproducible workloads, treadmills, bicycle ergometers, and stepping protocols are most commonly used. Test selection should be based on safety concerns, familiarity with and knowledge of the testing protocol, equipment availability, and client/patient goals, abilities, and conditions (e.g., the presence of orthopedic limitations).

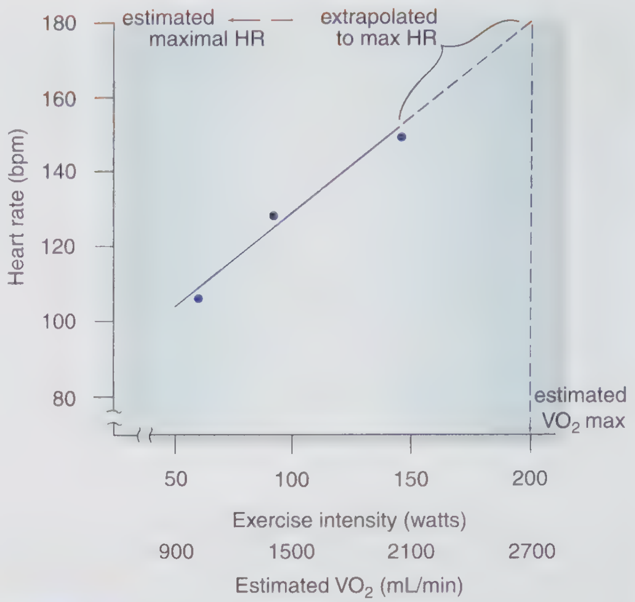

FIGURE 6-1 HR obtained from at least two (more are preferable) submaximal exercise intensities may be extrapolated to the age-predicted maximal HR. A vertical line to the intensity scale estimates maximal exercise intensity from which an estimated VO_2 max can be calculated. (From American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010.)

DISPLAY 6-7
Assumptions for Submaximal Exercise Testing

- A steady-state HR is obtained for each exercise work rate and is consistent each day.
- A linear relationship exists between HR and work rate.
- The maximal workload is indicative of maximal VO_2.
- The maximal HR for a given age is uniform.
- Mechanical efficiency is the same for everyone (e.g., VO_2 at a given work rate).
- The subject is not on medications that alter HR.

Note: The most accurate estimate of VO_2 max is achieved if all of the preceding assumptions are met.

American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010:73–74.

Bicycle Ergometer Tests Two common bicycle ergometer tests are the YMCA protocol and the Astrand–Rhyming test.[43] In the YMCA protocol, the client performs two to four, 3-minute stages of continuous cycling, designed to elevate the HR to between 110 and 150 bpm during two consecutive stages. The client begins cycling at 50 revolutions per minute (rpm) at a resistance of 150 kg per minute or 0.5 kg and progresses to greater resistance in subsequent stages based on HR recorded during the last minute of the first stage according to **Table 6-2**.

TABLE 6-2

YMCA Submaximal Bicycle Ergometer Test Protocol—Workload Settings

	HR < 80	HR 80–89	HR 90–100	HR > 100
Second Stage	750 kg/min	600 kg/min	450 kg/min	300 kg/min
	(2.5 kg)	(2.0 kg)	(1.5 kg)	(1.0 kg)
	(125 W)	(100 W)	(75 W)	(50 W)
Third Stage	900 kg/min	750 kg/min	600 kg/min	450 kg/min
	(3.0 kg)	(2.5 kg)	(2.0 kg)	(1.5 kg)
	(150 W)	(125 W)	(100 W)	(75 W)
Fourth Stage	1050 kg/min	900 kg/min	750 kg/min	600 kg/min
	(3.5 kg)	(3.0 kg)	(2.5 kg)	(2.0 kg)
	(175 W)	(150 W)	(125 W)	(100 W)

Resistance settings shown apply to ergometers with a 6 m/revolution flywheel.

For example, if HR = 85 at the end of the first stage, the second stage workload would be 600 kg per minute and the third stage workload would be 750 kg per minute.

The test is terminated when two consecutive stages yield a HR reading between 110 and 150 bpm. The two HR measures and corresponding workloads are plotted on a graph, and the line generated from the plotted points is extended to the age-predicted maximal HR and an estimation of VO_2 max is obtained.[43]

The Astrand–Rhyming test involves a single 6-minute stage, with workload based on sex and activity status:

- unconditioned females, 300 or 450 kg per minute (50 or 75 W)
- conditioned females, 450 or 600 kg per minute (75 or 100 W)
- unconditioned males, 300 or 600 kg per minute (50 or 100 W)
- conditioned males, 600 or 900 kg per minute (100 or 150 W)

Individuals pedal at 50 rpm and HR is measured during the fifth and sixth minutes. The two HR measures must be within 5 beats of one another and the HR between 130 and 170 bpm for the test to be completed. If the HR is <130 bpm, the resistance should be increased by 50 to 100 W and the test continued for another 6 minutes. The test may be terminated when the HR in the fifth and sixth minute differs by no more than 5 beats and is between 130 and 170 bpm. An average of the HRs is calculated and a nomogram is used to estimate VO_2 max (**Fig. 6-2**).[43] The value determined from the nomogram is corrected for age by multiplication of a correction factor (**Table 6-3**).

Treadmill Tests Submaximal treadmill tests are also used to estimate VO_2 max (**Table 6-4**). A single-stage submaximal treadmill test has been developed for assessing VO_2 max in low-risk individuals.[44] It involves beginning with a comfortable walking pace between 2.0 and 4.5 mph at 0% grade for a 2- to 4-minute warm-up, designed to increase HR to within 50% to 75% of age-predicted (220 – age) maximum HR, followed by 4 minutes at 5% grade at the same self-selected walking speed. HR is measured at the end of the 4-minute stage and VO_2 max is estimated using the following equation:

$$VO_2 \text{ max (mL/kg/min)} = 15.1 + 21.8 \times \text{speed (mph)} - 0.327 \times \text{HR (bpm)} - 0.263 \times \text{speed} \times \text{age (years)} + 0.00504 \times \text{HR} \times \text{age} + 5.98 \times \text{sex } (0 = \text{F}, 1 = \text{M})$$

Step Tests Step tests were developed based on a need to test large numbers of individuals expeditiously and represent another mode of submaximal exercise testing. Several protocols have been developed,[45] but only one will be presented. The Queens College Step Test requires a 16.25-inch step (similar to the height of a bleacher step).[45,46] Individuals step up and down to a 4-count rhythm (on Count 1 subject places one foot on step, on Count 2 subject places the other foot on the step, on Count 3 the first foot is brought back to the ground, on Count 4 the second foot is brought down). A metronome is useful to maintain the prescribed stepping beat. Females step for 3 minutes at a rate of 22 steps per minute, whereas males step at a rate of 24 steps per minute. At the end of the 3 minutes, a recovery 15-second pulse is measured, starting at 5 seconds into recovery while the individual remains standing. The pulse rate is attained and is converted to bpm by multiplying by 4. This value is termed the recovery HR. The following equations are used to estimate VO_2 max:

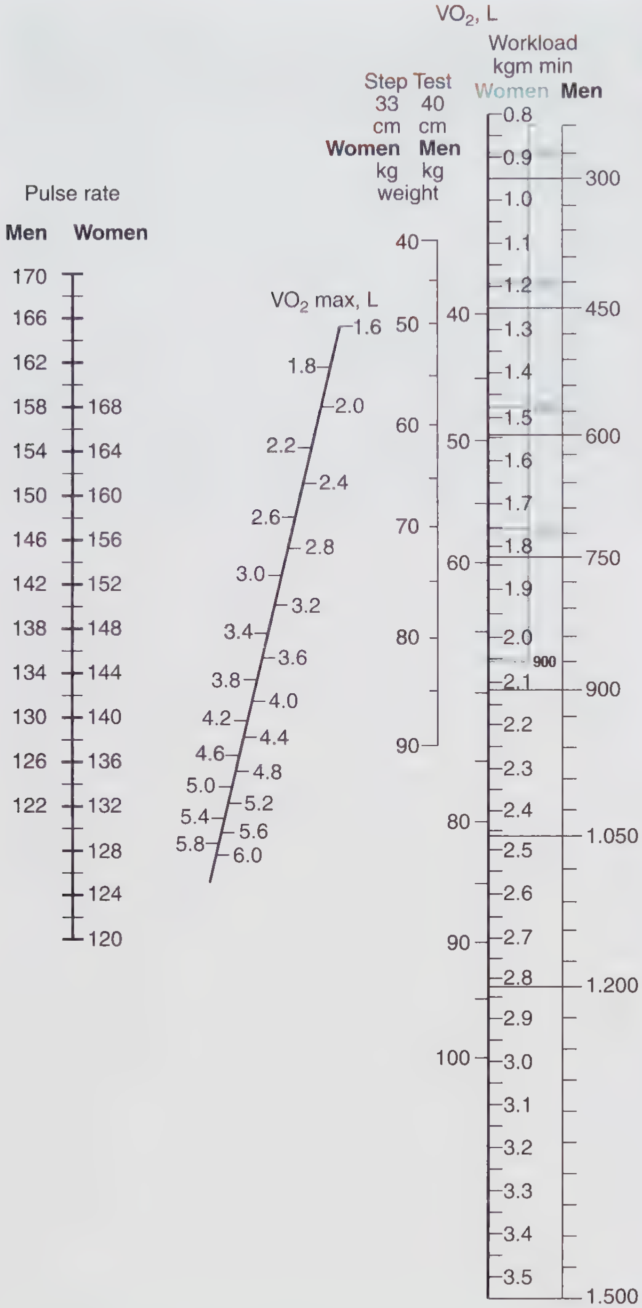
$$\text{Females: } VO_2 \text{ max (mL/kg/min)} = 65.81 - (0.1847 \times \text{recovery HR [bpm]})$$

$$\text{Males: } VO_2 \text{ max (mL/kg/min)} = 111.33 - (0.42 \times \text{recovery HR [bpm]})$$

Field Tests Field tests refer to exercise testing protocols derived from events performed outside, or in the "field." They are also submaximal tests and, as with the step test, are more practical for testing large groups of people, appropriate when time or equipment is limited, and when assessing individuals older than age 40.[45] A variety of field tests exist[45]; the Cooper 12-minute test and the 1-mile walk test will be discussed. In the Cooper 12-minute test, individuals are instructed to cover the most distance possible in 12 minutes, preferably by running, although walking is acceptable. The distance covered in the 12 minutes is recorded and VO_2 max estimated according to the following equation[45]:

$$VO_2 \text{ max (mL/kg/min)} = 35.97 \text{ (mile)} - \text{s } 11.29$$

A 1-mile walk test is another option in the field test category.[47] Individuals walk 1 mile as fast as possible without running and



Males: VO_2, max (mL/kg/min) = 111.3 – (0.42 × recovery HR [bpm])

FIGURE 6-2 The Astrand–Rhyming nomogram. A nomogram used to calculate aerobic capacity (VO_2 max) from pulse rate during submaximal work. The clinician must know the pulse rate, sex, and workload from the bicycle ergometer test performed on the client to determine absolute VO_2 max. VO_2 max values obtained from the nomogram should be adjusted for age by a correction factor (Table 6-3). (Reprinted from Astrand PO, Rhyming I. A nomogram for calculation of aerobic capacity [physical fitness] from pulse rate during submaximal work. J Appl Physiol 1954;7:218–221, with permission.)

the average HR for the last two complete minutes of the walk is recorded. A HR monitor is necessary to record and average the HR over the last 2 minutes. If a HR monitor is not available, a 15-second pulse can be measured immediately on test completion. VO_2 max is estimated from the following equation[47]:

$$VO_2 \text{ max (mL/kg/min)} = 132.85 - 0.077 \times \text{body weight (lb)} - 0.39 \times \text{age (years)} + 6.32 \times \text{sex } (0 = F, 1 = M) - 3.26 \times \text{elapsed time (min)} - 0.16 \times \text{HR (bpm)}$$

All clients should be closely monitored during exercise test performance. Vital signs should be assessed before, during each stage or workload of the test, and after the test for 4 to 8 minutes of recovery.[15] In addition, the rating of perceived exertion (RPE) is commonly used to monitor exercise tolerance.[48] RPE refers to the "degree of heaviness and strain experienced in physical work as estimated according to a specific rating method"[48(p.9)] and is an indicator of overall perceived exertion. The Borg RPE scale and instructions for use are shown in **Figure 6-3**.

Anthropometric Characteristics

Body composition is important to assess in individuals partaking in an aerobic exercise program because of the changes experienced in fat mass as a result of chronic training discussed earlier in this chapter. In addition, body composition is an important examination tool in the presence of obesity and is considered superior to simple measures of height and weight. The gold standard measure of body composition is hydrostatic or underwater weighing that requires specialized equipment and the patient to tolerate total body immersion. Because of these limitations, several reliable measures of body composition estimation have been developed and are used widely, including body mass index (BMI), bioelectric impedance, near-infrared interactance, skinfold measurements, and waist-to-hip ratio. Bioelectric impedance, near-infrared interactance, and skinfold measurements require specialized equipment and, in the case of skinfold measurements, specialized training; whereas the

The recommended quantity and quality of exercise for developing and maintaining cardiorespiratory and muscular fitness in healthy adults. Med Sci Sports Exerc 1990;22:265–274.)

BMI and waist-to-hip ratio can be measured using height, weight, and circumferential measurements. The clinician is referred to the ACSM's Guidelines for Exercise Testing and Prescription[43] for additional information about performing these tests (see **Building Blocks 6-2** to **6-6**).

BUILDING BLOCK 6-2

When answering this question, consider the case presented in Building Block 6-1:

How would you screen this patient/client prior to proceeding with an exercise program?

BUILDING BLOCK 6-3

When answering this question, consider the case presented in Building Block 6-1:

How would you approach establishing an exercise prescription for this patient/client?

BUILDING BLOCK 6-4

When answering this question, consider the case presented in Building Block 6-1:

What exercise test would you utilize with this patient/client?

BUILDING BLOCK 6-5

When answering this question, consider the case presented in Building Block 6-1:

How would you conduct the exercise test?

BUILDING BLOCK 6-6

When answering this question, consider the case presented in Building Block 6-1:

What is the patient/client's VO_2 max?

Circulation

Assessment of BP; HR, rhythm, and sounds; and RR, rhythm, and pattern is important to establish a baseline and to determine impairments. In addition, these measures can be assessed over time to determine the effect of aerobic training on the cardiovascular and pulmonary systems and to document improvement.

Environmental Factors

Because environmental factors may be barriers and facilitators of participation in aerobic exercise programs, it is important to examine the physical, social, and attitudinal environment impacting the patient.[40] For example, if the physical therapist prescribes an appropriate exercise to address an aerobic capacity impairment, yet the patient does not have access to a safe place to perform the exercise, the exercise prescription is rendered useless and the patient will not benefit. Ecologic models of health support that environmental factors are the most important to address in health behaviors such as physical activity and exercise; thus, they are very important for the physical therapist to assess prior to intervention.[49] This category of examination includes access to safe places to exercise and appropriate equipment; the presence of emergency procedures and plans; and the ability to participate in self-care, domestic life, work life, and community life.[40]

THERAPEUTIC EXERCISE INTERVENTION

Impaired aerobic capacity/endurance involves the support element of the movement system, and as such is the underlying impairment for numerous functional limitations and disabilities and is thus a priority to address with the intervention plan. A wide variety of aerobic endurance activities exist and are the most efficient techniques to achieve the goal of improved aerobic capacity. The modes and dosage specifics used when establishing an aerobic endurance exercise prescription will be presented. A primary objective of the exercise prescription is to assist in the adoption of regular physical activity as a lifestyle habit and thus should take into consideration the behavioral characteristics, personal goals, and exercise preferences of the individual.[43] Given the critical epidemic of obesity and physical inactivity in the United States and the strength of the association between regular physical activity and reduction in mortality and morbidity, physical therapists should ensure that they include exercise testing and exercise prescription with all patients/clients with whom they interact.[1]

Mode

Several modes of cardiovascular endurance training are available. Any activity that uses large muscle groups and is repetitive is capable of producing the desired changes. Such activities include walking, jogging, cross-country skiing, bicycling, rope jumping, rowing, swimming, or aerobic dance (see **Selected Intervention 6-1**). Although lap swimming is the most common aquatic cardiovascular exercise, water jogging, cross-country skiing, and water aerobics are also effective aquatic training methods. An upper body ergometer is a good cardiovascular training tool and is especially well suited for individuals unable to use their legs (see **Fig. 6-4**).

The choice of exercise mode depends on the patient's goals, likes, and specific physical condition. Performing an activity that is convenient, comfortable, and enjoyable increases the likelihood of adherence. The amount of impact is also an important consideration when choosing the exercise mode. For the individual with lower extremity degenerative joint disease or the overweight individual, impact activities should

SELECTED INTERVENTION 6-1

Elliptical

Refer to Case Study No. 10

Although this patient requires comprehensive intervention, only one exercise is described:

ACTIVITY: Elliptical

PURPOSE: To increase cardiovascular endurance and musculoskeletal muscle endurance of quadriceps, gluteals, hamstrings, calf, trunk, and upper extremity muscle groups

SUBSYSTEMS OF THE MOVEMENT SYSTEM: Passive, support

STAGE OF MOTOR CONTROL: Skill

POSTURE: Shoulders should be back, head up and slightly forward, chin up level and abdominals tight. Look forward, not down at your feet. Do not grip the handrails too tightly. Or "maintain a light grip on the handrails." Make sure that your weight is evenly distributed and that your lower body supports the majority of your weight.

MOVEMENT: Alternate hip flexion and extension in a walking pattern. Transfer weight completely from leg to leg during the activity, rather than shuffling or sliding the feet while bearing weight bilaterally. Move your arms in an alternate fashion with the legs (range of motion may be limited by individual needs).

SPECIAL CONSIDERATIONS: (a) All precautions to cardiovascular endurance exercise must be considered. (b) Individuals with balance and coordination difficulty should be assessed for ability to perform the activity safely.

DOSAGE: Ten minutes, adding 5 minutes every three sessions

RATIONALE FOR EXERCISE CHOICE: The elliptical is a total body exercise. Aerobic conditioning can be achieved, along with shoulder, trunk, hip, and leg extensor muscle endurance training.

EXERCISE GRADATION: This exercise can be progressed by increasing the frequency, intensity, or duration of activity.

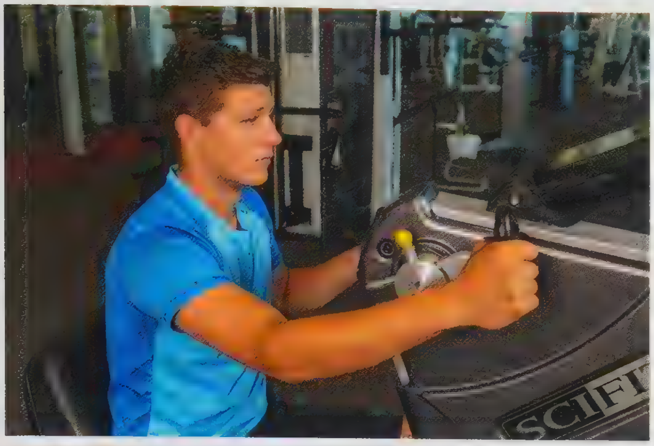

FIGURE 6-4 Upper body ergometer. An upper body ergometer is an exercise mode that provides an aerobic exercise alternative for those with significant lower extremity impairments or to provide variety in an exercise prescription. Because the smaller upper extremity muscles perform the exercise, lower HRs are experienced. In addition, it is difficult to monitor vital signs during activity. The seat on the device should be adjusted to allow slight elbow flexion in the outstretched position of the arm while the back maintains contact with the seat, and the seat height position should ensure that the shoulder is even with the axis of the crank arm.

be minimized. The pool is a better choice for those who need to minimize weight-bearing or impact. Weight-bearing can be completely negated by exercising in the deep end of the pool. For those desiring to return to impact activities, gradual impact progression can prepare the body for the demands of this type of loading (see **Patient-Related Instruction 6-1**).

Variety and cross-training in the cardiovascular endurance program are imperative. Alternating modes of activity can alleviate boredom and prevent overuse injuries resulting from repetitive activity. Individuals who have such low muscular endurance that they are incapable of performing the same repetitive activity for more than a few minutes can alternate activities within the training session and among sessions. Whereas one individual may bicycle 2 days per week, swim 2 days, and walk 2 days, another may bike, walk, and stair step for 10 minutes each daily.

Within one mode of exercise, several postures or equipment types are available. For example, during bicycling, the trunk posture selected depends on the goals. Bicycling may be performed on a recumbent bike (**Fig. 6-5A**), with the hips flexed 90 degrees or more and the low back supported, or it may be performed in an upright position with the arms moving (Fig. 6-5B), or in a forward-leaning position (Fig. 6-5C). The optimal posture for maximal exercise benefit should be emphasized (see **Patient-Related Instruction 6-2**).

Dosage

Type

The training session itself may be performed using a variety of training techniques, from continuous activity to interval training. Continuous training relies on the aerobic energy system to supply energy for the exercise session and can be carried out for prolonged periods (see website for review of energy systems). The individual exercises continuously, without rest, at a steady exercise rate. Although continuous in nature, several different activities can be combined within the same session, such as treadmill and bicycle or swimming and deep-water running.

Interval training incorporates rest sessions between bouts of exercise. This technique is useful for clients who are unable to maintain continuous exercise for the optimal length of time (e.g., 30 minutes) and for those recuperating from an orthopedic injury or who are deconditioned. When prescribing interval training, the ratio of the rest period to the training period determines the activity intensity and the energy system used. The aerobic energy system is used to a greater extent with longer training intervals and shorter rest periods. For example, performance of three bouts (intervals) of activity at an intensity of 50% of VO_2 max or greater for 10 minutes with a 2-minute rest period in between each bout would use the aerobic energy system.

The rest periods can be true rest (i.e., no activity) or a work-relief interval, during which light activity such as walking may be performed. High-intensity activity usually is combined with longer complete-rest intervals, and low to medium intensities are combined with shorter rest intervals or work-relief intervals. For example, a training session might include a set of ten 100-m sprints, in which each sprint may take only 10 to 20

Patient-Related Instruction 6-1

Return to Impact Activity

Any return to impact activities such as jogging, impact aerobics, or sports requiring running or jumping should be preceded by impact progression. This approach ensures readiness to return to the activity and decreases the likelihood of setback. Prerequisites for impact progression include the following:

1. Adequate muscle strength and endurance
2. Full range of motion in the joints
3. No swelling

A suggested progression is as follows:

1. Two-footed hopping
2. Alternate-footed hopping
3. Single-footed hopping (optional)
4. Skill drills (optional)

This progression should be implemented as follows:

1. Begin on a low-impact surface (e.g., pool, mini-tramp, shock-absorptive floor).
2. Subsequently progress to the terrain you will be using.
3. Begin with 5 minutes, and increase by 2- to 5-minute increments when you are able to complete three consecutive sessions without pain, swelling, or technique compromise.
4. Return to your full activity is determined by the criteria set by your clinician. Remember that returning to activity is different from performing sport drills. During practice drills, mental attention is often given to awareness and protection of a recovering injury. When returning to the game, the majority of mental attention is given to the game. Therefore, practicing skills while mentally engaging in that sport activity is an important component of return to sport.

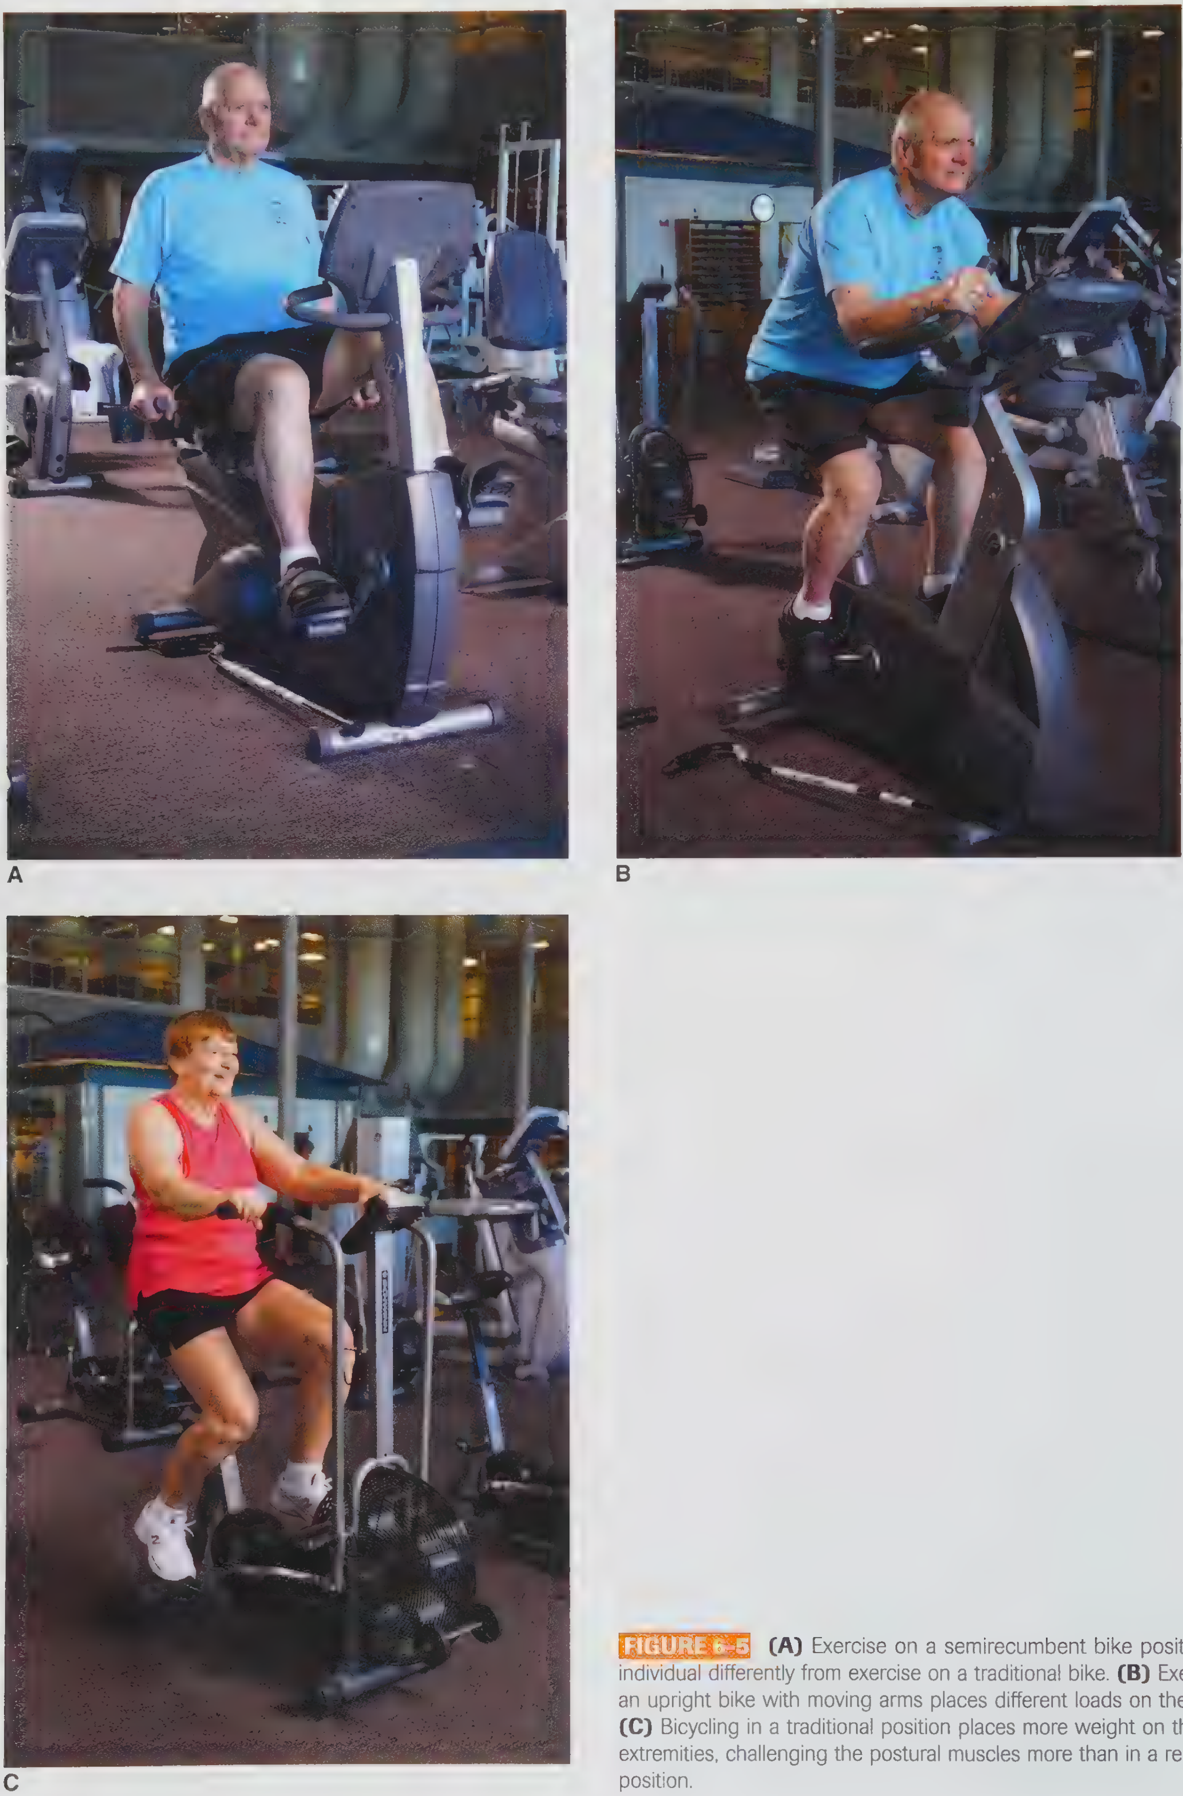

FIGURE 6-5 **(A)** Exercise on a semirecumbent bike positions the individual differently from exercise on a traditional bike. **(B)** Exercise on an upright bike with moving arms places different loads on the patient. **(C)** Bicycling in a traditional position places more weight on the upper extremities, challenging the postural muscles more than in a recumbent position.

Patient-Related Instruction 6-2

Bicycling Guidelines

The following guidelines will keep your bicycling experience healthy and safe:

1. Seat height: The seat should be set so that your knee is slightly bent in the down-most position. If you place your heel on the pedal in the down position, your knee should be perfectly straight. When you place the ball of your foot on the pedal, your knee should be bent at the correct angle (15 to 20 degrees of knee flexion with the ankle in 90 degrees of dorsiflexion).
2. Cadence: Your pedal cadence should be high, at least 60 rpm or more. Your clinician may have other recommendations, depending on your specific situation.
3. Resistance: The resistance should be low enough to allow a higher cadence. Resistance too high can place extra stress on the knee. Keeping the resistance low and the cadence high produces the desired benefits without hurting your knees.
4. Safety: If riding outside, always wear a helmet, and obey your local bicycle laws.

seconds to complete, with a 10-minute complete-rest interval between each sprint. Because high-intensity exercise of short duration uses the ATP-PCr and glycolysis systems for the provision of ATP, a longer rest period is required to allow muscle energy stores to be replenished (see Physiology Information on website). Less intense exercise, concomitantly, relying on the aerobic oxidative pathway, can be performed adequately from an energy availability standpoint for longer periods of time with shorter rest intervals that may consist of complete-rest or work-relief intervals.

Circuit training can be continuous or interval. Circuit training is a training technique in which the individual rotates through a series of exercise stations. A variety of upper extremity, lower extremity, core, and cardiovascular training exercises typically are included. The individual performs the activity at each station for a specified time (i.e., 30 seconds) and then moves on to the next station. The activity choices, activity intensity, and rest between stations determine the energy system used and whether the activity is interval or continuous. This type of training provides the opportunity for a well-balanced exercise program with variety. Multiple individuals can be trained simultaneously if there are adequate stations (see **Patient-Related Instruction 6-3**).

Patient-Related Instruction 6-3

Setting Up a Circuit

Your regular exercise routine can be enhanced and made more enjoyable by breaking up a continuous activity with stations of alternative activities. A circuit can be created outside along a normal walking or running route, or at your indoor exercise location. For example, a walking or jogging program through the neighborhood or on the treadmill can be broken up with the following activities performed at certain intervals throughout the session:

1. Calf raises
2. Abdominal curls or trunk plank
3. Push-ups
4. Squats
5. Dips
6. Lunge walks
7. Quadriceps, hamstring, and calf stretches

Sequence

Cardiovascular endurance training may be performed as part of a comprehensive rehabilitation program that includes mobility, stretching, and strengthening activities. General warm-up activities should be performed initially, followed by the cardiovascular training session and a cooldown including stretching. The warm-up period should last 5 to 10 minutes to prepare the body for exercise. Large muscle group activity such as walking, calisthenics, or bicycling should be performed with gradually increasing intensity. The warm-up session may be a lower-intensity version of the cardiovascular training activity. Walking at a slower speed for 5 minutes may be used as a warm-up activity for faster walking or jogging. The warm-up activities increase muscle blood flow, muscle temperature, and neural conduction. These changes, along with mental preparedness, can decrease the risk of muscle injury during exercise. After the warm-up, the more vigorous cardiovascular endurance session should be performed.

The exercise session should be concluded with a cool-down period of 5 to 10 minutes to allow redistribution of blood flow that has changed with exercise, including prevention of lower extremity pooling of blood by enhancing venous return to the heart. Active muscle contraction by continued walking, cycling, or low-level calisthenics assists with blood flow redistribution. Stretching should conclude the session to ensure maintenance of the working muscle's optimal length, which is more effective when performed once the muscles and joints are warm.

Frequency

The frequency of cardiovascular training should be determined through consideration of the patient/client's goals, the intensity and duration of exercise, and the patient/client's baseline fitness level. The optimal frequency to achieve fitness-related benefits for most individuals is three to five times per week,[1,43] with those initiating a program beginning at three to four times per week and progressing to five. The optimal frequency to attain health-related benefits is 3 days per week of moderate-intensity activity, although all 150 minutes could be achieved in 1 day.[1] Spreading activity out over several days per week reduces the risk of injury and prevents excessive fatigue.[1] The minimum amount of time that is thought to provide health-related benefits is 10 minutes of continuous activity.[1] The overload principle in terms of the interaction among intensity, duration, and frequency is important to consider when prescribing exercise. Individuals with very low functional capacities can perform daily or twice-daily exercise because the total amount of exercise, considering intensity, duration, and frequency, is low.[43] In a highly trained individual, exercise at a greater frequency may be necessary to produce overload, depending on the exercise intensity.

Intensity

As with frequency and duration, setting the intensity of exercise should be based on the overload principle and consideration should be given to the functional limitations, goals, and fitness level of the individual. Exercise intensity indicates how much exercise should be performed or how hard one must exercise and is typically prescribed on the basis of HR max, HR reserve, VO_2 max, RPE, or METs (metabolic equivalents). Prescribing exercise intensity using HR is considered the preferred method because of the correlation between HR and the stress on the heart and because it is readily accessible for monitoring during exercise.[12] Several methods involving HR can be used.

When prescribing exercise as a percentage of maximum HR, either directly measured or on the basis of age-predicted maximum HR, the training range should be between 55% and 65% to 90% of HR max.[43] A second method involves the use of the HR reserve or Karvonen formula:

$$\text{Target HR range} = ([HR_{max} - HR_{rest}] \times 0.60 \text{ and } 0.80) + HR_{rest}$$ [43]

To obtain a HR range, two intensity levels are calculated in the formula, one equivalent to 0.60 of VO_2 max and one equivalent to 0.80 of VO_2 max. If exercise is prescribed using VO_2 max, 55% to 75% is also used as a training range and VO_2 max should be stated in relative terms (mL/kg/min), which accounts for the individual's body weight. The RPE can also be used to prescribe exercise intensity, within the range of 12 to 16 on the RPE scale shown in Figure 6-3. RPE is especially useful for prescribing intensity for individuals who are unable to palpate pulse or when HR is altered because of the influence of medication and should be considered an adjunct to monitoring HR in all other individuals.[43]

METs may also be used to prescribe activity intensity. METs are used to estimate the metabolic cost of physical activity relative to the resting state. One MET is equal to 3.5 mL of oxygen consumed per kilogram of body weight per minute (mL/kg/min).[43] Therefore, when VO_2 is known, the intensity can be prescribed in METs by dividing relative VO_2 by 3.5 mL/kg/min. In general, walking at 2 mph is the equivalent of approximately 2.0 METs, and walking at 4 mph is the equivalent of approximately 4.6 METs.

Selection of an appropriate training range versus a specific training value has been recommended to provide greater flexibility in the exercise prescription, yet ensure that a training response will be achieved.[12] For example, an individual who is starting an exercise program might be given a target HR range between 60% and 70% of HR max instead of being told to keep target HR at a value equivalent to 60% of HR max.

Intensities between 70% and 85% HR max or 60% and 80% HR reserve are recommended for most people to experience improvements in cardiorespiratory endurance.[43] Health-related benefits can be realized at lower intensities, and thus lower intensities may be appropriate if the goal of exercise is to improve health rather than fitness.[1] The 2008 Physical Activity Guidelines support adults, including older adults, children, and adolescents performing moderately intense aerobic activity 150 minutes per week or vigorous activity 75 minutes per week. These guidelines can be applied without the need to measure HR when patients/clients are safe to perform activity without specific cardiovascular monitoring.[1] Suggestions for prescribing physical activity for health-related benefits can be found in the Duration section.

In the pool, HR is decreased when exercising while immersed to the neck because of the Starling reflex and is therefore a poor gauge of workload. The HR of deep-water exercise is 17 to 20 bpm less than that of the comparable land-based activity.[50]

Increase exercise intensity by adding resistance, increasing speed, changing terrain (e.g., uphills), removing stabilization, or adding upper extremity activity. The method for increasing intensity is goal specific and may be limited by other medical or physical conditions (e.g., rotator cuff tendinitis limiting the use of upper extremities). The intensity necessary to achieve a workload in the target training zone varies among individuals and usually correlates with the previously determined conditioning level.

Duration

Exercise duration can be manipulated to produce overload and a resultant cardiovascular training effect. Duration depends on the frequency, intensity, and the conditioning level of the patient. In general, exercise of greater intensity is performed for a shorter duration and exercise of lower intensity can be performed for a longer duration. Manipulation of these variables is goal dependent. If the patient is required to perform an activity for a longer duration (i.e., continuous walking as part of a job or recreation), progression of the activity program should focus more on increasing the duration and less on increasing the intensity.

The optimal duration recommended for aerobic training is between 20 and 30 minutes per session of exercise.[43] For individuals who are unable to perform 20 minutes of continuous exercise, discontinuous exercise can be prescribed. That is, several 10-minute bouts can be performed, for example, until eventually exercise can be tolerated for 20 to 30 minutes continually. Duration can be progressed up to 60 minutes of continual activity.[43] The same activity or different activities may be performed in each of these sessions (see **Patient-Related Instruction 6-4**).

Patient-Related Instruction 6-4

Frequency, Intensity, and Duration

Determining how often (frequency), how hard (intensity), and how long (duration) to exercise can be difficult. These parameters are related and must be balanced to find the right quantity of exercise for you. The following broad guidelines can be refined by your clinician:

1. Frequency: Generally, if you exercise more frequently (more times per day or days per week), the intensity and duration of those sessions should be lower. This recommendation allows adequate recovery before the next session. If the intensity and duration are high, you may not be fully recovered before the next session.
2. Intensity: The more intense the exercise, the shorter is the duration. Intense exercise cannot be sustained very long by most people.
3. Duration: Exercise that is lower in intensity can be sustained for longer periods. For example, sprinting can be sustained for seconds, but jogging can be sustained for up to several hours. The intensity and duration are inversely related; as one increases, the other must decrease.

Prescribing duration for a patient/client desiring health-related benefits should follow the 2008 Physical Activity Guidelines, aiming for 150 minutes of moderate aerobic activity per week or 75 minutes of vigorous activity.[1] Moderate activities like walking, bicycling under 10 mph, housework, and yard work can be performed for as little as 10 minutes at a time to count toward the 150-minute minimum. Collaborating with the patient/client to identify opportunities during the day and week to consistently be active can promote performance of physical activity and assist in meeting the 150-minute goal.[1]

PRECAUTIONS AND CONTRAINDICATIONS

In addition to the signs and symptoms of exercise intolerance described in the physiology of aerobic capacity and endurance section and Display 6-1, clinicians should be aware of the risks associated with exercise, as well as monitoring and supervision guidelines. The incidence of cardiovascular complications during exercise has been documented to be extremely low for individuals without significant cardiac disease, yet is higher for the most sedentary individuals when they perform unaccustomed or infrequent exercise.[43] For persons with cardiovascular disease, the incidence of cardiovascular complications during exercise is considerably greater; however, the overall absolute risk of cardiovascular complications during exercise is low when considered in light of the health benefits associated with chronic exercise (see **Building Blocks 6-7** and **6-8**).

BUILDING BLOCK 6-7

When answering this question, consider the case presented in Building Block 6-1:

How would you create an exercise prescription for the patient/client?

BUILDING BLOCK 6-8

When answering this question, consider the case presented in Building Block 6-1:

What normal cardiovascular changes would you expect during exercise?

In addition to understanding and following the risk stratification recommendations for supervision of exercise and exercise testing, the wise clinician will ensure that exercise prescriptions for sedentary individuals and those unaccustomed to exercise will start at lower intensities and progress at a slower rate. Patients should be educated about the signs and symptoms of exercise intolerance and to seek immediate assistance when these signs or symptoms occur. Clinicians who supervise patients engaging in vigorous exercise should have current training in cardiac life support and emergency procedures.

Endurance exercise places a significant load on the cardiovascular and musculoskeletal systems. Consideration should be given to any injury or disease affecting either of these systems. Individuals with degenerative joint disease should be encouraged to participate in non–weight-bearing exercises such as bicycling and water exercise, and those with low back pain should participate in activities that support or safely strengthen the back (e.g., semirecumbent biking, water activities). Individuals with osteoporosis should be encouraged to participate in weight-bearing activities. Positions and postures should be chosen that minimize the risk of fracture.

Graded Exercise Testing Contraindications and Supervision Guidelines

There are numerous contraindications to exercise testing, and guidelines for supervision of GXTs. **Display 6-8** lists the absolute and relative contraindications to exercise testing. The relative contraindications should be considered in light of the potential benefits of exercise and a less vigorous prescription created for individuals in this category.

DISPLAY 6-8

Contraindications to Exercise Testing

Absolute

- A recent significant change in the resting ECG suggesting significant ischemia, recent myocardial infarction (within 2 days), or other acute cardiac event
- Unstable angina
- Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
- Severe symptomatic aortic stenosis
- Uncontrolled symptomatic heart failure
- Acute pulmonary embolus or pulmonary infarction
- Acute myocarditis or pericarditis
- Suspected or known dissecting aneurysm
- Acute systemic infection, accompanied by fever, body aches, or swollen lymph glands

Relative*

- Left main coronary stenosis
- Moderate stenotic valvular heart disease
- Electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia)
- Severe arterial hypertension (i.e., SBP > 200 mm Hg and/or DBP > 110 mm Hg) at rest
- Tachydysrhythmia or bradydysrhythmia
- Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
- Neuromuscular, musculoskeletal, or rheumatoid disorders that are exacerbated by exercise
- High-degree atrioventricular block
- Ventricular aneurysm
- Uncontrolled metabolic disease (e.g., diabetes, thyrotoxicosis, or myxedema)
- Chronic infectious disease (e.g., mononucleosis, hepatitis, AIDS)
- Mental or physical impairment leading to inability to exercise adequately

**Relative contraindications can be superseded if benefits outweigh risks of exercise. In some instances, these individuals can be exercised with caution and/or using low-level end points, especially if they are asymptomatic at rest.*

American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010:54.

All clients should be closely monitored during exercise test performance. Vital signs should be assessed before, during each stage or workload of the test, and after the test for 4 to 8 minutes of recovery.[15] In addition, the RPE is commonly used to monitor exercise tolerance (Fig. 6-3).[48] Finally, individuals should be monitored for signs and symptoms of exercise intolerance. The guidelines for stopping an exercise test are presented in **Display 6-9**.

Supervision During Exercise

The screening or medical evaluation discussed in the screening examination section of this chapter provides information for determining which individuals may require supervision during exercise.[43] Referring to **Displays** 6-4 and **6-10** the clinician can determine whether a patient/client can exercise unsupervised or requires supervision. Notably, individuals with symptoms and cardiorespiratory disease who are considered by their physician to be clinically stable and who have been medically cleared for participation in an exercise program should be supervised during exercise.[43] Supervision means that the clinician is present during the exercise program and can monitor the patient/client response to exercise and provide support in the event that the patient/client develops symptoms during exercise.

DISPLAY 6-9
Indications for Terminating Exercise Testing

Absolute Indications

- Drop in SBP > 10 mm Hg from baseline BP despite an increase in workload when accompanied by other evidence of ischemia
- Moderately severe angina (defined as a 3 on standard scale)
- Increasing nervous system symptoms (e.g., ataxia, dizziness, or near syncope)
- Signs of poor perfusion (cyanosis or pallor)
- Technical difficulties in monitoring the ECG or SBP
- Subject's desire to stop
- Sustained ventricular tachycardia
- ST elevation (+1.0 mm) in leads without diagnostic Q-waves (other than V_1 or aVR)
- Relative Indications
- Drop in SBP of >10 mm Hg from baseline* BP despite an increase in workload in the absence of other evidence of ischemia
- ST or QRS changes such as excessive ST depression (>2 mm horizontal or downsloping ST-segment depression) or marked axis shift
- Arrhythmias other than sustained ventricular tachycardia, including multifocal PVCs, triplets of PVCs, supraventricular tachycardia, heart block, or bradyarrhythmias
- Fatigue, shortness of breath, wheezing, leg cramps, or claudication
- Development of bundle-branch block or intraventricular conduction delay that cannot be distinguished from ventricular tachycardia
- Increasing chest pain
- Hypertensive response (SBP of >250 mm Hg and/or a DBP of >115 mm Hg)

**Baseline refers to a measurement obtained immediately before the test and in the same position as the test is being performed.*

American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010:119.

DISPLAY 6-10
General Guidelines for Exercise Program Supervision

Unsupervised = Low-risk individuals from Display 6-4 with a functional capacity >7 METs

Professionally* supervised = Moderate or high-risk individuals from Display 6-4 with stable disease and regular physical activity habit with a functional capacity >7 METs

Clinically supervised = High-risk individuals from Display 6-4 with a functional capacity <7 METs

**Professional refers to a health/fitness professional supervision possessing a combination of academic training and certification equivalent to the ACSM Certified Health Fitness Specialist or higher Clinical supervision refers to a health/fitness professional possessing a combination of advanced college training and certification equivalent to the ACSM Registered Clinical Exercise Physiologist and ACSM Certified Clinical Exercise Specialist (or higher).*

Modified from American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010:175.

PATIENT-RELATED INSTRUCTION/ EDUCATION AND ADJUNCTIVE INTERVENTIONS

Patient education regarding cardiovascular endurance training and its effects is a critical component of a physical activity or exercise program. Clinicians should recall the recent recommendation of the U.S. Department of Health & Human Services that adults should perform moderate-intensity aerobic physical activity for a minimum of 150 minutes each week or vigorous-intensity aerobic activity for a minimum of 75 minutes each week to promote and maintain health. A combination of moderate and vigorous-intensity activity can be performed to achieve the recommendation.[1]

Patient education should include the "why" and the "how to" of the warm-up, training session, and cool-down phases. The patient should be alerted to signs or symptoms necessitating early cessation of the activity (including those in Display 6-1). These symptoms may be musculoskeletal (e.g., joint pain, muscle pain, cramps) or cardiovascular (e.g., shortness of breath, chest pain, light-headedness), or they may be specific to the patient's particular diagnosis (i.e., reproducing the patient's original symptoms). The patient should be counseled regarding modifications in the exercise program based on fatigue level and other activities performed that day.

As the patient is prepared for discharge, education regarding a maintenance program is critical to continued adherence with the exercise program. Progression through a conditioning program should be individualized and is dependent on the client's functional capacity, premorbid state, health status, age, and individual preferences, goals, and tolerance of the training.[43] The client's objective and subjective training responses should most heavily influence training progression.[15] Signs and symptoms of overtraining include exercise and nonexercise fatigue, reduction in maximum performance, decreased interest in training compared with normal, decreased HR and RPE values at the same workload, and increased complaints of aches and pains.[51]

Emphasizing the importance of continued physical activity in long-term health maintenance as a part of a healthy lifestyle can assist the patient in making physical activity a lifelong commitment. Information about safe progression, dosage, and signs and symptoms of overload can assist the patient in making appropriate choices.

The documented success of programs designed to encourage the adoption of regular physical activity is poor, with approximately one in five adults meeting the 2008 recommendation for 150 minutes of moderate physical activity per week.[52] Variations in adherence to the guidelines exist along geographic and socioeconomic factors, such as ethnicity, education, and income (http://www.cdc.gov/physicalactivity/data/facts.htm). Significant effort has been expended to identify factors that increase adherence to the recommended guidelines. These factors in sum indicate that programs and individuals prescribing exercise can and should adopt specific strategies to enhance compliance with exercise prescription, including regular physical activity to improve health. Examples of these strategies are shown in **Display 6-11**.

DISPLAY 6-11

Practical Recommendations to Enhance Exercise Adherence

- Obtain health care provider support of the exercise program.
- Clarify individual needs to establish the motive for exercise.
- Identify individualized, attainable goals and objectives for exercise.
- Identify safe, convenient, and well-maintained facilities for exercise.
- Identify social support for exercise.
- Identify environmental supports and reminders for exercise.
- Identify motivational exercise outcomes for self-monitoring of exercise progress and achievements, such as exercise logs and step counters.
- Emphasize and monitor the acute or immediate effects of exercise (i.e., reduced BP, blood glucose, and need for certain medications).
- Emphasize variety and enjoyment in the exercise program.
- Establish a regular schedule of exercise.
- Provide qualified, personable, and enthusiastic exercise professionals.
- Minimize muscle soreness and injury by participation in exercise of moderate intensity, particularly in the early phase of exercise adoption.

American College of Sports Medicine. ACSM's Guidelines for Exercise Testing and Prescription. 8th Ed. Baltimore, MD: Lippincott Williams & Wilkins, 2010:177–178.

The use of behavior change theories to enhance the adoption of exercise has received increased attention recently in the literature, specifically the application of the stages of change model, as discussed in Chapter 3. After identifying the stage the patient is currently in, the intervention can be tailored to enhance compliance and movement toward a lifelong habit. For example, an individual in contemplation is not quite ready for an exercise prescription. Efforts in this stage should focus on the provision of information about the costs and benefits of exercise, strategies to increase activity within the present lifestyle, and the social benefits of activity, for example.[53] Those in the preparation stage would benefit most from a thorough examination and exercise prescription, whereas those in the action or maintenance stage would benefit from learning about strategies to prevent relapse, making exercise enjoyable, and diversifying the exercise prescription to include more variety. Given the difficulty most people encounter when changing health-related behaviors, it seems prudent to use documented behavior change theories when possible, such as the stages of change model (see **Building Blocks 6-9** to **6-12**).

BUILDING BLOCK 6-9

When answering this question, consider the case presented in Building Block 6-1:

How would you recommend the patient/client progress the exercise program?

BUILDING BLOCK 6-10

When answering this question, consider the case presented in Building Block 6-1:

What education would you provide for the patient/client?

BUILDING BLOCK 6-11

When answering this question, consider the case presented in Building Block 6-1:

What physiologic adaptations to the exercise program would you expect after 6 months?

BUILDING BLOCK 6-12

When answering this question, consider the case presented in Building Block 6-1:

What psychological adaptations to the exercise program would you expect after 6 months?

LIFE SPAN ISSUES

Guidelines for Cardiovascular Endurance Training in the Young

Adolescents and children receive health-related benefits from regular exercise and should be encouraged to participate in regular activity because adopting an active lifestyle early in life may increase the likelihood of participating in physical activity in adulthood.[1] There are several key physiologic differences between children and adolescents compared with adults that the clinician should be aware of when prescribing aerobic exercise in young people. Resting and exercise BP values are lower in children than in adults, with a progressive increase with age seen until late adolescence when the values are similar to that of adults.[8] Children have smaller hearts and less total blood volume compared with adults, so SV is lower at rest and during exercise. To maintain CO, HR is higher in children compared with adults. Overall CO in children is lower than in adults for the same absolute rate of work, so a-vo_2 difference increases to compensate for the lower SV.[12] Aerobic capacity, when expressed in L/min, is lower in children because of a lower maximal CO capacity. However, as children develop and their pulmonary and cardiovascular function improves, aerobic capacity improves as well.[12]

Children lose more energy during exercise compared with adults when performing the same activity at the same intensity. In addition, children are less efficient at dissipating heat during exercise because they generate more metabolic heat per unit body size, sweat at a lower rate, and begin sweating at a higher core body temperature compared with adults.[43] Taken together, these factors indicate that children exercising in hot environments should do so at a lower intensity and they will need more time to acclimatize compared with adults.

Exercise testing in children is typically reserved for those with specific conditions in which cardiopulmonary capacity is useful to assess.[43] Exercise testing in children can be performed for the same reasons the clinician would test adults—to assess symptoms, tolerance, and cardiopulmonary response to exercise in a monitored setting.[43] There are both treadmill and bicycle protocols and norms for children that can be referenced for use when exercise testing children.[43] Further, equipment that is safe and sized correctly for children is necessary for accurate testing and may not be available in all testing laboratory settings. More commonly, physical fitness testing performed with children is more similar to the field tests discussed in the adult exercise testing section of this chapter. A popular physical fitness testing program is the Presidential Youth Fitness Program, measuring the major components of physical fitness (aerobic capacity, body composition, muscle strength and endurance, flexibility).[54] This program offers educational materials, tools, criterion-referenced standards, and interpretation of results for schools and communities to apply in group or individual programs.

Regular participation in physical activity during childhood will result in gains in strength, endurance, bone formation, self-esteem and self-efficacy, and skill development.[43] A program of activity will also minimize risk factors for cardiovascular disease, manage weight, reduce anxiety and stress, provide social interaction, and can be a great source of fun and enjoyment.[43] The 2008 Physical Activity Guidelines recommend that children and adolescents aged 6 to 17:

- Should do 60 minutes (1 hour) or more of physical activity daily.
  - Aerobic: most of the 60 or more minutes per day should be either moderate- or vigorous-intensity aerobic physical activity (activities in which large muscles are rhythmically moved). Vigorous-intensity physical activity should be performed at least 3 days per week.
  - Muscle-strengthening activities at least 3 days per week as a part of the 60 minutes or more of daily activity (these activities can be unstructured and part of play, including playing on playground equipment, climbing trees, and playing tug-of-war; or structured such as lifting weights or working with resistance bands).
  - Bone-strengthening physical activity at least 3 days per week as a part of the 60 minutes or more of daily activity (these activities should produce a force on bones that promotes bone growth and strength, such as running, jumping rope, basketball, tennis, hopscotch).
- Should engage in physical activities that are age-appropriate, enjoyable, and offer variety.[1]

Children are at low risk for cardiovascular disease and are able to adjust exercise intensity to tolerance, so they do not need a HR prescription.[43] No one program, activity, or methodology has been demonstrated to best improve physical activity in children.[43] Increasing children's physical activity participation on a regular basis and decreasing the amount of sedentary time spent are basic goals for a physical activity program for children. Fitness-based games and lifestyle activities should be used when addressing physical activity participation in children because they are fun and children are more likely to participate in activities that are fun versus highly structured. As children age, they can progress to league and team sports. Adolescents can benefit from league sports as well as cardiovascular exercise such as swimming, bicycling, and jogging. If desired, prescribing exercise using the parameters recommended for adults is safe for adolescents.

Children and adolescents are susceptible to overuse injuries; therefore, clinicians and parents should be aware of the signs and symptoms of overtraining. It is also important to recognize that children and adolescents should balance cardiovascular training with muscle strength and endurance training and activities to address flexibility, to address all of the elements of physical fitness.

Guidelines for Cardiovascular Endurance Training in the Elderly

Several factors affect the decline in physiologic function and physical performance that has been documented to occur with age. Technologic advances that require humans to expend less physical effort, decreased motivation levels and less energy, and the effects of aging all may contribute to the changes seen in the elderly and are sometimes difficult to differentiate. Maximum oxygen consumption decreases approximately 10% per decade with aging, beginning in the middle of the third decade in men and toward the end of the second decade in women. Maximum HR, SV, CO, and peripheral blood flow also decrease with age.[12] In the lungs, residual volume increases with age but total lung capacity remains unchanged, so less air can be exchanged with each breath. The lungs and chest wall also lose elasticity with aging.[12] Body composition changes seen with aging include an increase in relative body fat and a decline in fat-free mass.[12] All of these changes documented in the elderly can be slowed by participation in regular physical activity, making a physically active lifestyle a powerful age deterrent.

The same exercise testing principles presented earlier in this chapter apply to the elderly population. A wide variety of testing protocols exist that are appropriate for use with the elderly population and traditional protocols can be used with slight modification. Appropriate tests are those in which the initial workload is low (2 to 3 METs) and workload increments small (0.5 to 1.0 METs), and the test accommodates for impaired balance, coordination, vision, gait patterns, and weight-bearing.[43] The 6-minute walk test is used often as a measure of aerobic capacity in elderly patients and in elderly clients without disease.[55,56] To perform the test, patients walk as quickly as they can along a level surface for 6 minutes. The outcome measure of interest is the distance walked in feet or miles. The 6-minute walk test is a practical alternative to other exercise testing means in the elderly because it is easy to perform, patients can stop and rest anytime during the test, assistive ambulation devices may be used to perform the test, and it has been shown to be a reliable indicator of functional ability.[55,57]

The exercise prescription guidelines discussed in this chapter can be safely and appropriately applied to the elderly population. The 2008 Physical Activity Guidelines recommend the following guidelines for adults aged 65 years and older:

- 150 minutes a week of moderate-intensity, or 75 minutes a week of vigorous-intensity aerobic physical activity, or an equivalent combination. Aerobic activity should be performed in sessions of at least 10 minutes and preferably spread throughout the week.
    - To realize additional health benefits, 300 minutes per week of moderate-intensity aerobic physical activity or 150 minutes of vigorous-intensity aerobic physical activity can be performed per week, or an equivalent combination.
    - Muscle strengthening that is moderate or high intensity and involve all major muscle groups on 2 or more days per week.
    - Exercises that maintain or improve balance should be performed by adults at risk of falling.
    - When older adults are unable to do 150 minutes of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow.[1]

The effects of cardiovascular endurance training in the elderly include decreased BP, increased HDL-C, improved cardiovascular mortality rates, increased bone density, and maintenance of oxygen consumption values.[58] Chosen activities should minimize impact on the joints, emphasizing activities such as water exercise, bicycling, or stair climbing. As is true for all ages, exercise need not be vigorous and continuous to be beneficial. Select activities that are accessible, convenient, enjoyable, and safe for the participant. Older adults who are currently inactive should gradually increase their physical activity and should avoid vigorous aerobic activity at first. Although it may take months for those with a low level of initial fitness to achieve the recommended amount of regular physical activity, a gradual increase in the number of days per week and duration of activity will ensure a safe and injury-free approach to becoming more active.[1]

KEY POINTS

- Physical fitness is defined as a set of attributes that people have or achieve and includes cardiovascular endurance, or the ability of the whole body to sustain prolonged exercise.
- Aerobic capacity or maximal oxygen uptake (VO_2 max) is the highest rate of oxygen the body can consume during maximal exercise.
- During acute exercise, HR, SV, Q, a-vo_2 diff, BP, and RR increase proportionally to the exercise workload.
- Benefits of cardiovascular endurance training include positive changes in the cardiovascular and respiratory systems that provide protection from disease, and improved psychological well-being and quality of life.
- Impaired aerobic capacity can occur as a result of primary cardiovascular and pulmonary disease, diseases of other systems that limit mobility, prolonged bed rest, aging, and a sedentary lifestyle.
- Areas of the patient/client history to which the clinician should pay special attention during the examination of individuals with impaired aerobic capacity include risk factors for cardiovascular disease, social/health habits such as smoking and physical activity, functional ability, and medication history.
- Patients/clients should be appropriately screened prior to the initiation of a cardiovascular training program to ensure safety and minimize risks, thus the clinician should be aware of general screening guidelines.
- Tests and measures used to examine patients/clients with impaired aerobic capacity include GXTs, body composition, and tests and measures of circulation such as BP.
- Exercise prescription can be based on the results of an appropriate exercise test administered before the initiation of a cardiovascular training program.
- Physical activity can be performed to produce health- or fitness-related benefits depending on the patient/client's goals and motivations. Most importantly, individuals should be regularly active, performing a minimum of 150 minutes per week of moderate- or 75 minutes per week of vigorous-intensity aerobic physical activity or an equivalent combination.
- Cardiovascular endurance training can be performed using a variety of exercise modes and training techniques.
- Exercise prescription should be based on the individual's needs and interests and should take into consideration comorbidities that may affect activity performance.
- Cardiovascular endurance training is one aspect of a well-balanced exercise program including muscle strengthening and endurance activities and flexibility exercises.
- The clinician should be aware of the signs and symptoms of exercise intolerance and should be able to identify the contraindications for GXT.
- Supervision requirements for GXT and for the performance of aerobic exercise are based on the patient/client's history, risk factors, and abilities, and the clinician should be able to appropriately determine the level of supervision required.
- Education about the specifics of the exercise prescription, including progression, and the implementation of strategies to enhance compliance will increase the likelihood of the patient/client adopting cardiovascular exercise as a lifelong habit.

CRITICAL THINKING QUESTIONS

1. Consider Case Study No. 1 in Unit 7.
    a. What activities to maintain cardiovascular endurance would you recommend for Lisa as she recovers from her ankle sprain? Be sure to consider the demands of her sport.

   b. What activities would you recommend if she were a long-distance runner? A hockey player? A wrestler?
2. Consider Case Study No. 2 in Unit 7.
   a. Assuming the patient has met the short-term goals, to plan an intervention program to achieve the long-term goals, what test and measure would you select to assess aerobic capacity? What tests and measures to assess circulation would you monitor during the test of aerobic capacity?
   b. To design a long-term aerobic exercise program for Sarah, determine the best strategies to incorporate to enhance compliance and increase the likelihood that she will adopt exercise as a lifelong habit.
3. Consider Case Study No. 3 in Unit 7.
   a. Design an intervention program to improve this journalist's cardiovascular endurance, including techniques to enhance compliance.
   b. According to the Transtheoretical Model of Behavior Change, what stage of change would you place Cathy in and what strategies are appropriate to incorporate to move her to the next stage?
4. Consider Case Study No. 8 in Unit 7.
   a. Recommend a GXT for George, considering the examination findings and his premorbid condition.
   b. Make recommendations for a cardiovascular exercise program, considering George's examination findings and his job.
   c. How would your intervention plan be different if George worked as a long-distance truck driver?

CHAPTER

7 Impaired Range of Motion and Joint Mobility

LORI THEIN BRODY

Most patients with orthopedic conditions need mobility activities during the rehabilitation process. The clinician must provide hands-on rehabilitation techniques as well as instructions for a home exercise program. The execution of mobility activities is not as difficult as choosing the appropriate level of assistance and ensuring that the patient is performing the exercise correctly. Clear instruction and supervised practice in the clinician's presence can prevent misunderstandings about exercise performance.

Mobility exercises may be initiated early in the rehabilitation program and done throughout the rehabilitation program on a maintenance basis. Some individuals need progressive mobility exercises throughout the rehabilitation course, progressing from passive (PROM) to active assisted (AAROM) to active range of motion (AROM). The choice of mobility activities depends on the stage of healing, length of immobilization, number and kind of tissues affected, and the specific injury or surgery. Understanding of the effects of decreased mobility and remobilization is the key to making appropriate mobility exercise choices. The clinician must also realize that immobilization is relative; it can be externally imposed by a brace or cast, or the patient may "self-immobilize" by discontinuing the use of the limb.

When considering mobility, the terms *arthrokinematic* and *osteokinematic* motion must be differentiated. **Arthrokinematic motion** refers to movements of the joint surfaces. Roll, spin, and glide are terms used to describe arthrokinematic motion. Arthrokinematic motion is a necessary component of osteokinematic motion that refers to movement of the bones. **Osteokinematic motion** is described in terms of planes (e.g., elevation in the sagittal plane) or relative movements (e.g., flexion, abduction). Mobility can be impaired by alterations in arthrokinematic motion, osteokinematic motion, or both.

CONTINUUM OF MOBILITY

Although decreased mobility is the most obvious mobility impairment encountered, the concept of mobility is relative, with the degree of mobility occurring along a continuum. That continuum encompasses **hypomobility**, or decreased mobility, and **hypermobility**, or excessive mobility. Hypermobility should not be confused with instability. **Instability** is an excessive range of osteokinematic or arthrokinematic movement for which there is no protective muscular control.[1] For example, someone may have excessive arthrokinematic anterior, posterior, and inferior glide at the shoulder (i.e., hypermobility) that is asymptomatic. Loss of dynamic muscular control at the shoulder produces instability and symptoms.

At the hypomobility end of the continuum, the concepts of contracture and adaptive shortening are important for understanding hypomobility. A **contracture** is a condition of fixed high resistance to passive stretch of a tissue because of fibrosis or shortening of the soft tissues or muscles around a joint.[2] Contractures occur after injury, surgery, or immobilization and are the result of the remodeling of dense connective tissue. Immobilization of a tissue in a shortened position results in **adaptive shortening**, which is shortening of the tissue relative to its normal resting length. Adaptive shortening also can result from holding a limb in a posture that shortens the tissues on one side of the joint. For example, protracting the shoulders in a rounded posture results in adaptive shortening of the pectoral muscles. This shortening can be accompanied by **stiffness** or a resistance to passive movement.

Somewhere between the ideas of hypermobility and hypomobility lies the concept of relative flexibility. **Flexibility** is the ability to move a joint or a series of joints through a ROM. **Relative flexibility** considers the comparative mobility at adjacent joints. Movement in the human body takes the path of least resistance. If one segment of the spine is hypomobile because of injury or disease, the segment is stiffer and has more resistance to movement than adjacent joints. When flexion, extension, or rotation is necessary, the adjacent joints produce most of the movement because of the resistance to motion at the hypomobile joint. Likewise, stiffness in the hamstrings is often compensated by lumbar spine motion, placing more load on the spine. Lengthening the hamstrings minimizes the stress placed on the spine and is the basis for hamstring stretching, an approach used by some persons to remedy back pain.

Relative flexibility is not always an impairment. For example, because of its biomechanical and anatomic properties, L5 is more adapted to produce rotation than any other lumbar segment. It is *relatively more flexible* in the direction of rotation. This is a clinical problem (i.e., impairment) only if the motion becomes excessive and is not muscularly controlled. This problem may occur because of relative stiffness at other spinal segments (above or below L5) or at the hips. For example, golfing requires a significant amount of total body rotation. If the hips, knees, and feet are relatively more stiff in rotation than the spine, the discrepancy may impose excessive rotation in the spine. If the thoracic spine or upper lumbar segments are stiff in rotation, the difference may impose excessive rotation on the L5 segment. L5 is the site of relative flexibility in the direction of rotation.

MORPHOLOGY AND PHYSIOLOGY OF NORMAL MOBILITY

Normal mobility, in its broadest definition, includes:

- Osteokinematic motion (movement of bones)
- Arthrokinematic motion (roll, spin, and glide movements of the joint surfaces)
- Adequate tissue length to allow full ROM (i.e., passive mobility)
- Neuromuscular coordination and skill to accomplish purposeful movement (i.e., active mobility)

Structures involved in passive mobility include the joint's articular surfaces and interposed tissues (e.g., menisci, labrum, synovial lining), joint capsule, ligaments and tendons (including insertion sites), muscles, bursae, fascia, and skin. Mobility is maintained in most individuals by routine, daily use of their limbs and joints in normal daily activities. However, adaptive shortening can occur in those who spend long periods of time in single postures (e.g., sitting most of the day), resulting in a loss of mobility.

Normal mobility includes adequate joint ROM and muscle ROM. **Joint ROM** is the quantity of motion available at a joint or series of joints in the case of the spine. In contrast, **muscle ROM** is the functional excursion of the muscle from its fully lengthened position to its fully shortened position. Examination and treatment techniques for joint ROM impairments and muscle ROM impairments differ. Joint ROM impairments are examined using accessory or "joint play" motions (arthrokinematic motions) and are treated with joint mobilization, whereas muscle or other soft tissue ROM impairments are examined using flexibility (muscle length) tests and treated with ROM or stretching exercises.

IMMOBILITY, IMMOBILIZATION, AND REMOBILIZATION

Individuals can lose mobility at a joint for several reasons including:

- Trauma to soft tissue, bone, or other joint structures
- Surgical procedures such as total joint replacements, reconstructions, debridements, arthroplasties, osteotomies, and tendon transfers
- Surgery for nonorthopedic conditions such as mastectomy or other chest procedures
- Bed rest after cardiac, gynecologic, or other surgical procedures
- Joint disease such as osteoarthritis or rheumatoid arthritis
- Prolonged immobilization or bed rest for any reason
- Inability to move a joint because of neuromuscular disease
- Pain that inhibits movement

Immobility at a joint produces a self-perpetuating cycle that can be interrupted by several physical therapy interventions, including ROM activities, resistive exercises, or other manual therapy procedures such as joint mobilizations. Progressive adaptive shortening of the soft tissues occurs as the body responds to decreased loading. This shortening limits mobility and function, reducing the patient's ability to carry out normal activities of daily living, work, or leisure activities. The patient accommodates these limitations by substituting other joints or limbs to achieve functional goals, thereby contributing to the disuse. Pain results from disuse and progressive shortening of the joint capsule (a highly pain-sensitive structure), adding to the disuse, and perpetuating the cycle of immobility. Weakness ensues because of changes in the length–tension ratios, furthering the patient's disinclination to use the limb (**Fig. 7-1**).

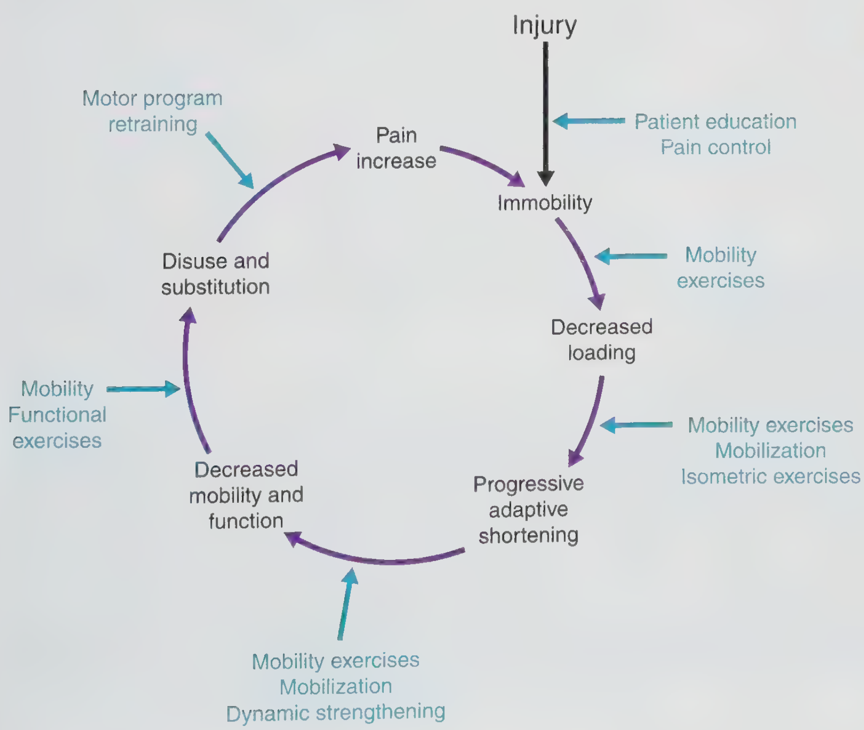

FIGURE 7-1 Self-perpetuating cycle of immobility.

TABLE 7-1

Effects of Immobilization and Remobilization on Muscle and Tendon

MUSCLE	TENDON
Position- and composition-specific muscle fiber atrophy	Decreased size and number of collagen fibers
Functional loss > muscle mass loss	Collagen fibers thinner and disorganized
Decreased electrical activity > atrophy	Decreased load tolerance
Increased connective tissue	Decreased water and GAG[a] content
Increased subcutaneous fat deposition	Increased synthesis and degradation of collagen
Remobilization: lengthy rehabilitation necessary to restore muscle performance especially with longer immobilization	Decreased tensile strength, elastic stiffness, and total tissue weight
	Remobilization: controlled mechanical stress increases tensile strength and energy absorption capacity, facilitates normal gliding and soft tissue relationships, prevents excessive scar formation

[a]GAG, glycosaminoglycan

Decreased mobility has profound effects on bone and soft tissues, reflecting the body's ability to adapt to various levels of loading. The plastic nature of these tissues works in positive and negative ways. The specific adaptation to imposed demands principle is based on Wolff's law and asserts that tissues remodel in accordance to the stresses placed on them. The effects of **overload** (tissue load greater than its normal usage), and its resulting hypertrophy, are well known, but the findings associated with underloading are less well known. Findings such as muscular atrophy and loss of joint motion are evident, but cellular changes, articular cartilage changes, and weakening of ligaments and their insertions are less obvious alterations.[3] The clinician must prevent these effects when possible and consider them when implementing a rehabilitation program.

Tables 7-1 to **7-4** summarize the consequences of immobilization or decreased mobility on various tissues.[4] Further information can be found on thePoint.lww.com/BrodyHall4e. Generally, most research has examined the effects of immobilization on healthy, uninjured tissues. This raises two important issues. First, immobilization usually is initiated in the presence of an injury (although tissue-lengthening procedures are exceptions), and the structural and mechanical properties of the injured tissues probably will be further compromised. The stages of healing can be found in Chapter 10 and should be considered in concert with the immobilization issues. Second, it is tempting to focus only on the injured tissue after immobilization. However, all surrounding tissues also are immobilized, and understanding the immobilization effects on these tissues ensures a safe and effective rehabilitation course.

Following immobilization, the patient typically goes through a course of structured remobilization.[5] The physiologic response to remobilization of previously immobilized tissues provides the scientific basis for many of the mobility interventions used. Be sure to consider the effects of remobilization on collagenous tissues prior to choosing any specific intervention techniques. The effects of remobilization on connective tissue vary with the type of connective tissue, the type of immobilization, and, most importantly, the length of immobilization. Response to remobilization interventions are not necessarily linear and excessive exercise can disrupt the healing process. How the

TABLE 7-2

Effects of Immobilization and Remobilization on Ligament and Their Insertion Sites

- Decreased total collagen mass
- Decreased strength and stiffness of ligament
- Decreased load to failure
- Shortening of ligament
- Increased stiffness of associated joint
- Disproportionate increase in young, immature collagen
- Bony resorption and weakening at insertion sites
- Increased avulsion rates
- **Remobilization:** can restore structural and mechanical properties of ligaments but takes longer than the original immobilization period

From References found on thePoint.lww.com/BrodyHall4e.

TABLE 7-3

Effects of Immobilization and Remobilization on Articular Cartilage

- Increased water content
- Decreased proteoglycan content
- Decreased chondrocyte population
- Decreased articular cartilage thickness and stiffness
- Articular cartilage softening
- Collagen fiber splitting and fibrillation
- Subchondral bone sclerosis
- Osteophyte development
- **Remobilization:** effects are time and load dependent; progressive joint deterioration may ensue with inappropriate loading postimmobilization

TABLE 7-4

Effects of Immobilization and Remobilization on Bone

- Decreased bone mass
- Decreased bone synthesis
- Decreased trabecular bone volume
- Weight-bearing bone loss exceeds nonweight-bearing bone loss
- **Remobilization:** depends upon bone quality prior to immobilization; may return to normal faster or bone changes may not be reversed

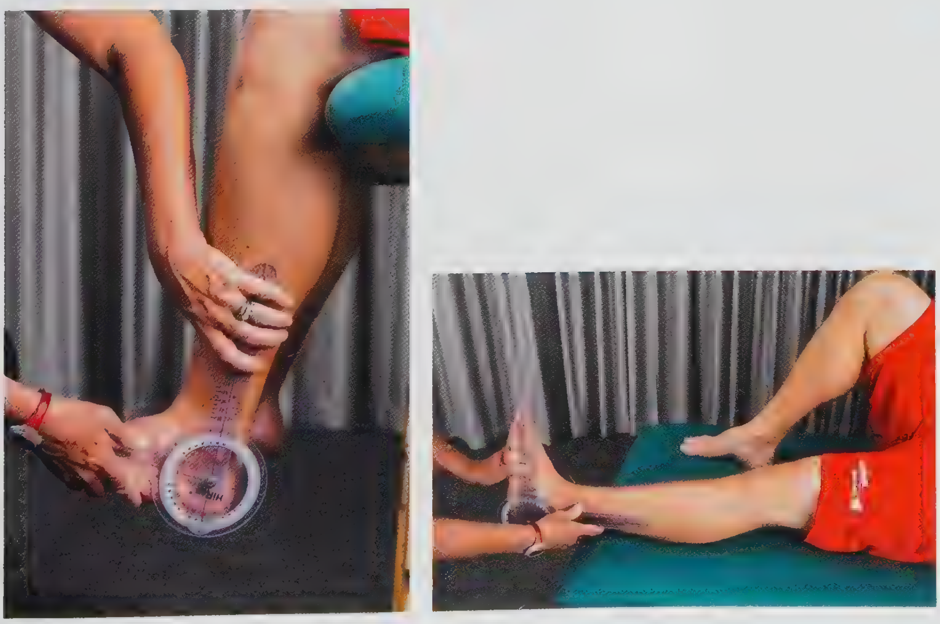
remobilization activity is dosed will impact the final quantity and quality of tissue. In-depth information on the specific tissue effects of remobilization on various tissues can be found on thePoint.lww.com/BrodyHall4e.

MOBILITY EXAMINATION AND EVALUATION

Performing a thorough examination before choosing a physical therapy intervention ensures appropriate indications and goal setting for the specific mobility technique(s) chosen. Moreover, the evaluation, including subjective examination and history taking, informs decisions about exercise dosage, activity type, and subsystems of the movement system specific to the individual.

The examination should identify the tissue(s) responsible for limited mobility. Noncontractile tissues that may limit passive mobility about a joint include the joint capsule, periarticular connective tissue, and overlying skin. Surgical incisions producing adhesions between the skin and underlying fascial layers limit their ability to glide during joint motion. Shortening, spasm, or contractures of the musculotendinous unit such as a Dupuytren's contracture can also limit the passive motion at a joint. Shortening of musculotendinous tissue should be differentiated from stiffness of other connective tissues. Stiffness in soft tissues is felt as an increased resistance to movement and can alter movement patterns passively and actively, resulting in musculoskeletal pain. Bone-on-bone approximation in the presence of degenerative joint disease, loose bodies, and pain can similarly limit passive mobility. The concepts of joint ROM and muscle ROM were clarified earlier. Examination procedures must identify the source(s) of decreased mobility to effectively direct the treatment. Joint osteokinematic motion is typically measured in cardinal planes with a goniometer, whereas joint arthrokinematic motion is evaluated with joint play assessment. Goniometric measurements are performed actively and passively, although the reliability of measurement is greater for active measures than for passive measures.[6] Isolated motions such as elbow flexion, knee extension, and ankle dorsiflexion are most commonly measured, but functional measurements with less stabilization and control can also be taken. Goniometric measurement of forward reach is a common functional assessment. Standards for normal goniometric mobility at each joint are published and provide a guideline for assessing mobility. When assessing joint ROM, the clinician must ensure proper patient positioning to avoid apparent joint motion limitations caused by poor muscle extensibility. For example, hip joint flexion ROM should be performed with the knee flexed to prevent limitations from hamstring excursion (**Fig. 7-2**).

Limitations in arthrokinematic motion decrease a patient's mobility, and increases in arthrokinematic mobility cause hypermobility. Arthrokinematic mobility is assessed through joint play maneuvers. Joint play is the movement of one articular surface on another and is not usually under voluntary control. Joint play is assessed by stabilizing one articular surface (by stabilizing the bone) and applying external pressure on the other to produce movement. Joint play assessment is typically applied in the loose packed position of the joint, which is the position where the joint is under the least amount of stress and the joint capsule has its greatest capacity. For example, applying an anteroposterior glide at the proximal interphalangeal joint of the index finger requires stabilization of the proximal phalanx while the distal phalanx is moved in an anteroposterior direction. This is performed in slight flexion, which is the loose packed position of this joint. In some cases, stabilization of one segment is provided by the surrounding bony and soft tissue structures and the supporting surface. For example, when performing posteroanterior unilateral vertebral pressure, the patient is stabilized in a prone position on the table while unilateral posteroanterior pressure is applied to the transverse process, producing rotation of the vertebral body that should be compared with the contralateral side.[1] Assessment of joint play can identify hypomobile, normal,



A B

FIGURE 7-2 **(A)** Joint ROM at the ankle. The knee is flexed to minimize effects of gastrocnemius tension. **(B)** Muscle ROM for the gastrocnemius.

FIGURE 7-3 Assessment of hip flexor muscle flexibility goniometrically using the Thomas test. The contralateral hip is flexed toward the chest to stabilize the pelvis in a neutral position. The therapist must palpate the pelvis to confirm the neutral position prior to continuing with the assessment. The affected lower extremity is slowly lowered and observed. To differentiate between 1-joint and 2-joint hip flexors (i.e., the iliopsoas and the rectus femoris/sartorius/tensor fascia lata), the therapist gradually flexes the knee until passive tension is reached. If the hip remains in the same position, regardless of knee position, the 1-joint hip flexors are at fault. If hip flexion increases with increased knee flexion, the 2-joint hip flexors are at fault.

or hypermobile conditions. These tests direct intervention for increasing capsular mobility, looking for other sources of mobility loss, or stabilization activities, respectively.

Assessment of joint ROM with a goniometer or joint play maneuvers does not identify the cause of limited motion. Joint ROM can be limited by capsular tightness, extrinsic soft tissue tightness, intrinsic joint blockage (i.e., knee meniscus tear blocking motion), or pain. Selective tissue tension testing assists the clinician in identifying the tissue at fault. Loss of joint motion in a capsular pattern or with a capsular end feel suggests that the joint capsule is the tissue at fault, and the treatment focus is joint mobilization. However, the clinician should remember that end-feel assessment is not a highly reliable measurement and that the pattern of capsular limitation does not always exist.[7]

Unidirectional loss of motion suggests some other soft tissue (muscle–tendon unit, skin, fascia, neurologic tissue) is at fault, and other ROM techniques may be employed. Muscle ROM is generally assessed using flexibility tests, a few of which are quantified. For example, hamstring extensibility can be assessed goniometrically using the 90–90 straight leg raise.[1] The Thomas test for hip flexor extensibility and the Bunnell–Littler test for hand intrinsic or joint capsule extensibility are examples of flexibility tests (**Fig. 7-3**). These tests, when performed correctly, can direct intervention for decreased musculotendinous extensibility as the cause of decreased mobility.

RANGE OF MOTION INTERVENTION FOR IMPAIRED MOBILITY

A variety of interventions are available to treat decreased mobility. After the tissues limiting mobility have been identified, appropriate ROM, stretching, or joint mobilization techniques should be applied. Adjunctive agents enhance the effectiveness of exercise interventions.

Subsystems of the Movement System

Although any of the subsystems of the movement system may contribute to decreased mobility, most mobility problems arise from passive system elements such as the neuromyofascia, capsuloligamentous, bony, and joint-related tissues. For example, loss of normal hip extension ROM may contribute to low back pain by transferring the extension mobility requirement from the hip to the low back (i.e., relative flexibility). In this case, impaired mobility in the hip contributes to low back pain impairment. The pain arises from compression of the posterior elements of the spine and subsequent inflammation around the nerve roots (i.e., pathology) and an inability to sit for long periods (i.e., activity limitation). If left untreated, this condition may lead to participation restrictions such as the inability to work at a desk, participate in recreational activities, or sit in a car (**Fig. 7-4**).

In this example, the passive subsystem elements are the shortened hip flexors and hip joint capsule pulling the pelvis into anterior tilt in addition to the weak (active subsystem) abdominal muscles that are unable to provide sufficient counterforce. The biomechanical elements are the increased anterior pelvic tilt and increased lumbar lordosis contributing to posterior element compression in the spine. The active element is an inability to recruit the abdominal muscles to improve the biomechanical elements. The cognitive/emotional element is depression related to chronic low back pain.

The subsystems of the movement system involved must be prioritized and those subsystems amenable to physical

FIGURE 7-4 Lumbar extension compensating for limited hip flexor mobility during a volleyball serve.

therapy intervention determined. In this situation, intervention to increase the length of the hip flexors, decrease stiffness in the hip joint capsule, and improve the neuromuscular firing and muscular endurance of the abdominal muscles should be instituted.

Considerations in Choosing Mobility Activities

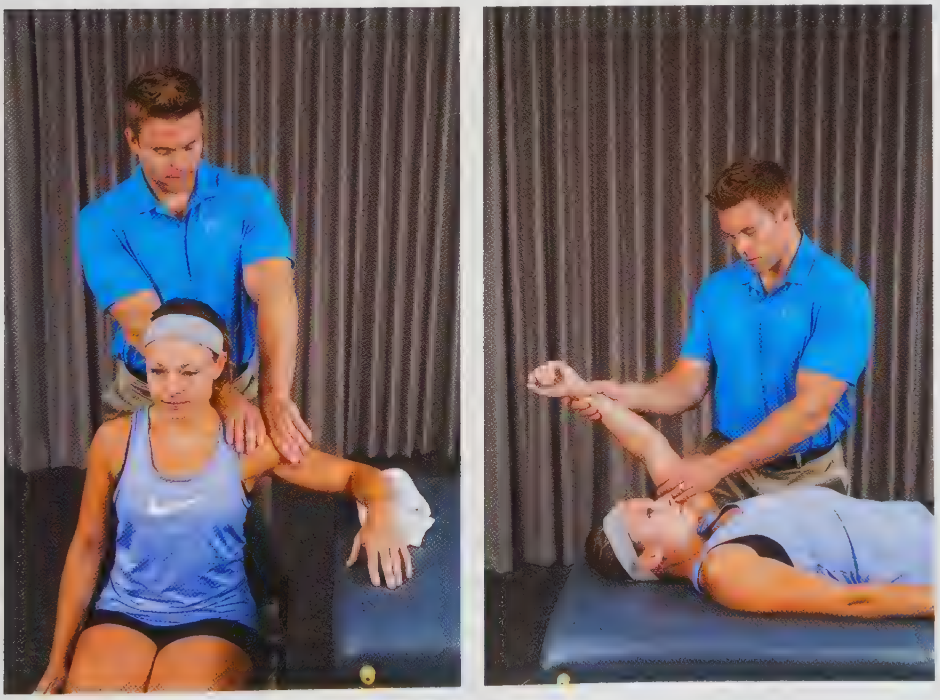
When choosing from the wide variety of mobility interventions available (i.e., joint mobilization, ROM exercises, neuromobilization, soft tissue mobilization, stretching) be sure to consider the availability of sufficient arthrokinematic motion, the hyper-/hypomobility continuum, and the prognosis. Arthrokinematic roll, spin, and glide are necessary prerequisites for normal osteokinematic mobility. Attempting to perform ROM activities in the absence of normal arthrokinematic motion at the joint surface does not improve the impaired mobility and may increase the patient's symptoms. Therapist applied or self-mobilization activities such as inferior glide or lateral distraction at the glenohumeral joint or long-axis traction at the hip, if indicated, should precede ROM exercises (**Fig. 7-5**).

When applying interventions to increase mobility, consider the continuum of hypomobility to hypermobility and the concept of relative flexibility. Hypomobility can be mistreated if the possibility of adjacent hypermobility is ignored. For example, if a stiff segment exists at L4–L5 and treatment is directed at decreasing stiffness there without stabilizing interventions directed at hypermobile segments above and below, symptoms of instability at these segments may increase. Treatment must include a comprehensive program to *improve the mobility at the relatively more stiff segments* or regions and to *increase the stiffness at the relatively more mobile segments*. Because motion always occurs along the path of least resistance, mobility occurs naturally at the stiff segment only if it is of equal mobility or more mobile than other segments. It is important to increase the stiffness at the site of relative flexibility. This is done by improving neuromuscular control, muscle performance capability, and length–tension relationships of the stabilizing muscles around the site of relative flexibility. These techniques are coupled with patient education, postural training, and movement patterns that improve the distribution of mobility.

Also consider the cause of decreased mobility and the prognosis for resolution of the mobility impairment. In some cases, such as idiopathic shoulder adhesive capsulitis, the specific cause of the problem is unknown, whereas the prognosis and final outcome are mixed. In this case, mobility interventions that the patient can perform independently will be an important component of the treatment program.[8,9]

Range of Motion

ROM activities at a joint or series of joints and articulations are commonly used to offset some of the deleterious effects of immobilization. Movement about a joint, whether passive, active assisted, or active, produces a load in the soft tissues; this loading can maintain the integrity of the tendon, ligament and bony attachments, articular cartilage, and muscle. The magnitude of the benefit is determined by the exercise and immobilization parameters and by the status of the tissues before immobilization. Mobility activities are specific exercises or functional activities performed to improve functional ROM about a joint. Mobility activities usually are performed through a joint ROM and can be performed in cardinal planes and multiple planes or using functional movement patterns (e.g., reaching, squatting). These activities can be performed actively, passively, or with active assistance. Fundamental ROM considerations can be found in **Display 7-1**.



A B

FIGURE 7-5 **(A)** Therapist performing inferior glenohumeral mobilization. **(B)** Therapist assists shoulder flexion following joint mobilization.

DISPLAY 7-1

Considerations When Performing ROM

- Ensure patient comfort and safety
- Ensure clinician safety by using good body mechanics
- Support any areas at risk of injury resulting from hypermobility, fracture, etc.
- Perform ROM slowly and rhythmically
- Move through as full a range as possible
- Use handling and cradling techniques that increase therapist contact with the patient to enhance relaxation (especially when performing PROM)
- Use cardinal plane motions, combined motions, or functional movement patterns

Passive Range of Motion

PROM exercises are mobility activities performed without any muscular activation (**Fig. 7-6**). These exercises are performed within the available ROM. Any overpressure at the end of the range would be categorized as stretching, not PROM. PROM and stretching can be combined to increase the ROM around a joint.[10]

Indications PROM is used when:

- Active movement may disrupt the healing process.
- The patient is physically or cognitively unable to move actively.
- Active movement is too painful to perform.
- Teaching active or resistive exercises.
- Relaxation is the goal.

Goals related to the prescription of PROM depend on the patient and the setting. In an orthopedic setting, PROM is often used to prevent the deleterious effects of immobilization after an injury or surgery. Prevention of joint contractures and soft-tissue stiffness or adaptive shortening, maintenance of the normal mobile relationships between soft tissue layers, decreased pain, and enhancement of vascular dynamics and synovial diffusion are goals of PROM.[10] These goals are difficult to measure and to document. The clinician must rely on his or her understanding of the pathologic process to provide the rationale for this intervention. Measurable outcomes related to PROM as prevention intervention may include decreased pain, expeditious restoration of motion and strength, and earlier return to function after activity is allowed (see **Self-Management 7-1**).

SELF-MANAGEMENT 7-1

Ankle Passive Range of Motion

Purpose: To increase ankle motion in all directions

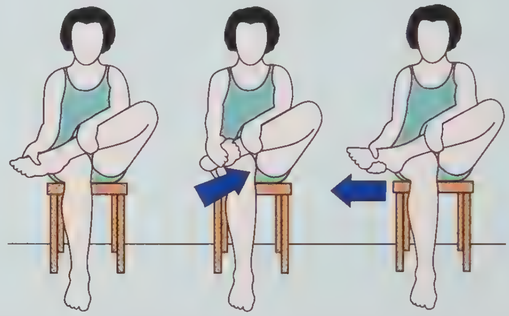
Position: In a sitting position with the ankle crossed across the knee, with a comfortable grip at the forefoot.

Movement Technique: Move the ankle in upward and downward directions. Move the ankle in and out. Stay in a comfortable ROM. Hold briefly at the end of the range in each direction.

Dosage:

Repetitions: ____________________

Frequency: ____________________



When the patient is comatose, paralyzed, on complete bed rest, nonambulatory, or cognitively unable to maintain joint ROM, PROM is used to achieve the same goals as the orthopedic setting. Because of the long-standing nature of these problems and the profound effects of long-term immobility, prevention assumes even greater importance. The patient usually requires PROM exercise two or more times each day, necessitating provision of services by family members or other assistive personnel.

Modes The exercise chosen should allow full available excursion. Several modes are available for performing PROM or stretching. Use pulleys, continuous passive motion devices, family members, or various household objects such as the floor,

A B

FIGURE 7-6 **(A)** Self-ROM for wrist flexion. **(B)** Self-ROM for wrist extension.

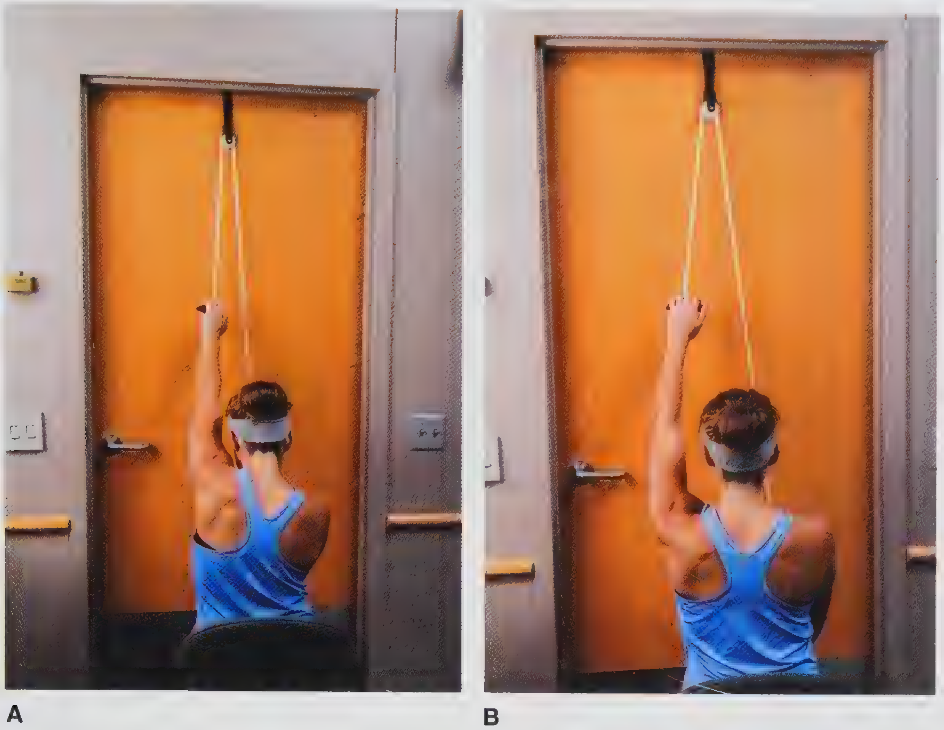


FIGURE 7-7 **(A)** Incorrect performance of shoulder flexion using pulleys. **(B)** Correct performance using proper posture and movement kinematics.

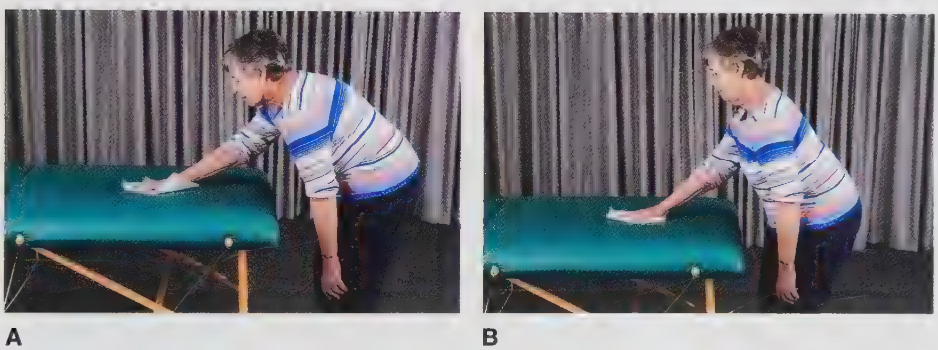

FIGURE 7-8 **(A)** Incorrect performance of passive shoulder flexion on a countertop. **(B)** Correct performance using proper posture and movement.

counters, or chairs to perform PROM. Holding the position at end range adds a stretching component to the PROM activity. Using pulleys to gain shoulder flexion can be helpful if performed properly without scapular or spinal substitution patterns (**Fig. 7-7**). The same can be said for self-mobilization activities such as stretching the arm forward on a counter (**Fig. 7-8**). Passive knee flexion can be easily performed using a towel and a smooth floor, by sitting on a chair, or while in a pool (see the section on ROM Self-Management).

Techniques and Dosage The clinician's skill in performing PROM can significantly alter the response. Handling techniques can affect the patient's comfort and ability to relax during treatment. When active muscle contraction is contraindicated, positioning and handling should allow the patient to fully relax. Any apprehension could result in protective muscle contraction and possible injury. Proper positioning allows adequate stabilization while the clinician's hand control provides stabilization and command of the affected limb. Effective PROM technique includes:

- Using a grip that provides control but considers the patient's condition.
- Avoiding painful areas or excessively tight grips that produce discomfort
- Performing PROM at a smooth and steady pace, avoiding abrupt movements or excessive speed that may cause protective muscle contraction.
- Monitoring the patient's response and being flexible enough to modify the technique when necessary.
- Tailoring the hand position, ROM, and speed for each patient.

The exercise dosage will vary with the purpose of the exercise. In general, the volume of exercise should be sufficient to achieve the physical therapy goals without overloading the tissues, particularly when performed during the healing process. It is best to perform fewer repetitions of an exercise, and return to that exercise performing additional set(s) of the exercise if the patient tolerates. For example, following cast removal for a Colles fracture, the therapist might perform 5 to 10 repetitions of wrist flexion and extension, followed by a finger activity. If tolerated, add an additional set or two of the flexion/extension activity, with alternate activities between sets.

SELF-MANAGEMENT 7-2
Knee-to-Chest Stretching

Purpose: To increase the mobility of the lumbar spine and hips into flexion

Position: Lying on your back, with your knees bent and feet flat on the floor

Movement Technique: Slowly bring one knee to your chest while grasping behind your knee. Bring the second knee to your chest. Hold for 15 to 30 seconds. Slowly lower one leg to the starting position, followed by the other leg

Dosage:

Repetitions: ____________________

Frequency: ____________________

Active Assisted Range of Motion

AAROM can be defined as mobility activities in which some muscle activation takes place. In this situation, the patient is unable or not allowed to fully activate the muscle. AAROM is used when some muscle activation through the ROM is allowed or desired, but the patient requires some assistance to complete the ROM. AAROM is frequently used to initiate gentle muscle activity after musculotendinous surgical procedures such as rotator cuff or Achilles tendon repairs. The amount of assistance throughout the ROM may vary. Some individuals may require assistance throughout the entire range, but others may require minimal or no assistance in some ranges but nearly maximal assistance in other ranges. This variation may result from a painful arc, limitations imposed by the disease or injury, changing length–tension ratios, or synergist action.

Active assisted exercise is indicated for patients who are unable to complete the ROM actively because of weakness resulting from trauma, neurologic injury, muscular or neuromuscular disease, or pain. In addition, the weight of the limb may impede active movement using proper mechanics, and assistance may be provided to ensure proper exercise performance. Lastly, some injuries or operations necessitate limitations in active muscle contraction in the early phase of healing (see **Self-Management 7-2**).

The expected goals with AAROM intervention are the same as those accomplished with PROM but extend beyond to include the benefits of muscle activation. These goals might include:

- Prevention of the negative effects of immobilization
- Prevention of joint contractures and soft tissue tightness
- Decreased pain
- Enhanced vascular dynamics and synovial diffusion[11]
- A stimulus for bone activity from the pull of the muscle on the bony attachment
- Muscle activity
- Enhanced proprioception and kinesthesia

Muscle contraction in this situation has little impact on true strength gains in most patients, but it teaches the patient how to actively fire the muscle. For example, individuals with rotator cuff injuries require assistance to activate these muscles after injury or surgery (**Fig. 7-9**). Moreover, active assisted exercise involves the patient in the rehabilitation process, rather than being a passive recipient of an intervention.

Hand placement and cueing during AAROM are important for optimal patient participation. When possible, tactile cueing should be on one side of the joint rather than using a grip on the flexor and extensor surfaces. This action cues the patient for the direction of assistance or resistance. This is particularly important when performing a technique such as AAROM when some ranges are assisted but others are not.

Active Range of Motion

AROM is defined as mobility activities performed by active muscle contraction. These activities can be performed against gravity or

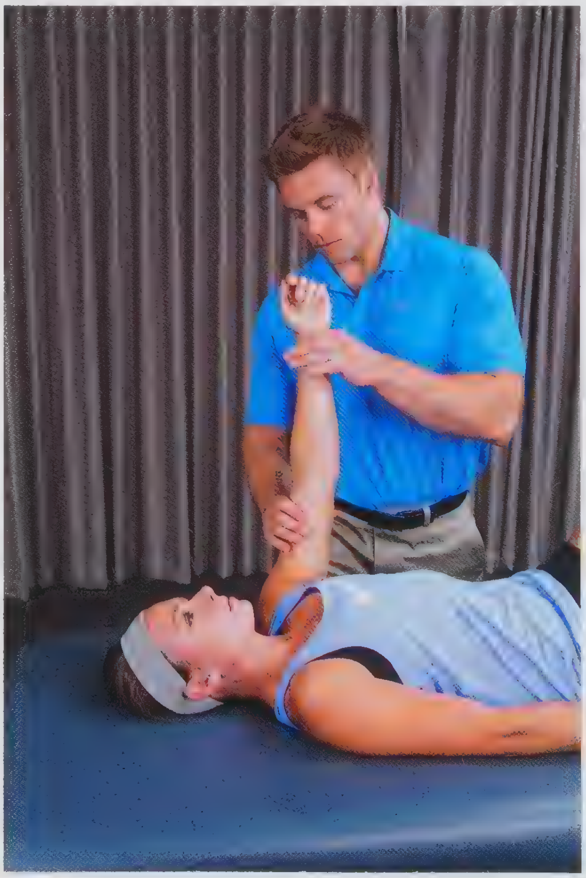

FIGURE 7-9 Active assisted shoulder flexion can be accomplished with assistance from the therapist.

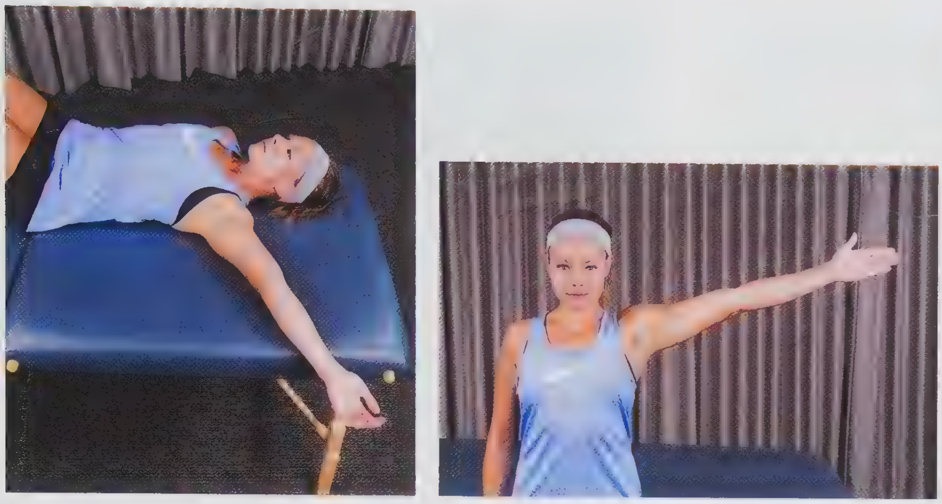

A B

FIGURE 7-10 **(A)** Active shoulder abduction in a gravity-minimized position. **(B)** Active shoulder abduction against gravity.

in a gravity-minimized position, depending on the individual's strength and the physical therapy goals (**Fig. 7-10**). Motions in cardinal planes, combination movement patterns, or functional activities such as reaching or combing one's hair are all examples of AROM. The expected goals or outcomes associated with AROM intervention include those associated with PROM plus the benefits of muscle contraction. These goals parallel those of AAROM, although the results are greater. In addition to the greater strength requirements, active exercise requires more muscle coordination because of the lack of assistance or guidance through the ROM. As with active assisted exercise, the strength gains are minimal in many patients. Only those with fair (3/5) strength or less can be expected to have their strength challenged. However, many patients can expect to be challenged proprioceptively and kinesthetically. For example, after knee injury or surgery, many individuals have difficulty activating the quadriceps femoris. Quadriceps setting exercises show patients how to activate the quadriceps, a prerequisite for functional activities. Although little or no tibiofemoral movement occurs, patellofemoral AROM occurs, with superior glide of the patella on the femur. An additional benefit of active exercise is independence in the rehabilitation program. Active exercise enhances the vascular benefits of ROM, with activities such as ankle pumps (i.e., repetitive dorsiflexion and plantarflexion) used postoperatively to prevent deep vein thromboses.

Indications As with AAROM, active exercise is indicated when active muscle contraction is desired. Many exercise programs begin with a regimen of active exercise to ensure proper exercise performance before the addition of resistance. In some situations, the weight of the limb alone produces optimal loading and makes a good starting point for the rehabilitation program. After learning the correct exercise technique, the patient can perform that exercise in a variety of modes that suit his or her preferences (see **Selected Intervention 7-1**).

Active mobility can be limited by the same noncontractile and contractile tissues that limit passive mobility. Shortening, stiffness, spasm, or contracture limit the joint's ability to move through a ROM. The strength and endurance of the muscle or muscle group can limit active motion. Strength below a fair (3/5) muscle grade implies an inability to complete the ROM against gravity. Poor neuromuscular coordination and balance, such as the inability to stand on a single leg, may limit active

SELECTED INTERVENTION 7-1

ACTIVITY: Wand elevation exercise in the pool

PURPOSE: To increase shoulder mobility in abduction, scaption, and flexion

RISK FACTORS: Ensure appropriate stabilization and arthrokinematic motion to prevent substitution

MOVEMENT SUBSYSTEM: Active subsystem

STAGE OF MOTOR CONTROL: Mobility

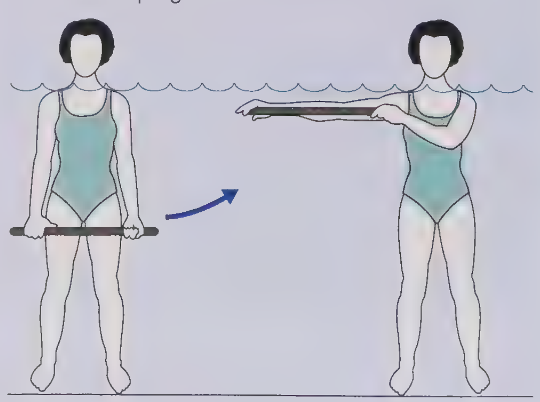
POSTURE: The patient is standing in chest-deep water, with a wand in the hands.

MOVEMENT: The patient allows the buoyancy of the water and the assistance of the uninvolved arm to lift the arm in the frontal, scapular, or sagittal plane. Relaxation of the shoulder muscles allows passive stretch into abduction, scaption, or flexion.

DOSAGE: Sets of three to five repetitions with 30-second holding at the end of the range.

RATIONALE FOR EXERCISE CHOICE: This exercise passively assists motion into a functional, frequently limited range. The intensity of stretch is easily modified by changing water depth.

EXERCISE GRADATION: The patient should discontinue use of wand and progress to active then resisted movements.



Wand shoulder abduction

mobility. Strength in an agonist may be adequate to complete the ROM, but antagonist firing because of neurologic pathology or faulty neuromuscular control patterns may limit motion. The patient may lack adequate speed of movement or agonist or synergist coordination to achieve purposeful movement. Cardiovascular endurance limitations in patients with chronic obstructive pulmonary disease, emphysema, or other cardiovascular conditions can hinder the performance of active exercise. All these situations may necessitate AROM as a therapeutic intervention (see **Building Block 7-1**).

BUILDING BLOCK 7-1

A 56-year-old man with a 6-year history of multiple sclerosis comes to physical therapy with complaints of poor left leg control and left leg fatigue with walking >¼ mile. Isolated hip flexor muscle and quadriceps muscle strength tests are 3+/5, but repeated testing reveals strength decrements after 10 repetitions, with the patient unable to complete the ROM. Describe a few simple exercises he might begin at home.

Technique Prior to performing AROM, ensure that muscle activation is warranted and determine any precautions. Examples of precautions might be working only through a portion of the ROM, performing ROM in a gravity-minimized position only, or modifying because of cardiac conditions. Once these are identified and the patient informed of these parameters, the therapist should demonstrate the exercise to be performed. Perform the exercise and then have the patient mirror the exercise, or using rhythmic initiation, the therapist may take the patient passively through the ROM and ask the patient to repeat this movement. Exercises can be performed through cardinal planes, diagonals, or functional movements. The speed, ROM, posture, and other important aspects of exercise performance should be monitored and explained to the patient. Mirrors are useful so the patient receives both verbal and visual feedback about performance.

Dosage Dosage for AROM depends upon the purpose of the activity. When using AROM to increase mobility, the exercise is typically dosed by the goal (i.e., continue repetitions until a ROM goal is achieved) or by the volume (i.e., number of repetitions × number of sets). For example, following shoulder surgery the patient might perform active shoulder flexion in side-lying until 100-degree flexion is achieved. Following knee surgery, the patient may be asked to perform 15 quadriceps set exercises every waking hour. When performing AROM as part of a strengthening routine, typical strengthening dosages should be implemented. The patient typically performs AROM exercise to fatigue, takes a rest interval, and performs additional sets. Patients performing AROM for position and kinesthetic sense should perform repetitions until form fatigue or muscle substitution. Again, this is followed by a rest interval and the exercise repeated or a different exercise initiated.

Active exercise should follow any passive technique to reinforce proper movement patterns and to overcome maladaptions to tissue stiffness. As new mobility is achieved, active exercise ensures the ability to use the new range effectively. For example, as hip flexion ROM improves from joint mobilization and stretching techniques, hand-knee rocking can be used to facilitate hip flexion ROM (see Fig. 17-26). As shoulder flexion mobility increases after stretching exercises, initiate active shoulder flexion exercises. Similarly, as knee flexion ROM increases after stretching, active knee flexion should follow (see **Self-Managements 7-3** and **7-4**). A few repetitions to reinforce the new ROM and movement pattern are generally sufficient.

SELF-MANAGEMENT 7-3
Active Range of Motion for Shoulder Flexion

Purpose: To increase active mobility in a forward and overhead direction

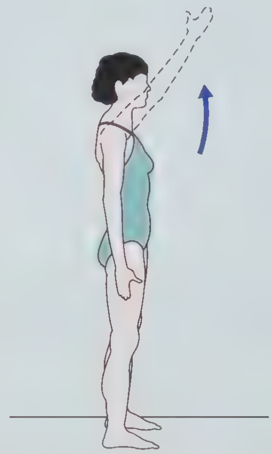
Position: In a sitting or standing position keeping your trunk in good alignment

Movement Technique: Reach your arm forward and up overhead. Reach as far overhead as is comfortable

Dosage:

Repetitions: ______________________

Frequency: ______________________



Independent PROM, AAROM, and AROM Activities

Most mobility conditions necessitating ROM intervention need these exercises daily. Therefore some exercises must be performed independently either by the patient or by a caregiver. For exercises provided by a caregiver, the therapist should instruct this individual in correct performance following the same guidelines utilized by the physical therapist. However, for the patient performing independent ROM activities, the therapist must provide tools, devices, or techniques that allow the patient to perform the ROM activity safely and effectively.

Pulleys ROM exercises can be implemented using a variety of different tools. Pulleys are one of the more common modes used for performing ROM exercises, particularly for the upper extremity. Pulleys are easily adjusted to increased shoulder ROM into cardinal planes such as flexion, abduction, and internal and external rotation (**Fig. 7-11A** and **B**). They can also be

SELF-MANAGEMENT 7-4
Active Knee Flexion

Purpose: To increase active range of knee flexion and to initiate muscle activity

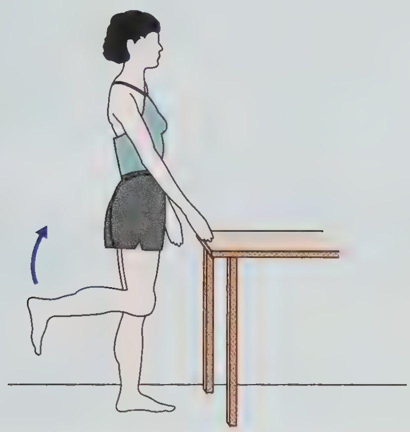
Position: Standing on your uninvolved leg on the floor or on a small step, with your involved leg hanging down next to the step, hold onto a stable object for support

Movement Technique: Slowly bend your involved knee up behind you, then lower it slowly and in a controlled fashion. Be sure to keep your knees in line with one another

Dosage:

Repetitions: ____________________

Frequency: ____________________



adjusted to increase mobility in diagonal or functional patterns (**Fig. 7-12** on page 152). Pulleys are simple as long as the patient is able to grasp the pulley handle. For those lacking hand strength or control, mitts or other assistive devices are available.

ROM exercises using pulleys can be passive or active assisted, and can incorporate stretching at the end of the ROM. Some combination of these activities is also possible. For example, the patient might begin by performing PROM and progress (either in the same exercise session or over time as healing permits) to AAROM. As tolerated, the patient might include stretching at the end of the ROM. Dosage is typically the same as if the exercise were applied manually by a physical therapist (see **Building Block 7-2**).

BUILDING BLOCK 7-2

A patient with adhesive capsulitis has been performing a home exercise program of pulleys working to increase independent active elevation of the shoulder. However, the patient is still unable to lift the arm against gravity above 90 degrees without scapular substitution. What are some changes to the exercise program that might make forward elevation easier?

A

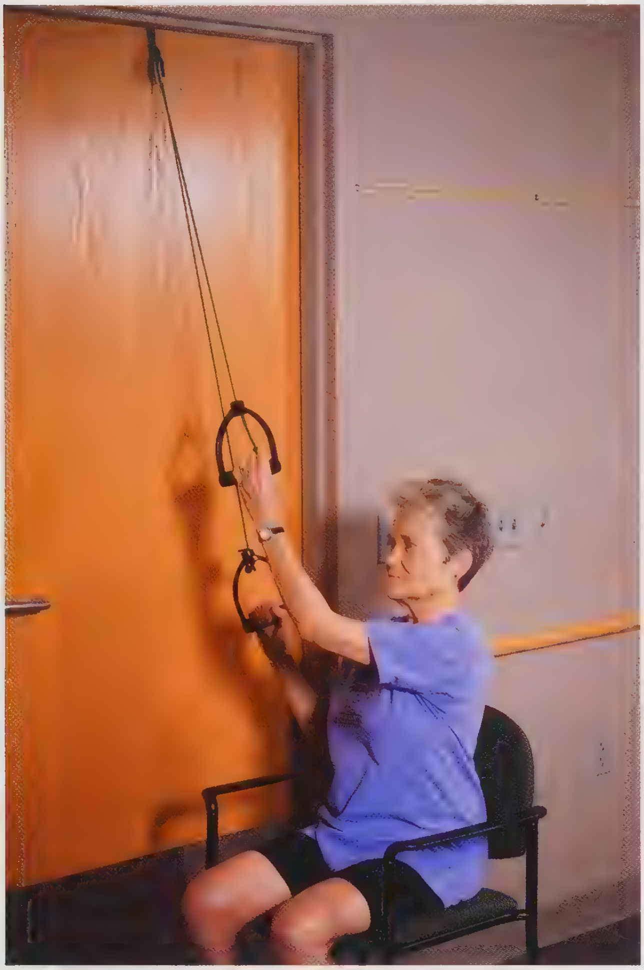

FIGURE 7-12 Pulleys to increase shoulder mobility in a functional diagonal pattern.

A

B

FIGURE 7-13 Cane exercise for shoulder: **(A)** external rotation and **(B)** abduction.

When using pulleys, instruct the patient to position themselves so that the pulley is directly in line with the axis of the joint being exercised. This facilitates normal biomechanics. If alignment is not correct, altered joint mechanics follows and may produce pain. Monitor the patient closely for proper mechanics, avoiding excessive scapular elevation as substitution for glenohumeral motion. Educate the patient on the importance of proper mechanics and supervise the patient performing the exercise independently prior to initiating this exercise.

Cane Exercises A cane, t-bar, dowel rod, or other similar device can be used to assist ROM exercises. Most of these exercises would be considered active assisted as most of these exercises require muscle activation to complete the ROM or to return to the starting position. Depending upon how the exercise is performed, these devices can be used effectively for stretching as well. Cane exercises are most frequently used for upper extremity ROM activities. In some cases, the uninvolved extremity guides the involved extremity while both are performing the same movement. Shoulder flexion and elbow flexion are good examples of this type of movement. In other cases, the uninvolved extremity guides the involved extremity in a unilateral movement pattern. Examples of this include shoulder external rotation and shoulder abduction (**Fig. 7-13A** and **B**). Combination activities such as extension and internal rotation can also be performed by grasping the end of the cane with the involved extremity while the uninvolved arm passively moves the arm into further internal rotation (**Fig. 7-14**).

Choosing cane exercises requires a good understanding of the limits of healing and confidence that the patient can perform the exercise competently without disrupting the healing

FIGURE 7-14 Cane used to increase shoulder extension and internal rotation mobility.

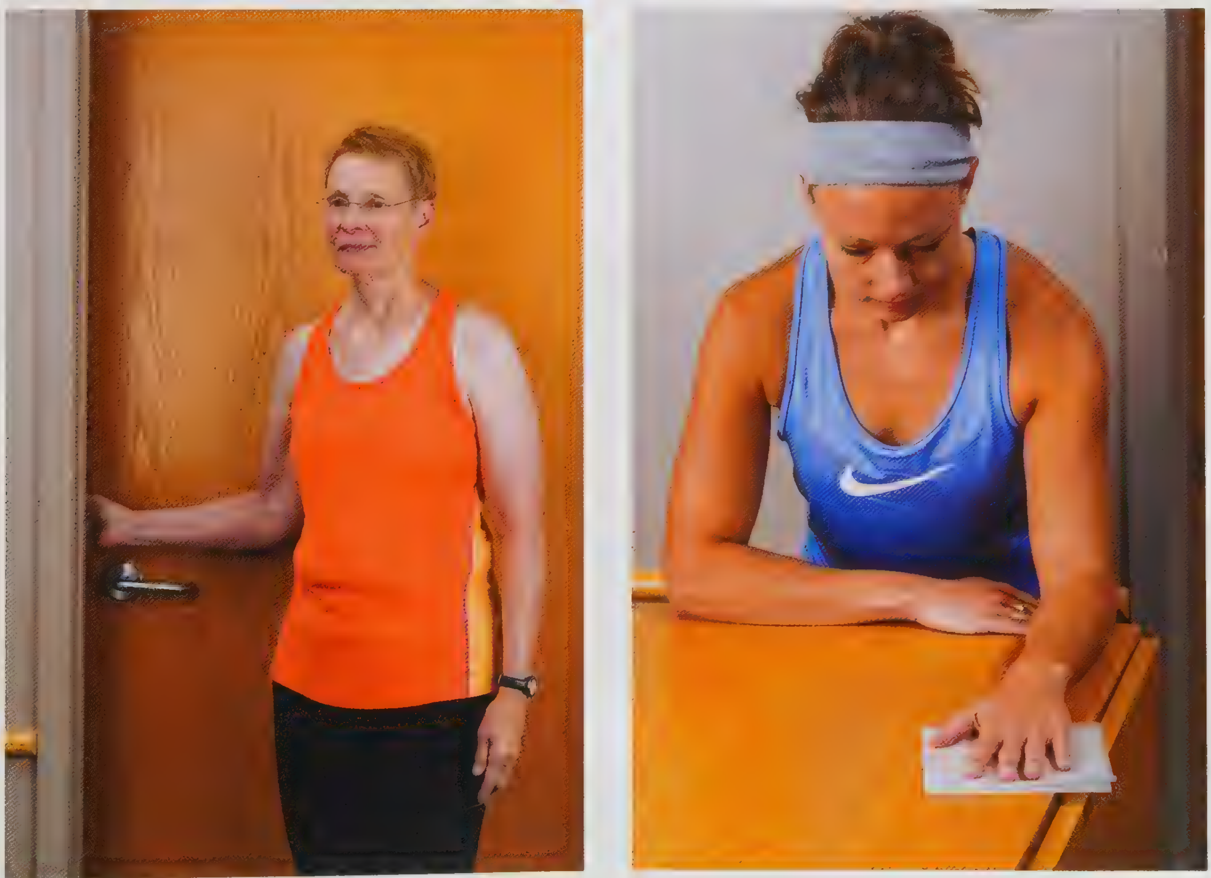
process. Although the cane is held in both hands, patients sometimes mistakenly believe that the involved extremity is not working during the activity. In many cases, the muscles are actively working and the exercise more closely resembles a guided AROM activity than a PROM or AAROM activity. If the exercise is truly passive, ensure that the patient understands the ROM limits for the exercise. When starting the exercise program, demonstrate and then guide the patient through the exercise performance. Dose the exercise the same as if the activity was being performed manually. Be sure to allow sufficient rest periods between exercise sets or sessions.

Horizontal and Vertical Surfaces Horizontal surfaces such as tabletops, desktops, floors and beds, and vertical surfaces such as walls, doors, and doorways provide ample opportunities for ROM exercises. Surfaces that allow the limb to slide easily (akin to a powder board or slide board) work best, although surface friction can be reduced by the addition of a towel, pillowcase, mitten, wax paper, or other similar material. Shoulder ROM in elevation can be performed by "walking" the fingers up a wall or doorway, or by walking the fingers out on a countertop, then forward bending at the hips to enhance the ROM (**Fig 7-15A** and **B**). Similarly, sitting at a desk, the patient can reach the arm forward on the desktop, and then slide the chair back to achieve greater overhead elevation. External rotation ROM can be performed by placing the hand in a doorway and turning away from the involved shoulder.

Use the floor or a bed to increase hip and knee flexion ROM. Either sitting or supine on the floor, slide the heel toward the buttocks to perform AROM. Pull a pillowcase or towel placed under the foot to perform PROM or AAROM (**Fig. 7-16**). Knee flexion ROM and ankle dorsiflexion ROM are easily performed sitting on a chair and sliding the foot back under the chair. A sock, pillowcase, or wax paper will decrease friction between the foot and the floor. Similarly, these activities can be performed in supine with one foot on the wall. Slide the foot down the wall to increase hip, knee, and ankle flexion. Crossing one ankle over the opposite knee and then sliding the foot down the wall will increase hip external rotation ROM.

These are only a few of the numerous examples of how horizontal and vertical surfaces can be used to perform self-ROM. When choosing an exercise, determine the amount of muscle activation allowed to ensure picking an exercise that can be done safely. Then query the patient about surfaces available at home and at work. Design a program that will be easy to perform in their living and working environments to increase program adherence. As best as possible, observe the patient performing the exercises. Dose the exercises the same as if they were being carried manually by the physical therapist (see **Building Block 7-3** on page 154).

Self-Range of Motion In the absence of tools, equipment, or other means of independent ROM, the patient can use the arms or uninvolved upper extremity to perform self-ROM



A

B

BUILDING BLOCK 7-3

The patient is a third-grade teacher who was recently out of a cast following a left wrist Colles fracture. He needs to increase his wrist AROM and PROM. Describe some activities he might do during his work day to increase ROM.

exercises. Self-ROM requires a baseline level of strength and coordination on the part of the patient, so the therapist should match patients with the appropriate level of activity. For example, a patient who has limited strength and mobility following a stroke may have insufficient strength or control to perform ROM on the involved arm or leg. Patients with multiple joint osteoarthritis or rheumatoid arthritis may not be able to use their arms to move other extremities because of pain.

Self-ROM can be performed in a variety of positions. The position chosen should consider the patient's strength and control, the desired working range, joint biomechanics (i.e., shoulder instability following a stroke, or hypomobility with impingement considerations), and the patient's ability to assume the preferred position(s). Modify the exercise as necessary to help the patient accomplish the activity. For example, when performing shoulder flexion ROM in supine, it may be necessary to flex the involved elbow to overcome gravity and lift the arm to the 90-degree position where gravity can begin to assist the exercise as the arm goes overhead.

In the upper extremities, the supine position allows the final range of shoulder elevation to be assisted by gravity. If this same exercise were performed in sitting or standing, the biomechanics of the exercise would increase the physical challenge of achieving the full overhead position. In contrast, the same exercise performed in supine allows gravity to assist at the end of the ROM (**Fig. 7-17A** and **B**). Upper extremity ROM activities that work well in supine are shoulder elevation, horizontal abduction and adduction, and rotation. Elbow flexion and extension and forearm pronation and supination are performed either in supine or sitting. In sitting, these activities are performed with the arm supported on the tabletop. Wrist and hand activities can be performed in supine but may work better in a sitting position with the arm resting on a tabletop. This position allows easier visualization of the activity being performed. Finger activities can be performed in nearly any position as long as visualization and stabilization are sufficient. In any case, be sure to observe the patient performing these exercises in the clinic to ensure proper performance. The patient may begin ROM exercises in one position and progress to an alternative position as improvement is made.

A B

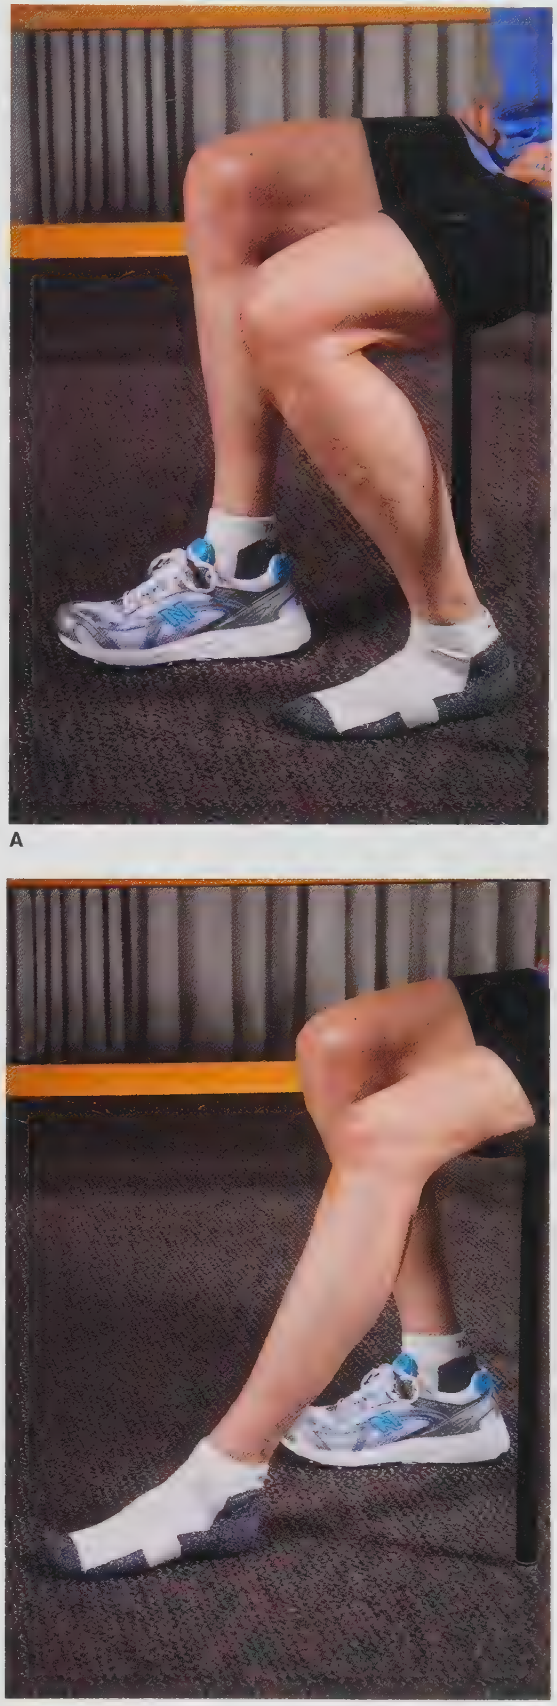
FIGURE 7-17 **(A)** Shoulder flexion in supine. Note that the moment arm length approaches zero at 90 degrees of forward flexion and further flexion becomes assisted by gravity. **(B)** Shoulder flexion in standing. The resistance because of gravity increases as the arm approaches 90 degrees flexion and continues to be resisted by gravity.

Like the upper extremities, lower extremity ROM can be performed in supine or sitting. In supine, hip and knee flexion can be performed by grasping behind the thigh with a towel or hands and pulling the knee toward the chest. This exercise requires abdominal strength to initiate the lift, and arm strength to pull the thigh toward the chest. Hip abduction and adduction can also be performed in supine, sliding the leg in and out, whereas hip internal and external rotation is performed in the same position, rolling the leg in and out. Rolling the leg internally and externally on a bed is relatively easy, whereas sliding the leg in abduction and adduction can be challenging against the friction of the bed. Some alterations can make this exercise simpler. First, if sufficient strength and control exist, the patient can slide the uninvolved ankle under the involved ankle and use the uninvolved leg to assist the activity. Also, lower friction surfaces can be used. A powder board or slide board under the involved leg can decrease friction. Lastly, wearing clothing and utilizing bedding of fabric that is "more slippery" than higher friction materials such as flannel will improve the ease of this exercise. If the patient is able to safely get down and back up off the floor and has tile, hardwood floors, or linoleum, the patient may lay supine on that surface with fabric that has higher friction and successfully perform the exercises on the floor.

Knee joint ROM exercises can be performed in supine by sliding the heel toward the buttocks, or in sitting. Sitting on the bed or floor, the patient slides the heel toward the buttocks. If ROM is to be passive, a pillowcase or towel under the foot can be pulled by the arms. In a chair, the patient can slide the foot forward and back, extending and flexing the knee, or if passive is preferred, the foot remains fixed on the floor and the patient slides his or her body forward and back over the fixed foot. Ankle PROM is easily performed passively by crossing the ankle over the opposite knee. Like the knee, PROM can also be performed with the foot fixed on the ground and moving the body anteriorly and posteriorly over it (**Fig. 7-18A** and **B**). Ankle AROM can be performed in nearly any position or posture. The same is true of the toes.

Trunk ROM exercises are more challenging because of the size and weight of the trunk. AROM exercises are performed in standing or sitting and involve trunk movements in cardinal, diagonal, or functional movement patterns. When performing PROM on land, it is usually performed in prone or supine, with the exception of side bending which is difficult to do passively independently. Passive extension is accomplished by a prone press-up, whereas flexion is performed in supine in a knee-to-chest exercise. Passive trunk rotation can be performed in hook lying, rolling the knees from one side to the other. However, on land, the effects of gravity may make these exercises uncomfortable. Many of these exercises are more comfortable in an aquatic environment.

Aquatic Environment The pool is an ideal place to perform ROM exercises. The water's buoyancy makes performance of any upward movement easier than on land. The effects of gravity resisting elevation are minimized and the water's buoyancy assists movement. Thus, many ROM activities requiring upward movement become AAROM exercises. This attribute of buoyancy is particularly useful for movements such as shoulder and arm elevation and hip flexion with knee extension during gait. The pool is particularly useful for individuals who lack the ability to perform self-ROM exercises on land. A few of the possible



A

B

FIGURE 7-19 Knee lift, moving the lower extremities on a fixed trunk in the pool.

reasons for this include multiple joint involvement, generalized weakness, paraparesis, or poor coordination.

Useful upper extremity movement patterns include cardinal plane flexion, extension, rotation, scaption, and abduction in a standing position. Combination patterns include functional diagonals, reaching and grasping, and pushing and pulling. Many of these combination patterns utilize all the joints throughout the upper quarter. Reaching behind the back also facilitates combination movements. These movements are generally supported or assisted by buoyancy.

Trunk movements are also easily performed in the water. Trunk rotation occurs passively by alternately flexing and extending the shoulder or actively by simply rotating the trunk. Side bending and flexion and extension can be performed by actively moving the trunk on fixed lower extremities, or by moving the lower extremities on a fixed trunk, such as when performing a knee lift (**Fig. 7-19**). Normal walking or exaggerated walking facilitates trunk rotation as a component of normal gait. Open chain hip abduction facilities trunk side bending.

Lower extremity movements are readily performed in isolation or in combination. Active hip flexion either with a straight leg or with a bent knee is assisted by buoyancy. Similarly, active hip abduction is assisted by buoyancy. Marching in place or across the pool is a functional ROM activity facilitating hip flexion motion. Sidestepping facilitates hip abduction ROM. Lunging, lunge walking, and squatting require multijoint movement in a functional pattern. Lifting the leg into hip flexion, abduction, and external rotation (i.e., figure 4 lifts) facilitates the functional movement of crossing one ankle over the knee to don socks and shoes. Nearly any joint motion of the lower extremity can be performed actively or with assistance in the pool. See Chapter 16 for more aquatic physical therapy suggestions.

STRETCHING

Stretching is one of the most common therapeutic exercise interventions applied by physical therapists. Although it is commonly prescribed and frequently utilized by rehabilitation experts, fitness experts, and the general public, proper applications and techniques are still not well understood. New information about the indications, effects, and optimal dosage of therapeutic stretching is published regularly.[12–15] The therapist must stay abreast of new information regarding stretching intervention as it becomes available.

Indications

Stretching techniques are used to increase the extensibility of the muscle tendon unit and the periarticular connective tissue. Stretching is used to increase flexibility, which depends on joint ROM and soft tissue extensibility. Stretching techniques fall into four broad categories: static stretching, ballistic stretching, dynamic stretching, and proprioceptive neuromuscular facilitation (PNF) stretching. Specific stretching exercises and methods within these broad categories can increase muscle and connective tissue extensibility and joint ROM.[16–28] The clinician must determine which stretching methods, in what sequence, and at what dosage can best resolve the impairments and activity limitations of each patient.

Stretching can be used to increase the length and to decrease the resistance to elongation (decrease stiffness) in a muscle-tendon unit or other connective tissue. However, there are some cases where stiffness and resistance to elongation might be preferred. For example, patients with paralysis or paresis because of spinal cord injury might rely on stiffness to provide stability in various postures or tasks. Similarly, patients with joint instability need some tissue stiffness around the joint to provide stability. Functionally, athletes involved in jumping sports need a combination of flexibility and stiffness to maximize performance.[13] However, in many cases, patients need increased extensibility of soft tissues because of existing hypomobility. Tissues with poor flexibility can produce pain locally in the inflexible tissue, in adjacent joints because of faulty biomechanics, or in opposing soft tissues as they become overworked attempting to overcome the resistance of the stiff or shortened tissue.

Other tissues besides the musculotendinous unit may require stretching. Loose areolar tissue, joint capsule, and supportive connective tissues may all benefit from stretching. Stretching can be combined with ROM exercises to maximize the impact of mobility activities. For example, a patient might perform ankle dorsiflexor and plantarflexor AROM followed by stretching of the Achilles tendon. Similarly, a patient might perform shoulder flexion PROM with a pulley followed by a prolonged stretch at end ROM.

Principles and Considerations in Stretching

Posture is a key aspect of any stretching activity performed. The starting and ending positions and the proper posture of associated joints are based on physiologic and kinesiologic factors. Physiologic factors such as the stage of healing affect the starting and ending positions for ROM and the position for stretching. For example, if a patient has just sustained an acute musculotendinous injury, the ending ROM avoids the extreme position of the muscle range that would place too much stretch on the injured tissue.

Kinesiologic factors include the normal osteokinematics and arthrokinematics at the joint. For example, proper performance of shoulder flexion requires normal arthrokinematic motion at the glenohumeral, sternoclavicular, and acromioclavicular joints and requires normal osteokinematic motion and associated

A B

FIGURE 7-20 **(A)** Seated hamstring stretch without appropriate lumbar stabilization stresses the lumbar spine because of lack of fixation. **(B)** Correct performance allows proper hamstring stretching.

arthrokinematic motion at the scapulothoracic articulation and thoracic spine. If motion is limited at any of these locations, substitution and faulty movement patterns occur. If an individual lacks glenohumeral arthrokinematic motion that limits glenohumeral flexion, scapulothoracic elevation or lumbar spine extension may substitute. Attempts to stretch the shoulder into further flexion can impinge subacromial soft tissues, cause substitution by adjacent joints, or both. The patient can learn an effective substitution pattern that prohibits normalization of movement patterns and the eventual progression to normal arthrokinematic and osteokinematic motion. Be sure to use joint mobilization techniques in this situation prior to performing stretching.

Another important kinesiologic factor is the stabilization of one attachment site of the muscle (usually proximal) or limb during stretching. For example, appropriately stretching the hamstring muscles requires proximal stabilization through proper lumbar and pelvic positions. Failure to stabilize proximally results in lumbar spine flexion, posterior pelvic tilt, and movement of the hamstring origin closer to the insertion, thereby minimizing the stretch (**Fig. 7-20A** and **B**). Maintaining correct posture that appropriately stabilizes is essential for effective stretching.

General procedures for stretching include a thorough examination to ensure stretching is indicated. Prior to stretching, the patient should perform a general warm-up to increase local blood flow and warm the tissue to be stretched. Active exercise for warm-up is preferable to local heat application, but hot packs can be used before stretching to warm local tissues. Use any relaxation technique necessary to enhance the stretching procedure. As with ROM techniques, use a grip technique that is comfortable for the patient or use family members or equipment such as pulleys, towels, or bands, or the pool for stretching. Stretching can be performed using equipment or steps, walls, or bars in the pool (**Fig. 7-21**). The buoyant atmosphere and water's warmth often make stretching more comfortable (see Chapter 16). As always, listen to the patient and modify techniques as necessary to ensure optimal outcomes. Ensure that the patient is feeling a stretching sensation and not pain or any other sensation. The patient should not stretch too aggressively. As a rule of thumb, the stretch should be mild and the stretching sensation should stop as soon as the stretch is released.

Neurophysiology of Stretching

In addition to the mechanical factors affecting stretching, the neurophysiology of the gamma system must be considered in exercise prescription. The muscle spindle and Golgi tendon organ (GTO) play important roles in the modulation of stretching. The muscle spindle is a specialized sensory organ comprised of intrafusal (nuclear bag and nuclear chain fibers) muscle fibers that lie in parallel with the extrafusal muscle fibers. Because they lie in parallel, stretching the extrafusal muscle fiber stretches and activates the intrafusal muscle fiber. The muscle spindle is sensitive to both changes in length and the velocity of these changes in the extrafusal muscle fiber. Type Ia and II afferent nerve fibers arise from the intrafusal fibers. The primary afferent nerve fiber from the nuclear bag intrafusal muscle fiber is principally sensitive to the rate of change of stretch.[29] If a muscle is stretched quickly, the type Ia fiber will facilitate contraction of the muscle being stretched as a protective mechanism to avoid injury. The type Ia receptor from the nuclear chain intrafusal muscle fiber responds to a maintained stretch and produces a maintained contraction. It is primarily affected by changes in muscle length, rather than velocity. Stimulation of type Ia fibers facilitates activation of the muscle being stretched. As with the type Ia fibers arising from the nuclear chain fibers, type II endings also arise primarily from the nuclear chain fibers and respond to maintained stretch with a maintained contraction.

FIGURE 7-21 Knee flexion stretching performed in the pool using buoyant equipment.

The GTO (type Ib fiber) attaches to the muscle tendon in series with the extrafusal muscle fibers and is sensitive to tension in the muscle caused either by stretching or by active muscle contraction.[29] Its function is protective, to prevent overstretching or excessive contraction of the muscle. When stimulated, the GTO inhibits its own muscle and facilitates its antagonist. This decreases the tension in the muscle being stretched. Thus the GTO can override the stimulus from the muscle spindle, facilitating relaxation of the muscle being stretched rather than contraction. The GTO is primarily responsible for the autogenic inhibition mechanism.

Static Stretching

DeVries[18–20] is credited with the initial research on the use and efficacy of static stretching and ballistic stretching. Static stretching is a method of stretching in which the muscles and connective tissue being stretched are held in a stationary position at their greatest possible length for some time period. Static stretching offers advantages of:

- Using less overall force
- Decreasing the danger of exceeding the tissue extensibility limits
- Lower energy requirements
- A lower likelihood of muscle soreness[19]
- Having less effect on type Ia and II spindle afferent fibers than ballistic stretching

When performing static stretching, position the patient to allow complete relaxation of the muscle to be stretched. This position requires a comfortable, supportive surface, or other external stabilization. Take the limb to the point at which a gentle stretching sensation is felt, and hold the stretch for 15 to 60 seconds (**Evidence and Research 7-1**). Relax the stretch and then repeat. Proper limb alignment ensures that the proper tissues are being stretched without causing injury to adjacent structures (see **Self-Management 7-5**).

SELF-MANAGEMENT 7-5
Hip Stretching

Purpose: To increase the flexibility of the lateral hip and thigh muscles

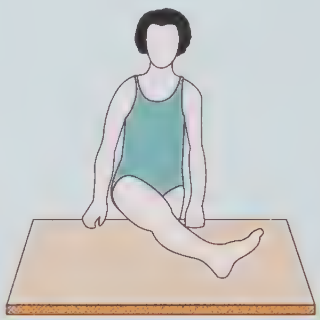
Position: Standing with the involved leg out on the surface (e.g., table, step) in front of you

Movement Technique: Keeping your hips square (do not rotate your hips), bring your leg across in front of you a few inches; next, roll your entire leg in the same direction (across your body). Hold 15 to 60 seconds or as directed by your physical therapist.

Dosage:

Repetitions: ______________________

Frequency: ______________________



EVIDENCE and RESEARCH 7-1

Patients always want to know how long to hold a stretch. In a group of subjects aged 21 to 39 years who stretched 5 days per week for 6 weeks, Bandy et al.[30] found that no increase in flexibility was found when the duration increased from 30 to 60 seconds or when the frequency increased from one to three times per day. Similarly, Ayala et al.[31] found no difference in 12 × 15-, 6 × 30-, and 4 × 45-second stretches when performed 3 days per week for 12 weeks. Note that the total stretching dosage was equal in all groups. This is in agreement with Cipriani et al.[32] and Johnson et al.[33] who suggested that the total stretch time per day was more important than any single stretch duration time. However, these studies were performed in young individuals. Feland et al.[34] found that subjects over 65 years of age demonstrated greater and longer lasting ROM improvements with 60-second stretch duration compared with 15- or 30-second durations.

Ballistic Stretching

Ballistic stretching uses quick movements that impose a rapid change in the length of muscle or connective tissue. Ballistic stretching takes the muscle to the end of its range and applies a rapid oscillating or "ballistic" stretch at end range.[35,36] Greater peak tension and greater energy absorption have been found with faster stretch rates, which is often the case with ballistic stretching.[37] Although ballistic stretching has been effective for increasing flexibility in athletes, there may be a greater chance of muscle soreness and injury.[19] Injury may result from excessive uncontrolled forces during ballistic stretching and proposed neurologic inhibitory influences (activation of type Ia afferent fibers) associated with rapid-type stretching.[22,38–43] For these reasons, ballistic stretching should be used only with selected patients, such as individuals preparing for active, dynamic, athletic, or plyometric activities. Research comparing ballistic stretching with static stretching has shown the two stretching techniques to produce different effects in the tissues.[44] Static stretching has been shown to decrease the passive resistive torque of the plantar flexors but having no effect on the Achilles tendon stiffness.[44,45] In contrast, ballistic stretching had no significant effect on the plantarflexor passive resistive torque, but decreased the Achilles tendon stiffness.[44]

The patient performing ballistic stretching should be well stabilized and comfortable. Move the limb until a gentle stretch is felt, and then gently "bounce" at the end range. Ballistic stretching is typically dosed as a number of repetitions or "bounces" for a certain time period. Ballistic stretching is often preferred over static stretching prior to many athletic activities (see "Stretching and Muscle Performance").

Proprioceptive Neuromuscular Facilitation Stretching

PNF stretching techniques are widely used by the physical therapy community. These techniques seek to capitalize on the use of the neurophysiologic concept of stretch activation. PNF stretching techniques use a contract-relax (CR) sequence, an agonist contraction (AC), or a contract-relax–agonist contraction (CRAC) sequence.[46] It has been suggested that PNF stretching techniques increase muscle ROM by using reciprocal and autogenic inhibition to induce relaxation.[47–49] Others add that increases in mobility following PNF techniques may arise from an increased tolerance to stretch, or by changes to the viscoelastic properties of the stretched muscle.[47,50] This type of stretching has been shown to increase ROM, maximal isometric strength, rate of force development, and musculotendinous stiffness.[48,51] The ability to increase ROM while concurrently increasing stiffness would be a great benefit to athletes, particularly those in jumping sports.

CR stretching utilizes autogenic inhibition. The therapist supports the patient's limb and brings it to the end ROM until gentle stretching is felt. At that point, ask for and resist an isometric contraction of the muscle being stretched for approximately 2 to 5 seconds and then ask the patient to relax the muscle. The therapist then passively increases the stretch. This procedure is repeated two to four times. Research has shown no difference in outcomes when the isometric hold duration was 3, 6, or 10 seconds.[52]

AC stretching uses the principle of reciprocal inhibition. Take the limb to the position of gentle stretch and ask for a contraction of the muscle opposite the muscle being stretched (the antagonist). This facilitates the stretch and inhibits the muscle undergoing stretch. For example, when stretching the hamstring muscles, a simultaneous contraction of the quadriceps muscles can facilitate the stretch. Hold the muscle contraction for 2 to 5 seconds and repeat the technique two to four times.

CRAC is a technique that combines CR and AC stretches. Take the limb to the point of gentle stretch, and perform a CR sequence (i.e., resistance applied against the muscle being stretched). After contracting the muscle being stretched, ask the patient to relax this muscle while contracting the opposing muscle group, thus facilitating the stretch. For example, when stretching the hamstring muscles, they are brought to a position of stretch. The hamstring muscles are contracted against resistance and then relaxed, and the quadriceps are contracted.

PNF stretching is indicated when muscle contraction in addition to stretching is appropriate. This type of stretching helps to improve strength and may help the patient better understand the continuum of contraction and relaxation. Some patients may find it easier to relax when contrasted with a muscle contraction. Each of these stretching techniques requires constant communication with the patient to ensure that neither overstretching nor excessive resistance produce muscle injury. These techniques can be performed independently with a family member or alone using a towel or other simple objects to provide resistance or assistance. Research shows both static and PNF stretching to be effective at increasing muscle ROM when dosage is equivalent.[53–56]

Dynamic Stretching

Dynamic stretching is a type of flexibility exercise where the limb is repeatedly taken through a ROM actively by the participant. The individual performs movements where the primary mover takes the limb through a ROM while the antagonist muscle relaxes and elongates.[57] For example, a reciprocal, dynamic knee extension with the hip at 90-degree flexion would be a dynamic flexibility stretch for the hamstring muscles (**Fig. 7-22**). The terms "dynamic stretching" and "dynamic warm-up" are often used interchangeably, as the term "stretching" typically implies taking a structure to its end range and holding it for some period. Typically dynamic stretching takes the structure to the limits of the range but does not hold this position. Other examples of dynamic stretching include lunge walking forward and back, lunges or squats up to a toe raise, hamstring curls, hip extensions, walking with hip rotations, and trunk activities. For those who cannot tolerate holding a static stretch, or who will be participating in activities requiring power or explosive speed, dynamic stretching is a good alternative to a traditional static stretching program (see **Building Block 7-4**).

BUILDING BLOCK 7-4

Denise is a 37-year-old mother of two who injured her right leg and hip in a motor vehicle accident (MVA) when she placed her foot against the floor of the car and sustained an impact injury up to her hip. She now has residual hip pain and limited mobility. She needs to increase hip external rotation ROM and hip strength. She is unable to tolerate a static stretch into hip external rotation. Please suggest alternatives.

FIGURE 7-22 **(A** and **B)** Dynamic knee extension as a warm-up activity for the hamstring muscles.

(Continued on next page)

B

FIGURE 7-22 (continued)

Measures of performance are better following dynamic stretching compared with static stretching[58–60] (**Evidence and Research 7-2**). Tendon stiffness and performance measures favor a dynamic warm-up compared with static or ballistic stretching prior to athletic activity.[62] Therefore, the type of stretching technique chosen should be specific to the patient and the purpose (i.e., increase flexibility, prepare for activity, etc.)

EVIDENCE and RESEARCH 7-2

A 4-week dynamic stretching warm-up resulted in increases in quadriceps peak torque, broad jump, underhand medicine ball throw, sit-ups, and push-ups compared with static stretching.[58] Similarly, performances in the T-shuttle run, underhand medicine ball throw, and the 5-step jump were improved immediately following a dynamic warm-up compared with a static warm-up.[59] Performance of high-speed motor skills such as the 10-m sprint also improved following dynamic warm-up compared with static stretching.[60] Gains in jump power poststretch were found in a group performing dynamic stretching prior to vertical jump.[61]

Effects of Stretching

Stretching is one of the most accepted interventions in rehabilitation. Different stretching techniques and dosage have been studied.[63,64] The effects of stretching are divided into acute effects and chronic effects. Acute effects are the immediate, short-term results of stretching and are the result of elongating the elastic component of the musculotendinous unit (see Figs. 11-2 through 11-4). Chronic effects are the long-term results of prolonged stretching and are the result of adding sarcomeres (usually because of immobilization in a lengthened position).[65] Different stretching techniques should be chosen based upon the immediate goal; a patient may use static stretching at times for the chronic effects, whereas using dynamic stretching for the acute effects at other times.

Chronic Stretching and Flexibility

The category of "chronic effects of stretching" has not been well defined. In general, chronic effects are the result of any regular ongoing stretching program of undefined dosage, and are contrasted with acute effects, which are the immediate, poststretching temporary changes. It appears that chronic stretching can improve flexibility, muscle performance, and functional performance.[64,66–70] Research has shown 30 minutes of daily stretching to increase the number of sarcomeres in series.[71] A study of immobilized soleus muscles found a 5% increase in length and a 4% increase in sarcomeres in series following a stretching dosage of 40 minutes per day, 3 days per week for 3 weeks.[72] Although regular stretching appears to increase flexibility, the research is not consistent about the dosage necessary to achieve these increases.[12,63,66,67,73,74] Differences in results may be because of the subjects under study, or research design issues (**Evidence and Research 7-3**).

EVIDENCE and RESEARCH 7-3

A large body of research supports increased flexibility outcomes following a regular stretching routine, typically ranging from 3 to 5 days per week, with a variety of stretching techniques (static, dynamic, ballistic, PNF) and stretching durations. Stretching hip flexor muscles for 1 to 2 minutes daily for 6 weeks resulted in significant ROM gains.[32] A 4-week program of stretching hamstrings found equal improvements in those who stretched daily compared with those who stretched three times per week provided they stretched at least two times per day.[75] Both static and dynamic hamstring stretching performed for 30 seconds three times per week for 4 weeks produced significant increases in hamstring length.[76] Sainz de Baranda[77] examined the American College of Sports Medicine's guidelines for stretching in a 12-week program with seven groups examining type of stretch and stretch dosage. All stretching groups improved flexibility compared with the control group, with no clear advantage for any stretch technique or stretch duration.

Research has shown that an 8-week program of regular stretching can increase active and passive flexibility and maximum torque and work.[49] Stretching using variable techniques (static, dynamic, PNF), with or without a partner and at varying dosages, has consistently shown increases in muscle flexibility[78,79] (**Evidence and Research 7-4**). Most research has been done on young healthy individuals, some active and some inactive. The differences in outcomes in some research may be because of the relative age, activity level, and baseline fitness of the population being studied. The effects of different stretching techniques in patient populations are relatively lacking. Therefore, it is essential that the limitations of the evidence and the appropriateness of application in any patient situation be thoroughly considered prior to implementing a program.

EVIDENCE and RESEARCH 7-4

Zebas and Rivera[28] demonstrated retention of gains from 2 to 4 weeks after the cessation of a 6-week stretching program. Research with inactive college students found improvements in hamstring flexibility following a 5-day per week × 4-week stretching program. These gains were subsequently lost during a 6-week no stretching period and then regained when the original stretching program was restarted. Flexibility gains in the second 4-week session were equivalent to the original flexibility gains.[80] Feland et al.[34] found retention of gains 4 weeks after cessation of a five times per week, 60-second hamstring stretching program in elderly individuals. Rancour et al. [81] found that stretching two to three times per week following a 4-week daily stretching program was sufficient to maintain gains made.

Regardless of the type of stretching method used, *chronic* stretching flexibility gains made may be retained even after the individual has stopped stretching for some time (**Evidence and Research 7-5**). For individuals with significant flexibility deficits, stretching should be part of their daily routine. After the goal is achieved, stretching one to three times each week may be sufficient to maintain gains.

EVIDENCE and RESEARCH 7-5

A study of an intense stretching program (40 minutes per day; 3 days per week × 10 weeks) resulted in significant improvements in flexibility, standing long jump, vertical jump, 20-m sprint, knee flexion 1 repetition maximum (RM), knee extension 1 RM, knee flexion endurance, and knee extension endurance.[67] However, other research has found no improvement in ROM, sprint time, or vertical jump following a 6-week stretching program.[66] These differing results highlight the important issues in determining the efficacy of chronic stretching. Significant effects on performance were found when the subjects were inactive or only recreationally active and the stretching was intense (15 stretches per session).[67] No improvement in performance was found when the subjects were collegiate track athletes who performed only four stretches.[66]

Chronic Stretching and Muscle Performance

Stretching has also been shown to improve muscle performance.[67] Increased hamstring torque production, bench press performance, trunk strength, power performance, and knee flexor and extensor strength and power have been demonstrated following stretching.[67,82–84] The mechanism of improved muscle performance with stretching is unclear. However, research has shown stretching to induce myoblast proliferation, increased muscle mass, and increased muscle fiber area.[65,85] A large body of animal research has shown less atrophy and improved muscle weight in soleus muscles that were stretched during immobilization compared with muscles that were immobilized only.[65,86,87] In some studies utilizing PNF stretching, the muscle contraction component may be responsible for increases in strength. Muscle activation in the contralateral leg working to stabilize the body while stretching has been suggested as another possible mechanism.[67] Regardless, a regular stretching program can improve muscle performance. There are limitations to the research and it is not being suggested that stretching can substitute for a well-designed resistive exercise program. For example, chronic stretching in collegiate track and field athletes demonstrated no improvement in flexibility, or sprint and vertical jump performances.[66] However, in situations where resistive exercise is contraindicated or the patient is unable to perform these activities, a stretching program has been shown to provide strength benefits.

Acute Stretching and Flexibility

The effects of routine stretching exercises are acute in nature. Most research has been done on the acute effects of stretching.[49] It is clear that acute stretching can increase the ROM and mobility of the connective tissue. Research has consistently found increases in flexibility immediately following stretching.[63,71]

The mechanism for short-term gains in flexibility after stretching techniques is unclear. Also, tissue compliance at rest is not necessarily related to tissue compliance during activity. It has been suggested that flexibility increases are not because of increased length or flexibility of the muscle, but rather because of an increased tolerance to the stretch.[88] Magnusson et al.[89] found that static and cyclic stretches both produce decreases in resistance to stretch, and that the increases in ROM were because of increased tolerance to the stretch, not to changes in the viscoelastic properties of the muscle. When comparing flexible versus inflexible individuals, the authors found that flexible subjects attained a greater angle of stretch with greater tensile stress and energy than inflexible individuals, apparently because of greater tolerance to the stretching sensation.[90] Additionally, strengthening exercises increased muscle stiffness that was unaltered by daily stretching.[91]

There is no agreement about which stretching technique is best.[16,17,21–25,27,28] According to some researchers, PNF techniques may be better than static or ballistic techniques for producing acute, short-term improvements in ROM.[92] These short-term improvements may result from contraction of antagonistic muscles while performing CRAC stretching, which is based on the principle of reciprocal inhibition.[38–42] Moreover, PNF techniques have been suggested to increase muscle performance as well, likely because of the isometric contraction component of the stretch.[67] Muscle stiffness has been decreased by performing a conditioning isometric or eccentric muscle action.[93] This muscle contraction causes a change in viscosity and resistance to molecular deformation, decreasing stiffness and resistance to stretch. Prestretch conditioning through active or passive movements (i.e., passive oscillations or active repetitive eccentric actions) may loosen actin–myosin bonds and increase stretching effectiveness.[46]

However, in the absence of continued activity, the short-term gains in flexibility may be lost. DePino et al.[94] found that improvements following four consecutive 30-second hamstring stretches were lost within 6 minutes of completing the last stretch. Following an *acute* stretching activity, hamstring flexibility returned to baseline levels within 3 minutes of concluding the stretch, although these subjects were resting quietly on a table with the hip and knee flexed between measurements.[94] In contrast, Ford et al.[63] found improvements that were retained for 25 minutes following the stretching session.

Acute Stretching and Muscle Performance

The impact of stretching on muscle and functional performance has been the subject of ongoing research. The conventional wisdom that stretching is necessary prior to an activity has been refuted. Importantly, the therapist must consider the population under study prior to drawing any definitive conclusions about the relative merits of any particular stretching regimen. In many cases, this research is done on healthy athletes who have no impairments. Thus, the applicability of this research to those patients with impairments or activity limitations because of hypomobility is limited.

In contrast to chronic stretching, acute static stretching of some lower extremity muscle groups has been shown to decrease muscle performance immediately after stretching.[57,95] Stretching, particularly slow static stretching, has been shown to reduce maximum strength, rate of force development, power, and explosive performance.[96] This appears to be true regardless of the type of stretch (static or CR).[97] A bout of three 45-second stretches with 15-second rest periods to the hamstrings, quadriceps, and plantar flexors resulted in a decrease in balance scores, and in reaction and movement time.[98] Stretches held for as little as 15 seconds still produced declines in muscle performance immediately following stretching.[99] Passive static and ballistic stretching prior to resistance training decreased the subsequent maximum repetition performance, suggesting impairments at the isolated muscle level.[62] Muscle groups involved in performing a functional countermovement vertical jump (i.e., hamstrings, gluteals, trunk extensors, quadriceps, and hip flexors) have been found to have decreased muscle performance immediately following static stretching.[95] A general warm-up plus static stretching resulted in significantly lower gains in vertical jump height compared with a warm-up alone or a warm-up plus dynamic stretching.[57] The static stretching appeared to negate the positive effects of the warm-up. The magnitude of inhibitory effects following an acute bout of stretching seems to be affected by stretching duration. A study of isokinetic strength following a 30- or 60-second bout of quadriceps stretching found that peak torque decrements were greater with the 60-second stretch compared with the 30-second stretch.[95] This finding is consistent with work showing that 60-second (8 minutes total) stretch of the calf, hamstring, gluteus maximum, and quadriceps muscles impaired a countermovement jump performance while the short-duration (30 second; 4 minutes) static stretch had minimal effects.[100] In general, if the individual is participating in a sport that requires explosive power, a dynamic warm-up is preferable to static stretching to sufficiently warm the tissue without compromising explosive power[101–103] (see **Patient-Related Instruction 7-1**).

Stretching and Joint Contractures

Joint contractures can occur following prolonged immobilization or surgery.[104] A joint contracture is an adaptive shortening of the connective tissue crossing and/or surrounding a joint that limits the ROM about that joint. The shortened tissues may be primarily the muscle–tendon unit or joint capsule.[104] However, following loss of joint ROM because of the primary soft tissue, other tissues secondarily shorten, lengthen, or are otherwise negatively affected. Depending upon the patient's history and the time interval between injury and physical therapy evaluation, it may be difficult to determine which tissue(s) are primarily at fault and which have secondarily adapted.

For those with joint contractures following prolonged immobilization, simple return to activity is insufficient in restoring joint ROM.[104] Stretching to the soft tissues and joint mobilization to the joint capsule are often employed to restore ROM.[105] Basic science research has shown that the tensile force produced by stretching, particularly long duration stretching, results in fibroblast proliferation.[106,107] Low-torque, long-duration stretching produced better outcomes than short-duration, high-torque activities.[108] This type of stretching can be applied manually but can prove tiring when applied by a therapist or a family member. Other tools or devices can be utilized to provide this stretch. For some, just the weight of the limb is sufficient to provide this stretch. For example, a prone hang with or without an ankle weight will provide a prolonged stretch for someone with a knee flexion contracture (**Fig. 7-23**). A similar stretch can be performed in long sitting with distal traction provided by a weight stack or resistive band. This can be combined with weights on the top of the knee to provide additional force into extension (**Fig. 7-24**).

External devices are also useful for providing prolonged stretch.[109] A drop-out cast can be used to increase knee extension ROM. A study of four patients with knee flexion contractures found that this intervention can increase knee extension ROM without compromising knee flexion ROM.[110] Serial casting can be used to provide a low load long duration stretch. The limb is casted in a position that provides a slight stretch to the

Patient-Related Instruction 7-1: Key Points About Stretching

Stretching to Improve Flexibility	Stretching Prior to Performance
1. Discuss the appropriate stretching technique and dosage with your physical therapist or health care provider 2. Stretching 3 to 5 days per week for 4 weeks or more should produce measurable gains in flexibility 3. Thereafter flexibility can be maintained with stretching at least two times per week 4. Precede stretching with a general warm-up to increase muscle temperature and local blood flow 5. Stretch only to the point of a medium stretching sensation	1. Discuss the appropriate stretching technique and dosage with your physical therapist or health care provider 2. The type of stretching recommended will vary with any injury or pathology and the type of activity you are performing 3. Stretching prior to explosive, jumping, or high-speed activities should be dynamic; any static stretching prior to this type of activity should be of short duration (<30 seconds) 4. Utilize static stretching for postactivity cool down

FIGURE 7-23 Prone hang to increase knee extension ROM.

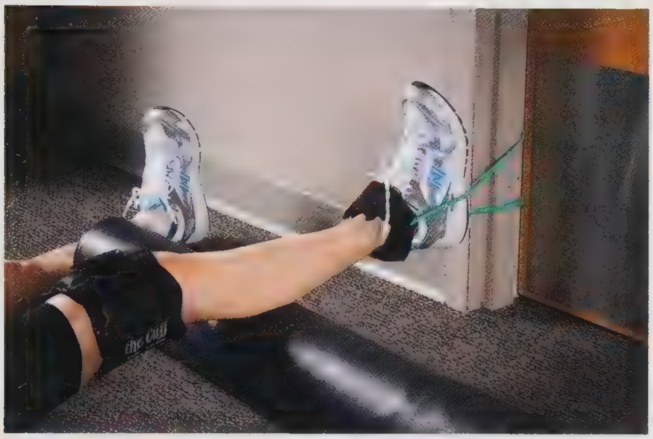

FIGURE 7-24 Prolonged passive knee extension with distal traction.

tissue. Once the tissue has accommodated to the new length, the cast is removed and a new cast applied, again, moving the limb into further stretch. Serial casting has the disadvantages associated with continuous immobilization. Significant atrophy and joint deterioration can occur from decreased loads on the tissues during immobilization. Because the immobilization is continuous, there is no opportunity for using the new range as it is acquired. Additionally, there is no opportunity to view the limb during immobilization. Atrophy, skin breakdown, or other complications can arise without the patient or clinician's ability to visualize the problem. Any suspected problem requires cast removal. Casting is also contraindicated in many patients because of such potential problems. Patients with diabetes, skin breakdown, hyperhidrosis, vascular disease, or sensory impairments are not candidates for serial casting.

Commercial dynamic splinting systems such as Dynasplint (Severna Park, MD) are available to provide low load long duration stretching (**Fig. 7-25A** and **B**). These systems can be rented or purchased for home use by the patient. A variety of commercial systems exist (i.e., Dynasplint, Ultraflex, LMB Pro-glide, EMPI Advance, and SaeboFlex), and each has its own design and specifications. Most provide a three- or four-point tension to distribute loads across a larger surface area, decreasing the high-stress region. Most importantly, these systems are designed to be used for only 6 to 8 hours per day.

A B

FIGURE 7-25 **(A)** Dynasplint used to increase upper extremity mobility. **(B)** Dynasplint used to increase lower extremity mobility.

This allows visualization of the limb both during and following the stretching session. It also allows use of the limb between stretching sessions, negating many of the problems associated with prolonged immobilization.

These commercial systems are available for many different joints including the shoulder, elbow, forearm, wrist and hand, jaw, as well as the knee, ankle, and foot.[111] The splints are applied by a therapist, and the patient or family member can learn how to don and doff the splint. The initial tension is set by the therapist and the patient is instructed in appropriate progression. Some splints, like the Dynasplint, have a preset load that remains constant during the stretching session. The tension should be at a low level that can be maintained for 6 to 8 hours without pain. Other splints, like the Joint Active System, allow the patient to set the tension at the beginning of the stretching session. The stretch is increased every few minutes throughout the 30-minute session. The sessions are repeated throughout the day. The commercial systems are typically available for either rental or purchase. These systems are an adjunctive treatment to therapeutic exercise and have shown good results for improving joint ROM.[112,113]

JOINT MOBILIZATION TO INCREASE MOBILITY

Manual therapy techniques such as joint mobilization are used to improve the mobility of joints. The *Guide to Physical Therapist Practice*[114] defines mobilization/manipulation as a "continuum of skilled passive movements to the joints and/or related soft tissues that are applied at varying speeds and amplitudes, including small-amplitude/high velocity therapeutic movement." Manipulation is a type of mobilization that is generally performed at a high velocity through a small amplitude. Various models of manual therapy exist, each with its own definitions and classification of mobilization/manipulation. For example, Maitland[115] describes five levels of mobilization, whereas Kaltenborn[116] specifies only three (**Fig. 7-26**). Regardless of the classification system, these schools of thought all focus on increasing joint mobility by increasing the joint play, or motion between the joint surfaces. Use of mobilization/manipulation techniques requires an understanding of the normal joint architecture, arthrokinematics, and the specific pathology to determine which interventions are appropriate (**Evidence and Research 7-6**).

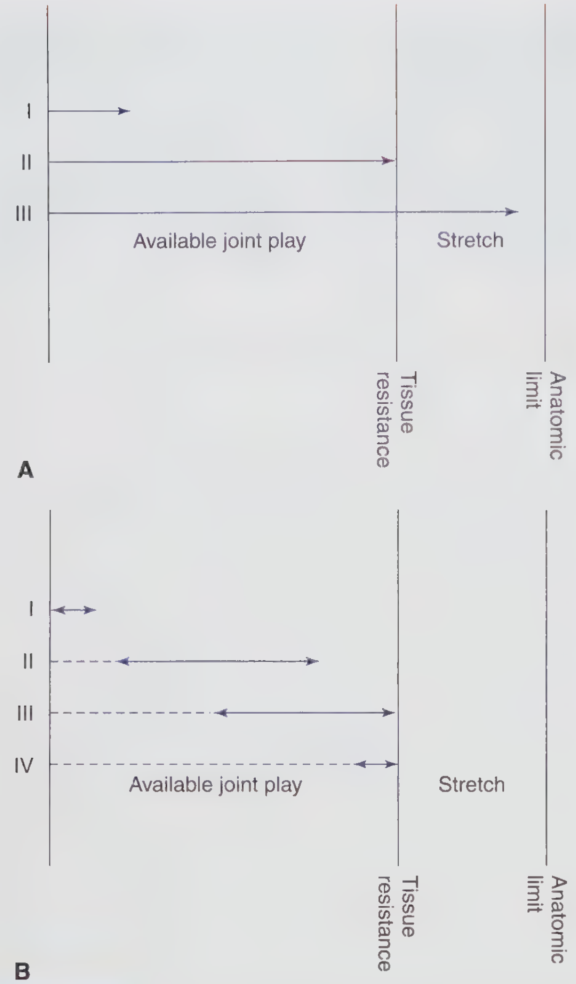

FIGURE 7-26 **(A)** Kaltenborn grades of mobilization. **(B)** Maitland grades of mobilization.

EVIDENCE and RESEARCH 7-6

Researchers have examined the ability of joint mobilization techniques to increase joint ROM.[117,118] Hsu et al.[117] examined the effects of anterior and posterior translational mobilization performed in the resting (loose packed) position and at end-range abduction on shoulder rotation and abduction ROM in cadaver specimens. Both anterior and posterior glides at end range increased abduction ROM, whereas these same glides performed in the resting position were less effective. Small increases in lateral rotation were found after anterior glides in the resting position and in medial rotation after posterior glides at end range.

Roubal et al.[118] found that inferior and posterior mobilizations after a brachial plexus block in patients with adhesive capsulitis increased motion in flexion, abduction, internal rotation, and external rotation. Range increased in all four directions despite no anterior mobilization treatment, suggesting that mobility was limited more by capsular tension than joint geometry. In a series of case studies, Vermeulen et al.[119] found increased ROM in all directions, increased joint capsule volume, and increased function in a group of patients with adhesive capsulitis treated with end-range joint mobilization.

Biomechanics of Joint Mobilization

Movement occurs at a joint when one joint surface moves on another relatively fixed joint surface. Roll, spin, and glide (also called slide) are the major categories of arthrokinematic motion found in human joints.

- Roll occurs when new points on one joint surface meet new points on the opposing joint surface.
- Spin is a pure rotational movement in which rotation occurs about a fixed axis. Motion of the radial head during pronation and supination is an example of spinning.
- Gliding or sliding occurs when one point on a moving surface continually comes in contact with new points on the opposing surface. Gliding is the predominant motion used in joint mobilization techniques.

In addition to roll, spin, and glide, compression and distraction of the joint can occur. Compression techniques are often used to facilitate muscular cocontraction and joint stabilization, whereas distraction is used in conjunction with joint mobilization to increase joint mobility or decrease pain. In most arthrokinematic motion, a combination of these movements occurs.

Some joint play must exist for arthrokinematic motion to proceed normally as the limb moves through the ROM (osteokinematic motion). The type and direction of arthrokinematic motion is determined in part by the relative shape of the joint surfaces. Most joint surfaces are classified as either ovoid or sellar. In an ovoid joint, one joint surface is concave, whereas the other is convex. For example, at the glenohumeral joint, the glenoid fossa is concave, whereas the humeral head is convex. In a sellar joint, both surfaces are both concave and convex. The carpometacarpal joint of the thumb is an example of such a joint. The convex–concave rule dictates the direction of gliding of one joint surface on the other and forms the basis for joint mobilization techniques. When a convex surface is moving on a fixed concave surface (such as the humeral head moving on the stationary glenoid during glenohumeraql abduction) the movement of the convex bone is in the direction opposite the convex articulating surface. In this case, the convex humeral head glides inferiorly as the humeral shaft moves superiorly. The opposite is true when a concave surface moves on a stationary convex surface. For example, movement of the concave tibial joint surface on the stationary concave femoral condyles is in the same direction as the tibial movement. Thus the tibial joint surface will move posteriorly as the tibia moves into flexion.

However, the human body does not always follow our rules, and the convex–concave rule is one of these. Following this rule at the shoulder would suggest that an anterior glide is used to increase mobility in external rotation, horizontal abduction, and extension, whereas a posterior glide is used to increase motion into internal rotation, horizontal adduction, and flexion. A study by Howell et al.[120] found that when the arm was placed in a maximally cocked position (abduction, extension, and lateral rotation) the humeral head was actually resting approximately 4 mm posteriorly. Additionally, Harryman et al.[121] found anterior humeral head translation with glenohumeral flexion and horizontal adduction and posterior translation with extension and lateral rotation. These apparent violations of the convex–concave rule may be the result of joint capsule tightening during rotation that is unique to the glenohumeral joint. Thus applying a single rule to all joints may mislead the clinician.

The primary indication for joint mobilization is a joint restriction resulting in a limitation in AROM and PROM at the joint. This is especially true in the case of a capsular end feel and loss of ROM in a capsular pattern. Remember that a number of structures can limit ROM at a joint; joint mobilization is most effective when the tissue limiting ROM is the joint capsule. This is generally assessed via joint play.

Joint mobilization is contraindicated in the case of joint infection, neoplasm, acute inflammation, or recent fracture. Caution must be used in cases of connective tissue disease, osteoporosis, hypermobility, or edema.

Mobilization Grades

Manual therapists use different mobilization grades depending upon their background and training. The two most commonly used grading systems are those developed by Kaltenborn and Maitland.[115,116] They are distinguished by the number of grades and the criteria for each grade. Kaltenborn[116] defines three grades of mobilization by the amount of force applied, whereas Maitland[115] describes his grades by the amplitude and position in the range. Kaltenborn techniques are a sustained translation, whereas Maitland's are an oscillation. Kaltenborn[116] grades are:

- Grade I: A low-level distraction force
- Grade II: A greater force that takes up the available joint play
- Grade III: A force that stretches the joint tissue after the available joint play has been taken up.

Maitland[115] grades are as follows:

- Grade 1: Small amplitude rhythmic movements near the beginning of the ROM
- Grade 2: Large amplitude rhythmic oscillations performed within the available range, but not reaching the limit
- Grade 3: Large amplitude rhythmic oscillations performed to the limit of the range and into the tissue resistance
- Grade 4: Small amplitude rhythmic movements performed at the limit of the range and into the tissue resistance
- Grade 5: Small amplitude, high-velocity thrust techniques performed at the end of the ROM for the purpose of breaking adhesions

Maitland[115] emphasizes not only the amplitude of the oscillations, but also the rhythm and amount of pressure. He suggests that grade I oscillations for pain must be extremely gentle using a very light touch. These oscillations stimulate joint receptors and decrease the perception of pain by the central nervous system. The rhythm of oscillations can be varied from quick staccato movements into a stiff range, to smooth, rhythmic oscillations into and out of the painful or stiff region. When using grade II oscillations, the greater the pain, the slower and smoother should be the oscillations. Note that Maitland grades I and II joint mobilizations do not stretch the capsule to the barrier; as such, they most likely do not increase mobility at the joint, but rather, are effected in controlling pain via the gate theory.

Joint traction or distraction is used to relieve the compression of painful joint surfaces and is used along with most mobilization techniques to separate joint surfaces during the mobilization procedure.

General Procedures

Be sure your patient is relaxed and positioned comfortably on the treatment table. Muscle guarding resulting from discomfort or apprehension will interfere with the treatment and place undue stress on both the patient and the therapist. Position yourself to optimize body mechanics, making use of body weight and leverage to minimize your energy expenditure. Use external devices such as the table, positioning, belts, and wedges to stabilize the patient and minimize therapist efforts. Be sure your grip is firm, using as large and wide a portion of your hand as possible. This will minimize painful pinching or a painful localized force application. Grasp as close to the joint line as possible with both the mobilizing and the stabilizing hand. Provide gentle traction to the joint while performing mobilizations. Understand the joint anatomy and arthrokinematics to minimize chances of painful joint compression forces. Oscillations are performed at a rate of 2 to 3 per second for approximately 1 minute. Reevaluate the joint and repeat, or choose another grade or direction as necessary.

Most joint mobilizations are initiated in the loose packed position of the joint. As stated earlier, this is the position where the joint capsule has its greatest capacity. The loose packed positions of most joints of the body have been identified and are listed elsewhere. As each person is unique, variations in the loose packed position (sometimes called the resting position) do exist. Kaltenborn[116] suggests finding the resting position by trying gentle traction in a variety of positions. This position with the most movement is the resting position. Kaltenborn suggests commencing mobilization in this position. If the purpose of the mobilization is to stretch the tissue, then perform the mobilization nearer the limit of mobility, closer to the barrier. Performing the mobilization closer to the end range has proven more effective in increasing motion than performing mobilizations in mid-range.

Applications to Specific Joints

Selected mobilization techniques for the spine and extremities will be described. Realize that this is only an overview of techniques and is not comprehensive. Additionally, many modifications are available, and the specific positioning will vary with available resources and patient and therapist preferences. The descriptions can be found in **Displays 7-2** to **7-8** and **Figures 7-27** to **7-44**.

NEURAL MOBILITY

Pain perceived in various regions of the upper quarter (neck, upper back, chest, shoulder, and arm) or the lower quarter (low back, buttocks, hips, and legs) can be the result of pathology in the spine and associated tissues, or from local structures. Neural tissues can be the source of pain, and vigorous stretching can exacerbate pain arising from these tissues.[122,123] A hallmark of neural tissue involvement in a pain syndrome is the response to provocation tests. Provocation tests are those examination procedures that selectively stress different neural tissues with functional positions.[122] These positions tension the neural tissues, and the area of tension or pathology can be identified by the results of these testing positions. For example, adding ankle

DISPLAY 7-2

Shoulder Joint Mobilization

Glenohumeral Anterior Glide

Purpose: To increase shoulder external rotation and extension
Position: Patient is prone with shoulder at edge of table and abducted to 90 degrees in scaption, elbow flexed to 90 degrees; mobilizing hand on posterior humeral head while stabilizing hand holds mid-humerus. Forearm on the patient can rest on a rolling stool for comfort and to encourage the patient to relax
Mobilization: Anterior force applied by mobilizing hand to humeral head while stabilizing hand applies gentle traction. The direction of mobilization is parallel to the plane of the joint; in this case the mobilization is from posterior and lateral to anterior and medial.
Glenohumeral Posterior Glide
Purpose: To increase shoulder flexion and internal rotation
Position: Patient is supine with the shoulder at the edge of the table, scapula stabilized by the table or towel roll; abducted to 45 degrees and elbow slightly flexed; mobilizing hand on anterior humeral head and stabilizing hand supporting elbow
Mobilization: Posterior force applied by mobilizing hand to humeral head while stabilizing hand applies gentle traction. The force is parallel to the plane of the joint

Glenohumeral Inferior Glide

Purpose: To increase shoulder abduction and flexion
Position: Patient is supine with the arm in 30- to 45-degree abduction; stabilizing hand supports scapula in axilla while mobilizing hand grasps distal humerus
Mobilization: Inferior force applied by mobilizing hand while stabilizing hand holds scapula steady, if necessary
Acromioclavicular Joint Anterior Glide
Purpose: To increase joint mobility
Position: Patient is positioned sitting; stabilize the scapula with thumb along the scapular spine and fingers along acromion; mobilizing hand placed on posterior clavicle near joint line
Mobilization: Mobilizing hand imposes an anterior force on the clavicle

Sternoclavicular Joint Superior/Inferior and Anterior/Posterior Glides

Purpose: Superior glide increases depression, whereas inferior glide increases elevation; anterior glide increases protraction, whereas posterior glide increases retraction
Position: Patient is supine with the stabilizing hand on the sternum and the mobilizing thumb or thumb and index finger on the proximal clavicle; alternatively both thumbs can be stacked one of top of each other on the proximal clavicle
Mobilization: Superior glide—the index finger applies a superior force to clavicle; inferior glide—thumb applies an inferior force to clavicle; anterior glide—thumb and index finger lift the clavicle; posterior glide—thumb applies a posterior force to clavicle

Scapular Mobilization

Purpose: To increase mobility at the scapulothoracic articulation
Position: Patient is in prone or side-lying; superior hand is along scapular spine while inferior hand grasps inferior angle of the scapula
Mobilization: Mobilize the scapula in elevation, depression, adduction, abduction, or rotation by pushing the appropriate direction

DISPLAY 7-3

Elbow Joint Mobilization

Elbow Humeroulnar Distraction

Purpose: To increase elbow joint mobility in flexion or extension
Position: Patient is supine with the elbow flexed to approximately 70 degrees, wrist resting on the therapist's shoulder; both hands grasp proximal ulna, humerus is strapped to the table OR one hand on humerus and one hand on ulna.
Mobilization: A distal force applied against the proximal ulna

Elbow Humeroradial Anterior or Posterior Glide

Purpose: Anterior glide to increase flexion, posterior glide to increase extension
Position: Supine with the elbow extended and supinated as far as possible; stabilizing hand grasping the medial distal humerus; proximal palm of stabilizing hand on anterior radial head with fingers on the posterior aspect
Mobilization: A posterior glide force provided by the palmar aspect of the hand, or an anterior force provided by the fingers

Elbow Radioulnar Anterior and Posterior Glide

Purpose: Anterior glide to increase supination, posterior glide to increase pronation
Position: Patient sitting or supine with the elbow extended and supinated as far as possible for posterior glide or extended and pronated as far as possible for anterior glide; stabilizing hand grasps proximal ulna with thenar eminence on anterior aspect and fingers on posterior aspect; mobilizing hand is in same position over the proximal radius
Mobilization: Posterior force on radial head for posterior glide; anterior force on radial head for anterior glide, both while stabilizing hand holds ulna steady

DISPLAY 7-4
Wrist and Hand Mobilization

Interphalangeal or Metacarpal Palmar and Dorsal Glide

Purpose: Palmar glide to increase flexion, dorsal glide to increase extension
Position: Patient's palm faces down with joint in resting position; stabilizing hand holds proximal bony segment while mobilizing hand grasps distal bony segment
Mobilization: With mobilizing hand, move distal segment toward the palm to increase flexion or toward dorsum to increase extension while applying gentle traction

Thumb Metacarpal–Carpal Radial and Ulnar Glides

Purpose: Ulnar glide to increase flexion; radial glide to increase extension
Position: Patient's hand is positioned with the ulnar side down, joint in a resting position; stabilizing hand grasps distal forearm with grip around trapezium while mobilizing hand grasps first metacarpal
Mobilization: With mobilizing hand, glide metacarpal toward radius to increase extension, or toward ulna to increase flexion while applying gentle traction

Thumb Metacarpal–Carpal Dorsal and Palmar Glides

Purpose: Palmar glide to increase adduction; dorsal glide to increase abduction
Position: Patient's hand is positioned with the palm either up or down, joint in a resting position; stabilizing hand grasps distal forearm with grip around trapezium while mobilizing hand grasps first metacarpal
Mobilization: With mobilizing hand, glide metacarpal toward palm to increase adduction, or toward dorsum to increase abduction while applying gentle traction

Wrist Palmar and Dorsal Glides

Purpose: Palmar glide to increase extension, dorsal glide to increase flexion
Position: Patient's forearm rests on table or wedge with the carpal joint at the edge; forearm is pronated for palmar glide and supinated for dorsal glide; stabilizing hand steadies the distal forearm against the table or wedge; mobilizing hand grasps the distal wrist
Mobilization: Apply a downward force with mobilizing hand while applying gentle traction

DISPLAY 7-5
Hip Joint Mobilization

Hip Distraction/Distal Traction

Purpose: Pain relief and general mobility
Position: Patient is supine or prone on the table, with the pelvis stabilized with a belt; therapist grasps either the distal thigh or the distal calf, depending upon whether or not you want distraction through the knee joint; a belt can be used around your waist and hands to reinforce the grip and allow use of body weight
Mobilization: A distal traction force is applied to the leg by shifting your body weight backward

Hip Lateral Traction

Purpose: Pain relief and general hypomobility
Position: Patient is supine with pelvis stabilized with a belt; the hip may be in any degree of flexion to extension depending upon the direction of hypomobility; mobilizing belt is placed around your pelvis and the patient's proximal thigh
Mobilization: Lean backward to apply a lateral traction force to the hip

Hip Anterior Glide

Purpose: Increase extension and external rotation
Position: Patient is prone with knee flexed to 90 degrees and a firm wedge or towel roll placed under the anterior pelvis; mobilizing hand just distal to posterior hip, and stabilizing hand grasps ankle to stabilize leg
Mobilization: Anteriorly directed force through mobilizing hand via forward weight shift

Hip Posterior Glide

Purpose: Increase flexion and internal rotation
Position: Supine with hip near full flexion, knee flexed, pelvis stabilized on table or with additional wedges or support; mobilizing hands on patient's knee
Mobilization: A posteriorly directed force through the long axis of the femur

DISPLAY 7-6

Knee Joint Mobilization

Tibiofemoral Anterior Glide

Purpose: Increase extension
Position: Patient is prone with the knee at the edge of the table; mobilizing hand is just distal to knee joint and stabilizing hand supports anterior ankle
Mobilization: Anteriorly directed force downward through mobilizing hand while stabilizing hand applies gentle distal traction

Tibiofemoral Posterior Glide

Purpose: Increase flexion
Position: Patient is supine or sitting with the knee at the edge of the table; mobilizing hand is just distal to the knee joint and stabilizing hand supports posterior ankle
Mobilization: A posteriorly directed force through mobilizing hand while the stabilizing hand applies gentle distal traction

Patellofemoral Joint Mobilization

Purpose: Increased general patellar mobility; and superior glide for increased extension, inferior glide for increased flexion
Position: Supine with knee supported by table, wedge, or towel roll; mobilizing thumb and index finger placed along patellar border oriented to direction of mobilization
Mobilization: Apply a medially, laterally, superiorly, or inferiorly directed force to the patella

DISPLAY 7-7

Foot and Ankle Mobilization

Ankle Anterior Glide

Purpose: Increase plantarflexion
Position: Prone with foot hanging just over the edge of the table; stabilizing hand under the anterior distal tibiofibular joint; mobilizing hand on the posterior calcaneus, just distal to joint line
Mobilization: Apply a downward, anteriorly directed force to the calcaneus while applying gentle traction

Ankle Posterior Glide

Purpose: Increase dorsiflexion
Position: Supine with foot just over the edge of the table; stabilizing hand under the posterior distal tibiofibular joint; mobilizing hand grasps anterior ankle just distal to joint line
Mobilization: Apply a downward, posteriorly directed force to the ankle while applying gentle traction

Ankle Traction

Purpose: Pain relief and general mobility
Position: Supine with leg stabilized by a strap and foot just over the edge of the table; both hands grasp the foot, one posterior on the calcaneus and the other anteriorly over the midfoot
Mobilization: Lean backward to produce a distal traction to the talocrural joint

Metatarsal and Phalanges Glide

Purpose: Increase mobility of toes
Position: Supine with foot over the edge of the table; stabilizing hand grasps metatarsal while mobilizing hand grasps phalanges
Mobilization: Apply dorsal and ventral mobilizations while applying gentle traction

DISPLAY 7-8

Spine Mobilization

Cervical and Thoracic Spine Posterior to Anterior Glide

Purpose: Increase segmental mobility and pain relief
Position: Patient is prone with towel under forehead or on mobilization table; therapist's thumbs placed one on top of the other, directly over the spinous process to be treated; spread hands over the adjacent neck or back area, keeping shoulders directly above treatment area
Mobilization: Apply a direct posterior to anterior force to the spinous process; this technique can also be performed with thumbs on the transverse processes unilaterally or bilaterally

Cervical and Thoracic Spine Lateral Glide

Purpose: Increase general mobility and unilateral pain relief
Position: Patient is prone; therapist's thumbs placed one on top of the other, directly over the lateral side (right or left) of the transverse. Process to be treated; spread hands over the adjacent neck or back area
Mobilization: Apply gentle pressure to lateral border of transverse process

Lumbar Spine Posterior to Anterior Glide

Purpose: Increase segmental mobility and pain relief
Position: Patient is prone; therapist's ulnar border of the hand over the spinous process to be treated; the other hand reinforces the mobilizing hand by resting on top of it and grasping the radial border of the wrist with the fingers; keep your shoulders directly over your hands; this technique can be modified to provide unilateral pressure to the transverse process using your thumbs adjacent to one another
Mobilization: A gentle rocking motion provides an anteriorly directed force over the spinous process

Lumbar Lateral Glide

Purpose: Increase segmental mobility and pain relief
Position: Patient is prone with the therapist's thumbs (one on top of the other) on the lateral side of the transverse process to be mobilized
Mobilization: Apply a horizontal pressure to the lateral border of the transverse process

dorsiflexion to a straight leg raise (SLR) maneuver increases the tension in the nervous system up to the cerebellum.[123] Adding hip movements to the SLR can help differentiate ankle symptoms arising from the neural structures versus local ankle structures.[124] In the upper extremity, components of shoulder abduction and lateral rotation, wrist and finger extension, forearm supination, elbow extension, and cervical lateral flexion can be used to determine involvement of median nerve structures.[124]

Mobilization of neural tissues is one part of an overall management strategy for patients with pain arising from these tissues. Mobilization can be passive, active, or some combination of both. Passive mobilization is rarely a treatment provided in isolation, but is generally combined with active movements, exercise, lifestyle modification, and education.[125] When performing direct nerve mobilization, Butler[124] recommends starting the movements farther from the presumed site of pathology, and beginning with the rest of the body "unloaded" where there is less tension throughout the connective tissue system. If the patient has a number of positive tension tests, consider starting with the least provocative of these positions and examine the response to treatment before moving to the more acute or sensitive positions. With a successful response to the passive mobilization, the intervention can be progressed by:

- Adding active movements
- Adding more components
- Increasing the repetitions
- Increasing the intensity of the technique
- Moving techniques closer toward the presumed site of pathology

For example, when tensioning an SLR, the patient can flex the cervical spine at the same time as dorsiflexing the ankle, thereby providing tension both from the proximal and distal ends.

Specific mobilization techniques have been described for problems in the extremities and trunk.[123,124] Mobilization begins with determining the starting position based upon examination results. Once a successful clinical program has been established, home exercises are incorporated to replicate the techniques used in the clinic (**Fig. 7-45A** and **B**). Further information on specific techniques can be found in Butler.[123,124]

Active movements following passive mobilizations should be functional. For example, when mobilizing the tissues associated

A

B

FIGURE 7-45 **(A)** Upper limb tension test 3 position. **(B)** Slump sit with ankle dorsiflexion.

with the median nerve, movements that place the wrist in extension with elbow extension are useful. A wall push-up, a chest pass with a ball, or reaching overhead with the wrist extended are all examples of active movements that replicate the passive mobilization techniques. Once active movements are initiated and tolerated, progress the patient through AROM to resistive ROM following previously described guidelines.

A number of precautions and contraindications should be considered when examining and treating patients with mobilization directed at neural structures. These can be found in **Table 7-5**.

SELF-MOBILIZATION

Mobilization techniques performed only in the clinic may be of insufficient frequency to produce a significant change. Therefore, adding self-mobilization to therapist-provided interventions may provide a therapeutic dosage resulting in significant improvements. Mobilizations can be in the form of joint mobilizations performed with the use of assistive objects, or they can be soft-tissue mobilizations or neural mobilizations designed to lengthen or relax associated soft tissues (**Fig. 7-46**).

Spine self-mobilization can be performed with the support of a chair or other rigid device that stabilizes the spine at a specific

TABLE 7-5

Precautions and Contraindications to Mobilizing Neural Tissues

PRECAUTIONS	CONTRAINDICATIONS
Potential of injury to other structures loaded during testing or treatment	Recent onset of or worsening neurological symptoms; acute, unstable symptoms
Tissue irritability	Cauda equina lesions
Worsening symptoms, especially if a rapid worsening	Injury to the spinal cord
Unstable neurological signs or signs indicative of active disease process	
General health problems, especially those that involve connective or neural tissue	
Dizziness or circulatory problems	
Frank spinal cord injury with a minor secondary cord problem potentially amenable to treatment

FIGURE 7-46 Neural flossing using a lateral hip stretch position with hip internal rotation.

level. The patient can then extend or extend and rotate over the fixed chair (**Fig. 7-47**). This is most effectively done for the thoracic or lumbar spine. Alternatively, spine self-mobilization can be done using foam rollers or similar equipment. Foam rollers can be used in a variety of ways to provide mobilization. Half-foam rollers can be placed flat side down with the patient lying on the curved part to mobilize the spine. Place a hypomobile segment at the end of the roll and relax the body over the edge to mobilize the segment (**Fig. 7-48**). The full foam roll can be used to mobilize soft tissue by rolling the stiff or shortened area over the roll (**Fig. 7-49**). Alternately, if a full foam roller is not available, in some situations, a 2-L bottle of water placed in the freezer and frozen can be substituted. Tennis balls taped together work well to mobilize soft tissues adjacent to the spine. Place the balls on either side of the spine while leaning against a wall. Slide up and down the wall to provide pressure and mobilization (**Fig. 7-50**).

Body rolling using a 6- to 10-in diameter hollow ball provides additional opportunities for home programs utilizing mobilization techniques (**Fig. 7-51**).[125] Techniques to mobilize,

stretch, and lengthen hypomobile tissues throughout the body are available for patients who have good general mobility. Many of these techniques require the ability to get up and down off the floor, to position the body, and to move over the ball. This is not possible for some individuals with multiple joint involvement. However, for those who are mobile enough to utilize these techniques, self-mobilization with these assistive devices can be useful.

MOBILITY EXERCISE DOSAGE

The stage of healing (see Chapter 11) and the tissue response to loading relative to the patient's examination findings determine the dosage of mobility exercises. Each patient should be considered on an individual basis, with the dosage matched to the patient's needs. These needs extend beyond the physical impairments to include psychosocial and lifestyle issues.

Sequence

Mobility activities can be performed as part of warm-up exercises before aerobic or strengthening activities or as independent rehabilitative exercises. Use PROM or AAROM to teach AROM exercises, and use AROM as a teaching tool for resistive exercise. The sequence of exercise depends on the purpose of the ROM activity. ROM exercise as preparation for more difficult exercise should occur before that activity. When mobility exercises are being performed for the benefit of ROM increases, they should be performed in a sequence of easier to more difficult.

Most exercises performed passively can also be performed actively or with active assistance. This makes an easy progressive sequence for the patient to follow. For example, a single knee flexion exercise can be easily progressed by changing instructions. Progress knee flexion with a towel to active assisted by using some muscle activity and some passive assistance from the towel (**Fig. 7-52A** and **B**). As the patient improves, the same exercise can be performed without assistance. The same is true for shoulder flexion exercises with a pulley or counter; the exercise can be performed with some level of assistance or completely actively.

The concept of active stretching is important when sequencing mobility activities. **Active stretching** is the use of active movement to stretch the antagonist or to use the agonist in its new range. Stretching a short muscle should always be complemented with active stretching by strengthening the opposing muscle in the shortened range. Based on scientific studies of length–tension properties of skeletal muscle, it is hypothesized that a stiff or short soft tissue structure cannot remain lengthened until opposing soft tissue structures shorten.[126] The opposing muscle must be strengthened because its length–tension properties have been disrupted because the short muscle is in need of stretch. It cannot generate sufficient tension in the short range to oppose the pull of the short muscle. By strengthening the lengthened muscle, particularly in the short range, its length–tension properties can improve, and it can provide a counterbalancing force to the short muscle. Therefore, stretching a shortened muscle without strengthening the lengthened muscle (preferably in a shortened range) may render stretching ineffective. Stretching a short muscle can be done passively through a self-stretch or manual stretch, but it should always be accompanied with active stretching through strengthening the opposing muscle in the shortened range (**Building Block 7-5**).

BUILDING BLOCK 7-5

A 48-year-old woman with rounded shoulders and kyphotic posture complains of neck and mid-back pain after 2 hours at her computer workstation. Describe a sequence of mobility and active contraction exercises she might use to address these postural impairments.

FIGURE 7-52 **(A)** AAROM using a towel followed by **(B)** AROM at the knee using muscle activation to slide the towel.

Active contraction of the antagonist in a shortened position is used to strengthen this muscle while simultaneously actively stretching the agonist. For example, after static stretching of the hamstrings, the patient can extend the knee in a sitting position while the paraspinal muscles stabilize the spine to prevent lumbar flexion. The quadriceps actively stretches the hamstrings into the new range. This repeated activity enhances mobility in the new range. This same sequence concept can be applied throughout the body, as in the treatment of low back and pelvic muscle imbalance. After static stretching of short hip flexor muscles, the patient should extend the hip in a walk stance position while the abdominal muscles stabilize the spine and pelvis (see **Self-Management 7-6**).

Frequency, Intensity, and Duration

As with resistive exercise, stretching dosage can be considered in terms of frequency, intensity, and duration. Frequency is how often the stretch is performed, while duration is how long the stretch is held, and intensity is how far into the end of the ROM the stretch is applied. ROM activities, because of their purpose and goals, are generally a lower intensity exercise performed for a shorter duration. These exercises can be performed more frequently and usually take place in the home or work environment. Choose exercises that can easily and effectively be performed independently by the patient or with the assistance of a family member.

The exercise frequency is related to the purpose of the exercise, which can be considered relative to physiologic, kinesiologic, or learning factors.

- Physiologic purposes are those that enhance fluid dynamics, support articular cartilage nutrition, and maintain the integrity of the periarticular connective tissues.
- Kinesiologic purposes include establishing normal arthrokinematic motion and are closely tied to learning factors or choosing the correct motor program.

Learning purposes include exercises to teach postural set, appropriate sequencing, and patterning of muscle contraction or to teach a complex motor skill. Exercises performed for physiologic or kinesiologic purposes are performed two to five or more times each day. The number of times depends on the environment and availability of exercise within that environment. If it is nearly impossible for an individual to perform exercises during the workday, asking him or her to carry out an exercise program five times each day is unreasonable. Similarly, if the ROM activities require the assistance of another, availability of that help dictates the frequency of the exercise program. As discussed in Chapter 3, an exercise prescription should fit within the context of the individual's day.

SELF-MANAGEMENT 7-6
Active Stretch for the Hip Flexor Muscles

Purpose: To stretch and use hip flexor muscles in the new range. This activity should follow hip-stretching exercises.

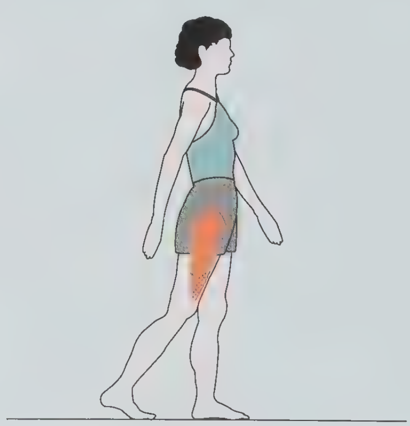
Position: In a stride position, with the leg to be stretched behind and with the opposite foot forward as in taking a step. Be sure to keep the back straight and abdominal muscles tightened.

Movement Technique: Shift your weight forward onto your front foot while maintaining proper hip and back position. Hold 30 to 60 seconds. Be sure that the hip of your back leg is being stretched as shown by the highlighted area in the illustration below.

Dosage:

Repetitions: ____________________

Frequency: ____________________



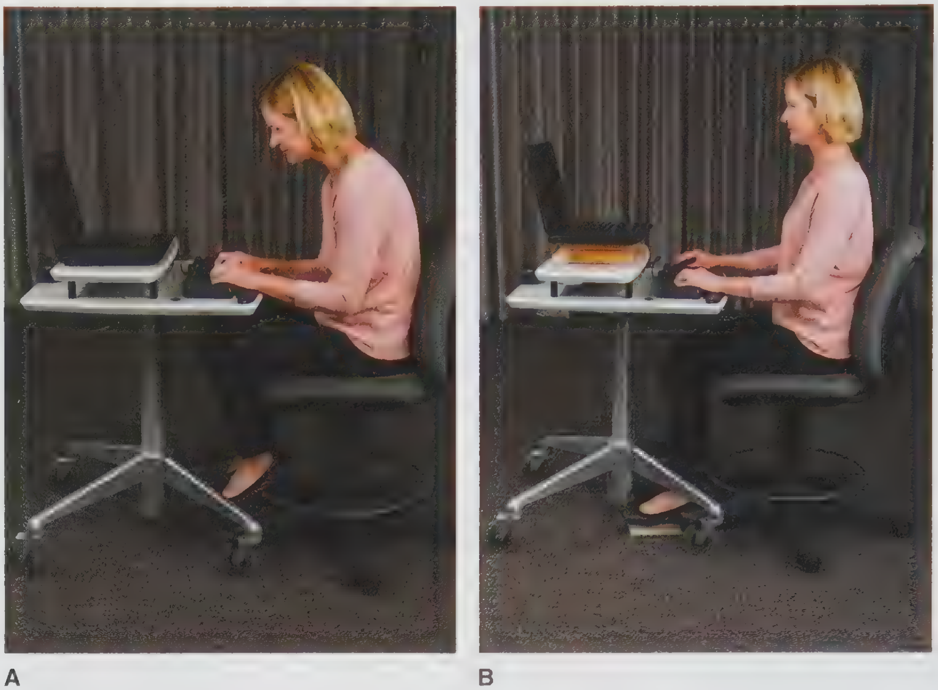


FIGURE 7-53 **(A)** Poor posture at desk can be retrained using postural retraining. **(B)** Good posture with proper pelvic posture and chin tucks.

Exercises performed as learning tools are usually performed more frequently during the day. Examples of these exercises are postural reeducation activities such as scapular retraction and depression, chin tucks while sitting at a desk, and knee extension while driving without posterior pelvic tilt or lumbar flexion (**Fig. 7-53A** and **B**). These kinds of exercises are often put "on cue" so that a specific stimulus can elicit the postural response, such as performing postural exercises every time the phone rings, every time a new page is started on a computer document, or every time an instructor poses a question. This type of programming places the exercise in the appropriate functional context, within the environment or situation where the exercise most needs to be performed. With time and repetition, individuals should find that when the stimulus elicits the response, they are already in the appropriate posture. The intensity of this type of exercise is low, and the frequency is therefore increased.

The number of sets and repetitions depends on the frequency and the number of exercises performed. When several exercises are being performed to maintain ROM during a period of bed rest or in the early healing stages of an injury, the sets and repetitions may be fewer as multiple components of the joint and periarticular connective tissues are being mobilized. Conversely, when only a few exercises can be performed because of healing constraints or other medical conditions, more sets and repetitions of those exercises can be performed. When exercises are being performed frequently throughout the day, fewer sets and repetitions are performed during each session. When active exercise is being used to increase endurance, more repetitions and longer duration rather than greater frequency is the rule. The guiding principle in ROM prescription is understanding the physiologic, kinesiologic, and learning factors associated with each exercise in relation to the patient and exercise goals.

The length of time a stretch must be held to facilitate an increase in muscle flexibility remains a point of disagreement among clinicians. The clinical literature states that stretches should be held for a minimum of 30 seconds in young individuals and 60 seconds in older individuals. There does not appear to be any advantage to holding a stretch longer than those periods.[127–129] A study of individuals aged 65 and older found that holding stretches for 60 seconds produced greater ROM gains that persisted longer than the gains for stretches held for 15 or 30 seconds.[34] A study of younger individuals found that holding stretches for 30 or 60 seconds produced greater benefits than stretches held 15 seconds, but there was no difference between the 30- and 60-second stretches.[127] Research into the viscoelastic tissue responses to stretching has shown little change after four repetitions of stretching, suggesting that only a few repetitions are necessary to produce most of the elongation.[37] Other research suggests that it is the total time per day that the stretch is performed that is significant. A study comparing 10-second stretches with 30-second stretches performed for a total of 2 minutes per day found equivalent increases in hamstring flexibility.[32] If a patient is unable to hold a stretch for 30 seconds, then a shorter duration but higher repetition dosage may be equally effective.

However, the time that a patient or an athlete wants to hold a stretch may be based on the individual's perceived need or comfort level. The intensity of stretching should be low to medium to prevent reflexive contraction. This contraction occurs in response to discomfort during stretching. The stretch should be comfortable enough to be easily held for 30 seconds.

HYPOMOBILITY EXERCISE PRECAUTIONS AND CONTRAINDICATIONS

PROM and stretching are not benign processes and are contraindicated when motion could disrupt the healing process. For example, passive motion into full shoulder external rotation may disrupt the healing process after a capsular shift procedure. Passive motion into hip adduction, flexion past 90 degrees, and internal rotation past neutral may result in dislocation of a recent total hip arthroplasty. Use caution to ensure that the activity is passive when active muscle contraction is contraindicated, such as after a tendon transfer procedure. Ensure that the activity is producing *joint* ROM in the case of PROM and *muscle* ROM in the case of stretching. Moreover, control the speed and patient comfort to prevent inadvertent muscle contraction to oppose the passive exercise. Active muscle contraction in response to fear or pain could disrupt the healing process. Be aware of local anatomy, arthrokinematics, and the effects of PROM on these tissues. For example, passive shoulder ROM into full overhead flexion without adequate humeral head depression may compress a recent rotator cuff repair under the coracoacromial arch, producing pain and disrupting the healing process.

As with PROM, AAROM is contraindicated when motion or contraction may disrupt the healing process or affect the individual's health status. For example, individuals with unstable cardiac conditions are not candidates for active assisted exercise. When performing exercise with an active component, ensure that the type of muscle contraction performed (e.g., concentric, eccentric, isometric) is indicated and that the amount of tension generated is appropriate. The indications and contraindications for these contraction types are described in Chapter 5. Emphasize the importance of muscle relaxation between exercise repetitions to ensure adequate blood flow to the working muscles.

Contraindications and precautions for AROM are the same as those for active assisted exercise. Muscle contraction that may disrupt the healing process or affect the individual's health status are contraindications to AROM. The type of muscle contractions being performed should be safe for the specific situation, and the clinician should allow muscle relaxation between repetitions.

Stretching is contraindicated in the case of acute inflammation or infection in the tissues being stretched. Signs of inflammation or infection include increased warmth, tenderness, redness, or localized swelling. When stretching inflamed tissues, the patient will often report a sensation of pain prior to any sensation of stretching. This is an important reason to ask patients *what* they are feeling, not just *if* they are "feeling" the stretch. Some patients will assume that it is okay to feel pain. Use caution in patients with recent fracture, particularly if the fracture has been immobilized for some time, as the associated soft tissues will have weakened simultaneously. Additionally, the fracture site should be stabilized manually or by a supportive surface and the stretch should be designed to avoid torque directly over the fracture site.

Patient's osteoporosis should approach stretching cautiously as a quick muscle contraction in response to discomfort, as well as the force across the bone can produce a fracture. Similarly, the elderly are at risk of stretching injuries because of increased soft tissue stiffness. Those who have been in prolonged immobilization or those with very weak muscles will be at risk of stretch-related injuries or may lack sufficient strength to oppose a stretch applied too vigorously.

CAUSES AND EFFECTS OF HYPERMOBILITY

Although most clinicians are familiar with the treatment of persons with decreased mobility, many patients have problems related to excessive mobility. Most individuals do not seek medical attention primarily for possessing excessive mobility about a joint or throughout the body. More frequently, patients seek medical attention for pain, fatigue, or tendinitis. These pathologies, impairments, and activity limitations often result from the hypermobility.

Hypermobility should be differentiated from instability. Hypermobility is excessive laxity or length of a tissue, and instability is an excessive range of movement, osteokinematic, or arthrokinematic, for which there is no protective muscular control. Despite hypermobility, the individual may experience no symptoms of instability. For example, individuals with anterior cruciate ligament–deficient knees may have measurable anterior laxity (i.e., hypermobility) at the tibiofemoral joint with no symptoms of instability. Conversely, individuals may have complaints of instability or "giving way" with no measurable laxity.

Hypermobility can be broadly categorized as excessive joint mobility resulting from trauma or a genetic predisposition (i.e., Ehlers–Danlos Syndrome, Hypermobility Syndrome) or as excessive tissue length. Patients with traumatic or atraumatic hypermobility may seek medical attention for a number of complaints, which may or may not include frank instability. Systemic hypermobility is often rated according to the Beighton Score (**Display 7-9**).

Hypermobility at a joint caused by traumatic injury can lead to true instability, particularly at the glenohumeral joint, where a traumatic anterior inferior dislocation can result in recurrent dislocation. Similarly, sprains to the lateral ankle ligaments or medial knee ligaments can result in hypermobility and instability.

DISPLAY 7-9

Total	/9

**Score one point for each side (left and right) if able to perform 1 to 4. Trunk flexion is 1 point for 9 total possible points.*

Atraumatic hypermobility is common at the glenohumeral joint; persons with multidirectional instability often seek medical attention for symptoms of rotator cuff tendinitis. At the knee, hypermobility can result in secondary patellofemoral pain.

Hypermobility can develop in response to a relatively less mobile segment or region. In a multijoint system with common movement directions (e.g., spine), movement occurs at the segments providing the least resistance. Abnormal or excessive movement is imposed on segments with the least amount of stiffness. With repeated movements over time, the least stiff segments increase in mobility, and the stiffer segments decrease in mobility. A thorough examination, seeking to understand the impairment contributing to the hypermobility, is necessary.

THERAPEUTIC EXERCISE INTERVENTION FOR HYPERMOBILITY

Treatment techniques for hypermobility should be directed at the related impairments and activity limitations and at the underlying causes of hypermobility. For example, a patient with hypermobility at the spinal level probably has pain and decreased mobility at adjacent segments. These impairments must be treated along with the underlying hypermobile segment. Although it is important to address the patient's current complaints, failure to recognize hypermobility as the underlying cause ensures the return of symptoms. Hypermobility should be treated only if it is associated with instability or is producing symptoms elsewhere (i.e., hypomobile segment) because of relative flexibility.

Stabilization Exercises

The concept of stabilization exercises gained popularity in the treatment of conditions of the spine. Stabilization exercises are dynamic activities that attempt to limit and control excessive movement. These exercises do not imply a static position, but rather describe a range of movement (i.e., the neutral range) in which hypermobility is controlled. Stabilization activities include:

- Mobility exercises for stiff or hypomobile segments
- Strengthening exercises in the shortened range for hypermobile segments
- Postural training to ensure movement through a controlled range
- Patient education

Supportive devices such as taping or bracing may be necessary initially to keep movement within a range where stability can be maintained. This range is different for every patient and condition. Patient education focuses on helping the patient find the limits of stability and work within those limits.

As mobility exercises to decrease hypomobility and stabilization exercises to increase stiffness improve symptoms, the stability limits increase, allowing the patient to work through a larger ROM. For example, a patient with an L4 spondylolysis may have short hip flexor and lumbar paraspinal muscles in combination with a hypermobile L4 segment. Stabilization focuses on increasing the length of the short muscles through static stretching, followed by active stretching through contraction of the abdominal muscles in a walk stance position. Initially, a stabilization brace may be used during exercise. As mobility of the short muscles and stiffness at the L4 segment improve, the brace can be discontinued and the walk stance position progressed to a lunge position.

Stabilization activities should be chosen based on the direction in which the segment is susceptible to excessive motion. In the previous example, the susceptible direction is extension; the spine tends to extend excessively, producing pain. Focus treatment on training the back to resist extension forces, rather than resisting motion in all directions. For the individual with anterior shoulder instability, the arthrokinematic motion of anterior glide is the symptom-producing hypermobility. Stabilization activities should focus on controlling anterior displacement and on treating the associated impairments.

Stabilization exercises can be performed in a variety of positions and using a range of equipment. When increasing the stability of a hypermobile segment, support (e.g., taping, bracing) and strengthening in the short range must be combined with mobility exercises for the hypomobile segment. This approach ensures balance in areas with variable relative flexibility. Gymnastic balls, foam rollers, balance boards, and proprioceptive exercises are effective ways to enhance stability.

Closed-Chain Exercise

Closed-chain exercise has been advocated for those with joint instability or hypermobility. For the lower extremity, exercises such as squats, lunges, or step-ups with the foot fixed are commonly used closed-chain activities. For the upper extremity, any weight-bearing exercise performed in the push-up or modified push-up position is considered to be closed-chain exercise. Weight bearing with the hands against the wall or on a table or countertop is also an effective closed-chain position for the upper extremity. The rationale for this exercise is muscular cocontraction, decreased shear forces, and increased joint compression, all of which offer stability to the joint. Some of this theory is supported by scientific and clinical research.[130,131] Other studies dispute some aspects of this rationale, such as muscular cocontraction with a closed-chain position.[132,133] Particularly for the lower extremity when the foot spends a lot of time in contact with the floor, using closed-chain exercise for hypermobility makes good clinical sense. However, for the upper extremity, the closed-chain position is rarely the position of function. The closed-chain position remains an effective position for upper extremity training for individuals with hypermobility, but open-chain stabilization techniques should be incorporated as well. More information on the effects of closed-chain exercise can be found in Chapter 14.

Open-Chain Stabilization

Open-chain stabilization activities are available for the lower and the upper extremities. PNF techniques such as rhythmic stabilization and alternating isometrics can be used effectively to facilitate cocontraction about a joint (see Chapter 15). These techniques are particularly effective in the latter stages of rehabilitation when performed in the position of instability, such as abduction and external rotation for treating anterior glenohumeral instability (**Fig. 7-54**).

Stabilization exercises for the spine are difficult to categorize, because the spine is often fixed at one end and open at the other end. It is not a true closed or open system. Stabilization

FIGURE 7-54 Rhythmic stabilization performed in a position of apprehension.

FIGURE 7-55 Forward flexed superman exercise is an example of an advanced spine stabilization exercise.

exercises for the spine are often initiated in a supine position with abdominal bracing exercises and progressed to sitting and standing positions. A variety of stabilization exercises can be performed on unstable surfaces such as a gymnastics ball or foam rollers to improve stability within a comfortable range. Sitting, prone, and supine activities combined with arm reaching and leg lifts can be used from early to advanced stages of stabilization training (**Fig. 7-55**). Many of these same activities can be used to improve stability throughout the upper and lower extremities.

Ballistic Exercises

Ballistic exercise has been shown to produce cocontraction about a joint through triphasic muscle activation. High-speed ballistic activities result in different patterns of agonist–antagonist muscle contractions from those of slower activities. Rapid ballistic movements result in synchronous activation of agonists and antagonists.[6,134,135] In contrast, the same movement pattern at a slow speed demonstrates only agonist muscle contraction, with braking provided by passive viscoelastic properties.[6] Although the viscoelastic properties also restrict movement at faster speeds, these properties are inadequate to halt fast movements.[134] These rapid ballistic movement patterns can be used with resistive tubing, balls, or inertial exercise equipment (**Fig. 7-56** on page 180). The amount of antagonist activity needed to halt a movement is related to the velocity of the activity, with higher velocities requiring greater muscle activation[134] (**Evidence and Research 7-7**).

Quick movements through small distances result in a large, quick antagonist burst, whereas slow movements over a long distance result in small and late antagonist bursts.[134] For example, flexing and extending the hip rapidly through a very small range elicit cocontraction of agonist and antagonist musculature, but flexing and extending slowly through a large range elicit reciprocal activation of the agonists and antagonists. If hip and pelvic stabilization is the goal, small-amplitude, fast movements are more likely to elicit cocontraction than slow, large-amplitude movements.

EVIDENCE and RESEARCH 7-7

Subjects were asked to produce fast flexion movements of the thumb and fast extension movements of the elbow over three distances and at a variety of speeds. All movements resulted in biphasic or triphasic muscle contraction. A linear relationship was found between peak velocity and the amount of antagonist activation needed to halt the movement. Movements made through large angles (i.e., large amplitude) showed less antagonist activity than those made through small angles at the same speed, and fast, small-amplitude movements demonstrated an earlier onset of antagonist activity. The distance during fast movements is controlled primarily by the first agonist muscle contraction, and increasing antagonist torque is associated with decreasing distance, ultimately controlling the movement time.[135] Producing fast movements requires large agonist torque production, followed by an equally large or larger antagonist torque.

Another factor that affects antagonist activity is the subject's knowledge of the necessity for such a contraction. On study

A B

FIGURE 7-56 Performance of rapid alternating shoulder flexion and extension at end ROM using resistive tubing.

provided a mechanical stop for preventing further movement in some elbow flexion and extension tasks.[134] When the subjects knew that the stop was in place, the antagonist burst disappeared after two or three trials. This resulted in a faster movement, suggesting that the antagonist activity brakes and slows the motion. Some cognitive control over the braking mechanism exists.

This research supports the use of rapid, alternating movements, moving quickly through a short distance. Large-amplitude movement does not produce the same muscular coactivation as small-amplitude movement.

Exercise Dosage

Dosage parameters depend on the purpose of the exercise and the patient's tolerance for the activity. Any time rapid, alternating movements are used, fatigue can alter the proper performance and thus the outcome of treatment. Watch for signs of fatigue that result in substitution patterns or loss of the desired stabilization. For rapid movements, sets for time often work better than a set number of repetitions. Patients can try to increase the number of repetitions of an exercise within the timed set.

As with all other exercise prescription, perform the exercise to fatigue without losing control or proper form. Monitor the time or number of repetitions, and, as the patient improves, change the exercise parameters to continue increasing the challenge. This may include increasing the resistance, repetitions, or speed or decreasing the rest interval.

Hypermobility Exercise Precautions and Contraindications

An important precaution when treating areas of hypermobility is to ensure that areas of relative flexibility are identified. Stretching techniques to improve mobility in a hypomobile area may increase hypermobility in an adjacent area. Reinforce correct dynamic stabilization to ensure that intervention is isolated to the correct segment. For example, failure to stabilize the pelvis during hip flexor stretching increases lumbar extension, potentially increasing hypermobility in this area.

Any time dynamic stabilization activities are being performed at the limits of stability (e.g., resisted shoulder rotation at 90-degree abduction and full external rotation in a hypermobile shoulder), be sure that the individual has adequate control to prevent instability or dislocation. Progress activities according to the patient's ability to control the limits of stability. Fatigue of dynamic stabilizing musculature places the patient at risk for injury, and the fatigue level should be monitored throughout the exercise session.

Many stabilization exercises use eccentric muscle contraction to provide stability. Eccentric contractions are associated with delayed-onset muscle soreness (see Chapter 5), fatigue, loss of control, and substitution. Consider this in the exercise dosage. Watch the patient closely for signs of fatigue and loss of control because the patient could be injured or develop excessive muscle soreness.

Any time activities are performed on a single limb, use caution to prevent falling and ensure that single-leg stance is indicated. Individuals with degenerative joint disease at the primary or adjacent joint may experience a symptom exacerbation because of excessive loads on the limb. A pool can minimize the quantity of weight bearing while performing single-leg stance activities (see Chapter 16).

LIFESPAN ISSUES

Be sure to consider that most studies on stretching and mobility exercises have been performed on young and middle-aged adults, and few have been performed on children or the elderly. However, because of the aging of the population, more and more studies are being carried out on the elderly to determine how their responses to treatment differ from that of younger individuals. As noted in the section on "Stretching," the elderly benefit from holding their stretches for a longer time than do younger individuals.

As with many adults, children exhibit variable degrees of mobility, from shortened and tight muscles to hypermobility. In general, flexibility remains relatively stable through age 8, and then declines until about the ages of 11 to 15.[136] This decline is probably because of the adolescent growth spurt. As with adults, flexibility in children can be improved by the stretching techniques outlined in this chapter. A study of elementary schoolchildren found that regular hamstring muscle stretching throughout the school year produced significant increases in SLR ROM.[137] Increases were greater for those stretching 4 days per week compared with those children stretching 2 days per week.

Joint mobilization techniques are not commonly used in children, although there may be special cases in which this technique is indicated. Joint mobilization has been considered for children with central nervous system disorders such as cerebral palsy.[138] As with adults, the primary indication for use in this population is joint hypomobility resulting from capsular tightness. However, use caution when using joint mobilization in any child. It may be contraindicated in some situations, such as Down syndrome in which joint hypermobility secondary to joint laxity is generally the case. Additionally, in any child with open epiphyses, the potential damage to the growth plate must be balanced against the potential benefits of joint mobilization. Alternative interventions to increase mobility may be safer choices.

Other issues exist at the older end of the life span. Joint mobility and muscular flexibility decline with aging.[34] Connective tissue changes occurring with aging impact the use of joint mobilization and stretching exercises. Aging muscle increases in stiffness as measured by passive length–tension plots, and the amount of muscle area occupied by connective tissue also increases.[139] Feland et al.[34] suggest using static stretching over PNF stretching because the muscles of the elderly are more susceptible to contraction-induced injury and have decreased capacity to recover from such injury. Older individuals have demonstrated greater muscle stiffness and a lower tolerance for stretching.[91]

Additionally, joint ROM decreases with aging. Declines of 20% in hip rotation and 10% in wrist and shoulder motion have been reported.[140] Walker et al.[141] showed declines in the lower extremity joint ROM of up to 57%. A 25% decrease in trunk-side bending between the ages of 20 and 60 have also been reported.[140] Before performing joint mobilization in the elderly population, consider their decreased joint capsule tensile strength, diminished articular cartilage water content, and increased bone fragility. Joint mobilization should be approached cautiously because of all these connective tissue changes.

ADJUNCTIVE AGENTS

Clinicians often use various treatments or techniques to enhance the effects of another treatment. Forms of tissue heating are the most common adjunctive agents used in combination with ROM exercises to increase mobility. The ability of collagen to be easily and safely deformed or stretched is enhanced by increasing the temperature of the collagen. Because muscle is primarily composed of collagen, the ability of the muscle to be stretched may be enhanced by increasing the temperature of the muscle.[142] The critical temperature for beneficial effects appears to be approximately 39°C or 103°F.[10,142–145]

Intramuscular temperature may be increased by heating modalities or through exercise. The therapeutic temperature required may be efficiently achieved for the time necessary to complete a flexibility program using a deep-heating modality such as ultrasound.[146,147] Physiologically, the easiest and most appropriate way to increase intramuscular temperature is through the use of exercise. Active, submaximal resistive exercise of the muscle groups to be stretched should be performed before stretching. This type of exercise is capable of producing temperature increases to approximately 39°C after 10 to 15 minutes.

Heating techniques may prepare the tissue for mobility activities by increasing the tissue temperature, promoting relaxation and pain reduction, and increasing the local circulation. Forms of heat other than exercise can be categorized broadly as superficial-heating and deep-heating agents. Although heat can increase local circulation and temperature, it is not a substitute for warm-up exercises before a planned activity. A warm-up exercise such as walking, bicycling, upper body ergometry, or AROM exercise should take place before any therapeutic ROM activities. This approach increases core temperature and prepares surrounding tissues for the forthcoming activity. More information on Superficial Heat and Deep Heat can be found on thePoint.lww.com/BrodyHall4e.

KEY POINTS

- The effects of immobilization on the injured and uninjured soft tissues are profound. All tissues are affected, including insertion sites and bone.
- These effects are the result of the specific adaptations to imposed demands principle; tissue responds to loads placed on them. When underloaded, the tissue weakens.
- The period needed to restore normal structural and mechanical properties to immobilized tissue can be two or more times the length of the immobilization period.
- Joint ROM should be differentiated from muscle ROM. The specific goal dictates the type of mobility activity prescribed.
- A variety of contractile and noncontractile tissues can limit mobility at a joint.
- PROM exercise is a mobility activity performed without muscle contraction. AAROM is a mobility activity in which some muscle activity takes place, and AROM exercise uses active muscle contraction to perform the exercise.
- To increase flexibility, static, ballistic, and PNF stretching techniques can be used. The type of stretch chosen depends on the individual's impairments and lifestyle. All techniques have been shown to increase short- and long-term flexibility.
- Joint mobilization is an integral component of a comprehensive mobility program when capsular restriction is a key finding.
- Pulleys, machines, the pool, or objects found in the home or office can be used to perform mobility exercises.
- Mobility exercise prescription depends on the specific goal of the activity and the environment in which it will be performed. Mobility exercises should be performed daily.

- Hypermobility can be as disabling as hypomobility. Stabilization exercises such as closed-chain and rapidly alternating movements may be incorporated.
- Adjunctive agents such as heat can be used to enhance mobility activities.

LAB ACTIVITIES

Perform the following activities with your partner. Not all positions are optimal for performing each of the exercises, but the clinician occasionally is unable to change the patient's position. If not the optimal position, which position would be better and why?

1. With your patient in supine, perform the following:
   a. PROM shoulder flexion
   b. AAROM shoulder abduction
   c. PROM shoulder internal and external rotation
   d. CR stretching for pectoralis major
   e. PROM hip and knee flexion
   f. CRAC stretching of the hamstring muscles
   g. PROM lumbar flexion
   h. PROM lumbar rotation
2. With your patient sitting, perform the following:
   a. PROM hip internal and external rotation
   b. AAROM knee extension
   c. CR stretching hip internal rotator muscles
   d. AAROM shoulder flexion
   e. AROM shoulder abduction
3. With your patient in a side-lying position, perform the following:
   a. PROM shoulder extension
   b. AAROM shoulder abduction
   c. CR stretching shoulder internal rotator muscles
   d. AROM shoulder flexion
4. With your patient in a prone position, perform the following:
   a. AAROM elbow extension
   b. PROM hip internal and external rotation
   c. AROM shoulder flexion
   d. CR stretching hip flexors
   e. CRAC stretching for gastrocnemius
   f. CRAC stretching for soleus
5. Decide how to best position your patient for the following:
   a. AROM shoulder external rotation in a gravity-minimized position
   b. AROM scapular elevation
   c. AROM wrist extension in a gravity-minimized position
   d. CR stretching of hip adductor muscles
   e. AROM shoulder abduction in a gravity-minimized position
   f. PROM cervical rotation
   g. Static stretching of the triceps muscle
6. Choose five of the previous exercises and write a description of those exercises for a patient in a home exercise program. Include a picture of the exercise.
7. Consider Case Study No. 6 from Unit 7. Instruct your patient in the first phase of the exercise program. Explain and demonstrate.
8. The clinician is treating a postal worker with rotator cuff tendinitis resulting from hypermobility. This man sorts mail all day at eye level. The rotator cuff tendinitis has resolved with intervention. Instruct this patient in an exercise program to treat the instability. Explain and demonstrate.
9. Instruct a patient in a self-stretching program for the quadriceps, hamstrings, and iliotibial band. Explain and demonstrate three different stretches for each muscle group.

CRITICAL THINKING QUESTIONS

1. Consider Case Study No. 2 in Unit 7.
   a. Although the patient needs to increase knee ROM in both flexion and extension, which direction would you emphasize first and why?
   b. Discuss the advantages and disadvantages for various exercise modes to increase this patient's active knee ROM.
2. Consider Case Study No. 4 in Unit 7.
   a. How would your treatment differ if the patient were an elderly woman with severe osteoporosis?
   b. How would your treatment differ if the patient were 25 years of age and the joint accessory motion testing result indicated hypermobility?
3. Consider Case Study No. 1. Given this patient's impairments and activity limitations, design a program to improve his hip mobility.
   a. Include in-house therapist-provided activities.
   b. Include a home exercise program including dosage parameters.
   c. What activities might you allow this patient to engage in to maintain an active lifestyle? Would any of these need to be modified in any way?

CHAPTER

8 Impaired Balance and Mobility

COLIN R. GROVE • JUDITH DEWANE • LORI THEIN BRODY

Balance is an important consideration when rehabilitating patients with a variety of conditions, and balance training is long recognized as integral to clinical practice.[1–4] Health conditions may result in or from impaired balance. For example, a patient who is status-post anterior cruciate ligament reconstruction, which was torn while playing basketball, may present with residual impairments in single-leg stance (SLS). Alternatively, a patient with impaired balance because of Parkinson's disease may fall resulting in a hip fracture and increased mobility-related disability. The rehabilitation plan of care for each of these patients should include a balance component. However, clinicians must be mindful that the skill of maintaining balance is multidimensional and impaired balance is not a simple impairment, such as impaired range of motion (ROM). Rather, impaired balance represents a super-impairment for which there are a variety of underlying body systems potentially at fault. Thus, the balance component of a plan of care will differ greatly between patients, often even between those with the same medical diagnosis.

DEFINITIONS

Balance is a multidimensional concept that involves both postural balance and locomotor stability. *Postural balance* is the ability to maintain equilibrium or the ability to maintain the center of mass (COM) relative to the base of support (BOS).[5] *Locomotor stability* is the ability to control postural balance during gait and while changing from one posture or position to another, such as going from sit-to-stand transition.[6] Stability during gait requires control of a moving COM that is not always within the BOS.

Postural sway is a component of balance and is the normal, continuous shifting of the body's COM over the BOS. Postural balance is maintained when a person is able to keep his/her postural sway within the *limits of stability* (LOS) or his/her maximum angle of displacement from vertical, before losing equilibrium. These limits represent the spatial area in which the individual can maintain equilibrium without changing his/her BOS.

A certain amount of anteroposterior and lateral sway normally occur while maintaining equilibrium. This *sway envelope* defines the LOS in anterior, posterior, and lateral directions. Normal anteroposterior sway in adults is 12 degrees from the most posterior to the most anterior position.[7] Lateral stability limits vary with foot spacing and body height. An average-height adult with 4 inches between their feet can sway approximately 16 degrees from side to side.[7] This stability limit is often characterized by a *cone of stability* (**Fig. 8-1A** and **B**). As long as an individual's sway envelope stays within the cone of stability, balance is maintained.

Individuals rely on a variety of balance *strategies* (coordinated neuromuscular synergies) to maintain postural balance. When sway approaches the LOS, a corrective strategy is necessary to maintain stability.[8] The strategies that govern postural balance without causing a change in the BOS are known as *in-place* strategies. In-place strategies include ankle and hip strategies. If sway exceeds the LOS, a corrective stepping or protective extension strategy must be employed to reestablish balance over a new BOS. These are referred to as *change-in-support strategies* and are used by the individual to establish a new BOS. Taking steps when lunging for a tennis ball or when bumped by someone are examples of change-in-support strategies.

A significant contributing factor to person's ability to manage balance within her LOS is the position of the COM relative to the BOS. If an individual's COM is aligned more anterior, posterior, or lateral than center, a smaller sway envelop is tolerated before losing balance (see **Fig. 8-1C**).[7] For example, persons with Parkinson's disease or with a significant thoracic kyphosis secondary to osteoporosis may have a static or dynamic anterior posture, decreasing tolerance for anterior sway. Alternatively, persons who are status-post right total knee arthroplasty or status-post left middle cerebral artery stroke may stand with their COM displaced toward the left. In such cases, the person may ambulate with a decreased ability to effectively load weight onto the right leg. This lateral postural displacement may increase this individual's risk for falling to the left.

Postural balance strategies result from highly coordinated balance functions. *Coordination* is defined as the ability to perform smooth, accurate, and controlled movements.[5,9] Coordination is easily recognized as necessary for the execution of fine motor skills such as writing, sewing, dressing, and the manipulation of small objects. Coordination also provides the foundation for performing gross motor skills such as walking, running, jumping, occupational tasks, and basic and instrumental activities of daily living (IADL). Coordinated movements are

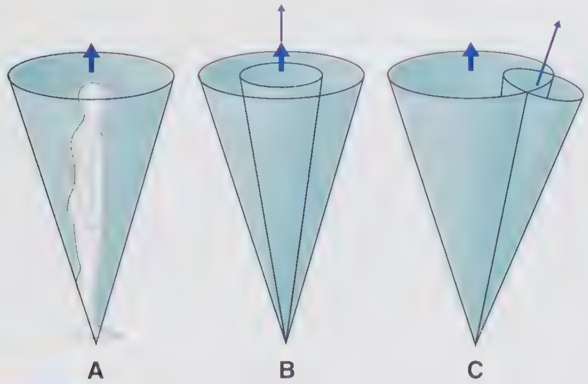

FIGURE 8-1 Relationships of the LOS, the sway envelope, and the COG alignment. **(A)** The LOS are described by a cone-shaped sway envelope. **(B)** When the COG is aligned in the center, the sway envelope remains within the LOS. **(C)** When the COG is offset, as in a forward leaning posture, the sway envelope exceeds the LOS, and a balance restoration strategy must be implemented to regain balance.

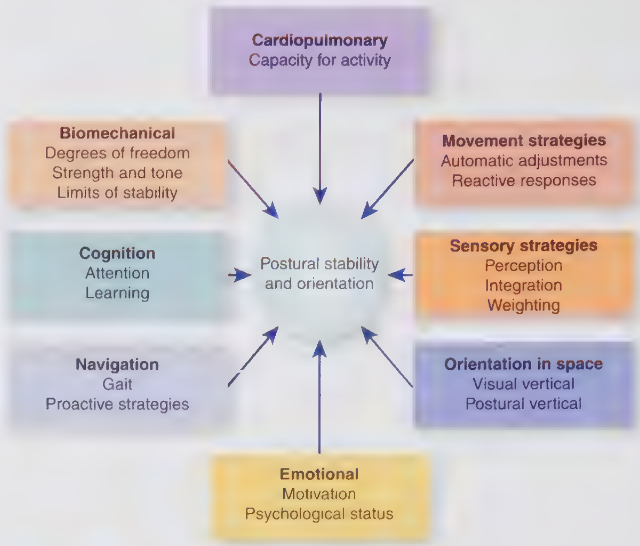

FIGURE 8-2 Systems model of postural stability and orientation.

characterized by proper sequencing and timing of synergistic and reciprocal muscle activity. In fact, skilled activities, such as throwing, kicking, hopping, and running, are not possible without appropriate balance function.[10] Thus, the concepts of coordination and balance are highly interrelated. However, despite their integrated relationship, balance and coordinated movements are felt to be controlled separately.[11] Observations of reprogramming of postural responses before measured changes in focal movement during a changing task or environmental context provide evidence of the integration of balance and coordination.[12]

Maintenance of postural balance requires that individuals have the ability to maintain a position of stability before, during, and immediately after voluntary activities, as well as the ability to react to external perturbations.[13,14] Balance functions also enable individuals to protect the body in the event of a fall[12] and allow for clear vision during head and/or body movements.

Postural balance is far more complex than a simple relationship between the COM and the BOS. Effective and efficient performance and integration of multiple body systems are required for postural balance.[15] Specifically, stability is accomplished through the interaction of biomechanical (articular and muscular), sensory feedback (somatosensory, visual, and vestibular), self-perception (orientation in space, subjective postural and visual vertical), dynamic control (control of walking and navigation), neuromuscular integration (neuromuscular synergies, and adaptive and anticipatory action), cognitive processing (multitasking, information processing), affective (motivation, preferences), and cardiopulmonary (activity tolerance) systems. **Figure 8-2** describes postural control and orientation from this perspective. Impairment in any of these systems can lead to altered balance and mobility function. A detailed examination enables the clinician to determine the system(s) at fault and to develop targeted treatment for impaired balance. Successful interventions also depend on the clinician's ability to prioritize interventions based on the relative impact of each underlying impairment in relationship to each other and the resulting activity limitations, participation restrictions, and mobility-related disability (see **Building Block 8-1**).

BUILDING BLOCK 8-1

A 75-year-old woman with multiple sclerosis (MS) presents to your clinic for evaluation and treatment of her gait instability following a recent fall. The patient fractured her right wrist as a result of the fall. The fracture was surgically repaired, and she has recently been cleared for full weight bearing through her right hand. Before the fall, the patient had been using a front-wheeled walker for several years because of decreased stability while walking. In fact, she has fallen four times in the past year. You note that she stops walking whenever she tries to converse with you on the way to the exam room. Her past medical history is significant for the additional problems of depression, an anal cyst, and hypertension. She is taking multiple medications, including disease-modifying agents, a benzodiazepine, prescription pain medication, a selective serotonin uptake inhibitor, and a calcium-channel blocker. She lives alone in the home that she bought with her husband 40 years ago. There are three steps to enter the home, which have a railing on the right side for ascending. Her three adult children live more than 2 hours away. The patient relies on volunteers for transportation because she is unable to drive. In fact, she rarely leaves her home. One of her regular companions spends 3 hours a day helping her with household chores and with completing her home exercise program for residual muscle weakness and adaptive shortening in her right wrist and hand.

Hypothesize impairments from each of the domains just discussed that you might find upon examination.

PHYSIOLOGY OF BALANCE

Identifying causes of and prescribing treatment for balance impairment requires an understanding of the various influences on balance control and their normal interactions. Again, biomechanical, sensory, self-perception, neural integrative, cognitive, and affective systems each directly influence postural balance. The individual must effectively and efficiently process contributions from these systems within the central nervous system (CNS), then choose, and execute an appropriate and integrated balance strategy. The actual movement or task performance, as well as the interaction with the environment, must then be evaluated for accuracy, and corrective action must be taken when necessary. An ecological model (**Fig. 8-3**) describes these interactions among the individual, the environment, and the functional task, with a circular network of domains demonstrating the integration of balance functions.[5,16] Any of these domains may dominate depending on the particular context.

Additionally, other individual body systems, such as the circulatory, respiratory, and integumentary systems, indirectly influence balance and mobility via the effects of disease, damage, or suboptimal function. For example, consider a patient with peripheral vascular disease who has swelling in the lower extremities and the subsequent impact of limitations in ROM on balance reactions. Alternatively, consider the impact a venous stasis ulcer on the plantar surface of the foot has on weight acceptance in a patient with diabetes mellitus. Both of these conditions will affect balance reactions.

The primary systems that influence balance and mobility are depicted in Figure 8-2. Each of these systems is considered to be within the *individual* domain. The role of the integumentary system in balance typically occurs in select situations, such as a case of a person with a burn that limits ROM or affects weight bearing. Thus, this system will not be addressed further herein. Additionally, the influence of the cardiopulmonary system will not be considered further in this chapter. Refer to Chapter 6 for further information regarding examination and treatment of impaired aerobic capacity and endurance.

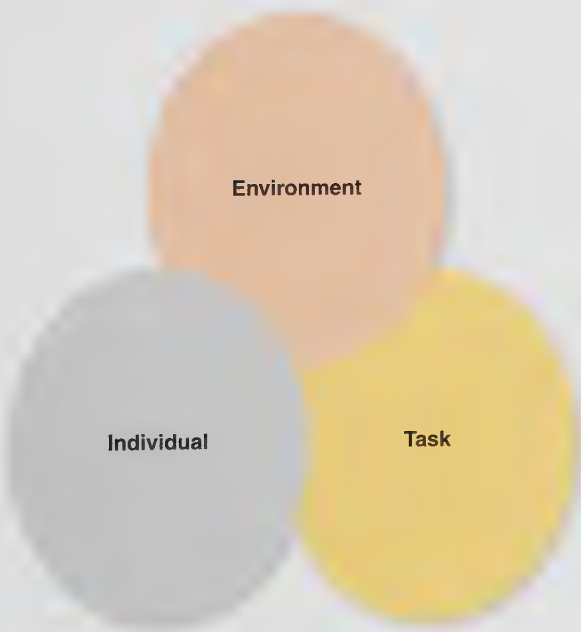

FIGURE 8-3 Ecological model of motor behavior.

Biomechanical Contributions

An individual's LOS is largely a function of the size of the BOS and any impairments in biomechanical, sensory, or neural structure or function in the lower extremities. Individuals who are prone to falling tend to have smaller LOS.[6] The most important biomechanical constraint on balance is the size and quality of the BOS, the feet.[15] Any limitation in size, strength, ROM, pain, or control of the feet will result in impaired balance.[17] Additionally, changes in lower-extremity strength, ROM, and flexibility can cause restrictions in moving the body on the BOS, which will ultimately effect balance control. As previously stated, suboptimal postural alignment also affects balance control. In addition to primary biomechanical impairments, impairments in biomechanics may develop secondary to impairments in other systems. Consider a patient with vestibular dysfunction who presents with complaints of pain and stiffness in the cervical region as a result of self-restricted head movement.

Contributions of the Sensory Systems

Three sensory systems contribute to the maintenance of upright posture and orientation: somatosensory, visual, and vestibular. These are considered to be the sensory triad of postural control (**Fig. 8-4**). No single sense directly determines the position of the body's COM; the combined feedback from each system must be integrated. The somatosensory system gathers information from the individual (e.g., position of one body segment vs. another or the position of the COM relative to the BOS), as well as the environment (e.g., various surface characteristics). The visual system provides information about task performance (e.g., orientation of the body relative to the task) and environmental cues (e.g., position relative to other objects, orientation to vertical, and environmental motion). The vestibular system provides an internal reference and final pathway, providing information about orientation of the head relative to gravity and movement of the head through space.[18]

Somatosensory Neurophysiology

The somatosensory system plays an important role in regulating posture and orientation. Information must be detected peripherally and transmitted centrally for processing. The peripheral receptors are an important source of that information. When a person steps onto a rug that slips beneath his/her foot, the

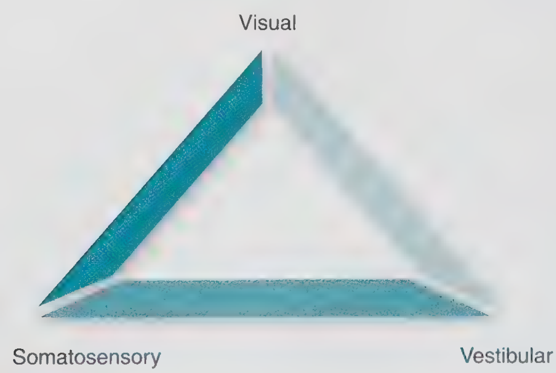

FIGURE 8-4 The triad of balance control.

acceleration of the slipping limb provides the first information to the balance system about impending peril. Information from the somatosensory system arises from the periphery. A variety of somatosensory receptors provide information about movement and joint position through the dorsal column to the medulla and brain stem.[18] This information assists in coordinating eye, head, and neck movements to stabilize the visual system and in maintaining postures and coordinated movement patterns.[19] The influence of each different form of somatosensory input varies. For example, joint afferent information does not contribute to a *conscious* sense of position.[19,20] This conclusion is based on studies in which local anesthetization of joint tissues failed to reduce joint position awareness and total joint replacement did not diminish joint position sense.[21] However, loss of proprioception function in the lower extremities has been associated with higher rates of falling.[22]

Visual Neurophysiology

The visual system contributes significant information about the body's position and movement in space. Vision plays a primary role in anticipatory postural control.[23] Incoming information from the visual system is used to pre-set the postural system for an anticipated change or perturbation.[23] The visual system provides information about the position of the head relative to the environment and orients the head to maintain level gaze. This system contributes significantly to head and neck posture.[23] The visual system also provides information about the movement of surrounding objects, thereby providing information about the speed of movement. Information entering the visual system travels through the optic nerve to the lateral geniculate nucleus (LGN) of the thalamus to the superior colliculus and inferior olivary nuclei. The LGN receives the largest projection and is the first center where information from the retina is represented.[23,24] From here, neurons project to the primary visual cortex in the occipital lobe (Brodmann's area 17). As essential as vision is to anticipatory control, clearly it is possible to balance without vision such as walking in the dark. Visual inputs can also be an inaccurate source of orientation information about self-motion, and the visual system has been shown to have difficulty distinguishing between self-motion and object motion.[23]

Vestibular Neurophysiology

The vestibular system provides information on orientation of the head in space with respect to gravity and acceleration. The vestibular system provides the gravito-inertial frame of reference for postural control.[23] Any movement of the head, including weight shifts to adjust posture, stimulate the vestibular receptors. There are two types of vestibular receptors: the semicircular canals and the otoliths of the macula. The semicircular canals function as angular accelerometers and sense angular acceleration of the head.[23] The otoliths sense linear position and linear acceleration. The semicircular canals are particularly sensitive to fast head movements, whereas the otoliths respond mostly to slow head movements, such as those movements during postural sway.[23] The vestibular nerve (a division of cranial nerve VIII) projects to the vestibular nuclei and to the cerebellum. In fact, the vestibular system is the only sensory system that has direct, monosynaptic input to the cerebellum. Two vestibulospinal tracts descend from the vestibular nuclei to the spinal cord for postural control.[24] These join several other descending pathways involved in postural control. Ascending projections include fibers to oculomotor nuclei to control eye movements and stabilize gaze via the vestibulo-ocular reflex. Ascending fibers also project via thalamic relays to the head of the caudate nucleus and to the parietal association area, where the information is integrated with other sensory information.

Interestingly, the vestibular system alone cannot provide the CNS a completely accurate picture of how the head and/or body is/are moving in space. The vestibular system is not able to distinguish between a simple head nod (head moving on a stable body) from a forward bend from the hips (head moving in concert with moving trunk).[23]

Neural Integration and Processing of Sensory Information

It is generally believed that the nervous system maintains an internal representation of the body in space. Balance control involves both postural and visual vertical orientation in space. Effective motor control depends on the accuracy of the internal maps of body and spatial orientation. Damage to the sensory systems or CNS may lead to impaired orientation in space. For example, the internal representation of visual, but not postural, vertical is tilted in individuals with unilateral vestibular loss.[25] However, the internal representation of postural, but not visual vertical, is tilted in individuals with hemi-neglect because of stroke.[25]

After information arrives from peripheral receptors, the information must be analyzed. Because no one sensory system can completely detail the body's position in space, the relative contributions from each system and integration of each system's information are critical. Integration and processing of incoming information occurs in the cerebellum, basal ganglia, and supplementary motor area.[26] The time required to process this information is important, particularly when a quick response is necessary. In adults, muscle response latencies to visual cues signaling perturbations to balance are slow, approximately 200 milliseconds, compared to somatosensory responses that are activated in 80 to 100 milliseconds.[23] Thus, the somatosensory system information is generally processed fastest, followed by the information from the visual and vestibular systems.[23,26] Researchers suggest that the nervous system preferentially relies on somatosensory inputs for controlling body sway when imbalance occurs from rapid displacement of the support surface.[23] However, balance function is also determined by the task and the context in which that task is being performed. Thus, the nervous system also needs information about the intended task and must resolve and ambiguity in sensory feedback from the environment in order to generate appropriate postural alignment, adjustments, and reactions.

Sensory organization is the process of resolving conflicting input; it is necessary because incoming information from a system may be inaccurate. For example, consider sitting stationary on a train in a station when an adjacent train begins moving forward. The visual system alone is unable to detect whether the adjacent train is moving forward or your train is moving backward. The brain must resolve inaccurate input from the visual system with the accurate information from the somatosensory and vestibular systems. However, somatosensory and visual inputs are prone to error. If an injury decreases the information processing rate, balance may be impaired. For example, individuals with sensory loss from any sensory modality are limited in their ability to reweight (adjust the emphasis) sensory information as required by changes in environmental context and, thus, are at increased risk for falling in certain situations.[6] If a single sensory system is impaired, other systems may adequately compensate for this impairment in most environmental contexts, and this concept is the basis for many treatment programs. However, balance may be significantly impaired if multiple sensory systems are damaged (see **Building Block 8-2**).

BUILDING BLOCK 8-2

Consider the impact of impairments in specific sensory systems. Patients with impairment in the somatosensory system are more likely to demonstrate imbalance in which conditions? In which environmental contexts would you anticipate persons with vestibular impairments to show the greatest instability?

Generating Motor Output—Movement Strategies

After the sensory information is transmitted centrally, the information is processed, and a response is selected, the response output must be executed. This process is referred to as *motor organization*. The process of motor response organization involves the execution of coordinated and properly scaled neuromuscular synergies[27] that must counteract either internal or external perturbations of the COM. Normal voluntary movement is dependent on complex excitation and inhibition of muscular contractions, accurately controlled in force and extent, and appropriately organized in space and time, with a number of relevant postural adjustments[28] in the head and neck, trunk, and extremities.[10] Complex movements take longer to process and program than simple tasks. Motor processes develop early in life, resembling adult performance between ages 3 and 4 years.[29]

The systems-level model of postural control proposed by Riach and Hayes[30] suggests that normal postural control is dependent on the parallel and integrated maturation of specific feedback (closed loop) and feedforward (open loop) mechanisms. The feedback mechanisms of postural control are the automatic postural responses; these involve activation of the labyrinthine righting reflex, vestibulo-collic reflex, vestibulo-spinal reflex, and functional stretch reflexes. The feedforward mechanisms involve preparatory adjustments in body position that accompany a variety of activities.

Automatic Postural Responses

Although a multitude of postural responses are available when someone is destabilized, two broad classes of *automatic* responses are common. There are four classically identified automatic postural responses:

- Ankle strategies
- Hip strategies
- Protective extension
- Stepping strategies

The ankle and hip strategies are *in-place* strategies because the BOS does not change. Alternatively, the protective extension and stepping strategies are *change-in-support* strategies. These responses are considered automatic because of their short response latencies. The earliest response latencies to surface perturbations are at 70 to 180 milliseconds, much longer than stretch reflex latencies of 40 to 50 milliseconds, but shorter than volitional reaction times of 180 to 250 milliseconds.[16] This suggests that balance is learned and therefore trainable. These pre-programmed strategies (or synergies) are the fundamental movement unit engaged when balance is disturbed.[5,14,16]

Rather than determining which muscles to activate and when, the brain only needs to recognize which synergy to engage to meet the task demands in the particular environment, when to engage it, and at what intensity to respond. This is an example of synergistic neuromuscular control. These synergies use feedforward control when the movement occurs too fast to rely solely on sensory feedback. The synergies can also function automatically using feedback control. Selection of these movement patterns is triggered initially by sensory feedback. Sensory feedback experiences throughout development help the CNS learn the rules used to engage these strategies. Treatment procedures for reactive balance control impairments focus on eliciting these pre-programmed synergies to maintain postural control. However, remember that the motor output is situation dependent. The response to a stimulus will vary depending on the environment in which it is elicited. Thus, be sure to vary the treatment environment appropriately; this allows the patient to develop movement strategies in a variety of situations.

The ankle strategy proceeds in a distal to proximal pattern and is utilized when displacements are small (**Fig. 8-5**). Posterior displacement of the COM results in activation of the anterior tibialis, quadriceps, and abdominals to counter backward movement. Conversely, anterior displacement of the COM produces activation of the gastrocnemius, hamstring, and trunk extensors to slow the forward movement.[16,26]

The hip strategy is activated when ankle motion is limited, the displacement is large, the COM is near the LOS, or the surface is unstable. In this case, a posterior displacement of the COM (i.e., anterior translation of the surface) results in a backward sway with activation of the hamstring and paraspinal muscles (**Fig. 8-6**). Anterior displacement of the COM (i.e., posterior translation of the surface) produces forward sway with

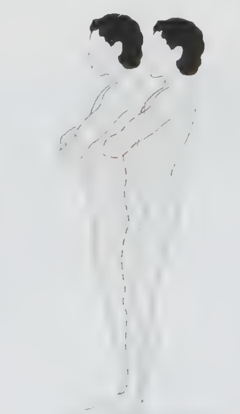

FIGURE 8-5 Ankle strategy in response to small perturbations.

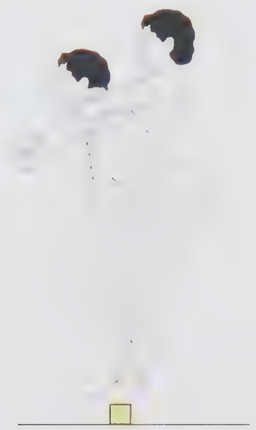

FIGURE 8-6 Hip strategy in response to larger perturbations.

contraction of the abdominal and quadriceps muscles. In each case, the muscle activation proceeds from proximal to distal in an attempt to return the COM over the BOS. Little ankle activity occurs in this synergy (**Table 8-1**).

If the displacement is great enough, the stepping strategy may be used to return the BOS under the COM. A forward, backward, or lateral step is elicited to regain postural balance in these circumstances.

Healthy individuals appropriately match the selection of a balance strategy to the demands of the situation. However, factors such as age, risk for falling, and the presence of disease significantly influence which balance strategies are activated and may result in specific types of balance impairments. For example, elderly individuals who are at increased risk for falling tend to use hip, protective extension, and stepping strategies more frequently than those who are not at increased risk.[31]

Anticipatory Postural Adjustments

Volitional movements, such as reaching, stepping, or lifting objects, cause displacements of the COM. The healthy individual is able to anticipate the postural requirements needed with these tasks and generate anticipatory movement strategies that prevent destabilization secondary to self-generated postural perturbations. These anticipatory postural adjustments are generated by feedforward mechanisms of postural balance. Feedforward control is characterized by actions that occur without sensory feedback. Research has identified numerous examples of this postural adjustment in healthy individuals (**Evidence and Research 8-1**).

EVIDENCE and RESEARCH 8-1

Examples of Feedforward Control

- Activation of the contralateral tibialis anterior before step initiation of the ipsilateral limb to pull the COM forward and over the stance limb.[32]
- Lower-extremity muscles are the first to be activated during reaching activities.[33]
- With a heel rise, the triceps surae are inhibited 150 milliseconds before lift off as the tibialis anterior pulls the COM forward over the anticipated new BOS.[34]

Persons with neurologic and orthopedic impairments may demonstrate poor feedforward postural control. Patients with Parkinson's disease often have impaired anticipatory postural adjustments and will become unstable during lifting tasks. Similarly, pain and muscle weakness may interfere with anticipatory adjustments following total joint replacement.

Additional Considerations

Some individuals, such as those with multifactorial disequilibrium, may have difficulty with both feedback and feedforward control mechanisms. It is often difficult to separate the feedforward and feedback aspects of postural control in a given task. Many tasks require both processes, and these control mechanisms operate in parallel with each other. Careful analysis of postural balance during task performance leads to a better understanding of impairments related to motor organization, and, thus, more targeted treatment interventions.

Though early research identified three fundamental movement strategies to maintain equilibrium (ankle, hip, and the stepping strategies),[16,26] more recent studies suggest that these strategies rarely occur in isolation.[15] Additionally, the selection and execution of these strategies depends on the intensity of the disruption, the relative location of the COM to the LOS, the individual's awareness, and the individual's posture at the time of perturbation.[26]

TABLE 8-1

Comparison of In-Place Strategies (Ankle and Hip)

	ANKLE STRATEGY	HIP STRATEGY
Used when. . .	Small displacement	Ankle motion is limited, the displacement is large or rapid, the COM is near the LOS, or when standing on an unstable surface
Posterior displacement of the COM	Anterior tibialis, quadriceps, and abdominals to counter backward movement	Backward sway with activation of the hamstring and paraspinal muscles
Anterior displacement of the COM	Activation of the gastrocnemius, hamstring, and trunk extensors to slow the forward movement	Forward sway with contraction of the abdominal and quadriceps muscles
Activation pattern	Distal to proximal	Proximal to distal

In addition, underlying balance impairments may vary within a specific patient population. For example, individuals with Parkinson's disease, who demonstrate poorly coordinated automatic postural reactions, show instability with external perturbations.[15] However, those with abnormalities in anticipatory postural adjustments show instability during self-initiated tasks.[15] Thus, knowledge of the individual's diagnosis is not sufficient to guide rehabilitation interventions. A careful and thorough examination encompassing each of the subsystems of balance control is needed.

Control of Walking—Navigation

Many of the concepts described thus far can also be applied to understanding adaptive control of walking. Patla[35] provides further insights into the requirements of adaptive gait. The nervous system must set up the body's initial posture and orientation necessary to initiate walking. Propulsive muscle activation patterns must be determined, executed, and coordinated. The individual must be able to initiate and terminate walking as desired. Dynamic stability must be maintained as the body encounters both expected and unexpected destabilizing forces. The individual must also be able to modulate locomotor patterns to accommodate for obstacles, changing terrain, and time constraints. The ability to navigate toward a point that is not seen is often required. Locomotor systems must also minimize fuel consumption and maximize structural integrity to promote longevity. The nervous system employs reactive, predictive, and proactive control strategies to accomplish these goals.

Reactive and predictive control of walking involves context-specific, neuromuscular synergies analogous to automatic postural responses and anticipatory postural adjustments involved during stance control. Proactive control strategies involve visually guided mechanisms used for obstacle avoidance or to alter global locomotor patterns in response to perceived or observed hazards in the environment.[35] For example, consider that walking characteristics change as one approaches a patch of ice on the sidewalk, even in advance of detecting any loss of traction under the feet.

Balance impairments related to any of the requirements for adaptive gait may arise related to a variety of health conditions. Persons with limited hip ROM secondary to osteoarthritis (OA) may have difficulty setting up the posture required to initiate walking. An individual with cerebellar ataxia may demonstrate instability in walking because of problems coordinating muscle activation patterns or may have difficulty terminating walking at the appropriate time. Consider the impact macular degeneration may have on an individual's ability to effectively recognize and avoid hazards in her path. The clinician may choose from a variety of tests developed to assist the understanding of balance impairments specific to the task of walking in order to drive clinical decision-making regarding rehabilitation of balance and mobility (see **Building Block 8-3**).

BUILDING BLOCK 8-3

The use of an assistive device, such as a front-wheeled walker, is an appropriate compensatory measure for individuals with a variety of balance impairments (e.g., ineffective use of postural reactions). Why would you prescribe exercises to facilitate appropriate postural movement strategies for an individual who will continue to use an assistive device after the conclusion of rehabilitation?

Higher-Level Influences

Information processing resources in the CNS are constrained. As a result, attention is both limited and selective. Attention has a significant influence on balance control.[36–39] The effect of attention is typically measured by the degree of interference between two tasks. The degree of interference is determined by several factors, including the *relative task difficulty*. This concept refers to the fact that specific factors, such as personal (e.g., age, pathology, medications) and environmental (e.g., noise in the treatment area), influence attention capacity in highly individual ways. For example, increased age and a high number of comorbid health conditions tend to increase relative task difficulty. Therefore, when examining the effects of attention on balance control, care must be taken with regard to the types of tasks that are chosen for a given individual.

The individual's focus of attention also plays a significant role. Consider whether the individual should be encouraged to have an internal or an external frame of reference when completing a specific task. Research has shown that having an internal focus of attention is associated with greater performance errors, whereas successful functional outcome is associated with an external focus of attention.[40] For example, asking a patient to simply focus on clearing her foot as she attempts to step over an obstacle (external focus) is more effective than instructing the patient to flex their knee 70 degrees (internal focus) as they try to clear the object.

The limbic system, emotional resources, and coping strategies also play important roles in determining balance control. Fear of falling significantly influences behavior. The selection of automatic postural responses is influenced by fear of falling.[41] Individuals make choices about the mobility based on the types of threats to postural instability encountered in their environment.[42] Confidence related to balance and perception of disability secondary to dizziness have also been shown to impact rehabilitation.[43,44]

CAUSES OF IMPAIRED BALANCE

Injury, disease, or suboptimal function of any of the major body systems can lead to impaired balance. The relationships between health, impairment, activity limitation, and participation restriction are complex and dynamic. Impairments in body structure or function alone do not result in specific activity limitations.[15] Rather, activity limitations that lead to participation restrictions depend on the individual's impairments and the mechanisms that a person uses to overcome those impairments.[15] Consider the potential impact of vestibular loss on two different people: one who works as a flight attendant, the other who is a skilled welder working on overhead scaffolding. Although both may need to work on learning how to balance on a moving surface with conflicting visual feedback, the level of challenge presented during rehabilitation, compensatory mechanisms available, and ultimately their ability to return to work may differ.

Damage to any of the sensory systems contributing to balance leads to balance impairment. Lesions produced by tumors, cerebrovascular accidents, or other insults often produce visual field losses, changing the individual's spatial orientation and altering balance responses. Loss of vision for any reason, including aging, can impair balance. Visual losses can often be compensated by input from other sensory systems. Damage to the vestibular system can also cause profound limitations. Viral infections of the vestibular nerve, the aging process, or head injury are among the possible causes of vestibular pathology. These individuals experience vertigo, or the feeling of falling or spinning even when stable.

Other lesions of the cerebellum, basal ganglia, or supplementary motor area can impair processing of the incoming information. Parkinson's disease, Huntington's disease, and cerebellar tumors affect balance and movement.[16]

Damage to proprioceptors has been implicated in balance deficits. Injury or pathology of the hip, knee, ankle, and back is associated with increased postural sway and decreased balance.[20,45–48] Numerous studies demonstrate impaired balance in patients with a variety musculoskeletal conditions (see **Evidence and Research 8-2**).

EVIDENCE and RESEARCH 8-2

Damage to proprioceptors implicated in balance deficits:

- Damage to the anterior cruciate ligament (ACL), posterior cruciate ligament, or meniscus results in altered mechanoreceptor activity and altered kinesthesia and joint position sense.[49–52]
- Sensory feedback improves after joint reconstruction, but remains abnormal.[53]
- Basketball players with a history of ankle sprain demonstrate increased mean sway and increased sway area.[54]
- Increased mediolateral postural sway in SLS on the injured side following unilateral ankle sprain persists after rehabilitation without neuromuscular reeducation.[55]
- Abnormal postural control significantly increases the risk (42% to 57%) for future ankle injuries.[56]
- Individuals who are status-post ACL reconstruction demonstrate better balance versus individuals with ACL-deficient knees, but performance remains significantly worse than healthy control subjects.[57]

Research demonstrates a relationship between balance and degenerative disease of the knee joint as patients with knee OA have significantly more postural sway than the healthy individuals.[46] Similarly, the relationships among degenerative joint disease, total joint replacement, and balance have been studied.[46,58] Significantly increased postural sway in both sagittal and frontal planes is seen status-post repair of a hip fracture.[59] Use of sensory feedback and dynamic standing balance are significantly impaired following total hip arthoplasty.[60] In fact, functional measures of balance demonstrate that postural control remains impaired at least 6 to 12 months post-surgery for hip replacement.[61,62] The unfortunate consequence is often a fall with rehospitalization. Patients show a 10% to 20% decrease in strength compared to the uninvolved hip 1 year after hip replacement.[63] Research also shows a 27% to 39% decrease in extensor and flexor torque 1 year after knee replacement[64] and decreased vertical loading on the involved side 2 years following hip replacement.[65] Thus, patients may have long-term mobility-related disability following these procedures.

Adults with low back pain demonstrate increased postural sway, increased posterior center of pressure displacement, and decreased stability in SLS.[45] Impaired sensory organization and abnormal automatic postural responses are observed in individuals status-post whiplash injuries.[66,67] Together, this collection of findings further illustrates the importance of spine and extremity function to balance control.

There are also many examples of balance impairments related to the combination of orthopedic and neurologic conditions. Consider the following examples. Exaggerated disability following stroke may occur secondary to undiagnosed arthritic hip on the less-involved side. Diagnosis of Parkinson's disease can occur after hospitalization for surgical repair of a hip fracture resulting from a fall. An elderly patient with multiple risk factors for falling, including dizziness, may present for rehabilitation of a distal radius fracture.

Age is also a primary consideration in balance impairment. Age appears to affect all aspects of the stability triad (i.e., somatosensory, visual, and vestibular) and all three stages of information processing (i.e., input from periphery, processing information, and generating motor output).[68] For example, the sensory input stage can be affected by losses in proprioception in the elderly. Barrack et al.[58] found a decline in joint proprioception as part of normal aging. This decrease, along with poor vision and impaired vestibular function, predisposes the elderly person to impaired balance and falls.[68]

Although declines in sensory input, especially declines in the acuity of sensory information, are found with aging, the primary problem appears to occur at the information-processing stage. Visually "noisy" environments with much visual stimulus from mirrors and windows can make information processing challenging.[68] Information processing can be improved by the use of high-contrast input, for which the difference between the signal and noise is clear.

After sensory information is processed and a response is selected, impaired balance can result from weakness, decreased mobility, impaired motor programming, pain, or impaired posture. The balance strategy chosen will be unsuccessful if the patient lacks the muscle strength, mobility, or motor programming to execute stabilization. Similarly, if the movement is inhibited by pain, the chances of falling are increased. If the patient has significant posture impairment such as a thoracic kyphosis, the sway envelope is decreased, and the chances of exceeding the LOS are increased.

EXAMINATION AND EVALUATION OF IMPAIRED BALANCE AND MOBILITY

Horak et al.[16] identified keys to examination and rehabilitation program design, including balance control:

- Knowledge of the systems controlling equilibrium
- Knowledge of the systems likely disordered by aging and pathology
- An understanding of the factors that are likely to influence recovery of function
- Attention to the environmental factors that influence balance and mobility
- Adherence to the concepts of motor learning that govern task development

Additionally, a clinical framework, such as the systems model set within an ecological context, can facilitate our thinking about examination and intervention.[13] Given that balance and mobility-related disability is both individually and contextually dependent, clinicians must also strive for a deep understanding of the *lived experience* of the individual. Furthermore, clinicians must thoroughly understand the myriad of tests available for examining balance and gait. Perhaps most important, the clinician must work with the patient to develop meaningful and realistic goals for rehabilitation. Basing clinical decisions on knowledge from each of these domains can enhance the clinician's ability to choose the right outcome measures for the right patient at the right time. Understanding the relative importance of specific impairments, activity limitations, and participation restrictions identified during the examination enhances the ability to prioritize the plan of care and select specific interventions.

The *Guide to Physical Therapist Practice*[69] describes three categories of balance assessments. They are:

- Balance during functional activities with or without the use of assistive, adaptive, orthotic, protective, supportive, or prosthetic devices or equipment (i.e., ADL or IADL scales, observations)
- Balance (static or dynamic) with or without the use of assistive, adaptive, orthotic, protective, supportive, or prosthetic devices or equipment (i.e., balance scales, dizziness inventories, dynamic posturography, fall scales, motor impairment tests, mobility skill profiles)
- Safety during gait, locomotion, or balance (i.e., confidence scales, diaries, fall scales, logs)

Thus, examination of balance impairment can range from simple to complex.[23,70] Simple, impairment-level clinical measures, such as the ability to maintain a SLS with the eyes closed or the Romberg test, are commonly used in clinics. Measures of activity limitations, such as the Berg Balance Scale (BBS) and Timed Up and Go (TUG) Test, are more commonly used by certified clinical specialists.[71] Additionally, computerized balance testing systems are increasingly incorporated into clinical evaluation and treatment.[72–74]

As stated, balance impairment can arise from many sources. Thus, it is critical that the examination differentiate between biomechanical, motor, sensory, and other contributing causes of imbalance. This is the hallmark of a systems approach to examination. The systems model of postural control and orientation provides the foundation for this discussion regarding examination of balance (Fig 8-2).

It is also imperative that the clinician understand what he/she is testing. Consider the example of the sternal nudge test. The clinician attempts to disturb the patient's balance by trying to push the patient with instructions such as, "don't let me push you over." The patient's response is to tighten all muscles in an attempt to resist the clinician's push. This tests the ability to tighten postural muscles, more so than balance reactions. Further, this test, like the SLS and Romberg tests, is a static test, and tells little about the individual's ability to maintain balance while moving. However, this test may be a relevant indicator of balance control in crowd situations, where a patient may get pushed. Consider what is being tested, what determines a positive test, and how this test would subsequently direct treatment. This highlights the importance of an organized, thoughtful examination process designed to sequentially and specifically test the various systems involved in balance.

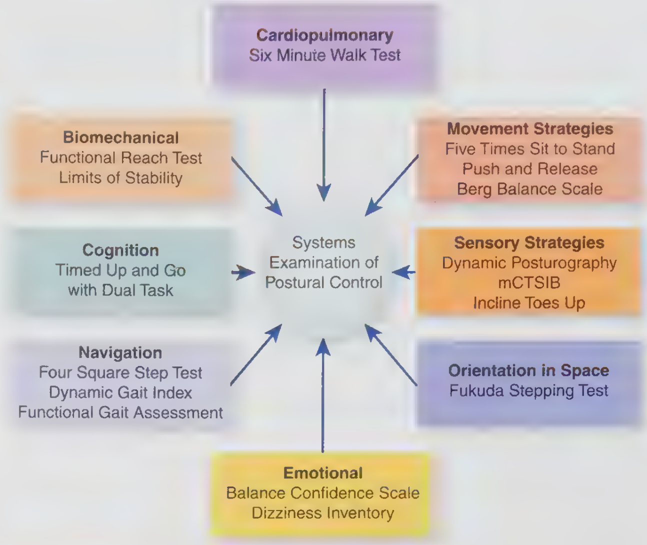

FIGURE 8-7 Examination of postural control from a systems model perspective.

Although most balance measures examine the performance of multiple body systems simultaneously, each assessment tool falls into a primary domain within the systems model (**Fig. 8-7**). The clinician should choose an evaluation battery that taps the multiple aspects of balance control, including musculoskeletal, sensory strategy, movement strategy, dynamic control, cognitive, and affective domains.

Biomechanical Domain

Evaluation of biomechanical causes of imbalance can be readily performed in the clinic. Crutchfield[5] emphasizes the importance of distinguishing among a normal neurologic system working with an abnormal musculoskeletal system, an abnormal neurologic system working with a normal musculoskeletal system, or a combination of both. Joint ROM, muscle length imbalance, impaired muscle performance, pain, or other postural abnormalities (e.g., kyphosis) can contribute to balance impairment. Loss of motion at a joint or series of joints (e.g., ankle, knee, and spine), decreased accessory motion, and muscle length imbalance alter posture and movement strategies. Likewise, muscle impairments such as weakness or loss of endurance alter movement strategies. For example, gluteus medius weakness results in a predictable alteration in gait known as trendelenburg gait. This weakness may prevent normal hip or stepping strategy use. Pain often produces changes in movement that, if continued, can produce secondary strength and mobility impairments. Limited ankle ROM prevents use of an ankle strategy, requiring the patient to use a hip strategy. This may be interpreted as faulty balance, although the hip strategy may be the best strategy available for that individual. Many of these impairments can be assessed using simple clinical measures such as goniometry and manual and functional muscle testing.

The Functional Reach Test (FRT)[75] and tests of stability limits are examples of functional balance measures that can guide clinical decision-making regarding potential biomechanical influences on postural stability. The FRT was originally developed as a performance-based assessment of unsupported dynamic standing balance. This test is performed by observing how far forward an individual can reach while standing. Population-based normative data and/or data regarding risk for falling based on FRT scores are available for the elderly[75] and children.[76] Another version of the FRT provides information regarding the ability of the patient to reach in multiple directions.[77] The FRT requires minimal equipment and time to administer. An individual's stability limits can also be quantified by performance-based scales, use of posture grids, or via computerized technologies utilizing force platforms.

Sensory Strategies Domain

Impairment of the sensory systems can result in balance impairment. Thus, each of the sensory systems contributing to balance control should be addressed. The somatosensory and visual systems may be tested directly. Basic, impairment-level tests of the lower-extremity sensations of light touch, vibration, proprioception, and kinesthesia should be considered. Screening for visual field defects, eye movement control, or sensitivity to visual motion may be pertinent depending on the specific case. The influence of the vestibular system must be tested indirectly and inferred through observing the performance of vestibular outputs, such as the vestibular-ocular reflex and postural stability in sensory-deprived conditions.

Several components of sensory organization (functional utilization of sensory feedback for postural stability) can be tested readily in the clinic; however, a full examination of sensory contributions to postural sway requires more elaborate equipment such as a visual-conflict surround and rotating platform. The Postural Dyscontrol Test or Clinical Test of Sensory Interaction in Balance (CTSIB) provides clinicians with data regarding the individual's use of visual, vestibular, and somatosensory systems in combination and isolation.[14,23] Systematically studying the contributions of each of these systems requires different testing situations, including standing with the eyes open on a fixed platform; standing blindfolded on a fixed platform; sway-referenced vision with fixed support; normal vision with sway-referenced support; absent vision with sway-referenced support; and sway-referenced vision and support[7] (**Fig. 8-8**).

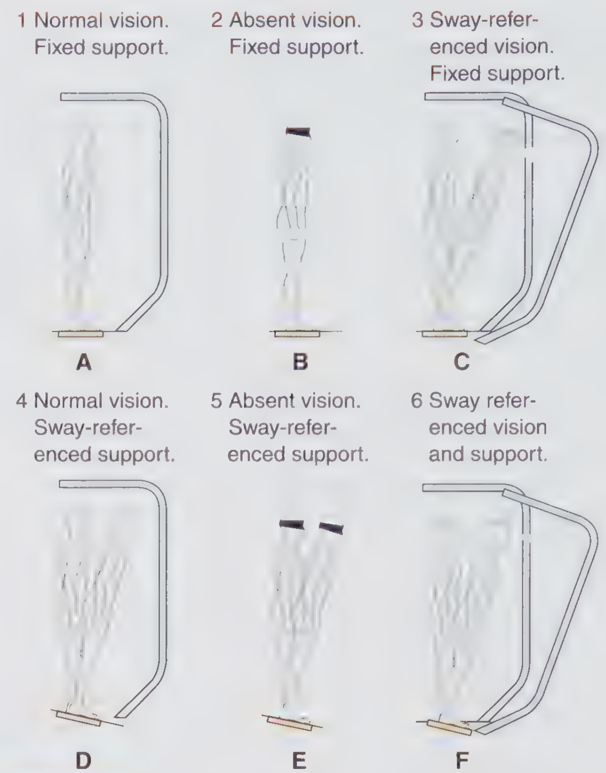

FIGURE 8-8 The six balance testing situations: **(A)** standing quietly, eyes open; **(B)** standing quietly, with eyes closed; **(C)** standing with a visual box, and eyes open; **(D)** standing, and body rotates with body sway; **(E)** standing, rotating platform, with eyes closed; **(F)** standing on a rotating platform with a visual box.

Observation of performance while standing with the eyes open on a fixed surface provides a global view of stability when all sensory modalities are potentially available. Removing vision by closing or blindfolding the eyes provides information on the contribution of the somatosensory system. In the situation with sway-referenced vision with fixed support, the visual box moved as the subject swayed, presenting a sensory conflict: movement took place, but the eyes did not register movement. Joint receptors sensed the movement, but the eyes did not. The vestibular system provided the resolving information, indicating that movement had taken place. During this testing, normal subjects sway very little. The situation of normal vision with sway-referenced support presents a different conflict. In this case, the platform rotates in conjunction with the body sway. The visual system records movement, but the joint receptors do not. Once again, the vestibular system presents the resolving information. Greater sway occurs in this situation than in the previous three situations because of differences in sensory processing times between the somatosensory and other systems. The greatest sway is observed in situations of absent vision with sway-referenced support and of sway-referenced vision and support, for which inaccurate information is furnished from more than one source. Platform rotation provides inaccurate information to the visual and kinesthetic systems in the situation of absent vision with sway-referenced support. The rotating platform and visual box provides inaccurate visual and somatosensory information in the situation of sway-referenced vision and support. These tests suggest that individuals rely primarily on the somatosensory system for orientation and postural control and that, when somatosensory and visual information are removed or inaccurate, the vestibular system is left to provide postural control.[5]

Modified CTSIB (mCTSIB) Test components	Biases which system
Eyes open, firm surface	All sensory systems available
Eyes closed, firm surface	Somatosensory (vision absent)
Eyes open, compliant surface	Vision (impaired somatosensory)
Eyes closed, compliant surface	Vestibular (impaired somatosensory, absent vision)

Cohen et al.[78] developed a streamlined version of the CTSIB. This modified version includes only the following four conditions (see table) This version has been used in adults,[78] children,[79] and patient's with vestibular disorders.[80,81] The test may be performed with or without the patient standing on a force platform. Various ways of describing performance have been proposed, such as using an ordinal scale.[14]

Movement Strategies Domain

Assessing motor organization (movement strategies) in balance control can be conducted within the context of functional task performance inside or outside the context of standardized clinical assessment tools. Simple measures that provide insight regarding use of in-place anticipatory and reactive movement strategies include the FRT (described previously) and the Five-times-sit-to-stand (5×STS) Test.[82] As a measure of upper-extremity reaching ability, the FRT also assesses postural adjustments that anticipate upper-extremity movement.[75,83] In addition to measuring functional lower-extremity strength, the 5×STS also provides a basis for evaluating balance control during transitions when moving between sitting and standing. In this test, the individual is asked to rise to standing and sit back down (without use of the hands) as quickly and safely as possible five times consecutively while being timed. Alternatively, the 30-second Chair Stand Test may be used for patients who are unable to rise from a chair without pushing off the armrests.[84]

Alternatively, the Push and Release Test (PRT) provides information about corrective stepping (change-in-support) responses.[85] As opposed to the sternal nudge or "pull test" in which the individual knows the perturbation is coming, the PRT creates instability by having the patient attempt to maintain stability after being unexpectedly released from a position of gently leaning into the examiners hands. The reliability, sensitivity, and specificity regarding detecting balance impairments with the PRT have been found to be superior to other tests of perturbed stance, such as the sternal nudge.[85] Much information regarding movement strategies can also be gleaned from observing performance on test batteries such as the BBS.[8,13] The BBS rates performance from 0 (unable to perform) to 4 (normal) for 14 different tasks. Each task is performed without using the upper extremities for assistance.

Dynamic Control Domain

None of the measures introduced thus far provide the clinician with the necessary information required to drive clinical decision-making regarding walking-related balance impairments. Insight into a patient's ability to step in multiple directions, a skill necessary for many functional tasks, including obstacle avoidance and navigation in crowded spaces, can be gleaned from the Four Square Step Test (4SST).[86] In the 4SST, the patient is asked to step over four standard canes arranged on the floor in the shape of a "plus sign." The test is timed and the patient must first step over each cane moving in a clockwise manner and then return to the starting position moving counter-clockwise. The TUG Test requires the patient to stand up from sitting in a chair, walk 3 meters, turn around, return to the chair, and sit again.[23,87] The reliability of this test is high, and it correlates well with the BBS.[88] The Dynamic Gait Index (DGI) is a measure of dynamic balance as it measures the patient's ability to modify gait in response to changing task demands.[23,89] The DGI has been shown to have good interrater and test–retest reliability.[23] Two major alternatives to the original DGI now exist. Wrisley and colleagues[90] expanded this test and created the Functional Gait Assessment (FGA) in part in an attempt to capture information regarding balance control in patients with high-level problems. Preliminary normative data for the FGA now exist.[91] Alternatively, Marchetti and Whitney[92] found that a four-item version of the DGI could provide accurate information about faller status with comparable sensitivity and specificity to the original DGI. The scoring system for the original DGI was recently expanded to account for additional factors that affect performance, such as the time required to complete tasks.[93] In order to evaluate higher-level skills, such as running, jumping, hopping, and skipping, clinician's may use the High-level Mobility Assessment Tool (HiMAT).[94,95] This tool was developed for use with patients status-post traumatic brain injury.

Cognitive Domain

The TUG Test has been modified to include the simultaneous performance of a secondary cognitive task.[39] Repeating the TUG Test in this manner allows the clinician to gather information regarding the influence of divided attention on balance control during walking. Careful consideration should be given to which secondary cognitive task the patient is asked to perform. Patients should be allowed to practice a similar cognitive task before engaging in timed walking. The details of the task, as well as the impact on walking performance and cognition should be documented clearly.

Affective Domain

Self-confidence related to balance and perception of disability secondary to dizziness represent two important affective influences on balance and mobility. The Activities-Specific Balance Confidence (ABC)Scale consists of 16 questions for which patient's are asked to rate their level of confidence that they will not lose their balance or fall while performing.[96] Average scores of less than 80% are considered abnormal and less than 50% have been correlated with a greater likelihood of being home bound.[96] The Dizziness Handicap Inventory (DHI) is an assessment tool used to gauge self-perceived disability related to dizziness.[97] The DHI consists of 25 questions divided between physical, functional, and emotional subscales. Scores range from 0 to 100, with higher scores indicating greater disability. The degree of disability has been correlated with functional balance measures[44,98] and prognosis for recovery.[43] Each of these questionnaires also provides insight into the patient's lived experience of their health condition (see **Building Block 8-4**).

BUILDING BLOCK 8-4

A 30 year-old previously healthy man is referred to physical therapy in the hospital two days after undergoing surgical resection of a vestibular schwannoma. The patient complains of vertigo, blurred vision, and feeling like he is intoxicated. He reports he has had difficulty walking to the bathroom with the nursing staff. What are the two tests of postural control that you would prioritize to be completed during the initial evaluation that could be used subsequently in the outpatient setting as outcome measures for this patient's rehabilitation? Why did you choose these tests?

Determining Risk for Falling

What is the likelihood that my patient will fall? This is one of the most important questions clinicians must answer. The ability to accurately answer this question has profound implications. Researchers and clinicians use each of the clinical tests of balance mentioned above to provide clues as to a person's risk for falling. The 5×STS Test, PRT, FRT, 4SST, BBS, Tinetti's balance and mobility assessment, TUG Test, and DGI are used frequently in the clinic to stratify risk for falling.[8,13,75,89] The cutoff score associated with falls risk may vary by age. For example, the cutoff score for the 5×STS was found to be 10 seconds for those under 60 years and 14.2 seconds for those over 60 years in a population of adults with balance disorders.[99] Cutoff scores may also vary by population. For example, a score of 15 seconds or longer on the 4SST identifies older adults with a history of multiple falls;[86] however, scores of 12 seconds or longer provide the same indication of prior falls status in persons with vestibular disorders.[100] Older adults who scored higher on the BBS were less likely to fall than those who scored below 45 out of the possible 56 points.[89,101] Different cutoff scores for the BBS are applied to individuals with Parkinson's disease[102] or those who are status-post traumatic brain injury[103] or stroke.[104] Like the BBS, the DGI can be used to determine falls status. Scores of less than 20 on the DGI indicate an increased association with previous falls, whereas scores of less than 17 are highly associated with prior falls status.[23] Likewise, individuals with vestibular disorders who score less than 19 on the DGI are 2.7 times more likely to have reported a fall in the previous 6 months.[105] Though performance indicators for the BBS and DGI have also been shown to vary by population and living arrangements, the BBS and DGI have been shown to agree 63% of the time for individuals with vestibular disorders.[83,106] It is critical that the clinician be mindful or *who* they are evaluating and *how* they are applying the information gathered. Further information regarding the psychometric properties, population-specific normative data, and/or cutoff scores related to falls risk for many of the assessment tools described in this text may be found online at thePoint.lww.com/BrodyHall4e.

Accurately diagnosing risk for falls is a complex and challenging task. This is due in part to the fact that most published indicators of falls risk only correlate with a person's recent history of falling. Predicting *future* falls requires careful analysis.[102,107,108] Currently, the best predictor of future falls is a history of previous falls.

Balance measures that look at the activity domain incorporate many of the impairment tests discussed above. The challenge for clinicians is to choose measures that will capture the difficulty and predict return to safe activities. The falls risk measures above cross multiple levels of activity. The BBS predicts fall risk as it relates to static and transitional movements. However, a ceiling effect is seen when looking at the person who needs to have dynamic balance during gait, or for the athlete who wants to return to sport. Measures such as the Star Excursion Balance Test (SEBT) have been shown to be sensitive to predict risk for injury as well as to measure recovery from injury.[109] The goal of the SEBT is to maintain single-limb balance while reaching with the contralateral limb in eight different directions.

Consider Jerry, a 19-year-old student who sustained a traumatic brain injury when he was struck by a car while riding his scooter without a helmet. In the acute hospital, while he was still confused and showing mild right hemiplegia, the BBS was useful to determine fall risk in his room. As he progressed in inpatient rehabilitation, Jerry was more mobile and ambulating with close supervision in part because he was not attending to the environment. Although he scored a 52/56 on the BBS (low risk), he only scored an 18/24 on the DGI as he tripped over objects, lost his balance when walking with head turns, and was inconsistent and tripped on the stairs. By the time Jerry reached the outpatient setting, he was walking independently on level surfaces, but movements were slow. Now the DGI score was 23/24, but his HiMAT score, a test that included running, skipping, hopping, and bounding was impaired. In addition, when the BESTest was administered, it suggested Jerry had specific balance impairments including sensory integration and dual-task activities. The acuity and setting must be considered when choosing the most appropriate balance measures.

Activity level is also important when choosing a balance measure. Remember Megan, the 12-year-old who had injured her ACL in Case Study No. 6, Unit 7. By 4 weeks post-ACL injury, she was walking independently without a device. One of her goals was to return to volleyball and tennis. In this case, the therapist used the Y-Balance Test (YBT) to look at Megan's balance. The YBT is derived from the SEBT and is a tool to test a person's risk for injury. The patient does repeated lower extremity reaching anteriorly, posterior medially, and posterior laterally with each leg. Different cut points exist for the YBT based on age, gender, and sport/activity level. In Megan's case, she had a significant 8 cm asymmetry between her involved and uninvolved leg during anterior reach, and her composite reach distance was only 84% of her limb length. These findings suggest a high risk of injury if she tried to return to sport at this time.[109] Interestingly, if the therapist had chosen the Berg, Megan would have scored 56/56, and on the DGI she would have scored a 23/24.

TREATING IMPAIRED BALANCE

Diagnosis and Prioritization

The most important factor in treating balance and mobility impairments is diagnosing the underlying cause(s) and the factors contributing to these impairments. Remember that balance problems can result from biomechanical, neuromuscular, sensory, cognitive, or affective impairments. These impairments may be considered primary (a direct result of a health condition) or secondary (occurring in response to the development of primary impairments). Matching intervention strategies to underlying impairments is critical. Impairments related to muscle performance, mobility, or pain should be addressed early in the rehabilitation process, with ongoing re-evaluation and interventions for continued balance impairment as the fundamental musculoskeletal problems resolve. Chapters 5, 7, and 10 provide specific activities to treat these impairments. If the problem involves motor learning, then it would be considered a modulator element. Modulator elements are addressed throughout the plan of care. Additional modifying factors, such as the need for psychological interventions or cardiac rehabilitation, may need to be addressed early and incorporated into the plan of care as well. For example, consider those with a primary problem of fear of falling. The impaired element of the movement system is within affective domain. A health psychologist or licensed counselor can assist the patient in developing the relaxation strategies needed in order for her to face her fear of falling and engage in the risks associated with balance rehabilitation. Often, the physical therapist works in collaboration with other professionals whose expertise would benefit the patient, but may be less familiar with balance disorders.

Customization

There is strong evidence to support prescription of an individualized intervention program for balance retraining. The treatment suggestions described below must be matched to specific underlying problems for each patient (see **Evidence and Research 8-3**).

EVIDENCE and RESEARCH 8-3

Evidence supports individualized intervention program for balance retraining:

- Rehabilitation that includes balance training results in improved balance[110] and greater success in return to play in athletes.[111]
- Customized balance rehabilitation is more effective than generic exercise programs for reducing dizziness and improving balance in individuals with vestibular disorders.[112]
- Customized, multidimensional exercise programs also improve balance and mobility and reduce falls in geriatric populations.[113]

Environmental Context

Rehabilitation takes place in an environmental context. There are three major factors to consider regarding the influence of the environment on balance rehabilitation:

- The physical location
- Appropriate safety measures
- Specific environmental features to be manipulated during task practice.

The physical location for balance training depends on the patient's situation. For the frail elderly or those with significant balance impairment, most training activities should take place in the clinic. Patients with higher baseline balance abilities and/or self-efficacy related to balance training or sufficient assistance at home will perform the majority of their training at home. Alternatively, patients who are ready to transition out of formal therapy may desire to include more challenging, balance-specific activities, such as T'ai Chi, yoga, and dance into their routine health and wellness program. Recommendations of community-based programs that are appropriate for his/her needs and abilities may be a part of a successful plan of care. For athletes or other active individuals, balance activities may be carried out independently at home, at a local health club, or in a local pool.

Safety is a key factor when making choices about the exercise environment. A stable support should always be available for regaining balance. This support should be placed such that it does not interfere with the exercise and does not cause injury during an attempt to regain balance. Be alert for correct posture, avoidance of substitution, proper performance, and safety when providing direct interventions. Foster the patient's self-awareness and error detection and correction. Simple activities such as postural awareness exercises may be performed safely at home by most patients. Realize that the clinic environment is designed for maximum patient safety and may not reflect real-world situations. Recommendations to perform exercises in a corner, narrow hallway, nearby sturdy furniture, or with various forms of assistance may be appropriate.

The environment has a significant impact on patients and the choices they make regarding mobility. Factors such as distance, temporal demands, physical load, ambient conditions, attentional demands, terrain, frequency of postural transitions, and traffic density are examples of key environmental variables.[42] Distance refers to how far the individual must walk to complete each trip outside their home. Temporal demands include factors such as crowd speed, traffic lights, and amount of vehicular traffic. Precipitation, temperature, and available light are examples of factors related to the ambient conditions. Whether or not the individual must carry a load, such as a purse or grocery bags, relates to the required additional physical demands of each trip. Relevant features of the terrain may include the presence of grades, curbs, stairs, uneven surfaces (grass), shifting surfaces (gravel), and moving surfaces (elevators and escalators). Factors such as presence of distractions or being accompanied by a spouse, partner, or friend are examples that alter the attentional demands of mobility. Even the occurrence of postural transitions such as the need to stop, start, turn, back up, and reach may influence choices about mobility. Individuals with mobility-related disability encounter fewer challenges and show avoidance behaviors with regard to temporal factors, physical load, terrain, and postural transitions.[42] The salience of these factors is unique to the individual.[114] This is another aspect of rehabilitation that should be customized for each patient.

Whether exercising indoors or outdoors, a multitude of external environmental conditions may overload the sensory systems, increasing the risk of a fall. Be sure to progress the patient to balance training in the types of environments they will encounter when they leave the clinic. This may require short "field trips" outside the clinic to reproduce these situations. If real-world experience is not possible, consider the use of photographs, video tape, virtual reality, or gaming to facilitate discussion, mental rehearsal, or simulated practice of specific functional tasks within meaningful environmental contexts.

Mode

A variety of modes, such as supportive chair, therapeutic ball, firm floor, foam roll, foam pad, balance board, or pool, may be used during treatment. The pool is a unique environment to train balance. The water's movement causes perturbations, and the water's viscosity slows balance loss, giving individuals more time to respond (see Selected Intervention 16-3 in Chapter 16). A warm water pool may be an especially good mode for rehabilitating balance in persons with severe arthritis. Balance skills learned in an aquatic environment may not readily transfer to land because of the differences in environmental conditions. Thus, land-based training should be recommended when the patient is ready. More sophisticated, computerized balance testing devices also provide unique opportunities for training. In fact, any mode used for testing balance can be used for training. One of the primary advantages of commercially available balance platforms is that they allow selective modulation of sensory systems and objective measures of progression.

Motor Learning

If a movement is performed repeatedly with sufficient sensory feedback, motor learning occurs and a pattern is formed that guides future performance of the motor program.[16,89]

Although the ankle, hip, and stepping strategies are examples of feedback control, these responses are controlled by motor programs that are pre-programmed collections of motor signals with a goal of achieving a specific task. In the case of restoring balance, sensorimotor experiences related to the goal of repeatedly aligning the COM over the BOS lead to development of pre-programmed, balance strategy, motor programs consisting of collections of motor signals with a goal of achieving a specific postural task. Each motor program contains specific information about *postural set* and the sequencing and timing of muscle activation. If a movement is performed repeatedly with sufficient sensory feedback, motor learning occurs and a pattern is formed that guides future performance of the motor program.[16,89]

Several models of motor learning exist in the literature. Fitts and Posner[115] proposed that the learner passes through three stages when mastering a new skill. Consider learning a new task such as playing the piano or learning to swim. The first phase is *cognitive*, in which full attention to instructions, the task, and performance feedback is necessary to develop gross problem-solving strategies. Performance during this phase is marked by a larger number of large errors, extreme variability, and little insight regarding how to improve.[116] The rehabilitation professional plays a critical role in this stage of learning balance control by working with the individual to select the appropriate tasks to be mastered, providing effective instruction, and guiding the individual with appropriate external feedback. The second phase is *associative*, in which further development and refinement of the movement strategies and acquisition of the ability to detect and identify one's own performance errors occur.[116] The movement patterns become more efficient, although still requiring attention to the task. The goal of training is to get the learner to the *autonomous* (third) stage so that the movement can occur with little thought. The ability to balance while coordinating other physical and cognitive activities is an example of functioning at the autonomous stage and is the penultimate goal of rehabilitation.

Factors such as the quality of instruction and practice, as well as the amount of practice, influence whether or not a person reaches the autonomous stage of motor learning. Continued practice alone may not move the patient toward this stage. The early phase of training a new skill requires feedback. Learning relies on intrinsic and extrinsic cues to refine the movement program. As the process moves toward the autonomous level, more feedback should become intrinsic. Thus, the learner should be encouraged to develop her own internal problem-solving skills. Consider learning to drive from home to work in a new city. In the early stage, concentration on the task is required, and the individual can be overwhelmed with sensory information (e.g., other cars, signal lights, and commercial signs). As driving this path is repeated, less attention to the task is required, until the drive eventually becomes automatic. Extraneous sensory information can be filtered out and only pertinent information processed. In most situations, repeating the pattern facilitates progression to the automatic stage. However, the patient must continue to learn and adapt to new situations. Continued exposure to new situations such as driving in unfamiliar areas teaches the nervous system how to learn or adapt quickly and effectively to new stimuli and situations.

The same learning process is applied to balance activities. As balancing on a single leg or on a balance board becomes easy, less attention is necessary, and the task becomes automatic. The nervous system must be challenged at a new level. This can be done by changing the surface, BOS, external perturbation, or visual or vestibular input (see Self-Management 21-1 in Chapter 21). Continued practice at grossly similar but continuously changing tasks can enhance the patient's ability to adapt to new situations. Exactly which tasks are practiced and which treatment variables are manipulated by the clinician depend on the unique balance impairments of the individual, as they relate to her function in daily life (see **Building Block 8-5**).

BUILDING BLOCK 8-5

Consider again your patient with MS and how her cognitive impairments may affect her rehabilitation. What strategies would you use to increase the likelihood of compliance with a home exercise program and a successful treatment outcome?

Intervention Strategies for Specific Systems—Examples

The following sections contain specific examples of interventions categorized under some of the primary subsystems supporting postural control. However, the same type of complexity represented in the model of normal balance function presented earlier also characterizes most, if not all, exercises prescribed as part of a balance rehabilitation program. Though a specific exercise (e.g., slow weight shifts on a non-compliant surface) may be prescribed for a primary purpose (e.g., retraining the ankle strategy), performance of this exercise requires the individual to draw on many other balance-related resources. Therefore, it is important to bear in mind the various biomechanical, sensory, neuromuscular, cognitive, and affective requirements for each exercise prescribed. This type of task analysis allows the clinician to use exercises for more than one purpose or to make relatively simple modifications to alter the intent or difficulty of a given exercise.

Developing Orientation in Space

Because stability generally precedes mobility, some patients need to begin by working on maintenance of static postural alignment. Use a stable surface such as a hard floor or rigid chair for initiating sitting, kneeling, standing, and single-leg standing. These body postures can be used to facilitate postural orientation and stabilization. Kinesiologic factors, such as achieving and maintaining proper COM alignment and control, as well as learning factors, such as internalization of balance strategies, provide the structural framework for the treatment postures chosen.

Utilize force platforms, scales, mirrors, or tape markings placed vertically on clothing while standing in front of a mirror to train the patient to distribute weight equally on each lower extremity and/or align his/her body posture correctly. However, it is worth noting that patients with visual-perceptual impairments may find working in front of a mirror confusing. For those needing work on core trunk stability first, training may be initiated in a sitting position, which provides an opportunity to develop a sense of trunk posture and equity of weight bearing while sitting. Train sitting balance, trunk stability, and weight distribution on a chair, table, or therapeutic ball (see **Self-Managements 8-1**, **8-2**, and **8-3** and **Fig. 8-9**). Use a variety of arm positions, such as forward or lateral reaching, to change the postural challenge. Utilization of an unstable surface such as a therapeutic ball further challenges balance. Static postures also may be used in combination with foam surfaces to alter the challenge to the patient. Keep in mind that unstable and foam surfaces will alter the sensory demands of this task.

More challenging static postures, such as standing heel to toe or a SLS, should be included when the patient is ready. These postures minimize ankle strategy use and facilitate a hip synergy. Training

SELF-MANAGEMENT 8-1
Minitrampoline Balance

Purpose: To improve stability in SLS.

Movement Technique: Level I: While standing on the minitramp with a stable object at hand, practice standing on one leg. Make sure that your knee is slightly bent. Use the stable object for balance only if necessary.

Level II: Close your eyes.

Level III: Perform repeated minisquats.

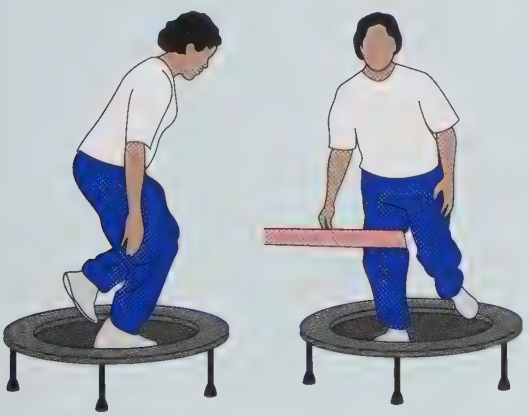
Level IV: Add resistance to the knee.

Level V: Add movement to the arms.

Dosage:

Repetitions: ______________________

Frequency: ______________________



SELF-MANAGEMENT 8-2
Sitting Balance on a Stable Surface

Purpose: To increase awareness of and expand stability limits.

Movement Technique: While sitting on a stable surface such as a chair, practice reaching forward, overhead, and to the side. You may you look in the direction you are reaching or in a different direction, as recommended by your therapist.

Dosage:

Repetitions: ______________________

Frequency: ______________________

SELF-MANAGEMENT 8-3
Sitting Balance on an Unstable Surface

Purpose: To increase postural stability and trunk balance.

Movement Technique: While sitting on the therapeutic ball, practice reaching forward, overhead, and to the side. You may look in the direction you are reaching or in a different direction, as recommended by your therapist.

Dosage:

Repetitions: ______________________

Frequency: ______________________

balance in altered stance positions is functionally relevant to tasks such as lower-body dressing. For the athlete, postures encountered in sport should be duplicated and systematically challenged in the clinic. Lunge positions, SLS with a variety of trunk postures, and squat positions are commonly encountered in sport.

After stability and optimal posture are achieved in static positions, dynamic movement should be superimposed on the activity (see **Selected Intervention 8-1**). Adding dynamic movement increases use of automatic postural adjustments during the preparation for movement and reactive strategies to counteract perturbations of the COM (see **Building Block 8-6**).

BUILDING BLOCK 8-6

How might you conduct retraining of orientation to vertical posture in standing for an outpatient who has moderate left-sided hemiparesis status-post right middle cerebral artery stroke and is not able to stand unsupported?

Retraining Movement Strategies

A variety of movement patterns superimposed on stable postures can increase the balance challenge and encourage development of both reactive and proactive balance strategies. Adding anteroposterior and lateral sway assists the patient in determining and increasing his/her stability limits. A variety of modes (e.g., supportive chair, therapeutic ball, firm floor, foam roll, foam pad, balance board, pool) and postures (e.g., sitting, half kneeling, tall kneeling, standing, SLS) using varying arm postures and/or movements may be used. Customize the intervention by selecting the mode and posture that provides the most appropriate combination of safety, functional relevance, and postural challenge for each patient. Trunk rotations with the arms in a variety of positions (e.g., abducted, forward flexed, arms across chest) with changes in head position (e.g., rotated, laterally flexed) to alter vestibular input can be combined in a multitude of ways. Proprioceptive neuromuscular facilitation (PNF) techniques in trunk rotation, called chops and lifts, are excellent dynamic movement patterns. These patterns include arm, trunk, and head rotation, flexion, and extension (see Chapter 15) (**Fig. 8-10**).

SELECTED INTERVENTION 8-1

Single-Leg Balance on a Foam Roller

ACTIVITY: Single-leg balance on foam roller with added dynamic activity

PURPOSE: To increase stability limits and dynamic balance

PRECAUTIONS: Patient safety: ensure readiness for activity and safeguards in case of balance loss; adequate trunk control

POSTURE: Standing on a foam roller with dynamic control of head, spine, and lower-extremity posture

MOVEMENT: Maintain balance while moving a ball into a variety of positions or while playing catch with ball

PROCEDURE: Isometric, concentric, and eccentric muscle contractions of the spine extensors, flexors, and abdominal oblique muscles. The closed-chain nature of the activity will produce cocontraction of lower-extremity musculature including, but not limited to the gastroc-soleus, quadriceps, hamstrings, and gluteal muscles.

DOSAGE: Three to six sets of 30-second intervals

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: A variety of single-leg instability situations are encountered in sports. The individual learns to control posture through core muscle contraction while performing a dynamic activity on an unstable surface.

For patients who need to train an ankle synergy, begin with weight shifts on a firm surface, with gradually increasing sway. Training of the ankle strategy is facilitated when the individual is asked to maintain balance on any surface that is wide, non-compliant, or stable; when slow balance reactions are required; or when the COM is far from the LOS. Using rehabilitation balls, foam rollers, and foam surfaces provides uneven or unstable surfaces and encourages a shift toward use of proximal muscles for balance control (**Figs. 8-11** and **8-12**). More challenging

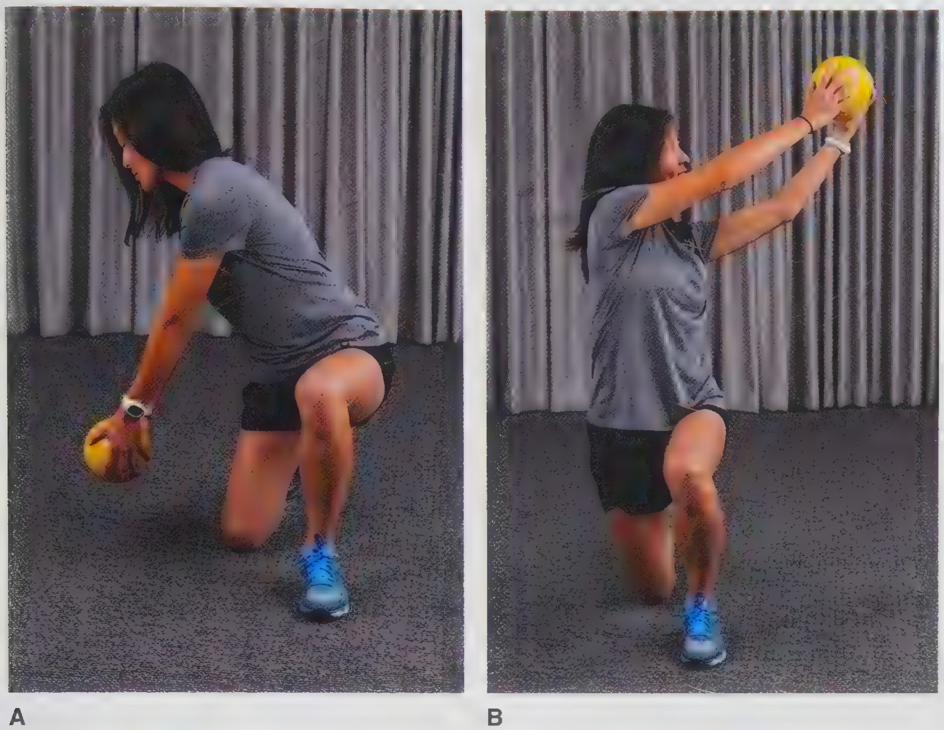

FIGURE 8-10 PNFs of chop and lift in half-kneeling position: **(A)** starting position and **(B)** ending position.

FIGURE 8-11 Foam rollers are used in bilateral stance when the person practices weight shifting while catching a ball.

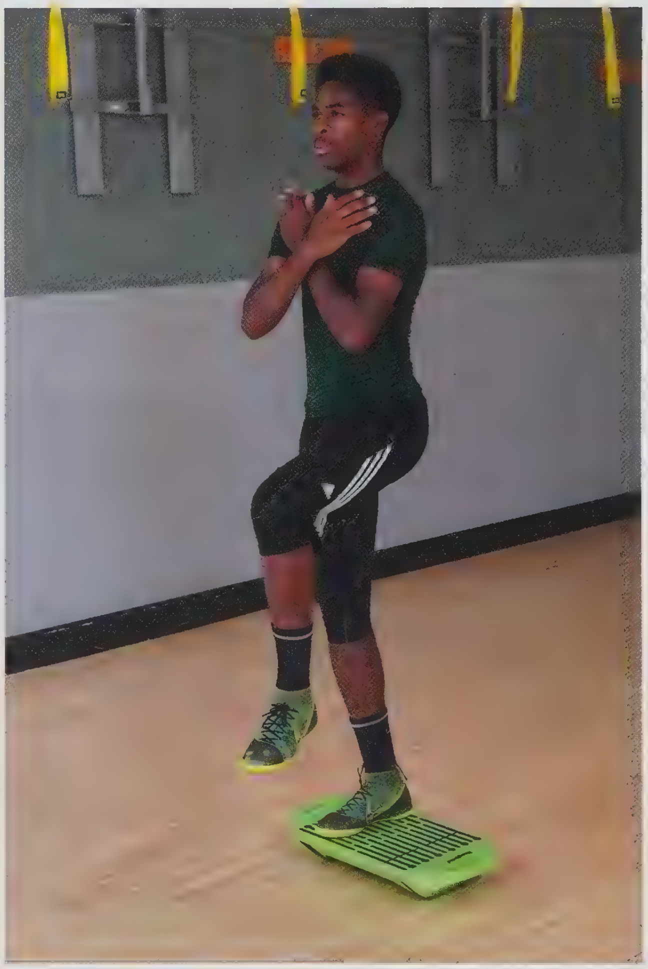

FIGURE 8-12 T'ai Chi exercise to improve single leg balance

FIGURE 8-13 **(A)** Single leg balance on an unstable surface. **(B)** Adding a soccer ball to drill activities increases the challenge.

surfaces such as a minitrampoline can also provide a variety of balance experiences that emphasize use of proximal musculature (see Self-Management 8-1). Modifying this simple task in these ways also alters the environmental demands and sensory feedback available for controlling balance and prepares the individual to face real-world challenges.

Balance beams, lines drawn on the floor, and balance boards are often used for balance training (**Fig. 8-13**). These intervention strategies are particularly useful for patients needing to train a hip synergy, as they prevent the use of an ankle synergy as a substitute. Training of the hip strategy is encouraged when the individual is asked to maintain balance on any surface that is narrow, compliant, or unstable; when rapid balance reactions are required; or when the COM is near the LOS.

Maki[31] suggests that training includes mimicking the varied and unpredictable events that precipitate falls in the elderly and that activities include not only COM displacements but also BOS compensatory movements. Thus, activities that require a change in BOS using stepping and reaching strategies should also be considered. Stepping exercises such as lunges provide an opportunity to control balance as the client first moves outside the stability limit and then restabilizes when his/her foot hits the ground. Starting with small steps and progressing to full lunges (**Fig. 8-14**) increasingly

FIGURE 8-14 **(A)** Minilunges are progressed to **(B)** full lunges.

FIGURE 8-15 Catching a ball in a variety of situations increases task complexity: **(A)** on an unstable foam, **(B)** combined with lateral lunges, and **(C)** moving to a specified spot on the floor in response to a verbal command.

challenges the patient. Adding a concurrent arm activity can further challenge balance. For example, reciprocally swinging the arms during stepping can make the task easier, but performing a PNF chop or catching a ball can make it more difficult (**Fig. 8-15**). Completely eliminating the arms for balance by holding them across the chest or overhead can make the exercise extremely difficult for a person with poor trunk and hip stability.

More advanced balance exercises include hopping, skipping, carioka, slide board, and rope jumping (see **Self-Management 8-4**). Perform these exercises in a variety of patterns, with exaggerated step length or knee lift. Many can be performed backward, with a variety of step techniques incorporated. The "hop and stop" can be performed on a firm surface or a soft surface such as foam or minitramp (**Fig. 8-16**). The patient is asked to hop single or double footed and to "stick" the landing without losing balance. Exercise equipment such as a stepper can also challenge balance if performed without hand support, backward, or with the eyes closed. Closing the eyes assists in emphasizing the use of somatosensory and vestibular feedback control of balance. For athletes, reproducing movement patterns found in their sports can prepare them for the return to activity. Many traditional sports drills can be modified for use in a clinical setting. Changing the speed of the stepping exercise to approximate functional speeds is essential to the movement strategy. These challenging tasks have elements of proactive and reactive dynamic balance. Consider which aspects to emphasize for each individual.

As mentioned previously, the pool provides an interesting and dynamic environment. The viscosity and movement of the water constantly challenge posture and balance. Any arm or leg movement can potentially disrupt the patient's balance. For example, performing bilateral shoulder horizontal adduction and abduction results in posterior and anterior displacement of the body, respectively. Perform this exercise with the feet in stride, in normal stance, in a narrowed stance, or in SLS for progressively increasing difficulty (see **Self-Management 8-5**). The increased unpredictability experienced in the water may help prepare the individual for changing environmental conditions in the real world (see **Building Block 8-7**).

SELF-MANAGEMENT 8-4
Slide Board

Purpose: To increase balance and coordination during a functional activity.

Movement Technique:
Level I: Laterally glide on a slide board.
Level II: Continuously catch and toss a ball.
Level III: Increase speed.
Level IV: Increase the number of balls tossed.

Dosage:

Repetitions: ____________

Frequency: ____________

SELF-MANAGEMENT 8-5
Shoulder Level Claps in the Pool

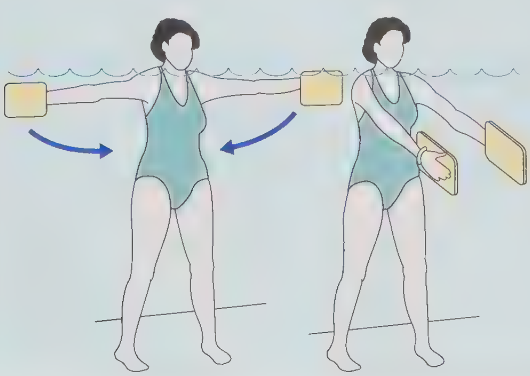
Purpose: To increase upper back and chest strength and to challenge balance.

Movement Technique: Level I: While standing in good postural alignment with your arms to the side at shoulder level, bring them forward and back to the starting position.
Level II: Bring your feet closer together.
Level III: Stand on a single leg.
Level IV: Close your eyes.
Level V: Add resistance to the hands.

Dosage:

Repetitions: ______________________

Frequency: ______________________



BUILDING BLOCK 8-7

List several ADL that require use of an ankle strategy that could be used as functional task practice in rehabilitation for a 52-year-old man who is in the chronic phase of recovery following an acute ankle sprain sustained while playing in a weekend basketball league. The patient is ferry boat operator and must stand for long periods of time. Choose the ideal mode of exercise and several exercises for retraining the hip strategy for a 60-year-old, morbidly obese woman, status post right total hip replacement. Explain your rationale. She is 2 months post-op and has minimal discomfort in the right hip. Her gait is antalgic, and she continues to use cane, and rates her osteoarthritic pain in the left hip and knee at 8/10 while walking.

Facilitating Sensory Strategies

Awareness of posture and the position of the body in space are fundamental to balance training. Jeka[117] demonstrated that the use of light touch through a cane or balance aid enhances the use of somatosensory and can reduce postural sway. Compensatory strategies such as this can be used to increase spatial awareness, as well as facilitate performance and minimize the fear and anxiety sometimes associated with balance retraining.

There are many ways to facilitate relearning sensory strategies. As noted above, the environmental characteristics, such as the support surface, can be altered to change the mode of balance exercise. Understanding how to manipulate the surface or other environmental cues is critical to providing the appropriate sensory context in which patients practice. To that end, patients should be trained in situations that enhance the nervous system's ability to attend to specific types of feedback.

Patients who need to develop effective use of somatosensory feedback for balance control begin activities with the eyes closed on a stable surface. Attention to surface cues can be enhanced by having the individual perform exercises with her shoes off, while standing on a textured surface, or by using knobby insoles in the shoes. If the ability to use existing visual cues effectively for maintaining stability is compromised, training the patient on a compliant or unstable surface with the eyes open and fixed on or attending to visual references in the environment is appropriate. Attention to visual cues can be enhanced by asking the individual to fixate gaze on a stationary target less than 5 feet away or by performing the task near a doorway or other distinct cues of vertical alignment. Alternatively, patients with difficulty using vestibular feedback about head position and acceleration should be trained on compliant or unstable surfaces with their eyes closed in order to force the nervous system to attend to vestibular inputs. The challenge to use vestibular cues for balance is increased by adding varied static head positions, active rotations, or tilts. Use caution with these activities for persons with vestibular disorders as these activities may cause dizziness. Real-world environments often present patients with confusing and conflicting sensory information. Thus, patients also need training in how to resolve conflicting inputs. For example, patients may need to learn how to balance when standing still in an environment with overwhelming motion of the crowd, lighting, or displays. Partially distorting or obscuring vision may also help encourage patients to resolve sensory conflicts. Whether or not these specific sensory manipulations are included in the plan of care depends in large part on the underlying impairments and the patient's prognosis for functional recovery. Thus, understanding the expectations for recovery of function as they relate to the patient's health condition and their response to its influence on their life is critical to effective treatment planning (see **Building Block 8-8**).

BUILDING BLOCK 8-8

What parameters or variables would likely manipulate when re-training sensory strategies for a 57-year-old woman with diabetes mellitus and associated peripheral neuropathy (diminished vibratory sensation below the ankles bilaterally) and retinopathy (legally blind in both eyes)?

Sequencing Considerations

Progression of exercise from simple to complex involves creating increasingly more challenging tasks for the individual to practice in meaningful environmental contexts. Variables related to the individual body systems contributing to balance control, characteristics of the environment, and task setup can be sequentially and systematically manipulated to develop and progress a customized intervention program. Remember, there are complex relationships between each of these domains. Thus, manipulation of one variable in any given domain has broad implications.

Task Variables

Appropriate sequencing related to postural demands involves progression from stable postures (e.g., sitting) to more unstable postures (e.g., SLS). Spatial characteristics such as the distance traveled with each step while side stepping or the amplitude of arm movements produced while performing single-limb stance should be considered. Generally, patients are progressed by increasing step length or the amount of reach. Temporal factors such as the velocity of movement and the time allowed to complete a series of movements can be used to influence performance. Patients may progress from slow movement to attempting to control ballistic movements while maintaining a particular posture. Encouraging increased speed is easily accomplished by decreasing the time allowed to complete a block of practice. Whether or not the patient is asked to manage a physical load or simultaneously manipulate an object in the hand while maintaining stability is another consideration. The patient may begin by practicing walking on a level surface and eventually progress to walking while carrying a full glass of water or a large bag of groceries. Other task-related variables include the frequency, intensity, and schedule for practice. Patients progress from less to more frequent practice, fewer to greater repetitions, and blocked to random practice in order to address variables such as managing fatigue, encouraging motor learning, and developing greater motor control.

Individual Variables

The individual body systems that contribute to balance control can also be manipulated to create appropriate challenges and facilitate progress. As stated, base element problems related to the biomechanical system should be addressed early. Cognitive factors should be considered in all cases regardless of age or condition because many real-world activities are frequently performed under dual-task conditions. Training should begin with intense concentration and minimal cognitive distractions. Progression related to cognitive demands may involve having the individual perform a simultaneous cognitive task that requires listening, comprehension, mathematics, problem solving, etc. The patient's emotional engagement in training in terms of self-efficacy and their level of anxiety are additional considerations. Some individuals may need to practice deep breathing or other relaxation strategies in conjunction with task practice. As an indicator of self-efficacy, the patient should be encouraged to perform exercises that he/she is at least 70% to 80% confident in his/her ability to safely exercise at home.

Facilitation of movement strategies as described earlier is often a critical component. The training plan should emphasize mastery of the appropriate use of in-place, automatic postural reactions for control of quiet stance before activities that involve executing change in BOS strategies, such as stepping correction responses. In terms of in-place responses, because the ankle strategy dominates stance control, this strategy should be addressed before impairments in the use of the hip strategy. To accomplish this, start in standing with simple sway activities that elicit an ankle strategy. Reinforce this strategy by verbal or tactile cuing and ensuring proper posture and firing patterns to prepare the patient for larger perturbations. Encourage the patient to gradually increase the stability limits by reaching or swaying farther. Progress the exercise by applying greater disruptions of the COM in order to elicit a hip strategy or a stepping strategy. After these responses are established, progress to more dynamic activities, unstable surfaces, and complex movement patterns. Additional critical variables involve the timing and scaling of these responses. Surface characteristics play major roles in movement strategy retraining as well. Progression is accomplished by increasing movement velocity and/or altering the surface.

Finally, sequencing training for appropriate use of sensory feedback for balance control described earlier should be considered. Generally, patients should be encouraged to perform exercises with all three major forms of sensory feedback available before progressing to practice in environments with complex sensory conflicts. The use of somatosensory feedback should be encouraged by simply having the patient close his/her eyes while practicing on a stable surface. Retraining the use of vision can be facilitated by having the patient practice on an unstable surface with his/her eyes open while fixating his/her gaze on a stable target nearby. Practice emphasizing the use of vestibular feedback by balancing with the eyes closed on an unstable or compliant surface. The dual sensory conflict created by practicing on an unstable surface while being exposed to visual feedback that is out of sync with his/her postural sway is the most challenging practice condition. For example, retraining the ability to maintain dynamic stability while skating forward on one foot, while simultaneously trying to control a moving hockey puck, as teammates and defenders streak passed one's peripheral vision is a daunting task for an athlete. Similarly, attempting to walk through a crowded outdoor marketplace, over uneven sidewalk tiles, while carrying a purse and bag full of purchases may be equally daunting for an elderly person.

Environmental Variables

The terrain is one of the most commonly manipulated environmental variables. Not only can changing the terrain increase the level of difficulty, but, as we have seen, changing the surface can also be used to facilitate the use of specific sensory systems or postural reactions. Progression is best carried out from stable surfaces to unstable surfaces, non-compliant to compliant surfaces, flat surfaces to inclines, and stationary surfaces to surfaces that move. For example, performing postural sway in all directions with the arms folded across the chest while sitting on a firm chair is a good precursor to adding arm movements or for performing the same exercise on an unstable therapeutic ball.

Ambient conditions play a major role, and manipulating vision can serve to increase the challenge or determine whether the visual or vestibular system dominates balance control. Typically, patients should exercise under good lighting conditions before progressing to practice in a dim room or in the dark.

Patients should demonstrate mastery in predictable environments before practicing under unpredictable conditions in order to minimize the effects of contextual variability. Vary displacements from those generated by the patient to an external force, and from an anticipated displacement to an unanticipated one to simulate balance control in crowds. Patients should be taught to handle motion in the world around them (optokinetics) by first practicing in environments with no or very little environmental motion, such as a plain exam room, and then progressing to more visually busy environments, such as a crowded grocery store. Increasing the movement in peripheral vision during exercises will also challenge the balance system more.

Beginning with simple tasks on a stable surface and moving to progressively more unstable surfaces and complex tasks is the sequence plan, regardless of the age or condition of the patient. For the athlete, progression to a balance board, minit-ramp, slide board, or computerized balance training system may occur rapidly. Although training the individual in postures or activities encountered in his/her sport can prepare him/her for those situations, many unpredictable situations occur, and unpredictable perturbations should be included in the training program to teach the nervous system to respond to novel situations (see **Building Block 8-9**).

BUILDING BLOCK 8-9

Describe an appropriate sequence for developing SLS for an otherwise healthy 22-year-old classical dancer recovering from left knee arthroscopy with resection of a medial meniscus tear.

Feedback

Learning factors are essential in planning the activity mode for treating balance impairment. Early in the treatment program, simple balance challenges with external feedback are necessary. This allows the patient to develop gross strategies to manage the perturbation. As the patient learns and develops these gross strategies, increasing the balance challenge while decreasing the external feedback allows internal strategies to develop. Initially, ask the patient to describe what obstacles are in his/her path and what his/her strategies will be to negotiate through the room (enhanced use of cognition). Try to add distractors later in the rehabilitation process and look for more automatic postural presets. In the case of balance training, learning is the ultimate goal.

Mirrors and force platforms can provide visual postural biofeedback, regardless of the position of exercise. This allows visual feedback (i.e., external feedback about position), which must be removed at some point to allow internalization of the balance strategies. Computerized force platforms allow for multiple variations of task practice with highly motivating performance feedback and the ability to readily track progress.

EXPANDED ECOLOGICAL MODEL OF BALANCE REHABILITATION

As stated previously, the ecological model describes the interactions among the individual, the environment, and the functional task.[5,16] The relationships between these domains are complex, dynamic, and lead to a highly individual experience of impaired balance and mobility. **Figure 8-17** presents the variables available for manipulation by the clinician when developing interventions within the ecological framework discussed in this chapter. Systematic and skillful manipulation of specific variables related to the individual, environment, and the task provides the clinician with endless opportunities to customize a rehabilitation program for each person.

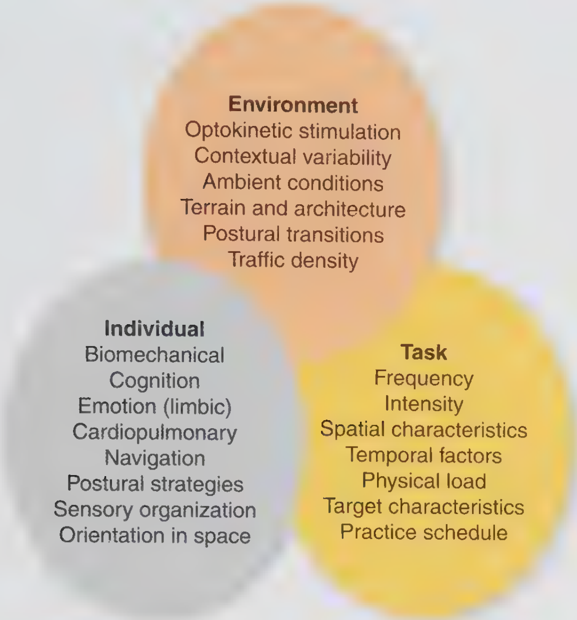


FIGURE 8-17 Expanded ecological model of balance rehabilitation.

PRECAUTIONS AND CONTRAINDICATIONS

The most important precaution in balance training is the individual's safety. Because the potential for falls is high, choose activities that are appropriate for the patient's skill level. A well-performed evaluation and initiation of activities at a lower level than determined by the examination can ensure appropriate exercise choice. It is safer to start the patient with tasks that are simpler and safer and progress to more complex exercises than to misjudge and place the patient in an unsafe situation. Again, measuring the patient's self-efficacy regarding his/her ability to safely perform the prescribed exercise regime at home can also assist in selecting the appropriate level of challenge. Simply have the patient rate his/her level of confidence on a scale of 0% to 100% regarding his/her ability to perform each exercise. Select exercises which the patient has a high level of confidence performing.

The surrounding environment should have maximum safety as the principal design factor. Eliminate obstacles or unsafe objects from the exercise area and provide additional stabilization for the patient. A gait belt, hand contacts from the clinician, parallel bars, or other stable external objects for the patient to hold should be immediately available. However, keep in mind that relying on such support alters balance responses. Balance training is contraindicated for persons who are inherently unsafe in balance-challenged positions. For example, those with cognitive impairments may be unable to understand the purpose and mechanics of the activity.

PATIENT EDUCATION

Patient education is an ongoing process for the patient with balance impairment. Safety is the most important area of education. Counsel the individual with significant balance impairments regarding use of assistive devices to maintain stability. A walker, one or two crutches, a cane, or hiking stick can widen the BOS, thereby increasing the stability limits. Evaluate the home for potential balance hazards. Loose rugs, slippery floors or bathtubs, uneven doorway thresholds, and stairs without railings may be hazards. A systematic review by Lyons and colleagues[118] concluded that there is insufficient evidence to determine the overall effectiveness of these strategies in terms of risk reduction when used alone. However, these authors encourage the commonsense use of home safety strategies given that there is no evidence that these strategies do not work. Footwear may also affect balance; thus, education regarding appropriate footwear is often essential. Shoes that slip on the foot or on the floor or shoes with rubber bottoms that stick on the floor may cause a fall. Additionally, consider the impact of eye conditions and surgical and optical vision correction strategies (glasses, mono-vision contact lenses, Lasik).

Educate the patient regarding the limits of his/her balance. Factors include time (e.g., walking more than 20 minutes), distance (e.g., after walking more than four blocks), time of day (e.g., better in the morning than in the evening), and environment (e.g., crowds, noise, lights). Coaching patients to anticipate and recognize situations that place them at risk can help them make appropriate, safe choices while still participating in desired activities.

The patient should be taught strategies to maximize balance in compromised situations. For reasons beyond their control, patients may find themselves in situations where their balance is at risk. For example, when coming out of a movie, a person may have difficulty adjusting to the light, noise, and crowds in the lobby. Patients should be counseled in strategies to optimize balance, which may include using an assistive device (when the patient normally does not use one), using a friend's arm for balance and escort through the lobby, sitting and planning a path where stable objects may provide some external assistance, or asking someone for assistance.

Falls—A Significant Problem

Falls by the elderly are of great concern, because the resultant injury and disability are significant. Each year, approximately 30% of persons older than 65 years of age fall, and one half of them fall multiple times.[119] Falls are a leading cause of death of persons older than 75 years of age.[120] Hip fracture–associated mortality is greater for women and has been reported as high as 8% to 18% within the first 2 years after fracture.[120] As many as 53% of patients fall within the first 6 months after hospitalization for a previous fall.[121] Previous falls and use of an assistive device before the fall resulting in hospitalization predict falls post-discharge.[121] Falls following hospitalization have been associated with significant balance impairments and mobility limitations as measured by lower BBS Scores and slower gait speed on average.[121]

Falls by the elderly have been attributed to increased postural sway and imbalance and to a decreased ability to balance on a single leg.[8,59,120,122] An individual's perceived stability limits may differ from their actual stability limits, making them susceptible to falls.[5] Most falls occur during walking, turning, or on stairs.[89,123] Lower maximum walking speed and diminished self-perception of balance have been found in patients with hip fractures.[59] Older individuals have demonstrated larger sway areas than young adults in upright stance and forward lean stance.[124] The elderly are rarely able to complete a test of SLS while blindfolded.[125,126]

A study of multiple factors predictive of future falling found control of lateral stability to be a significant predictor of future falling risk.[127] Thus, examination and intervention for lateral stability are important fall prevention measures. However, the single best predictor of future falls appears to be a history of previous falls.[65] Thus, clinicians should ask about prior falls. Many patients may have difficulty remembering if they have fallen more than 2 months prior. Thus, the clinician should ask the patient, "When was the last time you fell?"

Fear of falling is a separate factor to be considered.[89] An approximate 30% prevalence of fear of falling exists in non-fallers, and 60% or more in those who have fallen.[128] Fear of falling is associated with poorer health status, functional decline, activity restriction, depression and anxiety, and decreased quality of life. Maki[129] found reduced stride length, reduced speed, increased double-support time, and poorer clinical gait scores to be associated with fear of falling, but these factors did not have an independent association with actual falling. Increased stride variability (length, speed, and double support) was associated with falling but was not related to fear of falling. Clinically, balance-related confidence, as measured by the ABC Scale, and self-perceived need for personal assistance with outdoor ambulation have been associated with balance performance measures.[130] The subjects' perceived balance capability was correlated with current behavior, but not their history of falls.

Further, consider the potential impact of other factors such as medication use, footwear, and vision correction when assessing balance. Antidepressants and psychotropic drugs have been associated with an increased risk of falling, whereas diuretic use has not.[89,131] Falling indoors has been more frequently associated with walking barefoot or in stockings in an elderly population; thus, these patients should be encouraged to wear shoes indoors.[132] Individuals who wear bifocal and trifocal lenses are at significantly greater risk for falling.[133] Cataracts significantly influence balance, and cataract surgery has been associated with significant reductions in risk for falls and fall-related injuries.[134]

Finally, it is important to remember that falling is not just a problem of the elderly. Children and athletes fall frequently. Falling is also a very common problem for persons with a variety of health conditions, including MS[135] and Parkinson's disease,[136,137] and persons with vestibular disorders.[138,139] The consequences of falls are often greater in these groups and the elderly because of the fact that these populations are more susceptible to serious injury.

EFFECTS OF TRAINING ON BALANCE

A variety of effects have been noted with training. Some training programs emphasize base elements such as strength, mobility, and cardiorespiratory exercise, whereas other programs use specific postural and balance training, or some combination of activities. Population-level fall risk reduction programs have been implemented in countries around the globe in an attempt to proactively address risk factors on a community level as well.[140,141] In a systematic review by the Cochrane Collaboration, McClure et al.[142] suggested that effective community-based intervention programs could be instrumental in driving public health policy as a result of their impact in term of reducing falls and fall-related injuries.

Several community-level interventions have been developed and examined. T'ai Chi Chuan has been studied extensively for its effects on impairments in the elderly. Lan et al.[143] found increases in knee concentric and eccentric peak torque and the knee extensor endurance ratio in both men and women who performed T'ai Chi. Additionally, improvements in resting heart rate, 3-minute step test heart rate, modified sit and reach, total body rotation testing and SLS with eyes closed were found in a T'ai Chi group compared with a control group.[144] The effects of T'ai Chi directly on balance have been analyzed. Participating in T'ai Chi was found to reduce the risk of multiple falls by 47.5%.[145] Significant improvements have been found in self-reported physical functioning, general health status, arthritis symptoms, Sensory Organization Testing, and the DHI following T'ai Chi training.[146–149] However, others have found computerized balance training to produce greater improvements in balance measures than T'ai Chi, suggesting that T'ai Chi may delay the onset to first or multiple falls by improving confidence without actually changing sway measures.[145] This is consistent with others who found significant self-reported benefits of T'ai Chi training (improvements in daily activities) compared with individualized balance training.[150]

The Cochrane Collaboration found the following interventions to be effective in minimizing the effect of or exposure to risk factors for falling in the elderly on an individual level[151]:

- Multidisciplinary, multifactorial, health/environmental risk factor screening
- Individualized muscle strengthening and balance retraining, prescribed at home by a trained health professional
- Home hazard assessment and modification, professionally prescribed
- Withdrawal of psychotropic medication
- Cardiac pacing for appropriate patients
- T'ai Chi group exercise intervention (see **Evidence and Research 8-4**).

EVIDENCE and RESEARCH 8-4

Community-based programs effective in reducing fall risk in the older adult[137,142]:

- Participating in T'ai Chi was found to reduce the risk of multiple falls by 47.5%.[146–149,152]
- T'ai Chi may delay the onset to first or multiple falls by improving confidence without actually changing sway measures.[145]
- Stepping on program focuses on progressive balance and strength exercises, home safety, vision, and medication review and showed a 31% reduction in falls.
- Sherrington[153] found the critical components of effective exercise program included:
    - Minimum effective dose of two times per week for 25 weeks (>50 hours)
    - Challenging balance exercises in standing (feet close or one foot, minimal use of hands, and practiced controlled movements of their COM)
    - Did NOT include a walking program

The majority of patients with balance impairments will require skilled, individualized interventions that target the specific underlying impairments contributing to instability. The literature suggests that rehabilitation after lower-extremity injuries that includes balance training results in improved static and dynamic balance[110] and contributes to greater success in return to play in athletes.[111] A three times per week program of balance and lower-extremity strength training leads to improvements in balance measures equivalent to an individual 3 to 10 years younger, as well as increases in lower-extremity strength.[154] According to Gardner et al.,[155] successful falls prevention programs include activities for strength, endurance, and balance training. Specifically, these authors recommend individually tailored exercises, criterion-based progression for strength and balance training conducted three times a week, use of a walking program to increase aerobic capacity, and follow up with the exercise instructor over several months to 1 year. Adherence to a program guided by these principles has resulted in reduced risk for falling for up to 2 years.[156]

KEY POINTS

- Balance and coordination are separate concepts that are integral to each other and, together, support all skilled movement.
- Balance is a function of the interaction of multiple body systems including biomechanical, neuromuscular, sensory, perceptual, cognitive, emotional, and cardiopulmonary functions.
- Some musculoskeletal disorders or injuries are associated with balance impairment. Balance training should be incorporated into the treatment program.
- Aging is associated with balance impairment and places the elderly at risk for falls.
- Ankle strategies are used in response to small perturbations, and hip or stepping strategies are used to counter larger perturbations.
- Measurement of balance impairment should involve each of the assessment of each of the body systems contributing to postural control.
- Treatment should be aimed at the cause of the problem, whether biomechanical, sensory, motor, cognitive, affective, or a combination of impairments.

CRITICAL THINKING QUESTIONS

1. Consider Case Study No. 1 in Unit 7. Design a progressive balance program for this basketball player. How would your treatment program differ if she were a
   a. Gymnast
   b. Figure skater
   c. Wrestler
   d. Cross-country runner
2. Consider Case Study No. 5 in Unit 7. Design a progressive balance program for this woman. Include sitting, standing, and transitional postures and movements. What other interventions probably are necessary to improve her balance?
3. What aspects of home design can maximize an individual's independence if balance is impaired?

LAB ACTIVITIES

1. With a partner, perform the following activities. Which balance strategy is elicited and why?
   a. With the patient's feet shoulder width apart, attempt to gently disrupt the patient's balance.
   b. With the patient's feet shoulder width apart, attempt a larger disruption of the patient's balance.
   c. With the patient standing heel to toe, attempt to gently disrupt the patient's balance.
   d. With the patient standing on a balance beam, attempt to gently disrupt the patient's balance.
   e. Restrict the patient's ankle mobility with a brace or tape. Attempt to gently disrupt the patient's balance.
   f. Repeat a to c on a soft foam surface.
2. Compare the amount of postural sway observed when standing with the feet together in the following conditions. Which activities are the most challenging and why?
   a. Eyes open on a stable surface.
   b. Eyes closed on a stable surface.
   c. Eyes open on a thick foam surface.
   d. Eyes closed on a thick foam surface.
   e. Eyes open on a rocker board.
   f. Eyes closed on a rocker board.
   g. Repeat tasks a to f while simultaneously rotating or tilting the head.
3. Compare the length of time balance can be maintained in the following situations. Which muscles are working, and how are changes in COG compensated by postural changes? What do the arms attempt to do?
   a. SLS with eyes open (left and right)
   b. SLS with eyes closed (left and right)
   c. SLS, performing tubing-resisted shoulder horizontal abduction, unilateral and bilateral
   d. SLS, performing tubing-resisted shoulder flexion from 120 to 180 degrees of overhead flexion, unilateral and bilateral
   e. SLS, performing tubing-resisted hip extension
   f. Single-leg minisquats with the contralateral knee flexed
   g. Single-leg minisquats with the contralateral knee extended and hip flexed
   h. Single-leg minisquats on a minitramp
   i. Single-leg toe raises from a level surface
   j. Single-leg toe raises from the edge of a step
4. Compare muscle activity in the following situations:
   a. Single-leg minisquats on a minitramp, with tubing around the posterior knee pulling the knee into flexion
   b. Single-leg minisquats on a minitramp, with tubing around the medial knee pulling the hip into abduction
   c. Single-leg minisquats on a minitramp, with tubing around the anterior knee pulling the knee into extension
   d. Single-leg minisquats on a minitramp, with tubing around the lateral knee pulling the hip into adduction
5. Perform the following activities. Which activity is the most challenging to your balance?
   a. Repetitive single-leg hopping with arms free
   b. Repetitive single-leg hopping with arms across the chest
   c. Repetitive single-leg hopping with arms overhead
   d. Rope jumping on alternate feet
   e. Rope jumping on a single foot
   f. Single repetition of a single-leg hop, controlling and stopping the landing as quickly as possible (i.e., hop and stop)
   g. Hop and stop on a minitramp

CHAPTER

9

Impaired Posture and Movement

CARRIE M. HALL

It is intuitive for physical therapists to consider posture and movement as an underlying cause of, or contributor to, musculoskeletal pain syndromes (MPS)[1] (**Display 9-1**). However, much to our dismay, the literature generally does not support strong correlations between posture, movement, and pain.[5–10] Even in the presence of correlational evidence, it is difficult to suggest causation. Just because two factors are correlated does not necessarily mean that one causes the other (*correlation does not imply causation*).[11] (**Evidence and Research 9-1**) Causation is rarely as simple as we tend to assume and, perhaps for this reason, its complexities are often glossed over or even ignored. Misunderstanding causal links can result in ineffective actions being chosen, harmful practices perpetuated, and beneficial alternatives overlooked (**Evidence and Research 9-2**).

EVIDENCE and RESEARCH 9-1

Correlation does not prove causation. For example, in a widely studied case, numerous epidemiological studies showed that women who were taking combined hormone replacement therapy (HRT) also had a lower-than-average incidence of coronary heart disease (CHD), leading doctors to propose that HRT was protective against CHD. But randomized controlled trials showed that HRT caused a small but statistically significant increase in risk of CHD. Reanalysis of the data from epidemiological studies showed that women undertaking HRT were more likely to be from higher socioeconomic groups, with better-than-average diet and exercise regimens. The use of HRT and decreased incidence of CHD were coincident effects of a common cause (i.e., the benefits associated with a higher socioeconomic status), rather than cause and effect, as had been supposed.[12]

EVIDENCE and RESEARCH 9-2

Prins et al.[13] performed a systematic review to evaluate the evidence for the contribution of posture and psychosocial factors to the development of upper quadrant musculoskeletal pain in children and adolescents. The initial assumption by most would have been the faulty posture contributed to the pain when in fact, this review concluded that the *duration* of sitting posture and *psychosocial factors* may influence the experience of musculoskeletal pain among children and adolescents to a greater extent than the faulty posture itself.

DISPLAY 9-1

Definition of Musculoskeletal Pain Syndrome

MPS is defined as a localized, painful condition arising from irritation of myofascial, periarticular, or articular tissues.[1] Pain from acute trauma, such as strain, fracture, or dislocation, does not fall into this category. In addition, pain caused by systemic disease such as Parkinson's disease or cancer, inflammatory conditions such as rheumatoid arthritis, or chronic pain with peripheral and/or central sensitization are also excluded from this category.

For the purpose of this discussion, MPS is considered to be the result of cumulative microtrauma imposed on neuromusculoskeletal tissue. Microtrauma can occur from overuse, which is defined as repetitive or prolonged submaximal stress that exceeds the tissue's ability to adapt and repair.[2,3] Overuse can occur during a relatively short period, such as playing the first volleyball game of the season, or over a longer period, such as performing data entry tasks 8 hours a day, 5 days a week, for many years. Microtrauma can also be caused by movements repeated during activities of daily living (ADL) with less than optimal starting alignment or motor control strategies.[4]

When there is indeed a causal relationship between two factors, there is still the question of which is the cause and which is the effect. In other words, what is the direction of causation? By itself, a correlation tells us nothing about this. O'Sullivan[14] discusses the conundrum of whether faulty postures and movements cause pain (adaptive), *or* if pain leads to faulty postures and movements (maladaptive) (**Evidence and Research 9-3**).

Theoretically, it seems reasonable that sustained postures and repeated movements could be a risk factor associated with musculoskeletal symptoms. Most would agree that prolonged physiologic loads could precipitate symptoms through mechanical stress. A number of studies, though weak in design, have documented a link between sustained postures and tissue loading.[15–26] Unfortunately, much of the literature on sustained loading on spinal tissues has either been conducted on individuals without symptoms,[15–26] on cadavers,[27–31] or on animals.[32–34] These studies provide evidence about the possible deleterious effect on tissue from sustained loading, but do not provide evidence about the

EVIDENCE and RESEARCH 9-3

O'Sullivan summarizes in his master class paper:

> Chronic low back pain (CLBP) disorders must be considered within a biopsychosocial framework. The presence and dominance of the potential pathoanatomical, physical, neurophysiological, psychological, and social factors that may impact on these disorders is different for each individual with CLBP. It is critical that classification of CLBP pain disorders be based on underlying mechanism(s). It is proposed that motor control impairments may be adaptive or maladaptive in nature. Treatment of a pain disorder cannot be justified without an understanding of its underlying mechanism as there are subgroups of patients for whom physiotherapy treatment is not indicated. It is proposed that there is a large subgroup of CLBP disorders where maladaptive movements dominate the disorder, which in turn become a mechanism for ongoing pain. Physiotherapy interventions directed to the underlying driving mechanism have the potential to alter these disorders and impact on both the primary physical and secondary cognitive drivers of pain. This approach can be applied to all regions of the musculoskeletal system.[14]

symptom response to sustained loading in humans. In support of symptoms related to tissue loading, McKenzie[35] describes three mechanical syndromes, all of which are based on clinical presentations and the patient's response to repeated movements and sustained postures. One of these is the postural syndrome in which prolonged static loading of normal soft tissues results in discomfort triggered by sustained mechanical stress. The clinical presentation is usually observed in a young person who maintains sustained postures for long periods, most commonly sitting, which provoke transient symptoms that are abolished with the resumption of an upright posture (**Evidence and Research 9-4**).

EVIDENCE and RESEARCH 9-4

In a reliability study of 45 patients with low back pain, only one patient (2.2%) was thought to be classified with postural syndrome.[36] In two surveys with a combined total of 947 patients with spine pain, only 1% were classified with postural syndrome.[37,38] However, among a student population, 50% reported previous transient and mild postural-related backache.[26] None had sought treatment, but over a 3-day period, they reported 46 backache episodes, all triggered by sitting activities, most commonly when studying. Compared with a no backache control group, there were significant differences in the amount of time of uninterrupted sitting and the amount of lumbar flexion when sitting relaxed.

Correlating pain with faulty movement can be just as elusive. Research has shown that excessive arthrokinematic and/or osteokinematic movement can lead to pathology,[39] but pathology does not equate to pain.[40] Pain is more complicated than clinicians would like to think. Physical therapists are trained to look for explanations that are pathologically or kinesiologically driven. One of the issues confounding research results is use of the term *pain*. Though we use the term *musculoskeletal pain syndrome*, pain should not be used interchangeably with nociception. Nociception is the afferent activity in the peripheral and central nervous systems produced by stimulation of specialized free nerve endings called nociceptors or "pain receptors" that only respond to tissue damage caused by chemical (e.g., inflammation), mechanical (e.g., pinching, crushing), or thermal (heat and cold) stimulation.[41] Describing the mechanisms that signal pain is not the same as identifying the underlying cause of pain. Evidence demonstrates that nociception is neither sufficient nor necessary to experience pain[42–45] and that pain is a conscious experience that *can be* associated with nociception, but it is *always* modulated by a myriad of neurobiological, environmental, and cognitive factors.[46]

Despite the lack of evidence, the inclusion of postural assessment in the Guide to Physical Therapist Practice[47] and the accreditation standards suggest that the profession considers postural alignment to have a role in patient care. Sahrmann recognizes that despite very little research to support a relationship between musculoskeletal pain and "posture," she cannot imagine treating any patient without assessing posture or, more precisely, alignment.[1] For example, when a patient with low back pain has a flat back, the emphasis of treatment is different than when the patient has an excessive lumbar lordosis. Sahrmann outlines a sound rationale for the discrepancy between the research data and the clinical experience of generations of physical therapists (**Evidence and Research 9-5**).

EVIDENCE and RESEARCH 9-5

In a 2002 commentary, Shirley Sahrmann stated the following regarding the lack of evidence correlating posture and pain:

I believe some of the explanations are (1) a narrow definition of what constitutes posture; (2) attempts to find a linear correlation between pain and spinal curvature without identifying subgroups of extremes of increased or decreased curvature; (3) failure to consider alignment as only one of multiple factors causing pain; (4) attempts to relate postural faults and muscle weakness; and (5) limited research examining the relationship between alignment impairments and alterations in movement.[48]

She concluded that examination of alignment impairments has to be an important step in designing an appropriate treatment program for correcting mechanical impairments and that future studies need to better correlate relationships among specific alignment impairments, altered movement patterns, contributing muscle adaptations, patient modifiers, and mechanical pain problems.[48] Understanding these relationships will enhance our therapeutic intervention of these impairments.

Accepting that mechanically stimulated nociception (sustained postures or repeated movements) can be a trigger for pain, a clinician should consider the conditions when a mechanical stimulus in the periphery produces a painful response.[1,49–56] Posture and movement matter when mechanical stress is predictably related to sustained postural habits or repeated movement patterns and/or:

1. Is the underlying cause of nociception and pain (altering the pattern changes the experience of pain)
2. Contributes to the recurrence of a painful condition (altering the pattern reduces the ongoing pain)
3. Is associated with the failure of the condition to fully heal (altering the pattern allows injured tissue to heal in a timely fashion).

DISPLAY 9-2

Factors Influencing Posture and Movement Impairment

- Impairments of body functions
  - Range of motion
  - Muscle length/extensibility
  - Joint integrity and mobility
  - Muscle performance
  - Motor control
  - Balance and coordination
  - Pain
- Impairments of body structures (i.e., structural scoliosis, hip anteversion, and structural limb length discrepancy)
- Anthropometric characteristics
- Psychologic impairments
- Developmental factors (e.g., age)
- Environmental influences
- Disease or pathology

Intervention, under these circumstances, therefore should focus on correcting the factors predisposing or contributing to the sustained postures or repetitive movement. When correction is not possible (e.g., anatomic impairments, pathology, disease), modification of the posture or movement is indicated. **Display 9-2** summarizes the factors influencing impairments of posture and movement.

To prepare the clinician with appropriate interventions under the right circumstances, this chapter defines the terms used in the evaluation and treatment of impairments of posture and movement, discusses factors influencing impairments of posture and movement, and outlines the principles of therapeutic exercise intervention for correction of posture and movement impairments.

DEFINITIONS

Posture

Posture is often considered to be a static function rather than being related to movement. However, posture should be considered not only a static function but also in the context of the position the body assumes in preparation for movement. Traditionally, posture is examined in standing and sitting positions, but posture should be examined in numerous positions, particularly postures in which the patient frequently assumes and positions related to frequently performed movements. For example, standing on one leg is 85% of the gait cycle and therefore should be considered an important posture to be examined.[57]

A useful definition of posture was provided by the Posture Committee of the American Academy of Orthopedic Surgeons[58] (**Display 9-3**). Most physical therapists understand the relationship between posture and the musculoskeletal system, but an important message delivered by this definition is the interaction between posture, musculoskeletal tissues, and organ systems (e.g., lungs, abdominal, and pelvic organs). This definition suggests that, without optimal support, organ systems may not function optimally. For example, respiratory insufficiency can result from kyphosis (increased thoracic flexion) or kyphoscoliosis (kyphosis superimposed on a lateral curve).[59] These postural faults can reduce mobility of the thorax and thereby increase the work of breathing.[60] Chronically altered respiratory mechanics have been cited as a contributing factor to cardiopulmonary pathology (e.g., pulmonary hypertension, heart failure).[61]

DISPLAY 9-3

Definition of Posture

Posture is usually defined as the relative arrangement of the parts of the body. Good posture is the state of muscular and skeletal balance that protects the supporting structures of the body against injury or progressive deformity irrespective of the attitude (e.g., erect, lying, squatting, and stooping) in which these structures are working or resting. Under such conditions, the muscles function most efficiently, and the optimum positions are afforded for the thoracic and abdominal organs. Poor posture is a faulty relationship of the various parts of the body, which produces increased strain on the supporting structures and in which there is less efficient balance of the body over its base of support.

Posture or carriage of the body describes the global relationships of body parts and should be considered differently than the orientation or alignment of one segment in relation to an immediately adjacent segment. For example, spino-pelvic balance in the sagittal plane can be considered as a global postural relationship linking the head to the pelvis. However, the shape and orientation (alignment) of each successive anatomic segment (cervical, thoracic, lumbar spine; pelvis, sacrum, hip joints) are closely related and influence the adjacent segment (**Fig. 9-1**). Evidence in the literature demonstrates a relationship between the alignment of the sacrum, pelvis, femoral heads, and various spine pathologies[62] (**Evidence and Research 9-6**). It is critical that the practitioner examine both posture orientation and segmental alignment to understand the relationship of individual segments to one another and to global posture.

EVIDENCE and RESEARCH 9-6

In areas of the spine in which more flexion is present, the disk pressures are maximum and predispose the region to early disk degeneration with disk herniation. In areas where hyperlordosis is present, there is risk of facet hyperpressure and L5 spondylolysis by "crack nuts" effect. The disks L4–L5 and L5–S1 are generally protected. Those individuals with a large anteroposterior diameter of the pelvis and increased sacral slope are at higher risk of spondylolisthesis through L5 isthmic lysis by a "sliding" mechanism.[62,63]

For the purposes of this chapter, the focus will be on examining and treating posture in the global sense. The reader is referred to regional chapters to understand segmental alignment standards, the relationship of alignment faults to pathological conditions, and the treatment of existing segmental alignment faults.

Standard Posture

Although any posture a patient or client assumes for sustained periods on a daily basis should be evaluated and treated, this

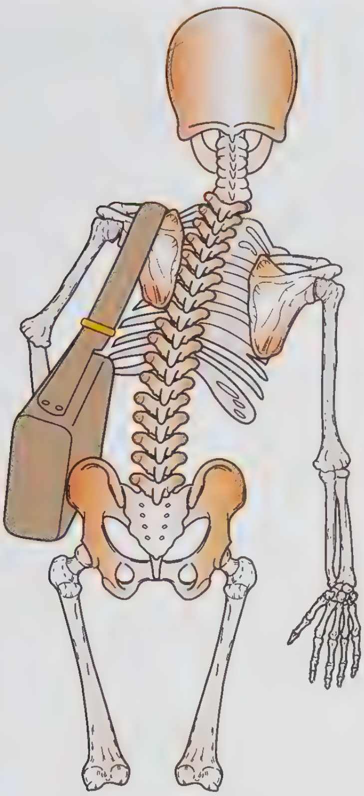

FIGURE 9-1 Spino-pelvic orientation of right thoracolumbar sidebend results in left neck on body sidebend. Specific alignment examples include right scapula depression and left scapula elevation. Later in this chapter, we will discuss the effect of alignment on muscle length and muscle performance. Consider the changes in length of the levator scapula, upper trapezius, and rhomboids in this example.

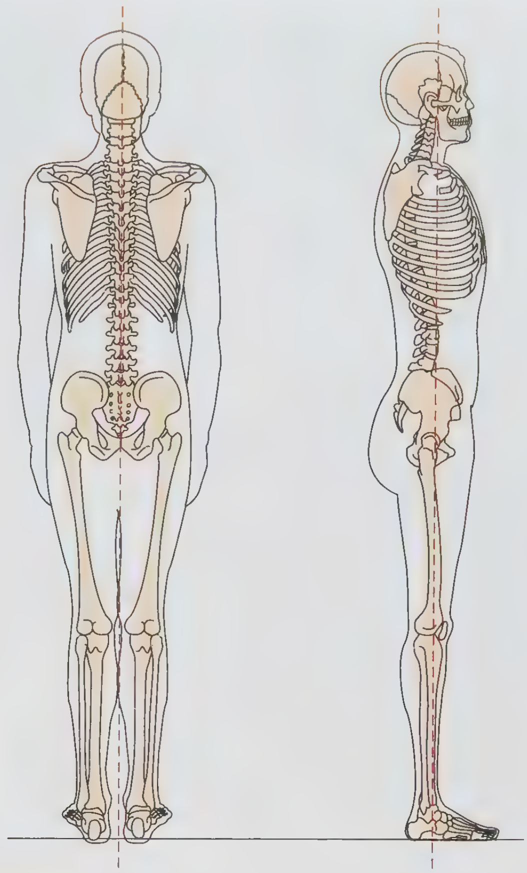

FIGURE 9-2 The back and side views of standard posture. The surface and anatomic landmarks that coincide with the side view are listed in Table 9-1.

chapter considers only the upright standing posture. The **standard posture** refers to an ideal posture rather than an average or normal posture. This standard should be used as a basis for comparison; deviations from the standard are called *impairments of posture*.

An evaluation of postural faults necessitates a standard by which individual postures can be judged. The standing posture is used as the standard in this chapter and is illustrated from the back and side (**Fig. 9-2**). In the back view, a line of reference represents a plane that coincides with the midline of the body. It is illustrated as beginning midway between the heels and extending upward to midway between the lower extremities, through the midline of the pelvis, spine, and skull. The right and left halves of the skeletal structures are essentially symmetric. Hypothetically, the two halves of the body are in equilibrium. The same line of reference can be imagined from a front view of the patient, noting any asymmetries.

In the side view, the vertical line of reference represents a plane that divides the body into front and back sections. Around this line of reference, the body is hypothetically in a position of equilibrium.

From a mechanical standpoint, it may be logical to assume that a line of gravity should pass through the centers of weight-bearing joints of the body. However, the on-center position is not considered stable, because it can be held only momentarily in the presence of normal external stresses.[64,65] For example, when the center of the knee joint coincides with the line of gravity, there are equal tendencies for the joint to flex and to hyperextend. The slightest force exerted in either direction causes it to move off center. If the body must call on muscular effort at all times to resist knee flexion, muscular effort is unnecessarily expended. To offset this necessity, the line of gravity is considered to be slightly anterior to the joint center. Ligamentous structures and ideal muscle length restrain the knee from moving freely posteriorly. At the hip joint, the same principles apply, but the hip is most stable when the line of gravity is slightly posterior to the center of the joint. The strong ligaments of the hip anteriorly prevent additional hip extension (**Table 9-1**).

The pelvis is the link that transmits the weight of the head, arms, and trunk to the lower extremities, and it is considered key to the alignment of the entire lower body. Because of structural variations of the pelvis (i.e., women tend to have a shallow pelvis, with the anterior superior iliac spine [ASIS] inferior to the posterior superior iliac spine), it is not appropriate to use an anterior landmark in relation to a posterior landmark. The pelvis is considered to be in a neutral position when the ASIS and the symphysis pubis are in the same vertical plane (see **Fig. 9-3A**). The anatomic structures and surface landmarks that coincide with the line of reference for the side view are listed in Table 9-1. Specific alignment of the upper extremity is summarized in **Display 9-4**.[1] Specific alignment of the lower extremity is summarized in **Display 9-5**.

TABLE 9-1

Anatomic Structures and Surface Landmarks that Coincide with the Line of Reference for the Side View of Posture

ANATOMIC STRUCTURES	SURFACE LANDMARKS
Through the calcaneocuboid joint	Slightly anterior to the lateral malleolus
Slightly anterior to the center of the knee joint	Slightly anterior to a midline through the knee
Slightly posterior to the center of the hip joint	Through the greater trochanter
Through the sacral promontory	Midway between the back and the abdomen
Through the bodies of the lumbar vertebrae	Midway between the front and back of the chest
Through the dens	Through lobe of the ear
Through the external auditory meatus	
Slightly posterior to the apex of the coronal sutures

Deviations in Posture

The following terms denote deviations in alignment with reference to the spine.[67]

- *Lordosis* is an increased anterior curve of the spine, usually of the lumbar spine, but it can affect the thoracic or cervical spine. If used without a modifying word, it refers to lumbar lordosis (**Fig. 9-4**).
- *Kyphosis* is an increased posterior curve, usually of the thoracic spine but sometimes of the lumbar spine. If used without a modifying word, the term refers to the thoracic spine (**Fig. 9-5**).

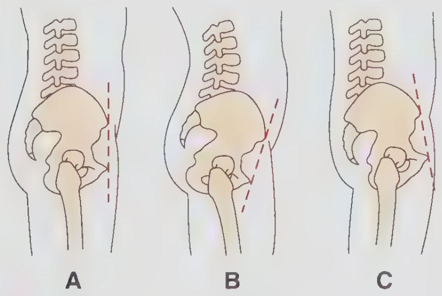

FIGURE 9-3 **(A)** The neutral position of the pelvis is one in which the anterosuperior iliac spines are in the same transverse plane and in which they and the symphysis are in the same vertical plane. **(B)** An anterior pelvic tilt is a position of the pelvis in which the vertical plane through the anterosuperior iliac spines is anterior to a vertical plane through the symphysis pubis. **(C)** A posterior pelvic tilt is a position of the pelvis in which the vertical plane through the anterosuperior iliac spines is posterior to a vertical plane through the symphysis pubis.

DISPLAY 9-4

Alignment of the Upper Extremity

Side View

- Humerus
  No more than one third of the head of the humerus protrudes in front of the acromion.
  Proximal and distal humerus in line vertically
- Scapula
  The inferior pole is held flat against the thorax (if the thorax is in ideal alignment).
  30 degrees anterior to the frontal plane (i.e., scapular plane)

Back and Front View

- Humerus
  Antecubital crease faces anterior; olecranon faces posterior.
- Forearms
  Palms face the body
- Scapula
  The vertebral border of the scapula is parallel to the spine and is positioned approximately 3 inches from the spine.
  The root of the scapula (where the spine of the scapula meets the vertebral border of the scapula) is at the level of T3.
  The vertebral border of the scapula is held against the thorax (if the thorax is in ideal alignment)
- Humerus

**These are general recommendations for alignment based on clinical observation. Precise alignment parameters will be denoted in Unit 6.*

DISPLAY 9-5

Alignment of the Knee

- Side view
  In the sagittal plane, the tibiofemoral angle should be 180 degrees.[66] If the angle exceeds 180 degrees, *genu recurvatum* (i.e., hyperextension) exists (**Fig. 9-6**).[66]
- Back and front view
  The normal angle between the tibia and femur in the frontal plane is about 170 to 175 degrees and is called the **physiologic valgus angle** of the knee.[66] If the valgus angle is <165 degrees, *genu valgum* (i.e., knock knees) exists.[66] Two types of valgus exist: structural and postural as depicted in **Figure 9-7**.[67] Conversely, if the tibiofemoral angle approaches or exceeds 180 degrees, *genu varum* (i.e., bow legs) exists (**Fig. 9-8**).[66]

- *Anterior pelvic tilt* refers to a position in which the vertical plane through the ASIS is anterior to a vertical plane through the symphysis pubis (Fig. 9-3B).
- *Posterior pelvic tilt* refers to a position in which the vertical plane through the ASIS is posterior to a vertical plane through the symphysis pubis (Fig. 9-3C).

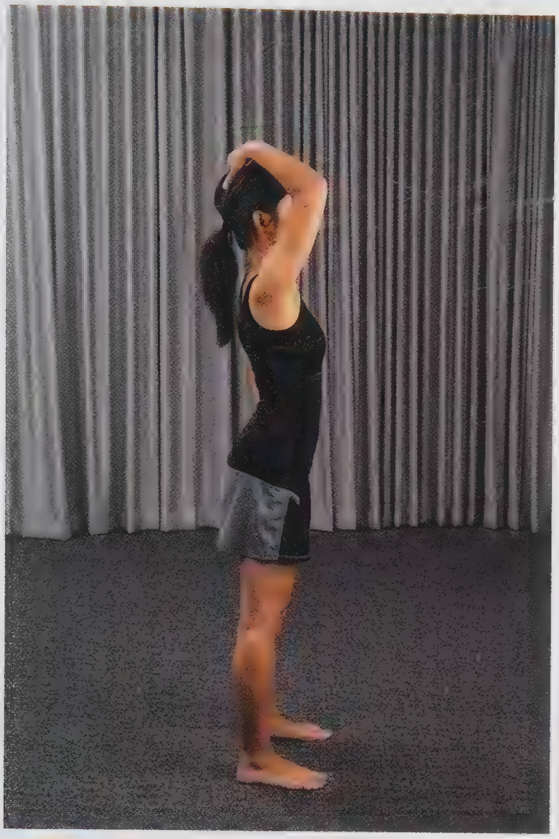

FIGURE 9-4 Marked anterior pelvic tilt and an exaggerated anterior curve of the lumbar spine. This curve is called a lordosis. Note that accompanying the anterior pelvic tilt and lordosis is flexion of the hip joint.

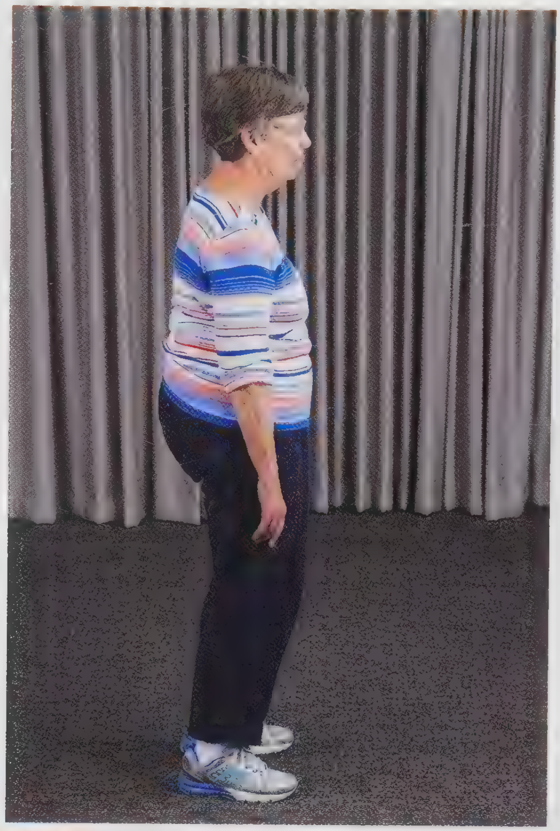

FIGURE 9-5 Person exhibiting an exaggeration of the normal posterior curve of the thoracic spine. This is called a kyphosis.

Display 9-5 denotes alignment terms and definitions related to the knee, while **Display 9-6** denotes alignment terms and definitions related to the shoulder girdle.

MOVEMENT

Movement is the action of a physiologic system that produces motion of the whole body or of its component parts.[71] Evaluating active movement in the clinical setting requires precise observation and palpation skills and extensive knowledge of kinesiologic principles.

A useful criterion for assessing precise or balanced movement is knowledge of the *path of instantaneous center of rotation* (PICR) during active motion.[1,72–74] The instant center of rotation describes the relative uniplanar motion of two adjacent segments of a body and the direction of displacement of the contact points between these segments (**Fig. 9-10**).[72] The instant center of rotation changes over time because of altered joint configurations and external forces. The PICR is a trace of the sequential instant centers of rotation for a joint in different positions throughout the range of motion (ROM) in one plane (**Fig. 9-11**).

It has been proposed that efficiency and longevity of the biomechanical system requires maintenance of precise movement of rotating segments; the PICR must meet a kinesiologic standard.[1] Deviations in the PICR from the ideal for a given joint imply that the arthrokinematic joint motions have become altered, even if the osteokinematic motion remains within the

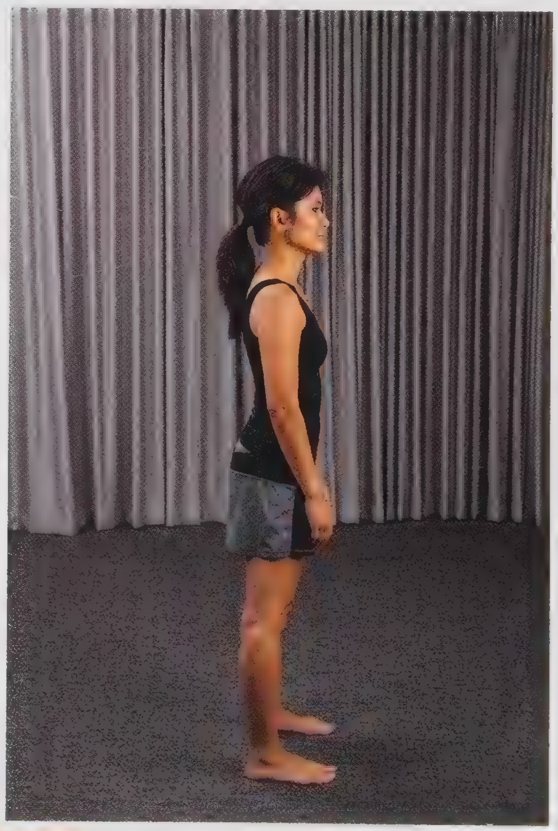

FIGURE 9-6 Moderate genu recurvatum or hyperextension of the knees.

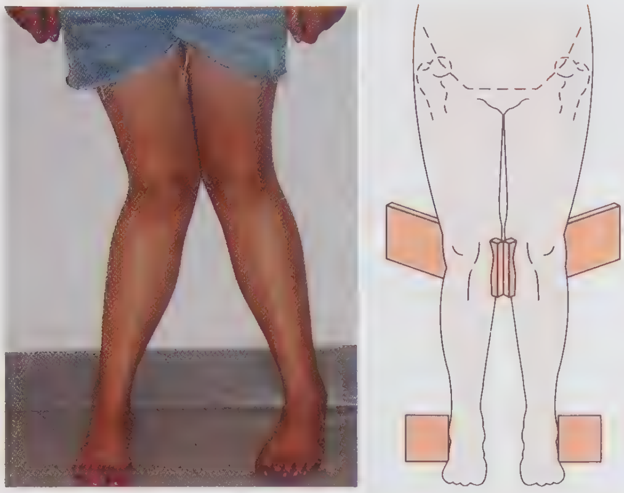
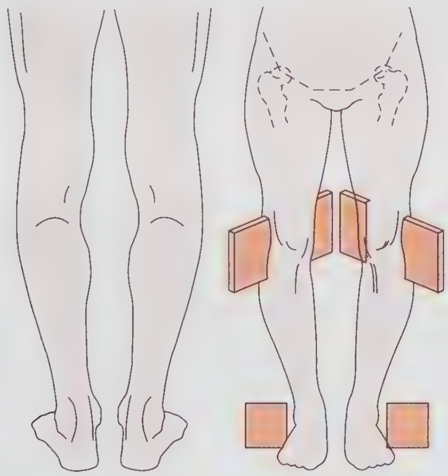


A B

FIGURE 9-7 **(A)** Person with a marked structural genu valgum or knock-knees. **(B)** Postural genu valgum results from a combination of medial rotation of the femurs, pronation of the feet, and hyperextension of the knees. With medial rotation, the axis of the knee joint is oblique to the coronal plane, and hyperextension results in adduction at the knees.



A B

FIGURE 9-8 **(A)** Mild degree of structural genu varum, or bow legs. **(B)** Postural genu varum results from a combination of lateral femoral rotation, supination of the feet, and hyperextension of the knees. When femurs laterally rotate, the axis of motion for flexion and extension is oblique to the coronal axis. From this axis, hyperextension occurs in a posterolateral direction, resulting in separation at the knees and apparent bowing of the legs.

normal range. The quality or precision of the osteokinematic motion is affected. Various investigators have shown that PICR deviations provide a noninvasive means of identifying pathomechanics.[59,61,69] However, because the radiologic[75] or computational modeling methods[76] used to determine the PICR are not available to physical therapists, clinically reliable tools for measuring the PICR need to be established. Techniques used to qualitatively examine uniplanar, multiplanar, and total body movement patterns include precise observation, palpation of joint osteokinematics and arthrokinematics, and palpation

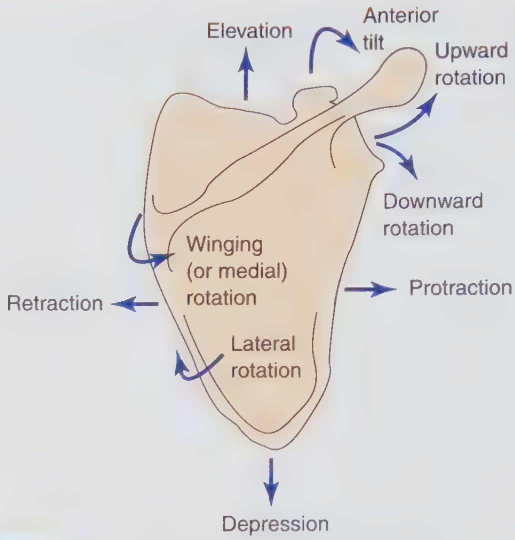


FIGURE 9-9 Positions and movements of the scapula.

DISPLAY 9-6
Alignment of the Shoulder Girdle (See Fig. 9-9)

- *Scapular retraction* is a rest position or movement in which the scapula is positioned or moving toward the vertebral column and occurs primarily at the sternoclavicular (SC) joint.[67,68]
- *Scapular protraction* is a rest position or movement in which the scapula is positioned or moving away from the vertebral column, also occurring at the SC joint.[67,68]
- *Upward rotation of the scapula* is a position or movement about an axis perpendicular to scapular plane[68,69] in which the inferior angle moves laterally and the glenoid fossa moves cranially.[68,69]
- *Downward rotation of the scapula* is a position or movement in which the inferior angle moves medially and the glenoid fossa moves caudally.[68,69]
- *Anterior tilt of the scapula* is a position or movement about a frontal axis parallel to the spine of the scapula[68,69] in which the coracoid process moves in an anterior direction and the inferior angle moves posteriorly and cranially.[67]
- *Posterior tilt of the scapula* is a position or movement in which the coracoid process moves in a posterior and cranial direction, whereas the inferior angle moves in an anterior and caudal direction.[67,68]
- *Elevation of the scapula* is a position or movement about a vertical axis in which the scapula moves cranially, and *depression of the scapula* is a position or movement in which the scapula moves caudally.[67,68]
- *Winging of the scapula or medial rotation* is a position or movement about a vertical axis perpendicular to the spine of the scapula[69,70] in which the vertebral border of the scapula moves posteriorly and laterally away from the rib cage and the glenoid fossa moves in an anterior and medial direction.[70] *Lateral rotation* of the scapula is the converse movement.[70]

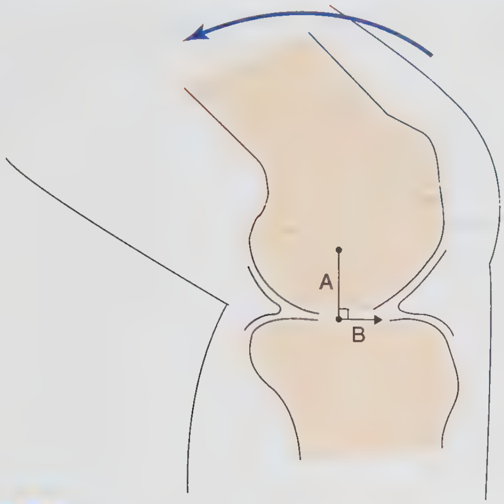

FIGURE 9-10 A normal knee with a line drawn from the instant center of the tibiofemoral joint to the tibiofemoral contact point (*line A*) forms a right angle with a line tangential to the tibial surface (*line B*). The *arrow* indicates the direction of displacement of the contact points. Line B is tangential to the tibial surface, indicating that the femur glides on the tibial condyles during flexion-extension motion.

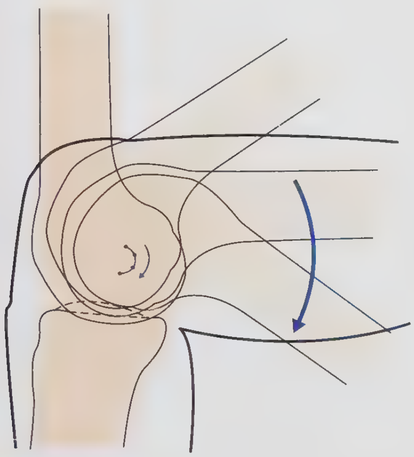

FIGURE 9-11 Semicircular PICR for the tibiofemoral joint in a normal knee.

or the use of surface electromyography to detect muscle activation patterns. The clinician relies on a thorough knowledge of kinesiologic principles to differentiate ideal from impaired movement patterns. A recommended reference to study clinical tools for assessing the PICR can be found in the recommended reading list at the end of this chapter.[1]

A major determinant of the PICR during active motion is the muscular force-couple action on the joint. **Force couple** is defined as two forces of equal magnitude but opposite direction with parallel lines of application.[65] The result of the forces is zero, meaning the body is not displaced (i.e., the body is in translatory equilibrium). The force couple causes the body to rotate around an axis perpendicular to the plane of the forces (**Fig. 9-12**).[65] In biomechanics, the instant center of rotation changes as the joint moves; consequently, the force-couple parameters change as the instant center of rotation changes.

Deviation of the PICR from the kinesiologic standard can be an indication of faulty muscle synergy in the force couple.

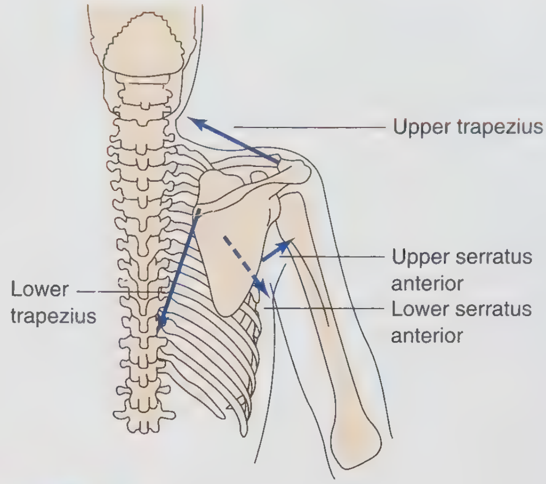

FIGURE 9-12 The action lines of the upper trapezius, lower trapezius, upper serratus anterior, and lower serratus anterior combine in a force-couple action to produce almost pure upward rotation of the scapula.

Muscle dominance is defined as one muscle of a synergistic group of muscles that exceeds the action of its counterparts, causing a deviation of the PICR and potential disuse of the other synergists.[1] The factors that affect force-couple balance are discussed later in this chapter.

CONTRIBUTORS TO IMPAIRED POSTURE AND MOVEMENT

Pathokinesiology is defined as the study of anatomy and physiology as they relate to abnormal movement.[77] Pathokinesiology emphasizes abnormalities of movement as a result of pathologic conditions. For example, in hemiparesis, the abnormal movement is the result of pathology involving the nervous system.[1] However, the reverse can also occur—pathology can result from abnormal movement. This can be defined as **kinesiopathology**.[1] When movement deviates from the kinesiologic standard, the cumulative effect of repetitive movement can be pathology. Therefore, it is reasonable to assume that maintaining precise movement patterns can minimize abnormal mechanical stress. Kinesiopathology can also result from repetitive movements and sustained postures associated with ADL including recreational, fitness, and sports activities. Clinicians use sustained postures and repetitive movements therapeutically to increase ROM and muscle length, improve joint mobility/stability, increase muscle performance, and improve motor control, balance, and coordination. Most often, adaptations such as these are considered advantageous; however, they can also be detrimental and contribute to movement impairments. Everyday activities can change muscle performance, ROM/muscle length, joint mobility/stability, and motor control, which in turn can alter the relative participation of synergists and antagonists and eventually movement patterns.

The following sections describe the relationship between posture and movement and physiologic, anatomic, and psychologic impairments, lifespan considerations, and environmental factors.

Range of Motion

The normal limitation of ROM in certain directions has postural significance in relation to the stability of the body, particularly in standing. ROM is impacted by joint mobility and soft-tissue extensibility. For example, dorsiflexion ROM at the ankle with the knee straight is normally about 10 to 15 degrees. To prevent excessive hyperextension of the knees, when standing barefoot with the feet nearly parallel, the tibia should not sway posteriorly beyond vertical alignment, nor should the hip move beyond its 10 degrees of extension. The combination of posterior sway of the tibia (ankle plantar flexion) with hip extension in standing creates knee joint hyperextension. Excessive segmental joint ROM (i.e., hip hyperextension) can allow proportional postural deviations in the corresponding directions. This is an often an overlooked impairment – excessive ROM or muscle length – but equally important to reduced ROM or muscle length.

With respect to movement, ROM impairment can contribute to movement dysfunction in that normal movement cannot occur at a joint with limited ROM. On the other hand, excessive ROM can allow extremes of movement that are detrimental to the joint, periarticular structures, and associated muscles. Typically, limited ROM at a joint encourages faulty movement at another segment. For example, a common faulty movement pattern seen associated with adhesive capsulitis of the shoulder is excessive scapula elevation.[78] Normal ROM at a joint does not ensure accuracy of the PICR during active movement. Recall that precise active movement is dependent on balanced active force couples acting on the joint.

Muscle Length

Impairment of muscle length can both be the *result of* impaired posture and movement as well as *affect* posture and movement. Prolonged posture alterations can result in muscle length changes. The time a muscle spends in the shortened range and the amount a muscle is contracted in the shortened range determines whether it becomes shortened.[79–81] Conversely, the stimulus for lengthening a muscle is the amount of tension placed on the muscle over a prolonged period.[79–81]

Sustained postures, particularly those postures that are maintained in faulty alignments, can induce changes in the muscles and supporting tissues that can be injurious, especially when the joint is at the end of its range.[82]

A clinical example can provide a better understanding of these concepts. Consider a person with thoracic kyphosis with a scapula positioned in medial rotation (winging), downward rotation, and anterior tilt. The lower trapezius muscle can experience sustained tension, resulting in lengthening, from the three-dimensional alignment faults coupled with gravity and the weight of a limb. In the case of the anterior tilt, the pectoralis minor experiences little to no counterbalancing tension from the lengthened lower trapezius and is assisted by gravity and the weight of the limb to remain in the shortened position. If the pectoralis minor contracts repeatedly in the shortened range (e.g., as an accessory muscle of respiration), it can develop adaptive shortening. Muscles that are sustained in a lengthened or shortened position develop changes in sarcomeres and length–tension relationships. This ultimately affects the force couple action of the muscles, thereby ultimately affecting the PICR during active motion[1] (see **Building Block 9-1**).

BUILDING BLOCK 9-1

With a scapula aligned in downward rotation, anterior tilt, and medial rotation, classify all the axioscapular muscles in this table as to whether they are at risk of a lengthening or shortening adaptive change.

Axioscapular Muscle	Short	Long
Serratus anterior		
Upper trapezius		
Middle trapezius		
Lower trapezius		
Levator scapula		
Rhomboid		
Pectoralis minor		

Joint Mobility

Joint mobility can be reduced *or* excessive. A joint can only move through a precise PICR if the joint has the available passive range in osteokinematic and arthrokinematic motions *and* the appropriate soft-tissue length to guide/restrict excessive motion. However, normal passive joint mobility does not guarantee precise PICR during active motion.

Impairments in joint mobility rarely occur in isolation. Active motion is usually affected by a combination of factors such as muscle length, muscle performance, joint mobility, and motor control. For example, during active shoulder medial rotation in the prone position with the arm abducted to 90 degrees, the shoulder should be able to medially rotate 70 degrees without an associated anterior glide of the head of the humerus or anterior tilt or superior glide of the scapula.[83] The active ROM can be limited by stiff or short lateral rotators, stiff periarticular structures (particularly the posterior capsule), and/or weak or poorly recruited medial rotators.

In some cases, though the ROM may be normal, the *quality* of motion is affected. For example, during medial rotation, one deviation of the PICR that may be observed or palpated is an arthrokinetic motion of the head of the humerus gliding excessively anteriorly. This movement may result from one or a combination of factors, such as those previously mentioned, combined with specific weakness or poor control of the subscapularis; dominance of the pectoralis major, latissimus dorsi, and teres major muscles; and/or excessive extensibility of the anterior capsule. Joint mobility, whether limited or excessive, can affect active motion, particularly when combined with other impairments of body functions (see **Building Block 9-2**).

BUILDING BLOCK 9-2

Explain why subscapularis is an important muscle to promote quality of glenohumeral medial rotation ROM.

Muscle Performance

A long-held belief is that deviations in posture reflect muscle weakness. However, the relationships between postural deviation and muscle strength have been questioned,[84,85] and the literature instead suggests that the relationship between muscle length and strength may contribute to postural deviation.[1]

Stretch weakness is a term used by Florence Kendall to describe the effect on muscles maintained in an elongated condition beyond neutral physiologic rest position.[67] This definition is based on the results of manual muscle strength testing.[67] For example, when the shoulders are maintained in a forward position and the scapulae are positioned in medial rotation (winging), downward rotation, and anterior tilt, the lower and middle trapezius muscles are positioned in an elongated rest position. The manual muscle test, when completed in midrange, as is typically done, would demonstrate weakness (**Fig. 9-13**). However, the apparent weakness of the posturally lengthened muscle may be an indication of altered length–tension properties such that the elongated muscle cannot produce tension in the shortened range (i.e., the manual muscle test position).[79–81] Length–tension properties of muscle are also discussed in Chapter 5.

If the elongated middle and lower trapezius muscles are tested in a relatively lengthened range, the force production capability is greater than in the traditional manual muscle test position. This phenomenon can be called a length-associated change.[82]

FIGURE 9-13 Manual muscle test position for the lower trapezius. Note that the arm is in elevation, positioning the scapula in upward rotation. The test position for the scapula is upward rotation, adduction, and depression. Failure to hold the test position indicates weakness.

For the muscle to become lengthened, it adds sarcomeres in series and, therefore, is capable of producing greater peak force than a normal-length or shortened muscle when tested at its optimal length. However, if the lengthened muscle is placed in a shortened position for manual muscle test, the filaments would overlap and be less efficient at producing force than a short or normal-length muscle. When testing muscles in the shortened range, a more appropriate description may be *positional strength*, because it indicates only the torque the muscle can create in the short range.[1] One form of stretch weakness may be positional weakness. Testing the muscle at multiple points in the range and comparing findings with those for the opposite extremity (or half of the body when examining axial muscles) can help to differentiate positional weakness from weakness resulting from strain, disuse, or neurologic involvement. The muscle with length-associated changes tests weak in the short range and strong in the lengthened range, whereas the other sources of weakness should test weak throughout the range.

The length–tension properties of the muscle correlate directly with the participation of the muscle in the force couple. The line of pull of its fibers determines the specific function of each muscle. No two muscles in the body have exactly the same line of pull. Whenever muscle weakness exists, the performance of some movement or the stability of some part of the body is affected. A muscle that becomes elongated over time exhibits positional weakness relative to the same point in the range of normal length or shortened synergists. Compared with its normal-length or shortened synergists, its participation in the force couple is lessened until it can achieve its optimal length–tension relationship. The result is a deviation of the PICR, which may contribute to repeated microtrauma and eventually to macrotrauma, pathology, further impairment, and disability.

A clinical example may illustrate the relationship between length–tension properties and movement. In an individual with a functional limb length discrepancy with a high iliac crest on the right, the right hip is in postural adduction, which places the gluteus medius on stretch. During gait, the gluteus medius participates in the hip abduction force couple to decelerate hip adduction from the initial contact to midstance phase (see **Selected Intervention 9-1** and **9-2**). The tensor fascia lata (TFL) does not necessarily encounter the same stretch stimulus as the gluteus medius when the hip is in postural adduction (particularly the anteromedial fibers) and therefore can create better tension for abduction at initial contact when the hip is in more relative adduction. However, because the TFL is also a hip flexor and medial rotator, without strong counterbalance from the gluteus medius (particularly posterior gluteus medius), the PICR of the hip can deviate in the direction of flexion and medial rotation. The overstretched gluteus medius can generate greater counterbalancing tension only after the hip is adducted, flexed, or medially rotated, which places the muscle on stretch. The posturally lengthened muscle affects the force-couple action and ultimately affects active movement patterns (see **Building Block 9-3**).

BUILDING BLOCK 9-3

What kind of injury can the gluteus medius sustain if it is chronically activated in a stretched position? Could this be an explanation of lateral hip pain?

SELECTED INTERVENTION 9-1

Prone Hip Abduction

See Case Study No. 9

Although this patient requires comprehensive intervention, one critical exercise is described:

ACTIVITY: Prone hip abduction through full ROM

PURPOSE: Strengthen 2+/5 gluteus medius through full range (need to increase the muscle's ability to create tension through full range)

RISK FACTORS: No appreciable risk factors

EFFECT OF PREVIOUS INTERVENTIONS: None

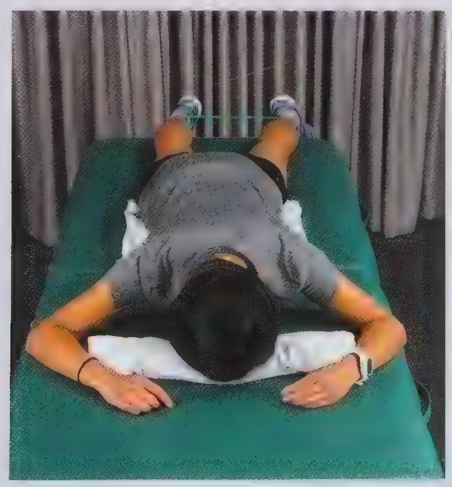
SUBSYSTEM OF THE MOVEMENT SYSTEM: ACTIVE

STAGE OF MOTOR CONTROL: Mobility

MODE: Resisted exercise in a gravity-lessened position

POSTURE: Beginning and ending position—prone, with a pillow under stomach, hip slightly laterally rotated, elastic around the ankle (**Fig. A**).

MOVEMENT: The hip extends just enough to clear from the supporting surface, abducts through the full available range (concentric), rests on the supporting surface, returns to a slightly extended position, and slowly adducts to the starting position (eccentric; **Fig. B**).



SPECIAL CONSIDERATIONS: Ensure that the gluteus medius is contracting throughout the entire activity (concentric and eccentric) and that the TFL is maximally relaxed. Ensure that full *end-range* motion is achieved and that the abdominal muscles are stabilizing the spine against extension and the pelvis against anterior tilt and side-bending forces imposed by motion of the hip. Be sure motion is isolated to the hip and that no motion occurs in the spine or pelvis.

DOSAGE

Special Considerations:

Anatomic: Gluteus medius
Physiologic: No strain, 2+/5 manual muscle test (MMT) grade
Learning Capability: Difficulty isolating gluteus medius over TFL may require tactile facilitation or surface electromyography with biofeedback on gluteus medius for better isolation.
Type of Contraction: Concentric during abduction motion and eccentric during adduction motion
Intensity: Light-resistance elastic tied around the ankle and taut in hip-neutral position
Speed of Activity: Moderate on concentric portions; slow on eccentric portion
Duration: To form fatigue for two sets (maximum of 30 repetitions)
Frequency: Daily
Environment: Home
Feedback: Initially tactile facilitation or surface electromyography with biofeedback, tapered after isolated contraction is achieved.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to increase the strength of the gluteus medius in isolation from the TFL. Because the MMT grade is 2+/5, a gravity-lessened position was chosen to allow full ROM. Light elastic was used to ensure concentric contraction of the gluteus medius during the abduction motion and eccentric contraction on the return from abduction in a gravity-lessened position. Full ROM is expected to work on length–tension properties of the gluteus medius (i.e., ability to create force throughout the range, including the shortened range).

EXERCISE MODIFICATION/GRADATION: As strength through a full range is developed, the exercise should be progressed to an against-gravity position (i.e., sidelying). After a 3+/5 MMT grade is achieved, standing functional activities should be introduced (i.e., stability and controlled mobility). After proximal stability and controlled mobility are achieved, the exercise can be progressed to functional gait activities (i.e., skill).

Within each activity level, specific dosage parameters can be manipulated to progress the exercise and prepare for gradation to the next level. At each level, care must be taken to ensure synergy between the gluteus medius and TFL in stabilizing the hip in the frontal plane by observing the pelvic and femur positions and preventing anterior pelvic tilt, Trendelenburg gait, or femoral medial rotation. In closed chain positions, neutral pelvic, tibial, and foot alignment about all three axes complement the hip position.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF SPECIFIC EXERCISE:

Posture: Educate the patient about asymmetric postures that reinforce a weak, lengthened gluteus medius (i.e., standing with weight shifted to the involved side, resulting in a high iliac crest).
Movement: During gait, think of contracting gluteal musculature at heel strike to prevent a Trendelenburg gait.

SELECTED INTERVENTION 9-2

See Case Study No. 9

PROBLEM: Right hip pain with prolonged weight bearing

SHORT-TERM GOAL (4 TO 6 WEEKS):

- Patient has 3+/5 muscle grade in gluteus medius
- Patient is able to walk 10 minutes with 2/10 pain and reduced Trendelenburg gait

LONG-TERM GOAL (12 TO 16 WEEKS)

- Patient has 4+/5 muscle grade in gluteus medius
- Patient is able to walk miles with 1/10 pain

Exercise	Early Phase	Late Phase
Hip abduction	Prone hip abduction (see Selected Intervention 9-1)	Sidelying hip abduction (Self-Management 19-4—Levels III-IV)
Active stretch Band (ITB)	Teach foam roll to self-mobilize ITB (Fig.7-49)	Active stretch at the end of Level V—Self-Management 19-4.
Functional training	Squat (Self-Management 19-8)	Split squat (Self-Management 19—Level III)

The theory of "core strength" in the lumbopelvic and cervical regions is another key concept that certainly pertains to optimal posture and movement.[86–89] Chapter 17 discusses the theory of core strength in detail along with therapeutic exercise descriptions to develop core strength. The reader is referred to the section "Muscle Performance" in Chapter 17, The Lumbopelvic Region for the literature review, and detailed discussion of this topic.

With respect to the endurance component of muscle performance, the fatigability of a muscle affects its participation in a force couple, particularly in repeated movements. Muscle fatigue affects movement, but muscle endurance often is not a factor in perpetuating optimal resting alignment; the length of the muscles and periarticular structures support optimal alignment. Little muscle activity is required to maintain a relaxed standing position.[90] However, in the presence of injury, even small demand on the musculature can be problematic.

Control of posture is a highly complex task in the human motor system. There is evidence that the postural control for stability and orientation requires proprioceptive input from numerous muscles in order to generate the appropriate torque in maintaining the body position.[91,92] The sensory organs involved in maintaining balance control and body orientation incorporates somatoafferent, vestibular, and visual input in order to assess the current body position. Consequently, the motor process coordinates postural strategies to decrease body sway and maintain it within the base of support. It has been suggested that the injury to the neck and/or the otolith structures that influence afferent feedback might contribute to loss of awareness and control of posture.[93] Therefore, the practitioner needs to look at global strategies as well as local, segmental strategies, when it comes to examining and treating posture impairment (see **Building Block 9-4**).

BUILDING BLOCK 9-4

Consider a 23-year old that sustained a second-degree ankle sprain. Provide an explanation as to why the physical therapist should consider closed chain balance drills in the plan of care.

Pain

The introduction to this chapter discussed the cautious approach to assigning correlation and/or causation of pain with posture and movement. Sometimes, under certain circumstances, posture and movement patterns matter, while other times, it is not so clearly associated.[13] One concept worth discussing is the notion that too much attention to posture and movement can in and of itself create an inadvertent "nocebo" effect. The nocebo effect is a detrimental effect on health produced by psychological or psychosomatic factors such as negative expectations of treatment or prognosis.[94] *What* we say to patients matters. If we place too much emphasis on posture and movement, the patient might feel they can never achieve a high level of adherence and performance and therefore not be effective at reducing pain levels. In addition, therapists can inadvertently contribute to maladaptive patterns with fear avoidance of postures and movements that the patient is told *cause* pain. We can use language such as "optimizing posture and movement patterns can help calm down the trigger from pain sensitive tissues," as opposed to giving them the message that they have pain because of posture and movement faults. Ultimately, we want to restore homeostasis to the system and "comprehensive capacity,"[95] a term used to refer to variability of the movement system, not just ideal posture or form, but the ability to position or move in a variety of patterns without provoking symptoms.

We have all had a painful limb and find ourselves moving differently because of the pain. Pain can induce abnormal movement (maladaptive), abnormal movement can induce pain (adaptive), and it can be difficult to differentiate cause from effect. When a mechanical stress perpetuates the symptom or prevents resolution of the painful condition, the mechanical cause must be diagnosed and treated. Ultimately, the posture habits and movement patterns contributing to the mechanical cause of pain must be modified to allow the nervous system to calm down and create a healing environment with the optimal stress for tissues to heal.[96]

Pain may or may not alter a given posture or movement, depending on the severity of the symptom and the magnitude or intensity of stress imposed by the posture or movement. However, pain that is predictably associated with posture and movement can lead the clinician to an understanding of the kinesiopathologic factors contributing to the pain. For example, a patient has shoulder pain during swimming; the movement impairments associated with the pain experienced during the swim stroke (nociceptive trigger) and secondarily the alterations to the movement pattern that reduce or eliminate the pain (calm down the nervous system) can drive the intervention.

A clinical test that can be administered is a prone 90/90 glenohumeral rotation test. The patient is positioned prone with the arm abducted 90 degrees with the elbow flexed 90 degrees and the forearm hanging vertically off the side of the table (see **Fig. 9-14**). The patient is asked to actively medially rotate his

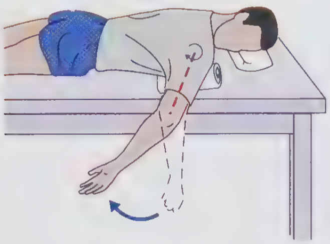


FIGURE 9-14 Illustration of movement test position for glenohumeral medial rotation.

shoulder. The examiner palpates and observes the PICR of the humeral head. If excessive anterior translation of the humeral head is observed and the movement is painful, the follow-up test is to teach the patient to control anterior translation and note the effect on pain. If the pain is reduced or eliminated with control over the anterior translation, this change will drive the intervention. The clinician must perform additional tests to determine the specific impairments that contribute to the anterior displacement of the head of the humerus such as a weak or overstretched subscapularis, stiff posterior capsule, and/or dominant and short teres major or anterior deltoid.

Treatment is based on resolving the impairments associated with the kinesiopathologic pattern during specific exercises and eventually during functional movement patterns. By treating the movement impairment, the pain often resolves without necessarily requiring direct treatment of the tissue that is the source of pain (see **Building Block 9-5**).

BUILDING BLOCK 9-5

Consider a 54-year-old female master swimmer with anterior shoulder pain after 15 minutes of freestyle swimming. She has had a full evaluation by her orthopedist including an MRI to R/O rotator cuff tear. Your physical therapy examination reveals the following primary impairments of body functions:

1. Painful weakness to glenohumeral medial rotation and adduction
2. 3+/5 lower and middle trapezius and serratus anterior

How could weakness of the glenohumeral medial rotators and scapular upward rotators contribute to pain in the anterior shoulder during swimming freestyle?

Anatomic Impairments and Anthropometric Characteristics

Anatomic impairments can predispose persons to impairments of posture and movement that can result in MPS. Individuals with anatomic impairments (e.g., scoliosis, kyphosis from Scheuermann disease, hip anteversion) can be at higher risk to develop MPS because of altered posture habits and movement patterns. For example, an individual with Scheuermann disease typically has moderate to marked kyphosis. This patient is prone to even more exaggerated kyphosis beyond the anatomic impairment because of the effect of gravity and the weight of the upper extremities on the kyphotic posture. Increased thoracic kyphosis can give rise to thoracic, neck, shoulder, low back, or lower quadrant pain because of compensatory spinal, shoulder girdle, pelvic girdle, and lower extremity alignments.

The patient may adopt movement patterns that perpetuate the kyphotic posture. For example, during forward bending, instead of initiating the movement with concentric phasic activity from the rectus abdominis and controlling the lowering with eccentric spinal and hip extensors, the bending movement may be produced by tonic concentric rectus abdominis activity and phasic eccentric deceleration from the spinal and hip extensors. The latter movement pattern would contribute to greater kyphotic forces on the thoracic spine than the former pattern.

Anthropometric characteristics can also contribute to impairments of posture and movement.[97,98] Consider a tall man with broad shoulders and a tall, narrow pelvis. Ideal lumbopelvic rhythm is such that motion at the lumbar spine should be accompanied by motion of the pelvis rotating over the hips.[99] The tall man with broad shoulders and a tall, narrow pelvis has a higher center of mass than an average-height woman with a relatively broader pelvis. When the man bends forward, the fulcrum point is more likely to be in the lumbar spine than at the hips because of the high center of mass. The man therefore has a greater tendency to bend with excessive lumbar flexion and limited pelvic rotation (**Fig. 9-15**). With this forward bending strategy used over a lifetime, the hip joint is at risk for developing hypomobility in the direction of flexion, and the lumbar segments are at risk of becoming hypermobile in the direction of flexion. The hypermobility of the lumbar spine into flexion may be carried over to other postures and movement patterns such as sitting, reaching, and sports activities such as the follow-through phase in serving the ball in tennis. Related impairments of muscle length and performance can result from impairments of movement and contribute to perpetuating and further exaggerating faulty movement (see **Building Block 9-6**).

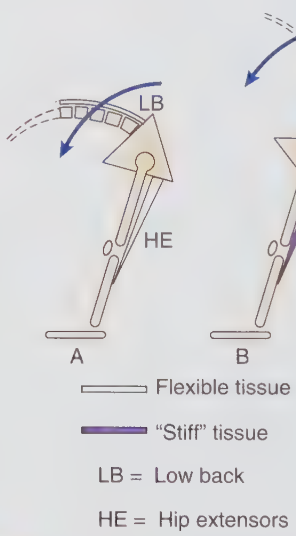

FIGURE 9-15 **(A)** Normal lumbopelvic rhythm. **(B)** Faulty lumbopelvic rhythm with less movement of the pelvis relative to the hips. In men, this could result from the anthropometric characteristics of a heavy upper body relative to the lower body.

BUILDING BLOCK 9-6

The valgus angle of the male is different from that of the female with females tending toward higher valgus angles. How could the valgus angle in the female athlete predispose her to noncontact anterior cruciate ligament injury? What preventive exercises would you want to include in the training regimen of the female athlete?

Psychologic Impairments

The link between posture and movement and the experience of pain has been discussed in some detail already in this chapter, but it is worthy of further exploration from a psychologic point of view. Research points to a complex and dynamic interaction of biologic, psychologic, and social variables influencing movement and its relationship to pain and pain-related disability.[100] There is growing evidence that pain-related fear may be a particularly important mechanism in the onset and maintenance of pain-related disability.[101–106] Pain-related fear refers to the extent that an individual believes that certain movements or actions will result in either increases in pain levels or exacerbation of an injury that is associated with pain[106] and it is usually associated with avoidance of those movements or activities.[106–109] A reduction in activities on an ongoing basis can lead to the establishment of a negative cycle characterized by altered movement patterns, physical deconditioning, decreased self-efficacy, and negative affect.[110] This can result in a detrimental impact upon the musculoskeletal and cardiovascular systems,[111] further worsening the pain problem and leading to still greater avoidance of activities. Such a cycle, termed "fear-avoidance,"[111] is thought to be maintained by both the reduction in anxiety that comes from the successful avoidance of feared activities[112] and the further entrenchment of pain-related fears as the individual allows themselves few opportunities to "challenge" their beliefs about the consequences of certain movements.

There is considerable empirical support for the notion that pain-related fear is related to disability in patients with chronic pain.[104,113] Studies have shown that patients with high pain-related fear tend to overestimate their expected levels of pain in certain situations and to terminate activities earlier than those who predict less pain.[114] There are also indications that pain-related fear may be more strongly associated with disability than either pain severity or other biomedical characteristics of the patient's condition.[101,103,109,111,115] For example, Waddell et al.[116] found that fear-avoidance beliefs about pain were better predictors of self-reported disability in ADL than were the anatomic pattern of pain, the time pattern of pain, or pain severity. And although this research is compelling, and we cannot underestimate the fear-avoidance component of movement impairment, we must also pay close attention to the quality of movement. We must teach the patient to move efficiently, safely, and with the least biomechanical stress to the affected tissues to address the impairments of body functions contributing to the pain.

It is beyond the scope of physical therapy practice to deal with the complexity of the biopsychosocial framework contributing to pain and movement impairment. A multidisciplinary approach toward complex chronic pain is warranted. If the physical therapist determines that the psychological state of the patient is inhibiting recovery, referral to an appropriate mental health practitioner is indicated. Physical therapy intervention may need to pause until the psychological condition improves, or it can proceed if it is determined that continued intervention is beneficial to psychologic recovery. As the psychological status improves, the PT's role is to reintroduce movements that have been avoided. As movement is restored, confidence improves, and fear avoidance reduces—thus breaking the cycle of pain and fear avoidance of movement (see **Building Block 9-7**).

BUILDING BLOCK 9-7

Consider a 45-year-old female with a chronic history of hip and low back pain. She is able to perform a comprehensive self-management program safely and has been able to control her pain 80% of the time. However, she is fearful to return to her health club which you feel is necessary for her to improve her global physical condition. How would you assist her in returning to her gym setting with a comprehensive gym-based program?

Lifespan Considerations

We all have observed the effect of age on posture and movement. Children are not expected to conform to an adult standard of posture and movement, primarily because the developing individual exhibits much greater mobility and flexibility than the adult.[117] Developmental deviations appear in many children at about the same age and improve or disappear without any corrective treatment, despite unfavorable environmental influences.[117] However, developmental deviations are perpetuated by habit in some children. Repeated observation (not a single examination) can determine whether a developmental deviation is being perpetuated by habit. If the condition remains static or if the deviation increases, corrective measures are indicated. A young child (younger than 5 years) is not likely to have habitual faults and can be harmed by corrective measures that are not needed. When screening a developing child, check ROM of the hips and spine to see if the postural impairment is flexible. If not, radiographs may be necessary and immediate attention may be required (**Fig. 9-16**). Developmental changes occur in the feet, knees, hips, pelvis, trunk, and shoulder girdle. **Display 9-7** lists the common developmental deviations in children that should gradually diminish as the child reaches adolescence and adulthood.

One particular anatomic impairment that is not considered a normal developmental posture occurs during adolescence. Physical therapists working with preadolescent and adolescent populations should be routinely screening for the onset of scoliosis. After scoliosis is diagnosed, the adolescent can be referred to a physician specializing in the treatment of scoliosis and a comprehensive management plan can be developed.

FIGURE 9-16 Physiologic lordosis of puberty. This form of lordosis (*red arrow*) is seen during late childhood just prior to puberty. The spine is flexible and the lordosis disappears on forward bending (*white arrow*).

DISPLAY 9-7

Developmental Deviations in Posture

Feet

- Flat arches are normal in the small child.
- By age 6 or 7, expect good arch formation.

Knees

- Genu valgum is normal in a child age 5 or younger (about 2 inches in between ankles is normal for an average-height child).
- By age 6 or 7, genu valgum should be diminished or gone.
- Postural genu varum in the school-age child is not acceptable, and corrective measures should be taken, because it is difficult to change in the young adult.
- Genu varum may be compensatory for genu valgum by hyperextension of the knees.

Hips

- Femur medial rotation is the most common and often results from hip anteversion, foot pronation, knee hyperextension, postural genu varum, and less often, genu valgum. Check for structural sources and treat with the appropriate corrective measures.
- By adolescence, the femur should be in near-neutral alignment.
- Femur lateral rotation is more common in young boys.
- Persistent lateral rotation should be treated, because it can be detrimental in adulthood.

Lumbopelvic Region

- A protruding abdomen is normal for a child.
- By the age of 10 to 12, the abdomen should no longer be protruding.
- Lordosis peaks at age 9 to 10 and should gradually diminish thereafter.
- Handedness patterns emerge in school-age children, most commonly with the hip high and shoulder low on the dominant side. This should be monitored if it is borderline or excessive.

Shoulder Girdle

- Scapular tilting is normal in school-age children.
- The prominence should diminish as the child approaches adolescence.

From Kendall HO, Kendall FP, Boynton DA. Posture and Pain. Huntington, NY: Robert E. Krieger Publishing, 1970.

There is evidence that alterations in movement begin to occur in late middle age, probably because the functional abilities gradually decline.[118] In the broad sense, the execution of voluntary movements requires two goals to be achieved simultaneously: accurate performance of a goal-directed movement on the one hand, and maintenance of equilibrium and appropriate posture, or set of postures, on the other (for a review, see Horak and Macpherson[119] and Massion et al.[120]). Aging adds an additional challenge with coordination between equilibrium and movement, causing progressive impairments at the level of the central nervous system as well as in the sensory motor system. According to Millanvoye,[121] decrements in performance are initially imperceptible, become detectable around the age of 40 to 45 and only become noticeable to the point that they cannot be ignored after the age of 60. Thus, the possibility of early detection of minor changes between young and aging adults in the coordination between equilibrium and movement may provide a window into the evolution of fall risk as individuals age. Identification of these changes and their time course could provide the basis for preventive rehabilitation programs to diminish the risk of traumatic falls and to enhance maximum autonomy.[122] Exciting research is on the horizon in this area, with a greater emphasis on prevention as we understand the effect of aging on equilibrium and movement.

Environmental Influences

The activities in which an individual participates and the surrounding environment may have favorable or adverse effects on posture and movement. The nature of the activities and the time spent doing them and whether the effect of *habitual* postures and *repeated* movements during one activity are reinforced or counteracted by *habitual* postures or *repeated* movements in other activities determine the overall, cumulative posture and movement effect. Stresses are put on the basic structures of the human body by increasingly specialized and limited or repetitive activity (e.g., working endless hours at a computer display terminal, going home exhausted, sitting most evenings in a recliner chair in front of a television).

The activities of an individual must be considered as a whole in gauging their postural or movement effects. Concentration on one type of activity can ensure muscle imbalance, but a combination of activities may be almost as unfavorable if each involves the same kind of movement or position. For example, a person working at a video display terminal who engages in piano playing in her leisure time has no real change in the type of activity.

Several environmental factors, such as workstations, beds, pillows, car seats, school chairs and desks, and footwear, influence posture and movement. These environmental influences should be made as favorable as possible. **Patient-Related Instruction 9-1** outlines important tips for proper workstation ergonomics. This would be a useful handout to provide all your patients that spend time at a computer workstation. When major adjustments cannot be made, small adjustments often help considerably. A discussion of environmental influences is not complete without reference to body mechanics related to lifting and carrying. These strategies should be examined and favorably modified as much as possible for the individual's circumstances.

EXAMINATION AND EVALUATION

Posture

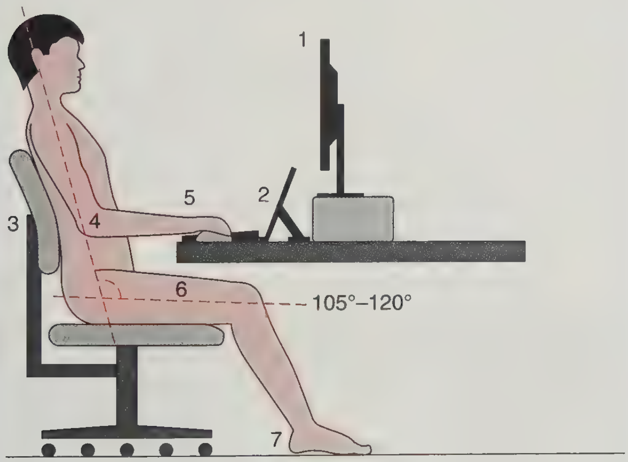
The bony landmarks and postural reference points that were discussed earlier in the chapter are put to practical use in plumb line tests for postural alignment (**Fig. 9-17**). In standing, the patient's posture should be examined twice: once in their "typical" posture and once in a "standardized" posture. To observe the patient's "typical" posture, have the patient march in place 10 times, take a deep breath and exhale. This encourages the patient to stand in their natural, weight-bearing posture. The plumb line should bisect the patient's pubic tubercle, as the feet are allowed to be in an asymmetrical distance from the midline. The therapist should then observe the patient from the front, both sides and the back, noting any asymmetries. For example, a person who stands with the majority of their weight

Patient-Related Instruction 9-1

Checklist for a User-Friendly Workstation

Sitting position is an important factor in keeping your body aligned properly to minimize stress on your back and muscles. Leaning back slightly into your chair's back rest relaxes your back muscles and promotes blood circulation. Leaning back too far however can result in an awkward neck posture.

1. Eye level: The top of the screen should be at eye level; lower for bifocal wearers. Screen distance at arm's length (18 to 36 inches).
2. Document holder: Centered between monitor and keyboard or next to the screen.
3. Chair backrest: Provides firm lower back support. The chair backrest and seat should be easily adjustable for height and tilt by the user.
4. Keyboard and mouse: Keyboard height promotes relaxed arms with forearms parallel to the floor. If you use a mouse or other pointing device, it should be placed next to the keyboard.
5. Wrist position: Straight (neutral). Wrist rest—padded, moveable wrist rest, same height as the front of the keyboard. (Do not use a wrist rest while keying.)
6. Knee position: Knees should be at or below hip level. Provide ample legroom under your work surface.
7. Feet position: Feet should rest firmly on the floor or footrest.



Reclined sitting
Leaning back slighlty into your chair's back rests relaxes your back muscles and promotes blood circulation. Leaning back to far can result in awkward neck postures.

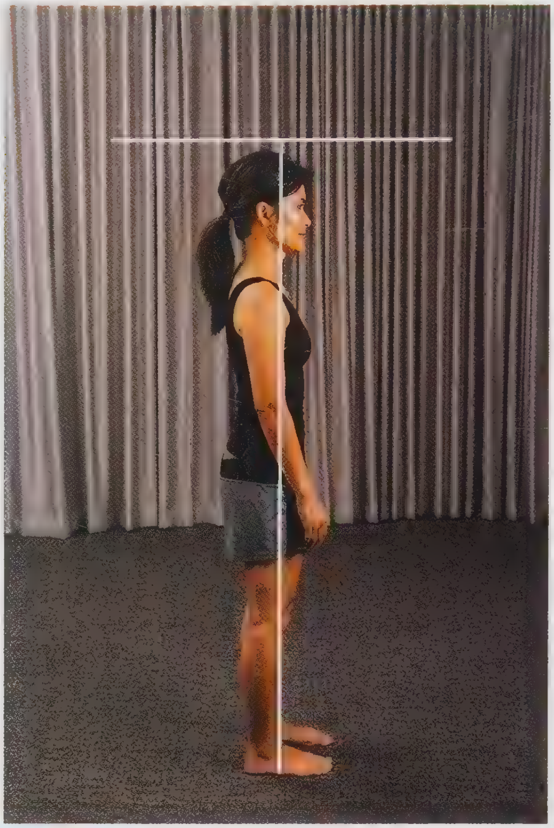


FIGURE 9-17 For the purpose of testing, the client steps up to a suspended plumb line. For the back or front view, the subject stands with feet equidistant from the line; for the side view, the point on the plumb line is just anterior to the lateral malleolus. The base point should be the fixed reference point, because the base is the only stationary or fixed part of the standing posture.

on their right lower extremity with their left lower extremity in hip abduction may experience stretch weakness of the right hip abductors and shortness of the right hip adductors. In addition, this posture creates right lumbar sidebending with shortening of the right quadratus lumborum and lengthening of the left quadratus lumborum. Once the patient's natural posture has been observed and asymmetries noted, the therapist should then observe posture from a "standardized" position. To standardize the position, have the patient place one foot on either side of the therapist's foot. The therapist then removes their foot from between the patient's feet. The plumb line should bisect this space. The advantage of using the therapist's foot as a reference is that the position is repeatable at every patient visit, regardless of plumb line availability. The patient should again be observed from the front, both sides and back, noting any asymmetries in this position. The amount of deviation of the various points of reference from the plumb line reveals the extent to which the subject's alignment is faulty. When deviations from plumb alignment are evaluated, they are described as slight, moderate, or severe.[67] Additional alignment tests can be performed in several positions, such as sitting, recumbency, and single-limb stance. Side to side differences as well as deviations from acceptable standards can be noted.

In addition to standard posture assessment, the physical therapist must also examine specific segmental alignment of adjacent segments in a region. For example, the position of L5 relative to S1 may be relevant in a lumbar condition. If L5 is in a slight rotation, this may be a source of nociception due to the biomechanical stress on the tissues of the motion segment. Treatment of this specific segmental alignment fault may be vital to the reduction of symptoms and the overall recovery of the patient.

Posture can assist the clinician in generating hypotheses regarding muscle length. For example, anterior pelvic tilt can suggest short hip flexors and elongated abdominal muscles. Specific muscle length tests are necessary to validate the hypotheses, and determine actual muscle length. Definitions of terms regarding muscle length are outlined in **Display 9-8**.

DISPLAY 9-8

Definitions of Terms Regarding Muscle Length

- Tautness is defined as muscles or ligaments put on tension. It implies a state in which slack is taken up in the muscles or ligaments.
- A short muscle limits the ROM as it relates to the kinesiologic standard.
- An elongated muscle is longer than the kinesiologic standard; tautness appears after the motion has exceeded the normal joint range.
- The term tight is often used interchangeably with short or taut, but these terms do not have equivalent meanings. On palpation, a muscle that is short and drawn taut feels tight. A muscle that is elongated and drawn taut also feels tight on palpation. Because the word tight implies that a muscle should be stretched, the terms short and elongated are preferred to describe muscle length to ensure that stretching is applied only to short muscles.
- Stiffness is defined as the change in tension per unit change in length.[123] When passive motion of a joint is assessed, all the tissues crossing the joint contribute to the resistance, which can be referred to as joint stiffness.[1] For the purposes of this text, stiffness refers to the resistance present during the *passive* elongation of muscle and connective tissue, not during *active* muscle contraction.

Movement

Examination of movement in the clinical setting can be challenging. Computerized movement analysis equipment is costly and is not user-friendly in the typical physical therapy setting. Video applications are readily available to the consumer and can provide acceptable analysis and feedback. In addition, the clinician can rely on the following test procedures for single-joint movement analysis:

- Palpation skills and precise observation of basic movement patterns at a single joint can be used to determine how closely the movement pattern replicates the kinesiologic standard PICR for a given limb for that movement (e.g., observing or palpating the glenohumeral or scapulothoracic joints while raising the arm in flexion; or the spine, pelvis, knee, ankle, or foot during standing hip and knee flexion).
- Palpation or surface electromyography can be used to determine the pattern and synchronization of muscle activity for a given movement, which is compared with known kinesiologic standards

The clinician can rely on the following test procedures for analysis of multiple-segment movement:

- When performing a gait analysis, break the movement into phases, and look at each segment or component (i.e., group of segments) during each phase and relate the segmental movements to the process of movement. For example, the step-up can be broken into a swing and stance phase (**Fig. 9-18**). Each segment can be analyzed and relationships can be determined. For instance, a hip-hike strategy in the lumbopelvic region is related to insufficient hip and knee flexion and ankle dorsiflexion in the swing phase, and a Trendelenburg position (pelvis is dropped on the side opposite to the weak hip abductors) in the stance phase is related to similar abnormal movement patterns (i.e., hip adduction occurs in a hip-hike and Trendelenburg position).
- Similar movement pattern descriptions can be developed for each basic movement required for ADL (e.g., rising from sit to stand, step-down, bed mobility, reaching). By describing movement pattern strategies, the variations in movement patterns and deviations from efficient and healthy patterns can be determined. The reader is referred to a more complete reference on this topic for specific regional movement impairment syndromes.[1]

A B

FIGURE 9-18 Step-up consisting of **(A)** the swing phase in which the hip and knee are flexing to bring the foot to the surface of the step and **(B)** the stance phase in which the body is being raised onto the step.

Additional examination techniques can offer clues to expected outcomes. By compiling results of ROM, muscle length, joint mobility, and muscle performance tests, the clinician can hypothesize about the quality of the PICR and the muscle recruitment patterns during active movement. The minimal essential tests of muscle length that should be included in any posture or movement examination of the lower and upper quadrant are listed in **Display 9-9**. The minimal essential tests of positional strength that should be included in any posture or movement examination for the trunk, upper quadrant, or lower quadrant are listed in **Display 9-10**. Reexamination of the movement after additional tests have been performed can enable the clinician to better understand the complexity of movement.

DISPLAY 9-9

Essential Muscle Length Tests

Lower Quadrant

- Hamstring: This test should distinguish between the medial and lateral hamstrings.
- Gastroc-soleus: This test should distinguish between the gastrocnemius and soleus.
- TFL and iliotibial band
- Hip flexors: This test should discriminate among the TFL, rectus femoris, and iliopsoas.[1]
- Hip rotators: This test should distinguish between the medial and lateral rotators.

Upper Quadrant

- Teres major and latissimus dorsi
- Rhomboid major and minor and levator scapula
- Pectoralis major
- Pectoralis minor
- Shoulder rotators: This test should distinguish between the medial and lateral rotators.

DISPLAY 9-10

Essential Positional Strength Tests

Trunk

- Abdominal muscles: separate tests should be performed for the rectus abdominis and internal oblique, external oblique.[67] In addition, the transversus abdominis should be assessed for its ability to contract.[124]

Lower Quadrant

- Iliopsoas
- Gluteus medius
- Gluteus maximus
- Hamstrings
- Quadriceps
- TFL

Upper Quadrant

- Serratus anterior
- Upper, middle, and lower trapezius
- Infraspinatus and teres minor
- Subscapularis[1]

INTERVENTION

Healthy, effective, and efficient posture, alignment, and movement are considered to be an integral part of general well-being. Although posture and movement alterations can each be considered as one type of impairment, they cannot be considered in the same way as impairment of muscle performance, ROM, muscle length, or joint mobility. Impairment in posture and movement can be the result of many factors, including physiologic, anatomic, psychologic, and environmental factors.

To develop an efficient, effective intervention for the treatment of posture and movement impairment, all impairments, activity limitations, and participation restrictions resulting from and contributing to posture and movement impairment should be understood. The effect of predisposing risk factors, previous interventions, and environmental influences should also be taken into consideration.

This chapter has presented a foundation for developing therapeutic exercise interventions to treat posture and movement impairments. The remainder is devoted to describing therapeutic exercise intervention for posture and movement according to the intervention model described in Chapter 2.

The Movement System

Any or all subsystems of the movement system can be involved directly or indirectly in the development of posture and movement impairment and therefore should be addressed in treatment. Passive and active subsystems usually require direct intervention for the correction of both posture and movement impairments, whereas the neural subsystem is more critical to movement impairments than posture impairments. Impairments of the cognitive/emotional subsystem can limit the progress of an individual with posture or movement impairments. If this is the case, appropriate referral to a mental health practitioner may be required to reach the desired functional outcome. Impairments of the support subsystem can affect posture and movement directly (i.e., faulty breathing patterns or reduced energy for movement) or indirectly through oxygen transport deficits in systemic disease that contributes to further faults in posture and movement.[61] **Display 9-11** provides examples of impairments of the subsystems of the movement system associated with posture and movement.

Other bodily systems may be involved directly or indirectly and should be considered if necessary to improve posture or movement. For example, a patient who presents with posture and movement impairments about the hip may present with comorbidity of urinary incontinence caused by pelvic floor weakness and estrogen depletion.[125] Full correction of posture and movement impairments about the hip may not be achieved without attention to the pelvic floor dysfunction, which is caused by impairments of the movement, urogenital, and endocrine systems. The link between the movement system and urinary incontinence is discussed in Chapter 18. In this case, without considering the associated urogenital problems and hormonal imbalances, the pelvic floor problem may not resolve, preventing optimal function of the pelvic floor muscles. Because two of the pelvic floor muscles are also used for hip function (i.e., obturator internus and piriformis), dysfunction of the pelvic floor may contribute to posture and movement impairment of the hip,

DISPLAY 9-11
Movement System Factors Contributing to Impairment of Posture and Movement

Passive Subsystem

- Impairments of body structures such as scoliosis or hip anteversion
- Impairments of body functions such as postural genu varum, thoracic kyphosis, or hip adduction as a result of chronically standing asymmetrically
- Anthropometric characteristics such as broad pelvis, tall pelvis, long legs, etc.
- Overstretched gluteus medius, contributing to high iliac crest and functional limb length discrepancy

Active Subsystem

- Easily fatigued serratus anterior, contributing to reduced scapular upward rotation with repetitive overhead activities
- Gluteus medius strain, contributing to reduced activity level and altered movement patterns
- Neural Subsystem
- Reduced or loss of innervation of the gluteus maximus associated with standing in hip hyperextension to avoid using the gluteals eccentrically with controlled hip flexion
- TFL dominance during hip flexion, contributing to hip flexion with medial rotation
- Latent timing of the vastus medialis oblique, contributing to patellofemoral movement impairment

Support Subsystem

- Inappropriate breathing patterns associated with abnormal rib cage alignment and with rib and thoracic spine movement patterns

Cognitive/Emotional Subsystem

- Depression associated with slumped posture or shuffling gait
- Fear avoidance of movement
- Increased muscle tension associated with stress

which may contribute to further pelvic floor dysfunction, and so on as the cycle continues. *All* the systems involved must be addressed to resolve the posture and movement impairment at the hip.

Activity and Dosage

Numerous activities or techniques can be chosen to restore healthy and efficient posture and movement:

- **Stretching** short muscles and improving extensibility of stiff myofascial tissues
- Improving **muscle performance** in muscles exhibiting atrophy, weakness, strain, or poor endurance
- **Supporting** and **strengthening** elongated muscles in the shortened range
- Optimizing **body mechanics, ergonomics,** and **posture awareness**
- Normalizing segmental **alignment**
- Awareness training of **preferred postural patterns**
- Optimizing **balance and coordination**
- Teaching proper motor **control** strategies for optimal control over segmental, intersegmental, and total body movement
- Training appropriate **breathing strategies**

This is not an all-inclusive list in that essentially all therapeutic exercise interventions can affect posture and movement. Because posture and movement are components of the intervention model, every activity or technique should promote optimal posture and movement. Generally, when teaching exercise activity or technique, the clinician should not compromise kinesiologic standards of posture and movement unless modification is necessary as a result of the disease, pathology, or physiologic or anatomic impairment. However, the clinician may decide to allow the patient to exercise and move in nonoptimal patterns to demonstrate comprehensive capacity and develop confidence that he/she can tolerate less than ideal movement without provoking symptoms. Of course, strict adherence to optimal posture and movement is indicated under the following conditions:

- Postacute injury to protect damaged tissue
- High load activities
- Interruption of posture and movement habits associated with pain
- Temporary changes to desensitize the ecosystem
- Respect for adaptation

Identifying and prioritizing the subsystems of the movement system, combined with knowledge of the physiologic status of the component impairments, can help to determine the activities or techniques needed, including the posture, movement, and mode parameters. Dosage parameters depend on the component impairment (e.g., ROM, muscle length, joint mobility, and muscle performance), stage of motor control, and physiologic status of the tissue being addressed.

To illustrate these points, consider a patient with a mild lower trapezius strain with thoracic kyphosis and abducted, anterior tilted, and downwardly rotated scapulae at rest (**Fig. 9-19**). The patient uses excessive scapular abduction, medial rotation, and anterior tilt during forward-reaching activities. Prevention of these impairments is preferable, and there should be careful scrutiny of any posture, activity, or technique that allows further stretching of the lower trapezius. The ideal length of periarticular structures and myofascial tissue helps to maintain ideal

FIGURE 9-19 This figure illustrates abduction and downward rotation of the right scapula relative to the left.

posture alignment with a minimum of muscular effort. When these tissues become overstretched, they fail to offer adequate support, the joint(s) deviate(s) from the neutral position, posture becomes faulty, and muscular effort or excessive passive tension is required to maintain ideal alignment. In this case, it is possible that the lower trapezius is strained by overstretching, and that the posture (thoracic kyphosis), scapula alignment (abducted and downwardly rotated), and movement patterns (scapula abduction, anterior tilt, and medial rotation) perpetuate this condition. Treatment of passive properties (i.e., short range support [i.e., taping—see Chapter 25], active strengthening of the lower trapezius) coupled with biomechanical alterations (i.e., reduced thoracic kyphosis, altered workstation ergonomics), and neural factors (train reaching patterns without excessive scapula abduction, anterior tilt, or medial rotation) is indicated. Combining interventions to passive, active, and neural subsystems is more powerful and time efficient than focusing on any one subsystem in isolation.

With respect to the active subsystem, the goal is to improve muscle performance by altering length–tension properties of the lower trapezius. This component of muscle performance impairment is often overlooked but is critical to achieving muscle balance to restore healthy and efficient posture and movement. The tendency may be to stretch the opposing short pectoralis minor and major (also contributing to impairment of scapula posture and movement). However, if attention is focused *only* on stretching the short muscle without supporting and strengthening the lengthened muscle, equilibrium about the joint cannot be achieved. Another example of this principle is in the case of a person with an anterior pelvic tilt and lumbar lordosis. If the hip flexors are stretched without adaptive shortening of the abdominal muscles (see Chapter 17), the pelvis does not assume a neutral position in relaxed standing.

One activity that may be useful in this situation is to strengthen the adaptively lengthened muscles in the shortened range. The premise of this intervention strategy is to improve the strength of the lengthened muscle in the short range, where it has the greatest difficulty creating tension. If the focus of the exercise is on strengthening without attention to the ability to create tension in the shortened range, the exercise may reinforce muscle imbalance by increasing strength in the lengthened range. Careful decisions must be made regarding the stage of motor control, posture, mode, movement, and dosage parameters to provide the optimal stimulus for strengthening without overloading the target muscle or promoting substitution of a dominant synergist (i.e., upper trapezius) or antagonist (i.e., pectoralis minor or major). The physiologic status of the tissue (i.e., length-associated changes or degree of strain) must be considered when determining each of these parameters.

Stability may be the starting point for the stage of motor control because strengthening is the chosen activity and specificity is critical so as not to strengthen in the lengthened range or the overused antagonist. Often, the lengthened muscle is unable to hold the limb against gravity when positioned in the short range as a result of the altered length–tension properties. Shortening the lever arm or exercising in a gravity-lessened position may be necessary for optimal strengthening (see Self-Management 25-2 in Chapter 25). As the muscle becomes stronger in the shortened range, lengthening the lever arm and exercising against gravity can modify the exercise. Submaximal isometric contractions in the short range may be ideal initially, moving toward concentric–eccentric contractions throughout the range as muscle performance and length tension improve and the tissues heal (if strain or tendinopathy is present). After stability and mobility are restored, the exercise can be progressed to controlled mobility and skill, with ultimate progression to functional movement patterns involving the total body as the final level of difficulty.

Dosage should follow the guidelines for strength training to improve muscle performance and generate hypertrophy of the lower trapezius to provide counterbalancing stiffness to the antagonists (pectoralis major and minor). Eventually, endurance dosage parameters can be applied as more functional movements are incorporated.

Simultaneous stretching of the pectoralis minor and major is not recommended due to the techniques that are often used for this type of stretching. The typical corner or doorway stretch (see Fig. 25-6) has a tendency to place excessive stress on the anterior capsule of the glenohumeral joint and thus is discouraged. In this case, the "freest segments moves," and the anterior capsule will undergo unnecessary lengthening and the pectoralis muscles will remain shortened. Progressive strengthening of the trapezius has an elongating effect on the pectoralis minor and major and is a form of "active stretch" that is highly recommended (see Self-Management 25-2 and Display 25-13).

It may also be necessary to address breathing patterns (Breathing in Thoracic in Chapter 24) if it is determined that the pectoralis minor is stiff because of overuse as an accessory muscle of respiration. Stretching addresses the passive subsystem, and breathing addresses the support subsystem. Both of these interventions can begin at the mobility stage of motor control, progressing somewhat parallel to that for the lower trapezius toward controlled mobility and skill.

Ultimately, the isolated joint function of optimal movements of the scapula must be incorporated into total-body movement patterns (i.e., controlled mobility and skill). When this stage is appropriate, movement impairments of related areas may emerge. Perhaps the scapula abducts during forward-reaching movements because of a lack of hip flexion during reaching patterns or a lack of thoracic or hip rotation during cross-body reaching patterns. The related areas may require intervention to restore normal function to the shoulder girdle.

Patient-Related Instruction and Adjunctive Interventions

Education regarding attention to postural alignment in frequently held or prolonged occupational or recreational positions is key to (a) optimizing joint position for rest and function, (b) reducing the tension placed on elongated muscles, and (c) increasing the tension placed on shortened muscles to restore muscle balance. Photographs of the patient in a typical rest posture and corrected posture can serve as powerful feedback for inducing change. Video of various movement patterns used repeatedly in ADLs and recreational activities can also serve as powerful feedback. Ergonomic modifications may be necessary to improve the patient's environment (see Patient-Related Instruction 9-1). If an on-site visit to the workplace is not feasible, a photograph of the workstation can be analyzed to provide suggestions for change. Other posture habits, including recumbent positions, can be analyzed and suggestions offered. Pillows under the head, under or between the knees, or under the waist in sidelying

FIGURE 9-20 The use of pillows under the head, under the waist, and between the knees can position the spine in optimal alignment in sidelying.

(**Fig. 9-20**) can be suggested to offer optimal support to body regions while in recumbent positions. Footwear is another topic about which the physical therapist can provide recommendations (see Chapter 21).

Adjunctive interventions such as supportive devices (e.g., corsets, bracing, orthotics, taping) can be used temporarily to assist in creating length-associated and proprioceptive changes or used permanently to provide partial or complete correction of impairments of body structures. For example, taping can be used temporarily in the thoracic region to provide proprioceptive input for a patient about his or her kyphotic posture (**Fig. 9-21**). Every time the patient moves into excessive thoracic flexion, the tape serves as a reminder. Conversely, a permanent supportive device such as a corrective orthotic may be necessary to improve alignment throughout the kinetic chain and gait kinetics and kinematics in an individual with structural forefoot varus (see Chapter 21).

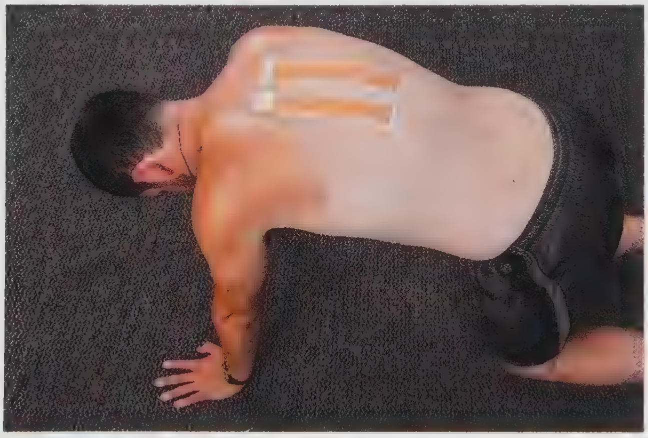

FIGURE 9-21 Taping along the thoracic spine can serve as biofeedback to discourage excessive thoracic flexion. The tape is best applied with the patient in a quadruped position, with the thoracic spine in a neutral position.

KEY POINTS

- Despite our intuition, strong correlations between posture, movement, pain, function, and activity participation do not exist in the literature.
- Posture and movement matter when alterations to the patterns reduce or eliminate pain, the patient is recovering from acute injury to protect damaged tissue, activities are performed under high load conditions or for prolonged periods of time, or you are choosing to use the activity for tissue adaptation or desensitization .
- Be cautious of creating a nocebo effect by placing too much emphasis on the "right" way to move. Instill a level of confidence in comprehensive capacity and focus on variability versus one right way to move.
- We have kinesiological standards to guide evaluation and treatment.
- Evaluation of posture and movement impairment requires identification of deviations in posture and movement from acceptable standards and assessment of contributing factors such as impairments in body functions and environmental, structural, developmental, and emotional factors.
- Therapeutic exercise intervention for posture and movement impairment involves prioritization of the subsystems of the movement system and related impairments, careful determination of the appropriate activities or techniques and stage of motor control, and accurate prescription of dosage parameters for a successful outcome.
- Successful treatment of impaired posture and movement can directly affect the kinesiopathologic factors responsible for the development, perpetuation, or recurrence of MPS.

CRITICAL THINKING QUESTIONS

1. How are posture and movement impairments related to MPS?
2. Define ideal posture as it relates to surface landmarks from a side view.
3. Consider Case Study No. 9 in Unit 7.
   a. Given this patient's posture alignment, what muscles would you predict to be too long? What muscles would you predict to be too short?
   b. List the passive, active, and neural subsystems of the movement system that contribute to this patient's movement impairment.
   c. Develop an initial list of exercises, posture education, and movement retraining for this patient. Progress one of the listed exercises with respect to the stages of motor control.

LAB ACTIVITIES

1. Assess your laboratory partner's posture from the front, side and back views. Given your partner's alignment, which muscles would you predict to be too long or short?
2. Design an exercise program that stretches muscles that may be too short and strengthens muscles that are too long.
3. Assess your partner's strategy of rising from sit to stand. Break the movement into component parts. Assess the feet, ankles, knees, hips, pelvis, and lumbar, thoracic, and cervical spine about all three axes of motion during each component of the movement.
4. How would you provide feedback to change your partner's motor control strategy in rising from sit to stand? What verbal, tactile, and visual cues would you provide? What passive and active impairments may be contributing to the movement impairment?
5. Assess your partner's strategy of balancing on one limb. How does your partner move his or her center of mass over the base of support? What happens at the foot, knee, hip, pelvis, and spine? Do you think your partner uses a correct strategy? If not, what is faulty? Is one side different from the other? What contributing factors may be responsible for the faulty movement strategy? Develop hypothesis as to what impairments you would further identify. (i.e., Trendelenburg stance and its relationship to hip girdle strength)

CHAPTER

10

Pain

LORI THEIN BRODY

Pain is a psychosomatic experience that is affected by cultural, historic, environmental, and social factors. The prevalence of chronic pain increases from ages 18 to 70, and approximately 23% of patients in their seventh decade report chronic pain.[1] It is more common in women than in men. Unlike impairments such as motion or strength loss that can be observed and measured with tools such as goniometers and dynamometers, pain is elusive. Although limited motion produces observable activity limitations or participation restrictions, pain produces activity limitations and participation restrictions that are not always observable by the outsider. This situation produces anxiety for the patient and can be a source of conflict with spouses, family members, friends, and coworkers. The clinician must recognize the far-reaching impact of pain on the patient and provide him or her with strategies to manage the pain.

DEFINITIONS

Pain is a component of most musculoskeletal conditions seen in the clinic and oftentimes, the main reason the patient is seeking medical care. The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[2] This definition has been reviewed but remains unchanged since its publication in 1994.[3] **Acute pain** is associated with muscle strains, tendinitis, contusions, surgery, or ligamentous injuries. Although it is important to acknowledge and treat acute pain, this pain is usually short-lived. Most individuals can tolerate this type of pain because they know that it is temporary. Acute pain is often successfully treated with nonnarcotic analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs) and agents such as ice.

Chronic pain is pain that persists after the noxious stimulus has been removed. It includes persistent pain after healing of an acute injury and pain with no known cause. It is not simply acute pain that has persisted too long. There may be no relationship between the extent of pathology and the intensity or anatomic location of the pain. Chronic pain produces profound changes in the physical, emotional, psychological, and social aspects of the patient's life (**Display 10-1**). Chronic pain is a major component of problems such as fibromyalgia, chronic fatigue syndrome (CFS), myofascial pain syndrome, autoimmune diseases, and low back pain. Physical therapy focuses on treating the pain, the motion and muscle impairments, and the activity limitations and participation restrictions that result.

DISPLAY 10-1

Characteristics of Chronic Pain Syndrome*

1. Use of prescription drugs beyond the recommended duration and/or abuse of or dependence on prescription drugs or other substances.
2. Excessive dependence on health care providers, spouse or family
3. Secondary physical deconditioning attributable to disuse and/or fear–avoidance behaviors
4. Withdrawal from social activities, including work, or recreation
5. Failure to return to preinjury function after a period of disability, resulting in inability to return to usual roles in work, family, recreation
6. Development of psychosocial sequelae after the incident, including anxiety, fear–avoidance, depression, or nonorganic illness behaviors

Three or more characteristics required for diagnosis.[4,5]

Referred pain is pain felt at a site far distant from the location of the injury or disease. Although the pain is felt elsewhere, the pain is still very real. Examination and evaluation can become difficult in the absence of understanding common pain referral patterns. The therapist should always consider other distant sources of pain when examining the patient with acute or chronic pain.

PHYSIOLOGY OF PAIN

Pain is a complex sensory experience. The physiology of pain is far too complex to be covered in detail in this text. However, this brief overview provides an understanding of the physiology of pain and the scientific basis of interventions used to treat it.

Sources of Pain

Acute pain results from microtraumatic or macrotraumatic tissue injury. **Microtrauma** is defined as a long-standing or recurrent musculoskeletal problem that was not initiated by a single precipitating event. Microtrauma is exemplified by the overuse injury where repetitive activity exceeds the tissue's ability to repair and remodel according to the imposed loads. The athlete playing in a weekend tennis tournament and the worker putting in overtime are prone to microtraumatic injuries. **Macrotrauma** is defined as an immediately noticeable injury involving sudden, direct, or indirect trauma.[6] Macrotrauma can produce pain through direct injury of tissues. Joint dislocations injure the joint capsule and periarticular connective tissue, and ligament or tendon injuries damage the respective collagenous tissues. Microtrauma and macrotrauma result in an inflammatory response that secondarily produces pain. Macrotrauma also produces pain directly through damage to the **nociceptors**, which are high-threshold sensory receptors of the peripheral somatosensory nervous system. Nociceptors are capable of transducing and encoding noxious stimuli.[3]

Chronic pain can arise suddenly or develop very gradually. It has strong psychological, emotional, and sociological effects.[7,8] Individuals with chronic pain tend to have significant sleep disturbances, depressive symptoms, appetite changes, and decreased activity and socialization.[5,9,10] Theories about the source of chronic pain suggest increased sensitization of nociceptors and spinal level changes that perpetuate positive feedback loops in the pain-spasm cycle.[11] This phenomenon is termed **central sensitization**. Central sensitization is defined as "increased responsiveness of nociceptive neurons in the central nervous system (CNS) to their normal or subthreshold afferent input."[3] It is theorized that central hypersensitivity arises from adjacent diseased tissues.[12–14]

This hypersensitivity can arise from local pathology (i.e., disk herniation, facet pathology, stenosis) or from inflammation in conditions such as osteoarthritis and rheumatological which sensitize the dorsal horn neurons to the inflammation. This pathology of a joint or muscle drives afferent input to the spinal cord, increasing the activity of the dorsal horn, spinothalamic tract, and thalamic neurons. The elevated activity increases the frequency of background firing of dorsal horn neurons and increases sensitivity to noxious and nonnoxious peripheral stimulation and joint motion. Repetitive stimulation with progressive buildup of the response in the dorsal horn neurons is termed "windup" and is a critical concept in understanding chronic pain[15] (**Table 10-1**).

When damage to the central nociceptive system occurs, *nonnociceptive* afferent activity becomes capable of eliciting pain.[16] Stimuli that were previously innocuous (i.e., active movement, touch, temperature, pressure) become painful. This is referred to as nonnociceptive pain (NNP). These nonnociceptive afferents are not abnormal, but are working with a sensitized CNS. Bennett[15] describes four clinical features of NNP. They can be found in **Display 10-2**. The pathophysiology of NNP includes central sensitization of ongoing or past nociception, convergence of nociceptive and nonnociceptive inputs on the same secondary neuron in the dorsal horn, the experience of pain on wide dynamic range (WDR) neurons, and an expansion of the receptive fields, extending pain beyond the original boundaries.[15]

TABLE 10-1

Characteristics of Central Sensitization

1. Sensory processing changes in the brain (pain as well as other inputs)
2. Dysfunction of antinociceptive descending opioid pathways
3. Facilitation of descending pain promoting pathways
4. Increased activity in the brain in areas involved in acute pain sensations
5. Additional brain activity in areas not typically involved in acute pain sensations
6. Expansion of painful areas
7. Associated central symptoms such as fatigue, sensitivity to light and other usually nonnoxious stimuli, sensitivity to stress
8. Cognitive deficits

DISPLAY 10-2

Characteristics of Nonnociceptive Pain

1. Pain appears to be inappropriate compared with tissue pathology, or no tissue pathology may be evident
2. Hyperalgesia, where pain is greater than expected given the stimulus
3. Allodynia, where normally nonnoxious stimuli produce pain
4. Painful region extends beyond expected based on original tissue pathology (but is not referred pain)

Patients often report progressively increasing areas of pain. The pain seems to spread from the originally painful area to adjacent areas. The peripheral receptive field of dorsal horn neurons increases in response to chronic pain and may be responsible for this enlarging painful area.[17] The basis for some of these changes may be an increased sensitization of WDR neurons from nociceptive input, causing them to respond more intensely to more nonnociceptive input and to afferent input from a larger area.[16] After being sensitized to nociceptive input from peripheral nerves, the WDR neurons will respond to nonnoxious stimuli as intensely as they had to other stimuli before sensitization.[15] Chronic pain that seems to spread along a limb or to adjacent areas may result from:

- Increased receptive field area
- Increased background firing
- Increased sensitivity to mechanical stimuli after acute or chronic inflammation

Referred pain is considered to be an error in perception. For example, pain originating from deep visceral tissues may refer to the cutaneous region with the same segmental innervation. Pain originating from the genitourinary system may refer to the low back because of the common T11–L2 segmental origin. Cardiac pain refers to the shoulder because of the common T1–T2 segments. As afferent input from the visceral receptors synapse in the dorsal horn, information is also incoming from skin afferents. Convergence of this incoming information in the dorsal horn results in the sense that the pain is originating from the skin. This same principle underlies the use of electrical stimulation at remote sites to decrease visceral pain.

Pain Pathways

Pain is transmitted from nociceptor and nonnociceptor afferents in the periphery. Nociceptors in the periphery are activated by mechanical stimuli such as strong pressure, irritants such as chemicals (e.g., bradykinin, substance P, histamine), or noxious elements such as excessive heat or cold.

Nociceptors in peripheral tissues transmit pain information through A-delta and C fibers. **A-delta fibers** are small, myelinated fibers carrying information about pain and temperature. The information is carried to the spinal cord at an approximate speed of 15 m per second.[18] The A-delta fibers are most responsive to mechanical stimuli and probably are responsible for the sensation of pain in acute injuries. **Type C fibers** are slow, unmyelinated fibers carrying information about dull aching or burning pain from polymodal receptors. **Polymodal receptors** are receptors that respond to a variety of stimuli such as temperature and pressure. Type C polymodal fibers are found in the deeper layers of skin and in virtually all other tissues except the nervous system itself. They are also known as "free nerve endings" and are responsive to thermal, chemical, and mechanical stimuli. Type C fibers probably are responsible for the continued sensation of pain after the noxious stimulus has been removed. Transmission speed to the spinal cord is approximately 1 m per second.

At the spinal cord level, A-delta fibers enter the dorsal roots sending collateral fibers that ascend and descend several segments before entering the gray matter. These fibers terminate on the cells of laminae I and V. The slower C fibers also enter the dorsal root and then enter the gray matter and synapse at the level of entry or ascend or descend a level or two before entering the substantia gelatinosa at laminae II and III. Some processing of information occurs in the spinal cord before the information is transmitted to higher levels. Important receptors at the termination of the primary nociceptive afferents in the dorsal horn have been found, in particular *N*-methyl-D-aspartate (**NMDA**), which are activated and placed in a state ready for activation.[19] Activation of the NMDA receptors causes spinal cord neurons to be more receptive to all inputs. These receptors are a primary mechanism in the development of windup, central sensitization, and changes in peripheral receptive fields.

Going further into the spinal cord, we find three types of interneurons within the dorsal horn that are categorized by their response to peripheral stimulation:

- Low-threshold mechanosensitive, responding only to innocuous stimuli such as touching the skin
- Nociceptive-specific, responding only to high-threshold noxious stimuli
- WDR, responding to a wide variety of noxious and non-noxious stimuli

Within the spinal cord, additional contributors to perpetuation of chronic pain include:

- Changes in the firing patterns of the WDR interneurons
- Convergence of stimuli from various receptors in the dorsal horn (the theoretical basis underlying the gate control theory)
- Presence of substance P, a neuromodulator shown to be responsible for the transmission of noxious information in the spinal cord.[17] It lowers the synaptic excitability threshold, sensitizing second-order spinal neurons. Substance P also facilitates the expansion of receptive fields and the activation of WDR interneurons by nonnociceptive afferent impulses.[15]

From the dorsal horn, these signals ascend through the contralateral spinothalamic tract **(ascending pathway)** in the ventrolateral white matter of the spinal cord to the ventral posterolateral nucleus of the thalamus. The spinothalamic tract transmits noxious and thermal information. The spinothalamic tract also sends collateral branches to the periaqueductal gray (PAG) nucleus of the brain stem. Synapses in this pathway are morphine-sensitive and are an important component of the pain-modulating system. Stimulation of the PAG nucleus has produced analgesia. The thalamus is capable of some conscious awareness of pain before this information reaches the postcentral gyrus of the cerebral cortex.[20] In addition to the spinothalamic tract, some noxious stimuli ascend in the ipsilateral dorsal column of the spinomedullary system (**Fig. 10-1**).

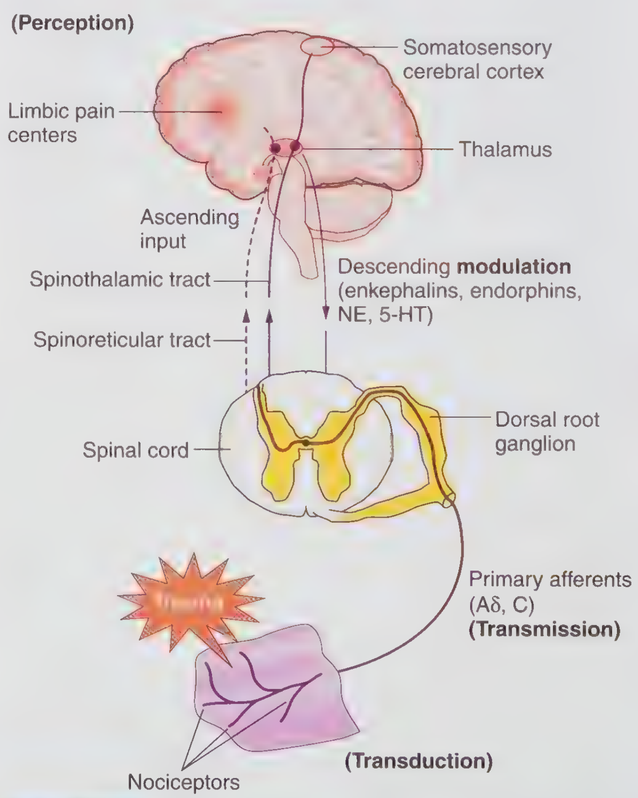

FIGURE 10-1 Diagram of the ascending and descending pain-related pathways. (From DeLeo JA. Basic science of pain. J Bone Joint Surg Am 2006;88(Suppl 2):58–62. doi:10.2106/JBJS.E.01286.)

Descending impulses also influence pain perception. The individual who continues to play sports despite a broken bone or the grandmother who lifts a car to save a child are examples of these descending influences at work. These systems are complex, and the relationships of the system components are being investigated. An overview is given to explain the rationale for some pain control interventions.

Descending pain control occurs through opiate and nonopiate systems. Release of *endogenous opiates* from the brain stem related to exercise has gained widespread publicity in the popular press. The "runner's high" that occurs with long-distance running has been attributed to the release of β-endorphin and methionine-enkephalin from CNS higher centers. Location of these opiates varies among the PAG, hypothalamus, thalamus, substantia gelatinosa, and midbrain structures.[11] Input to the enkephalinergic interneurons in the substantia gelatinosa comes from fibers descending from the midbrain (i.e., PAG) that use serotonin as the transmitter. Injection of opiates into the spinal cord inhibits noxious stimulus-elicited dorsal horn neuron activity.[11] Other neurons descending from the midbrain use noradrenaline as their transmitter and provide an analgesic action through direct inhibition of dorsal horn nociceptive neurons, rather than through the enkephalinergic interneurons.[18]

The analgesic effect of endogenous opiates does not extend to all patients with chronic pain.[21–24] Whereas exercise in healthy individuals induces the release of endogenous opioids from the pituitary and hypothalamus, exercise in patients with chronic pain has shown dysfunction of the inhibitory endogenous pain control mechanisms.[22,24,25] The cause of this dysfunction in some patients with chronic pain is still unknown, although heritability may be a factor.[26] Additionally, patient expectations regarding analgesia appear to impact descending inhibition.[27] Even when patients expected analgesia and reported decreased pain, the levels of spinal activity suggested continued inhibitory endogenous dysfunction.[28] This dysfunction in the descending inhibitory system may be the reason for "flares" in some individuals following exercise. This dysfunction appears to be limited to those with clear evidence of central sensitization[25] (**Evidence and Research 10-1**). Exercise prescription in patients with chronic pain should be highly individualized and flexible. Continued research in the area of descending influences in patients with chronic pain may provide more effective pain control interventions and better guidance regarding therapeutic exercise in the future.

EVIDENCE and RESEARCH 10-1

Patients with central sensitization may do poorly with an exercise program, experiencing postexercise flares owing to lack of descending opioid influences. However, clinicians may be able to use exercise in other body regions to treat pain. Anderson et al.[29] found that treating pain in one region of the body reduced sensitivity to pressure in other body parts. Patients may be able to exercise body parts that are nonpainful in order to address the central sensitization. In their review paper, Daenen et al.[30] suggest that aerobic exercise is best for migraine prevention, whereas specific neck and shoulder exercises are more effective in tension-type headaches. They also note that there is a lack of endogenous analgesia in some patients with chronic pain, reinforcing the notion of individualized programming. Additionally, sufficient recovery strategies are highly recommended.

Pain Theory

Melzack and Wall proposed the gate theory of pain in 1965, with revisions added in 1982.[11] This theory replaced previously held pain theories such as the specificity and patterning theories.[11] The cornerstone of the gate theory is the convergence of first-order neurons and associated second-order neurons within the substantia gelatinosa (**Fig. 10-2**). The system has four components, namely, afferent neurons, internuncial neurons within the substantia gelatinosa, transmission cells (T cells), and descending control from higher centers.[31] The activity of T cells is regulated by the balance of large- and small-diameter fiber input from the periphery and by descending control from higher cells. This balance regulates the transmission of pain information.

The substantia gelatinosa modulates incoming information (i.e., regulates position of the gate) presynaptically, before information is passed to second-order neurons. When incoming information increases substantia gelatinosa activity, presynaptic inhibition occurs, closing the gate. Information is not passed from first- to second-order neurons for further transmission to higher centers. If peripheral receptors associated with large-diameter myelinated fibers are stimulated, activity in the substantia gelatinosa may close the gate to the slower C fiber pain information transmission.

This theory provides the rationale for interventions to "close the gate" to pain transmission. Several peripheral stimuli can close the gate to pain.

- Input from thermal modalities such as heat and cold can successfully "block" pain transmission from slower fibers at the substantia gelatinosa and decrease pain.
- Electrical impulses from transcutaneous electrical nerve stimulation (TENS) application can preferentially block pain impulse transmission (discussed in the "Adjunctive Therapies" section).
- Exercise can successfully decrease pain by stimulation of joint afferent receptors. These signals travel along A-beta fibers, which have larger diameters and carry information at higher speeds (30 to 70 m per second) than the slower pain fibers.
- Mechanical stimulation of peripheral receptors can be achieved through tissue massage.

Further revision of the gate theory of pain continues, because descending control from higher centers also influences the transmission of pain information. Although many of these interventions provide temporary relief, there is little evidence

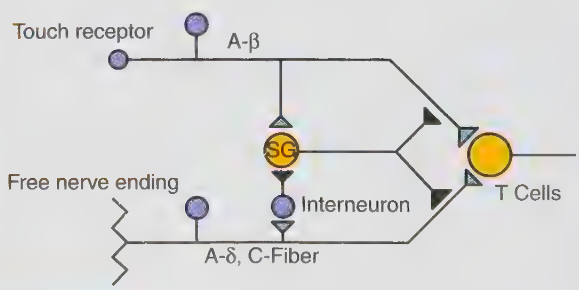

FIGURE 10-2 The gate control theory of pain. T cells, central transmission cells; SG, substantia gelatinosa.

for long-term significant improvements in chronic pain with these interventions.

EXAMINATION AND EVALUATION

A variety of tools help the clinician assess and monitor the patient's pain level. Tools such as the McGill Pain Questionnaire (MPQ) assess affective qualities of pain, whereas the visual analog scale (VAS) is a nominal scale assessing pain intensity. Because of the multifaceted nature of pain, assessment should include information on the pain's intensity, location, and pattern over a 24-hour period (i.e., quantity of pain) and descriptors assessing the affective aspects (i.e., quality of pain). The impact of pain (i.e., activity limitations and participation restrictions) on the patient's life should be determined. Frequently, tools such as the Beck depression and Beck anxiety questionnaires are used to assess the psychological aspects of the patient's pain.

Clinicians perform examinations to determine the source of the patient's pain. This examination directs the subsequent treatment program to the source of pain. Structures within the musculoskeletal system have different levels of pain sensitivity. The periosteum of the bone is a highly pain-sensitive structure, whereas the joint capsule, ligaments, tendons, and muscle are less pain sensitive. Interestingly, research has found that in healthy subjects, isometric muscle contraction normally increases the pain threshold, whereas in patients with fibromyalgia, the pain threshold actually decreases.[32] Additionally, compared with skin receptors, sensory input from muscle is a more potent catalyst of central sensitization.[15] Fibrocartilage and articular cartilage are not pain-sensitive structures, although injury or damage to these structures can produce a synovitis that results in pain. Perform a thorough evaluation to determine the source of the pain and to assess the characteristics of that pain. However, remember the pathophysiology of chronic pain and realize that the pain region and intensity may extend beyond discernible tissue pathology.

Pain Scales

The VAS (0 = least pain and 10 = worst pain) is used to assess pain intensity. The simplest clinical tool consists of asking the patient to rate his or her pain on a 0 to 10 scale and recording this in the medical record. Follow-up visits ask the same question to determine the response to treatment. This type of scale has advantages and disadvantages. The clearest **advantage** is the ease of use. The patient is not burdened with forms to fill out or multiple questions to answer. Language and cultural barriers do not affect the use of this simple scale. The **disadvantage** is the minimal information acquired with such a tool. Only pain-intensity information is gathered. Information regarding the affective aspects of pain, pattern of pain, and the impact of the pain on the patient's life is absent. The patient is likely to remember the previous pain score, which reduces the reliability of this type of measurement. This type of scale presumes equal intervals between successive levels (i.e., the difference between a 1 and a 2 is equal to the difference between a 3 and a 4), and this may not be the case for the patient. Be sure to clarify the question being asked.

- Are you interested in the patient's current pain level or average pain level over the last 24, 48, or 72 hours?
- Are you interested in the worst pain and best pain in the last 24 hours?
- or in the last 7 days?

Clarifying the question is critical because of the variable nature of the patient's pain. Pain is often mediated by multiple factors such as time of day, activity level, and medication use. Consistency in collecting and interpreting these data is essential when using them to assess the efficacy of an intervention.

The VAS can be administered in several different forms (**Fig. 10-3**). A line with words placed at intervals along the line commonly is used. A single word may be used at each end, such as "no pain" and "worst pain," or several words may be placed along the continuum. The more words and lines dividing the continuum, the more likely the patient is to recall previous answers. Improve the reliability of a VAS by eliminating division marks and only marking both ends of the scale. The patient then places a mark along the scale corresponding to his or her current pain level. The distance from the left or right can be measured to assess progress. The direction of the scale should be altered occasionally. Reverse the "no pain" and "worst pain" sides of the scale or turn the scale from horizontal to vertical to minimize patient recall.[33] Combine these scales with other assessments, such as the location of pain (using a body diagram) and subjective descriptions of the quality of pain (see **Building Block 10-1**).

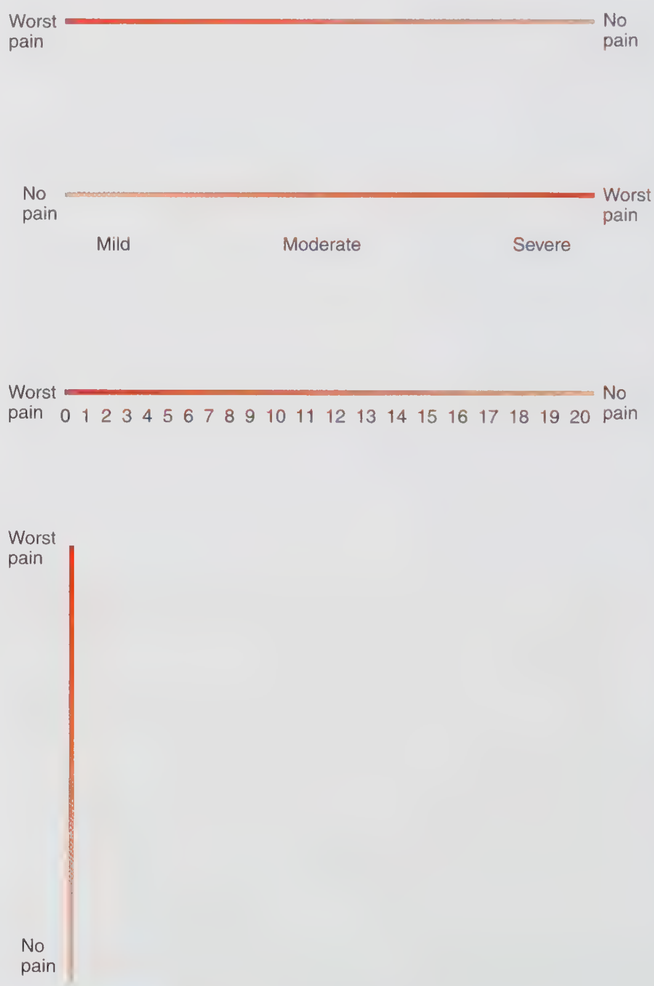

FIGURE 10-3 Variations of a visual analog scale.

BUILDING BLOCK 10-1

A 36-year-old woman with chronic neck pain and posttraumatic stress disorder has been coming to physical therapy weekly for soft-tissue mobilization. The first week she reports her pain level at 8 on a 0 to 10 scale. On subsequent visits, she reports her pain ranging from 5 to 9 on a 0 to 10 scale. Please provide recommendations on ways to gather pain information that would guide and inform her plan of care (primary goal: pain reduction).

McGill Pain Questionnaire

The MPQ is one of the most widely used tests for the measurement of pain, and several forms of the questionnaire have been developed.[34–38] This pain questionnaire consists primarily of three classes of word descriptors to assess the subjective aspects of pain. The MPQ also contains an intensity score, a body diagram, and an assessment of pain relative to activities and pain patterns. The three major measures are the pain rating index (PRI), the number of words chosen (NWC), and the present pain intensity (PPI).

Part 1 contains word descriptors classified as three categories (i.e., sensory, affective, and evaluative) and 20 subcategories. Subcategories contain two to six words that are qualitatively similar but of increasing intensity. For example, one subcategory assesses the thermal aspects of pain through the descriptors "hot," "burning," "scalding," and "searing." Each word is assigned a numeric value. The patient is allowed to choose only one word from each subcategory and is not required to select an item from every category. The values are summed and the mean determined; the mean is the PRI score. The total number of subcategories selected is summed as the NWC score (**Fig. 10-4**).

FIGURE 10-4 The McGill-Melzack Pain Questionnaire. (From Melzack R. The McGill Pain Questionnaire: major properties and scoring methods. Pain 1975;1:277–299.)

The PPI is determined by use of a 5-point scale, asking about the current pain level and the level of pain when it is at its worst and at its best. Part 2 categorizes the pattern of pain as constant, periodic, or brief and asks about activities that increase or relieve pain. A body diagram allows the patient to mark where the pain is located. The patient marks *E* for external pain and *I* for internal pain and then uses a VAS to document the quantity of pain.

The MPQ better assesses the many dimensions of pain with greater sensitivity than a VAS. The disadvantage is the time required to complete the questionnaire. A short form of the MPQ has been developed to address this issue. This form has been validated in various patient populations.[19,20]

Disability and Health-Related Quality of Life Scales

A variety of tools have been developed to assess pain and the impact of pain and resulting disability on patients' lives. Research into chronic musculoskeletal pain found that the International Classification of Functioning, Disability and Health (ICF) components of Mobility and Community life were the most impacted in patients who were admitted to a multidisciplinary rehabilitation program for chronic pain.[39] Most tools broadly assess physical, social, and psychological function. Some tools assess health perceptions, satisfaction, and various impairments. Each tool taps into these domains in a different way and at a different level. The tool must be matched to the population of interest.

The scales are classified in several ways but are broadly categorized into disease-specific and generic measures. Disease-specific scales are specific to a particular disease and are more responsive to issues of that particular population. Generic tools are applied across a variety of disease categories; the information has little relevance to a specific disease, and other important issues may not be tapped. However, use of these tools allows comparisons among disease or injury categories.

Commonly used generic tools are the Quality of Well-Being scale (QWB), the Sickness Impact Profile (SIP), the Duke Health Profile (DUKE), and the Short Form-36 (SF-36). The QWB taps five health concepts (i.e., physical functioning, mental health including psychological distress, social or role functioning, mobility or travel, and physical or physiologic symptoms), and the SIP measures 12 concepts. Neither of these tools assesses pain directly. The DUKE measures seven health concepts, including self-esteem, health perceptions, and pain. The SF-36 is a derivative of the Medical Outcomes Study-149, a 149-item tool used as a generic assessment. The SF-36 is a 36-item tool measuring seven health concepts, including pain. Use caution when choosing a generic health assessment tool to ensure that critical parameters are being measured. The tool's range must allow for improvement or decline in the patient's status without exceeding the upper or lower limits of the measure (**Fig. 10-5**).

One way to minimize some of the potential problems associated with generic tools is to use a disease-specific tool in combination with a generic measure. The Oswestry Low Back Disability Questionnaire, the Waddell Disability Index, and the Disability Questionnaire are used for individuals with back pain; and the McMaster-Toronto Arthritis Patient Reference Disability Questionnaire, the Arthritis Impact Measurement Scales (AIMS), the Health Assessment Questionnaire, and the Functional Capacity Questionnaire are used for individuals with arthritis (**Fig. 10-6** on page 251). These disease-specific tools must match the population tested. Reliability of the tool must be determined for the population being evaluated. For example, if the AIMS reliability has been established for Caucasian women who are 65 or older, this tool may not be reliable or valid when applied to men between the ages of 40 and 60.

Other tools tap some of the psychosocial aspects of the pain experience. A large body of literature has developed around the issue of anxiety, fear and avoidance of pain in patients with chronic pain.[40–42] Fear–anxiety–avoidance models of pain and tools attempting to measure these constructs have been developed and tested.[43–51] The fear–anxiety–avoidance models were originally developed to explain the transition from acute to chronic pain. Now these models and measurement tools are used to formulate multidimensional treatment plans for patients with chronic pain, as well as to determine the effectiveness of different interventions. Frequently, physical activity and rehabilitative exercises are a component of these intervention plans, as providers guide patients through structured activities to minimize their fear of movement.[52,53] The Fear–Avoidance Beliefs Questionnaire is commonly used to assess the patient's response and accommodations to the pain. Similar tools such as the Pain Anxiety Symptoms Scale (PASS), the Anxiety Sensitivity Profile, and the Fear of Pain Questionnaire attempt to determine how fear and anxiety impact a patient's function.[43,44,54–56]

The literature on **fear–anxiety–avoidance** models suggests that anxiety and fear are separate cognitive constructs, with fear being a present-oriented emotive state associated with an imminent threat, whereas anxiety is a more general, future-oriented emotive state existing without an imminent threat.[43] It has been suggested that the pain-related fear is more disabling than the pain itself.[57] Although this may be an oversimplification of the problem and true in only a small subsample of patients, the statement highlights the importance that fear-anxiety–avoidance models have in patients with pain. The fear–avoidance beliefs can impact the transition from acute to chronic pain, and have been studied in patients with low back pain. Heightened focus on pain-related fear during the acute phase increased the risk of future chronic low back pain and disability.[45,51,58] Moreover, people with higher fear–avoidance beliefs who were currently pain free had a greater risk of future low back pain.[59,60]

Fear–anxiety–avoidance behaviors can have a profound impact on a patient's physical, psychological, and social well-being. Avoidance behaviors are aimed at preventing a situation from occurring.[61] For patients with chronic pain, it is not possible to avoid pain, so these patients tend to avoid activities that they perceive will increase their pain. This may manifest as complete avoidance of some activities or decreased performance of activities. Pain-related fear has been associated with decreased walking speed,[62] decreased muscle performance,[63,64] and decreased physical task performance.[65] Patients may begin to avoid social situations that they fear will increase their pain. This can lead to increasing social isolation and decreased physical activity. The decreased physical activity associated with

SF-36 HEALTH SURVEY

Instructions: This survey asks for your views about your health. This information will help keep track of how you feel and how well you are able to do your usual activities.

Answer every question by marking the answer as indicated. If you are unsure about how to answer a question, please give the best answer you can.

1. In general, would you say your health is:

(circle one)

Excellent	1
Very good	2
Good	3
Fair	4
Poor	5

2. Compared to one week ago, how would you rate your health in general now?

(circle one)

Much better now than one week ago	1
Somewhat better now than one week ago	2
About the same as one week ago	3
Somewhat worse now than one week ago	4
Much worse than one week ago	5

3. The following items are about activities you might do during a typical day. Does your health now limit you in these activities? If so, how much?

(circle one number on each line)

ACTIVITIES	Yes, Limited A Lot	Yes, Limited A Little	No, Not Limited At All
a. **Vigorous activities** such as running, lifting heavy objects, participating in strenuous sports	1	2	3
b. **Moderate activities**, such as moving a table, pushing a vacuum cleaner, bowling, or playing golf	1	2	3
c. Lifting or carrying groceries	1	2	3
d. Climbing **several** flights of stairs	1	2	3
e. Climbing **one** flight of stairs	1	2	3
f. Bending, kneeling, or stooping	1	2	3
g. Walking **more than a mile**	1	2	3
h. Walking **several blocks**	1	2	3
i. Walking **one block**	1	2	3
j. Bathing or dressing yourself	1	2	3

FIGURE 10-5 The SF-36 assessment tool. (From Medical Outcomes Trust; Boston, MA, 1992.)

(Continued on next page)

4. During the past week, have you had any of the following problems with your work or other regular daily activities as a result of your physical health?

(circle one number on each line)

	Yes	No
a. Cut down on the **amount of time** you spent on work or other activities	1	2
b. **Accomplished less** than you would like	1	2
c. Were limited in the **kind** of work or other activities	1	2
d. Had **difficulty** performing the work or other activities (for example, it took extra effort)	1	2

5. During the past week, have you had the following problems with your work or other regular daily activities as a result of any emotional problems (such as feeling depressed or anxious)?

(circle one number on each line)

	Yes	No
a. Cut down on the **amount of time** you spent on work or other activities	1	2
b. **Accomplished less** than you would like	1	2
c. Didn't do work or other activities as **carefully** as usual	1	2

6. During the past week, to what extent has your physical health or emotional problems interfered with your normal social activities with family, friends, neighbors, or groups?

(circle one)

Not at all 1

Slightly 2

Moderately........ 3

Quite a bit........ 4

Extremely........ 5

7. How much bodily pain have you had during the past week?

(circle one)

None 1

Very mild 2

Mild 3

Moderate 4

Severe 5

Very severe 6

8. During the past week, how much did pain interfere with your normal work (including both work outside the home and housework)?

(circle one)

Not at all 1

A little bit 2

Moderately........ 3

Quite a bit........ 4

Extremely........ 5

FIGURE 10-5 *(continued)*

9. These questions are about how you feel and how things have been with you during the past week. For each question, please give the one answer that comes closest to the way you have been feeling. How much of the time during the past week—

(circle one number on each line)

	All of the Time	Most of the Time	A Good Bit of Time	Some of the Time	A little of the Time	None of the Time
a. Did you feel full of pep?	1	2	3	4	5	6
b. Have you been a nervous person?	1	2	3	4	5	6
c. Have you ever felt so down in the dumps that nothing could cheer you up?	1	2	3	4	5	6
d. Have you felt calm and peaceful?	1	2	3	4	5	6
e. Did you have a lot of energy?	1	2	3	4	5	6
f. Have you felt downhearted and blue?	1	2	3	4	5	6
g. Did you feel worn out?	1	2	3	4	5	6
h. Have you been a happy person?	1	2	3	4	5	6
i. Did you feel tired?	1	2	3	4	5	6

10. During the past week, how much time has your physical health or emotional problems interfered with your social activities (like visiting with friends, relatives, etc.)?

(circle one)

All of the time.......... 1

Most of the time 2

Some of the time.......... 3

A little of the time.......... 4

None of the time.......... 5

11. How TRUE or FALSE is each of the following statements for you?

(circle one number on each line)

	Definitely True	Mostly True	Don't Know	Mostly False	Definitely False
a. I seem to get sick a little easier than other people?	1	2	3	4	5
b. I am as healthy as anybody I know	1	2	3	4	5
c. I expect my health to get worse	1	2	3	4	5
d. My health is excellent	1	2	3	4	5

FIGURE 10-5 *(continued)*

Health Concepts, Number of Items and Levels, and Summary of Content for Eight SF-36 Scales and the Health Transition Item

Concepts	No. of Items	No. of Levels	Summary of Content
Physical Functioning (PF)	10	21	Extent to which health limits physical activities such as self-care, walking, climbing stairs, bending, lifting, and moderate and vigorous exercises
Role Functioning Physical (RP)	4	5	Extent to which physical health interferes with work or other daily activities, including accomplishing less than wanted, limitations in the kind of activities, or difficulty in performing activities
Bodily Pain (BP)	2	11	Intensity of pain and effect of pain on normal work, both inside and outside the home
General Health (GH)	5	21	Personal evaluation of health, including current health, health outlook, and resistance to illness
Vitality (VT)	4	21	Feeling energetic and full of pep versus feeling tired and worn out
Social Functioning (SF)	2	9	Extent to which physical health or emotional problems interfere with normal social activities
Role Functioning Emotional (RE)	3	4	Extent to which emotional problems interfere with work or other daily activities, including decreased time spent on activities, accomplishing less, and not working as carefully as usual
Mental Health (MH)	5	26	General mental health, including depression, anxiety, behavioral-emotional control, general positive affect
Reported Health Transition (HT)	1	5	Evaluation of current health compared to one year ago

FIGURE 10-5 *(continued)*

avoidance behaviors can also lead to further physical decline. Decreased aerobic fitness and decreased trunk mobility and muscle activation patterns have been found in patients with chronic low back pain.[66]

When treating patients with acute or chronic pain, the therapist must give consideration to all components of pain. Although patients with acute pain may not exhibit all components of the fear–anxiety–avoidance models, researchers and clinicians are attempting to determine which factors in the acute pain situation might predict those patients who will go on to develop chronic pain.[45,49,50,67]

Generic, psychosocial, and disease-specific tools can be administered together to strengthen the information obtained. For example, the SF-36 may be combined with the Oswestry Low Back Disability Questionnaire for individuals with low back pain. A major concern about combination application is the burden placed on the patient who must fill out a number of questionnaires.

THERAPEUTIC EXERCISE INTERVENTION FOR PAIN

Although many commonalities exist, the approaches to treating acute pain differ from the approaches to chronic pain. Application of acute pain interventions in the case of chronic pain will lead to frustration for the caregiver and the patient. Some combination of exercise and manual therapy is used; specific choices depend on the patient's circumstances. The treatment program should be tailored to each patient and be responsive to the pain pattern. For example, muscle stretching exercises are advocated for treating patients with myofascial pain resulting

INSTRUCTIONS

Check only one box in each section which best applies to you. We realize you may consider that two of the statements in any one section relate to you, but please just mark the box which most closely describes your problem.

SECTION I - PAIN INTENSITY

- ❑ I can tolerate the pain I have without having to use pain killers.
- ❑ The pain is bad but I can manage without taking pain killers.
- ❑ Pain killers give complete relief from pain.
- ❑ Pain killers give moderate relief from pain.
- ❑ Pain killers give very little relief from pain.
- ❑ Pain killers have no effect on the pain and I do not use them.

SECTION II - PERSONAL CARE (Washing, Dressing, Etc.)

- ❑ I can look after myself normally without causing extra pain.
- ❑ I can look after myself normally but it causes pain.
- ❑ It is painful to look after myself and I am slow and careful.
- ❑ I need some help but manage most of my personal care.
- ❑ I need help every day in most aspects of self care.
- ❑ I do not get dressed, wash with difficulty and stay in bed.

SECTION III - LIFTING

- ❑ I can lift heavy weights without extra pain.
- ❑ I can lift heavy weights but it gives extra pain.
- ❑ Pain prevents me from lifting heavy weights off the floor, but I can manage if they are conveniently positioned, e.g., on a table.
- ❑ Pain prevents me from lifting heavy weights, but I can manage light to medium weights if they are conveniently positioned.
- ❑ I can lift only very light weights.
- ❑ I cannot lift or carry anything at all.

SECTION IV - WALKING

- ❑ Pain does not prevent me from walking any distance.
- ❑ Pain prevents me from walking more than 1 mile.
- ❑ Pain prevents me from walking more than 1/2 mile.
- ❑ Pain prevents me from walking more than 1/4 mile.
- ❑ I can only walk using a stick or crutches.
- ❑ I am in bed most of the time and have to crawl to the toilet.

SECTION V - SITTING

- ❑ I can sit in any chair as long as I like.
- ❑ I can only sit in my favorite chair as long as I like.
- ❑ Pain prevents me from sitting for more than 1 hour.
- ❑ Pain prevents me from sitting for more than 30 minutes.
- ❑ Pain prevents me from sitting for more than 10 minutes.
- ❑ Pain prevents me from sitting at all.

FIGURE 10-6 The Oswestry Low Back Disability Questionnaire. (Adapted from Fairbank JCT, Davies JB, Couper J, et al. The Oswestry Low Back Pain Disability Questionnaire. Physiotherapy 1980;66:271–273.)

(Continued on next page)

from shortening of sarcomeres found with sustained muscle fiber tension. However, resistive exercises are contraindicated in the early phases because of the early fatigue and lengthy recovery in muscle with active trigger points.[68]

As with many other medical conditions, the science of caring for people with acute or chronic pain is constantly growing. Clinicians must be aware of new research and literature that can provide strong evidence for interventions chosen. The American College of Occupational and Environmental Medicine regularly revises its recommendations for the treatment of various work-related disorders and includes a chapter on chronic pain (www.acoe.org). Progressive resistive exercise programs are the cornerstone of intervention programs for workers with chronic pain.

Acute Pain

The typical patient with acute pain has recently sustained an injury or undergone a surgical procedure. The pain is related to the acute trauma of an initial injury or an exacerbation of

SECTION VI - STANDING

- ❑ I can stand as long as I want without extra pain.
- ❑ I can stand as long as I want but it gives me extra pain.
- ❑ Pain prevents me from standing for more than 1 hour.
- ❑ Pain prevents me from standing for more than 30 minutes.
- ❑ Pain prevents me from standing for more than 10 minutes.
- ❑ Pain prevents me from standing at all.

SECTION VII - SLEEPING

- ❑ Pain does not prevent me from sleeping well.
- ❑ I can sleep well only by using tablets.
- ❑ Even when I take tablets I have less than six hours sleep.
- ❑ Even when I take tablets I have less than four hours sleep.
- ❑ Even when I take tablets I have less than two hours sleep.
- ❑ Pain prevents me from sleeping at all.

SECTION VIII - SEX LIFE

- ❑ My sex life is normal and causes no extra pain.
- ❑ My sex life is normal but causes some extra pain.
- ❑ My sex life is nearly normal but is very painful.
- ❑ My sex life is severely restricted by pain.
- ❑ My sex life is nearly absent because of pain.
- ❑ Pain prevents any sex life at all.

SECTION IX - SOCIAL LIFE

- ❑ My social life is normal and gives me no extra pain.
- ❑ My social life is normal but increases the degree of pain.
- ❑ Pain has no significant effect on my social life apart from limiting my more energetic interests, e.g. dancing, etc.
- ❑ Pain has restricted my social life and I do not go out as often.
- ❑ Pain has restricted my social life to my home.
- ❑ I have no social life because of pain.

SECTION X - TRAVELING

- ❑ I can travel anywhere without extra pain.
- ❑ I can travel anywhere but it gives me extra pain.
- ❑ Pain is bad but I manage journeys over two hours.
- ❑ Pain restricts me to journeys of less than one hour.
- ❑ Pain restricts me to short necessary journeys under 30 minutes.
- ❑ Pain prevents me from traveling except to the doctor or hospital.

FIGURE 10-6 *(continued)*

a preexisting injury. Pain medication may be taken for a short time after the injury or surgery. Acute pain is expected to resolve substantially over the course of a few days. Although some residual pain may continue for weeks after the injury or surgery, most pain is expected to resolve with only minimal discomfort remaining.

Acute pain of this type is treated with a combination of medication (i.e., prescription or over-the-counter medication at the patient's discretion), gentle exercise, and ice. Ice is preferred over heat in the first 24 hours, and may be changed to heat thereafter depending upon the injury acuity and patient preference. Exercise is prescribed on the basis of the specific injury or surgery and is directed at restoring the motion, strength, and function of the injured body part. Rehabilitation of the injured area is the prime focus and provides the framework for exercise prescription. Exercise in this phase is directed toward the primary joint and at prevention of injury at adjacent joints because of compensation. Include patient education about pain-relieving postures or positions (i.e., sleeping positions) and skills to fulfill the activities of daily living and the instrumental activities of daily living (see **Patient-Related Instruction 10-1** and **Building Block 10-2**).

Chronic Pain

Treatment of chronic pain requires a team approach because of the multidimensional nature of the pain. Chronic pain is disabling and interferes with all aspects of the person's life. The clinician must work closely with the physician, psychologist, vocational counselor, social worker, alternative health care providers, and the patient. In this way, a comprehensive treatment program can be established to ensure all aspects of the pain are being addressed. Many adjunctive treatments and alternative therapies are often explored by the patient, often because of the protracted course of improvement in chronic pain.[42,69] Herbal remedies, acupuncture, reflexology, and other therapies are often part of a patient's complete treatment program. An open dialogue with the patient ensures a thorough understanding of all therapies occurring simultaneously.

Patient-Related Instruction 10-1

Management of Acute Pain

An increase in acute pain is a sign of doing too much. This may disrupt the healing process. In this situation, you should do the following:

1. Find a position of comfort that decreases or eliminates your pain. Your clinician can help you learn what these positions are.
2. Use a pain-relieving treatment such as ice for 10 to 15 minutes every hour.
3. In the short term, use an assistive device such as crutches, a cane, or a walker if your leg is involved; a sling or splint for your upper extremity; or a corset for your back. These devices reduce the stress on the injured area.
4. Take your medications as prescribed.

BUILDING BLOCK 10-2

A 15-year-old track runner strained the hamstring muscle yesterday while running the hurdles. The athlete and his parents present to a Saturday morning injury clinic. They would like advice on how to manage this acute injury.

Therapeutic Exercise Guidelines for Patients with Chronic Pain

Therapeutic exercise is a major component of the treatment plan,[70–72] and has been shown to be effective in improving impairments and activity limitations in patients with chronic pain.[73–78] Different types of therapeutic exercise programs, including those focused on strength training, aerobic conditioning, or flexibility appear to be successful in improving patient symptoms.[25,30] Given the individual nature and complexity of chronic pain, some guidelines for its prescription are warranted (**Display 10-3**). Realize that these are broad, general guidelines. The specific cases of fibromyalgia and CFS will be addressed later in the chapter.

A critical component of chronic pain treatment is a realistic understanding of the goals of the treatment plan. Patient education is a key component; the clinician must explain the likely source of pain, activity modifications or postures to minimize pain, and the expected outcomes of intervention to the patient at a level the patient can comprehend. Patient expectations about the outcomes of interventions, particularly those related to pain relief, can have measurable physiologic effects at both the brain and spinal cord levels.[27,28] The goals of the therapeutic exercise program extend beyond treatment of impairments. Activity limitations and participation restrictions related to depression, sleep, and appetite are also of concern. Improvements in sleep patterns, mental state, and appetite may be the first markers of successful intervention, improving before any change in impairment measures (see **Patient-Related Instruction 10-2** and **Building Block 10-3**). Ultimately, the goal is to return patients to the highest level of function while independently managing their pain.

DISPLAY 10-3

Guidelines for Therapeutic Exercise Prescription for Patients with Chronic Pain

1. Understand and clarify goals with the patient to ensure appropriate expectations.
2. Prioritize goals emphasizing both impairments and activity limitations as well as primary, secondary, and tertiary prevention.
3. Consider the patient's current physical state and whether exercise will increase or decrease pain.
4. Consider the patient's current psychological status and whether exercise will be a stress reliever or stress producer.
5. The exercise program must allow sufficient recovery to prevent symptom escalation.

Patient-Related Instruction 10-2

Why You Should Exercise When You Have Chronic Pain*

You should exercise when you have chronic pain, because exercise can:

1. Improve problems such as inflexibility, loss of mobility, or weakness, which contribute to your pain.
2. Decrease pain by inhibiting transmission of pain impulses.
3. Improve your sleep at night.
4. Control weight gain, which often occurs from inactivity and can have negative physical and psychological consequences.
5. Prevent secondary musculoskeletal complications of pain such as further weakness, immobility, and flexibility at other joints.
6. Prevent secondary cardiovascular changes such as increases in blood pressure, elevated cholesterol levels, or diabetes complications.
7. Enhance your sense of well-being, self-esteem, and accomplishment.

* Not all people with chronic pain respond in the same way to exercise. Be sure to discuss your exercise program with your health care provider.

BUILDING BLOCK 10-3

A 48-year-old woman comes to physical therapy for multiple joint problems. She has a history of undifferentiated spondyloarthropathy, s/p L chest wall nonmalignant tumor resection, ankylosing spondylitis, s/p L hip labral tear resection, R knee pain, CFS. She is unable to do any work at all. She can walk <1/8 mile, and can stand <30 minutes without significant pain. Pain averages 6 on a 0 to 10 scale. Her sleep ranges from being mildly disturbed to completely disturbed. She complains of falling, especially when moving backward.

Considering the number of problems this patient faces on a daily basis, what are some priorities in goal setting that you might discuss with this patient?

Program goals and design must consider the primary complaint(s) and potential secondary problems that must be prevented.[68] Direct the therapeutic exercise program toward the source of the pain, musculoskeletal impairments that directly relate to activity limitations and participation restrictions. In addition, consider potential secondary problems that must be prevented.[45] Identify the multiple sources involved in the production of pain in order to facilitate prioritization of interventions. Interventions to inhibit pain input or to facilitate nonnociceptive input are incorporated while simultaneously addressing associated impairments and activity limitations. Therapeutic exercise can: (1) affect the pain directly through endogenous opiates; (2) indirectly affect pain through facilitation of nonnociceptive input; and (3) treat the associated impairments and activity limitations. Exercise programs similar in design may have very different goals from one patient to the next: although the specific program may appear to be straightforward, the clinical decision-making process underlying that exercise prescription is complex in this patient population. For example, some pain or discomfort may be necessary to achieve pain inhibition through endogenous opiates in some patients, whereas exercising into discomfort or pain may be contraindicated in others.[30] This type of intervention requires ongoing communication regarding the purpose of the exercise and alternative options to ensure that the intervention is meeting patient needs and thereby improving program adherence.

When designing the therapeutic exercise program, consider the current physical status of the patient and determine whether therapeutic exercise is likely to increase or decrease pain. Therapeutic exercise can reduce pain and improve function in patients with osteoarthritis, rheumatoid arthritis, chronic low back pain, neck pain, headaches, and fibromyalgia.[79–82] However, not all patients with the same diagnosis will respond similarly to an exercise program; for example, patients with fibromyalgia who have central sensitization may have a very different prognosis with exercise than those who do not.[30] Tailor the therapeutic exercise prescription to the specific physical needs and status of the individual patient. See Table 10-1 for exercise guidelines for individuals with dysfunctional endogenous analgesia.

The psychosocial component of the patient's pain can significantly impact participation and response to the therapeutic exercise program. Exercise is considered a stress, and this stress can be positive, producing improved resilience and function, or it can be negative, contributing to the cycle of pain and dysfunction. Too much stress, whether physical or psychological, can trigger the neuroendocrine responses of the adrenal–hypothalamic–pituitary-axis (HPA) to further nociceptive sensitization, increasing pain sensitivity[12,83–86] (for a complete discussion of the HPA and the role of cortisol in pain and stress, see Hannibal and Bishop[86]) (**Fig. 10-7**). Therefore, the decision to exercise or not, as well as the mode of exercise, the dosage, and recovery strategies, must be carefully considered.[25,30]

Recovery strategies are an integral component of the exercise program and stress management program. All patients with chronic pain need recovery strategies to maintain homeostasis and balance with the stress producers in their lives. Because exercise is a stress, insufficient recovery can worsen rather than alleviate pain. Many individuals can manage their pain-related and non–pain-related stress if sufficient recovery is available. Researchers have described the importance of recovery in maintaining balance and preventing overtraining in athletes.[87–89] Many of the same principles can be applied to patients with chronic pain. Recovery is multidimensional and includes both within (physiologic and psychological) and between (social) individual components.[30] Recovery strategies can take many forms and are not necessarily time dependent. Because recovery plays such a critical role in successful management of chronic pain, it is the responsibility of the therapist to educate the patient regarding adequate recovery. General characteristics of recovery can be found in **Display 10-4**.

General Recommendations for Activity and Mode for Patients with Chronic Pain

The activity chosen to treat the individual with chronic pain depends on the source of the pain and results of the evaluation process. In addition to the specific interventions chosen to treat the source of the pain, other activities can help the patient. In particular, active movement (vs. passive treatment) is of benefit. Patients with chronic low back pain who were

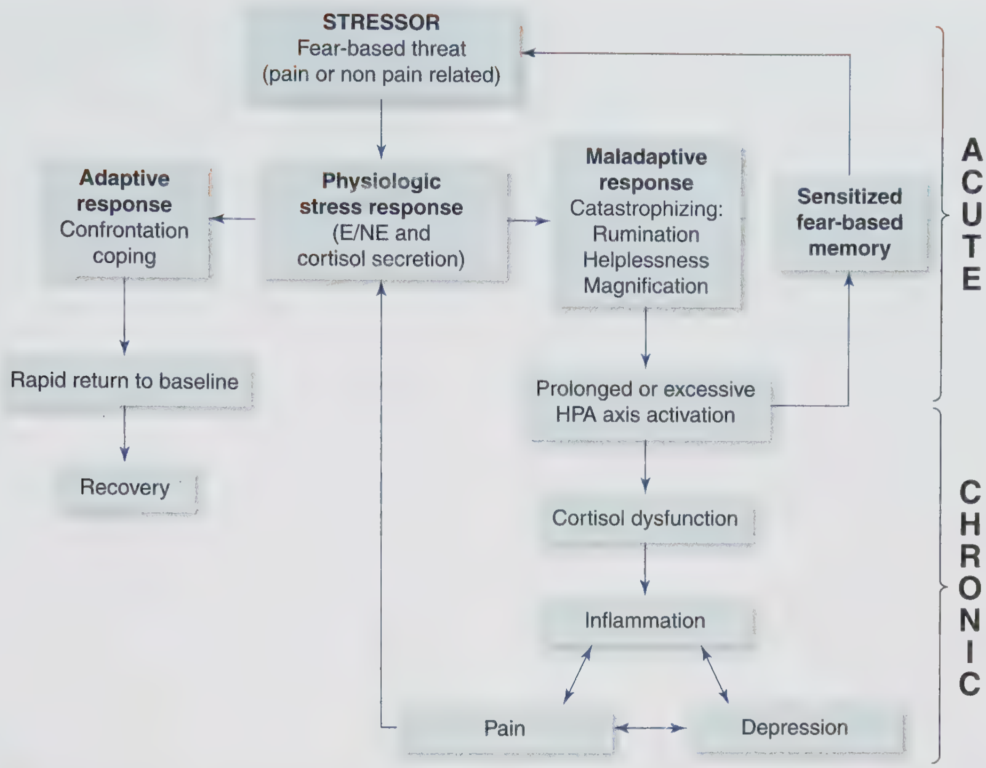

FIGURE 10-7 Proposed role of stress-related hypothalamic–pituitary–adrenal (HPA) axis activation in the transition from acute to chronic pain. (From Hannibal KE, Bishop MD. Chronic stress, cortisol dysfunction, and pain: a psychoneuroendocrine rationale for stress management in pain rehabilitation. Phys Ther 2014;94(12):1816–1825,with permission.)

randomly assigned to active rehabilitation compared with passive (massage and heat) treatment had significantly improved back pain intensity, functional disability, and lumbar endurance measured at a 1-year follow-up.[90] In addition, individuals in pain are susceptible to changes in posture and movement patterns. These changes can perpetuate the original symptoms or cause secondary impairments or activity limitations. Regardless of the activity chosen, the therapeutic focus should be on awareness and use of proper posture and movement patterns (**Evidence and Research 10-2**).

DISPLAY 10-4
General Characteristics of Physical and Psychological Stress Recovery Processes*

1. Recovery needs depend upon the type, magnitude, and duration of stress.
2. Recovery requires a complete break from, a reduction of, or a change from the stress.
3. Recovery strategies and needs are highly individual.
4. Recovery is intentional and self-initiated with the goal of restoring homeostasis.
5. Each individual needs a certain quality and/or quantity of recovery activities to balance stress levels. Individuals should have more than one strategy available.
6. *Disturbed recovery*, or impaired recovery, processes can occur if the recovery process is interrupted.
7. Recovery is closely associated with situational conditions (i.e., sleep, socialization, work, etc.).

EVIDENCE and RESEARCH 10-2

Ongoing deep lumbar muscle dysfunction despite resolution of pain has been suggested as a factor in recurrent low back pain.[91] Electromyographic changes in the deep lumbar muscle responsible for spine stabilization show altered firing patterns, even after symptom resolution. Muscle activation patterns in patients with low back pain differed from healthy controls during core stabilization exercises, suggesting that muscle dysfunction may be an impairment remediated by physical therapy intervention.[81] Impaired motor control of the transversus abdominis and internal oblique muscles along with primary motor cortex changes are associated with chronic low back pain, and deep muscle training along with peripheral neurostimulation can remediate these impairments.[92]

Movement therapies such as Feldenkrais, Ai Chi, T'ai Chi, and yoga are helpful in restoring appropriate movement patterns (**Fig. 10-8**). Total-body movement patterns are often more successful than isolated joint movement when treating individuals with chronic pain. Rhythmic activity of large muscle groups and/or nonpainful limbs should be the activity of choice.

Using a therapeutic ball allows a variety of large muscle group activities to be carried out along with increasing posture awareness (**Fig. 10-9**). Many of these activities are done in a group setting or individually at home, providing flexibility to suit the needs of each patient (see **Self-Management 10-1**). Group treatment of patients with fibromyalgia resulted in improved function and decreased tender points.[93] Balance these activities with specific exercises to address the individual patient's impairments and activity limitations.

Diagonal patterns used in proprioceptive neuromuscular facilitation (PNF) techniques (see Chapter 15) are useful for teaching the patient position and posture awareness although still using multisegmental movement. In addition to assisting in movement awareness, PNF patterns can increase mobility and muscle performance together with ensuring proper muscle recruitment during movement. Substitution patterns often are difficult to observe but are easily palpated during PNF exercises. Bilateral, symmetric patterns are particularly helpful when one side is involved and needs retraining through the uninvolved side. If moving the involved limb is too painful, movement of the opposite limb can have positive central effects. Bilateral patterns that emphasize trunk flexion and extension or rotation and sidebending are effective for normalizing specific movement patterns. These same patterns can be performed in a pool (see **Self-Management 10-2**).

In addition to performance of land-based exercise, the pool is a useful tool in the application of therapeutic exercise for those with chronic pain (see Chapter 16). The advantages include unweighting from the buoyancy and the warmth and contact of the water on the skin. Unweighting the sore limb or painful back allows movement with less pain and provides the opportunity for correct posture and movement patterns during activity or stretching (**Fig. 10-10**; see **Self-Managements 10-3**,

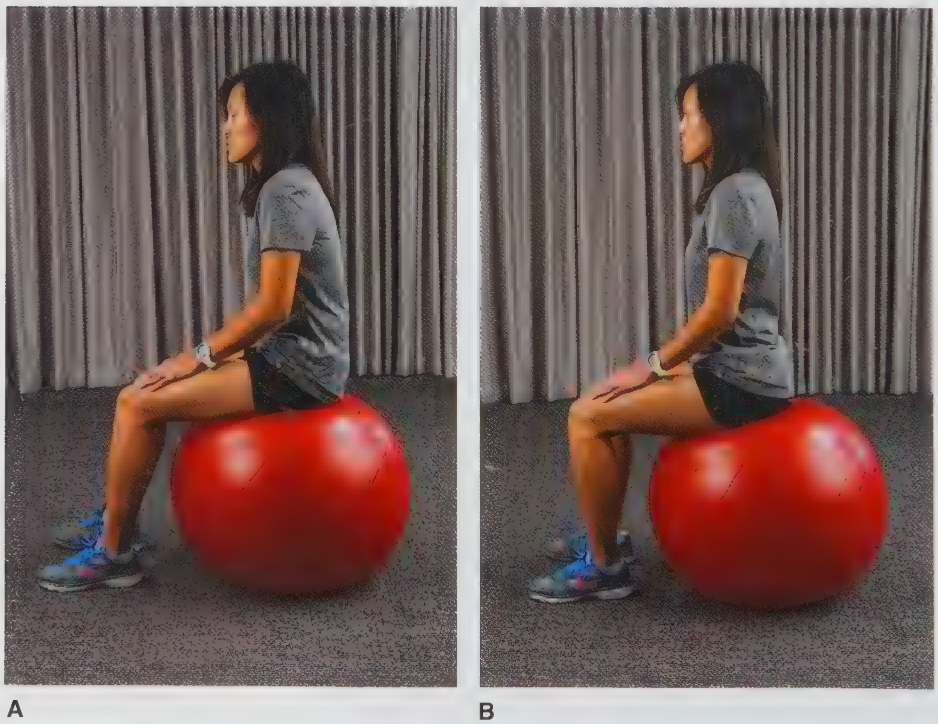

FIGURE 10-9 Therapeutic ball exercises such as pelvic rocking can be performed at home and in the clinic. **(A)** Start position. **(B)** End position.

SELF-MANAGEMENT 10-1
Yoga Exercise

Purpose: To promote relaxation and pain relief and to increase mobility in the low back and hips.

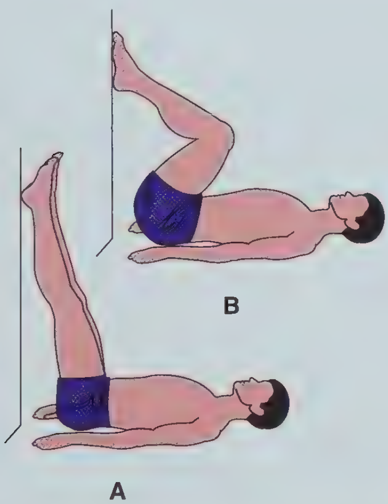
Position: Lying supine, with legs elevated on the wall (**Fig. A**).

Movement Technique: Let the knees and hips bend, sliding the leg down the wall to a comfortable position (**Fig. B**). Hold 10 to 15 seconds, and return to the starting position.

Dosage:

Repetitions: ______________________________

Frequency: ______________________________



SELF-MANAGEMENT 10-2
Proprioceptive Neuromuscular Facilitation Postural Technique

Purpose: To improve postural control while moving the arms and sitting on an unstable surface.

Position: Sitting on a therapeutic ball, with both feet flat on the floor, grasp wrist or a resistive band with both hands over one shoulder (**Fig. A**).

Movement Technique: Level 1: Keeping your arms straight, rotate your trunk and shoulders down past your opposite hip (**Figs. B** and **C**).

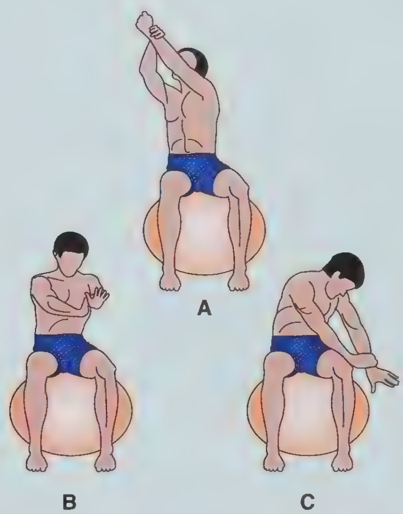
Level 2: Increase the resistance.

Level 3: Perform with one foot off the floor.

Dosage:

Repetitions: ______________________________

Frequency: ______________________________



10-4, and **10-5**). Movements that are too painful to perform on land are performed with greater ease and less pain in the water (**Fig. 10-11**). Disadvantages include pool access, difficulty in determining proper muscle recruitment and movement patterns as a result of distortion from the water's refraction, and resistance caused by the water's viscosity. The viscosity of water provides enough resistance to exacerbate some chronic pain conditions. Choose positions and movement patterns to minimize resistance caused by turbulence (i.e., controlling the speed of movement) and viscosity (i.e., minimizing the surface area; see **Self-Management 10-6**). Palpation and tactile cueing while in the water can ensure proper muscle recruitment.

Aerobic exercise is effective for treating chronic pain and is frequently recommended in the treatment of conditions such as fibromyalgia. The pool can also be used for aerobic exercise, keeping in mind the effects of viscosity and turbulence (see **Self-Management 10-7** and **10-8**). This resistance can produce muscle fatigue before reaching aerobic exercise levels.

FIGURE 10-10 Deep water bicycling.

SELF-MANAGEMENT 10-3
Hip External Rotation Stretch

Purpose: To increase mobility of the hips.

Position: While facing the ladder, set the foot of the hip to be stretched on a step of the ladder. Slide the foot across to the edge of the step. Keeping your foot there, let your knee roll out. Hold for 10 to 15 seconds.

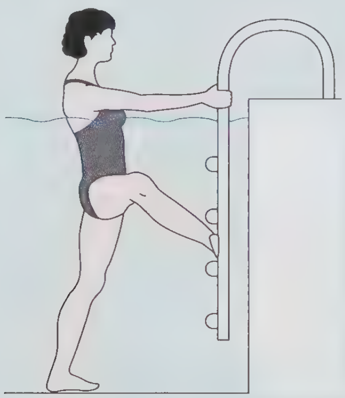
Movement Technique: Level 1: Assume the position just described until you feel a gentle stretch in your hip.

Level 2: Assume the position just described until you feel a gentle stretch in your hip. Use your hands to push your knee farther into rotation.

Dosage:

Repetitions: ______________________

Frequency: ______________________



SELF-MANAGEMENT 10-4
Deep Water March with Barbell

Purpose: To increase mobility through the low back, hips, and knees.

Position: In water depth equal to your height or deeper, use a barbell or other buoyant equipment to support yourself.

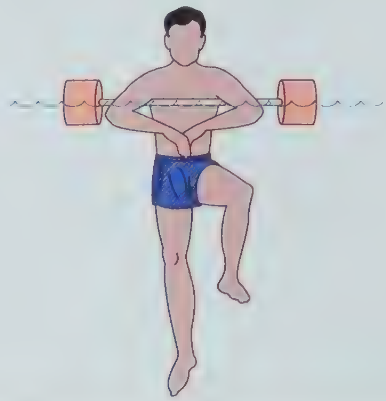
Movement Technique: Level 1: March in place through a comfortable range of motion at a comfortable speed.

Level 2: Add buoyant equipment to feet and ankles, increase the speed of marching, or do both.

Dosage:

Repetitions: ______________________

Frequency: ______________________



SELF-MANAGEMENT 10-5
Elbow Flexion Extension

Purpose: To increase mobility in the elbows, increase muscle strength and endurance in the upper extremities, and increase trunk stability.

Position: Standing in shoulder-deep water, with your feet in a comfortable stance and arms at the sides.

Movement Technique: Level 1: Flex and extend the elbows with thumbs pointing up.

Level 2: Turn your palms up.

Level 3: Add gloves or other resistive equipment.

Dosage:

Repetitions: ______________________

Frequency: ______________________

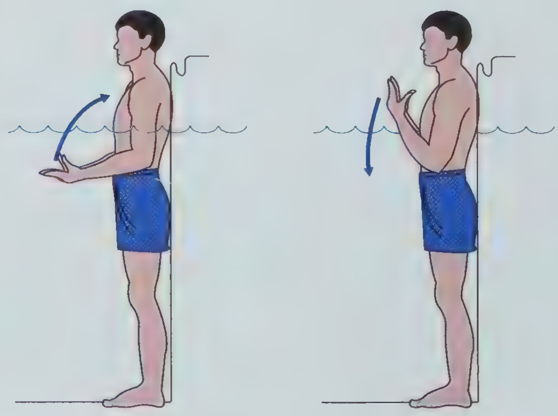


FIGURE 10-11 Knee lifting is an active, core exercise that is non-weight bearing.

SELF-MANAGEMENT 10-6
Water Walking, Forward and Sideways

Purpose: To increase mobility throughout the trunk, arms, and legs; increase trunk stability; and increase muscular strength and endurance in the arms, legs, and trunk.

Position: Stand in water between waist and shoulder deep; deep water provides more resistance to walking.

Movement Technique: Level 1: Step sideways, raising your arms out to the sides as you step and bringing back down to the sides as you bring your feet together.

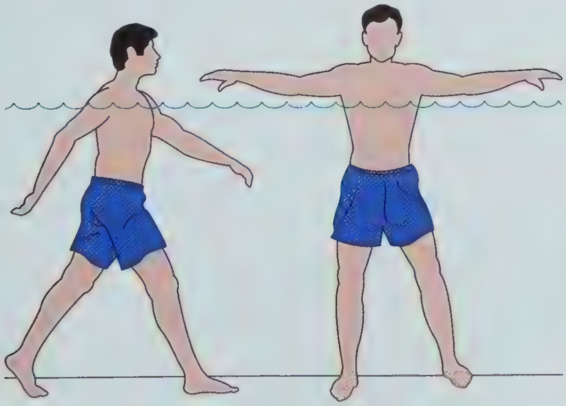
Level 2: Walk forward with the opposite arm and leg reaching forward together. Be sure to walk normally using a heel-to-toe pattern.

Level 3: Add resistance gloves to hands.

Dosage:

Repetitions: ______________________

Frequency: ______________________



SELF-MANAGEMENT 10-7
Supine Kicking with Optional Arm Movements in a Pool

Purpose: To increase strength and endurance of the neck, trunk, hip, and leg extensor muscles and to increase cardiovascular endurance.

Position: Supine with arms in a comfortable position overhead or at the side

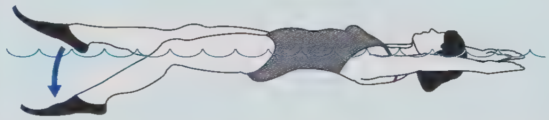
Movement Technique: Level 1: Rhythmic, repetitive kicking, keeping knees relatively straight and kicking from the hips; large or small fins may be used.

Level 2: Add arm movements in an underwater backstroke pattern. Bring arms up along the sides of your body to the shoulders, extend them straight out to the sides, then pull back down toward your sides.

Dosage:

Repetitions: ______________________

Frequency: ______________________



Intensity levels of 70% of the maximum aerobic capacity is necessary to trigger endogenous pain inhibitory mechanisms.[94] However, in patients with chronic pain, the exercise may need to begin at a much lower, tolerable level to avoid increasing central sensitization of pain. On land, walking is a simple form of continuous exercise that can be performed by many persons. Walking is particularly effective because it can be performed for several short bouts several times each day. A stationary bicycle or other aerobic equipment preferred by the patient can be included in a cross-training manner. Other exercises enjoyed by the individual and viewed as stress-relieving, such as aerobic dance, recreational dance, or traditional lap swimming, should be incorporated.

Dosage

Exercise dosage depends on the specific component of the movement system being treated and the purpose of the exercise, but some generalities about exercise and pain should be considered. Although discomfort can be expected, the exercise dosage should not increase the pain that caused the patient to seek medical attention in the first place. The chosen speed, repetitions, intensity, and duration should not increase pain within the exercise session, nor should symptoms increase after exercise.

SELF-MANAGEMENT 10-8
Jumping Jacks in a Pool

Purpose: Increase strength in shoulder and hip abductor muscles, initiate gentle impact, and initiate exercise using large muscle groups.

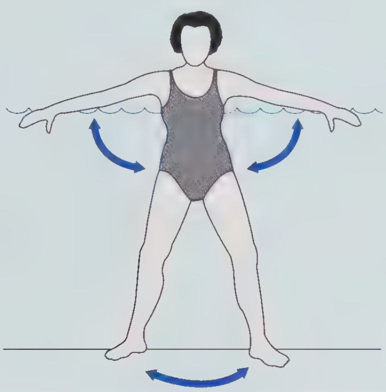
Position: Start in chest-deep water, with feet together and arms at sides.

Movement Technique: Bring both feet out to the sides while simultaneously bringing arms out to the side, shoulder height. Return to the starting position.

Dosage:

Repetitions: ____________________

Frequency: ____________________



If using aquatics as the exercise medium, the water's resistance can be a concern. Keep the first session brief (5 to 7 minutes) to assess the response to this intervention. As tolerance is demonstrated, the intensity or the duration may be increased (see **Patient-Related Instruction 10-3**). The overarching goal is to increase the total volume of exercise (see Chapter 5). Initially, exercise volume might remain stable, whereas variables within the total volume (i.e., sequence, contraction type, etc.) are changed. When the optimum combination of variables is achieved, exercise volume can be slowly expanded (see **Building Block 10-4**).

BUILDING BLOCK 10-4

The patient in Building Block 10-3 has been performing a therapeutic aquatic exercise program of slow-speed single plane shoulder movements, single plane hip movements, walking, and abdominal muscle isometrics. She exercises for 30 to 40 minutes and is tired at the end of the program, but has no increase in pain. She is doing the exercise program 4 days per week. How might her program be progressed?

Patient-Related Instruction 10-3

How Often and Hard Should You Exercise with Chronic Pain

1. Ideally, you should do something every day, at least once per day. Your clinician can give you further guidelines.
2. Many people do well by performing several short bouts of exercise spread throughout the day. These sessions may be only 5 to 10 minutes long.
3. Any aerobic activity should be continuous, working up to 10 to 20 minutes over time.
4. Stretches should be intense enough to feel a gentle pulling sensation.
5. Other exercises should be performed slowly until slight fatigue is felt or as otherwise instructed by your clinician.
6. If you feel any sharp, stabbing pain or numbness or tingling as a result of the exercise, discontinue the exercise. Use your pain-relieving measures, and tell your clinician.
7. You may feel some discomfort during or for a short time after exercise. This discomfort should not be confused with the pain that brought you to the clinic. Avoid exercises that increase this pain, but you may continue to exercise with some of the discomfort.
8. Ask your clinician if you are unsure about what to feel with your exercise program.

The frequency is determined by the activity type and purpose and by the quantity of exercise performed before pain is experienced. For example, if only a few repetitions of activity at a low intensity for a short duration can be performed before experiencing pain, the exercises may be performed with greater frequency. Availability also affects frequency. A pool may not be available more than once each day or even less often. The frequency must be balanced against the intensity and duration of an activity. Some exercise should be performed daily, and matching a land-based exercise program to complement the pool program is necessary. Be sure to consider the patient's other daily activities (work, ADLs, IADLs), and still allow sufficient recovery to prevent perpetuating the pain-activity cycle.

After the pain-free dosage is determined, progress the exercise parameters to those best suited to treat the patient's underlying pathology, impairments, or activity limitations. Advance the activity to a functional progression aimed at decreasing or abolishing participation restrictions.

ADJUNCTIVE AGENTS

Adjunctive agents are essential in the treatment of pain. In the case of chronic pain, more agents are used. The disabling nature of chronic pain leads individuals to seek out any other potentially pain-relieving therapy such as medications, chiropractic, massage therapy, relaxation techniques, acupuncture, biofeedback, and psychological care.[68] Acupuncture, herbal remedies, dietary changes, and a host of other therapies may be employed. In particular, real acupuncture has proven better than sham acupuncture for relieving pain, improving global ratings, and decreasing morning stiffness.[68] It has been recommended as an adjunctive treatment in the management of fibromyalgia, chronic low back pain, myofascial pain, and osteoarthritis. Continuous communication with the patient and other health care providers ensures optimal treatment and avoids conflicting interventions. Remain open-minded and supportive as the patient searches for solutions to his or her pain.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation has been proven useful in the treatment of some types of pain.[95] Stimulation of the posterior tibial nerve and sciatic nerve was performed to see the effect on WDR neurons in the spinal cord. Results showed that electrical stimulation of peripheral nerves leads to inhibitory input to the pain pathways at the spinal cord.[96] One mechanism of pain relief with the application of an electric current is based on the gate theory of pain. Application of TENS selectively activates large A-alpha and A-beta fibers, which are stimulated at lower thresholds than the smaller C fibers. These impulses travel to the dorsal horn of the spinal cord, where facilitation of the small interneurons of the substantia gelatinosa inhibits pain transmission through presynaptic inhibition. Activation of these large-diameter fibers closes the gate to small-diameter fiber transmission.

Other theories suggest that TENS may function through antidromic (i.e., conducting impulses in a direction opposite to normal) stimulation of afferent neurons. Antidromic stimulation may decrease pain by blocking the nociceptive input to the spinal cord, and it may stimulate release of substance P, resulting in vasodilation. Vasodilation can decrease pain by increasing local circulation, which removes metabolic waste products and supplies oxygenated blood for healing. The increased local circulation may decrease local ischemia enough to decrease pain.[31]

TENS may affect the opiate pain-modulating system. Ascending projections from small-fiber afferents reach the PAG, which is rich with opiates. The PAG provides descending input to the dorsal horn, which probably is opiate-mediated. TENS may provide some analgesia through opiate-mediated activation of the brain stem. TENS can be used in a variety of ways that increase a patient's function. It can be worn continuously, during activity, or after activity.

The parameters for TENS application are varied. Consult any appropriate textbook for discussion of the benefits of different parameter settings.

Heat

Heat is commonly used as a primary or adjunctive agent to decrease pain. Trauma can produce a pain-spasm cycle that activates nociceptors. The nociceptors detect pain that produces reflex muscle activity that, if prolonged, results in muscle ischemia. The ischemia excites muscle nociceptors that perpetuate the muscle spasm. Chemical release at the time of injury or resulting from inflammation can also stimulate nociceptors. Vasoconstriction associated with a sympathetic response or vasoconstriction resulting from muscle spasm can produce pain. The application of heat can decrease pain from any of these sources.

According to the gate theory, heat application can decrease pain directly. Thermal sensations are carried to the dorsal horn of the spinal cord through large-diameter myelinated fibers. These impulses can close the gate, blocking the transmission of pain impulses through small-diameter fibers. The thermal sensations are transmitted to conscious levels preferentially over pain sensations. The increased circulation resulting from heat application decreases pain through two mechanisms. First, pain resulting from ischemia decreases as the local circulation is increased. The increased circulation may break the pain-spasm cycle as pain decreases and the muscle is provided with oxygenated blood. Second, the increased circulation may remove noxious chemicals associated with injury or inflammation, thereby decreasing pain.

Superficial heat in the form of hot packs is commonly used in the clinic and home to decrease pain and as a precursor to therapeutic exercise. Local heat application increases the extensibility of tissue, preparing it for subsequent exercise. Immersion in a warm pool or whirlpool can also decrease pain, although the water temperature is significantly lower than that of a hot pack because of the size of the area heated. The warmth and buoyancy effects of the water combine to decrease pain sensation. Ultrasound or diathermy can increase the heat's depth of penetration. Any of these modalities can provide valuable assistance in the reduction of pain. However, it is important to remember that the best way to heat a muscle is to exercise it.

Cold

Cold treatments are commonly used to decrease pain. Cold decreases pain through some of the same mechanisms as heat. Cold sensation is carried to the dorsal horn of the spinal cord through large-diameter afferent fibers and is capable of closing the gate to pain signals through smaller-diameter fibers. The drop in tissue temperature blocks synaptic transmission of any input, rendering the gate inactive. The decrease in pain may help to break the pain-spasm cycle. In acute injury, the vasoconstriction produced by cold may prevent edema that produces pain. Because the application of cold is somewhat noxious, the afferent input to the brain stem through the PAG could cause the release of endorphins at the spinal level; the decrease in pain would be modulated by higher centers.

Cold usually is applied by means of ice in the form of packs, bags, or ice massage. The length of application depends on the size of the area to be cooled, the area of the body to be cooled, the mode of application, local circulation, and patient sensitivity.

Medication

Drug therapy is commonly prescribed for individuals with acute or chronic pain. Many medications are available and act through different mechanisms and at different sites to relieve pain. Medications are administered orally, by intramuscular injection, by injection into other structures, or by intravenous infusion. The dosage necessary to produce analgesia varies among individuals and for various medications.

Acting peripherally, NSAIDs are commonly prescribed. Several chemical classes exist, all of which inhibit the synthesis or release of prostaglandins.[97] Analgesia generally occurs within

24 hours of NSAID administration, and anti-inflammatory responses occur with continued administration. The major side effect of NSAIDs is gastrointestinal upset. Many NSAIDs are enteric-coated and long acting, decreasing the frequency of administration. Local injections of anesthetic agents can provide relief from pain in localized areas. Trigger-point injections with an anesthetic agent are commonly performed in individuals with chronic pain, particularly pain arising from myofascial tissues. Recently, botulinum toxin type A has been effective in reducing pain as measured by VAS, palpable muscle firmness, and pressure pain thresholds when compared with saline (placebo) injections.[68]

Cyclooxygenase (COX)-selective drugs are another classification of nonopioid analgesic medications. The COX-2 selective drugs (e.g., celecoxib, rofecoxib) work by inhibiting the synthesis of prostaglandins. These medications may decrease pain and inflammation with less gastric irritation.

At the spinal cord and higher levels, a variety of medications can be administered. When treating centrally mediated pain, the preferred first line of medications includes the tricyclic antidepressants, serotonin-selective reuptake inhibitors (SSRIs), and the anticonvulsive medications gabapentin and pregabalin. Antidepressant medications have analgesic effects, and administration may relieve pain at levels below those necessary to achieve antidepressant effects. These medications may be used at levels that have analgesic and antidepressant benefits. SSRIs typically cause less cardiovascular or anticholinergic side effects than tricyclics.[98] Side effects of the SSRIs include headache, nausea, tinnitus, insomnia, and nervousness. Tricyclic antidepressants also have significant side effects, including orthostatic hypotension, potentially predisposing patients to falling. The tricyclics also have a significant impact on the cardiovascular system, including altered heart rate, rhythm, and contractility, particularly in patients with existing cardiac disease.[98] Therefore, SSRIs are generally preferred to tricyclics in patients with known cardiac disease.

Anticonvulsive medications such as gabapentin are used to treat neuropathic pain. Pregabalin has also been successfully used to treat neuropathic pain.[99] A recent study showed that the use of pregabalin (Lyrica) was cost neutral compared to "usual care" and resulted in a small but significant increase in the quality of life in patients with peripheral neuropathic pain.[100] Other medications such as muscle relaxants like benzodiazepines also act as analgesics. Moreover, they help patients relax and sleep, which significantly improves their quality of life.

Narcotics acting at opioid receptors are also used to treat pain. Side effects of opioids include postural hypotension, sedation, and confusion. These effects may lead to a risk of falls, which should be considered in any rehabilitation program. Morphine and other strong narcotics are commonly used to relieve end-of-life pain and cancer pain. Bennett[15] suggests that opiates are the most effective medications for managing chronic pain and should not be withheld because of fear of addiction. Addiction is the use of medication for its mind-altering properties with manipulation of the medical system to acquire them. This is very different from the physical dependence seen in patients who need these medications to obtain pain relief.

Some patients receive inadequate pain control from traditional administration methods because of individual differences in absorption and metabolism of drugs or because of fluctuating plasma levels of the drugs or their metabolites. In this situation, patient-controlled analgesia (PCA) may be indicated. The PCA system infuses a drug in a desired location on demand or at a continuous rate.[101] Opioid analgesic drugs such as morphine, meperidine, and hydromorphone are commonly used.[101] In an on-demand system, a small button on the PCA system releases a preset dose of medication. The constant-rate infusion delivers a small but continuous dose to maintain steady plasma levels of the analgesic. A variety of safety features (i.e., the pump is programmed to prevent an overdose) are included in the system. Chronic pain from cancer, surgery, or labor and delivery is a common reason for the use of PCA.

SPECIAL CONSIDERATIONS IN CHRONIC PAIN: COMPLEX REGIONAL PAIN SYNDROME, FIBROMYALGIA, AND CHRONIC FATIGUE SYNDROME

Significant impairments exist in patients with fibromyalgia syndrome (FMS), including widespread pain,[102] decreased joint range of motion,[103] and impaired respiratory[104] and cardiovascular status.[93] Patients frequently decrease work hours and change tasks,[105–107] and they develop significant conflicts about life roles.[108] Twenty-five percent of patients with CFS are bedridden or unable to work.[109] Complex regional pain syndrome (CRPS) is a painful and debilitating condition of unknown origin, which profoundly affects patients and their families. These disabilities have negative economic and quality of life effects. Patients with FMS, CRPS, and CFS are being seen increasingly in the physical therapy clinic because carefully prescribed exercise has been shown to be of value in improved aerobic performance, tender point pain, well-being, pain levels, and self-efficacy.[110–116] Unfortunately, these conditions are poorly understood by the public and many health professionals. An understanding of the problems these patients encounter will provide a basis for a solid rehabilitation program.

Complex Regional Pain Syndrome

Complex regional pain syndrome is a term used to describe a cluster of signs and symptoms, including pain disproportionate to the injury, vasomotor and trophic changes, stiffness, swelling, and decreased function. Other terms for CRPS have included reflex sympathetic dystrophy (RSD), sympathetically maintained pain, causalgia, sympathetic dystrophy without pain, shoulder–hand syndrome, and Sudeck atrophy. The uncertain role of the sympathetic nervous system in CRPS led the IASP and the American Pain Association to recommend the use of the term CRPS to replace the term RSD.[117]

CRPS is three to four times more common in women, is found more frequently in the upper extremity, and peaks in the 50 to 70 age group.[118] The diagnostic rates for CRPS have decreased approximately 50% since the IASP revised their diagnostic criteria.[119,120] Most acute cases, defined as diagnosis <1 year (also called "warm" CRPS), tend to resolve with conservative care, with reports of resolution of CRPS type I of 74%.[121] Patients with chronic CRPS (diagnosis >1 year, also called "cold" CRPS) have a poorer prognosis; at 6 years postdiagnosis, 30% reported being completely recovered, 16% reported decline, and 54% considered their disease as stable.[120]

Etiology

As with other forms of chronic pain, CRPS has a complicated and unclear etiology. CRPS develops most frequently after trauma, including fractures (accounting for ~45% of cases), crush injuries, sprains, contusions, and surgical procedures.[117] Although a few cases develop without a known antecedent event, the fact that trauma was involved implicates the inflammatory process as key in the early phase, and anti-inflammatory measures are recommended in the early phase.[122–124] It has been considered as a type of neuropathic pain by some, but not by others.[119,123] Some have suggested that genetic factors may predispose some individuals to CRPS.[119,124] Other research suggests that CRPS may be a type of autoimmune disease.[120] Most consistently, CRPS follows the same pattern as other forms of chronic pain, with a complex interplay of peripheral and central mechanisms that result in central sensitization and its sequelae. Central changes at the cortical and spinal cord levels involving ascending and descending pathways, NMDA receptors, windup and allodynia, which have been previously discussed, are also implicated in CRPS.

Signs and Symptoms

Several common features and two major classifications of CRPS have been identified. The common features are local tissue damage or nerve damage that initiates a reflex response in the peripheral nervous system and CNS. Several disorders with the same abnormal clinical findings share these criteria with CRPS. The two types have been classified by the absence or presence of nerve involvement (see **Display 10-5**). A third type has been added for coding purposes:

- CRPS Type I: resembling RSD (without nerve involvement).
- CRPS Type II: equivalent to causalgia (with nerve involvement).[117]
- CRPS- NOS: patients who partially meet the CRPS criteria. Developed to capture those previously diagnosed with CRPS who do not meet the updated criteria.[42]

Several impairments are associated with CRPS and may include pain and inflammation, swelling, stiffness, vasomotor disturbances, trophic changes, bone demineralization, and dystonia.[117] Initial activity limitations are numerous and are based on pain-limited use of the extremity. An ADL checklist is helpful to monitor even small improvements in functional tasks.

Pain disproportionate to injury severity is the primary clinical feature of CRPS. In the upper extremity, pain is found throughout a large part of the arm, from the upper arm distally to and fully including the hand. In the lower extremity, pain can begin in the foot and spread proximally up the leg. The pain is often described as burning initially and eventually changing to pressure, aching, and binding sensations. Pain is often constant, starting locally at the original injury site and spreading throughout the extremity. The pain often leads to disuse and self-immobilization of the extremity, along with the known consequences of this response. In addition to constant pain, hypersensitivity to touch occurs, with extreme sensitivity to any kind of tactile stimulation. Occasionally, sympathetic and trophic changes occur with minimal complaints of pain or pain related only to motion of stiff joints.

Excessive swelling at the injury site is often the first objective sign noticed in the early phase. Swelling can subsequently spread throughout the distal upper extremity. Initially, it has a fusiform and pitting appearance, but it later takes on a hard and brawny character that contributes to joint stiffness. In the hand, periarticular thickening is observed at the interphalangeal (IP) joints. Edema is difficult to control even with otherwise successful intervention techniques.

Joint restriction with CRPS is often more profound than expected for the associated diagnosis. Unlike the traditional joint stiffness experienced after injury that decreases with ROM and functional use, individuals with CRPS tend to lose motion over time and seem to be refractory to improvement with traditional active and passive exercises and dynamic splinting. Fibrosis of

DISPLAY 10-5
Clinical Diagnostic Criteria for Complex Regional Pain Syndrome

1. Continuing pain, which is disproportionate to any inciting event.
2. Must report at least one symptom in three of the four following categories:
   - Sensory: Reports of hyperalgesia and/or allodynia.
   - Vasomotor: Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry.
   - Sudomotor/Edema: Reports of edema and/or sweating changes and/or sweating asymmetry.
   - Motor/Trophic: Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nails, skin).
3. Must display at least one sign* at the time of evaluation in two or more of the following categories:
   - Sensory: Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement).
   - Vasomotor: Evidence of temperature asymmetry and/or skin color changes and/or asymmetry.
   - Sudomotor/Edema: Evidence of edema and/or sweating changes and/or sweating asymmetry.
   - Motor/Trophic: Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nails, skin).
4. There is no other diagnosis that better explains the signs and symptoms.

**A sign is counted only if it is observed at the time of diagnosis.*

***Research criteria for CRPS are recommended that are more specific, but less sensitive than the clinical criteria; they require that four of the symptom categories and at least two sign categories be present.*

From: International Association for the Study of Pain. White paper on Classification and Diagnostic Criteria for Pain [whitepaper], 2015. http://iasp.files.cmsplus.com/Content/ContentFolders/Publications2/ClassificationofChronicPain/Part_II-A.pdf. Accessed August 14, 2015.[125]

ligaments limits motion about joints, and adhesions in tendon sheaths limit the gliding properties of the tendon, producing inflammation and pain. These changes contribute to the vicious circle of pain and inflammation. Palmar and plantar fasciitis can be seen, and nodules and thickening of the fascia can be palpated. In the hand, this stiffness contributes to limited metacarpophalangeal (MCP) and IP extension.

Discoloration of various degrees occurs with vasomotor instability. Pallor results from vasoconstriction of the arterial and venous systems. Redness is evident when there is dilation of both sides of the vascular tree. Blueness (cyanosis) is usually present with vasoconstriction of the venous system.[126] Sudomotor changes include hyperhidrosis (excessive sweating) in the early stages and dryness in later stages.

Bone demineralization is a reliable sign of CRPS and assists in making the diagnosis. Although some demineralization takes place with immobilization, the bulk of calcium loss results from increased blood flow in the periarticular bone.[126] Sudeck[127] described the condition as "inflammatory bone atrophy." Untreated cases progress from "spotty" osteoporosis to diffuse osteoporosis.

Trophic changes in the skin are initially caused by swelling and later by nutritional changes in the hand. The skin appears glossy or shiny, and evidence of subcutaneous tissue atrophy is present. Excessive and dark hair growth may be present. The nails become coarse, rigid, and curved.[127]

Interventions for CRPS

Interventions for CRPS are changing as new information on the etiology and prognosis are better understood. Previously, when the primary etiology was believed to be sympathetic nervous system dysfunction, sympathetic blocks were standard of care. However, as new information arises, other interventions are being tested. Ketamine, a NMDA antagonist, has been effective in decreasing CRPS pain.[120,128–130] Drugs or medications that address free radicals have been researched by some and suggested to be effective (vitamin C, oral corticosteroids, topical dimethyl sulfoxide, calcium channel blockers).[120] Graded motor imagery, mirror therapy, and physical and occupational therapy have evidence for positive effects.[129] Physical therapy is particularly effective in acute cases and addresses the impairments (pain, edema, mobility, strength) and activity limitations experienced by the patient.[120]

Therapeutic exercise must be approached practically and cautiously. Traditional exercises for restricted joints are often painful and exacerbate the pain cycle and vasomotor instability. Pain must be controlled before progressing to other treatment techniques. Modalities such as heat and cold may be helpful in reducing pain but must not aggravate the vasomotor tone. Elevation and moist heat before edema massage and exercise can improve tissue extensibility and tolerance to exercise.

Fibromyalgia Syndrome

Fibromyalgia syndrome is characterized by widespread body pain (in all four quadrants and the axial skeleton) and tenderness, fatigue, and morning stiffness.[1] These patients are highly sensitive to both painful and nonpainful stimuli, including touch, temperature, chemical, light, sounds, and smells.[131] Although the cause of FMS is uncertain, it tends to predominately affect females (80% to 90% of patients). Patients typically are between 20 and 60 years of age,[132] although there have been reports of children being affected.[133,134] The prevalence of fibromyalgia is about 2% of the general population, affecting approximately 5 million adults in 2005.[135] Persons with FMS are estimated to constitute about 7% of the patients seen in general medical practices and up to 20% of the patients in general rheumatology practices.[132,135] Patients with fibromyalgia account for nearly 2.2 million ambulatory care visits annually.[136,137] Fibromyalgia has a significant impact on quality of life, with these patients scoring the lowest on 7 of 8 subscales of the SF-36 compared to patients with other chronic diseases, and having a 3.4 times greater likelihood of being diagnosed with major depression compared with age-matched peers without fibromyalgia.[138–140]

Etiology

One of the characteristics of FMS is the absence of consistent, positive laboratory findings.[102] Because its symptoms mimic those of other diseases (e.g., rheumatic diseases, multiple sclerosis, malignancies, hypothyroidism, anemia), a thorough medical evaluation is necessary to exclude other possible causes of the presenting complaints.[141] Onset of FMS can be insidious; it may occur after a viral infection[142–144] or trauma.[143–145] It may also be related to stress[146]; sleep disruption such as occurs in sleep apnea, sleep myoclonus, and alpha-delta sleep[147,148]; or be related to CNS mechanisms.[149] Increased excitability of spinal cord neurons after an injury, increased receptive field size of the neurons, and reductions in pain threshold are indicative of progressive central sensitization.[131] It seems likely that multiple factors contribute over time until a threshold is reached such that a final event appears to be the precipitating factor.[150]

Many researchers have attempted to identify the causative factors of FMS, but the pathomechanics remain elusive. Historical references to FMS-like symptoms are found as far back as Hippocrates.[151,152] Straus[152] cites the treatise of an 18th-century physician who describes such a disorder found predominately "among women. . . who are sedentary and studious," and that he felt was "precipitated by antecedent causes including grief and intense thoughts." In the 1800s and early 1900s, muscle inflammation (giving rise to the term *fibrositis*) was considered a cause. The term fibrositis has generally been disregarded for want of histological evidence of inflammation in the muscles of patients with FMS.[153,154] Later research into the possible causes of FMS has focused on peripheral (muscle physiology) and central (CNS function) phenomena.

Peripheral Origin Aggressive exercise is not well tolerated by patients with FMS and often results in increased perception of pain and fatigue.[155–158] Muscle adaptation to decreased activity has been hypothesized to be at least partially responsible for the adverse reaction to overexertion, and muscle morphology and physiology in patients with FMS have been investigated[159] (**Evidence and Research 10-3**). It is not clear whether localized metabolic or morphological changes in muscle can account for the pain and fatigue associated with FMS. Peripheral changes may contribute to increased pain signals to the spinal cord, contributing to windup and central sensitization.[131] Even low levels of nociceptive input from the periphery can maintain the central sensitization. It is likely that peripheral mechanisms interact with central to increase central sensitization.

EVIDENCE and RESEARCH 10-3

A large body of research has examined the muscle morphology in FMS for the etiology of this syndrome. No muscle morphological changes specific to FMS have been found, but the muscles of patients with FMS have the appearance of inflammatory infiltrates, muscle pH changes related to ischemia, reduced oxidative capacity, and fiber changes.[131,154] In very few muscle samples, evidence suggesting a mitochondrial disorder and possibly microcirculation compromise was documented, but these changes were not widespread in the muscle.[153,160–162] Neither muscle energy metabolism[163,164] nor enzyme levels[156] vary from those of controls, although a recent study showed decreased use of phosphorous metabolites at maximal work levels.[165] Reports of decreased exercise-induced muscle blood flow in patients with FMS[166] were not, however, accompanied by the expected decrease in capillary density that this finding suggested.[161]

Epidural blockade does reduce FMS tender points,[167] and there is evidence of increased nociceptor reactivity in patients with FMS,[168] which suggests that peripheral pain may be a contributor. Electromyographic studies suggest that the muscle itself is capable of normal work but that there may be a central mechanism limiting that work by producing symptoms of FMS and CFS, which the patient interprets as pain and fatigue (**Evidence and Research 10-4**).

EVIDENCE and RESEARCH 10-4

Muscles of patients with FMS do not show a drop in surface electromyographic activity during short pauses between muscle contractions, which may be a response to perceived pain and fatigue.[169] Studies found that patients with FMS or CFS do not sustain repeated muscle contractions at the same intensity as controls.[170–172] Other studies show that they do.[173–174] However, when electrical stimulation of muscles accompanied repeated contractions, the contraction intensity and duration matched those of controls.[175]

Central Nervous System Origin Pain modulation may be disrupted in FMS at the spinal cord level or in higher CNS centers. Although endorphin levels have been found to be normal,[176–178] lowered levels of serum tryptophan[179] and elevated levels of substance P[180] may amplify pain perception. Blunting of the hypothalamic–pituitary axis to stressors is also a factor.[131]

Pituitary hormone secretion changes have been found in patients with FMS.[181–183] Growth hormone is adversely affected by sleep deprivation.[184] The production of an FMS-like state in healthy volunteers through alpha-delta sleep induction[185] may point to a role for abnormal growth hormone secretion in FMS symptom production.[161]

The limbic system has also been implicated as a contributor to FMS. This area affects sensory gating and processing of sensory input.[186] Autonomic nervous system dysfunction has also been suggested by the results of several studies.[156,187] An inverse relationship between sympathetic reactivity and pain sensitivity has been found. Stress and anxiety associated with FMS would be expected to increase sympathetic tone, but the expected commensurate increase in plasma and urinary catecholamines was not found.[188] A lowered level of sympathetic activation has been postulated, and may be a source of increased pain sensitivity in patients with FMS.[189]

Like other patients with chronic pain, central sensitization and "windup" occur in patients with FMS.[131] Patients with chronic pain described their pain as dull, aching, or burning; these symptoms are transmitted by the unmyelinated C fibers. When this type of pain is evoked, the perceived pain is greater for patients with FMS than for controls.[131] In patients with FMS, fibers that previously had no association with pain stimuli now begin transmitting pain, furthering the central sensitization phenomenon.[131]

There may be a genetic predisposition to FMS because first-degree relatives of patients with FMS have a higher than expected frequency of FMS. It has been proposed[190,191] that FMS can occur with exposure of genetically susceptible individuals to any one or a combination of the triggers associated with FMS onset.[132–134,141,176]

Signs and Symptoms

FMS is a chronic condition in which symptoms wax and wane but are typically unrelenting. In addition to pain and fatigue, this population experiences lowered respiratory function,[104] joint range of motion, decreased muscle strength and endurance,[93,192–194] and below average cardiovascular fitness levels.[93] FMS is listed in the American College of Rheumatology (ACR) classification of rheumatic disease as an extraarticular disorder. In a multicenter study,[102] which established the 1990 ACR criteria for definition of FMS, the most common symptoms of patients with FMS were:

- Fatigue, sleep disturbance, and morning stiffness (73% to 85% of patients)
- Pain all over, paresthesia, headache, and anxiety (45% to 69% of patients)
- Irritable bowel syndrome
- Sicca syndrome (i.e., dry eyes and mouth)
- Raynaud phenomenon (<35%)

In this same study, factors found to affect the musculoskeletal symptoms of patients with FMS included cold, poor sleep, anxiety, humidity, stress, fatigue, weather changes, and warmth, as they did to a lesser degree in control subjects. These are still the accepted guidelines for the classification of fibromyalgia.[134]

The diagnostic criteria for FMS were developed from this study (**Display 10-6**). The diagnosis is based on finding at least 11 of 18 tender points (**Fig. 10-12**) in the presence of widespread pain (i.e., pain in all four quadrants of the body, including at least part of the axial skeleton) persisting for at least 3 months' duration. Tender points were defined as anatomically discrete and reproducible areas of heightened pain perception in patients with FMS. Diagnosis may also be made when the full 11 of 18 tender points are not present but other features commonly found in the study are.[150]

Activity Limitations

Several studies have examined the effect of FMS on everyday life. Fifty-five percent of working patients were found to have changed work tasks and to work shorter hours than before the illness. Motor tasks were reported as being more difficult to perform than before FMS onset, and 67% reported no or short pain-free periods.[105]

The lack of objective findings in light of the patients' perception of their illness is stressful and can lead to feelings of rejection and of being misunderstood or disbelieved. These feelings compromise their ability to cope with the illness. Daily routines are disrupted, conflicts about life roles emerge and

DISPLAY 10-6

Classification of Fibromyalgia*

1. History of widespread pain.
   Definition: Pain is considered widespread when ALL of the following are present: pain in the left side of the body, pain in the right side of the body, pain above the waist, and pain below the waist. In addition, axial skeletal pain (cervical spine or anterior chest or thoracic spine or low back) must be present. In this definition, shoulder and buttock pain is considered as pain for each involved side. Low back pain is considered lower segment pain.
2. Pain in 11 of 18 tender point sites on digital palpation.
   Definition: Pain on digital palpation must be present in at least 11 of the following 18 tender point sites:
   Occiput: bilateral, at the suboccipital muscle insertions
   Low cervical: bilateral, at the anterior aspects of the intertransverse spaces at C5–7
   Trapezius: bilateral, at the midpoint of the upper border
   Supraspinatus: bilateral, at origins, above the scapula spine near the medial border
   Second rib: bilateral, at the second costochondral junction, just lateral to the junctions on upper surfaces
   Lateral epicondyle: bilateral, 2 cm distal to the epicondyles
   Gluteal: bilateral, in upper outer quadrants of buttocks in the anterior fold of muscle
   Greater trochanter: bilateral, posterior to the trochanteric prominence
   Knee: bilateral, at the medial fat pad proximal to the joint line
   Digital palpation should be performed with an approximate force of 4 kg. For a tender point to be considered "positive," the subject must state that the palpation was painful. *Tender* is not to be considered *painful.*

**For classification purposes, patients are said to have fibromyalgia if both criteria are satisfied. Widespread pain must have been present for at least 3 months. A second clinical disorder does not exclude the diagnosis of fibromyalgia.*

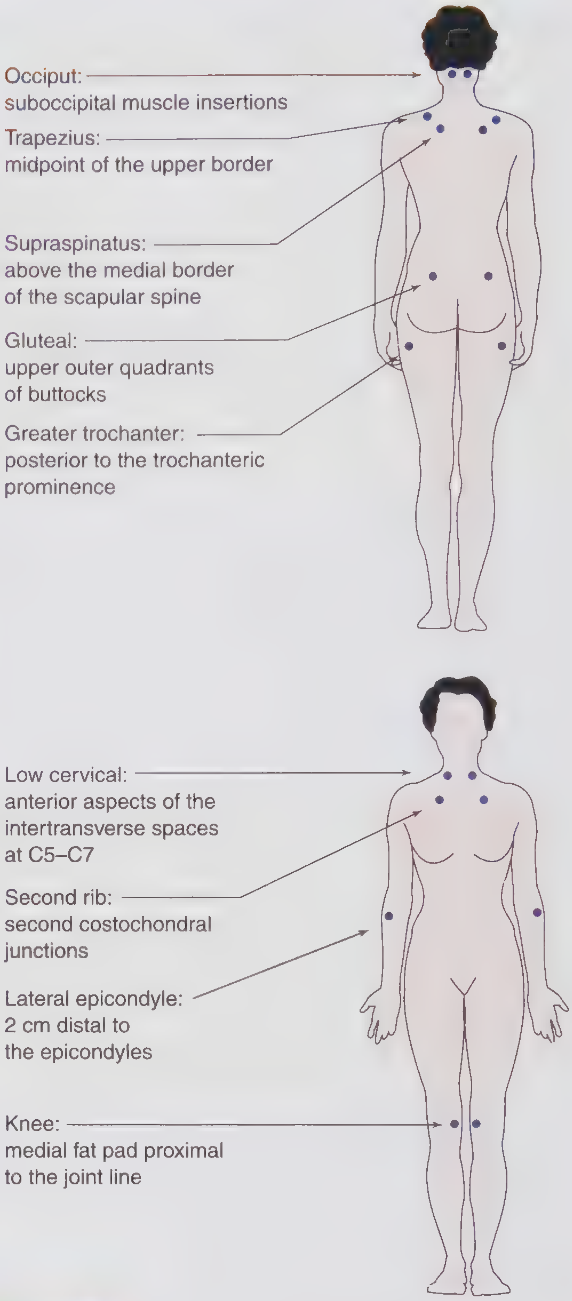

FIGURE 10-12 Location of 18 tender points.

lead to further stress, and loss of physical fitness and loss of future opportunities occur. Patients need early and adequate information, along with acknowledgment of the conditions to minimize psychosocial consequences.[108]

Chronic Fatigue Syndrome

Chronic fatigue syndrome is characterized by profound fatigue. Descriptions of similar illnesses are found throughout the medical literature.[151,152] These disorders include neurasthenia, myalgic encephalomyelitis, and chronic Epstein–Barr virus infection (i.e., "yuppie flu"). With an estimated incidence of 0.1%, CFS is much less prevalent than is FMS, and studies suggest that CFS affects both sexes and occurs across almost all races and ethnic groups.[195]

Etiology

Various studies have looked for the causes of CFS.[196,197] Neuroendocrine changes, especially in hypothalamic hormone production or release of corticotrophin-releasing hormone, have been found.[198] Patients with CFS also have widespread pain with characteristics of central sensitization similar to patients with FMS.[199,200] Up to 70% of patients with CFS simultaneously present with FMS.[135] Involvement of the HPA axis facilitates the inflammatory pathways and combined with the oxidative pathways (associated with mitochondrial dysfunction) produce pain, fatigue, cognitive impairments, and depression.[201,202] Mitochondrial dysfunction has been found in patients with CFS.[203–205]

Signs and Symptoms

The onset of CFS is typically sudden, and the fatigue is profound. Twenty-five percent of patients with CFS are bedridden or unable to work, and 33% can work only part-time.[109] Patients with CFS may tolerate exertion at first, but 6 to 24 hours later, symptoms often increase.

In 1994, the Centers for Disease Control and Prevention (CDC) published a working case definition of CFS[206] (**Display 10-7**). This definition is still current.[207] Unexplained, debilitating fatigue of at least 6 months' duration that is unalleviated by rest, and four of eight listed symptoms are required for case definition.

Among the eight symptoms detailed by the CDC, sleep disruption is reported by about 95% of patients with CFS. Other common complaints include neurocognitive difficulties, muscle weakness, frequent need for naps, dizziness, shortness of breath, and adverse responses to stress.[107] Comparison of the diagnostic criteria for FMS and CFS shows a broad overlap, and their exact relationship is in question.[195]

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON IMPAIRMENTS

Clinical manifestations of FMS and CFS include evidence of impairments that affect functioning. Studies carried out over the past 10 years[110–112,208–212] and reviews of treatment approaches for FMS and CFS[113,195,213] support the need for multidisciplinary intervention in the treatment of these impairments. Pharmacology, psychotherapy, education, and aerobic exercise are used successfully in many cases.[214–216]

Therapeutic exercise can address six main areas of impairment:

1. Muscle power functions
2. Exercise tolerance functions (impaired aerobic capacity)
3. Mobility of joint functions (impaired ROM)
4. Muscle endurance functions (impaired posture)
5. Emotional functions (impaired response to emotional stress)
6. Pain

There will be overlap in the impairments addressed within any given session, but it is advisable to start with an emphasis on the less demanding regimens (e.g., relaxation and muscle stretching) early in the course of treatment to build patient confidence in exercise and a greater acceptance of more aggressive exercise later. As treatment progresses, increase the intensity and difficulty of the intervention, monitoring patient response and adjusting (and teaching the patient to monitor and adjust) appropriately, working toward functional goals (**Table 10-2**). Therapeutic intervention for a structured return to physical activity is suggested for patients with CFS because complete inactivity appears to promote fatigue.[195] Although little literature exists on the effect of exercise for CFS,[162] one study showed improvement in global self-assessment scores for patients with CFS after aerobic exercise training.[212] Treatment of FMS-like symptoms of CFS could follow the FMS protocols suggested in the next sections, and physical symptom exacerbation should guide progression of the program.

Impaired Muscle Power Functions

Muscle performance in patients with FMS declines compared with the case in controls. Perception of pain and fatigue may limit production of muscle contraction force and eventually affect functional activities of the patient because of resulting deconditioning. Once existing muscle imbalances are successfully addressed, patients can begin to direct their energy toward general strengthening routines for conditioning, especially if this goal is a priority for them. There is evidence that increasing general strength levels affects FMS symptoms positively.[116,215]

The same conditions apply to exercise prescription for general strengthening as to treatment of specific movement faults. The program should start with low-resistance and low-repetition work, avoid static holding, monitor symptoms, and progress slowly. Allowing the patient to choose the form of exercise may increase enjoyment and compliance. Exercise can be isometric or isotonic. If isometric activities are chosen, avoidance of

TABLE 10-2

Exercise for Patients with Fibromyalgia

Early Phase

- Goal: stress and pain management
- Progressive relaxation
- Diaphragmatic breathing
- Visualization
- Active movement of nonpainful areas
- Stretch

Midphase

- Goal: musculoskeletal balance
- Self-mobilizations
- Active movement involving more joints
- Strain–counterstrain
- Muscle system balance exercises
- Core stabilization
- Functional movements
- Early aerobic exercise: recumbent bike, unloading equipment, easy exercises in water

Late Phase

- Goal: transition to wellness
- Stretch
- Musculoskeletal balance
- General strength: resistance tubing, machines, free weights
- Aerobic exercise: non–weight-bearing to weight-bearing and nonjarring activities (elliptical, stepper, seated stationary bike, treadmill) and water exercises (aerobics, flotation belt)

TABLE 10-3

Sample Strengthening Program

Water Program: 3 d/wk

- Warm-up: slow walking forward, backward, sideways: with or without arm movement depending upon upper extremity involvement (approximately 5 min)
- Slow-speed arm movements with short lever arm and decreased surface area (5–10 repetitions)
- Flexion/extension
- Horizontal abduction/adduction
- Abduction/adduction
- Rotation
- Slow-speed leg kicks into flexion and abduction (5–10 repetitions)
- Squats or stepping exercise
- Bicycling with legs
- Gentle stretching and walk for cool down

Land Program: 3 d/wk

- Walking in home or around neighborhood
- Abdominal muscle strengthening (e.g., pelvic tilts, bridging, stabilization)
- Stepping exercise (such as wall slide, squat, stair step exercise)
- Upper extremity exercise with very light resistance (1–2 lb or less)
- Gentle stretching exercise

prolonged static holding is important. Contractions should not be held longer than 3 to 5 seconds, with three to six repetitions of the exercise performed three times each week, a level that has been demonstrated to increase periarticular muscle strength.[217]

In dynamic exercise, slow movement through full range with return to the lengthened range allows a slight muscle stretch between contractions. Resistance exercise using free weights, tubing machines, or the water's viscosity are all useful if dosed properly, including appropriate recovery time. Aquatic therapy has been shown to be very effective for strengthening and aerobic exercise for patients with FMS.[216] Closed chain lengthening exercises such as T'ai Chi, Pilates, or yoga are useful when the patient is ready for active movement. If no prior weight training has been done by the patient, calibrating the response by starting with three to five repetitions of three to five exercises at the lightest weight and monitoring the response over 24 to 48 hours can provide the baseline of the patient's tolerance. Patience is important in introducing exercise to decrease setbacks. **Table 10-3** provides a sample program.

Exercise Tolerance Functions: Impaired Aerobic Capacity

Because aerobic exercise may have a positive effect on some of the impairments seen in patients with FMS and CFS, including endurance, pain, and flexibility, it should be introduced as soon as possible. Patients with FMS who participate in an aerobic exercise have been shown to improve overall well-being, improve ability to perform aerobic exercise, decrease tender point pressure pain, and reduce overall pain.[214] Exercise programs were performed for at least 20 minutes per day, 2 to 3 days per week and included strength training. The exercise should progress to being of moderate intensity.[215]

Initially, only a few minutes of the activity should be allowed (2 to 5 minutes, unless the patient is already active for longer periods without symptom flares) to allow the gradual buildup of tolerance. By the late phase of rehabilitation, the patient may be ready to work on elevation of the heart rate to 50% to 60% of the maximum heart rate. Monitoring techniques including the training index, pulse determination, and use of the perceived exertion scale[218] should be discussed, so pacing and progress can be monitored. The patient should keep a record of exertion and symptoms to facilitate this. A variety of electronic equipment is available to make tracking activity simpler.

During the first session, it may be a good idea to make a contract with the patient to start preaerobic activities of daily walking, even if only one-half of a block. For the patient who is able to walk more than one-fourth of a mile, a high school track offers several advantages. Typically, it has a shock-absorbing surface; it is a safe place to use headphones without worrying about traffic, which may make it more enjoyable; accurate distance estimates are possible, so progress in distance and rate can be tracked; and the patient who fatigues part way through can usually walk back to a car rather than all the way home or have to ask someone to come for him or her. It is important to consider the patient's interests and goals in designing a walking program and in suggesting a particular environment. Initially, the rate of walking should be slow and comfortable until tolerable levels, without a flare of symptoms, can be established.

Another approach to introducing exercise gently is to have the patient exercise on a recumbent bike or walking in a swimming pool. During the first session, the patient should walk or pedal about 2 to 3 minutes; 1 to 2 minutes can be added each session (at first not more than once a day) until, by the late phase of treatment, the patient may reach 15 minutes. After the patient is able to exercise on the bike or pool for 20 to 25 minutes, it should be possible to allow the patient to choose some other form of nonjarring aerobic exercise that is personally enjoyable. Community pool programs with classes for patients with fibromyalgia have the added benefit of social contact. For some patients with FMS, socializing has been markedly decreased because of fatigue and pain. Nonjarring sources of aerobic exercise for slightly more advanced patients may include a treadmill, ski machine, seated push–pull arm and leg machines, rowing ergometer, and minitramp (see **Selected Intervention 10-1**).

SELECTED INTERVENTION 10-1

Treatment of the Patient with Fibromyalgia

See Case Study No. 7

Although this patient requires comprehensive intervention, as described in the patient management model, one exercise is described.

ACTIVITY: Hand-to-knee pushes

PURPOSE: To increase abdominal and hip flexor muscle strength; improve single-leg balance and trunk stability; and increase upper quarter strength through closed chain activity.

RISK FACTORS: No appreciable risk factors

STAGE OF MOTOR CONTROL: Stability

POSTURE: Standing position on a single leg. The opposite hip and knee are flexed to 90 degrees. The opposite hand of the flexed leg pushes isometrically against the movement of hip flexion. A neutral spine is maintained, and concentration on abdominal muscle contraction is emphasized.

MOVEMENT: Isometric contraction of the abdominal, hip flexor, and contralateral upper quarter muscles.

SPECIAL CONSIDERATIONS: Ensure proper posture of the trunk, pelvis, and weight-bearing limb. Cue for an abdominal muscle contraction, using palpation as necessary. This exercise is contraindicated when an isometric muscle contraction is contraindicated.

DOSAGE: Hold contraction for 3 to 6 seconds at a comfortable intensity that does not cause hip flexor or shoulder fatigue. Repeat on the opposite side.

TYPE OF MUSCLE CONTRACTION: Isometric

Intensity: Submaximal

Duration: Hold for up to 6 seconds

Frequency: During each pool session

RATIONALE FOR EXERCISE CHOICE: This exercise addresses the many components of fibromyalgia, including trunk stability, single-leg stance stability, abdominal muscle endurance, and upper and lower quarter muscle endurance.

EXERCISE GRADATION: This exercise is progressed to greater intensity and more repetitions. More advanced stabilization exercises incorporating upper and lower extremity movements with resistance are then added.

When introducing aerobic exercise routines, the therapist should let the patient know that continuous monitoring and pacing are important. During periods of symptom flares, the patient should be encouraged to modify exercise intensity appropriately and not discontinue altogether (**Evidence and Research 10-5**). It is easy for patients to become discouraged and stop a program. Their records and the encouragement of the clinician may help them push through this difficult time and allow them to comply with what appears to be one of a few treatment approaches with a positive impact on FMS.

EVIDENCE and RESEARCH 10-5

In several studies of the effects of aerobic exercise on FMS, the first 10 to 12 weeks were problematic for musculoskeletal symptom flares and for adherence.[110,115] A systematic review of exercise in FMS[219] reports adherence to exercise and attrition in study subject numbers (25% average in the studies cited) was a problem. Some patients complained of a flare of pain or fatigue during and after exercise, and it is pointed out that positive findings reported with exercise in these studies might be attributable to attrition bias. Mengshoel,[115] however, maintains that patients can perform low-intensity dynamic exercise without a flare of symptoms.

Mobility of Joint Functions: Impaired Range of Motion

Restrictions in joint ROM may exist at any joint held for prolonged periods in abnormal alignment. Joints particularly affected by static poor posture can include craniovertebral, cervicothoracic, scapulothoracic, glenohumeral, radiohumeral, midthoracic, lumbopelvic and pelvofemoral, and subtalar joints. Intervention with soft-tissue and joint mobilization techniques where deemed appropriate should always be supported with exercises designed to balance muscles around the affected joints. Patient efficacy and responsibility with self-treatment in this chronic condition is an important part of patient education for self-management.

Where joint hypermobility or poor proximal stability is present, concurrent use of stabilization training (e.g., in craniovertebral flexion during self-stretch of suboccipital muscles, uptraining of longus capitis, and downtraining of scalenes and sternocleidomastoid muscles) is necessary for the preservation of good joint alignment.

Flexibility exercises should be graded for exertion and time. The typical 20- to 30-second hold during stretching may be too long when effort is required to hold a limb. Passive support or decreased time may be necessary. Stretching should never be painful. Breathing instruction during training is important as breath holding can be a characteristic of patients with FMS[104] (see **Self-Managements 10-9**, **10-10**, and **10-11**).

Muscle Endurance Functions: Impaired Posture

The biomechanical faults resulting from poor postural alignment can contribute to FMS pain,[113,149] and poor postural alignment can play into the reduced respiratory capacity of patients. Postural

SELF-MANAGEMENT 10-9

Neuromuscular Relaxation of Suboccipital Muscles

Purpose: To restore normal length to one group of suboccipital muscles and to decrease craniovertebral compression and possibly relieve headache.

Position: Lie on your back with your knees bent, feet flat on the floor, and neck supported on a small pillow or towel roll.

Movement Technique: Gently tuck your chin without lifting your head.

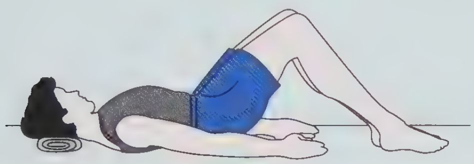
Hold for 6 seconds.

Relax.

Dosage:

Repetitions: ______________________

Frequency: ______________________



SELF-MANAGEMENT 10-10

Neuromuscular Relaxation of a Second Set of Suboccipital Muscles

Purpose: To restore normal length to a second set of suboccipital muscles and to decrease cranio-vertebral compression and possibly relieve headache.

Position: Lie on your back with your knees bent, feet flat on the floor, and neck supported on a small pillow or towel roll.

Movement Technique: Glide your head to the right without bending your neck.

With one fingertip on the bone behind your right ear, gently push your head to the left, but resist isometrically with your muscles on the right side of your neck.

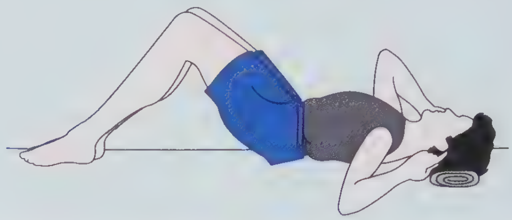
Hold for 6 seconds.

Repeat on the opposite side.

Dosage:

Repetitions: ______________________

Frequency: ______________________



SELF-MANAGEMENT 10-11

Neuromuscular Relaxation of a Third Set of Suboccipital Muscles

Purpose: To restore normal length to a third set of suboccipital muscles and to decrease cranio-vertebral compression and possibly relieve headache.

Position: Lie on your back with your knees bent, feet flat on the floor, and neck supported on a small pillow or towel roll.

Movement Technique: Lift your chin about one-eighth of an inch, so your head tips back.

Bring your right ear toward your right shoulder one-eighth of an inch, so your head tips to the right.

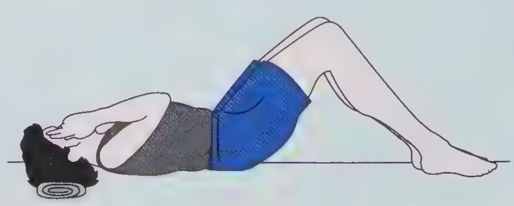
Turn your head one-eighth of an inch to the right, so your head rotates to the right.

With one fingertip on the right temple, gently push your head back to the left, but use your neck muscles to resist, so no motion occurs.

Dosage:

Repetitions: ______________________ times on each side (do not alternate)

Frequency: ______________________



assessment in all postures typical for the patient (standing, sitting, resting, and static or repetitive work postures) is important. Instruction regarding appropriate adaptation of standing, sitting, and lying surfaces with shock-absorbing pads, supports, and equipment realignment may be needed. And, often, verbal and manual cueing for proper muscle recruitment to maintain good alignment is necessary.

Along with stretching, strengthening for muscle balance around affected joints is necessary. The Sahrmann approach to muscle balance (see Chapter 9) appears to be an especially effective and well-tolerated approach to treating patients with FMS. These exercises are specific and can be progressed slowly, allowing pacing to minimize overexertion. Most do not require resistance equipment and are easily related to functional tasks (e.g., reaching overhead without shoulder or back pain, standing without back or hip pain).

Static posture is a starting point for return to function where dynamic activity against gravity is required. Stabilization exercises for trunk and proximal limb girdle muscles are useful when muscle weakness or joint hypermobility impairments exist and proximal control during functional tasks with the limbs is compromised. This is especially true for spinal segmental dysfunction. An approach that has been nonstressful for patients is the use of graded-resistance tubing attached to the wall or door, with the performance of scapular strengthening exercises while neutral trunk alignment is maintained (**Fig. 10-13**). This exercise can be progressed in difficulty by adding movement of the entire body (e.g., stepping) against resistance while holding a neutral alignment.

Stability control is an important part of functional activity, one that is frequently lost in deconditioned patients. Closed-chain activities and movement therapies, including T'ai Chi Chuan, Feldenkrais, and low-level therapeutic ballet classes, are exercise strategies that may help restore periarticular muscle balance and function and stimulate vestibular balance (**Fig. 10-14**). These classes may be more enjoyable for patients, and may increase adherence. Introduction of these strategies should be slow, probably after successful introduction of concentric forms of exercise, and always according to the patient's tolerance and carefully monitored for progression of intensity, duration, and frequency.

FIGURE 10-14 T'ai Chi is an excellent exercise strategy to help restore control and balance to the movement patterns of deconditioned patients. The teacher should have experience working with patients with joint problems or chronic illness.

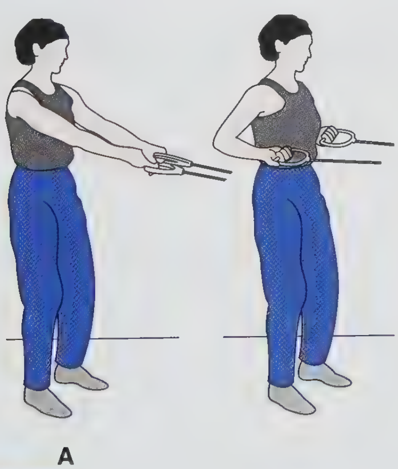


FIGURE 10-13 The use of graded-resistance tubing attached to the wall, with performance of upper extremity PNF diagonals provides a nonstressful stabilization exercise. **(A)** Holding onto the tubing, the patient crosses her wrists with her palms facing downward. **(B)** Maintaining her hand at waist level, the patient bends her elbows as she turns her palms upward.

Emotional Functions: Impaired Response to Emotional Stress

If the evaluation indicates a need for stress management, it should be initiated in the early phase of treatment, probably within the first or second visit. Stress management may include an exercise program with relaxation, deep breathing, and stretching exercises. These are unlikely to be stressful to most patients and usually provide benefits that are immediately obvious and typically pleasurable. This approach can provide a positive introduction to the benefits of exercise and offer an opportunity to demonstrate that exercise does not have to mean maximal exertion to be beneficial. Progressive relaxation, autogenic deep breathing, and visualization exercises (see Chapter 24) can be taught, or tapes can be made available to patients for use at home. In addition, patients may benefit from referral to an appropriate mental health professional for related services.

Instruction in diaphragmatic and lateral costal expansion breathing (see Chapters 22 and 24) can help respiratory function and is a good adjunct to any treatment requiring soft-tissue or joint mobilization of the thoracic cage (see **Self-Management 10-12**). Relaxation in a warm pool along with

SELF-MANAGEMENT 10-12

Neuromuscular Relaxation of Tight Rib Joints

Purpose: To decrease tightness at the rib joints and decrease posterior costovertebral pain.

Position: With the help of your therapist or after you are experienced, push on the rib in the front that corresponds with the level of pain on the back.

Even though this might not have seemed painful to you until you touched it, it will feel almost like a red-hot type of pain if it is the correct level. The place you push in front is on the same side as the back pain and near where the rib attaches to the sternum.

After you have located the spot, place the fist of the same-side hand flat against the spot.

Press the opposite hand on top of your fist; your elbow on the side of the pain sticks out.

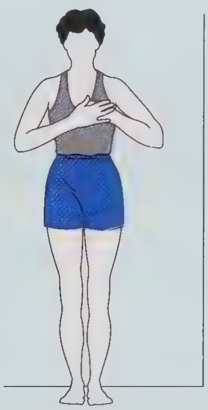
Movement Technique: Stand next to a wall or have a partner gently resist that elbow as it starts to elevate from your side.

Hold for a slow count of 6. *Be very gentle with resistance.*

Dosage:

Repetitions: ________________
times on each side (do not alternate)

Frequency: ________________



diaphragmatic breathing while immersed provides resistance to the muscles of inspiration. General stretching following accepted guidelines (see Chapter 7) can be prescribed if no joint instability has been identified. It is often necessary to make the patient aware of the distinction between stretch and pain, which can be difficult when generalized pain and aching is chronic and patients have learned to disregard these signals. If static stretching is uncomfortable, consider gentle dynamic mobility to begin.

In introducing these exercises, it may be useful to suggest that the patient choose a pleasurable place at a time when interruptions are minimal. Ensure proper recovery time so that the stress and recovery components stay in balance, maintaining homeostasis.

PRECAUTIONS AND CONTRAINDICATIONS

Exercise can be a two-edged sword for patients with FMS or CFS. Overexertion can lead to a relapse or exacerbation of symptoms.[110,115,162,208,211] Because most persons with FMS or CFS have experienced this phenomenon, they may resist the idea of exercise, and adherence to an exercise program may be difficult (see Chapter 3).

Pacing

Pacing is crucial for patients who are chronically fatigued.[220] For people who have been active exercisers before the onset of the disease, the inability to meet previous exercise goals may be a source of grief or frustration. Others may fear that exercise means lap swimming or jogging. The concept of therapeutic exercise and the importance of pacing need to be carefully explained.

Most patients have experienced symptom flares with overexertion. Initiating an exercise routine requires starting slowly, with few repetitions (three to five may be enough the first time), light resistance (none to very minimal), and a limited number of exercises (usually, three are enough). Feedback 24 to 48 hours after exercise is necessary for pacing the progression of the program. Exacerbations of FMS were triggered in one study that looked at the effects of repetitive dynamic muscle contraction and sustained static muscle contractions in patients with FMS and in sedentary, healthy control subjects. It was found that, 24 hours after exercise, exercise-induced extremity pain had not returned to preexercise levels in patients with FMS.[158] Patients need sufficient recovery time and strategies, and these will vary from one individual to the next. The training index is one form of monitoring that can be used to help the patient in pacing. The training index was originally introduced for use in cardiac patients by Hagberg[221] and modified by Clark[222] for use in patients with FMS. This is a quantitative measure of exertion based on simple calculations using pulse rate and the duration of exercise. The training index provides target values for basic cardiovascular fitness, which may be used by patients to track their progress toward these goals. Some patients may find it helpful to keep a diary of daily activities to monitor possible correlations between symptoms and activity levels, and this may also be a useful pacing tool.

Pharmacological and Psychological Intervention

Pharmacological therapy is based on findings of neurohormonal alterations and sleep disruption in CFS and FMS and on treating associated symptoms (e.g., fever in CFS, muscle pain, and gastrointestinal irritation in CFS and FMS). Low-dose tricyclic medications, which in much larger doses act as antidepressants, may be beneficial in addressing pain and sleep disruption. Selective serotonin-uptake inhibitors may help the fatigue component.[213] Buchwald[195] points to anecdotal reports of antiviral and immunomodulating drugs in the treatment of CFS. Simms[213] offers a complete review of the pharmacological treatment of FMS.

The association of pain, fatigue, depression, and disordered sleep of FMS and CFS is a sign of central sensitization.[151,223–225] These symptoms are additionally stressful for many patients and those around them.[108] The effects of these chronic, long-term conditions can be profound.[105,108] Various types of psychotherapeutic and educational interventions aimed at teaching coping strategies and lifestyle adjustments have been found to be beneficial. These include cognitive behavior therapies as well as self-management techniques such as mindful meditation.

One study[226] showed a 63% rate of return to work by patients with CFS after 1 year of cognitive behavioral therapy, and a study by Buckelew et al.[227] correlated higher self-efficacy with less pain and impairment in physical activities for patients with FMS. Self-efficacy can be defined as a belief that one can successfully do a thing. Self-efficacy has been shown to impact behavior, motivation, thoughts, and emotions.[227] A meditation-based stress-reduction program was also shown to be effective in improving physical symptoms.[228] Because CFS and FMS may be long-term, life-changing conditions, individual and group psychotherapy may be beneficial. In a review of programs using education for self-management of FMS, Burkhardt and Bjelle[229] concluded that self-efficacy and life quality can be enhanced for patients who undergo even short-term intensive treatment, with improvement lasting beyond the end of the program. Several organizations sponsor support groups and education classes throughout the United States and Canada (see **Patient-Related Instruction 10-4**).

Patient-Related Instruction 10-4

Organizations for Information About Fibromyalgia Syndrome and Chronic Fatigue Syndrome

For information about fibromyalgia or CFS, contact one of these organizations:

- The Arthritis Foundation is an excellent source of information, has support groups, and provides leadership training. Phone numbers of local chapters can be found in phone books.
- Fibromyalgia Alliance of America provides patient information and support group resources (FMAA, PO Box 21990, Columbus, OH 43221-0990, (614) 457-4222).
- Chronic Fatigue Immune Deficiency Syndrome Association of America, Inc., provides patient information, support group resources, and data on research, treatment, and conferences (CFIDS Assoc., PO Box 220398, Charlotte, NC 28222-0398, (800) 848-7373).

KEY POINTS

- Pain impairment occurs with most musculoskeletal conditions and must be treated as a primary impairment along with any secondary limitations that may result.
- Nociceptors, or pain receptors, transmit impulses from the periphery to the dorsal horn of the spinal cord and higher CNS levels.
- Pain information is transmitted through A-delta and C fibers, which are small, unmyelinated neuronal fibers.
- Information is processed within the spinal cord and then ascends through the contralateral spinothalamic tract to the thalamus.
- The gate theory of pain states that incoming information from nonpain receptors (e.g., thermal, mechanical) can close the gate to pain information.
- Chronic pain may result from increased sensitization of nociceptors and spinal level changes that perpetuate positive feedback loops in the pain-spasm cycle.
- Descending impulses can influence pain perception through several mechanisms, including endogenous opiates.
- Pain can be assessed through direct measurement tools such as the VAS or MPQ questionnaires or through quality of life scales such as the SF-36.
- Fear–anxiety–avoidance models help explain transitions from acute to chronic pain and can be measured with different tools.
- Therapeutic exercise is a cornerstone of treatment for chronic pain. It can remedy pain (through gating mechanisms and descending influences), secondary limitations caused by pain, and associated impairments and activity limitations.
- FMS and CFS are increasingly recognized in clinic patient populations, have widespread effects, and limit functioning.
- Exercise appears to be one of a few effective treatments for FMS and possibly for CFS.
- Because of the fatigue and ease of symptom exacerbation with exertion, exercise prescription must be done carefully and thoughtfully, tracking responses continuously.
- Exercise for the treatment of FMS and CFS can be expected to address stress, posture, and mobility impairments; impaired muscle performance; and cardiovascular endurance.
- Exercise should be introduced slowly and progressed from exercises likely to lead to success to those that may be more stressful. Relaxation, breathing, stretching exercises, and gentle, limited walking exercises can progress to strengthening and to slowly progressing aerobic exercises.
- Physical therapy treatments should always attempt to model the concepts of pacing and limiting overexertion and overcommitment as they apply to daily activities of the patient and in therapeutic exercise.
- The physical therapist should attempt to encourage good communication and establish mutually acceptable goals in an attempt to contribute to the patient's adherence to the exercise program.
- Aerobic exercise should be progressed slowly, be nonjarring, and be pleasurable if possible.
- During physical therapy treatment, patients often are undergoing adjunctive treatments from other medical disciplines, which may stress them in terms of energy, time, and resources. The therapist should be aware of the other commitments and help the patient prioritize realistically.

- The use of physical agents for pain control should be taught as self-treatment techniques, because using clinic time for their application may not be the best use of the patient's resources.
- Patients should be taught appropriate self-mobilization or neuromuscular techniques to cope with chronic biomechanical faults so that they have tools to manage their condition independently.

CRITICAL THINKING QUESTIONS

1. Consider Case Study No. 5 in Unit 7.
   a. This patient has pain with standing and walking. What interventions may improve this patient's ability to stand and walk without pain?
   b. This patient has pain with lumbar extension. How does your therapeutic exercise intervention address this problem?
   c. What suggestions can you give this patient to allow her to participate in social activities without pain?
2. Consider Case Study No. 7 in Unit 7.
   a. Design an exercise program to prevent further decline of her general deconditioning, with consideration of her overall fatigue and daily demands.
   b. Provide this patient with suggestions for energy-reducing measures to allow her to complete daily tasks without increasing pain or fatigue.
3. Outline the questions you would ask in the subjective portion of an evaluation of a patient with FMS. Be sure you cover the areas of their presentation that may affect development of the condition and that may contribute to its exacerbation.
4. What physical tests and measurements would you perform in the objective portion of the evaluation?
5. What forms of exercise would you need to introduce over time to the patient with FMS?
6. List the order in which you would probably introduce the various types of exercise over the course of treatment of the FMS patient.
7. Discuss special considerations for introducing exercise.
8. List the functional goals of physical therapy treatment that would be appropriate for this clinical population.

Special Physiologic Considerations in Therapeutic Exercise

UNIT **3**

CHAPTER 11

Soft-Tissue Injury and Postoperative Management

LORI THEIN BRODY

Most musculoskeletal problems resolve with conservative management. Patients who develop overuse injuries, or have mild sprains, strains, or contusions, can expect to return to full function within a matter of days or weeks. For example, most patients with acute low back pain recover within 12 weeks without surgery.[1] However, some musculoskeletal problems do not resolve with conservative management alone. In these cases, surgical intervention may be necessary to return the patient to optimal function. Understanding the fundamentals of connective tissue physiology and response to stress forms the basis for rehabilitation programs designed for both conservative and postoperative management. Be sure to consider this information in the context of interventions used to improve mobility, aerobic capacity and muscle performance, as discussed in Chapters 5, 6 and 7. Appropriate management of acute injuries may prevent an acute injury from becoming a chronic condition (see Chapter 2).

PHYSIOLOGY OF CONNECTIVE TISSUE REPAIR

Soft tissues, including ligament, tendon, cartilage, bone, and other connective tissues, respond to injury in a relatively predictable fashion. The repair process is similar in all connective tissues, although some variability between tissues (e.g., bone) exists. Healing is also affected by age, lifestyle, and systemic factors (e.g., alcohol abuse, smoking, diabetes mellitus, nutritional status, general health) and local factors (e.g., degree of injury, mechanical stress, blood supply, edema, infection).[2,3] Understanding the healing phases helps the clinician choose interventions that are appropriate at various points in the healing process.

Microstructure of Connective Tissues

Tendon, ligament, cartilage, bone, and muscle are some of the major connective tissues in the body. The four main components of connective tissue are:

- Fibers (i.e., collagen and elastin)
- Ground substance with associated tissue fluids
- Solids (i.e., glycosaminoglycans such as proteoglycans)
- Cellular substances (i.e., fibroblasts, fibrocytes, and cells specific to each connective tissue)[3]

The function of the various connective tissues is based on the relative proportions of intracellular and extracellular components such as collagen, elastin, proteoglycans, water, and contractile proteins. At least 15 types of collagens (types I through XV) are known and differ fundamentally in the amino acid sequence of their constituent polypeptide chains, resulting in different slightly functions of each collagen (**Table 11-1**).[4,5]

Ligament is connective tissue attaching bone to bone. Water makes up nearly two-thirds of the weight of normal ligament, and collagen makes up 70% to 80% of the ligament's dry weight.[6] Nearly 90% of the collagen is type I, and 10% or less is type III collagen. Elastin is found in tiny quantities in ligaments, making up <1% to 2% of the total weight. Proteoglycans, another important solid found in ligaments, constitute <1% of the ligament's weight, but they are essential because

TABLE 11-1

Collagens of Connective Tissue

TYPE	DISTRIBUTION
I	Bone, ligament, tendon, fibrocartilage, capsule, synovial lining tissues, skin
II	Cartilage, fibrocartilage
III	Blood vessels, synovial lining tissues, skin
IV	Basement membranes
V	Pericellular region of articular cartilage when present,[a] bone, blood vessels
VI	Nucleus pulposus
VII	Anchoring fibers of various tissues
VIII	Endothelial cells
IX	Cartilage matrix[a]
X	Hypertrophic and ossified cartilage only
XI	Cartilage matrix[a]
XII	Tendon, ligament, perichondrium, periosteum
XIII	Skin, tendon

[a]Small amounts (<20%). From Walker JM. Cartilage of human joints and related structures. In: Zachazewski JE, Magee DJ, Quillen WS, eds. Athletic Injuries and Rehabilitation. Philadelphia, PA: WB Saunders, 1996:123.

of their water-binding properties.[2] This overall makeup of the ligament renders it a stiff structure with very little elongation when stressed or tensed.

Tendon is a connective tissue attaching muscle to bone. Collagen forms 70% of the dry weight of tendon, and the overall proportions are 30% collagen, 2% elastin, and 68% water.[7] The low proportion of elastin accounts for the low elasticity of tendon. If tendon were more elastic, the tendon would elongate with muscle contraction, rather than transmitting force to the bone. Muscle contraction would fail to move its insertion toward the origin, and no movement would take place. The structure provides some information about the function of this tissue.

Articular cartilage is composed of similar components, with nearly 80% of its weight from water. The high water content in articular cartilage, as in other viscoelastic tissues, is responsible for the mechanical properties of the tissue. The collagen makeup is primarily type II collagen, with small proportions of other collagen types.[5] Proteoglycans and their associated glycosaminoglycans are water-loving, or hydrophilic, molecules. Proteoglycans are responsible for the water-binding capabilities of articular cartilage, and proteoglycan loss results in a decreased water content and loss of the tissue's mechanical properties. Weight-bearing causes tissue compression and fluid extrusion from the tissue, while unweighting pulls fluid back in because of the hydrophilic nature of the proteoglycans. This action provides nutrition and lubrication for the articular cartilage. Thus, intermittent weight bearing is critical to the health of articular cartilage. As proteoglycans are lost with degenerative joint disease, the ability to resorb fluid is impaired, decreasing the ability to absorb shock or transmit loads.

Bone is composed of solid and fluid components, similar to other soft tissues of the body. Organic compounds such as type I collagen and proteoglycans constitute approximately 39% of the total bone volume.[8] Minerals contribute nearly half of the total bone volume, and fluid fills the vascular and cellular spaces comprising the remaining volume. The primary minerals found in bone are calcium hydroxyapatite crystals. These minerals differentiate bone from other connective tissue and provide bone with its distinctive stiffness.

Response to Loading

When connective tissues are loaded, the *stress* can be plotted against the *strain* providing much information about the material properties of the tissue. The relative contributions of composite materials determine the mechanical properties of the specific tissue. However, some general concepts about connective tissue responses can be determined.

Tensile loads are resisted primarily by the collagen fibrils, which respond first by straightening from their resting crimped state. This straightening requires little force (**Fig. 11-1**). In the elastic portion of the curve, the collagen fibers respond to the load in a linear fashion up to 4% elongation.[7,9] After the load is removed, the tissue returns to its original length, a characteristic of the elastic range only up to the elastic limit. Beyond this point, removal of the stress does not result in a return to the tissue's original length. If the tissue is elongated beyond approximately 4%, plastic changes begin to occur (i.e., plastic range) as the cross-links begin to fail. Permanent deformation is the chief characteristic of the plastic range. After some fibers fail, the load on the remaining fibers is increased, accelerating tissue

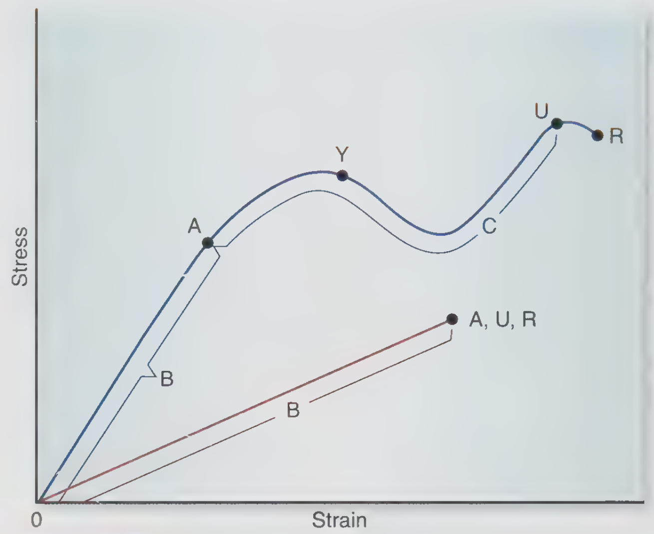

FIGURE 11-1 The stress–strain curve showing the elastic limit (A), elastic range (B), yield point (Y), plastic range (C), ultimate strength (U), and the rupture strength (R). (Adapted from Cornwall MW. Biomechanics of orthopaedic and sports therapy. In: Malone TR, McPoil T, Nitz AJ, eds. Orthopedic and Sports Physical Therapy. 3rd Ed. St. Louis, MO: Mosby, 1997:73; Rees JD, Wilson AM, Wolman. Current concepts in the management of tendon disorders. Rheumatology 2006;45:508–521.)

failure. The curve plateaus or even dips at the *yield point*. The *ultimate strength* is the greatest load the tissue can tolerate, and *rupture strength* is the point at which complete failure occurs.

The area under the curve represents the amount of strain energy stored in the tissue during loading. The viscoelastic nature of connective tissue results in an imperfect recovery after deformation, known as *hysteresis*. This difference between the loading curve and the unloading curve represents energy lost. This energy is lost primarily in the form of heat. A stretched tissue becomes warm in the process.

Other tissue qualities related to the load deformation curve are resilience and toughness. *Resilience* reflects a material's ability to absorb energy within the elastic range. As a resilient tissue is loaded quickly, work is performed, and energy is absorbed. When the load is removed, the tissue quickly releases energy and returns to its original shape. *Toughness* is the ability of a material to absorb energy within the plastic range. A critical quality of connective tissues is their ability to absorb energy without rupturing.

A relationship exists between stress and strain called the *elastic modulus*. The elastic modulus is the ratio of the stress divided by the strain and reflects the amount of stress needed to produce a given strain (i.e., deformation). The greater the stress necessary to deform the tissue, the stiffer is the material. For example, bone has a higher elastic modulus than meniscus and deforms less with a given load.

Cyclic loading alters the load deformation curve. Heat accumulates in the area of loading, disrupting the collagen crossbridges. Cyclic loading produces microstructural damage that accumulates with each loading cycle. Damage accumulates faster at higher intensities of cyclic loading.[10] Failure as a result of cyclic loading, called *fatigue failure*, is the physiologic basis underlying stress fractures. *Endurance limit* or *fatigue strength* is the stress below which fatigue cracks in bone do not begin to form.[10]

Connective tissues also demonstrate viscoelastic properties that provide these tissues with their uniquely mutable characteristics. These properties are creep and relaxation. When a tissue is held with a constant force, it begins to lengthen until equilibrium is reached or until the tissue ruptures, depending on the magnitude of the force. This property is called *creep*. When a tissue is pulled to a fixed length, a certain force is required. As the tissue is held at this length, the amount of force necessary to maintain that length decreases. This property is called *relaxation*. These properties allow connective tissues to adapt to and function in a variety of loading conditions without being damaged. Tissues pulled into tension (i.e., stretched) lengthen and relax, which provides the rationale for stretching exercises to lengthen shortened soft tissues (**Figs. 11-2** to **11-4**).

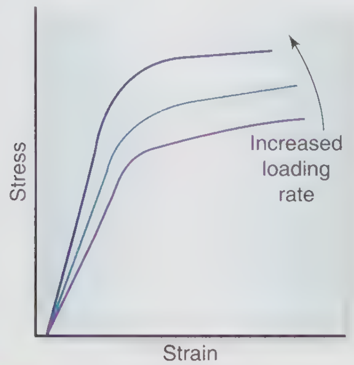

FIGURE 11-2 Three stress–strain curves for cortical bone tissues tested in tension at three different loading rates. As the testing rate increases, the slope (the elastic modulus) of the initial straight line portion increases. (Adapted from Burstein AH, Wright TM. Fundamentals of Orthopaedic Biomechanics. Baltimore, MD: Williams & Wilkins, 1994:120.)

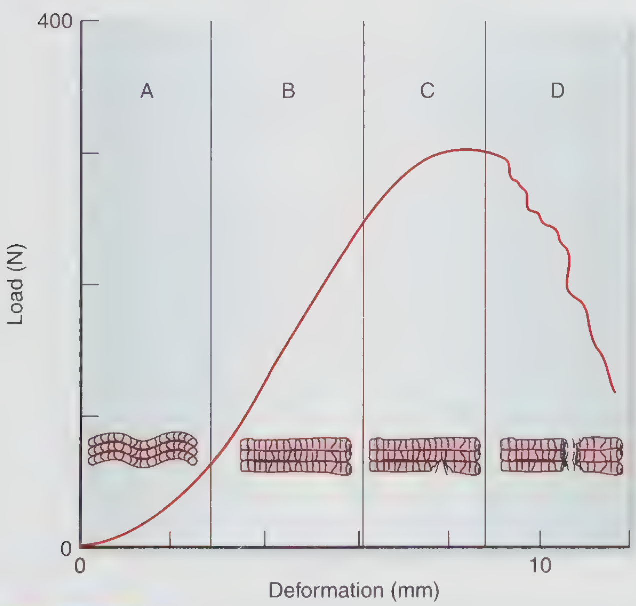

FIGURE 11-3 Stress–strain curve for ligament. As the ligament is distracted, fibers become progressively recruited into tension **(A)** until all the fibers are tight **(B)**. The parts of the ligament that are tightened first are likely to be the first to fail **(C)** as the ligament reaches the yield point. Progressive fiber failures quickly result in ligament failure **(D)**. (Adapted from Frank CB. Ligament injuries: pathophysiology and healing. In: Zachazewski JE, Magee DJ, Quillen WS, eds. Athletic Injuries and Rehabilitation. Philadelphia, PA: WB Saunders, 1996:15.)

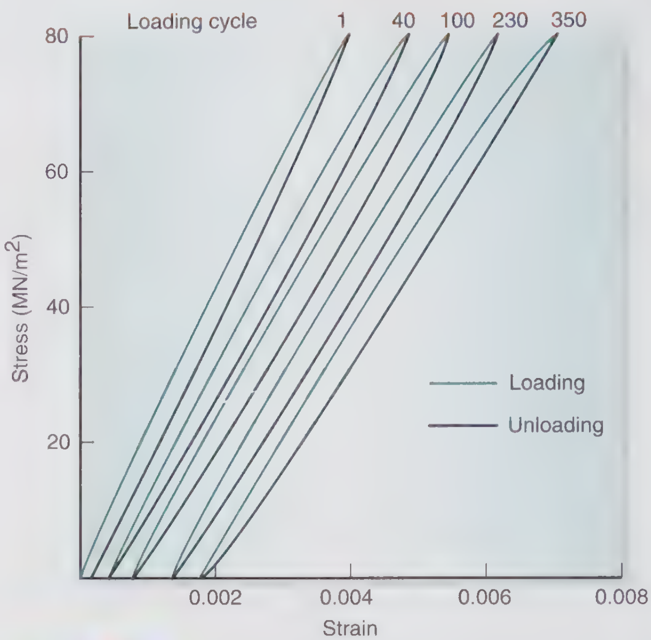

FIGURE 11-4 Effects of cyclic loading. When bone tissue is loaded cyclically to 90% of its tensile yield strength, nonreversible behavior (i.e., damage) is seen. By the 350th loading cycle, the elastic modulus has changed appreciably. (Adapted from Burstein AH, Wright TM. Fundamentals of Orthopaedic Biomechanics. Baltimore: Williams & Wilkins, 1994:125.)

Phases of Healing

The clinician must understand the phases of healing to formulate a plan of care matching the tissue's loading capabilities. The phases of healing provide a framework into which the rationale for physical therapy interventions fit. Understanding the healing process gives the clinician the tools to treat a variety of injury and surgical conditions.

Injury to the soft tissues arises from a number of sources. Physical traumas such as a sprain, strain, or contusion are most common, whereas injuries can also occur from bacterial or viral infections, heat, or chemical injury. Trauma causes direct damage to the cells in the immediate area of the injury, causing bleeding in the interstitial spaces. The bleeding initiates a cascade of events that promote healing of the injured tissue. The process can be considered in phases, although the continuum is an oversimplification of a very complex process. How the soft-tissue injury is managed is often responsible for the outcome of the injury. Any of four outcomes may result from the inflammatory process:

(a) Resolution when the injury is mild and transitory
(b) Replacement of the normal cell with fibrosis
(c) Abscess formation in the presence of an infection
(d) Progression to chronic inflammation resulting from persistent injury or individual factors (i.e., diabetes, corticosteroid use, and hematologic disease)[11]

Inflammatory Response

Healing of acute injuries passes through four major phases, beginning with the acute vascular-inflammatory response (**Fig. 11-5**). The purpose of the vascular changes is to mobilize and transport cells (white blood cells and leukocytes) to the area to initiate

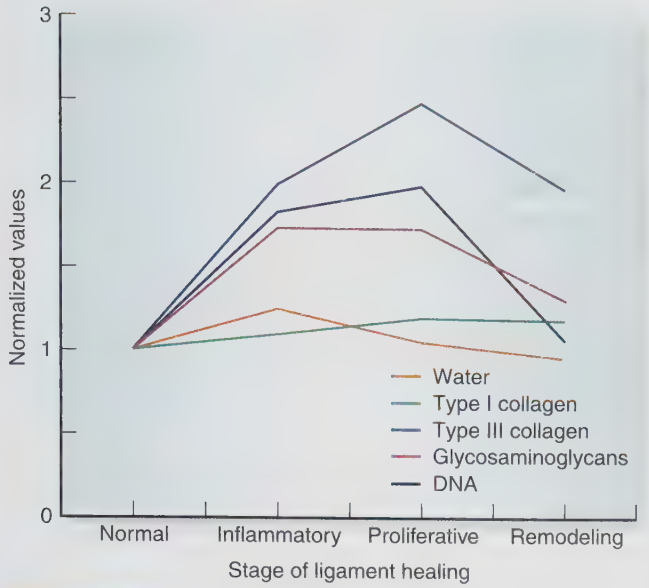

FIGURE 11-5 Changes in components of rabbit MCLs at various stages of healing. Values are normalized to that of uninjured ligament (normal = 1). (Adapted from Andriaacchi T, Sabiston P, DeHaven K, et al. Ligament: injury and repair. In: Woo SL-Y, Buckwalter JA, eds. Injury and Repair of the Musculoskeletal Soft Tissues. Park Ridge, IL: American Academy of Orthopaedic Surgeons, 1988:115.)

healing. When connective tissue is damaged, injured cells in the area release chemical substances (e.g., prostaglandins, bradykinin) that initiate the inflammatory response. The gap in the torn tissue is filled with erythrocytes and platelets.[1] The platelets form a plug to contain the bleeding and provide a scaffold for substances that will stabilize the clot. Local bleeding is a strong chemotactic stimulus, attracting white blood cells such as neutrophils and mononuclear leukocytes that help rid the site of bacteria and cellular debris through phagocytosis. Concurrently, in adjacent uninjured vessels, vasodilation occurs to increase local blood flow while capillary permeability is altered to allow greater exudation of plasma proteins and white blood cells. This produces swelling and edema in the area. In this phase, the damaged tissues and microorganisms are removed, fibroblasts are recruited, and some wound strength is provided by the weak hydrogen bonds of collagen fibers.[12] The inflammatory phase is essential in initiating the healing process. This phase is initiated immediately and lasts 3 to 5 days.[12]

Signs and symptoms observed in this phase are pain, warmth, palpable tenderness, and swelling. Pain and tenderness are caused by mechanical and chemical stimulation of nociceptors, and warmth and swelling are caused by acute inflammation. Limitations in joint or muscle range of motion (ROM) from pain or direct tissue damage are likely to occur. AROM testing usually reveals limited movement, and PROM reveals an empty end-feel, with pain limiting movement.

Focus **treatment procedures** in this phase at decreasing pain and edema while preventing a progressive chronic inflammation. Ice is effective at reducing pain and edema. Compression also controls edema by forcing fluid to areas of lower hydrostatic pressure in the capillaries and lymph vessels.[11] Maintain the mobility and strength of adjacent joints and soft tissues while the acutely injured areas are rested (see **Patient-Related Instruction 11-1**).

Patient-Related Instruction 11-1

Acute Injury Management

Take the following steps when an acute musculoskeletal injury or a flare-up of a preexisting injury occurs:

1. Ice the area for 10 to 15 minutes using cold packs or ice. Do this as often as possible throughout the day.
2. If possible, elevate the body part above the heart to decrease swelling.
3. Apply compression in the form of an elastic sleeve or bandage. Remove the compression at night for sleeping.
4. Use a supportive or assistive device (e.g., sling, splint, cane, crutches, walker) to rest the injury.
5. Contact your clinician or physician regarding the need for further examination and evaluation.
6. Resume previous program of care when instructed or able.

Proliferative/Fibroplasia Phase

The second phase, lasting from 48 hours to 6 to 8 weeks, is marked by the local presence of macrophages directing the cascade of events occurring in this proliferative phase. This phase may be referred to as the "repair-regeneration" phase, as there is a concurrent attempt at repair (replacement of the original tissue with scar tissue) and regeneration (replacement of the damaged tissue with the original tissue type).[13] Fibroblasts are actively resorbing collagen and synthesizing new collagen (primarily type III). The new collagen is characterized by small fibrils, disorganized in orientation and deficient in cross-linking.[12] Consequently, the tissue laid down in this phase is vulnerable and susceptible to disruption by overly aggressive activity. The greatest rate of collagen accumulation occurs between days 7 and 14.[13] As this phase progresses, a gradual decrease in tissue macrophages and fibroblasts occurs, and a grossly visible scar filling the gap can be seen.[14]

The warmth and edema resolve during this phase. Palpable tenderness decreases, and the tissue can withstand gentle loading. Pain is felt concurrent with tissue resistance or stretch of the tissue.

Treatment procedures in this phase include ROM exercises, joint mobilization, and scar mobilization to produce a mobile scar. These interventions are most effective during this stage of healing. Gentle resistance may be applied to maintain mobility and strength of the musculotendinous unit (**Building Blocks 11-1** and **11-2**).

BUILDING BLOCK 11-1

A 72-year-old woman with a history of left knee osteoarthritis experienced an increase in symptoms after a day of walking for the Relay for Life 3 days ago. She reports pain averaging 4 to 5 on a 0 to 10 scale during weight bearing, moderate swelling, and difficulty negotiating the stairs in her home. She is retired, but is an avid walker and enjoys weight lifting. Provide this patient with intervention strategies for this phase of treatment.

BUILDING BLOCK 11-2

Progress the 72-year-old patient from Building Block 11-1 to the next rehabilitation phase. Assume expected progress during the first phase.

In **bone**, this phase is referred to as the callus phase. Osteoclasts perform a function analogous to the macrophages in soft tissue. These cells debride the fracture ends and prepare the area for healing. The infrastructure for healing is assembled, including a capillary structure supporting callus formation. This callus bridges the gap between the fracture ends. The callus is an unorganized scaffold of cartilage that is easily deformed. Although bone repair is relatively weak at this point, limited activity is allowed. Gentle, cyclical loading promotes remodeling and maturation.

Treatment goals focus on applying light loads that will provide a stimulus for the tissue to remodel. Keep these loads within the tolerance of the newly formed tissue by monitoring signs and symptoms closely. Any increase in pain, warmth, or edema is a signal that the loads are exceeding tissue capabilities. Loads can be in the form of stretching, joint mobilization, ROM activities, light resisted exercises, or weight bearing.

Remodeling and Maturation

As healing progresses to the third phase, the remodeling stage, a shift is made to the deposition of type I collagen. This phase is characterized by decreased synthetic activity and cellularity, with increased organization of extracellular matrix. The collagen continues to increase and begins to organize into randomly placed fibrils with stronger covalent bonds. At this point, tension becomes important in providing orientation guidance to the organizing collagen. The new collagen must orient and align along the lines of stress to best accommodate the functional loads required. This tension can be imposed by stretching, active contraction (in the case of the musculotendinous unit), resistive loads, or electrical stimulation. Active tissue remodeling occurs throughout this phase up until approximately 4 months postinjury. The final end point is unknown and the tissue will continue to remodel and mature for 1 to 2 years postinjury. Although patients are discharged from formal rehabilitation by the time they reach the maturation phase, it is important for them to continue their rehabilitation exercises. The tissue will continue to mature according to the stresses placed upon it, even following completion of formal rehabilitation.

As with the remodeling-maturation phase in soft tissues, loading is important in the final phase of bone healing. In this phase of bone healing, woven bone (i.e., immature bone) is replaced by well-organized lamellar bone.[3] Normal loading is necessary to remodel the bone in accordance with the stresses that it will bear (i.e., Wolff's law). The linkage of electrical charges with mechanical loading is called the piezoelectric effect.[3] Piezoelectric effects in the calcium hydroxyapatite crystals resulting from loads orient the crystals along the lines of stress. In long, weight-bearing bones, activity differs on the concave and convex sides. On the concave side, osteoblasts lay down more bone where the bone is subject to compression (i.e., negative charge). On the convex side, osteoclasts digest bone that is subject to tension (i.e., positive charge). Imposition of normal functional loads is necessary for the final remodeling of bone. Electrical stimulation is used to enhance bone healing using the same piezoelectric effect.

PRINCIPLES OF TREATING CONNECTIVE TISSUE INJURIES

A variety of procedures are available to achieve physical therapy goals. Although detailing every situation the clinician may encounter is difficult, specific principles guide the decision-making process. These principles provide a framework and rationale for intervention choices.

Restoration of Normal Tissue Relationships

After connective tissue injury, the relationships among a variety of tissues are altered. After injury or immobilization, the tendon may fail to glide smoothly through the tendon sheath, the nerve may be adhered to surrounding tissues, folds of joint capsule may become adhered to one another, the skin may bind to underlying tissues, or fascial layers may fail to glide on one another. These normal relationships must be restored, or painful and restricted movement may result. Interventions such as active muscle contraction, passive joint motion or mobilization, modality use, or massage restore those relationships. Begin these preventive interventions as early as the healing process allows, often within the first 48 hours. Additionally, the normal length–tension relationship of the muscle must be recovered to ensure optimal function. Muscles damaged by contusion, disrupted by surgical procedures, or placed in a shortened position during immobilization are susceptible to these alterations. Use stretching techniques to restore the normal length–tension properties. For example, the Achilles tendon should be stretched regularly while a patient recovers from an ankle sprain or fracture.

Optimal Loading

After a connective tissue injury, a cascade of events facilitate the body's healing process. If this cascade is interrupted, healing is disrupted and chronic inflammation may ensue. During each of the healing phases, choose treatment procedures that aid the healing process without disrupting the normal chain of events. This requires optimal loading or choosing a level of loading that neither overloads nor underloads the healing tissue (**Fig. 11-6**). Effective application of optimal loads requires a thorough understanding of the mechanism of injured tissue loading, including which planes of movement place the greatest loads on the healing tissue (**Building Block 11-3**).

BUILDING BLOCK 11-3

While it may be obvious that the mobility of tissues adjacent to the injured area should be mobilized, what about tissues more directly involved in the injury? For example, following a lateral ankle sprain, should the peroneal muscles be mobilized? Why or why not?

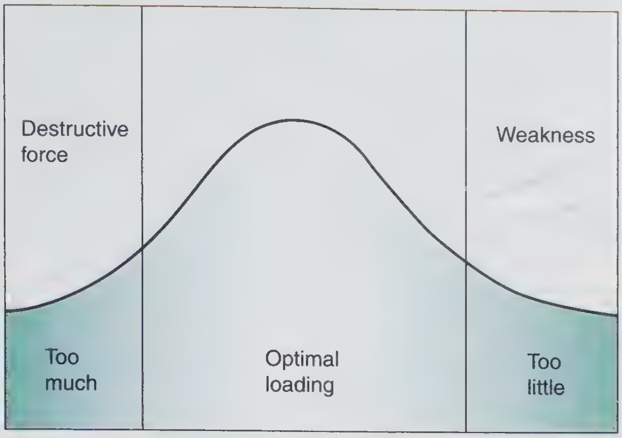

FIGURE 11-6 Optimal loading. Choose a load that neither overloads nor underloads the tissue of interest. (From Porterfield JA, DeRosa C. Mechanical Low Back Pain. Philadelphia, PA: WB Saunders, 1991:13.)

Consider the biomechanical effects of daily activities and therapeutic activities in the context of the stage of healing, and individual factors such as age, quality of the tissue, nutritional status, and fitness level. A stress that underloads a tissue in the remodeling phase probably overloads the tissue in the inflammatory phase (review Table 5-8). An exercise that underloads a young athlete after an acute fracture would probably overload an elderly individual after a pathologic fracture. The medial collateral ligament (MCL) of the knee is loaded most in the frontal and transverse planes, with the knee near terminal extension. Avoid activities that load the knee in this manner during the acute phase. However, in the late phases, when remodeling of the ligament is necessary, frontal and transverse plane loading are precisely the stimulus needed. Designing the treatment program requires consideration of all of the factors in the intervention model within the injury framework (see **Patient-Related Instruction 11-2**).

Specific Adaptations to Imposed Demands

Although the concept of optimal loading guides the *quantity* of activity (e.g., volume, intensity), the specific adaptations to imposed demands (SAID) principle expands to include the *type* of activity chosen. The SAID principle is an extension of Wolff's law, which states that a bone remodels according to the stresses that are placed on it. The SAID principle implies that soft tissues remodel according to the stresses imposed on them. Exercise is specific to the posture, mode, movement, exercise type, environment, and intensity used. For example, an exercise may be chosen to prepare the quadriceps muscle for weight bearing. The quadriceps muscle contracts eccentrically in a closed chain through the first 15 degrees of knee flexion during the loading response of gait. A closed chain eccentric quadriceps exercise such as a short-arc (0 to 15 degrees) leg press is a better choice than concentric isokinetic exercise. This is an example of the SAID principle guiding the activity choice (**Building Block 11-4**).

Patient-Related Instruction 11-2

Signs of Overload

The following signs and symptoms suggest that exercise or activity is too much and should be decreased or modified:

1. Increased pain that does not resolve within the next 12 hours
2. Pain that is increased over the previous session or comes on earlier in the exercise session
3. Increased swelling, warmth, or redness in the injury area
4. Decreased ability to use the part

BUILDING BLOCK 11-4

A 26-year-old recreational soccer player sustained a second-degree MCL sprain 8 weeks ago and is preparing to return to soccer. Design a late phase exercise program that would prepare this athlete to return to soccer. Assume full ROM and strength within 10% of the opposite leg.

The SAID principle also guides exercise prescription parameters. For example, in the late stage of healing, a patient returning to tennis should increase the speed and intensity of exercise, whereas the patient returning to marathon training should increase the exercise duration. When the stage of healing and optimal loading parameters allow, training should as closely as possible reflect the specific demands of the patient's functional task.

Preventing Complications

Be sure to consider the effects of the connective tissue injury on surrounding tissues. For example, immobilization imposed while a fracture is healing is unhealthy for the joint's articular cartilage, ligaments, and surrounding musculature, although it is necessary for bone repair. Muscle atrophy and weakening of the immobilized ligaments ensue during the immobilization period. Use any available interventions that might minimize these effects. For example, electrical stimulation or isometric muscle contractions can be used to retard strength losses in the muscle, tendon, and tendon insertion sites. Active muscle contractions also prevent thrombus formation after surgery. ROM exercises at joints above and below injury sites may preserve some soft-tissue relationships and prevent loss of mobility. Weight-bearing loads the articular cartilage and lessens degradation caused by immobilization.

MANAGEMENT OF IMPAIRMENTS ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION AND LOCALIZED INFLAMMATION

Patients with acute soft-tissue injuries such as sprains and strains are commonly treated by physical therapists. Management of these injuries is discussed together because of the many similarities, and any differences are highlighted.

Sprain: Injury to Ligament and Capsule

A sprain can be defined as an acute injury to a ligament or joint capsule without dislocation. Sprains occur when a joint is extended beyond its normal limit, and the ligament or capsule tissues are stretched or torn beyond their limit. Sprains are common at the ankle (i.e., anterior talofibular and calcaneofibular ligaments), knee (i.e., medial and lateral collateral ligaments, anterior [ACL] and posterior cruciate ligaments [PCL]), wrist, and spine. A sprain may resolve with short-term immobilization, controlled activity, and rehabilitative exercises, but other sprains may require surgery to stabilize the joint.

Sprain Classification

Sprain severity occurs along a continuum from microscopic tearing and stretching of ligament or capsule fibers to complete disruption of the ligament. Sprains are classified by severity based on clinical examination or special testing (e.g., magnetic resonance imaging, arthrometer testing).

- Grade I sprains are mild sprains in which the ligament is stretched, but there is no discontinuity of the ligament.
- Grade II sprains are a moderate sprain in which some fibers are stretched and some fibers are torn. This produces some laxity at the joint.
- Grade III, or severe sprains, are a complete or nearly complete ligament disruption with resultant laxity (**Table 11-2**).

Examination and Evaluation Findings

Examination findings following a ligament sprain include ecchymosis and edema. Functional mobility losses include the mobility of a single joint (ICF b7100), the mobility of several joints (ICF b7101), or the loss of stability of a single (ICF b7150) or multiple (ICF b7151) joints. Additionally, muscle performance or power functions are typically decreased. When sprains occur in the lower extremity, gait pattern functions are impaired, and when the upper extremity is involved, functional reach and the ability to hold and manipulate objects may be impaired. Sprains of the spine can impact many aspects of functional mobility such as self-care, home and community mobility, and work. Joints proximal and distal to the primary joint injury may have associated injuries or compensation. Determine activity limitations and identify the relationship between impairments and those activity limitations.

TABLE 11-2

Classification of Sprain

GRADE	DESCRIPTION	CHARACTERISTICS
I	Mild	Fibers are stretched without loss of continuity; no laxity on physical examination
II	Moderate	Some fibers are stretched and some are torn
		Some laxity observed on examination
III	Severe	Ligament completely or nearly completely torn; laxity results

From American Academy of Orthopaedic Surgeons. Athletic Training and Sports Medicine. Park Ridge, IL: American Academy of Orthopaedic Surgeons, 1991.

Strain: Musculotendinous Injury

A strain is an acute injury to the muscle or tendon from an abrupt or excessive muscle contraction. Strains are usually the result of a quick overload to the muscle-tendon unit in which the tension generated exceeds the tissue's capacity. Strains occur when a contracting muscle is excessively or abruptly stretched in the opposite direction. The person who reaches quickly to catch a falling object or the individual who suddenly stops or changes direction when walking or running is susceptible to a muscle strain. Overuse injuries are another type of muscle strain.

Strain injuries are difficult to classify and can be graded as mild, moderate, or severe based on clinical examination findings such as pain, edema, loss of motion, and tenderness. Muscle strains can be complete or incomplete, although complete tears are less common.

Most strain injuries occur at the myotendinous junction.[15] Structural features of the sarcomeres and connective tissues in this area suggest that load transmission occurs across the musculotendinous junction. As with many other structures in the body, transitions from one tissue type to another are areas of increased stress and risk of injury. In this case, the transition zone from contractile to noncontractile tissue creates an area of increased stress that is susceptible to injury. Factors that may contribute to muscle strain injuries include poor flexibility, inadequate warm-up exercise, insufficient strength or endurance, training errors, and poor coordination.[15]

Examination and Evaluation Findings

A history of an abrupt decelerating movement, change of direction, or quick stretch suggests a muscle strain injury. On physical examination, the musculotendinous junction or the muscle belly may be painful. Pain in the injured muscle is reproduced clinically by active or resistive contraction of the muscle and by stretching it. For example, a quadriceps strain is reproduced by stretching the knee into flexion and by resisting active knee extension. The muscle may need to be put on stretch during the muscle contraction, or may need to be loaded in a weight-bearing position to stress the lesion. Occasionally, localized swelling and warmth may be observed.

Application of Treatment Principles

Although each intervention program should be directed toward the specific impairments, activity limitations, and goals for each patient, some general guidelines can help the clinician make informed choices that will maximize recovery and return to function.

Inflammatory Phase

Treatment principles in the early phase include optimal loading and prevention of secondary complications. As the inflammatory response initiates the healing response, an environment conducive to healing must be established. The appropriate balance of rest and loading ensures loads within the optimal loading zone for the patient's age, medical condition, and injury severity. Overload may perpetuate bleeding or the inflammatory response beyond its useful purpose, and underload may result in complications such as motion loss, scar tissue adhesions, or ectopic ossification.

FIGURE 11-7 Physical therapist cueing a patient to contract the hamstring muscle with the cue "Imagine you are going to bend your knee, but don't actually lift your foot from the ground."

Modality use in this phase usually includes cryotherapy and compression with elevation to decrease bleeding and swelling. Most injuries allow passive, active-assisted, or active ROM in a pain-free range, although exercise may be contraindicated in some severe cases. Isometric muscle contraction, in the absence of moderate or severe muscle strains, can lessen atrophy and serve as a learning activity, reminding the patient how to contract involved muscles (**Fig. 11-7**). Because the muscle is the primary tissue involved in a strain, active muscle contraction capability may be limited or reduced significantly. When treating lower extremity injuries, assistive devices, immobilizers, and weight-bearing restrictions can maintain tissue loading within the optimal loading zone. Treatments that impose rest or restriction must be balanced with activity that offsets the negative effects of immobility (see **Selected Intervention 11-1** and **Building Block 11-5**).

BUILDING BLOCK 11-5

A 63-year-old woman sprained her left knee 4 days ago when she slipped on the ice. She sustained first-degree sprains of her MCL, joint capsule, and ACL. Due to underlying arthritis, her swelling and functional instability were significant. She has a 2+ effusion, is unable to fully bear weight on the left, has limited ROM, and poor quadriceps function. Provide a list of goals and interventions for the first phase.

SELECTED INTERVENTION 11-1

Isometric Ankle Eversion for the Patient After Ligament Reconstruction

See Case Study No. 1

Although this patient requires comprehensive intervention as described in the patient management model, one specific exercise is described.

ACTIVITY: Isometric ankle eversion

PURPOSE: Increased ability to produce torque in the peroneal muscles without excessively loading the acutely injured tissue

RISK FACTORS: No appreciable risk factors

STAGE OF MOTOR CONTROL: Mobility

POSTURE: Any comfortable position such as sitting or supine. The lateral border of the foot is stabilized against a stationary object.

MOVEMENT: Patient performs an isometric ankle eversion contraction against a stationary object.

SPECIAL CONSIDERATIONS: Ensure that muscle contraction is at a submaximal level during the acute phase. Maximal muscle contraction can overload recently injured tissues. Be sure eversion is not substituted with tibial external rotation, hip abduction, or external rotation.

DOSAGE

TYPE OF MUSCLE CONTRACTION: Isometric

Intensity: Submaximal

Duration: To fatigue, pain, or 20 repetitions

Frequency: Hourly or as frequently as possible during the day

Environment: Home

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to begin retraining the peroneal muscles. Isotonic exercises can overload the muscle in the acute phase, but submaximal isometric contraction maintains loading within the optimal loading zone. Gentle isometric activation "reminds" the muscle how to contract, providing a foundation for further strengthening in later phases.

EXERCISE MODIFICATION OR GRADATION: As healing progresses, isometric contractions may be performed at multiple angles. Isometric contractions should be progressed to isotonic exercise through a ROM. Closed chain exercise should be incorporated as weight bearing allows.

Getting the correct dosage is the greatest challenge. No standards exist to provide the clinician with precise frequency, intensity, and duration of exercise. This is one reason why the intensity of physical therapy services is greater in the early phase of rehabilitation. More frequent contact with the clinician can ensure that the exercise dosage is appropriate for the patient's current physical condition. Modify the rehabilitation program as changes occur.

Proliferative/Fibroplasia Phase

As healing progresses to the proliferative phase, treatment principles focus on restoration of normal tissue relationships, optimal loading, and preventing complications. Complications in this phase may result from changes in movement patterns to accommodate pain, weakness, or motion loss. These movement pattern changes can create excessive loads on uninjured tissues that can become painful. These changes also become habitual and can be difficult to correct. Examples of these habits are hiking the shoulder (i.e., scapular elevation) during forward reaching and ambulating with a flexed knee gait. Faulty movement patterns are deleterious for the long-term health of the joint and should be corrected as quickly as possible.

Restoration of normal tissue relationships can prevent these faulty movement patterns by reestablishing joint ROM and muscle length. Manual therapy, including joint mobilization techniques, stretching, and massage techniques, as well as postural education exercises, can facilitate restoration of these relationships. Connective tissue massage performed by the patient can increase scar tissue mobility (**Fig. 11-8**). This type of self-management increases the activity dosage to a level that can impact outcomes. Muscle contraction of the muscle opposing the short muscle is an active stretching technique that can restore normal tissue relationships via reciprocal inhibition (**Fig. 11-9** and **Building Block 11-6**).

FIGURE 11-8 Scar mobilization performed by the patient.

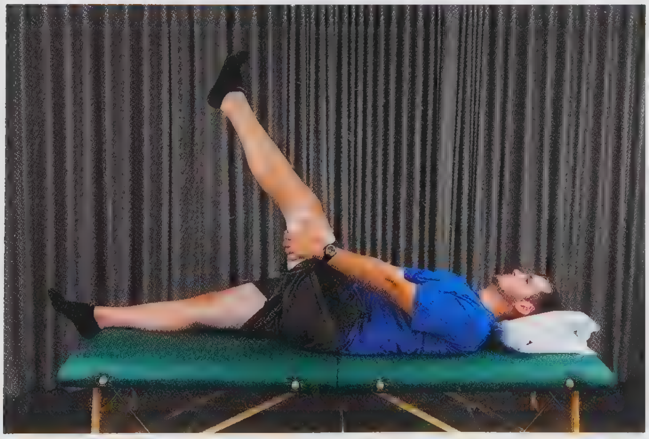

FIGURE 11-9 Active quadriceps contraction facilitating a hamstring stretch.

BUILDING BLOCK 11-6

The patient from Building Block 11-5 is now 8 weeks postinjury. She has regained full motion of her knee. Strength testing reveals strength to be with 75% of the contralateral limb. Her knee is stable to clinical ligamentous stability testing. However, she complains of a feeling of "giving way, wobbliness, and instability" in her left leg, especially with stairs, ramps, and uneven surfaces. She desires to return to trail hiking and gardening. Please progress her rehabilitation program at this stage (it is understood that you have continued to progress her program throughout the past 8 weeks).

Optimal loading concepts provide the framework for exercise parameters. Understanding the effects of muscle contraction and the location and direction of loading on the healing tissue is fundamental to optimally loading the tissue. Loading is important in the repair-regeneration phase, because loads help orient newly forming collagen fibrils along the lines of stress. Excessive loading disrupts the healing process, and underloading results in randomly organized collagen. Weight bearing, active and resistive mobility activities, massage, and functional movement patterns can provide these loads. It is the clinician's charge, along with input from the patient, to prioritize these activities to close the gap between current and desired functional performance. By the end of this phase, mobility and a strength base should be established.

Remodeling and Maturation Phase

As the patient returns to activity, the guiding principles are optimal loading and SAID. The type and magnitude of loads encountered in the patient's daily routine, including work and leisure activities, determine the specific interventions chosen (**Fig. 11-10**). The goal in the final phase is to "fine-tune" or convert the baseline strength and mobility into functional movement patterns and activities that address the patient's activity limitations and participation restrictions. The exercises generally consist of more whole-body patterns and functional activities related to the patient's lifestyle. At the same time, consider the status of healing tissue and the loads placed on it

FIGURE 11-10 Example of impact loading in a horizontal position as a transitional activity between strengthening and impact loading in a vertical position.

FIGURE 11-11 A soccer drill performed by a soccer player is an example of a graded, progressive study.

as you choose activities. For example, repeatedly throwing a fastball on a repaired elbow MCL excessively loads the repair at this point. A graded, progressive functional exercise is necessary to resume activities with such loads (**Fig. 11-11**). In the final phase, the patient should be instructed in a comprehensive home program to ensure continued maturation of the tissue according to the patient-specific loads.

Tendinopathy

Tendon failure can occur as a result of macrotrauma or microtrauma. Tendons are able to withstand high loads, but if these loads become repetitive, injury may result. Injury occurs on a microscopic or macroscopic level, with damage to the structural proteins and the blood supply. Adequate recovery and healing time must be allowed or tendinopathy will develop. As the understanding of tendon disorders has progressed, new classification schemes of tendon injury have been developed. In addition to the global categories of acute and chronic, tendon injuries have been subclassified as paratenonitis, tendinosis, tendinitis, and paratenonitis with tendinosis.[16] Each of these subcategories has specific treatment ramifications, which will vary with classification. However, all tendon injuries will be discussed together for simplicity.

Classification of Tendon Injuries

Tendon injury can be classified by etiology (macrotrauma, microtrauma), by duration (acute, chronic), or by presumed histopathology (tendinitis, paratenonitis, tendinosis). Tendinopathy is a global term for tendon disorders without presumptions about histopathology, duration, or etiology. Historically, the most common term for tendon injury was "tendinitis," implying inflammation.[17] The term "tendinosis" is used as a histologic description of degenerative tendon without inflammation. Examination of tissue with chronic tendinopathy has found little evidence of inflammation.

Tendon may be injured by acute macrotrauma, such as landing from a jump, or microtrauma, such as the trauma associated with repetitive uphill walking. Acute macrotraumatic injuries occur as a result of a sudden contraction, often decelerating in nature.[16] Loads during normal activities generally do not exceed 25% of the tendon's ultimate tensile strength.[18,19] However, loads during high-level activities, such as kicking, have been found to exceed this average level. For example, loads estimated in a weight lifter at the time of patellar tendon rupture were 17 times body weight.[20] Most macrotraumatic injuries occur at the musculotendinous junction and result in a profound inflammatory reaction.[21] This reaction initiates the phases of healing outlined previously.

Microtrauma, or repetitive loads without adequate recovery time, can also result in injury to the tendon. *Paratenonitis* is an inflammation of the outer layer of the tendon (i.e., paratenon), whether lined with synovium or not.[16,22] Histologically, inflammatory cells are found in the paratenon or peritendinous areolar tissues, and, clinically, the cardinal signs of inflammation such as pain, crepitation, swelling, and palpable tenderness occur. Treatment procedures, including anti-inflammatory measures, are indicated.

Tendinosis is an intratendinous degeneration without an inflammatory response.[17,23,24] It is generally caused by atrophy from aging, microtrauma, or vascular trauma. Histologic findings include fiber disorientation, hypocellularity, scattered vascular ingrowth, and occasional necrosis or calcification.[16,22] Because there is no inflammatory response, none of the cardinal signs of inflammation are present, and anti-inflammatory measures are ineffective. A nodule may be palpable but nontender. Tendinosis may also occur with paratenonitis, in which paratenon inflammation accompanies intratendinous degeneration. Symptoms in this case may be confusing, combining signs of inflammation with a chronic degenerative tendon. Histologically, scattered vascular ingrowth may be present, although no true intratendinous inflammation exists. Areas of neovascularity are evident in both Doppler studies and ultrasound.[17,24] Degenerative Achilles tendons show high blood vessel density compared with healthy tendons.

The term *tendinitis* is used to describe an acute inflammatory process, usually the result of overuse in a young individual. Histologically, tendinitis is classified into three subgroups, each with different findings, from purely inflammation to inflammation superimposed on preexisting degeneration to calcification and tendinosis changes in chronic conditions. The symptoms in this group are proportional to the vascular disruption or atrophy and can be inflammatory, depending on the duration (**Table 11-3**).

TABLE 11-3

Classification Terminology of Tendon Injury

NEW	OLD	DEFINITION	HISTOLOGIC FINDINGS	CLINICAL SIGNS AND SYMPTOMS
Paratenonitis	Tenosynovitis, tenovaginitis, peritendinitis	An inflammation of only the paratenon, lined by synovium or not	Inflammatory cells in paratenon or peritendinous areolar tissue	Cardinal inflammatory signs: swelling, pain, crepitus, local tenderness, warmth, dysfunction
Paratenonitis with tendinosis	Tendinitis	Paratenon inflammation associated with intratendinosis degeneration	Same as above, with loss of tendon collagen, fiber disorientation, scattered vascular ingrowth, but no prominent intratendinous inflammation	Same as above, with often palpable tendon nodule, swelling, and inflammatory signs
Tendinosis	Tendinitis	Intratendinous degeneration resulting from atrophy (aging, microtrauma, vascular compromise)	Noninflammatory intratendinous collagen degeneration with fiber disorientation, hypocellularity, scattered vascular ingrowth, occasional local necrosis, or calcification	Often palpable tendon nodule that is asymptomatic; no swelling of tendon sheath
Tendinitis	Tendon strain or tear	Symptomatic degeneration of the tendon with vascular disruption and inflammatory repair response	Three recognized subgroups; each displays variable histology, from pure inflammation to inflammation superimposed on preexisting degeneration in chronic conditions: (1) acute, (2) subacute, (3) chronic	Symptoms are inflammatory and proportional to vascular disruption, hematoma, or atrophy-related cell necrosis. Symptom duration defines each group: (1) <2 wk, (2) 4–6 wk, (3) 6 wk

From American Academy of Orthopaedic Surgeons. Athletic Training and Sports Medicine. Park Ridge, IL: American Academy of Orthopaedic Surgeons, 1991

Etiology and Risk Factors

A number of causes have been linked to the development and progression of tendinopathy. These causes include, but are not limited to:

- Age[25,26]
- Overuse and training errors[27,28]
- Insufficient recovery[27]
- Smoking[29]
- Hypercholesterolemia[30,31]
- Diabetes[32]
- Genetics[33–35]

In general, an imbalance between tendon loading and recovery leads to tendon failure on a microscopic and eventually macroscopic level. How much loading an individual's tendon can withstand varies with risk factors as noted above. For example, a patient who is obese and has type II diabetes will require closer attention to exercise dosing and recovery as compared to a patient without these comorbidities (**Evidence and Research 11-1**). Likewise, elderly individuals participating in sports should be cautious with any sudden increase in exercise dosage (**Evidence and Research 11-2**). The overarching issue is determining the balance between loading and recovery necessary to maintain tendon loading within the optimal loading zone.

EVIDENCE and RESEARCH 11-1

Ultrasound examination of the Achilles tendon in patients with type I and type II diabetes showed poorer ultrastructure, a potential risk factor for tendinopathy.[32] The tendon degeneration in this population has been linked to metabolic disorders that trigger persistent low-grade inflammation, including hypercholesterolemia.[30,31,36] Obesity contributes to tendinopathy both through mechanical mechanisms and metabolic, as evidenced by changes in both weight-bearing and non–weight-bearing tendons.[37] Tendons of patients with obesity show impaired remodeling, lipid deposition, and disorganization. Metabolic measures suggest a chronic, low-grade inflammation.

EVIDENCE and RESEARCH 11-2

Increasing degeneration of the rotator cuff tendon makes it challenging to know if the pathology seen on imaging following a shoulder injury in the elderly is new or if it has been long-standing. Research shows an overall prevalence of rotator cuff abnormalities of 9.7% in those <20 years of age compared with 62% in those >80 years (odds ratio = 15)[38] Studies of mice tendons have shown fiber realignment changes suggesting decreased ability to respond to load in older subjects.[39]

Treatment Principles and Procedures

Treatment of tendinopathies is based on the specific tendon injury, framed within the context of the tendon's role in function. Restoring the tendon to optimal length, cellularity, and ability to withstand loads is fundamental to complete rehabilitation. The optimal loading zone is the foundation for choosing loading techniques. Educate the patient about strategies that maximize symptom resolution and minimize harmful effects (**Fig. 11-12**). Using assistive devices or splints can minimize loads on overworked tendons during necessary activities.

Rehabilitation should be of appropriate intensity, frequency, and duration such that, when combined with essential activities of daily living, it keeps loading within the optimal loading zone.

Anti-inflammatory measures are helpful when inflammation is a component of the tendinopathy. If you are treating inflammation as the primary problem, the injury may be treated in the localized inflammation practice pattern. Physical agents such as ultrasound and cold packs can be used as adjunctive agents for pain control, allowing greater participation in the therapeutic exercise program.

Incorporate stretching if muscle length is inadequate for the demands placed on the musculotendinous unit. In cases of recovery from an acute tendon injury, stretching is critical for restoring the normal length of the tissue. Moreover, in the early stages, stretching is a stimulus for the proper alignment of healing collagen. In healing tissue, gentle stretching to provide a stimulus for fiber orientation without disruption of the immature collagen facilitates the remodeling process. In the early stages of recovery, stretching should be light, imparting a gentle stimulus for repair, rather than a vigorous intensity that may disrupt the healing process.

FIGURE 11-12 A wrist splint can be used to decrease loads on the wrist extensor musculature during work activities.

In the chronic tendon injury, stretching increases the tissue's resting length, allowing loading through a greater range and force dispersion over a larger surface area. Changes in resting length may affect the muscle spindle, altering its sensitivity and resultant muscle stiffness. As with resistive exercise, stretching should be prescribed according to intensity, frequency, and duration parameters. Too often, these prescriptive factors are neglected, leading to overload. For example, patients often believe that a strong stretching sensation is necessary to adequately stretch the muscle. However, a strong stretch can be just as damaging to an injured muscle-tendon unit as too much resistance. Patients should feel a "low" to "medium" stretching sensation during the stretch, without an increase in symptoms after the stretching session. While stretching is frequently recommended in the treatment of tendinopathy, little evidence exists to support its use.[40,41]

Progressive resistive exercises are a key component of the intervention program. Eccentric muscle contractions have been implicated in the development of tendinopathies.[42–45] Eccentric contractions allow the series elastic component (SEC) to contribute to force production. Tendon and other connective tissue proteins in parallel with the muscle fiber form the SEC.[9] Eccentric contractions usually precede concentric contractions in activities such as jumping, allowing the SEC to contribute to force production. The force generated in the tissue during eccentric contractions depends on the velocity of the stretch, the distance moved, and the amount of load placed on the tissue (e.g., body weight, external loads). These parameters are used in the rehabilitation of tendon injuries.

Curwin and Stanish[9] outlined a progressive resistive exercise program in an attempt to strengthen tendon tissue. Because eccentric muscle contractions allow the SEC to contribute to force production and because eccentric muscle contractions are frequently associated with the development of tendinopathies, this muscle contraction type is emphasized. Before an effective eccentric contraction can be performed, the individual must first be able to isometrically hold at the starting position. Thus, the first appropriate resistive exercise may be a submaximal isometric contraction. As the individual progresses, an eccentric program is initiated, with a progression of speed built into the program. The resistive eccentric program is performed slowly for the first 2 days, progressed to a moderate speed for 3 days, and then to a fast speed for 2 days. The resistance is then increased, and the speed progression instituted again. This program is easily performed at home, and intensity, frequency, and duration are clearly outlined to prevent overload (**Fig. 11-13**). Be sure to begin and end each session with a warm-up.

A

B

FIGURE 11-13 Eccentric wrist extensor work with a wrist weight is performed by the patient. **(A)** Uninvolved hand lifts the relaxed involved hand. **(B)** Involved wrist then lowers the weight eccentrically.

Others have advocated for a more aggressive eccentric training program.[42,44,46,47] This type of training has been studied in the Achilles and patellar tendons using high loads and decline boards; it has also been studied in lateral epicondylitis (**Evidence and Research 11-3**). This type of heavy load eccentric program has been successful in treating chronic Achilles and patellar tendinopathy, and has been more successful than programs using concentric contractions[42,45–47] (**Evidence and Research 11-4**). It is theorized that eccentric training interferes with the neovascularization apparent in chronic tendinosis, in a manner similar to that of sclerosing injections[44,46,47] (**Evidence and Research 11-5**).

As with any soft-tissue injury, rehabilitation activities must mimic the demands placed on those tissues on return to activity. The prescription parameters are framed around the functional outcome. For the individual returning to a work, leisure, or home environment that places him or her at risk for reinjury, appropriate modifications to the environment or to the individual (e.g., technique, adaptive, or supportive devices) must be made as part of the prevention and long-term care program.

EVIDENCE and RESEARCH 11-3

Patients with chronic lateral epicondylitis were divided into control (usual care) and eccentric exercise groups. The eccentric group used an isokinetic dynamometer that progressively increased the speed and eccentric resistance in a programmed manner based upon a repetition maximum criteria.[48] Results favored the eccentric group for significant pain reduction, increased strength, improved tendon thickness and structure on imaging, and a marked improved in disability status. Page[49] also found positive results with a home program utilizing a flexible bar to perform eccentric contractions. Using this bar, Tyler et al.[50] found significant improvements in pain levels, strength and functional outcome measures.

EVIDENCE and RESEARCH 11-4

Subjects with patellar tendinosis trained with either painful eccentric contractions (on a decline board) or painful concentric contractions (15 exercises, 3 sets, 2 times per day × 12 weeks) while stopping all sports for the first 6 weeks. At a mean of 32 months' follow-up, 9/10 subjects in the eccentric group were satisfied, with significant improvements in pain and functional outcome scores. In contrast, 9/9 subjects in the concentric group were dissatisfied, showing no change in pain or function.[43]

EVIDENCE and RESEARCH 11-5

Ultrasound examination has provided insight into the relationship between neovascularization and tendinopathy. Ohberg and Alfredson[44] performed dynamic ultrasound examination of 41 tendons in 30 patients with chronic mid-portion Achilles tendinosis who underwent eccentric training. At a mean of 28 months' follow-up, 36/41 had a good results. Thirty-two of these 36 tendons showed no remaining neovascularization, while 5/5 tendons with a poor result showed remaining neovascularization. Divani et al.[51] found the site of maximum neovascularization to correlate with the site of pain in patients with mid-portion Achilles tendinopathy. Yang et al.[52] found 97% of the pathologic Achilles tendons investigated to have neovascularization, 56% of which were associated with the location of tendon thickening. The pain level was positively associated with the area of thickening. In contrast, van Snellenberg et al.[53] found neovascularization in both painful and nonpainful tendons raising the question of a threshold of neovascularization at which the patient becomes symptomatic.

Articular Cartilage Injury

Articular cartilage injury can lead to both short-term and long-term activity limitations and participation restrictions. The pain associated with damage to the articular cartilage can impact a person's ability to stand, sit, walk, or perform other important functional tasks necessary for self-care or employment. Damage to the articular cartilage can occur from mechanical injury or from other nonmechanical trauma. Nonmechanical traumas include infection, inflammatory conditions, or prolonged joint immobilization and can result in loss of proteoglycans. Proteoglycan degradation or suppression of synthesis from these conditions results in articular cartilage damage that may be irreversible. Mechanical damage to the articular cartilage (i.e., chondral injury) or to the articular cartilage and underlying bone (i.e., osteochondral injury) can happen as a result of blunt trauma, frictional abrasion, or excessive weight-bearing forces.[54] For example, knee hyperextension injuries or ankle rotational injuries can result in chondral or osteochondral injuries and ligamentous injuries. Excessive weight bearing and joint compression combined with rotation produce high shear forces on the articular cartilage, resulting in chondral or osteochondral injury.

In addition to the mechanism of injury, articular cartilage damage is also classified by size and depth. While more complex grading systems exist, a simple classification describes whether it is partial or full thickness and the width of the lesion. Other important information includes the status of the joint surface and the location of the lesion. All of these factors (depth and diameter, articular surface and lesion location) have implications for prognosis and treatment.

Articular cartilage has a poor healing response. In adults, the tidemark prevents the underlying bony vascular supply from providing nutrition to the articular cartilage. The articular cartilage receives its nutrition by diffusion of synovial fluid. Therefore, chondral injuries that do not penetrate the underlying subchondral bone will lack sufficient blood supply to create a healing response. While these injuries may not heal in adults, they may not worsen in the presence of loading that stays within the patient's optimal loading zone. This requires education and guidance through an appropriate rehabilitation program.

Etiology and Risk Factors

While the cause of articular cartilage injuries in acute trauma is obvious, a poor healing response or chronic articular cartilage degeneration in some patients can be a frustrating situation. Chronic, progressive deterioration of articular cartilage can ensue following an acute injury such as an ACL sprain, ankle osteochondral injury or hip labral injury. Risk factors such as smoking, genetics, body weight, joint congruity, additional joint injury, concomitant injuries, occupation, strength, biomechanics/malalignment, sex, estrogen loss, dietary intake, and age have been implicated[55–63] (**Evidence and Research 11-6**). Of these risk factors, a history of previous injury to the same joint, particularly at the knee and hip, appears to increase the odds of developing osteoarthritis significantly (**Evidence and Research 11-7**).

EVIDENCE and RESEARCH 11-6

Patients sustaining joint injury, particularly meniscal injuries at the knee, have a high risk of developing osteoarthritis. Three hundred seventeen patients who had undergone meniscal resection 15 to 22 years earlier but had an intact ACL underwent radiographic and clinical evaluation. Symptomatic osteoarthritis (OA) was found in 27% of operated knees compared with 10% of control knees. Obesity, female sex, and preexisting early-stage OA were associated with a poorer outcome.[64] Valgus knee alignment also increases the risk for lateral compartment OA, likely through the mechanism of meniscal injury.[65] Similarly, varus aligned knees were at a higher risk of medial compartment OA.[63]

EVIDENCE and RESEARCH 11-7

Kramer et al.[66] note that the risk of developing posttraumatic OA after joint injury ranges from 20% to more than 50%, even in the presence of anatomic fracture fixation, ligament reconstruction, and restoration of normal joint biomechanics. Richmond et al.[67] found that a history of previous joint injury increased the odds ratio of developing knee OA to 3.8, and hip OA to 5.0. A study of female soccer players 12 years after their index ACL injury found radiographic changes in 82% of index knees, and 51% of those met the radiographic criteria for OA compared with 7% on the uninvolved side.[68] Anderson et al.[69] note that joint ligamentous or capsular injury results in a nearly 10-fold increase in the risk of OA.

The large number of both intrinsic and extrinsic risk factors accounts for the large variability in outcomes of articular cartilage injuries. Genetics can account for up to 50% of the risk of developing OA.[56] We inherit not only our connective tissue cellular and extracellular components, but also body morphology (i.e., varus or valgus alignment, kyphosis) predisposing some to higher OA risks. While the genetic factors, age, sex, and other intrinsic risk factors are fixed, the lifestyle factors are not. Activity level, diet, and other extrinsic factors may be the only opportunities to effect the progression of articular cartilage decline. These might include:

- Diet and nutritional modifications
- Weight loss
- Lifestyle changes (i.e., work and leisure activities)
- Appropriately dosed activity choices
- Injury prevention strategies
- Loading adjustments such as shoe/surface changes, braces/orthotics, assistive devices
- Training in posture and appropriate movement patterns
- Mobility and strengthening
- Education associated with all these factors

Treatment Principles

Minimum requirements for healthy articular cartilage are freedom of motion, equitable load distribution, and stability.[70] Beyond this, issues such as appropriate body weight, efficiency of movement to minimize joint loads, and avoiding overload[64] are important in long-term joint health. Exercise is healthy for joints; joint motion and alternating joint loading and unloading provide articular cartilage nutrition.[71] This nutrition is achieved by diffusion of synovial fluid across the joint surface. When joints are immobile or held in a single position for long periods of time (such as sleeping or riding in a car), stiffness and pain ensue due to lack of joint surface nutrition. Therefore, use a period of "preconditioning" or warm-up at the beginning of an exercise session or after periods of rest. Gentle muscle contraction exercises or ROM activities serve as good preconditioning exercises for people with articular cartilage injury (see **Display 11-1**).

Initiate treatment focused on restoration of joint osteokinematics and arthrokinematics as a primary goal. The aggressiveness of other interventions such as muscle performance exercises and progressive weight bearing is dictated by other factors and medical management of the injury. The articular cartilage has a better chance of recovery after injury or surgery when the loads across the recovering joint surface are controlled and progress as healing occurs. Optimal recovery is more likely to take place in the presence of equal load distribution (i.e., medial and lateral compartments in the knee) and joint stability. For example, a knee with significant varus or valgus alignment excessively loads the medial and lateral compartments, respectively. This loading is the rationale for tibial osteotomy procedures, which attempt to balance load distribution medially and laterally. An unstable knee (anterior or posterior cruciate deficient) also places greater loads on the articular cartilage, and rehabilitation after articular cartilage injury or surgery in an unstable knee must proceed

DISPLAY 11-1

Principles of Treating Articular Cartilage Injuries

1. Understand and apply the biomechanics of the joint of interest and its relationship to the rest of the kinetic chain.
   - Avoid shear forces across the lesion.
   - Utilize proximal and distal joint relationships to improve mechanical loading.
2. Respect the biomechanics of lubrication and nutrition.[72]
   - Adult articular cartilage gets its nutrition by diffusion, primarily through cyclic loading and unloading (i.e., weight bearing followed by unloading in a repetitive fashion) and motion.
   - Continuous static loading (i.e., continuous weight bearing) is deleterious to the articular cartilage.[73]
3. Avoid chronic and acute joint overload.[72]
   - Work or leisure activities that require prolonged standing or working in a single position can overload joints in the spine and extremities.
   - Obesity or malalignment can magnify these loads.
   - Avoid impulsive loading such as impact activities.
4. Design programs and educate patients regarding appropriate exercise and activity programs.
   - Consider mode, frequency, intensity, and duration.
   - Multimodal including muscle performance, aerobic and mobility activities.
   - Allow sufficient recovery.

cautiously. A patient with Ehlers–Danlos syndrome will have more difficulty recovering from an acute articular cartilage joint injury than a patient without this connective tissue disease.

Restoration of motion in a compromised joint allows loads to be distributed across a greater joint surface area, decreasing peak focal loads. Mobility activities enhance fluid dynamics in the joint, assisting with lubrication and nutrition of the joint. Active and passive ROM activities are important for the recovery of articular cartilage lesions.

In addition to the restoration of motion, normalization of gait and increased muscle performance decrease loads on the articular cartilage.[74] Effective eccentric muscle forces during the loading response of gait can minimize articular cartilage and subchondral bone loads at the tibiofemoral joint. Strengthening activities play an important role in the protection of articular cartilage. Muscle performance exercises must be performed at a dosage that minimizes shear forces and maintains compressive forces within the tissue tolerance. Little empirical clinical evidence exists to provide guidance in program design.[74] Guidelines are generally a compilation of basic science, animal studies, biomechanics, and expert opinion.

Consider alternative exercise modes for patients with articular cartilage injuries of the lower extremity. Clinical research has shown the effectiveness of aquatic rehabilitation for persons with knee arthritis.[75] Water-based programs have shown significant reductions in pain and improvements in strength function in patients with knee and/or hip arthritis.[76–79] Compliance rates were 84% for water therapy and 75% for land therapy. Patients frequently report that pain is lower with exercise in the water compared with exercise on land.[78] Continued participation following the conclusion of formal rehabilitation is also common following aquatic therapy, theoretically maintaining gains achieved in therapy.[80,81] The results reinforce the notion that patients can improve strength and function effectively in either a land or aquatic environment. The key is the ability to provide a comprehensive program, whether on land, in the water, or some combination of both, that the patient will enjoy and continue once formal rehabilitation is completed.

Contusion

A contusion occurs as the result of a blow and can occur in any area of the body to a variety of tissues. No break in the skin occurs, although blood vessels below the skin may be injured, causing ecchymosis in the area. If the damage is more extensive and large blood vessels in the area are disrupted, a localized area of blood may accumulate in deeper tissues, forming a hematoma. When a deep-tissue hematoma occurs, ecchymosis may or may not be seen on the skin surface. For example, quadriceps femoris contusions frequently result in hematoma formation. This hematoma is easily palpable within the muscle, but is rarely accompanied by ecchymosis. The severity of this type of injury can be deceptive, and if left untreated, may progress to myositis ossificans. Myositis ossificans is the formation of heterotopic bone within the muscle, which can lead to impairments in muscle performance, flexibility, and pain.

Treatment Principles

Simple contusions generally resolve in a timely manner without secondary complications or long-term consequences. However, this will be determined by the extent and location of the contusion. Be sure to consider the many layers of soft tissue comprising most injured areas. Contusions that occur in areas of high loads or poor blood supply may eventually result in a chronic inflammation. For example, a blow to the Achilles tendon may result in secondary Achilles tendinitis. Also, deep muscle contusions are at a high risk for long-term complications. Quadriceps and biceps brachii contusions, if left untreated, may result in myositis ossificans or ectopic bone formation within the muscle. This bone results in significant impairments such as loss of motion and muscle performance, as well as activity limitations relative to gait or arm use. These impairments and activity limitations can result in participation restrictions in those who are physically active as part of their lifestyle.

Treatment principles are therefore grounded in an understanding of the consequences of the specific contusion. ROM must be restored as quickly as possible, although in the case of a deep muscle contusion, aggressive mobility early on can increase bleeding. Thus, a balance must be struck between treating the impairments and causing further damage. In the case of a quadriceps contusion where the risk of myositis ossificans is high, this balance can be difficult. Use ice to control swelling and local inflammation as necessary. Use measures of pain, muscle length, and muscle performance to guide the aggressiveness of treatment for this condition. When these measures decline, the pace of the program is too aggressive, potentially causing further damage. Muscle performance measures must be restored, and these activities progressed to functional skills such as walking, stair climbing, and upper extremity work tasks. Submaximal isometric contractions can be safely initiated in the early phases, and these exercises progressed to more challenging muscle performance activities as healing progresses.

MANAGEMENT OF IMPAIRMENTS ASSOCIATED WITH FRACTURES

A fracture can be defined as a break in the continuity of the bone.[82] Most fractures are the result of an acute injury (i.e., macrotrauma), although stress fractures can occur as the result of microtrauma. Fractures are categorized by:

- Whether the skin is broken (i.e., open or closed)
- The amount of disruption (i.e., displaced or nondisplaced)
- The type of fracture (e.g., greenstick, comminuted)

The type and degree of force required to fracture a bone usually injures the surrounding soft tissue as well. Most fractures are treated in the practice pattern of impairments associated with fracture. However, patients undergoing surgical stabilization may be more appropriately treated in the bony and soft-tissue surgical procedures pattern. All fractures are discussed together for clarity.

Classification of Fractures

Fracture classification is first determined by whether or not the fractured bone is protruding through the skin. Fractures breaking the skin surface are considered open fractures; those that do not break the skin are classified as closed fractures. The continuity of the ends of the fracture is then considered. If the bone on all sides of the fracture remains in anatomic alignment,

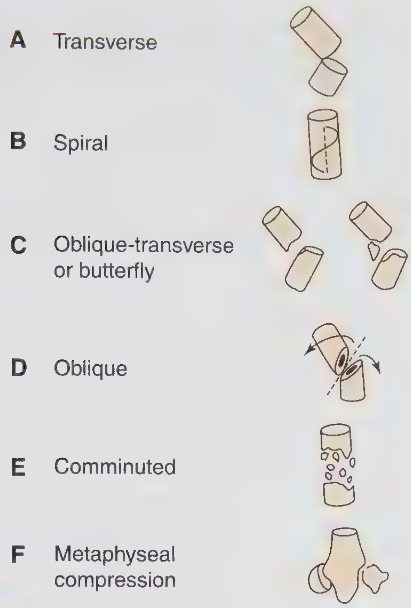

FIGURE 11-14 Types of fractures. **(A)** Transverse, **(B)** spiral, **(C)** oblique-transverse or butterfly, **(D)** oblique, **(E)** comminuted, and **(F)** metaphyseal fracture.

the fracture is considered nondisplaced. Nondisplaced fractures are more difficult to diagnose and require special studies such as radiography to verify. Fractures in which the ends of the bones are not in anatomic alignment with each other are considered displaced fractures. Finally, fractures that extend into the joint are considered intraarticular fractures and can significantly impact joint biomechanics. Failure to restore normal mechanical relationships can place the patient at risk of progressive osteoarthritis.

Fractures are described by the type of break or disruption (**Fig. 11-14**). A **greenstick** fracture is an incomplete fracture that occurs in children. It is so named because of its resemblance to a green stick or twig that partially breaks when bent. **Epiphyseal** fractures also occur in children and are fractures through the growth plate. Salter and Harris[83] subclassified epiphyseal fractures into five different types depending on the extent of fracture affecting the epiphysis and metaphysis. Children are also susceptible to **avulsion** fractures, in which a tendon or ligament is separated from its attachment by a small piece of bone. Because of the relative strength of the collagenous tissues compared with bone in this population, it is not uncommon to see young persons avulse structures such as ACLs or the proximal origin of the hamstring muscle from the bony attachments (**Building Block 11-7**).

BUILDING BLOCK 11-7

A 65-old female fell on ice and sustained a proximal humeral fracture. She has mild osteoporosis. She was immobilized in a sling for 6 weeks and presents to physical therapy for a rehabilitation program. Which associated tissues should be considered and assessed at this point? Presume sufficient healing of the fracture.

Comminuted fractures break into more than two fragments and are often the result of significant trauma, such as a fall or motor vehicle accident. **Pathologic** fractures occur in damaged or diseased bones, as in the elderly with osteoporosis. These fractures are produced with surprisingly minimal force. **Stress** fractures are overuse injuries in which the bone's ability to remodel is incapable of keeping up with the breakdown resulting from activity. Stress fractures occur in persons involved in repetitive activities such as running and jumping and in those with decreased bone density.

Application of Treatment Principles

When designing the rehabilitation program, consider associated soft tissues that have been injured and subsequently immobilized. Although the fracture may be of primary importance from the physician's perspective, rehabilitation of the associated soft tissues may be more challenging than the healing of the fracture. These soft tissues may have been injured at the time of fracture, they may be impaired because of the resultant immobilization, or both. Be sure to relay this information to the patient so realistic expectations after fracture treatment can be developed. Often patients believe that when the fracture is healed the limb should be functional. Soft tissues can take longer to recover than bone, and ensuring that the patient understands this is important for prognosis and program adherence.

Immobilized Fractures

The fracture site and joints above and below the fracture usually are immobilized for some time to allow healing. For patients with external fixation (e.g., cast, splint), physical therapy treatment focuses on rehabilitating the soft tissues that were damaged at the time of fracture and that were subsequently immobilized. The effects of immobilization on soft tissues are profound and consist of:

- Softening of the articular cartilage
- Shortening and atrophy of musculotendinous units
- Decreased mobility of the joint capsule and periarticular connective tissues
- Decreased circulation

Consider these changes when initiating rehabilitation after immobilization. Optimal loading and restoring normal tissue relationships are the goals when rehabilitating patients after fracture immobilization.

Initially, joint mobilization, stretching, and other gentle mobility activities can begin to restore ROM and normal soft-tissue relationships without overloading the tissues. Gentle strengthening in the form of isometrics or gentle isotonics stimulates increases in muscle performance. These same activities and controlled weight bearing load articular cartilage to reverse the changes resulting from immobilization. Electrical stimulation or biofeedback may be necessary in treating significant muscle atrophy. As impairments improve, initiate activities to alleviate any remaining activity limitations to facilitate the patient's return to work, leisure, and community activities.

Surgically Stabilized Fractures

Fractures of the hip and femur are examples of fractures that are frequently treated with surgical stabilization. The lengthy immobilization and significant lifestyle restrictions make conservative treatment of some fractures unrealistic. Open reduction and internal fixation (ORIF) provides immediate fixation of the fracture without the deleterious effects of immobilization.

When treating the individual who underwent surgical fixation of an acute fracture, treatment principles in the early phase focus on recovery from the traumas of the original injury and subsequent surgery. The principles are the same as those for treating soft-tissue strains, sprains, and contusions when addressing postfracture and postoperative pain. When choosing exercises, be sure to consider the effects of the magnitude and direction of loading on the fracture site. The stability of the fracture and fixation guides exercise choice, and this information should be obtained from the patient's medical record or from the physician. For example, a patient with a fixated patellar fracture may avoid weight bearing to prevent distraction loads at the fixation site, but a patient with a fixated tibia fracture may be allowed to bear weight to compress the fracture. Activities that address impairments and activity limitations while keeping loads within the optimal loading zone can then be safely chosen.

Stress Fractures

Stress fractures are a type of overuse injury in which the osteoblastic activity cannot keep pace with osteoclastic activity. This occurs when repetitive loading without adequate recovery is imposed. The metatarsals, tibia, and spine are common sites of stress fractures (**Evidence and Research 11-8**).

EVIDENCE and RESEARCH 11-8

Athletes participating in repetitive sports and military recruits are at a high risk of stress fracture. Data from a high school surveillance program found a rate of 1.54 stress fractures per 100,000 athlete-exposures, with the highest rates in girls' cross-country, girls' gymnastics and boys' cross-country.[84] In sex-comparable sports, girls had higher rates of stress fractures and overall sustained more stress fractures (63%) than did boys (37%). The lower leg and lumbar spine were the most common sites of injury. Participation in ball sports as a youth has been suggested as a way to prevent stress fractures due to the multidirectional and odd loading nature of ball sports, compared with activities such as running and swimming.[85] Stress fractures of the ankle and foot are also common in the military and have been associated with low vitamin D levels.[86,87]

The most important aspect of stress fracture care is decreasing loading to allow healing to occur. This may range from leisure activity limitation to short-term immobilization. During this phase, rehabilitation procedures include treating any impairment of mobility, muscle balance, or movement patterns that may have predisposed the individual to a stress fracture. For example, in the individual who participates in a symmetrical sport, such as running, a biomechanical evaluation of running mechanics is warranted to identify any impairments that may have resulted in asymmetric loading, leading up to the stress fracture. In addition, if decreased bone mineral density is suspected as an underlying problem, institute education or referral for proper evaluation and testing (**Building Block 11-8**).

BUILDING BLOCK 11-8

Consider the patient in Building Block 11-7. She has active shoulder flexion from 0 to 85 degrees, abduction from 0 to 75 degrees, external rotation from 0 to 15 degrees, and internal rotation from 0 to 35 degrees. Passive ROM is slightly greater. Cervical spine ROM is decreased in all directions by ~25%. Provide a sample beginning rehabilitation program.

Once increased loading at the fracture is allowed, determine the patient's optimal loading zone, or current capacity. The patient must learn which exercise or work parameters (e.g., intensity, repetitions, duration, and frequency) keep within that capacity. As tolerated, progress activities using the parameters described in Chapter 5 (Fig. 5-20). Progress parameters moving from patient's current status toward their desired performance or capacity. Choose activities that duplicate the activities to which the patient will be returning. If possible, the activity should be used as a component of the rehabilitation program. Use the functional activity, whether work, leisure, or recreational activities, as the measure of progress, and allow full return when the fracture has healed and is no longer painful to load.

MANAGEMENT OF IMPAIRMENTS ASSOCIATED WITH BONY AND SOFT-TISSUE SURGICAL PROCEDURES

Surgical procedures necessitating rehabilitation can be broadly categorized into soft-tissue procedures and bony procedures, although bony procedures intimately affect the surrounding soft tissues. Soft-tissue procedures are operations primarily directed at the soft tissues, such as tendons, ligaments, or joint capsules. In contrast, bony procedures are operations primarily directed at bone and adjacent tissues. These categories are not exclusive, because surgery often includes soft tissues and bone. However, the primary procedure may predominantly affect one or the other, and rehabilitation follows those guidelines. Not all surgical procedures can be discussed here, and as new surgical techniques are employed, the rehabilitation may change. The physical therapist should focus on the principles of treating patients with different categories of procedures, rather than on specific diagnosis-based protocols.

Frequently, a course of conservative management, including physical therapy, precedes surgery, and follow-up therapy is provided in the postoperative period. This gives the physical therapist the opportunity to participate in the patient's care in two critical perioperative periods. Many specific physical therapy outcomes can be achieved when the therapist has the opportunity for a preoperative visit. This visit allows positive interaction and development of a good rapport between the therapist and patient. Instruction in the postoperative exercise program occurs at a time when full attention can be given to the rehabilitation program, without the complications of postoperative pain and nausea. Instruct the patient in crutch training, wound care, bed mobility, precautions and contraindications to certain movements, and use of any immobilization or supportive equipment so that the patient is not overburdened with multiple instructions after surgery. Emphasize the importance of adhering to the prescribed exercises in the postoperative program. Consult with the patient about expected outcomes and return to function to reinforce realistic expectations after surgery.

Soft-Tissue Procedures

A multitude of soft-tissue procedures are routinely performed by surgeons and include transfer, reattachment or realignment of tendons, ligament reconstructions, capsular tightening, debridement and synovectomy procedures, and stabilization techniques. Regardless of the specific procedure, consider the stages of healing and the effects of immobilization and remobilization on connective tissue. In addition to the specific tissues involved in the surgery, consider adjacent tissues that may be affected indirectly by the surgery. These tissues may include supporting musculature, tissues at adjacent joints, articular cartilage, and associated joint structures (see **Display 11-2**).

Some soft-tissue procedures often require a longer recovery period than bony procedures because of the difficulty in obtaining fixation in soft tissue. Capsular reefing or tightening surgeries in which soft tissue is sutured to soft tissue or tendon transfer or repair procedures in which soft tissue is attached to bone require adequate healing time to ensure fixation. Most importantly, be sure to understand the surgical procedure and communicate with the surgeon to ensure optimal rehabilitation for the patient.

The goals of therapeutic exercise in the perioperative period are to restore motion, strength, and function and to reduce pain. The principles of optimal loading and SAID provide the framework for intervention choices. Be sure to observe for and educate the patient about potential postoperative complications such as infection or deep vein thrombosis. Prevention of these complications by early detection minimizes the risk of and protracted course of care associated with these problems. The rehabilitation program should include exercises and modality treatments to be performed at home to reinforce self-management of the condition.

Ligament Reconstructions

The most common sites of ligament reconstructions are the ulnar collateral ligament at the elbow, the lateral ankle ligaments, and the ACL, PCL, and MCL of the knee. Ligament reconstruction should not be confused with a primary ligament repair. Ligament reconstructions generally use other tissues (e.g., tendon) to create a new ligament, rather than repairing the original ligament. Communication with the surgeon regarding the specifics of the procedure provides the clinician with information critical to proper patient care.

Not all individuals with ligament injuries are candidates for reconstructive procedures. Ample evidence exists supporting the conservative management of knee MCL injuries in the presence of an intact ACL. Many individuals are able to return to their previous activity levels after ACL injury without surgical reconstruction. Decisions regarding the appropriateness of reconstructive procedures are based on the patient's activity level, clinical signs and symptoms, and the natural history of the injury.

The postoperative rehabilitation course after ligament reconstructions depends on factors such as the graft material, fixation, quality of the tissue, status of the joint surfaces, comorbidities, and associated injuries. In the knee, ACL reconstructions using the bone-patellar tendon-bone have solid, bone-to-bone fixation, whereas ACL reconstructions with other graft material may have soft-tissue fixation. Frequently, associated injuries or procedures affect the rehabilitation (e.g., meniscus repair, ulnar nerve transposition). Comorbidities such as diabetes or degenerative joint disease may alter the typical postoperative procedures by accelerating some aspects (e.g., mobility), but in other cases, it may slow down elements of the rehabilitation program (e.g., weight bearing). Every individual should be considered in light of the specific situation.

Impairments after ligament reconstructive surgeries include pain, swelling, and loss of mobility and strength. Weight bearing and all weight-bearing activities are impaired after lower extremity procedures. These impairments may result in activity limitations, including inability to perform activities of daily living such as bathing, dressing, and household chores or an inability to participate in leisure activities. Associated participation restrictions may include an inability to fulfill expected roles as worker, student, or spouse (see **Selected Intervention 11-2**).

DISPLAY 11-2

Rehabilitation Considerations Following Soft Tissue Surgical Procedures

- Respect the stages of healing
- Consider the effects of the original injury, if any, on adjacent tissues
- Address the additional impact of immobilization on all tissues in the kinetic chain (i.e., articular cartilage, ligament, and tendon insertions)
- Understand the implications of an underlying disease process (i.e., osteoarthritis, rheumatoid arthritis), if any
- Modify the treatment plan based on comorbidities (i.e., diabetes, heart disease)
- Adjust interventions based on patient response to the treatment program

Tendon Surgery

Surgery to repair or transfer tendons is commonly performed in orthopedics. Whether a tendon has been torn acutely or has undergone a degenerative process over a protracted period, surgery to repair or debride the injury can maximize the outcome. Common areas of tendon surgery include the tendons of the hand and the rotator cuff, and Achilles, the patellar and quadriceps tendons. As with ligament injuries, not all tendon ruptures need to be treated surgically. Many individuals return to a high level of function despite an unrepaired rotator cuff tear or conservative management of an Achilles tendon rupture.

The specific rehabilitation program depends to a great extent on the location and function of the musculotendinous unit, the location and extent of damage within the musculotendinous unit, the quality of the tissue, and the ability of the surgeon to effectively repair the damage. Areas of poor blood supply, inferior tissue quality, extensive damage, or comorbidities can deleteriously affect the surgical outcome. Communicate with the physician to ensure an understanding of the quality of the surgical repair to avoid overtreating or undertreating the patient.

SELECTED INTERVENTION 11-2

Quadriceps Setting for the Patient with a Knee Injury

See Case Study No. 10

Although this patient requires comprehensive intervention as described in the patient management model, one specific exercise is described.

ACTIVITY: Quadriceps setting

PURPOSE: To increase superior glide of the patella, to teach activation of the quadriceps, and to maintain or increase strength in the quadriceps muscle

RISK FACTORS: No appreciable risk factors

STAGE OF MOTOR CONTROL: Mobility

POSTURE: A variety of positions such as long sitting, supine, or standing. Initially, the exercise is performed with the knee fully extended.

MOVEMENT: Isometric contraction of the quadriceps muscle

SPECIAL CONSIDERATIONS: Ensure normal tracking of the patella. Avoid substitution with hip extensor musculature. Check quadriceps muscle contraction by attempting to perform a medial-lateral glide of the patella during the contraction. With an effective quadriceps set, the patella should not be mobile.

DOSAGE

TYPE OF MUSCLE CONTRACTION: Isometric

Intensity: Submaximal to maximal

Duration: Hold for up to 6 seconds for up to 30 repetitions

Frequency: Hourly or as frequently as possible

RATIONALE FOR EXERCISE CHOICE: Quadriceps setting is a key exercise to maintain the health of the extensor mechanism. This activity lubricates the patellofemoral joint, increases superior glide of the patella (necessary for full knee extension), and increases or maintains quadriceps muscle strength. Full knee extension with quadriceps activation is necessary for a normal gait.

EXERCISE GRADATION: Quadriceps setting is a foundation exercise that serves as a precursor to other exercises. This activity is progressed to more difficult exercises that require quadriceps muscle activation (i.e., any closed chain exercise).

Key issues after a tendon injury are the prevention of mobility impairment without overloading the tendon repair and prevention of excessive atrophy. Immobilization results in loss of normal tendon gliding within the tendon sheath and the associated soft-tissue and joint adhesions due to the postoperative restrictions placed on muscle-tendon stretch and contraction. Unlike ligament reconstruction surgery, after which strengthening exercises can be initiated early, these same exercises may overload the repaired tendon (**Table 11-4**).

Debridement

Surgical debridement is performed alone or in combination with other procedures at a number at joints. Debridement refers to the removal of tissue from an area until healthy tissue is exposed. The purpose is to remove potential sources of pain or irritation and, in some cases, to stimulate a healing response. For example, in osteoarthritic knees, debridement may remove osteophytes and loose bodies, shave or trim areas of roughened articular cartilage, and trim or remove areas of torn meniscus. When performing a ligament reconstruction, the remains of the torn ligament are debrided before the reconstruction is performed, and the torn ends of a tendon are debrided before tendon repair.

Because of the variety of situations in which this procedure is used, rehabilitation is dictated by the primary procedure. Rehabilitation after debridement that accompanies tendon or ligament repair follows the repair guidelines. Debridement performed primarily (e.g., arthritis) is guided by the underlying pathology. Understanding the extent of debridement and the status of the joint (e.g., location, extent, and depth of articular cartilage changes, meniscus tears) ensures appropriate pacing of the rehabilitation program.

Synovectomy

Synovectomy, the removal of the synovial lining of the joint, is a procedure performed primarily in the case of rheumatoid arthritis and other diseases such as pigmented villonodular synovitis. The purpose of synovectomy in the case of rheumatoid arthritis is to remove the inflamed synovium and thereby relieve pain and swelling and perhaps retard the progressive joint destruction associated with chronic inflammation.[88] This procedure is performed only after conservative measures to control the pain and swelling have failed.

Rehabilitation after synovectomy is guided by the primary pathology, such as rheumatoid arthritis. Because this procedure has been performed as a last resort to control pain and swelling, every effort should be made during rehabilitation to restore motion and strength without increasing pain or swelling. These two factors guide the pace of the rehabilitation program and provide the clinician with the parameters for optimal loading.

Decompression

Decompression procedures are used to relieve pressure in an area and are commonly performed at the shoulder to reduce pressure on the subacromial soft tissues and in the spine to reduce pressure on the spinal cord. Surgery in the wrist to relieve pressure in the carpal tunnel and fasciotomies in the leg to reduce compartment pressures may be considered forms of decompression. Excessive pressure in these areas may result from bony or soft-tissue architecture, and decompression involves the release or removal of these soft tissues and shaving or removal of bony sources of pressure.

Rehabilitation after a decompression is guided by the primary pathology and the status of the tissues decompressed, which depends on the amount and duration of compression and on the type of tissue compressed. For example, if excessive pressure on a nerve has caused neurologic changes, rehabilitation focuses on recovery of nerve function. In the spine, a decrease in neurologic symptoms in the arm (following cervical spine decompression) or the lower extremity (following lumbar decompression) is a sign that the decompression has been successful. As neurologic symptoms decrease, progressive strengthening of the core and extremity musculature should increase. If pressure has caused poor muscle function (e.g., rotator cuff), rehabilitation focuses

TABLE 11-4

Sample Rehabilitation Program Following an Achilles Tendon Repair

	PRECAUTIONS	ROM	THERAPEUTIC EXERCISE	PROGRESSION CRITERIA
Phase 1: Inflammatory phase to early proliferative phase surgery to 2 wk	Boot locked in 20–30 degrees PF Touchdown WB using axillary crutches Avoid long periods of dependent positioning	NA for ankle; well limb and proximal joint mobility	Well limb training UBE or upper body circuit	Time-based; 2 wk postoperative
Phase 2: Proliferative fibroplasia phase 2–4 wk postoperative	Continue use of boot progressing to 10 degrees PF at week 2 and 0 degrees PF at week 3	AROM exercises in all ranges Joint mobilization	Isometric exercise of all muscle groups; submaximal for plantar flexion	Time-based: 4 wk postoperative
	WBAT using crutches and boot Watch for appropriate wound healing		Hip and core strength UBE or upper body circuit	Pain-free active DF to neutral No wound complications
Phase 3: Late proliferative fibroplasia phase 4–8 wk	Wean from boot Start with ¼–½ in heel lifts in tennis shoes for short distances on level surface Gradually reduce heel lift	Continue AROM, stretching, and joint mobilization	Progressive isotonic strengthening Static balance exercises Frontal and sagittal plane stepping drills Low-velocity functional movements Hip and core strength Pool exercise	Normal gait Squat to 30 degrees knee flexion with normal mechanics Stork stand with good control for 10 s. AROM from 5 degrees DF to 40 degrees PF
Phase 4: Remodeling phase ~8 wk	Compensations Forceful impact	Continue ROM to 15 degrees DF and 50 degrees PF	Frontal and transverse plane agility drills, progressing from low to high velocity and to sagittal plane Progress hip and core exercise	Squat and lunge to 70 degrees knee flexion with good mechanics AROM to 15 degrees DF and 50 degrees PF
			Multiplane single leg stance activities Bike, cross trainer, swimming	
Phase 5: Maturation phase ~4 months to discharge	Postactivity soreness should resolve within 24 h. Avoid anything producing abnormal movement patterns	ROM as necessary	Impact control exercises progressing from 2 footed through alternate footed to single footed Movement control exercises Work- or sport-specific activities	Completion of functional progression or similar measure

DF, dorsiflexion; PF, plantarflexion; WB, weight bearing; UBE, upper body ergometer; WBAT, weight bearing as tolerated.

on recovery of muscle function. As rehabilitation progresses, avoid using activities or positions that may excessively compress the tissue just decompressed (**Table 11-5**).

Soft-Tissue Stabilization and Realignment Procedures

Soft-tissue stabilization procedures are performed in the case of joint instability resulting from capsular laxity. Capsular laxity can be the result of an acute injury such as a dislocation, or can be part of an overall pattern of hypermobility that has become symptomatic. Soft-tissue stabilization procedures are performed most frequently to correct an unstable shoulder and may be combined with other stabilization procedures (e.g., bony stabilization). A variety of surgical techniques can stabilize a joint with capsular laxity. Each technique has risks and benefits that should be evaluated on a case-by-case basis. Likewise, soft-tissue realignment procedures are performed to redirect the pull of soft tissues that may or may not be the result of instability. For example, proximal patellar realignment is used to enhance the effective pull of the vastus medialis obliquus on the patella. Regardless of the procedure, the fixation usually is soft tissue to soft tissue, without bony stability, which is an important factor in the early rehabilitation phases.

TABLE 11-5

Sample Rehabilitation Guidelines Following Rotator Cuff Repair with Subacromial Decompression

	PHASE 1: INFLAMMATORY PHASE TO EARLY PROLIFERATIVE PHASE	PHASE 2: PROLIFERATIVE FIBROPLASIA PHASE	PHASE 3: EARLY REMODELING-MATURATION PHASE	PHASE 4: REMODELING-MATURATION PHASE
Timeframe	Postoperative to 2 wk	Week 2–5 or 6	Week 6 to phase 3 goals met	Phase 3 goals to discharge
Immobilization	Sling continuously	Gradually wean out of sling; fully out of sling by week 6	NA	NA
Range of motion	Elbow, wrist, and neck AROM: up to 100 degrees elevation and 35 degrees external rotation	PROM progressing to AAROM for shoulder girdle in all cardinal planes Passive pendulum Neck and scapular mobility exercise; joint mobilization at cervical spine and scapulothoracic region as needed UBE within ROM limits and without resistance	AAROM progressed to AROM PROM to end range GH joint mobilization Cervical and thoracic mobility as needed	Mobilization as necessary for normal arthrokinematics
Neuromuscular exercise	Ball squeezes	Postural exercises Scapular retraction Core strengthening Submaximal multiple angle isometrics for shoulder rotation Manual resistance for secondary and distal musculature	Isotonic shoulder strength Scapular strength progressed to plyometrics Submaximal elastic resistance and isokinetic exercise	Total arm strength emphasizing patient's functional needs
Cardiorespiratory	Walking, stationary bike, or cross trainer with sling	Walking, stationary bike, or cross trainer with sling	May begin running if 5/5 strength in rotation	Sport- or work-specific
Progression criteria	Time-based: 14 d postoperative	Minimum 5 wk postoperative; pain controlled and mobility returning	Full AROM 5/5 strength Negative impingement signs	
Other	Ice or other modalities for pain			

AROM, active range of motion; GH, glenohumeral; AAROM, active assisted range of motion; UBE, upper body ergometer; PROM, passive range of motion.

Because of the lack of rigid fixation and length of time necessary for soft tissue to heal, the loads placed on the repair site are controlled for some time after stabilization. For example, when an anterior capsular shift is performed to stabilize a shoulder with anterior inferior glenohumeral instability, external rotation is limited for a short time after surgery to avoid stretching the anterior capsule excessively. Because the repaired tissue is noncontractile, muscle activation is usually allowed early in rehabilitation, as long as ROM precautions are considered. As rehabilitation progresses into the range that stresses the repaired tissue, be alert for signs of progressive loosening of the repair, such as complaints of slipping or instability. Depending on the specific procedure, mobility recovery should be full, without the return of instability symptoms.

Rehabilitation following stabilization procedures focuses on restoring mobility, strength, and function. The rate of progression of mobility activities may vary from one person to the next due to individual variations. Some patients progress slowly due to concern that the stabilization will "stretch out" or loosen. Differences in tissue quality, joint architecture, and surgical technique impact the progression of mobility activities (**Table 11-6**).

Meniscal and Labral Repairs

The meniscus of the knee and the labrum of the hip and shoulder are common sites of fibrocartilage repair. When repairs are performed in the shoulder, they are often at the superior aspect of the labrum where the long head of the biceps inserts into the labrum. Repair of torn menisci of the knee is commonly performed alone or in combination with other procedures such as ACL reconstruction. In the knee in particular, the repair is of a soft tissue with an inferior blood supply. Healing may be enhanced by associated procedures to increase the blood supply to the area.

Important issues during rehabilitation include understanding the loads placed on the repair when the joint is in a variety of positions. These positions should be avoided in the

TABLE 11-6

Sample Rehabilitation Program Following an Anterior Shoulder Reconstruction with Bankart Repair

	PHASE 1: PROLIFERATIVE FIBROPLASIA PHASE	PHASE 3: PROLIFERATIVE AND EARLY REMODELING PHASE	PHASE 4: REMODELING PHASE	PHASE 5: REMODELING AND MATURATION
Timeframe	Weeks 2–6 postoperative	Weeks 6–10 postoperative	Weeks 10–15 postoperative	Weeks 18+
Range of motion	Sling immobilization for 3–4 wk	Continue AAROM and AROM	Posterior glides if posterior capsule tightness present	As needed
	No external rotation with abduction for first 6 wk	Gentle joint mobilization as necessary	Stretching and joint mobilization for any motion limitations	
	PROM/AAROM for all ranges except external rotation only to neutral	Cervical spine and scapular AROM		
	Begin AROM week 5			
Therapeutic exercise	Submaximal shoulder isometrics beginning week 3	Core strengthening	Progressive multiplane resistive exercise	Total arm/core functional exercise Dumbbell, resistive band, and medicine ball exercise
	Elbow, forearm, wrist, and hand exercise	Postural exercise	Stabilization exercises using PNF, rapid alternating, or closed chain techniques	Higher velocity strengthening and control exercise Inertial exercise
	Cervical spine and scapular exercise	Rotator cuff strengthening in nonprovocative position		Plyometric exercise
	Well limb activities	Scapular strengthening and dynamic control		Progress to functional program: throwing, swimming, and racquet sports
		Partial weight-bearing exercise		
Cardiorespiratory fitness	Walking and stationary bike with sling	Walking, stationary bike, elliptical trainer	Walking, biking, elliptical trainer, and running	Sport- or work-specific
Criteria for progression	Full AROM in all ranges except ER	Full AROM	Continued strength and function progress without apprehension or impingement	Discharge to sport/work when functional progression complete
	5/5 IR/ER strength in neutral	5/5 IR/ER strength at 45-degree abduction		
	Negative apprehension and impingement signs			

AROM, active range of motion; AAROM, active assisted range of motion; IR/ER, internal rotation/external rotation; PNF, proprioceptive neuromuscular facilitation; PROM, passive range of motion.

early stages when the repair is still fragile. For example, full overhead positions may be avoided early after glenohumeral labral repairs in the superior zone. Full knee flexion in weight bearing is limited for several weeks after meniscal repair, because this position places high loads on the meniscus. Return to activities such as impact loading, jogging, deep knee flexion, and pivoting should be approached cautiously, particularly in the early postoperative phase.

Communicate with the surgeon regarding the location and extent of tissue repair. The type, location, and extent of tear provide important information about the rehabilitation protocol. At the knee, the margins of a longitudinal tear will be approximated with weight bearing, via hoop stress, whereas the margins of a radial tear will be disrupted. Tears located in the peripheral one-third, or vascular zone, have a better prognosis than those in the central one-third, or avascular zone. However, surgical techniques have improved and meniscus tears in the avascular zone are repairable with good success.[89,90]

Meniscal allografts are used in situations in which patients have undergone a complete meniscectomy, and are generally young and active (age 50 or less), have a varus alignment and mild to moderate tibiofemoral arthrosis. The goal is to perform the surgery early before extensive articular cartilage damage occurs.[91] In fact, meniscal allograft transplantation is contraindicated in patients with significant arthrosis.[92]

Rehabilitation following meniscal repair or transplantation focuses on limiting weight-bearing forces to control compressive and shear forces.[92] The rate of program progression will depend upon many individual factors, most importantly keeping joint loads within healing tissue tolerance. Appropriate progression requires attention to external factors (i.e., age, joint surface quality, body mass index, joint alignment, etc.) and internal factors (i.e., size and location of lesion, direction of tear, etc.). Maintain close communication with the surgeon to ensure progression that is consistent with surgical findings and procedures.

The rise of hip arthroscopy has expanded the understanding and treatment of hip pathology. Procedures such as debridement of loose bodies of removal of osteophytes that were previously performed as open techniques can now be done more efficiently arthroscopically. Additionally, arthroscopy has helped identify previously underrecognized problems such as labral tears and chondral injuries.[93] These injuries occur as acute traumatic episodes in athletic activities, such as landing directly on the greater trochanter. This impact can produce shearing of the articular cartilage on the acetabulum resulting in a chondral injury.[93]

Injuries to the acetabular labrum can occur acutely or as the result of aging and degeneration.[93–95] Femoral acetabular impingement can produce anterosuperior labral and chondral lesions.[95] Labral injuries have been classified into four different types and occur in different locations.[95] Symptoms are similar to those of a meniscal or shoulder labral tear, where the patient experiences pain, clicking, catching, and instability. Hip arthroscopy can help to identify and correct the injury.[96] Like surgery for a torn meniscus, arthroscopy to debride the unstable labrum, maintaining as much of the tissue as possible, will lead to the best outcomes. A sample rehabilitation program following hip arthroscopy can be found in **Table 11-7**.

TABLE 11-7

Sample Rehabilitation Program Following Hip Arthroscopy for Labral Tears

	PHASE 1: INFLAMMATORY AND EARLY PROLIFERATIVE PHASE	PHASE 2: PROLIFERATIVE FIBROPLASIA PHASE	PHASE 3: REMODELING AND MATURATION PHASE
Timeframe	Postoperative to week 2–3	Completion of phase 1 to approximately week 6	Completion of phase 2 to discharge
Weight bearing	Crutches and limited weight bearing; normalize gait	Discontinue crutches when gait is normal without pain medication	Full weight bearing
ROM	AAROM, PROM all planes Gentle hip mobilization and distraction	Continue ROM and mobilization until full or desired ROM is achieved	Maintenance, patient-specific stretching
Neuromuscular exercise	Gait activities: marching, weight shifting, and normalizing gait (may use pool)	Progressive gait activities including balance, direction changes, and functional movements (may use pool)	Gentle impact on shock absorptive surfaces, 2 ft–2 ft progressing to single foot
	Isometrics of all hip and knee musculature	Nonimpact hip and core muscle strengthening (resistive bands, swiss ball, etc.)	Progress to multiplane
	Short-arc dynamic hip exercises	Lower extremity strengthening (PNF, leg press, knee extensions, etc.)	Dynamic control exercises reproducing functional activities Running program if returning to running sport
			Sport- and work-specific drills
			Progressive hip, leg, and core strengthening
Cardiorespiratory	UBE or pool without kick	Nonimpact: stationary bike, cross trainer, swimming, and deep water running	Sport- or work-specific in neuromuscular and cardiorespiratory demands
Progression criteria	Normal gait without assistive device or pain medications on level surface	Normal gait on all surfaces Completion of functional movement patterns without compensation Single leg balance ≥15 s	Return to work or sport when functional progression and/or work conditioning program is passed
	Functional ROM without pain		
	Good leg control during slow movements

Bony Procedures

Rehabilitation is often necessary after bony surgical procedures to restore motion at adjacent joints, strengthen related soft tissues, and increase general endurance. Most articular cartilage surgeries are a combination of soft tissue and bony procedures. The number of available procedures suggests that there is no one optimal treatment for those with articular cartilage injuries. Many individual parameters such as age, body mass, activity demands, status of the primary and adjacent joints, as well as specifics of the lesion itself weigh heavily in surgical planning.[97,98] The specific procedure, tissue damage, and the patient's general health, balanced with the optimal loading and SAID principles, guide intervention choices. The focus of these sections will be on the knee due to the volume of research and high utilization at this joint. However, use of many of these procedures is being successfully extended to other joints.

Surgical Management

Surgical management of articular cartilage defects can be thought of as a spectrum: from palliative care to reparative management to restorative intervention. Articular cartilage defects are similar to potholes in the street. Palliative care "ignores" the pothole and just cleans up the edges surrounding the pothole. Reparative techniques fill the articular cartilage defect (pothole) with a native, suboptimal substance (such as filling a hole in a concrete road with tar). Restorative techniques fill the articular cartilage defect with the same structure, as filling a concrete pothole with concrete. Each surgical technique, its advantage and disadvantage, will be discussed.

Palliative Management: Lavage/Debridement

Surgical procedures to remove loose fragments and other mechanical or chemical irritants may provide some temporary relief to joint pain in the degenerative joint. Simple arthroscopic irrigation (lavage) along with removal of loose bodies or other tissue fragments can produce improvement in many patients. The purpose of these procedures is to reduce inflammation and mechanical irritation by washing away fragments of cartilage and calcium phosphate crystals from the joint.[99] This procedure can decrease mechanical symptoms as well as night pain in the short-term following surgery.[100] In some patients, lavage can decrease symptoms for up to 3 years. Additional debridement including smoothing of fibrillated joint surfaces, removal of osteophytes, or partial synovectomy may further reduce symptoms.[99] Patients with good joint space, a short duration of symptoms, good alignment, and a stable knee may do well with this procedure. However, neither lavage nor debridement addresses the underlying pathology, so improvements are short lived. As a result, the benefits of these procedures may be limited, and the improvements restricted to a small proportion of patients.

Reparative Management: Microfracture

Other patients may require more aggressive treatment that attempts to stimulate healing. Microfracture is a procedure performed alone or in combination with other procedures in cases of articular cartilage lesions. This procedure is performed most commonly at the knee, where articular cartilage lesions may result from degenerative joint disease or acute injury. The microfracture technique can be used for isolated defects or for bipolar or "kissing" defects, where defects on opposing joint surfaces contact one another. These lesions produce impairments such as pain, swelling, and motion loss, as well as activity limitations such as the inability to walk distances, stand for long periods, or negotiate stairs.

The surgical procedure involves a diagnostic arthroscopy and correcting any associated intraarticular pathology. The zone of calcified cartilage is debrided, taking care to avoid abrading the subchondral bone. Subsequently, a surgical awl, drill, or pick is used to make several small holes or "microfractures" in the subchondral bone. This procedure basically makes a partial thickness articular cartilage lesion a full-thickness lesion, because the awl, drill, or pick passes through the tidemark zone into the subchondral bone. This procedure creates a roughened surface to which a blood clot can adhere. This procedure stimulates a healing response and local fibrocartilage ingrowth. Unfortunately, the mechanical properties of the replacement fibrocartilage are significantly inferior to the original tissue, similar to filling a concrete pothole with tar.[99,100]

Rehabilitation after microfracture varies with the extent and location of the articular cartilage lesion. Large lesions on weight-bearing surfaces have a poorer prognosis than small lesions on non–weight-bearing surfaces. The joint with extra loads from excessive body weight, malalignment, or instability is likely to require a longer rehabilitation course, with a greater likelihood of overloading the new fibrocartilage. These individuals may have weight-bearing and exercise limitations for up to 8 weeks after surgery. Depending upon the size and location of the lesion, weight bearing can be progressed to partial weight bearing between weeks 2 and 4. The patient should be full weight bearing by week 8.

Restoration of motion and strength as quickly as possible without disrupting the healing process provides the best opportunity for healing of this fresh injury (**Fig. 11-15**). Many surgeons advocate the use of continuous passive motion with their patients for up to 6 weeks postoperatively to create a healing environment.[100] Typically, PROM is performed immediately without restrictions in most cases.

Strengthening exercises in the early phase consist of multiangle isometrics and non–weight-bearing leg-raise activities. The pool is an effective place for gait training, ROM, and functional training, and is initiated when incisions have healed. A stationary bike with light resistance can be used for mobility and strengthening as early as week 3 to 4. By week 4, with the progressive increase in weight bearing, balance and light weight-bearing activities such as wall slides, mini-squats and lunges can be initiated or advanced. Hip and core strengthening are important as well. Strengthening exercises should continue and replicate functional activities by weeks 8 through 16, with gradual return to activities over the next 2 months.[101] High-impact activities can be considered at 6 to 8 months postoperatively.

Restorative Management

Osteochondral Autograft Transplantation Several surgical techniques attempt to restore and preserve articular cartilage. More aggressive techniques are indicated in the case of full-thickness defects of the weight-bearing surface of a joint.[99,102] The osteochondral autograft transplantation (OAT)

FIGURE 11-15 Using activities in a gravity-minimized environment can progressively load the lower extremity. **(A)** Begin walking in deeper water and progress to **(B)** walking in shallow water. Walking faster also increases the weight-bearing forces. Educate patients to avoid this common mistake of ipsilateral arm and leg movement in the water.

procedure transfers articular cartilage tissue from areas of low loading to areas of high loading. In addition to the knee, OAT procedures have been used with lesions on the talus, tibia, humeral capitellum, and femoral head.[102] Indications include focal chondral or osteochondral defects of weight-bearing surfaces or joint surfaces that are frequently loaded, age <50 years, concurrent treatment of instability, malalignment and meniscal injuries, and compliance with weight-bearing restrictions.[102] This procedure is performed most often at the knee, where bone plugs are removed from trochlea and intercondylar notch and placed on the articular surface lesions. When multiple plugs are used to fill a larger defect, the procedure is often termed a "mosaicplasty." Problems with this procedure are related to limitations in the graft size, obtaining good congruity of the graft and adjacent articular cartilage, and graft fixation. Additionally, few areas of a joint surface are truly "non–weight bearing," resulting in significant risk of donor site morbidity.[102]

Rehabilitation after an OAT procedure will vary with the size and location of the lesion and fixation stability. The general rules about rehabilitating any articular cartilage lesion apply here and are modified based on individual patient factors. General guidelines allow unloaded PROM as tolerated with emphasis on restoring full motion as quickly as possible, whereas AROM varies depending on the size, location, and fixation of the lesion. Typically, there is no period of strict immobilization. Particular attention should be paid to treatment of the underlying causes of the original articular cartilage lesion. Patients are generally non–weight bearing for 2 to 4 weeks, followed by a gradual progression of weight bearing over the next 3 to 4 weeks. This varies with the size and location of the lesion. Lesions that are found on a non–weight-bearing surface may be non–weight bearing for 1 week only. Muscle performance activities include isometric contractions in pain-free ranges and the non–weight-bearing leg raises immediately. Concentric active exercises in ranges that do not engage the lesion can begin as early as 1 week with light resistance as early as the second week after surgery.[102] Strength and functional activities progress and include balance and proprioception drills by 6 to 12 weeks postoperatively.[101] Low-impact activities are allowed at 6 to 8 months, while higher impact activities such as running and aerobics are no allowed until 8 to 10 months following surgery[101] (see **Table 11-8**).

Autologous Chondrocyte Implantation

The autologous chondrocyte implantation (ACI) procedure is indicated for cases of large, full-thickness chondral lesions located on the femoral condyles or trochlear groove. Patients should be under 50 years of age and be willing to adhere to the postoperative protocol.[97] The lesion typically ranges in size from 2 to 10 cm^2 in diameter, but ACI has been successfully used in lesions up to 20 cm^2.[103] Other prerequisites include good alignment, ligamentous stability, and good ROM.[98] Any associated pathology must be corrected prior to or at the time of surgery. While ACI can be used in joints with multiple chondral lesions, ACI is contraindicated for "kissing lesions" or significant bone loss.[99]

This procedure is performed in two stages. In the first stage, two to three full-thickness samples of healthy articular cartilage are harvested from the patient, typically from the superior peripheral edges of the lateral or medial femoral condyles.[97] These samples are cultivated and held until the second stage, performed anywhere from 6 weeks to 18 months after graft harvest.[97,99] The patient should obtain full motion and sufficient strength prior to the second procedure. In the second surgical procedure, the cartilage defect is debrided, avoiding disruption of the subchondral bone. Once the lesion

TABLE 11-8

Rehabilitation Program Following OAT Procedure

	PHASE I: INFLAMMATORY PHASE TO EARLY PROLIFERATIVE PHASE	PHASE 2: PROLIFERATIVE FIBROPLASIA PHASE	PHASE 3: REMODELING PHASE	PHASE 4: MATURATION PHASE
Timeframe	Weeks 0–6	Weeks 6–12	Weeks 12–26	Weeks 26+
Weight bearing	Brace locked in full extension	Discontinue brace	Full WB	NA
	Status will vary with location and size of lesion; follow physician guidelines	Progress WB based upon physician recommendations		
	Generally NWB for up to 4 wk with progressive WB by 25%/wk	*Generally* full WB by 8–10 wk		
Range of motion	PROM as tolerated CPM for up to 8 h/d	Continue PROM AROM in ranges that do not engage lesion	Full ROM Continue stretching as needed	Continue maintenance stretching
	Immediate full extension	Continue mobilization and stretching Knee flexion to ~130 degrees by week 8–10		
	Stationary bike as tolerated			
	Joint mobilization			
	Flexion goal of 90 degrees by ~2 wk			
Therapeutic exercise	Quadriceps sets	Partial WB weight shifts	Continue progressing strength exercises	Progress strengthening
	Multiangle isometrics	Gentle leg press, wall slides, and lunges with resistive bands or weights through partial ROM	Increase resistance	Progress balance and proprioception activities
	Leg raises	Partial WB balance and proprioception drills	Leg press 0–90 degrees	Functional progression
	Pool exercises	Partial ROM resisted knee extension	Squats 0–60 degrees Step-ups	Impact activities as determined by individual needs
	Well limb exercise		Lunge walking,	Return to work or sport
			Elliptical trainer	
			Progressive walking, bicycling	
			Functional activities that are nonimpact	

NWB, non-weight-bearing; WB, weight bearing; PROM, passive range of motion; CPM, continuous passive motion; AROM, active range of motion; ROM, range of motion.

is debrided and prepared, a periosteal flap is harvested from a different site (typically the superior medial tibia) and sutured over the lesion. The suture line is sealed with fibrin glue to ensure a watertight seal at the edges of the periosteal flap.[104] The cultured chondrocytes are injected under the periosteal flap and the injected site closed with additional sutures and fibrin glue. Periosteal flap hypertrophy can be a complication in up to 20% of patients. As such, synthetic flaps are beginning to be utilized with good success.[103]

Rehabilitation after ACI is similar to that of other articular cartilage procedures. A balance must be found between protection of the healing tissue and loading of the maturing tissue. The actual progression will vary with the size and location of the defect.[97,101] In general, full unloaded PROM is allowed early on, and the patient will be non–weight bearing or touch-down weight bearing for the first 2 to 4 weeks, with progressive weight bearing over the next 2 to 4 weeks. Weight bearing is performed with axillary crutches and the knee locked in full extension. Full weight bearing without crutches is expected by 6 to 9 weeks. Full passive knee extension is expected immediately, with knee flexion to 90 degrees by week 2 and 130 degrees by week 8.[97,101] Isometrics that do not engage the lesion are initiated and progressed to short-arc isotonic exercises, again, in positions that do not engage the lesion. The pool is an ideal place to initiate and progress activities, particularly gait, weight bearing, and balance activities. Return to activity is anywhere from 6 to 12 months depending upon the lesion, patient factors, and type of activity.

Open Reduction and Internal Fixation

ORIF of a fracture is commonly performed when closed reduction is impossible or when fracture healing would be protracted if treated without fixation. The goals of ORIF are to stabilize a fracture while allowing early motion and activity, to decrease the chances of nonunion, and to decrease the deleterious effects of immobilization on the limb. Surgical fixation may use plates, screws, wires, or other forms of hardware to stabilize the bone and fragments. In most situations, the hardware is left in permanently, although it may be removed in the case of superficial discomfort or loosening after the bone is healed.

Rehabilitation after ORIF is directed at any impairments or activity limitations associated with the injury. Any force great enough to fracture a bone is likely to have produced some local soft-tissue damage, which must be treated as well. Restrictions (e.g., weight bearing, motion) are specific to the location and severity of the fracture and to the extent of associated soft-tissue injury. In general, surgical fixation stabilizes the fracture, and treatment focuses on associated soft-tissue damage and restoration of full function.

Fusion

Fusion is the operative formation of an ankylosis or arthrodesis.[105] Fusions are performed most commonly in the spine, although some joints in the extremities are fused. Spinal fusions are used to treat problems such as instability, facet pain, and disk disease. Glenohumeral joints are fused in cases of severe pain, especially in the presence of neurologic injury (e.g., axillary nerve, long thoracic nerve) that severely restricts functional use of the arm. Knee joints are fused as a last resort when severe arthritis produces pain and disability and total joint replacement is not a treatment option. Fusions about the ankle are used to treat hindfoot pain and arthritis.

The postoperative rehabilitation program must consider the mechanical changes that occur as a result of the fusion. Because mobility is limited at a joint (or series of joints in the spine), adjacent joints compensate to restore the presurgical mobility. How effectively these joints compensate or overcompensate has a profound impact on the result. If the hip and ankle are unable to adequately compensate for a fused knee, the patient has difficulty getting in and out of a car, a chair, and on and off the floor. Because the spine is a series of joints, adjacent segments can often compensate for fusion at one or more levels. However, adjacent segments may become hypermobile in response to the fusion, creating pain above or below the fusion. An important aspect of postoperative rehabilitation is focused on the adjacent joints and procedures necessary to ensure the long-term health of these joints. The muscles must be retrained to function in a new movement pattern.

Osteotomy

Osteotomy, the surgical cutting of a bone, is a procedure performed to correct bony alignment. This procedure is performed most commonly at the knee to correct excessive genu varus or valgus. Excessive varus or valgus places increased loads on the medial and lateral compartments of the knee, respectively. This may result in degeneration of the articular cartilage in that compartment. The purpose of performing an osteotomy is to decrease the load incurred by the compromised compartment and to disperse the load over a larger area. To correct for excessive varus, a high tibial osteotomy (or valgus osteotomy) is performed at the proximal tibia. To correct for excessive valgus, a distal femoral osteotomy is performed. These procedures remove a wedge of bone from the respective site, and the "fracture" is fixated with hardware.

Rehabilitation focuses on the precipitating issues that led to surgery (usually degenerative joint disease) and the preservation or restoration of motion and strength. An important consideration is the change in loading patterns on the articular cartilage. The compartment that has been excessively loaded will have decreased loading; the other compartment that has been underloaded will have increased loading. How well a compartment adapts to the increased load depends on many factors. The health of the articular cartilage in this compartment is probably the most important factor. Weight-bearing activities may have to be restricted until the joint can adapt to this change.

MANAGEMENT OF IMPAIRMENTS ASSOCIATED WITH JOINT ARTHROPLASTY

Joint replacement surgery is performed to remedy significant joint deterioration after other conservative or surgical measures have been exhausted. Joint replacement is performed in many joints, including the hip, knee, glenohumeral joint, elbow, wrist, and carpometacarpal joint in the hand. The chief goal of joint arthroplasty is pain relief. Generally, the patient cannot expect increased joint motion, strength, or function other than that resulting from a decrease in pain.

Joint replacement is categorized by component design (i.e., constrained, unconstrained, or semiconstrained), fixation (i.e., cement or cementless), and materials (i.e., cobalt-chrome alloy, titanium alloy, or high-density polyethylene). A *constrained* design allows motion in only one plane; an *unconstrained* design allows motion in any axis. A *semiconstrained* design allows full motion in one plane and some motion in other planes. Fixation is achieved with cement or with some type of biologic fixative. Biologic fixation may include a porous coat or similar surfaces that allow bony ingrowth into open areas on the surface. Recovery of components with this type of fixation is difficult in the patient in need of revision arthroplasty. Materials usually are a combination of metals and plastic.

In addition to total joint arthroplasty, joint resurfacing procedures are also available. Total surface arthroplasty (TSA) is being performed more routinely at the hip joint. While patients in the past underwent total joint arthroplasty for pain relief, more patients are requesting TSA to improve their quality of life and to remain active. TSA preserves more bone. In the hip procedure, the prosthesis is metal-on-metal, where the acetabulum is lined with a metal cup and the femoral head is capped with a metal prosthesis. Unlike a total hip arthroplasty, the femoral head is not removed in a TSA.

Rehabilitation issues are joint- and prosthesis-specific. In general, restoration of motion, strength, and function and consideration of the underlying cause of the surgery constitute the rehabilitation framework. Unlike a total hip arthroplasty, there are no limitations in hip ROM with a TSA. Consideration must also be given to the adjacent joints, which may be compromised by the same disease process and the excessive loads placed on them in the perioperative period. After recovery from the operation, the patient generally feels much better than before the surgery, with less pain in the affected joint. Education regarding the long-term health of the resurfacing procedure and the adjacent joints is a large component of the patient care program.

KEY POINTS

- The composition and structure of connective tissues provide information about each tissue's mechanical properties and function.
- The unique viscoelastic characteristics of connective tissues are the result of their fluid and solid constituent materials.
- When connective tissues are loaded, the stress (i.e., force per unit area relative to the strain) or change in the length per unit length provides information about the tissue's ability to withstand loads.
- The viscoelastic properties of relaxation, creep, and hysteresis are the physiologic basis for changes seen with stretching.
- The stages of healing along with knowledge of the specific injury provide the clinician with guidelines for intervention selection throughout the episode of care.
- Restoration of normal tissue relationships, optimal loading, the SAID principle, and prevention of secondary complications are broad rehabilitation principles that guide treatment.
- Acute soft-tissue injuries such as sprains, strains, and contusions necessitate early intervention to avoid secondary complications.
- Management of tendon injuries and prognosis varies according to the injury classification.
- Interventions used in the treatment of bony or surgical procedures should have a solid foundation in basic science and require an understanding of the anatomy and kinesiology of the area.

CRITICAL THINKING QUESTIONS

1. Consider Case Study No. 2 in Unit 7, before her total knee replacement surgery. Presume that she came to your clinic 2 years earlier in an attempt to delay surgery. At that time, her motion was decreased by 15%, and her overall strength was decreased by 20%. Describe her exercise program. Provide the rationale for restoration of her joint motion and strength in the case of osteoarthritis of the knee.
2. The patient in the first question is given a home exercise program to carry out for 2 weeks, after which she returns to the clinic for reevaluation and progression.
   a. Explain to this patient how to differentiate the discomfort associated with some exercise from pain that may be related to harming her knee.
   b. Compared with her previous visit, her knee is more swollen and warm to the touch. She has lost 5 degrees of knee extension and 10 degrees of knee flexion. Her gait is significantly impaired. What are your recommendations at this time? When should you see her again and why?
3. Why are repeated eccentric muscle contractions associated with tendinitis?
4. If eccentric muscle contractions contribute to tendinitis, why are they used to treat tendinitis?
5. Consider Case Study No. 6 in Unit 7. How would your acute-phase mobility program differ if the patient
   a. Were generally hypermobile, demonstrating elbow hyperextension, knee recurvatum, and thumb to volar forearm?
   b. Were generally hypomobile, with a history of excessive scar formation?
6. Consider Case Study No. 1 in Unit 7. Previously this patient was seen for nonoperative treatment. Unfortunately, he continued to be symptomatic and unable to return to activity. He underwent arthroscopic debridement of the hip, removing loose bodies, smoothing labral irregularities, and resecting the pathologic cartilage/bone mass. He is now 2 weeks postoperative and sent for rehabilitation. He is to start full weight bearing this week.
   a. What are the key considerations as you initiate his program? Does his previous rehabilitation impact your decision-making?
   b. What signs or symptoms might suggest that the program is moving too quickly? Too slowly?

LAB ACTIVITIES

1. A patient comes to the clinic on a Monday morning with acute Achilles tendinitis after a weekend tennis tournament.
   a. Instruct your patient in a home exercise program, including dosage, to be performed until he or she returns in 4 days.
   b. Explain to your patient about adjunctive agents and give any special instructions.
2. The patient returns 4 days later and is in a subacute phase of injury.
   a. Demonstrate five stretching techniques for the Achilles tendon.
   b. Instruct the patient in a home stretching program, including dosage.
   c. Demonstrate three ways to strengthen this muscle group, including dosage, using
      i. concentric only
      ii. isometric only
      iii. eccentric only
3. This patient has improved with the exercise program and desires to return to basketball. Demonstrate the final phase of the rehabilitation program to prepare the patient for this activity.
4. Instruct each of the following patients on five exercises to increase knee flexion mobility:
   a. A 19-year-old student 2 weeks after a grade II MCL sprain of the right knee with a 0- to 90-degree ROM
   b. A 75-year-old woman who is unable to get up and down off the floor 2 weeks after a total right knee replacement with a 0- to 60-degree ROM

CHAPTER

12 Therapeutic Exercise for Arthritis

LORI THEIN BRODY • KIMBERLY D. BENNETT

PATHOLOGY

An important principle of therapeutic intervention is that treatment should consider the underlying causes of disease as well as the resulting effects on body function and structure, activity and participation (see Chapter 1). This approach necessitates an understanding of the pathology and its relation to broader functional effects in order to guide treatment design, including the choice of intervention, understanding of precautions, and formulations of rational goals.

Arthritis literally means joint inflammation, but there are approximately 100 different types of arthritis (inflammatory and noninflammatory, affecting not only joints but soft tissue as well). Osteoarthritis (OA) and rheumatoid arthritis (RA), two of the most common forms of arthritis, are discussed in this chapter. OA represents a type of nonsystemic, mostly noninflammatory, localized pathology. In contrast, RA is a systemic, inflammatory disease that usually involves multiple joints and often affects organ systems. Because these two diseases have distinctly different pathologic mechanisms, and because of the widespread systemic effects of RA, some of the exercise design considerations vary.

Since many of the same principles of degenerative and inflammatory processes are encountered in the less common forms of inflammatory arthritis, similar thought processes can be applied to developing exercise approaches for patients with these diseases. Effects of the two diseases on joints and related structures are listed in **Table 12-1**.

Osteoarthritis

Etiology

Osteoarthritis is characterized by the breakdown of articular cartilage under load with resultant changes in bone and other soft tissue periarticular structures. The view that OA is the result of passive wearing of cartilage with time is being replaced with an

TABLE 12-1

Effects of Osteoarthritis and Rheumatoid Arthritis on Joint Structure and Function

STRUCTURE	FUNCTION	EFFECTS OF OSTEOARTHRITIS	EFFECTS OF RHEUMATOID ARTHRITIS
Cartilage	Shock absorption, joint congruence	Thickening to softening to thinning to loss	Erosion of cartilage
Synovium	Secretes synovial fluid for nutrition of cartilage, lubrication, and stability	Secondary involvement occasionally	Microvascular lining cells activated by inflammatory process, pannus formation
Ligaments	Stability, reinforce capsule and limit movement, guide movement	Abnormal joint alignment stresses	Erosion weakens
Muscles	Reinforce joint capsule, reflex joint protection, move joints	Immobility shortens; pain causes guarding and reflex inhibition, leading to weakness	Joint deformity interferes with peak torque generation; immobility causes shortening; myositis weakens; pain and effusion cause guarding and reflex inhibition, leading to weakness
Bone	Structural support	Subchondral bone remodeling changes shock-absorbing properties, joint margin spurring leads to bony blockade and pain	Erosion leads to joint deformity, bony blockade, pain
Extraarticular system		Increased energy expenditure from abnormal movement patterns	Myositis, anemia, sleep disruption, fatigue, increased energy expenditure from abnormal movement patterns

increased understanding of the interaction of biomechanical and molecular events which produce osteoarthritic changes, though there is a highly positive correlation of incidence with age.[1,2]

Clinical Manifestations

Osteoarthritis typically affects weight-bearing joints and joints of the hand, is usually unilateral, and often unicompartmental; it has no direct systemic effects.

The pathologic changes in OA reflect damage to the articular cartilage and the joint's reaction to that damage. Cartilage damage diminishes the joint's ability to withstand loading forces which further stresses the articular cartilage, leading to tissue damage that can result in low-grade synovial inflammation. If chronic, inflammation can lead to fibrosis of the joint capsule and resultant range restriction. Hypertrophic bone formation at joint margins (i.e., marginal spurring) leads to joint deformity and pain (**Fig. 12-1**).

Extraarticular soft-tissue structures are affected by asymmetric joint deformity which in turn further affects joint function. A common example of this imbalance is seen in the osteoarthritic knee. Lateral compartment cartilage loss results in a valgus deformity of the knee, which stretches muscles and ligaments medially and shortens soft-tissue structures laterally. In addition to affecting alignment of the knee and weight bearing through the joint, the deformity changes the mechanical advantage of medial and lateral muscle groups and the stability of the joint as stretched ligaments become lax. Joint pain and swelling, together with splinting and guarding, can lead to muscle disuse atrophy and loss of this important component of the shock-absorbing system. Significant functional deficits can develop as these clinical changes progress. In running, the tibiofemoral joint experiences forces 2.5 to 3.0 times body weight[3] and in deep knee bends, the patellofemoral joint is exposed to forces 10 times the body weight. Impairment of the joint elements responsible for efficient shock absorbing will in turn lead to further joint breakdown during activity.

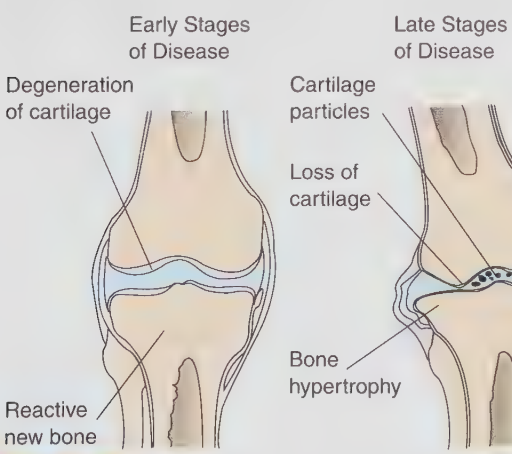

FIGURE 12-1 Osteoarthritis starts with asymmetric cartilage loss, which leads to abnormal forces on the joint. Soft-tissue imbalance, joint malalignment, and bony hypertrophy can result. Inflammation is not the major component of the osteoarthritis process. (Adapted from AHPA Arthritis Teaching Slide Collection. American College of Rheumatology, Atlanta, GA.)

Although cartilage failure may be the primary event in OA, the overall effect of the disease is rarely confined to the involved joint.[4] Patients with OA in the lower limb demonstrate impairments in adjacent and contralateral joints. In attempting to improve overall function, the exercise program should focus on impairments at the affected joint and on secondary impairments and activity limitations at associated joints caused by the primary impairments and by inactivity (see **Building Block 12-1**).

BUILDING BLOCK 12-1

A 65-year-old male is referred to therapy with complaints of left (L) knee pain. Since his recent retirement, he has spent three mornings a week at a driving range, and two times a week playing 18 holes of golf. He thinks his knee pain has gotten worse since his retirement when he was more sedentary. In addition to making it difficult for him to participate in his normal weekly golf game with friends (he is now limited to nine holes and that is getting painful enough that he is thinking of stopping altogether), he is finding it increasingly difficult to get up and down stairs, or to sit down and get up from a low chair due to pain and a perception of weakness in his L leg.

He takes no medication, reporting to you that though his doctor has told him to take an over the counter anti-inflammatory, he has chosen not to as he doesn't believe in medicine and especially doesn't want to become dependent on pain medication.

Review of systems shows a moderately hypertensive individual, who is overweight. His radiology report states that there is marked cartilage degeneration in the left medial compartment of the tibiofemoral joint which is apparent in the varus angle of his L knee compared to right (R). He recently noted that when he is on his feet a lot, his R knee can bother him as well. His doctor has suggested increased activity for both weight and hypertension control.

1. Which joints should be examined in the initial evaluation of this patient?
2. What tests should be performed in this examination?
3. Write a problem list based on the information in this case including at least two impairments of body structure or function, two for activity, and two for participation restrictions.

Rheumatoid Arthritis

Etiology

Rheumatoid arthritis is a disease of unknown etiology characterized by chronic, erosive synovitis in which an immune event triggers transformation of synovial cells causing them to proliferate. RA affects approximately 0.05% to 1% of the world population with geographic and racial variations.[5] An invasive, fibroblast-like cell mass called pannus develops and erosion of cartilage and bone follows. Synovial fluid accumulates, and the joint swells, distending the capsule, pulling on its periosteal attachment, and causing pain and potential rupture. Ligaments and muscles around the inflamed joint are also subject to weakening and potential rupture. The precise cause of RA is unknown, but appears to be an interplay between genetics and environmental factors[6] (**Evidence and Research 12-1**).

EVIDENCE and RESEARCH 12-1

Studies of twins suggest an underlying genetic susceptibility in RA that may be triggered by environmental factors, within a framework of chance.[6,7] The extraarticular manifestations of RA implicate other systems in the etiology as well as the clinical presentation. Smoking and other forms of bronchial stress have been linked to RA, as has periodontal disease, the hypothalamic-pituitary-adrenal axis, the gastrointestinal microbiota, and infectious agents such as Epstein–Barr virus.

Diagnosis

Laboratory tests for diagnosis of RA often have limited sensitivity and specificity, high levels of false-positive and false-negative results, and a lesser capacity than patient self-report questionnaire scores to provide a sensitive measure for documenting future improvement, recognizing incomplete responses, and predicting work disability and premature mortality. Laboratory tests are useful in many patients and essential in a few, but physicians and patients often attribute disproportionate importance to laboratory tests in rheumatic diseases.[8] Clinical decisions in RA are recognized to be guided primarily by a patient history and physical examination in contrast to other chronic diseases, in which clinical decisions are guided by biomarkers such as blood pressure, laboratory tests, or imaging studies.[9] However, the only quantitative data in the medical records of many patients with RA in usual care are laboratory tests. This practice reduces the capacity to monitor, recognize, and document clinical improvement or deterioration in patient status according to quantitative data. Laboratory tests may not detect serum abnormalities unless their presence is related to another disease process. The rheumatoid factor test is generally negative. If the rheumatoid factor is found in the serum of older patients, its presence may be unrelated to the arthritis because false-positive results for rheumatoid factor increase with age in the normal population[10–12] (**Evidence and Research 12-2**).

EVIDENCE and RESEARCH 12-2

Analyses of 287 patients with RA seen in three clinical care centers indicated that at presentation elevated erythrocyte sedimentation rate (ESR) was abnormal in 57% and C-reactive protein (CRP) in 58% of patients.[10] By contrast, scores on a patient questionnaire were abnormal for physical function in 70% and pain in 89% of patients.[10] Self-report scores have been found to be as responsive to change over time as any of the RA Core Data Set measures.[11,12] Core Data Set for assessment of RA includes seven measures: three from the physical examination—swollen joint count, tender joint count, and physician estimate of global status; three from the patient history information—physical function, pain, and patient estimate of global status; and one laboratory test—ESR or CRP.[13] Criteria for measurement is continuously changing based upon new outcome measures.[14] There is no statistical advantage to joint counts or laboratory data versus patient questionnaire or global estimate data on the basis of relative efficiencies. The most specific measures are not necessarily the most sensitive or efficient measures to distinguish active from placebo treatments. Furthermore, patient self-report questionnaire data are the most feasible and cost-effective measures in terms of time and resources for the medical system.[15] Therefore, a strong case could be made that scores for physical function and pain, although only indirectly related to pathophysiologic mechanisms, are at least as valuable as ESR to monitor the clinical status of patients with RA.

Clinical Manifestations

Loss of cartilage and bone integrity, soft-tissue disruption, and swelling lead to joint dysfunction as they do in OA, but often the deformities are more severe, and usually the entire joint is affected rather than just one joint compartment (**Fig. 12-2**). As the disease becomes more chronic, contralateral joints are affected. The joint changes are usually reversible if the disease remits within 1 year and no structural deformity has occurred. Early diagnosis and intervention with newer pharmaceuticals and an emphasis on education regarding joint protection strategies is important as irreversible changes usually occur between the first and the second year in more chronic forms of RA.[6]

Classification of RA and subsequent treatment choices have evolved and changed over time. Patients diagnosed with RA prior to the mid-1980s were typically treated with the least aggressive pharmacologic agents first, often starting with nonsteroidal and

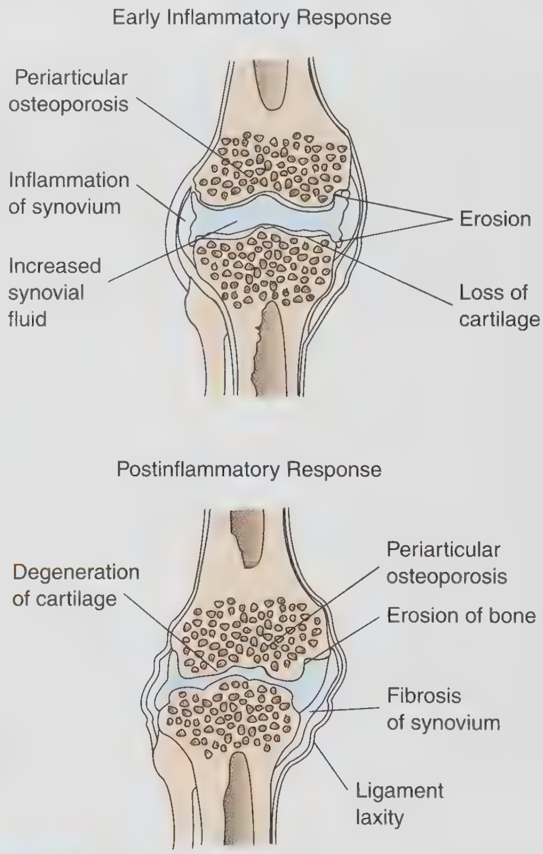

FIGURE 12-2 Early inflammatory joint response to rheumatoid arthritis includes pannus formation and erosion of cartilage and bone. Postinflammatory irreversible joint changes include destruction of cartilage, bone, and soft tissues and fibrosis of the joint capsule. Damage affects joint alignment, stability, and ROM. (Adapted from AHPA Arthritis Teaching Slide Collection. American College of Rheumatology, Atlanta, GA.)

then steroidal medications followed eventually by cytotoxic drugs like colloidal gold. As newer cytotoxic and biologic drugs aimed at interfering with immune system events leading to joint damage became available, this approach changed and patients diagnosed in the 1990s and later were typically treated with steroidal and cytotoxic drugs immediately. Therefore, patients with disease onset prior to the 1980s may have more extreme joint deformities as once joint deformities are present, they are not reversible. The newer approach is aimed at minimizing joint deformity in the patient with RA upon the onset of the disease.

Additionally, the 1987 criteria for diagnosis of RA focused on identifying patients with clearly established RA, and therefore missed patients in the early stages of disease, when disease-modifying treatments would be most effective.[16,17] The American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) worked together to develop a new classification system, which was released in 2010. A comparison of the classifications can be found in **Table 12-2**.[5,16,18] **Display 12-1** summarizes the classification of RA progression. Unlike OA, RA has systemic effects such as fatigue, malaise, anemia, and sleep disorders (i.e., pain and abnormal sleep cycles). Nearly 40% of patients develop extraarticular manifestations while 15% develop severe extraarticular problems at some point.[19,20] Organ systems, including lungs and the cardiovascular system, may also be affected. Medications used to treat RA may contribute to myositis, gastrointestinal distress, and sleep disruption. These systemic effects should be considered in designing exercise programs for the patient with RA. Some of the extraarticular manifestations of RA can be found in **Table 12-3**.

The course of RA is variable and characterized by exacerbations (i.e., flares) and remissions. During a flare, joints are hot and swollen, morning stiffness is present and often lasts longer than 60 minutes, and systemic effects may be more obvious. This is considered an *acute phase* of the disease. As the pain, swelling, systemic effects, and morning stiffness decrease, the disease state is considered to be *subacute*. Between exacerbations, the disease state is considered *chronic*.

The clinician needs to consider the phase of RA when designing an exercise program. After prolonged inflammation, synovial membranes fibrose, decreasing the vasculature such that joints may not appear hot and swollen. These are referred to as burned-out joints. Although it may appear that the disease has gone into remission (i.e., the subacute or chronic phase) and has ceased to damage the joint, the joint destruction and systemic effects continue, and the disease state remains active.

Because symptoms wax and wane, the type and intensity of appropriate exercise also varies. *Be sure to consider the phase of RA when designing an exercise program, and teach patients how to modify the program to match the phase of their illness* (see **Building Block 12-2**).

TABLE 12-2

Comparison of the 1987 Revised Classification of Rheumatoid Arthritis with the 2010 ACR/EULAR Classification

1987 CLASSIFICATION[a]	2010 CLASSIFICATION[b]
Morning stiffness in and around joints lasting at least 1 hr before maximal improvement for at least 6 wk	Number and sites of joints involved (score 0–5)
Soft-tissue swelling of three or more joints for at least 6 wk observed by a physician	Serologic abnormality (score 0–3)
Swelling of the PIP, MCP, or wrist joints for at least 6 wk	Elevated acute-phase response (score range 0–1)
Symmetric swelling for at least 6 wk	Symptom duration (2 levels; range 0–1)
Rheumatoid nodules	
+ Rheumatoid factor	
Radiographic erosions and/or periarticular osteopenia in hand and/or wrist joints	

[a] Classified as definite RA with a score of at least 6 and: confirmed presence of synovitis in at least one joint and absence of an alternative diagnosis that would better explain the synovitis. From Aletaha D, Neogi T, Silman AJ, et al. 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative. Arthritis Rheum 2010;62(9):2569–2581.

[b] Classified as RA when when four or more criteria are met. From Arnett FC, Edworthy SM, Bloch DA, et al. The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. Arthritis Rheum 1988;31(3):315–324.

PIP, proximal interphalangeal joint; MCP, metacarpal-phalangeal joint.

DISPLAY 12-1

Classification of Progression of RA

Stage I, Early

*1. No destructive changes on roentgenographic examination
2. Roentgenologic evidence of osteoporosis may be present

Stage II, Moderate

*1. Roentgenologic evidence of osteoporosis, with or without slight subchondral bone destruction; slight cartilage destruction may be present
*2. No joint deformities, although limitation of joint mobility may be present
3. Adjacent muscle atrophy
4. Extraarticular soft-tissue lesions, such as nodules and tenosynovitis, may be present

Stage III, Severe

*1. Roentgenologic evidence of cartilage and bone destruction in addition to osteoporosis
*2. Joint deformity, such as subluxation, ulnar deviation, or hyperextension, without fibrous or bony ankyloses
3. Extensive muscle atrophy
4. Extraarticular soft-tissue lesions, such as nodules and tenosynovitis, may be present

Stage IV, Terminal

*1. Fibrous or bony ankyloses
2. Criteria of stage III

**The criteria prefaced by an asterisk are those that must be present to permit classification of a patient in any particular stage or grade.*

From Schumaker HR Jr, ed. Primer on the Rheumatic Diseases. 10th Ed. Atlanta: Arthritis Foundation, 1993:188–190.

TABLE 12-3

Extraarticular Manifestations of Rheumatoid Arthritis

- Vasculitis/athergenesis, stroke
- Neuropathy
- Pleuritis
- Pericarditis/myocardial infarction
- Secondary Sjogren's syndrome
- Eye disease
- Osteoporosis/osteopenia
- Sarcopenia
- Fatigue, cognitive dysfunction
- Feity's syndrome

Clustering of extraarticular manifestations in patients with rheumatoid arthritis. J Rheumatol 2008;35(1):179–180; Picerno V, Ferro F, Adinolfi A, et al. One year in review: the pathogenesis of rheumatoid arthritis. Clin Exp Rheumatol 2015;33(4):551–558.

BUILDING BLOCK 12-2

1. List at least three characteristics of RA that distinguish it from osteoarthritis.
2. List three special considerations in designing an exercise program necessitated by the clinical manifestations of RA.

In addition to the local pathologic changes caused by both RA and OA, the resulting joint pain and effusion in both diseases trigger protective and reflex spasm and immobility. Immobility leads to further muscle atrophy and loss of normal protective reflex responses.[3,21] Immobility combined with non-weight bearing contributes to cartilage breakdown, aggravating the condition. Diminished joint complex integrity can also lead to movement patterns that are energy inefficient, limiting activity in an already fatigued patient. For these reasons and because of the effects of low-dose steroids on muscle[22] and the destructive effect of myositis in RA, muscles often atrophy significantly. Type II fiber deficits occur in patients with RA and OA,[23,24] and isometric strength deficits have been reported for these patients compared with controls.[21,25–27] These impairments underlie the development of functional deficits as patients find it more difficult, painful, and less efficient to move. The combination of fatigue, pain, decreased activity and systemic effects can lead to early mortality in patients with RA.[28] Exercise correctly prescribed can address impairments and functional deficits.[29–31]

Various classifications have been useful in guiding exercise prescription and in teaching patients to monitor and appropriately modify their home programs and activities of daily living (ADLs). In the classification of functional status proposed by the ACR, patients are divided into four groups based on their ability to perform self-care, vocational activities, and avocational activities (**Display 12-2**). Most exercise program studies that looked at exercise effects considered patients in functional class I, II, and occasionally, III.

Another classification scheme that may guide the therapist in exercise program design examines the radiologic and clinical evidence of disease progression (see Display 12-1 and **Building Block 12-3**).

DISPLAY 12-2

Classification of Functional Status of Patients with RA*

Class I: Completely able to perform usual ADLs (self-care, vocational, and avocational)*
Class II: Able to perform usual self-care and vocational activities, but limited in avocational activities
Class III: Able to perform usual self-care activities, but limited in vocational and avocational activities
Class IV: Limited in ability to perform usual self-care, vocational, and avocational activities

**Usual self-care activities include dressing, feeding, bathing, grooming, and toileting. Avocational (recreation, leisure) and vocational (work, school, homemaking) activities are patient desired and age- and sex-specific.*

From Hochberg MC, Chang RW, Dwosh I, et al. The American College of Rheumatology 1991 revised criteria for the classification of global functional status in rheumatoid arthritis. Arthritis Rheum 1992;35:498–502.

BUILDING BLOCK 12-3

RA-1

A 54-year-old woman with a 30-year history of RA is referred to therapy with complaints of pain, weakness, fatigue, and an increasingly difficult time doing her half time job as a computer programming instructor, her house work, and cooking due to these factors. She lives with her husband in a one-story house with five stairs with railing to enter the house. Her adult children live out of state; her husband does most of the heavy work around the house and is not currently working due to a job layoff, so they depend on her job for health insurance.

Her RA was originally treated with nonsteroidal anti-inflammatories, followed by steroidal treatment then colloidal gold, and finally with methotrexate. She has joint deformities in the feet, hands, knees, and elbows. She has had multiple tendon transplants and fusions in her feet, tendon transplants in her hand, and has both elbow and knee ligament laxity. She reports that with the onset of the gold treatment and then methotrexate, the progression of joint deformities stopped. She continues to take methotrexate.

Her main complaint at this visit is bilateral shoulder pain, difficulty driving due to shoulder pain when holding and turning the wheel, and neck and shoulder pain when she turns her head. She is having increasing shoulder pain at the end of a work day.

Review of systems is unremarkable except for slight hypotension, and increased respiratory and heart rate (HR) from resting rates of 12 and 72 respectively to 20 and 90 after walking 200 ft. Gait is inefficient with hip hiking and trunk rotation initiating swing phase and lumbar hyperextension with rollover to toe-off phase of gait.

RA-2

The patient is a 32-year-old, right (R) hand dominant female competitive tennis player. She was diagnosed 3 years ago with RA following episodes of pain and swelling in bilateral (B) hands and feet. She was started initially on prednisone and methotrexate. Prednisone was then withdrawn as methotrexate took effect. She presents today with complaints of R elbow pain while playing tennis and as well

(continued)

BUILDING BLOCK 12-3 (*continued*)

as pain when using her arm at home for cooking and gardening. No other joint pain is reported except occasional brief twinges of left (L) elbow pain. She has not played tennis in 6 months and has stopped all gym exercise due to fear of aggravating her symptoms.

She has been taking methotrexate since the RA was diagnosed and had a cortisone injection to the area of the common extensor tendon origin 3 weeks ago. This gave her about 50% relief of pain at rest, but with any use, symptoms flare again. She takes no other medication and has no other significant medical history.

R medial and lateral epicondylar provocation testing is positive. R elbow and wrist range of motion (ROM) is normal though she complains of tightness with both wrist flexion and extension and palpation is positive for pain in both flexor and extensor muscle groups. Mild joint laxity is present with varus and valgus testing R > L elbow. The R elbow joint is warmer than the L per palpation.

Her goal is to return to doubles tennis and to household tasks including cooking and gardening, pain free.

1. For the patients listed in cases RA-1 and RA-2, write out instructions to give them to recognize when they may be entering a stage of acute inflammation (either autoimmune- or activity-triggered) and what their actions should be.
2. To which functional class does the patient in case RA-1 belong? The patient in case RA-2?

EXERCISE RECOMMENDATIONS FOR PREVENTION AND WELLNESS IN OA AND RA

There is no direct way to prevent RA. On the other hand, the literature suggests that certain factors including obesity, trauma, hypermobility, and inflammation correlate with the development of OA.[28] An exercise regimen aimed at maintaining appropriate body weight, sustaining good postural alignment, developing good muscular strength and length, and correctly using joints in ADLs may be logical and desirable for joint protection. Because OA has a genetic basis in some persons and, in some cases, is correlated with trauma, infection, and inflammation, exercise is not a guarantee against developing OA. A well-designed therapeutic exercise program can remediate the impairments and activity limitations associated with arthritis and reduce the impact of risk factors for disease progression. Despite this, many individuals with RA are inactive according to recommended standards.[28] Intervention includes assessing and treating impairments and resulting functional losses in an attempt to avoid disablement, within the framework of associated comorbidities and barriers to participation.

THERAPEUTIC EXERCISE INTERVENTION FOR COMMON IMPAIRMENTS

Exercise programs to address common impairments and activity limitations affecting a person's ability to function in society are necessary. A recent review of randomized controlled studies on the effect of water exercise on hip and knee OA showed positive short-term effects on function, quality of life, and pain[29] (**Evidence and Research 12-3**). Ongoing exercise is of particular importance in patients with RA who are twice as likely to suffer from cardiovascular disease.[32] Importantly, these patients must also learn to pace their activities due to the cyclical nature of RA flares.

EVIDENCE and RESEARCH 12-3

A large study of 220 participants determined the effect of aerobic exercise on symptoms, function, aerobic fitness, and disease outcomes in patients with RA at 1, 6, and 12 weeks. Positive effects were found on walk time and grip strength; overall fatigue, pain, and depression symptoms were positively influenced. There was no finding of increased disease activity with exercise.[30] A study[31] of the effect of short-term intensive training in posthospitalization patients with RA or following joint replacement in patients with OA showed long-term (52 week) gains in ROM and self-reported function. Training was physiotherapist led and consisted of mobility, strength, aerobic and functional activities. A Cochrane review of dynamic exercise programs focusing on muscle strength and/or aerobic capacity found positive short- and long-term effects of this exercise with no deleterious effects noted.[33]

In OA, the goal of treatment is to decrease pain and any inflammation which is present, to restore normal joint mobility, to improve muscle function, and to reestablish normal movement patterns throughout the kinetic chain. Any adaptive changes in joints proximal, distal, or contralateral to the affected joint and its surrounding structures must also be addressed. Performing basic functional tasks (e.g., sit to stand to sit, balance, timed walking, performing household, vocational, and recreational activities) and optimizing cardiovascular fitness are the tasks of an exercise program designed for a patient with OA (**Fig. 12-3**).

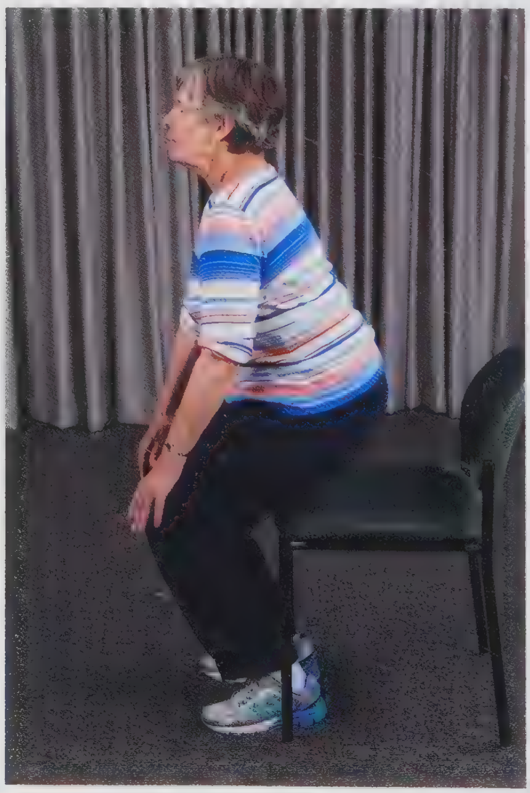

FIGURE 12-3 Sit to stand from chair.

FIGURE 12-4 Manual dexterity assessments.

For patients with RA, exercise program considerations are largely those outlined for OA, but because of the variability of its course and the possible systemic involvement of the disease, careful monitoring by the physical therapist and the patient is necessary. Patients must be taught to recognize symptom development and the stage of the illness and how to modify activity appropriately.

The patient with arthritis typically presents with pain, mobility impairment, imbalances in muscle length, and faulty movement patterns, all of which contribute to impaired muscle performance, and cardiovascular endurance impairment. The clinician must evaluate these factors bilaterally throughout the entire extremity kinetic chain and the trunk. It is equally important to look at functional movement patterns, including gait, stair negotiation, sit to stand to sit, and manipulation of tools and the environment when hands are involved (**Fig. 12-4**).

The exercise program must carry the effects of therapy beyond treatment of a localized joint problem to issues of function in an attempt to reverse the disablement process. In planning an exercise regimen, impairments at the primary joint and secondary impairments and activity limitations must be addressed. Limitations may occur along a continuum of function, ranging from deficits in high-level athletic performance to an inability to perform self-care activities.

The aims of treatment are to decrease impairment while improving function. Functional improvement includes ADL and instrumental ADL performance and improved muscle and cardiovascular conditioning. Incorporate functional activities into the exercise routine to ensure that functional skills are mastered and carried into daily life. Protect affected joints during exercise and during functional activities (see **Building Block 12-4**).

BUILDING BLOCK 12-4

1. Write a problem list including at least two impairments to body function or structure; two activity limitations, and two participation restrictions for cases RA-1 and RA-2.
2. Write one goal for the patient in each case addressing activity and participation deficits.

Pain and Fatigue

Pain and fatigue are significant impairments found in patients with arthritis, particularly those with RA. Fatigue in patients with RA is multidimensional, including physical, emotional, environmental, and personal factors.[34] In addition to its relation with pain, fatigue in RA is also associated with anxiety, depression, reduced self-efficacy, disturbed sleep and impaired social functioning.[35] Although physical therapists generally address physical factors, understanding associated factors is critical for successful program design (**Evidence and Research 12-4**).

EVIDENCE and RESEARCH 12-4

In a review of the relationship between RA and fatigue, Nicklaus et al.[34] found that causes of fatigue can be related to: illness-related aspects (i.e., pain, disease activity markers, comorbidities, symptoms, disease duration), physical functioning (i.e., sleep disturbance, disability measures), cognitive and emotional issues (i.e., depression), social and environmental factors (i.e., interpersonal events, social support), demographics (i.e., sex) and baseline fatigue levels. Models of this relationship have been suggested but none validated.

Be sure to minimize pain during therapeutic exercise because pain may lead to other impairments. Joint pain and swelling together with splinting or guarding can inhibit periarticular muscle function, lead to disuse atrophy, suppress the normal protective reflex response, and cause further cartilage breakdown.[3,21,36,37] These changes can lead to inefficient movement patterns, thereby decreasing cardiovascular endurance and further limiting activity. The changes may also disrupt the soft-tissue balance around the joint, affecting its stability, alignment, and active motion. When a joint is abnormally aligned, muscles can no longer generate peak force, contributing to strength deficits.

Studies have examined the effects of exercise on arthritis[38,39]; the use of exercise to restore muscle balance and joint range for cardiovascular conditioning and to improve functional status was associated with no increase in pain in some studies and with a decrease in pain in others.[26] Patients often present with some degree of pain in the affected joints, which may prevent exercise to the full extent possible or signal the presence of an inflammatory process. In either case, revising or modifying the exercise program can maximize patient participation, which could potentially control the inflammatory processes.[33] Any exercise-induced pain necessitates modification of the exercise.

Exercise Modification in Response to Pain and Fatigue

Systemic deconditioning, muscle weakness, joint irritability, and cardiorespiratory disease are common in patients with inflammatory arthritis and necessitate ongoing evaluation of the patient's response to treatment to ensure appropriate and timely modification of the exercise prescription. Irreversible joint changes (i.e., cartilage loss, bony deformity, or ligament

laxity) together with systemic symptoms (i.e., fatigue, reduced cardiovascular capacity) require modification of exercise to avoid worsening joint irritation or undue fatigue.
Importantly:

- Modify or avoid any exercise that increases joint pain.[40,41]
- Teach the patient to differentiate between muscle reaction to exercise and joint pain.
- Undue fatigue after exercise in deconditioned patients indicates a need to further modify the exercise prescription. Keep in mind that fatigue can be either systemic or exercise-induced, or both.
- Instructions to the patient with a rheumatic disease should include sleep and rest guidelines.[42]

Compliance with exercise programs increases when exertion and pain are within acceptable limits for the patient.[27,38] The patient's reaction to exercise should be carefully monitored, and self-monitoring skills should be taught as an essential element of the therapy program (see **Building Block 12-5**).

BUILDING BLOCK 12-5

1. Each of the patients in cases OA, RA-1, and RA-2 have been prescribed an exercise routine at their first visit. List at least two questions important to ask all of them at the beginning of their second visit regarding the routines.
2. The following scenarios exist during the second visit. List your response to them:
   a. In case OA, the patient noted increased pain with the exercise routine prescribed at the last visit.
   b. In case RA-1, the patient reported no increase in shoulder pain, but an overall increase in fatigue in general and especially when she had a few late nights staying up to do her physical therapy exercises, after completion of the rest of her household chores.
   c. In case RA-2, the patient admits she didn't do her exercises.

Impaired Mobility and ROM

Osteoarthritis and RA often contribute to mobility impairment. ROM can be diminished by several factors:

- Stiffness and shortening of muscles or tendons from spasm, guarding, or habitual postures
- Capsular stiffness or contracture
- Loss of joint congruity because of bony deformity

These conditions lead to muscle imbalances that can initially limit joint mobility and lead to joint contractures and muscle weakness affecting the entire limb; this can spiral into affecting the whole body. Be aware of the muscle groups most typically affected by OA and RA in specific joints. Muscle shortening leads to weakness and joint malalignment. For example, in hip OA, hip flexor shortening and hip flexor and extensor weakness are common (**Table 12-4**; **Fig. 12-5**). A thorough musculoskeletal evaluation should indicate which of these factors are present. Consider which of these ROM impairments are amenable to physical therapy intervention and can lead to functional improvement. These are the only mobility impairments that should be addressed in goal setting.

When goal setting, consider that cartilage maintenance depends in part on joint movement.[36] Design passive, active, and active-assisted ROM exercises to ensure that affected joints move through the full range available to them. When possible, choose exercises that will increase the working ROM so that loads can be distributed over a larger articular cartilage surface area thereby decreasing focal loads.

Passive ROM is rarely necessary, except in cases of acute joint exacerbation or of severe muscle weakness and inflammation in RA. These patients may need some combination of rest and light activity. Perform one or two repetitions of gentle passive movement through full available range each day to avoid contracture and to ensure maintaining full ROM. Too many repetitive passive ROM movements may increase joint inflammation.[40] For patients in all classes of RA or who have OA, perform active ROM exercises daily for affected joints.[43]

When weakness prevents the patient from attaining full ROM, assistance from another person or another limb may be required to achieve full available range. Typically, patients start with one to five repetitions and progress to performing 10 repetitions daily.

When **muscle shortening** is the cause of range limitations, passive stretch controlled by the patient or clinician may be provided as long as the joint is stable. Considerations outlined in Chapter 7 regarding stabilization of proximal and distal attachment sites to avoid stressing joints above and below the target muscle are especially important in this population. In patients with RA for whom the integrity of muscle, tendon, or ligament is in question (especially in smaller joints), *gentle* active ROM exercises are preferable. As a safety measure, it is important that the patient be safely positioned while performing active ROM exercises to ensure they do not fall, lose control of a limb, or apply more force than is intended.

Ligament laxity can occur in the cervical spine of patients with RA, and special considerations, especially for stretching exercises, apply. A more detailed description of these precautions is given in the section "Precautions During Strengthening Exercises When Ligament or Capsular Laxity Exists."

Patients who have RA with prolonged morning stiffness or OA with brief morning stiffness (<0.5 hour) may benefit from instruction in a ROM and stretching routine targeting the stiff areas. This exercise can be done before retiring at night, in the morning after a warm shower, or during both periods.

Instruct the patient in self-mobilization techniques as part of a home exercise program in cases of OA in which capsular restriction limits movement but no acute joint irritation or bony block exists[44] (see **Self-Management 12-1**). Capsular stiffness in patients with RA often results from joint distension, and further distractive forces on this inflamed and often weakened tissue should be avoided. When stability is good, passive application of grade 1 oscillations by a skilled therapist to relax periarticular spasm and gate pain prior to performing passive or active ROM activities may be beneficial (see Chapter 7).

TABLE 12-4

Common Patterns of Joint Restriction in Osteoarthritis and Rheumatoid Arthritis

JOINT	RESTRICTION	STRETCH	STRENGTHEN
Hip (OA/RA)	■ All planes, especially internal rotation and extension	■ Flexors ■ Extensors ■ Internal and external rotators ■ Tensor fascia lata	■ Abductors ■ Extensors
Knee (OA/RA)	■ Extension	■ Hamstrings (quadriceps)	■ Quadriceps
Ankle and foot (RA)	■ Ankle dorsiflexion ■ MTP flexion ■ PIP extension	■ Ankle dorsiflexors and plantarflexors ■ Tarsal invertors and evertors ■ Toe flexors and extensors	■ Toe extensors and flexors ■ Tibialis posterior ■ Abductors
Shoulder (RA)	■ Abduction ■ Flexion ■ External and internal rotators	■ Careful in deranged joints ■ PROM, AAROM, AROM	■ External rotation ■ Biceps ■ Triceps
Elbow (RA)	■ Extension lost early	■ Careful in deranged joints ■ PROM, AAROM, AROM	■ Biceps ■ Triceps
Hand and wrist (RA)	■ MCP extension ■ Wrist extension ■ First web space	■ Careful in deranged joints ■ ROM wrist daily ■ Stretch wrist flexors and extensors, forearm pronators and supinators, hand intrinsics	■ Finger extensors ■ Wrist extensors

AAROM, active assisted range of motion; AROM, active range of motion; MCP, metacarpophalangeal joint; MTP, metatarsophalangeal joint; OA, osteoarthritis; PIP, proximal interphalangeal joint; PROM, passive range of motion; RA, rheumatoid arthritis; ROM, range of motion.

Osteoarthritis: clinical features and treatment. In: Schumaker HR Jr, ed. Primer on the Rheumatic Diseases. 10th Ed. Atlanta: Arthritis Foundation, 1993:188–190.

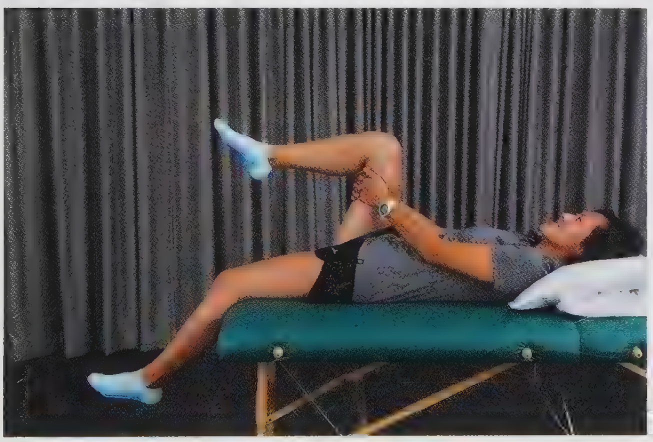

FIGURE 12-5 Hip flexor stretching with protection of lumbar spine, contralateral and distal limb.

Impaired Muscle Performance

The same forces which lead to ROM losses affect, and can in turn be affected by, muscle imbalances which occur around the involved joint or joints.

Strengthening of weakened muscles is an important part of regaining muscle balance around the joint. Strengthening can be done isometrically, isotonically, or isokinetically (see Chapter 5). Each form of exercise has its place in rehabilitation of patients with arthritic joints, depending on the state of the joint. Isokinetic equipment is most readily available in a clinical setting and is not likely to be practical for independent exercise programs; it is not discussed here (see **Building Block 12-6**).

SELF-MANAGEMENT 12-1
Self-Mobilization of the Shoulder Joint

Purpose: To stretch the tight capsule and muscles around the shoulder, which are limiting movement

Position: Sit on a straight-back chair as shown, with a folded towel padding your arm.

Movement Technique: Let your arm hang down.

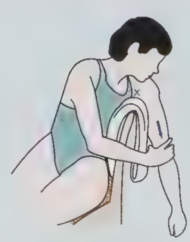
Grasp it just above the elbow with your opposite hand.

Repeat a gentle, rhythmic series of downward tugs, trying to keep your shoulder muscles relaxed.

Dosage:

Repetitions: ______________________

Frequency: ______________________



BUILDING BLOCK 12-6

1. The patient in the case OA has demonstrated loss of both active and passive ROM of L knee extension with end range pain. What objective tests should be used to determine the source of this restriction?
2. An exercise routine to address soft-tissue restrictions around the knee has been prescribed. What protective guidelines should be provided to the patient?
3. The patient in case RA-1 complains of morning pain and stiffness "all over." What recommendations should be provided to them?
4. The patient in case RA-1 is bed bound with an acute flare of symptoms. There is concern about maintaining her shoulder ROM. What instruction should be given to a family member caring for her? How would advice differ if her finger joints were involved?
5. Both patients in cases OA and RA-1 are found to have capsular tightness affecting joint ROM. How should the recommendations to them differ from case RA-2?

Isometric Exercise

Isometric exercise is most appropriate when acute flares in OA and RA occur, but use caution to avoid increased intraarticular inflammation.

Isometric Exercise in RA Patients with acute exacerbations of RA:

- Are supporting and limiting use of the involved joint(s)
- Are positioned to prevent deformity
- May have one or two daily applications of passive ROM applied to large joints
- May have one or two daily applications of active ROM applied to small joints

In this stage, preventing muscle atrophy is important. Muscle strength declines significantly in patients on bedrest[45] (**Evidence and Research 12-5**). Because it appears that isometric contractions are associated with the least joint shear and intraarticular pressure increases,[46] this form of exercise is often prescribed in the acute and subacute phases of the disease. A single isometric contraction at two-thirds of maximal effort, which is held for 6 seconds, increases strength in a non-impaired individual; three maximal contractions, with 20-second rest periods, performed three times each week increase strength in patients with RA.[40,47] However, maximal isometric contraction raises blood pressure and may increase joint pain; therefore, consider performing isometric contractions at a submaximal level.

EVIDENCE and RESEARCH 12-5

Ten days of bed rest resulted in a significant reduction in knee extension one repetition maximum strength, knee extension performance at 60 degrees per second, and isometric knee extension strength.[48] Drummond et al.[49] found 7 days of bed rest to decrease leg lean mass by 4% and to increase the body's ability to mount an exaggerated inflammatory response. Functionally, patients demonstrated decreased stair climbing ability, maximum aerobic capacity, floor transfer test, 5-minute walk time, and chair stand.[48]

As a means of increasing muscle strength without raising blood pressure significantly, Gerber and Hicks[50] described a program of brief isometric exercise (BRIME) of one to six isometric contractions, held for 3 to 6 seconds, with 20-second rests between contractions (see **Self-Management 12-2**).

Isometric contractions performed at one joint angle only strengthen the muscle at that specific angle.[51] For this reason, repetitions at various angles may be desirable (see Chapter 5). During an acute exacerbation of arthritis, it may be necessary to limit contraction to one joint angle to avoid stressing the joint.

Isometric Exercise in Osteoarthritis In the acutely painful osteoarthritic joint, especially if there is significant inflammation and swelling, intraarticular pressure and shear forces should be limited while preventing muscle atrophy. Isometric contractions are often the exercise of choice in this stage. The same considerations apply as for the patient with RA. Brief intense isometric exercises are appropriate when controlling blood pressure is an issue (see **Selected Intervention 12-1**).

For the patient with an acute arthritic joint, the home program should start with 5 to 10 repetitions of 6-second contractions with the patient revising that number based upon the response. The

SELF-MANAGEMENT 12-2
BRIME–Isometric Quadriceps Contraction

Purpose: To maintain or slightly increase strength of quadriceps muscles during acute knee joint inflammation when the joint is otherwise held at rest while avoiding an increase in blood pressure

Position: Sit with the back supported or in a supine position; bend one knee and straighten the other.

Movement Technique: Tighten the quadriceps of the straight leg at an intensity that does not increase pain.

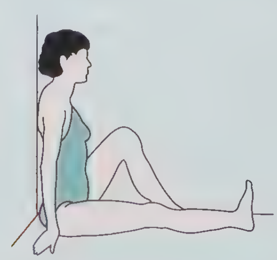
Hold 3 to 6 seconds.

Rest 15 seconds.

Dosage:

Repetitions: ______________________

Frequency: ______________________



SELECTED INTERVENTION 12-1

Hand-to-Knee Pushes

See Case Study No. 11

Although this patient requires comprehensive intervention as described in other chapters, only one exercise will be described. This exercise would be used in the early to intermediate phases of this patient's rehabilitation.

ACTIVITY: Standing hand-to-knee pushes

PURPOSE: To increase the muscle performance of the hip abductor (stance limb) and abdominal muscles

STAGE OF MOTOR CONTROL: Stability

MODE: Aquatic environment

POSTURE: Standing on one leg with your back against a wall, maintaining a proper lumbar alignment by pelvic tilting. Bend the opposite knee and flex the hip to approximately 90 degrees.

MOVEMENT: With the hand opposite your flexed hip, press isometrically against your knee. Maintain good spinal posture throughout the exercise. Hold for a count of three. Return to the start position.

DOSAGE: Perform five to seven repetitions with each knee, two to three sets to form fatigue.

EXPLANATION OF PURPOSE OF EXERCISE: Hip abductors on the stance limb are trained to maintain transverse plane pelvic position, while the abdominals work to maintain pelvic tilt against the isometric exercise. This exercise is performed in the upright position to enhance carryover to daily activities, but is performed in a gravity-lessened environment to reduce weight bearing on the single-stance limb.

number of repetitions may vary throughout the day and with the patient's activity level. The patient can gradually increase sets and repetitions as tolerated if symptoms are not exacerbated. As acute pain, swelling, and inflammation resolve, the patient will progress to an isotonic routine.

Dynamic Training

Dynamic muscle strengthening occurs when muscles contract as they shorten (i.e., concentric contractions) or lengthen (i.e., eccentric contractions), resulting in movement of the joint they cross. The advantages of dynamic exercise include increased movement of the joint, resulting in maintenance of capsular, ligament, and muscular flexibility. Joint stress and intraarticular pressure are higher with dynamic exercise as compared to isometric exercise.[34] Dynamic training is therefore appropriate for patients with chronic, subacute RA of classes I and II and for most patients with OA.

In prescribing an exercise regimen for patients with OA, both the use of low resistance and high repetition (to fatigue) and the use of high resistance low repetition exercise can be successful as long as the arc of motion does not irritate the joint[52–54] (**Evidence and Research 12-6**).

EVIDENCE and RESEARCH 12-6

Jan et al.[55] studied the effects of high- and low-resistance strength training in 102 elderly patients with knee OA. Significant improvements in all strength and function measures were found in both groups compared with controls, with the high-resistance group demonstrating a greater effect size. Thirty-three patients divided into intervention and control groups (high speed, low speed, or control) showed similar increases in leg press strength in the intervention groups.[55] King et al.[56] found improvements in a small single group sample of 14 patients with advanced knee OA and varus malalignment who underwent a 12-week high-intensity isokinetic program. A Cochrane systematic review of high- versus low-intensity exercise in people with hip or knee OA concluded that there was insufficient evidence to recommend one intensity of exercise over another for this population due to the poor quality of the existing research.[57]

The use of free weights, machines, resistance tubing, water and body weight can be appropriate ways to apply resistance, but their limitations and advantages must be considered in relation to the individual needs of the patient. For example, patients are less likely to lose control of resistance tubing than a free weight, but tubing resistance continues to increase as it is stretched, diverging from the muscle's normal torque curve. Used correctly, machines offer the advantage of stabilizing the body and exercised joint but may not offer a low enough resistance to allow a very deconditioned patient to use them. The aquatic environment provides resistance while minimizing the effects of gravity, but designing challenging eccentric contractions can be difficult for some muscle groups. Body weight exercises, which can range from mini squats to single-leg squat reaches, offer movement patterns which are the basis of function. Body weight exercise may also be introduced through functional activities such as walking, stair climbing, sit to stand, bending, and squatting (**Fig. 12-6**). Inclusion of these activities in the strengthening routine provides the clinician with an opportunity to confront safety issues involving balance and body mechanics while addressing daily activities. Bracing, assistive devices, and exercise intensity can then be considered in this context as well. The choice of resistance modality depends on the patient's presentation and the goal of treatment.

In general, start with lower weight to allow assessment of the joint's response to the resistance program. Increase the program appropriately, while individualizing the program to meet the needs of the patient. Modify the exercise dosage based upon the patient's response to the program (see Chapter 5 and **Building Block 12-7**).

BUILDING BLOCK 12-7

In the following scenarios, describe the most appropriate exercise choice to address the listed problem. Include type of muscle contraction, number of repetitions, appropriate forms of resistance (if any), stretches and any precautions your patient should take.

1. The patient in case RA-1 is now bed bound with an acute flare of joint pain and swelling and systemic effects including fatigue and apparent myositis. Prescribe an exercise routine

(continued)

BUILDING BLOCK 12-7 (continued)

which is safe for her to do to preserve current quadriceps strength (remember her knees are hypermobile into extension due to ligament laxity).

2. The patient in case OA is having problems walking up and down stairs with a step over step gait due to pain and perceived weakness.
3. The patient in case RA-2 is having difficulty pulling open heavy doors, putting on her emergency brake, and using a pen to write for more than 8 to 10 minutes due to hand weakness and elbow pain.
4. List considerations which would guide the choice of exercises.

FIGURE 12-6 Partial squat at sink.

Impaired Aerobic Capacity

Both OA and RA can negatively impact cardiorespiratory performance either through pain and disuse mechanisms or through primary disease processes. Patients affected with either disease have decreased cardiorespiratory endurance, walking time, and total work capacity compared with controls.[26,27,39,40] These patients may also have difficulty with weight control due to exercise limitations. Addressing the cardiovascular endurance impairment of patients with arthritis has several benefits, including improved cardiorespiratory status and endurance,[53] improved sense of well-being,[38,58] weight control, and improved walking distance[43] (see Chapter 6). Cardiovascular training should be a major part of therapy programs for patients with OA and RA.

Mode

Cardiovascular programs for patients with OA or RA of the weight-bearing joints need to be designed to minimize joints stress and impact, to encourage calcium uptake into bone, to encourage large muscle group engagement, and to account for any balance impairments. Several options are available, but adherence to a program is likely to be better when patients are able to pursue activities they find pleasurable.[59] Accessibility and cost factors may also be important for some people. Patient input into this aspect of the program design is important. For those needing weight loss or control, research suggests that effective weight loss can occur through both land-based and water-based exercise, with some research suggesting that overall body composition and metabolic profiles are better following aquatic-based exercise compared with land-based exercise.[52,54,60,61]

Water is a good medium for exercise and has demonstrated positive effects on pain, muscle strength, flexibility, depression, and anxiety.[38,62,63] Water provides a means of unloading joints; when immersed in a depth from the waist to the neck, body weight is far less than on land (see Chapter 16). Water provides a medium that can both resist and facilitate movement:

- It allows performance of movement patterns that may not be possible on land because of balance or strength deficits.
- It can relax muscles.
- It can modify pain perception through sensory stimulation.

Aquatic therapy can facilitate social interaction in class settings or during family recreation. This aspect may be an added benefit for a population that may be socially limited due to decreased participation in physical activities.

Cardiovascular work can come from walking in the shallow end of a pool, skiing, cycling or running in deeper water, water exercise classes, or swimming (**Evidence and Research 12-7**). Swimming is best done by skilled persons with good form so that abnormal movement patterns of the back, neck, and shoulders are prevented. Use of a snorkel and swim mask for prone swimming can be beneficial for patients with cervical spine disorders. Supine flutter kicking or elementary backstroke can help maintain a more neutral alignment when swimming and is readily performed by those who are not skilled swimmers.

EVIDENCE and RESEARCH 12-7

Numerous studies on underwater running, walking, and cycling have been performed, although most have been done on individuals without pathology. Hall et al.[64] examined the cardiorespiratory effects of underwater treadmill walking (immersed to the xiphoid) compared with land treadmill walking in 15 women with Class 1 or Class 2 RA. Results showed that HR and rate of perceived exertion (RPE) increased with increased speed and that the RPE was higher in the water at all speeds. At a given oxygen consumption level, the HR was approximately 9 beats per minute and the RPE 1 to 2 points higher than on land. Underwater treadmill walking at 4.5 km per hour was sufficient to achieve similar energy demands to land treadmill walking. Be aware that this HR response at this immersion level is very different from the typical HR response to deep water running (see Chapter 16).

Stationary or recreational bicycling can improve strength and cardiovascular conditioning in patients with OA or RA. Consider initiating bicycling on a stationary bike to limit balance and environmental factors and to control the initial exercise dosage. A variety of exercise bikes are available, all with different designs and features. Having patients exercise on different bikes can help them determine the features that best suit them. It also provides an opportunity for the physical therapist to discuss bike fit to ensure the least joint stress and the best posture and support for the patient. When appropriate, progress to recreational cycling if this is within the patient's goals. A walking program can improve cardiovascular endurance. Several studies have shown additional benefits of a walking program for patients with arthritis including reduction in pain, increase in flexibility and strength, and improvement of function.[38,65–68] Assessment for balance, safety, and current levels of function combined with advice regarding supportive footwear, acceptable walking surfaces, and progression of activities are necessary. Most neighborhoods have high school tracks that make an ideal exercise arena because of shock-absorbing level surfaces, easily calibrated distances, freedom from traffic hazards, and easy accessibility to a car to return home when the person becomes fatigued. Many shopping malls make their hallways available before hours for mall walking. This is ideal in inclement weather or as a social opportunity, and it provides frequent opportunities for resting if necessary. This form of exercise, however, is not without risk, because falls are always possible, and an assistive device or walking poles might be considered where balance is a problem.

Devices such as treadmills, elliptical machines, or recumbent trainers offer options for low-impact, potentially limited weight-bearing activity. This equipment requires more agility, balance, and coordination than outdoor or mall walking. Whichever form of exercise is chosen, cross-training can prevent boredom, stimulate different muscle groups, and alternate joint stress from session to session. Consider using a variety of devices within the same exercise session.

Exercise Dosage

To modify exertion during training sessions, patients should be taught to monitor their HRs or reliably apply the Borg perceived exertion rating technique[69] (see Chapter 6). Patients must also know their training parameters. Those who are deconditioned will be working at a higher percentage of their aerobic capacity than a more conditioned individual with the same disease process, or a younger, more fit individual. Be sure to monitor exercise HR and RPE and monitor for fatigue. Exercising at a HR below the recommended values can limit aerobic capacity and symptoms improvements[30] (Evidence and Research 12-8). Therefore, it is best to closely monitor exercise programs to ensure sufficient intensity while protecting patients from overexercising (**Evidence and Research 12-8**).

EVIDENCE and RESEARCH 12-8

A group of 220 patients with RA were randomized into control, class exercise, and home exercise. The exercise groups performed low-impact aerobic exercise three times per week for 12 weeks either in a class format or at home with a videotape. Participants were given their target HR and told to gradually increase their HR as tolerated. After 12 weeks, both exercise groups showed significant improvements in walk time and grip strength with no increase in measures of disease activity. Aerobic fitness improved the most in the class exercise group but the difference was not statistically significant. Those in the exercise class performed at a higher intensity (as measured by exercising HR) than the home-based group, although they performed the same number of exercise sessions. The home group had less symptom improvement compared with the class group.[30]

Whatever form of cardiovascular exercise is chosen, it should be fun and satisfying for the patient. This is an important link in maintaining or regaining function, because the more closely training fits with patient goals, the more effective it is.

Special Considerations in Exercise Prescription and Modification

The impairments common to patients with arthritis can pose specific challenges in designing a safe, effective exercise routine. The possibility of joint inflammation, laxity, and deformity in RA and OA and of systemic effects in RA necessitate precautions during exercise. Pain in both conditions can interfere with function and therapeutic exercise, and must be addressed through exercise and activity modification, therapeutic interventions, and education.

All positive findings from the initial evaluation should be considered when identifying the specific impairments to be addressed with therapeutic exercise. These findings guide decisions about the prescription variables and necessary precautions. Program design considerations include:

- Protecting joints during strengthening when ligament or capsular laxity exists
  - Example: avoid valgus load across an arthritic knee joint when medial-lateral instability exists
- Restoring muscle balance when splinting, postural habit, or pain inhibition has selectively weakened muscle groups around one or more joints
  - Example: strengthening scapular stabilizing muscles around the thoracic spine to improve posture in patients with cervical arthritis
- Normalizing specific joint movement patterns
  - Example: scapular stabilization and normal shoulder posture during arm elevation, avoiding shoulder elevation
- Restoring functional activities
  - Example: sit to stand or stair negotiation
- Treating pain and inflammation during and after exercise
  - Example: ice, soft-tissue mobilization, Grade I and II joint mobilizations
- Considering systemic variables such as fatigue levels, irritability of joints, and cardiovascular fitness, especially in the patient with RA
  - Example: breaking exercise program into several smaller exercise sessions

Joint Instability

Joint instability caused by ligament laxity, muscle atrophy, or bony joint deformity can affect arthritic joints (see Figs. 12-1 and 12-2) and must be assessed during evaluation. Muscle strengthening around these joints can increase stability, but it is undesirable to load these joints in a way that aggravates the instability. For example, in medial or lateral collateral ligament laxity of the knee, dynamic abductor or adductor strengthening without increased joint stress may be performed by placing the resistance proximal to the knee joint rather than at the ankle (**Fig. 12-7**). Other protective approaches may include bracing of the knee during exercise or the use of a closed chain pattern if proximal muscles are adequate to stabilize the knee in good alignment and the loading forces are tolerated by the joint.

In the small joints of the hand and foot, ligament laxity caused by the erosive effects of RA or asymmetric joint deformity from cartilage destruction and marginal spurring resulting from OA need to be considered as carefully in exercise prescription as they are in instructions for joint protection during ADLs.

Restoring function in hand, foot, and knee joints can be difficult in this context due to the relatively long lever forces of muscles crossing these joints where ligament laxity often is present. Intervention with exercise aimed at function in these joints will often have to be done in conjunction with ring splints, bracing, foot orthotics and special shoes, medication, therapeutic modalities, and the use of adaptive equipment. Functional use of pens, kitchen utensils, levers, and buttons (including keyboards) in hand rehabilitation, for example, provide opportunities for a combination of strengthening and safe functional training (**Fig 12-8**). Ligament integrity during ROM activities is a crucial safety issue for the upper cervical spine. RA can affect the ligaments of the upper cervical spine and middle spine segments (i.e., C5 and C6 areas) and can cause erosion of the dens.[70] Any patient presenting with upper cervical spine instability or long tract signs should be referred to the physician for consideration of immobilization. Patients with a history of RA who do not have objective signs of cervical instability should be warned that any cervical spine ROM exercise that results in cardinal signs, including perioral numbness, drop attacks, bilateral or quadrilateral paresthesias, or nystagmus, should be discontinued and they should consult their physicians.[40]

FIGURE 12-7 Standing abduction with band above knee.

FIGURE 12-8 It is important to incorporate functional activities (e.g., writing, crocheting, piano) into the treatment plan. Here, the patient with arthritic fingers practices functional skills.

Joint Protection

Joint protection can be approached through mechanisms that unload the joint, attenuate shock, and maximize neutral joint alignment. In addition to use of splints and braces, the following approaches may be implemented to decrease joint forces:

- Unweighting joints through the use of assistive devices (e.g., following hip replacement, use of a cane on the contralateral side reduced joint reaction forces on the ipsilateral side, but increased loads on the contralateral side[71–73]
- Attenuating shock forces in weight-bearing joints, although the effectiveness of adding shock absorptive insoles has been questioned[74,75]
- Using a water medium or unloading equipment, such as the Alter-G, in a clinic setting[71]

Weight reduction is an important goal of exercise for patients with pathologic joints and often a major goal of exercise programs. Obesity is a major risk factor for the development of OA; every pound of weight lost results in a fourfold reduction in knee loads per step.[76,77] Strengthening and recovery of joint reflex mechanisms offers increased joint protection, and normalizing joint alignment to as nearly neutral as possible distributes forces more symmetrically through the joints.[78]

Choosing exercise equipment that does not stress joints (e.g., cuff weights for upper extremity strengthening rather than free weights when there is wrist or finger joint instability), that can be of low enough resistance to ensure control of the joint by the patient (i.e., some machines do not start at a low enough weight setting for deconditioned individuals), and that encourages movement in physiologic patterns (e.g., shoulder abductor strengthening should be done in shoulder external rotation and in caption) contributes to patient safety during exercise. By understanding the factors necessary for good joint health, the therapist is able to design an exercise program that protects the unhealthy joint from forces it is unable to resist while helping the patient achieve muscle balance around the affected joint in an effort to improve joint physiology (see **Building Block 12-8**).

BUILDING BLOCK 12-8

1. The patient in case OA was referred in part to establish a cardiovascular routine for help with weight control and hypertension. Design one possible routine which will also help him reach his goal of returning to play golf with friends. Set target HR and explain how he should be taught to monitor this. List precautions to teach him.
2. The patient in case RA-1 shows signs of cardiovascular deconditioning (increased heart and respiratory rate with a 200-ft walk). Design a possible aerobic conditioning routine for her, including a way for her to assess her level of exertion. List precautions and protective devices to suggest for her.

Coordination of Multiple Medical Interventions for Energy Conservation

A patient with more advanced or complicated arthritis may have a multidisciplinary health care team consisting of a rheumatologist, orthopedic surgeon, psychologist, vocational counselor, orthotist, nurse, podiatrist, nutritionist, occupational therapist, and physical therapist. Demands made on the patient's time, energy, and financial resources by individual team members must be considered. Duplication of services should be avoided, whereas teamwork to provide positive functional outcomes should be practiced.

PATIENT EDUCATION

Chronically affected patients should be educated about their conditions during treatment and given self-help literature and information about community resources such as the Arthritis Foundation. Some treatments may be appropriately applied by family members or caregivers, and their involvement in treatment sessions to learn these techniques and to ask questions can be an efficient use of treatment time.

Working with patients with arthritis can be an exciting challenge to the physical therapist. This is an opportunity to apply the principles of exercise prescription in a situation demanding knowledge of joint and muscle pathology, the ability to do careful and complete assessment, the ingenuity to modify treatments to fit the determined requirements, and the ability to motivate patient cooperation. The benefit to the patient of this successful process can be an improvement in the quality of her life.

KEY POINTS

- Exercise can mitigate impairments that lead to functional deficits in patients with RA and OA and has a positive effect on numerous quality of life variables.
- The stability and mobility of a normal diarthrodial joint depend on the integrity of its anatomic parts. The disease processes of OA and RA attack these anatomic parts and affect joint integrity and function.
- The pathology of one diarthrodial joint in a kinetic chain can adversely affect joints proximal and distal in that same chain as well as in the contralateral joints. Exercise prescription should consider these joints when assessment indicates the need.
- Pain is a common impairment in patients with OA or RA. Management of pain with therapeutic modalities, safe alignment, bracing, and pacing is a necessary component of exercise prescription.
- Joint movement is necessary for maintaining joint health. Passive, active assisted, and active ROM exercises are appropriate, and the choice depends on the severity of involvement of the joint as well as the phase of inflammation of the joint.
- Isometric exercise is useful in maintaining strength of the muscles around an affected joint. It can be done without aggravating an inflamed joint and without raising blood pressure in patients when this is a consideration by using BRIMEs.
- Dynamic training offers the advantage of strengthening periarticular musculature through available joint range and increasing cartilage nutrition. Certain precautions must be followed, especially in strengthening muscles around unstable joints.
- Cardiovascular conditioning is frequently necessary for patients with OA or RA. It has a positive effect on the quality of life. Following specified guidelines, it is possible to prescribe exercise that does not aggravate existing joint pathology.
- Because of inflammation and joint instability, exercise prescription must include special precautions such as joint bracing, nonjarring movements, conjunctive therapeutic modality use, and pacing.
- Patients' adherence to an exercise program often depends on their belief in the program and on sharing common goals with the therapist. For this reason, the therapist must be aware of patients' beliefs and goals when designing an effective treatment program.

CRITICAL THINKING QUESTIONS

1. Consider Case Study No. 3 in Unit 7.
   a. Assuming that this patient has moderate osteoarthritis in her lumbar spine and knees and mild arthritis in her hips, create three different exercises to address the limited lower extremity endurance. Which muscle groups will you focus on and why?
   b. This patient returned to physical therapy a week later reporting that a friend told her that to get her legs stronger she should go up and down her 15-step staircase 10 times per day. Her knees are now swollen and more painful than when you saw her the first time. What are your recommendations at this time and why? Will your previously prescribed exercise program change?

c. Describe how you might design a walking program to improve her activity limitations in conjunction with her program to address her various impairments. How might you progress it and what are the key signs that the program is aggravating her arthritis?

2. Consider Case Study No. 7 in Unit 7.
   a. Given the findings in this patient's active and passive range of motion, list all the mobility impairments you would focus on. Understanding that this is subjective, prioritize and group the mobility impairments into those of most, moderate, and least important to restore normal movement patterns.
   b. Create two different exercise options to address the mobility impairments in your most and moderate groupings. Given her passive range of motion findings, how would you counsel this patient regarding the intensity of and pain levels during these exercises? Why?
   c. What muscle groups would you start with in her strengthening program? Would you begin strengthening immediately? Why or why not? If so, describe three exercises you might begin with.

CHAPTER 13

Therapeutic Exercise in Obstetrics

ELIZABETH A. V. BLOOM • MELISSA FISCHER • M. J. STRAUHAL

From the moment of conception, pregnancy profoundly alters a woman's physiology. Body system changes happen throughout the entire pregnancy and postpartum months. These changes are necessary to provide for the diverse needs of fetal growth and development, meet the metabolic demands of pregnancy, and protect her normal physiologic functioning.[1–4] By considering these changes, the physical therapist can carefully implement a therapeutic exercise program that is safe for the mother and fetus. Reasons for prescribing therapeutic exercise include:

- Primary conditions unrelated to pregnancy
- Disorders related to the physiologic changes of pregnancy, such as back pain, faulty posture, or leg cramps
- Physical and psychological benefits
- Pelvic floor dysfunction
- Preventive measures (**Display 13-1**)

During pregnancy, physical therapists have the opportunity to introduce important lifestyle changes that can be beneficial to both mother and fetus. Therapeutic exercise during this phase in life can play an important role in immediate intervention and in prevention of dysfunction and disease in the future. Today, the American College of Obstetricians and Gynecologists (ACOG) recommends that all pregnant women who are free from medical or obstetric complications engage in 30 minutes or more of moderate intensity physical activity on most days of the week.[5]

DISPLAY 13-1

General Benefits of Exercise During Pregnancy

Metabolic Benefits

- Preserve or increase maternal metabolic and cardiopulmonary capacities
- Manage gestational diabetes
- Prevent excessive weight gain

Musculoskeletal Benefits

- Promotes good posture and body mechanics
- Prevents connective injury due to laxity
- Prevent/manage low back pain, diastasis recti, and urinary incontinence
- Improve muscle tone

Manage Pregnancy/Postpartum Complications

- Decrease risk of venous stasis, deep vein thrombosis (DVT), varicose veins, edema, and leg cramps
- Decrease risk of bone loss due to higher estrogen levels
- Psychological benefits: improved mood, body image, and reduction in postpartum depression

Labor and Delivery Benefits

- Facilitates labor: endurance, possible decrease in pain perceptions, and improve relaxation
- Promote faster recovery
- Reduce postdate deliveries

Data from references 6, 7, 44, 70, 126, 160, and 195.

PHYSIOLOGIC CHANGES RELATED TO PREGNANCY

Physiologic changes occur in the maternal endocrine, cardiovascular, respiratory, and musculoskeletal systems.

Endocrine System

The endocrine system regulates hormonal changes that affect soft tissue and smooth muscle. Relaxin, estrogen, and progesterone cause fluid retention, growth of uterine and breast tissue, greater extensibility and pliability of ligaments and joints and a reduction in smooth muscle tone. Hormonal changes and structural adaptations alter gastrointestinal function.[3] Nausea, vomiting, changes in appetite, constipation, heartburn, and abdominal pain may interfere with a pregnant woman's ability and motivation to perform an exercise program (**Evidence and Research 13-1**).

EVIDENCE and RESEARCH 13-1

Studies have shown that the basal metabolic rate increases during a normal pregnancy by as much as 15% to 30% by term (i.e., birth occurring between 38 and 42 weeks of gestation).[1–4,6] The pregnant woman requires approximately 300 kcal more per day to meet this increased metabolic need.[1,2,4] Metabolic need increases (up to 500 kcal per day) in pregnant women who regularly exercise and also for postpartum lactation needs (i.e., secretion of milk by the breasts).[1,2,7,8] The thermoregulatory abilities of the body are affected by endocrine changes. For example, pregnant women may notice feeling warmer during activities of daily living (ADL); in addition, increased sweat production from elevated metabolism may be observed. Thermoregulatory adaptations appear early in pregnancy and may protect fetal development and limit thermal stress in women who exercise during pregnancy.[9]

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) is defined as glucose intolerance of variable degrees with onset or first recognition during pregnancy.[10] The prevalence of GDM is increasing globally. In the United States, up to 14% of pregnancies are complicated by GDM.[11] Established risk factors for developing GDM are those with a high body mass index (BMI), history of diabetes in a first-degree relative, previous macrosomic infant (birthweight of more than 8 lb, 13 oz), history of GDM in previous pregnancies, and advanced maternal age.[12] Modifiable risk factors include obesity, physical inactivity, dietary fat, smoking, and certain medications.[13] All pregnant women should be screened for GDM, because it can occur even when no risk factors or symptoms are present. Management consists of nutritional modification, careful monitoring of glucose levels, and possible insulin therapy.[7,13]

Cardiovascular conditioning exercise facilitates glucose use and reduces the amount of insulin needed to keep blood glucose levels normal, and it may play an important role in the management of GDM.[7,13–23] One study documented that women with GDM who trained with arm ergometry lowered their levels of glycemia better than with dietary changes alone.[19,20] Physical training may help avoid or delay insulin therapy.[24]

In 2004, the American Diabetes Association recommended that pregnant women without medical or obstetrical contraindications should be encouraged to exercise moderately as a part of preventing GDM.[25] A review by Russo et al. suggests a 28% lower risk of GDM among an exercise group compared to the control group, showing just how important exercise can be for managing this condition.[26] A physical therapist's exercise prescription should be individualized and include duration and intensity recommendations for women with GDM. Hypoglycemia means that levels of glucose in the bloodstream are too low to meet the body's energy needs. In pregnancy, hypoglycemia may develop in women whose bodies cannot adjust to the increased glucose requirements of the fetus, with or without exercise.[27] Some pregnant women feel better when they eat frequent, small, high-protein meals with an emphasis on complex carbohydrates (i.e., whole grains, fruits, and vegetables) rather than simple sugars (i.e., sweets).[27] Women who have GDM should consult a nutritionist regarding dietary recommendations before and after exercise (**Evidence and Research 13-2**).

EVIDENCE and RESEARCH 13-2

A recent meta-analysis suggests that physical activity in pregnancy provides a slight protective effect against the development of GDM.[28]

Even if there is no improvement in maternal glucose control, exercising three to four times each week for 30 minutes does improve cardiorespiratory fitness in pregnant women with GDM.[15,29] Since overt diabetes mellitus develops in 50% or more of women with GDM, they are at greater risk of cardiovascular complications.[7,30]

Pregnancy provides an excellent opportunity to educate these patients, instruct them in an exercise program, and stress the importance of continuing exercise after delivery[31,32] (see **Building Block 13-1**).

BUILDING BLOCK 13-1

Consider a 29-year-old pregnant woman at 32 weeks' gestation. She has just been diagnosed with GDM. What exercise advice might you give this patient to help her control her high blood sugar? What might you tell this patient about the effects of exercise during her pregnancy on her future health?

Cardiovascular System

Maternal hemodynamic changes include a blood volume increase of 30% to 50% that peaks in the middle of the third trimester.[3,7,33] The increase in maternal blood volume varies with the size of the fetus and with multiple fetuses (e.g., twins, triplets).[7] In normal pregnancy, one-sixth of the total maternal blood volume is within the uterine vascular system.[3] An increase in kidney blood flow improves removal of metabolic waste associated with fetal growth resulting in increased urine production and frequency. Increased skin blood flow helps with heat dissipation but makes the pregnant woman appear flushed.

Anemia

Hemoglobin levels fall progressively because of a greater increase in plasma than of red blood cells.[1,2,4,6,7] A deficiency in red blood cells, hemoglobin, or both is called anemia, and during pregnancy, this deficit is called physiologic dilutional anemia (i.e., 15% below nonpregnant levels).[7] Several types of anemia can develop during pregnancy including iron-deficiency anemia, folate-deficiency anemia, and vitamin B_{12} deficiency. Iron-deficiency anemia occurs when there is not enough iron to produce sufficient amounts of hemoglobin. This is the most common form of pregnancy-induced anemia. In pregnancy, iron stores are heavily called on to increase blood volume and to produce and provide hemoglobin for the placenta and fetus.[34–36] Symptoms of mild iron deficiency may be experienced early in pregnancy and include fatigue, light-headedness, and decreased exercise tolerance. Women are prescribed supplemental iron to prevent anemia during pregnancy and during breast-feeding. An inconvenient side effect of iron supplementation is constipation. Oftentimes, aerobic activity can help manage constipation brought on by intake of iron supplements.[37]

Folate and vitamin B_{12} are required for production of new cells including healthy red blood cells. When there is not enough folate and vitamin B_{12} in the diet, blood cell production is impaired, reducing oxygen transport to tissues throughout the body. Adequate folate levels are achieved through supplementation; vitamin B_{12} is found in meat, poultry, milk, and eggs.

Hemoglobin concentration determines the oxygen-carrying capacity of the blood. The amount of oxygen transferred across the placenta is influenced by maternal and fetal hemoglobin concentrations.[7] Changes in cardiac output, stroke volume, and heart rate contribute to an increase in oxygen distribution.[7] When a pregnant woman exercises, many of the variables that determine the transfer of oxygen across the placenta are affected. Physiologic adaptations to pregnancy and to exercise appear beneficial to both mother and fetus.[9,38–42]

Factors contributing to oxygen distribution include an increase in cardiac output by 30% to 50% and an increase in resting pulse by 8 beats per minute (bpm) in the early weeks of pregnancy to a plateau of about 20 bpm at 32 weeks.[1–3,7] During normal pregnancy, cardiac output is influenced by increased maternal weight, basal metabolic rate, blood volume and by decreased arterial blood pressure and vascular resistance.

Hormonal changes influence the decrease in total systemic vascular resistance by 25% and in total peripheral vascular resistance by 30%. This helps to balance the change in cardiac output and produces an arterial blood pressure decrease of 5 to 10 mm Hg for the duration of the pregnancy.[1,2,4,6] Peripheral vasodilation keeps the blood pressure within normal limits despite the increase in blood volume during pregnancy[3] (see **Building Block 13-2**).

BUILDING BLOCK 13-2

Describe changes in the cardiovascular system which are fetoprotective in the exercising woman.

Hypertension

Gestational hypertension affects 10% of pregnancies and can lead to preeclampsia or eclampsia (see **Display 13-2**). Women who are hypertensive during pregnancy are at greater risk of future cardiovascular or cerebrovascular events.[43] Pregnancy may lead to sedentary behavior and excessive weight gain, placing these women at increased risk for chronic diseases. It has been suggested that exercise may help prevent preeclampsia.[29,44] Unfortunately, these studies are considered insufficient due to a lack of randomization.[45]

A recently published animal study demonstrates that exercising during the early stages of pregnancy may protect the mother from developing high blood pressure. The theory is that expression of proteins may play a role in blood vessel health.[46]

Supine Hypotensive Syndrome

Body position also influences hemodynamic changes. As pregnancy progresses, supine hypotensive syndrome (SHS) (sometimes called inferior vena cava syndrome) may develop in females when lying on their back.[47] The increased weight and size of the uterus (usually after the fourth month of pregnancy) may occlude the aorta and inferior vena cava. The obstruction of venous return and subsequent hemodynamic adjustments from aortic compression results in decreased cardiac output.[1–4] Research suggests that a variety of factors are involved in determining the possible severity and significance of SHS.[47] Signs and symptoms of SHS are presented in **Table 13-1**. The ACOG recommends that pregnant women avoid supine lying after the first trimester.[5] Pregnant woman are encouraged to lie on their side as pregnancy progresses. A physical therapist with a thorough understanding of SHS and the rationale behind position changes can take a flexible approach to treatment and exercise in the supine position and reduce the risk of SHS (**Evidence and Research 13-3**).

DISPLAY 13-2

Cardiovascular System Changes that Contribute to Oxygen Distribution During Pregnancy

- Blood volume changes—increases 30% to 50%, peaks in the middle of the third trimester.
- Folate, vitamin B_{12}, and iron supply can affect blood cell and hemoglobin production, and low supply can contribute to anemia.
- Cardiac output can increase by 30% to 50% and resting pulse increases 8 to 20 bpm, and is influenced by:
  - Increased maternal weight
  - Increased basal metabolic rate
  - Increased blood volume
  - Decreased arterial blood pressure 5 to 10 mm Hg
  - Decreased vascular resistance

EVIDENCE and RESEARCH 13-3

As many as 60% of women may experience symptoms at some time during pregnancy, but the incidence of true SHS is about 8%, with risk peaking at 38 weeks' gestation.[47] Kotila and Lee[48] estimated the incidence of severe cases of SHS to be <1% of the 2,000 women they studied. Some studies report that, even with diminished circulation to the fetus, uteroplacental perfusion remains sufficient.[48] Other studies have determined that uterine blood flow changes are significantly less during supine exercise compared to supine rest.[49]

The earliest sign of impending SHS is an increase in maternal heart rate and a decrease in pulse pressure. Spontaneous recovery usually occurs with a change in maternal position, even if very slight.[3,4,47] Maximum venous return and cardiac output are obtained in the left lateral recumbent position, but the right lateral recumbent position also reduces symptoms.[1,2,4,47]

SHS is specific to the supine position, although anatomic anomalies (e.g., bicornuate uterus, which has two horns or horn-shaped branches) may predispose a small number of women to symptoms in sidelying positions. Prolonged and motionless standing also can occlude the inferior vena cava and the pelvic veins during pregnancy, decreasing cardiac output, increasing venous pressure, and contributing to edema and varicosities in the lower extremities.[3]

TABLE 13-1

Supine Hypotensive Syndrome

SIGNS	SYMPTOMS	SIGNS IN SEVERE CASES
Pallor or cyanosis	Faintness	Unconsciousness
Muscle twitching	Dizziness	Incontinence
Shortness of breath	Restlessness	Impalpable pulses
Hyperpnea	Nausea and vomiting	A lifeless appearance
Yawning	Chest and abdominal discomfort or pain	Convulsions
Diaphoresis	Visual disturbances	Cheyne–Stokes respiration (cycles or shallower and deeper breathing)
Cold, clammy skin	Numbness or paresthesias in the limbs	
A wild expression	Headache	
Syncope	Cold legs	
	Weakness	
	Tinnitus	
	Fatigue	
	Desire to flex hips and knees	
	Anguish	

Data from references 33 and 35.

Awareness of hemodynamic changes and SHS becomes important to the physical therapist when performing manual therapy techniques or prescribing exercises that require supine positioning or prolonged standing. Accommodating to a more upright or sidelying position (especially in the third trimester) or frequent position changes may be appropriate when working with patients at risk for SHS. Suggestions for position changes include placing a small wedge or pillow under the right hip in supine, raising the head and shoulders 20 to 30 degrees, semi-sitting, prone (on a special support or with use of pillows or wedge to decrease abdominal compression and ensure patient comfort), or quadruped (i.e., all-fours position). Changing positions from lying to upright should be done cautiously to decrease symptoms of orthostatic hypotension. In addition, SHS can be induced by increased abdominal pressure, which should be considered when positioning a patient in prone or when prescribing a maternal external support that may put pressure on the abdomen.[42] The physical therapist should encourage the pregnant patient or client to shift positions frequently during exercise, work, and treatment to avoid stasis and hypotension. Because supine positioning during labor has been associated with lower fetal oxygen saturation, position changes apply to the laboring woman as well[50] (see **Building Block 13-3**).

BUILDING BLOCK 13-3

SHS is a concern as pregnancy progresses. Describe the signs and symptoms of SHS and discuss exercise adaptations for your pregnant patients/clients.

Respiratory System

The respiratory system also adapts to the many changes in pregnancy. By 15 weeks' gestation, significant changes in lung volumes and capacities are present.[51] Hormonal changes produce increased mucus in the respiratory tract with associated increases in sinus and coldlike symptoms.[1,4] The diaphragm displaces upward by about 4 cm, but diaphragmatic excursion increases.[1,2,4,7] An increased pulmonary ventilation rate (i.e., the total exchange of air in the lungs measured in liters per minute) during pregnancy is achieved by the woman breathing more deeply, increasing tidal volume (i.e., the amount of gases exchanged with each breath).[1–3,7] The respiratory rate increases only slightly (approximately two breaths per minute), but there is an associated increase in respiratory minute volume, which is the amount of air inspired in 1 minute.[1–4,6]

Lung compliance increases and airway resistance decreases from the relaxing effect of progesterone on smooth muscles.[7] This has been referred to as hyperventilation of pregnancy. Although arterial blood gases reflect an increase in oxygen and a decrease in carbon monoxide, causing mild respiratory alkalosis, this is not true hyperventilation. This mild maternal alkalosis promotes placental gas exchange and prevents fetal acidosis.[7] It may be perceived as dyspnea at rest and during exercise or as a decrease in the tolerance for exercise and exertion. In early pregnancy, it is unrelated to the encroachment of the uterus on the diaphragm. Later, as the lower costal girth is increased, greater breathing movement takes place at the middle costal and apical regions compared with the abdomen.[5]

Oxygen consumption increases by 10% to 20% during pregnancy. This, combined with a reduction in functional residual capacity, results in a lower oxygen reserve.[7,48] With increasing body weight, more oxygen is required to exercise, and a woman reaches her maximal exercise capacity at a lower level of work.[49] Maximal exercise capacity of pregnant women may decline by approximately 20% to 25% in the second and third trimesters of pregnancy. Previously, there was some concern that muscles active during exercise would draw oxygen and blood flow away from the uterus. However, this notion has been thoroughly disproven in recent studies. Some evidence suggests that pregnancy and advanced gestation are not associated with reduced aerobic work capacity or increased respiratory distress at any given work rate or ventilation during non–weight-bearing or weight-supported exercise[7,47,50] (**Evidence and Research 13-4**).

EVIDENCE and RESEARCH 13-4

It is widely accepted that aerobic exercise improves the physical fitness levels of healthy, pregnant women.[51] Recent evidence also supports exercise for previously sedentary pregnant women without adversely affecting fetoplacental blood flow or fetal growth.[52–54]

With increasing body weight, more oxygen is required to exercise, and a woman reaches her maximal exercise capacity at a lower level of work.[55] Maximal exercise capacity of pregnant women may decline by approximately 20% to 25% in the second and third trimesters of pregnancy. Some evidence suggests, however, that pregnancy and advanced gestation are not associated with reduced aerobic work capacity or increased respiratory distress at any given work rate or ventilation during non–weight-bearing or weight-supported exercise.[7,56,57]

Musculoskeletal System

The physical therapist is perhaps best suited to address the multiple musculoskeletal changes that occur during pregnancy. Many of these changes may make the childbearing woman more vulnerable to injury and pain.[58] Most women will experience some degree of musculoskeletal discomfort during pregnancy. Approximately 25% will have disabling symptoms.[59] Although the physiologic and morphologic changes in pregnancy are normal, musculoskeletal symptoms should not be considered normal despite the fact that they are common.

Optimal weight gain by the mother during pregnancy is important to pregnancy outcome, but a wide range in weight gain is compatible with good clinical outcomes.[1–4] The pattern of weight gain may also have important implications. Birth weight of the infant parallels maternal weight gain. There are potential hazards for the mother and the infant when weight gain is restricted, and exercise should not be used to decrease weight. Both low birth weight (<2,500 g; <5 lb 5 oz) and high birth weight (>4,000 to 4,500 g; 8 lb 13 oz to 9 lb 15 oz) are associated with poor fetal outcomes.[60] An average maternal weight gain of 12.5 kg (27.5 lb) is usually recommended during pregnancy, but the desirable range is related to prepregnancy weight status and BMI (see **Display 13-3** and **Evidence and Research 13-5**).

DISPLAY 13-3
Weight Gain Recommendation During Pregnancy*

Prepregnancy Status	BMI	Recommended Weight Gain
Underweight	Less than 18.5	27.5–40 lb (12.5–18 kg)
Normal weight	18.5–24.9	25–35 lb (11.5–16 kg)
Overweight	25–29.9	15–25 lb (7–11.5 kg)
Obese	30 and greater	11–20 lb (5–10 kg)

**http://www.acog.org/Patients/FAQs/Obesity-and-Pregnancy. Accessed June 12, 2015.*

EVIDENCE and RESEARCH 13-5

Recent studies have shown that lower gestational weight gain limits, especially among obese women, are associated with a decreased risk of adverse maternal and fetal outcomes.[61] Excessive weight gain during pregnancy and GDM are not only associated with obesity and diabetes later in life for the mothers, but also with higher birth weight and obesity in their children.[7,62]

The enlargement of the uterus and its contents, increases in blood volume and extracellular fluid, and an increase in breast tissue contribute to weight gain during pregnancy.[1,2] The nonpregnant uterus is approximately 6.5 cm long, 4 cm wide, and 2.5 cm deep and weighs 50 to 70 g.[1–3,55] By term, the uterus drastically increases to 32 cm long, 24 cm wide, and 22 cm deep and weighs about 1,100 g.[1–4] By the end of 12 weeks, the uterus becomes too large to remain wholly within the pelvis and becomes an abdominal organ.[1–3] It enlarges more rapidly in length than in width. This gradual increase in size and weight causes an upward and forward shift in the woman's center of gravity, which may result in an increased lumbar lordosis and compensatory thoracic kyphosis. Enlarging breasts, gaining up to 500 mg each, add to this tendency. This can result in a change in the resting position of the scapulae, with the scapulae protracted and tilted anteriorly. Over time, this will result in lengthened scapular retractors and shortened scapular protractors. In addition, this will cause the head to shift forward and posterior neck muscle activity must increase to support the head. Posterior suboccipital muscles may also increase activity, extending the head on the neck to maintain eyes horizontal (i.e., optical righting reflex). The subcostal angle of the thorax increases from approximately 68 degrees in early pregnancy to approximately 103 degrees in late pregnancy to accommodate the fetus.[1–4,7] After delivery, this rib angle change may not fully revert to the prepregnancy state. Chest circumference typically increases by 5 to 7 cm during pregnancy. In the last trimester, the trunk may rotate to the right (dextrorotation) as the growing uterus rotates to the right on its long axis. This most likely occurs because of the position of the rectosigmoid (lower portion of the sigmoid colon and upper portion of the rectum) on the left side of the pelvis.[1,2,7]

Changes in hormones contribute to joint laxity and subsequent hypermobility (see **Building Block 13-4**). This joint laxity can contribute to increased foot pronation during pregnancy. Poor foot alignment affects the mechanics of the lower kinetic chain. Unlike other joints in the body that return to their normal prepregnancy position, the foot may not.[3] The postpartum woman may notice a permanent increase in shoe size. Since laxity and weight gain change foot biomechanics, the physical therapist should make recommendations regarding proper footwear and possibly orthotics for support during pregnancy. In addition, the therapist must educate the patient/client that, postpartum, the feet may change and the orthotics, shoes, and exercises that were effective during the pregnancy may no longer be appropriate (see Chapter 21).

BUILDING BLOCK 13-4

Consider how hypermobility can specifically impact cardiovascular activities such as walking or jogging during pregnancy. Discuss how you would educate a pregnant patient/client about changes to her current exercise program. Provide recommendations for protection against joint pain as a result of hypermobility.

Hormonal changes facilitating ligamentous laxity, softening of cartilage, and proliferation of synovium also influence postural changes. Postural changes in response to pregnancy can be further exaggerated by work, ADLs, recreation, and exercise. Mechanical changes during pregnancy may aggravate preexisting conditions. Musculoskeletal complaints associated with pregnancy and postpartum may not get serious consideration and the consequence may be underreferring to physical therapy in this population.

THERAPEUTIC EXERCISE INTERVENTION IN PREGNANCY

The following sections address common impairments seen in women during pregnancy and the postpartum period. Sample musculoskeletal evaluations that incorporate adaptations for manual muscle testing and limit the number of body position changes for the pregnant client can be found in *Obstetric and Gynecologic Care in Physical Therapy*[63,64] and *Clinics in Physical Therapy: Obstetric and Gynecologic Physical Therapy*.[55]

Uncomplicated Antepartum Pregnancy

Focusing on the balance of muscle length and strength in key postural muscles in pregnant and postpartum women is extremely important. Length-associated changes arising from the typical kyphosis-lordosis posture can be prevented by addressing the posterior neck muscles, the middle and lower trapezius muscles, the transversus abdominis (TA), external and internal obliques (EO and IO, respectively), hip extensors, and the pelvic floor. Adaptive shortening is common in the anterior shoulder muscles, lumbar paraspinals, and hip flexors. Appropriate active and passive stretches should be prescribed for these areas. Lumbar, sacroiliac, and pubic symphysis problems may be greatly relieved by lumbopelvic stabilization exercises and by the use of external supports during pregnancy.[65–67]

Muscle Performance

Abdominal Strength Goals for performing abdominal exercises during pregnancy include improvement in muscle balance and posture, support of the growing uterus, stabilization of the trunk and pelvis, and maintenance of function for more rapid recovery after delivery. Abdominal muscle strengthening exercises during pregnancy may reduce the development of a diastasis recti abdominis (DRA).[68] Most pregnant women can perform abdominal exercises in supine with frequent position changes. Exercises such as supine hip and knee flexion with hip abduction and lateral rotation (see Self-Management 17-3) and progressive leg slides (see Self-Management 17-1) are appropriate as long as the neutral spine position is maintained. In the case of an anterior pelvic tilt and lumbar lordosis, the client can be taught to use the abdominal muscles (particularly the EO) to tilt the pelvis in a posterior direction. This activity can be performed in a variety of positions (e.g., sitting, standing) and can be used to actively stretch the low back extensors while strengthening the abdominal muscles.

Some precautions should be followed when training abdominal muscles during pregnancy. Bilateral straight-leg raising and leg-lowering exercises should be avoided during pregnancy because of the vulnerability of the vertebral joints, excessive pull on an overstretched abdomen and risk of Valsalva maneuver. When a woman has SHS, the supine position should be avoided, and the use of sidelying, sitting, standing, and quadruped positions can be creatively used to train the patient in abdominal facilitation and neutral spine. The quadruped position is excellent for performing concentric and eccentric contractions of the abdominal muscles (see **Self-Management 13-1**).

SELF-MANAGEMENT 13-1
Quadruped Abdominal Exercise

Purpose: To train the patient in abdominal facilitation when a supine position is uncomfortable or contraindicated (e.g., SHS)

Position: On hands and knees

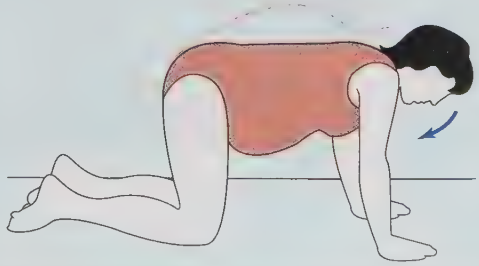
Movement Technique:

1. Concentric contraction
   a. Inhale, allowing the abdomen to expand.
   b. While exhaling slowly, pull the tummy in while maintaining neutral spine. (To stretch back extensors, push the lower back up and tuck the chin down.)
2. Eccentric contraction.
   a. Slowly relax your tummy, and return to the starting position.

Dosage:

Repetitions: ____________________

Frequency: ____________________



Pelvic Floor Strength The pelvic floor muscles may undergo length-associated changes from the long-standing pressure of the growing uterus. Hormonally softened tissue further complicates the increased load on the pelvic floor. A vaginal birth or a lengthy and unproductive second stage of labor (i.e., pushing phase) before cesarean section poses problems for a vulnerable pelvic floor. There is the potential for direct trauma to the muscles with an episiotomy (an incision in the pelvic floor made during childbirth to enlarge the vaginal opening and allow faster delivery), tears, or lacerations. In addition, pudendal or obturator nerve stretch injuries may occur during delivery.

The importance of pelvic floor muscle strength cannot be overemphasized (see Chapter 18). It plays a vital role in supporting the internal organs (such as the rectum, vagina, and uterus) by preventing downward displacement (i.e., prolapse or pelvic relaxation). Pregnancy and postpartum pelvic floor dysfunction may manifest as pelvic organ prolapse, urinary or fecal incontinence, pelvic pain from muscle spasm, painful episiotomy, tears, or joint malalignment (sacrococcygeal involvement). A strong, coordinated pelvic floor may result in improved control and relaxation during the second stage of delivery[69] and in postpartum recovery. Attention to the pelvic floor muscles should occur early in the pregnancy and should continue throughout the duration of the pregnancy and postpartum phase[55,70] (see Chapter 18). A basic program involves lying in a hook-lying position (gravity neutral). Contract the pelvic floor muscles for 10 seconds, followed by bringing soles of feet together and knees apart with relaxation of pelvic floor for 10 seconds (see **Fig. 13-1**). Repeat the cycle 20 to 25 times.

Though internal pelvic examination by a physical therapist should wait until clearance from the obstetrician at the 6-week postpartum follow-up visit, the patient may begin pelvic floor coordination exercises immediately after birth. Pelvic floor contractions immediately after delivery are essential in restoring muscle tone, reducing edema, facilitating circulation, and relieving pain, especially if an episiotomy has been performed or if the perineum was torn. The perineum comprises the pelvic floor and associated structures occupying the pelvic outlet; the area is bound anteriorly by the pubic symphysis, laterally by the ischial tuberosities, and posteriorly by the coccyx. The patient should be instructed to contract or "brace" the pelvic floor muscles with coughing, sneezing, or laughing; avoid Valsalva maneuvers when lifting the infant; and initially support the sutured perineum manually during defecation. To avoid developing overactive pelvic floor muscles, the physical therapist should instruct patients in pelvic floor coordination exercises as instructed in Figure 13-1.

Pelvic floor strengthening should continue in the postpartum phase and beyond to restore muscle tone and to enhance normal bowel, bladder, and sexual functions. A systematic review reported that pelvic floor muscle exercises were effective in reducing or resolving urinary incontinence postpartum.[71] The supportive function of the pelvic floor is additionally challenged by lifting and carrying the infant and various pieces of childcare equipment (e.g., stroller, infant seat, and diaper bag) (see Chapter 18).

Joint Integrity and Muscle Length

Joint Hypermobility During pregnancy, there is a systemic increase in joint mobility. However, studies investigating the relationship between increased joint mobility and serum relaxin levels are conflicting.[72] To date, there are no studies that document a higher incidence of exercise-induced peripheral joint injuries during pregnancy.[40,72]

Abdominal Muscle Length

Diastasis Recti Modifications to exercise for abdominal muscles are necessary for a woman with DRA.[70,73,74] In standing, the abdominal wall supports the uterus and maintains its longitudinal axis in relation to the axis of the pelvis.[2] The muscles of the abdomen that must lengthen to accommodate the enlarging uterus and growing fetus in pregnancy are the EO and IO, TA, and rectus abdominis. The linea alba is formed by the crossing fibers of the aponeuroses of these muscles, making a tendinous seam from the sternum to the pubic symphysis. Hormonal changes and the increasing mechanical stress placed on these structures during pregnancy may result in a painless separation of the linea alba.[55] The rectus muscles separate in the midline, creating a DRA. The rectus muscles can be split up to 2 cm apart above the umbilicus, but remain in contact with each other below the umbilicus. A separation greater than this is considered to be a DRA.[55,70,73,74] The prevalence of DRA has been estimated to be as high as 100% during pregnancy and reduces to 40% 6 months postpartum without any specific intervention.[75]

If the DRA is severe, the anterior uterine wall may be covered by only skin, fascia, and peritoneum. If extreme, the gravid uterus drops below the level of the pelvic inlet when the

A B

FIGURE 13-1 Pelvic floor coordination exercises. **(A)** Resting in a semi-reclined position, contract pelvic floor muscles for up to 10 seconds. **(B)** Externally rotate the hips and relax the pelvic floor muscles for 10 seconds.

woman stands. The pelvic inlet is bound posteriorly by the body of the first sacral vertebra, laterally by the linea terminalis, and anteriorly by the horizontal rami of the pubic bones and pubic symphysis.[2] Descent of the fetal head below this point is called engagement and occurs normally during the last few weeks of pregnancy or during labor. Upright exercise should be restricted if engagement occurs at any other time during the pregnancy, which is a risk factor with extreme DRA.[2]

The presence of a DRA potentially reduces the ability of the abdominal wall muscles to contribute to their role in trunk and pelvic girdle alignment, motion, and stability; support of pelvic viscera; and by way of increasing intra-abdominal pressure, forced expiration, defecation, urination, vomiting, and the second stage of labor (i.e., pushing).[55] As an adjunct to therapeutic exercise, an external support in the form of an abdominal binder, lumbopelvic support, or sacroiliac belt can assist the patient in achieving improved body mechanics and postural alignment for the patient with DRA. When a diastasis is present, the external support helps to reestablish and maintain normal alignment of the abdominal wall to prevent further stretch weakness. These supports are worn during upright exercises and ADLs (see **Building Block 13-5**).

BUILDING BLOCK 13-5

Consider a postpartum patient who has decided to return to a high impact boot camp style workout classes to get back in shape. She reports that they do a lot of planks, sit-ups and burpees in the class. She has a palpable three-finger width diastasis at the umbilicus. What modifications would you recommend she make when attending the class?

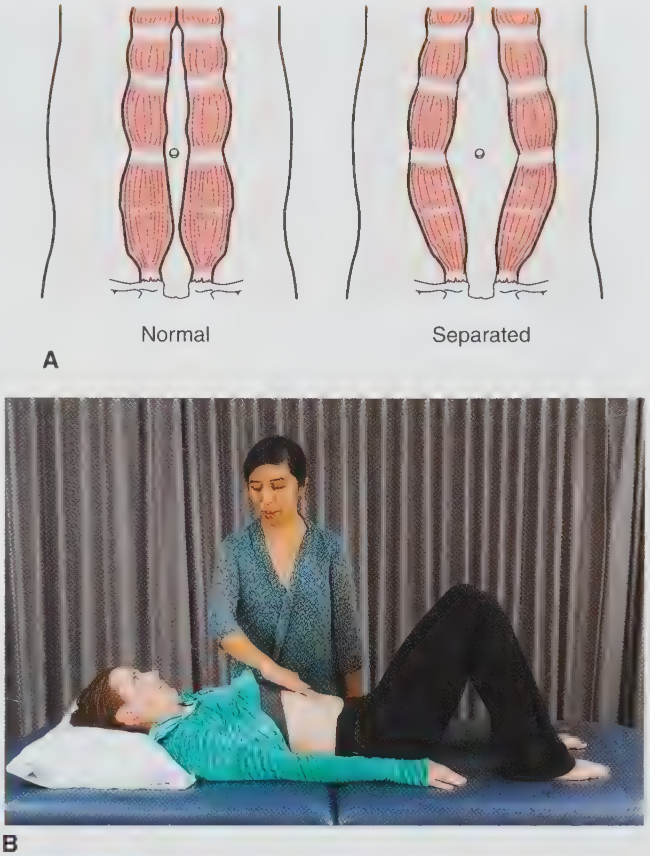


FIGURE 13-2 **(A)** Comparison of a normal abdomen with a DRA. **(B)** The therapist checks for a central bulge in the abdomen and measures the amount of separation between the rectus muscles.

Although weight management and exercise can minimize the effects of DRA during pregnancy, correction of a DRA should be done postpartum. During pregnancy, if a DRA is limiting function or causing symptoms such as low back pain, the patient can work with a therapist to manage symptoms. Management would likely include learning to recruit abdominal and pelvic muscles to stabilize the spine during movement. In addition, wearing an external support may assist with stabilization.

Even if a DRA was not present during pregnancy, a separation could have developed during the second stage of labor. A DRA does not always resolve spontaneously after delivery and may persist well into the postpartum phase. Immediate postpartum prevalence of DRA is about 35%.[76] Studies suggest that women who exercised during pregnancy are less likely to develop DRA.[76] DRA should be evaluated and reduced before aggressive abdominal strengthening begins. To evaluate the abdominal wall for a DRA, have the postpartum woman lie in the supine hook lying position. With the chin tucked and arms extended to the knees, have the patient actively raise her head and shoulders until the scapulae clear the surface. The therapist checks for a central bulge in the abdomen and, with fingers placed cephalocaudally, measures the amount of separation between the rectus muscles 2 inches above, 2 inches below, and at the level of the umbilicus.[55,74] Each finger represents approximately 1 cm (**Fig. 13-2**).

Postpartum, the physical therapist can instruct in diastasis correction exercises to maintain alignment and help to prevent further separation. The patient is positioned hook lying with arms crisscrossed over the abdomen. As the patient manually approximates the recti muscles toward midline, she performs a posterior pelvic tilt, and slowly exhales while lifting her head. The scapulae should clear the surface.[70] Exhalation prevents an increase in intra-abdominal pressure, engaging the TA first with a neutral spine.[55] The additional support of a large sheet folded lengthwise under the patient's back may be helpful to reduce strain on the upper body and neck (see **Self-Management 13-2**). The two ends of the sheet are brought up and crisscrossed over the abdomen to simulate support of the abdominal wall. The patient can grip each end of the crossed sheet to support the recti muscles toward the midline If DRA is detected in a postpartum patient, they are encouraged to avoid unsupported curl ups, trunk rotation exercises, and sitting straight up from a supine position, as these activities may encourage further separation.

Postpartum exercise is vital for the restoration of normal muscle function. Pelvic floor and abdominal contractions may be started within the first 24 hours after delivery to restore tone. It is important to remind the patient that these muscles may not provide adequate support initially for the trunk and low back, which are more vulnerable to injury.[77] In some cases, the temporary use of an abdominal binder is advisable. Because of their synergistic relationship, persistent DRA beyond the childbearing years may play a role in the development of pelvic floor dysfunction.[78]

SELF-MANAGEMENT 13-2
Correction of DRA

Purpose: To correct a DRA and improve the length–tension relationship of abdominals (rectus abdominis)

Position: Backlying with knees bent and feet flat. Cross hands over the midline of the abdomen.

Movement Technique:

1. Fold a sheet or towel lengthwise under your low back. Cross the sheet over the midline, holding the opposite ends in each hand.
2. Inhale. As you exhale draw umbilicus toward spine (engaging transversus abdominus).
3. Tuck your chin, pull outward on the ends of the sheet, bringing your abdominal muscles closer together. Slowly raise your head off the surface while pulling the belly muscle toward the midline.
4. Slowly lower the head and relax, then release your grip on the sheet.

Dosage:

Repetitions: ____________________

Frequency: ____________________

Pelvic Floor Muscle Length

During pregnancy, patients sometimes have difficulty relaxing the pelvic floor muscles and experience overactivity in the muscle groups, resulting in muscle impairment. If pelvic floor tension myalgia exists, with or without coccygodynia, emphasize pelvic floor relaxation as a part of a multifaceted plan of care.[79] After ruling out the possibility of referred pain from L5–S1, the patient can be instructed in a self-management technique to relax the pelvic floor muscles. For example, the patient can sit semi-reclined with support at the low back. The therapist should assist the patient in helping to identify the pelvic floor muscles via verbal/tactile cues. (Though internal pelvic exams are not conducted during pregnancy, a pelvic-floor trained therapist may conduct external pelvic exam.) Have the patient contract the pelvic floor muscles for a few seconds, then externally rotate the hips and place the soles of the feet together (see **Fig. 13-3**) and relax the pelvic floor muscles for 10 seconds. For the patient with pelvic pain, contraction of the muscle is used to improve proprioception and to restore full mobility by identifying overactive pelvic floor muscles, followed by practicing voluntary relaxation. This relaxes the pelvic floor and should be practiced several times each day. The use of a donut cushion or sitting with layers of towels under the thighs may be useful in keeping pressure off the coccyx.[55,80]

If pelvic floor muscle tension has caused sacrococcygeal malalignment, direct mobilization of this articulation may be performed to reduce pain.[81] This technique also is appropriate for a subluxed coccyx after childbirth.[63]

Posture

For the pregnant woman, postural awareness is vital due to the shift in the center of gravity, weight gain, and hormone-related increased joint mobility. Lumbar lordosis may result from pregnancy, or pregnancy may exaggerate a preexisting lordosis. Ideal postural alignment, as defined by Kendall et al.,[82] involves a minimal amount of stress and strain and is conducive to maximal efficiency of the body (refer to Chapter 9 for the definition of ideal alignment of the spine and pelvis). During pregnancy, the center of gravity shifts anteriorly, which may result in anterior rotation of the ilium. This accentuates and increases the normal anterior curve of the lumbar region, creating a lordosis (Fig. 13-3) (see **Patient-Related Instruction 13-1**). Muscle weakness resulting from length-associated changes in the abdominal muscles and the hip extensor muscles results in poor control of the pelvis (in this case, an anteriorly tilted pelvis). However, adaptations to biomechanical changes during pregnancy vary among women, and even between pregnancies in the same woman. Anterior pelvic tilt and lumbar lordosis have not been consistently observed and

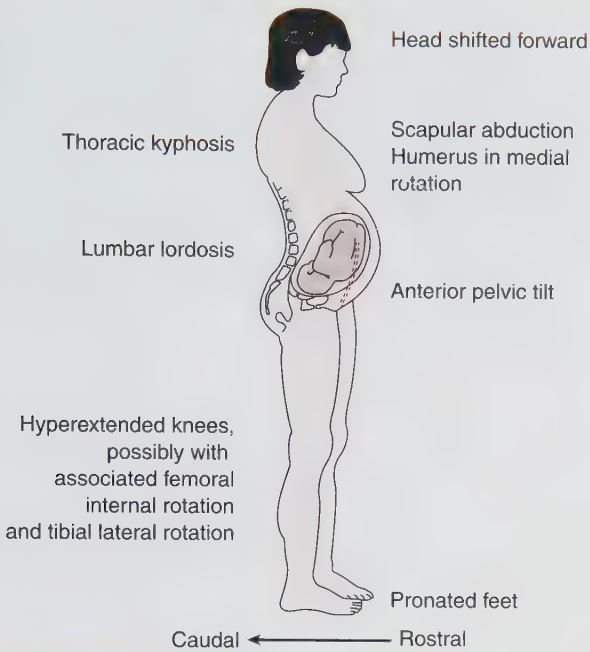

FIGURE 13-3 Incorrect posture during pregnancy.

are not necessarily associated with reports of pain.[83,84] Frequent inner core activation (see Patient-Related Instruction 17-1) in various positions enhances muscular control and strength and the postural awareness required throughout the day to relieve pain and fatigue in the low back.

A lordosis at the thoracolumbar junction may cause mechanical stress on the muscles and ligaments, producing foraminal narrowing. The result may be radicular irritation manifesting as pain along the course of the iliohypogastric and ilioinguinal nerves anteriorly and posteriorly—a common referral source of pain for prepartum and postpartum women.[55] Radicular symptoms may also be experienced in the upper extremities, chest, and neck because of a compensatory thoracic kyphosis, shoulder protraction, and increased cervical lordosis. Changes in the transverse diameter of the chest may mechanically aggravate preexisting costovertebral or thoracic joint dysfunction.

Thoracic kyphosis may develop during pregnancy and persist postpartum, related to childcare tasks, such as nursing/feeding, holding the baby, and lifting a car seat. Performing wall slides with the back to the wall (see Display 25-14, Fig. 1) facilitates strengthening of the scapular upward rotators and the thoracic erector spinae and stretches the pectoral muscles. This exercise can reduce thoracic kyphosis and lift the rib cage off the uterus by promoting balance in length and strength of the anterior and posterior upper quarter muscles. Performing this exercise frequently throughout the day can reduce postural pain and discomfort. Another useful exercise to improve posture during pregnancy is a wall abdominal contraction with a posterior pelvic tilt (**Fig. 13-4**). This exercise helps to maintain tone in the abdominal region and normal hip flexor length, both of which support the lumbar curve and pelvic position. Frequent changes in position and proper posture and body mechanics during daily activities at home and at work apply to both pregnant and nonpregnant women.

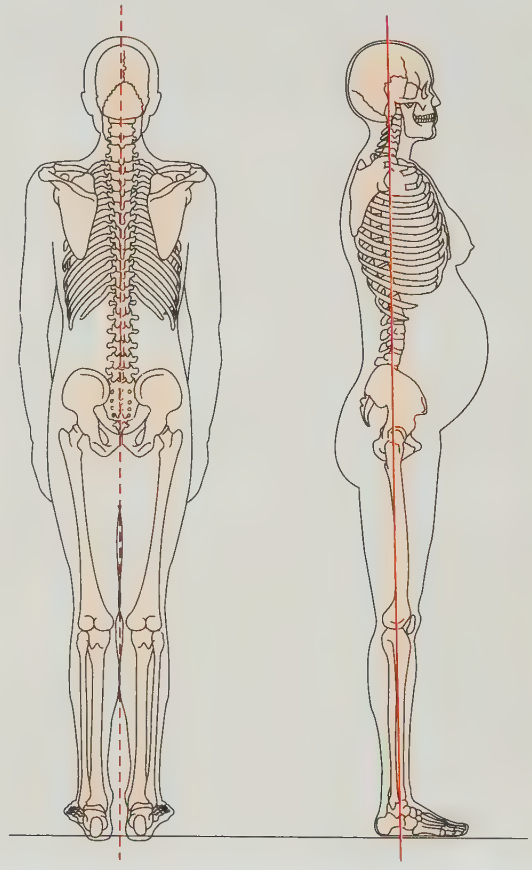
Postural dysfunction may persist into the postpartum period, especially when caring for the new infant. The patient must

Patient-Related Instruction 13-1

Postural Correction

To correct posture during pregnancy, follow the steps below. Perform these steps simultaneously as often as you can—at least six times per day. Try them during different daily activities such as brushing your teeth, washing the dishes, or standing in line. Maintain them while performing exercises in the standing position.

1. Elongate the neck by drawing the chin back and keeping eyes level.
2. Lift your breastbone, ribs, and head without arching your lower back, as though you are trying to be taller. Squeeze your shoulder blades together slightly, while keeping shoulders relaxed away from your ears. Breathe normally; do not hold your breath.
3. Tighten your deep lower abdominals for low back support. The pelvis should be in a neutral position.
4. Soften your knees (unlocked) and keep your knees facing forward.
5. Pull "up and in" with the pelvic floor muscles.
6. Shift your weight slightly so half of your weight is on your heels and half is on the balls of your feet. Slightly lift the arches of your feet without rolling out on the sides of your feet.



accommodate to multiple body changes that occur rapidly. Weight loss and a change in the center of gravity produce postural readjustments. Ligaments and connective tissue may remain under hormonal influence for up to 12 weeks postpartum and

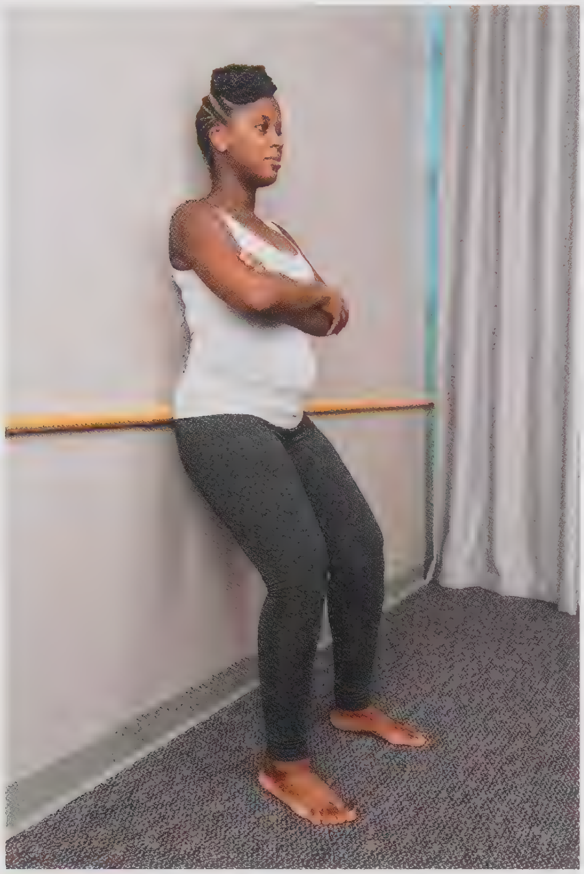


FIGURE 13-4 Wall abdominal contractions with a posterior pelvic tilt. Stand with feet 6 to 12 inches in front of the wall, keeping feet about hip width apart. Rest back against the wall. Pull belly button in towards spine and bend hips and knees, sliding flattened low back against the wall. Maintain abdominal contraction while straightening hips and knees in flattened or neutral position. Stop when low back moves into extension.

may continue with breastfeeding.[7] Feeding or nursing, repetitive bending and lifting, and carrying a car seat all challenge the recruitment and endurance of postural muscles. Proper body mechanics and joint protection should be stressed to decrease abnormal forces on joints that are at increased risk of injury because of hormonally induced laxity. Exercises should focus on scapular stability, anterior chest wall flexibility, and core and hip strengthening to support daily demands on the new mother (see Chapters 9, 17, 25 for specific exercises).

If the mother is breast-feeding, the neck and upper back muscles are affected by the increased weight of the lactating breasts and by the positions assumed by the mother during nursing. Exercises that improve postural awareness and the length–tension properties of the anterior and posterior neck muscles (see Chapter 23) and scapular muscles, such as the lower and middle trapezius, are appropriate (see Chapter 25). Certain exercises may be uncomfortable for a nursing mother to perform because of breast tenderness (e.g., prone positioning). Attention should be paid to sitting posture and positioning of the baby during breast-feeding. External supports for the baby and the patient's spine may be helpful to maintain spinal alignment and decrease muscle compensation.

Gait

During pregnancy, assess gait for adaptations or muscle imbalances. Evaluate the patient for hip abduction weakness, which may present as a Trendelenburg gait. In addition, assess knee position to determine alignment, observing for any knee valgus, varus, or recurvatum. Finally, assess the patient for excessive foot pronation. If present, determine if the patient would benefit from appropriate strengthening exercises and/or orthotics. Interestingly, three-dimensional motion analysis suggests there are minimal changes to gait mechanics in the pregnant patient.[85]

Aerobic Capacity

When a woman has maintained good physical condition during pregnancy, her postpartum fitness is improved. After labor and delivery, exercise can usually be resumed before the 6-week checkup.[55] Return to exercise should be gradual and based on her comfort level. Postpartum exercise guidelines are listed in **Display 13-4**.

Pain

Approximately 50% to 90% of women experience back pain during pregnancy.[4,7,84,86,87] Many women with chronic back pain link the onset to pregnancy.[83,88,89] Back pain may occur

DISPLAY 13-4

Postpartum Aerobic Exercise Guidelines

1. Gradually return to exercise with a goal of regular exercise (at least three times per week). The process of reversal to the prepregnant state is thought to take 6 to 8 weeks (although the anatomic effects of relaxin may persist as long as 12 weeks; longer if breastfeeding).
2. Correct anemia before engaging in moderately strenuous activities. Stop exercising if vaginal bleeding increases or bright red blood appears.
3. Avoid moderately strenuous activities if excessive vaginal bleeding occurs or soreness of an episiotomy persists.
4. Avoid ballistic movements, extreme stretching, and heavy weight lifting for 12 weeks or longer if joint laxity persists.
5. Use the same precautions (such as exercise caution with high impact activities) as in pregnancy to prevent musculoskeletal injury, for approximately 12 weeks.
6. Provide good support to the breasts during exercise, especially if nursing. Nursing mothers should feed the infant before exercising to avoid discomfort.
7. Target heart rates and limits should be established in consultation with a physician and may be based on the fitness level during and before pregnancy.

Postpartum Strengthening Exercise Guidelines

Avoid exercises that raise the hips and pelvis above the chest, such as bridging, knee-chest positions, and inverted postures, until postpartum bleeding has stopped completely. These positions put the body at risk for a rare but fatal air embolism through the vagina.

Data from references 7, 56, 70, 157, and 195.

at any time throughout the pregnancy but most commonly occurs between the fourth and the seventh months.[36] Back pain causes include:

- Biomechanical strain from increases and imbalances in joint loading resulting from increased body mass and dimension
- Postural changes, such as lumbar lordosis creating increased stress on the facet joints, posterior ligaments, and intervertebral disks
- Postural changes that aggravate a preexisting condition, such as spondylolisthesis, degenerative facet joint disease, lateral stenosis, and muscle imbalances
- Ligamentous laxity affecting the sacroiliac joints (SIJs), pubic symphysis, and sacrococcygeal joint
- Muscle fatigue from overload on key muscles including back extensors, abdominals, and pelvic floor

The relationship between postural changes during pregnancy and back pain is unclear.[84] Back pain is not entirely explained by biomechanical changes that can be measured by postural assessment. The source of pain is likely to be multifactorial, but there are common patterns of presentation. These are lumbar pain (LP), pelvic girdle pain (PGP), and nocturnal pain.[83,88,90–92] Inconsistencies in terminology and diagnostic criteria have made comparisons of prevalence, interventions, and outcomes difficult.[91]

Evaluation and exercise prescription for pregnancy-related back pain must be individualized. Higher levels of prepregnancy fitness and physical activity appear to decrease the risk for pregnancy-related LP and PGP.[83,88,90,93] Patients may need to be advised to adjust their exercise habits as the pregnancy progresses. Back pain and other pregnancy-related discomforts may be minimized by reducing the duration and intensity levels of exercises.[7,94]

Lumbar Pain LP is described as pain in the lumbar spine with or without radiculopathy. It is aggravated by prolonged standing or sitting or repetitive lifting. LP responds to treatment focused on posture, body mechanics for ADLs, and exercise similar to the nonpregnant population (see Chapter 18).

Pelvic Girdle Pain Recently published European guidelines on PGP propose that the diagnosis of PGP be reached after exclusion of lumbar, gynecologic, and urologic causes.[91] They define PGP as pain that is experienced between the posterior iliac crest and the gluteal fold, particularly in the vicinity of the SIJs. In some areas, SIJ is the preferred term over PGP; in this context, the two terms may be used interchangeably. The pain may radiate into the posterior thigh. Pain can occur in conjunction with the pubic symphysis or exclusively in the pubic symphysis. Several tests have been described to identify PGP.[83,88,95–97] Ronchetti et al.[98] reported on diagnostic tests with acceptable intra- and interrater reliability, sensitivity, and specificity for the PGP population. These include the posterior pelvic pain provocation test (or thigh thrust test), active straight leg raise test, hip abduction and adduction resistance test, the Patrick (Fabere) test, and palpation of the long dorsal sacroiliac ligament test. They concluded that each test provoked a particular aspect of PGP dysfunction. For diagnostic confirmation and assessment of PGP severity, a combination of tests is necessary[98] (see **Building Block 13-6**).

BUILDING BLOCK 13-6

A 31-year-old pregnant female presents with complaints of low back pain. What tests might be used to assess this patient's impairment and distinguish her complaints from PGP?

The prevalence of PGP during pregnancy is approximately 20%; patients at risk of developing PGP report a history of low back pain and previous pelvic trauma.[91] Other risk factors include a previous pregnancy, multiparity, a physically demanding job, and poor ergonomics.

The SIJ area has been described as the most common location of pregnancy-related back pain and is aggravated by extremes of hip and spinal movement and asymmetrical loading of the pelvis.[83,84,88,99] Patients with PGP commonly report difficulties with walking (waddle gait), standing, particularly single leg stance activities (dressing, stair-climbing), activities that require a straddle (in/out of bath or car), rolling in bed, and sexual activities.

Pain in the pelvic joints may occur very early in pregnancy, possibly because of circulating hormones. Although the lumbar spine and the hips may refer pain into the pelvic region, a variety of alterations in SIJ and pubic symphysis configuration and movement may produce impairments resulting in activity limitations. Although many women experience PGP with transitional movements, there is evidence that the degree of joint and ligamentous laxity is not related to the amount of pain experienced in PGP.[91] Some women may be able to tolerate changes in the pelvic joints better than others, and may be able to compensate for decreased joint stability through muscle function.[91] Contraction of the TA significantly decreases the excessive mobility of the SIJ.[100] As such, instruction in TA firing in a pregnant patient with PGP may be of great benefit. **Self-Management 13-3** describes a simple muscle energy technique combined with recruitment of TA to manage pain with transition movements. A pregnant patient with pelvic instability and SIJ laxity may benefit from performing a pelvic shot-gun technique (hip isometric adduction, followed by isometric abduction) and submaximal TA muscle contraction to prevent/reduce pain with transition movements (see Self-Management 13-3). Muscle imbalances in the major muscles influencing lumbopelvic joint stability must be addressed (see Chapter 18 and **Evidence and Research 13-6**)

EVIDENCE and RESEARCH 13-6

Gutke and colleagues[92] reported an association between PGP and muscle dysfunction suggesting instability as a likely cause of PGP during pregnancy manual therapy techniques may be used to reduce asymmetry and abnormal motion. Randomized controlled trials have shown stabilizing exercises (those that incorporate specifically the transverse abdominis, multifidi, pelvic floor muscles, and hip muscles) to be effective interventions to manage PGP during pregnancy[101] and postpartum.[102,103]

Stretching techniques must be performed gently and cautiously because of possible joint hypermobility or true articular instability. The therapist must perform a thorough examination to determine if stretching is truly indicated. If stretching is indicated, the pregnant patient should be encouraged to perform slow, gentle stretching and avoid ballistic stretching.[65–67]

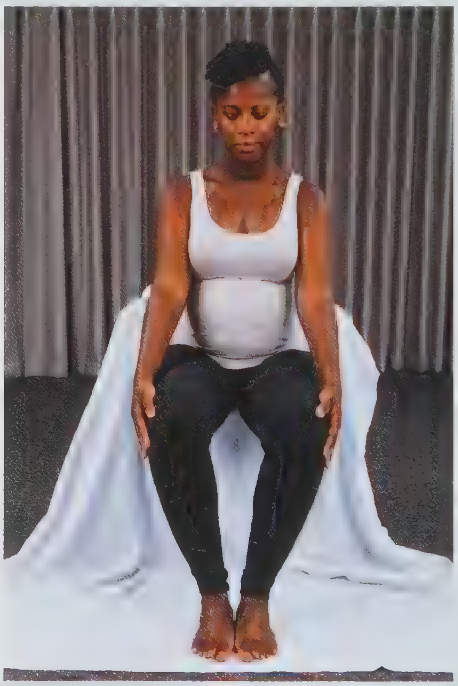
SELF-MANAGEMENT 13-3
Pelvic Alignment Before Transition Movements

Purpose: To realign pelvis and reduce pelvic girdle and/or pubic symphysis pain with transition movements

Position: Seated, with two fists between the knees.

Movement Technique:

1. Perform an isometric contraction of the hips, squeezing fists with 5 lb of force. Hold contraction for 5 seconds. Relax.
2. Place open hands to the outside of the knees and perform an isometric contraction of the hips toward the hands, with 5 lb of force. Hold isometric contraction for 5 seconds. Relax.
3. Slightly contract the lower abdominal muscles or lift the belly using your abdominal muscles.
4. Maintain normal breathing and this abdominal contraction as you move from one position to another. Then relax.



The pubic symphysis is the only bony junction that can be referred to as the "vulnerable midline."[70] This area includes the abdominal and pelvic floor muscles that are connected in midline by a tendinous seam. There is marked widening of the pubic symphysis by 28 to 32 weeks of gestation, from approximately 4 to 7 mm.[1] Widening begins early in pregnancy and facilitates vaginal delivery; unfortunately, it can lead to pelvic discomfort and gait unsteadiness in late pregnancy. Wide leg motions (such as hip circumduction) or reciprocal movement of the lower extremities such as stair-climbing or turning in bed may cause pain in a lax pubic symphysis. If such pain occurs, leg exercises may need to be eliminated until the joint is stabilized. According to the European PGP guidelines, pubic symphysis dysfunction is best identified by palpation of the pubic symphysis and by the modified Trendelenburg test.[91] The ACPWH recently released a collaborative document titled Pregnancy-Related Pelvic Girdle Pain that updates their previous pubic symphysis dysfunction recommendations.[104] This guide for pregnant and postpartum women includes general advice and information on physical therapy and exercise. Recommendations include avoidance of wide or reciprocal movements of the lower extremities, elimination of exercises or ADLs that provoke pain, and reduction in prolonged postures (sitting or standing). In addition, vigorous stretching of the hip adductor muscles should also be avoided because this exercise may result in pubic symphysis separation[105] (see **Building Block 13-7**).

BUILDING BLOCK 13-7

A pregnant patient has difficulty with walking, turning in bed, and getting in and out of her car. What exercises might minimize her discomfort?

Women with persistent PGP postpartum often have serious pain during pregnancy.[91] If muscle tension in the pelvic floor is increased as a result of pain from an infected or poorly healed episiotomy or tear, initiate downtraining of the pelvic floor muscles. Modalities in the form of superficial heat, ultrasound, ice, transcutaneous electrical nerve stimulation (TENS), and perineal massage may help to reduce discomfort.[86]

Nocturnal Back Pain Nocturnal back pain is described as "cramplike" and is thought to be linked to increased blood volume and pressure on the inferior vena cava.[106] Decreasing venous flow could result in hypoxia of neural tissues. Position changes during sleep are recommended.[107] The pregnant patient is encouraged to sleep on her side and avoid sleeping in supine. Using supportive pillows may help make different positions more comfortable.

Other Sources of Pain The round ligaments are two rounded cords that run from the superior angle of the uterus on either side to the labia majora. During pregnancy, these ligaments must stretch with the growing uterus and may intermittently pull on local nerve fibers and other soft tissue structures, resulting in sharp pain in the groin or lower abdomen. This is especially true with sudden position changes. Gentle side stretching in tailor or regular sitting positions with arms overhead may relieve this discomfort (**Fig. 13-5**). This stretch may also help relieve heartburn and the feeling of shortness of breath as it lifts the rib cage upward and away from the pelvis.

Transient osteoporosis (TO) during pregnancy is self-limiting and spontaneously resolves postpartum.[108,109] Despite the rarity of fractures, pregnant women with TO may develop pain in the back, groin, hip, or lower extremities.[110] Careful attention should be paid to medical and family history because preexisting osteopenia and genetics play a role in the degree of bone loss.[111–113] Exercise history is vital in the differential diagnosis because a woman with compromised skeletal integrity, such as an amenorrheic athlete, may be at a higher risk of osteoporosis and fracture during pregnancy and lactation.[114] Immobilization and inactivity are risk factors for TO and should be considered when treating a woman on bed rest for a high-risk pregnancy. Early recognition of TO and intervention with protective weight bearing are important in keeping the condition self-limiting and without long-term sequelae.[59]

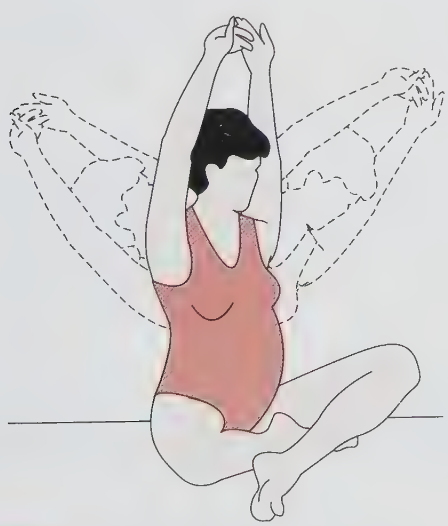


FIGURE 13-5 Gentle side stretching in tailor sitting.

Resumption of prepregnancy bone mineral density (BMD) varies between 2 and 12 months postpartum and is compromised by lactation.[115,116] Profound detrimental effects on maternal BMD during lactation are due to the cumulative effects of prolonged estrogen deficiency and calcium loss. Studies have proven that lactation-induced bone loss is less in exercising women. More research is needed to address types of exercises (high impact and site specific) and exercise duration postpartum.[114] Lactation-induced osteopenia is reversible with cessation of breast-feeding.

Stress–Cognitive Element Influences

Postpartum depression (postpartum blues) is one of the most common complications of childbearing.[117] The prevalence rate is 13% and may occur because of physiologic readjustments and endocrine upheaval. This transient depression may initially interfere with exercise performance, but physical exercise is also emerging as an effective intervention strategy.[117] Support and involvement of the spouse and family members can make a difference in the new mother's desire to exercise after delivery.[118] Because group postpartum exercise classes encourage mothers to exchange experiences and work through problems together, this may be a beneficial outlet for women with postpartum depression. Many classes incorporate exercises that include the infant and the mother.

High-Risk Antepartum

When the outcome of pregnancy is adversely affected by maternal or fetal factors, the pregnancy is identified as high risk.[119,120] Bed rest is used in nearly 20% of all pregnancies to treat a wide variety of conditions. Bed rest may be prescribed when a pregnancy becomes complicated at conception, when preexisting maternal disease such as heart disease is present, or as the pregnancy advances. It is estimated that approximately one of four complicated pregnancies leads to the birth of a premature baby.[121]

Lifespan Considerations

More women are choosing to delay childbearing until their fourth or fifth decade. Their decision may be influenced by a career, new marriage, financial security, and infertility problems.[122] Women who delay childbearing may expect good pregnancy outcome but higher incidence of obstetric complications.[123–128] These include preeclampsia, placenta previa, placental abruption, breech presentation, preterm delivery (before 32 weeks), and low birth weight. There is increased risk of operative delivery, including use of forceps, vacuum extraction, and cesarean section. Although pregnant women with diabetes and hypertension are at increased risk of adverse perinatal outcome irrespective of age, these complications increase almost linearly with age.[129]

The detrimental effects of inactivity in the form of bed rest vary according to the duration of bed rest, the patient's prior state of health and conditioning, and activity performed during bed rest. Much has been written about the negative effects of bed rest, many of which occur within the first 3 days. These effects include decreased work capacity, orthostatic hypotension, increased urine calcium (possibly leading to bone loss), decreased gastrointestinal motility (leading to constipation), and increased risk of DVT. Because maternal activity appears to modulate bone mineral acquisition during intrauterine life, bed rest may be detrimental to fetal as well as maternal bone health.[130] The theoretical basis for bed rest during a high-risk pregnancy is to promote uterine and placental blood flow and to reduce gravitational forces that may stimulate cervical effacement (i.e., obliteration of the cervix in labor) and dilation.[131-134] The left lateral recumbent (which maximizes blood flow to the mother and the fetus) or Trendelenburg position may be recommended. Bathroom privileges may be restricted. Typically, these patients report musculoskeletal, cardiovascular, and psychosocial complaints.

Even modest activity can reduce the detrimental effects of bed rest.[119,120] Therapeutic exercises for this patient population focus on several features:

- Improvement in circulation
- Promotion of relaxation
- Avoidance of increased intra-abdominal pressure by minimizing abdominal contractions during exercise, basic ADLs, bed mobility, transfers, and self-care
- Avoidance of Valsalva maneuvers
- Prevention of decreased muscle tone and deconditioning effects
- Prevention of musculoskeletal discomfort

Activity guidelines for the high-risk antepartum patient are outlined in **Display 13-5**.[6] Contraindications to any form of exercise include increased bleeding, contractions, blood pressure, or leakage of amniotic fluid; exacerbation of the condition (depends on the diagnosis); unstable conditions; and extreme cases when the patient should not move more than needed for basic care.

Muscle Performance

General strengthening and range of motion exercises help prevent or reduce decreased muscle tone and the negative effects of bed rest. Encourage frequent position changes in bed to avoid SHS and prevent musculoskeletal discomfort. Static positioning, joint stiffness, and decreased circulation can contribute to discomfort. Fluid retention and direct compression from immobility may lead to peripheral nerve impairments (discussed later in this chapter).

These strengthening and range of motion exercises can be performed in supine:

- Neck rotation and side bending
- Gentle isometric neck extension into a pillow
- Shoulder presses down and back into a pillow
- Unilateral heel slides, hip internal rotation and external rotation, hip abduction and adduction, and terminal knee extension off a pillow
- Graded pelvic floor contractions if performed correctly (with minimal abdominal muscle activation or breath holding)

These strengthening and range of motion exercises can be performed in the sidelying position:

- Unilateral shoulder circles (downward and backward), arm circles, hand and wrist active ROM, knee extension with hip flexed, partial knee to chest, and hip external rotation
- Unilateral resistive band (or light weights) for upper extremities only: biceps curl, triceps press, shoulder press, diagonal lift, shoulder extension, and horizontal abduction and adduction (avoid proprioceptive neuromuscular facilitation pattern D2 upper extremity extension with or without resistive band because it facilitates the abdominal muscles)
- Graded pelvic floor contractions

The support of a spouse, family members, and friends can greatly reduce the anxiety and stress the high-risk antepartum patient may experience. The patient on bed rest will experience significant activity limitations and participation restriction, as it will limit her roles as mother (if she has other children), spouse, and provider (unless she can work from her bed). The physiologic effects of stress can also take its toll, and the patient and caregivers must understand the rationale for bed rest and the importance of therapeutic exercise to enhance fetal and maternal outcomes. Most patients are home for their duration of bed rest, although some women are hospitalized. A home visit to teach the patient and family proper exercise performance may be appropriate (see **Self-Management 13-4**, **Patient-Related Instruction 13-2**, and **Evidence and Research 13-7**).

DISPLAY 13-5
Activity Guidelines for the High-Risk Antepartum Patient

1. Obtain approval from the health care provider before any exercise.
2. Avoid lifting legs against gravity (including kicking off covers). Lower extremity movement may increase symptoms (e.g., increased bleeding, contractions, blood pressure, leakage of amniotic fluid). If symptoms increase, lower extremity exercises should be deferred. Active assisted or passive range of motion exercises for the lower extremities may be appropriate.
3. Do not perform resisted lower extremity exercise.
4. Do unilateral exercises, except for ankles and wrists, to avoid activities that require stabilization by abdominal muscles.
5. Progress the number of exercises and repetitions gradually.
6. Do not overdo. Exercises may become more difficult as pregnancy progresses and fatigue increases or when medicated with tocolytics (medications used to stop or control preterm labor). You may need to modify exercises if tocolytics increase fatigue or give the patient the "jitters." Timing exercise further from dosage time is helpful.
7. Avoidance of abdominal contractions during exercise is necessary to help eliminate expulsion forces and uterine irritability, especially with preterm labor.
8. Avoid Valsalva maneuvers or bearing down. This increases the intra-abdominal pressure and pressure on the uterus. A Valsalva maneuver must be avoided during bed mobility, transfers, exercises, or bowel movements to avoid irritating the uterus. The therapist should instruct the patient to exhale on any effort.
9. Comfort measures include body mechanics and positioning in bed to support the spine and abdomen in proper alignment. In sidelying, pillows between the legs, under the abdomen, and behind the back and shoulders may be helpful. Encourage frequent position changes.
10. If symptoms increase with bed rest exercises, stop and report to the physician.

SELF-MANAGEMENT 13-4
Sidelying Exercises for the Patient on Bed Rest

Purpose: To maintain mobility of the lower extremities while on bed rest restrictions

Position: Sidelying. Place a pillow under your head and between your knees.

Movement Technique:

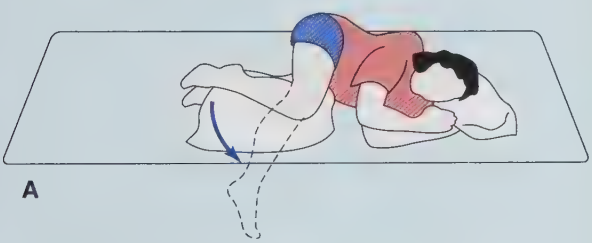
1. Knee flexion/extension with the hip flexed. Begin with the hip partially flexed. Bend and straighten the knee as shown in **Figure A**.
2. Knee flexion/extension with the hip extended. Begin with the hip in a straight position. Bend and straighten the knee as shown in **Figure B**.
3. Knee-to-chest exercise. Slowly draw the knee up to the chest and then slide it back as shown in **Figure C**.

Precaution: Stop exercising if contractions or pain is experienced.

Dosage:

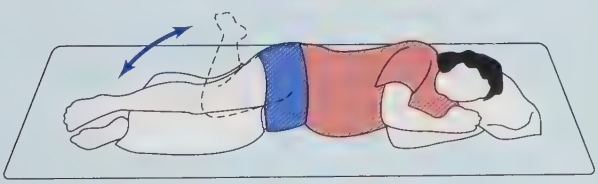
Repetitions: ______________________________

Frequency: ______________________________

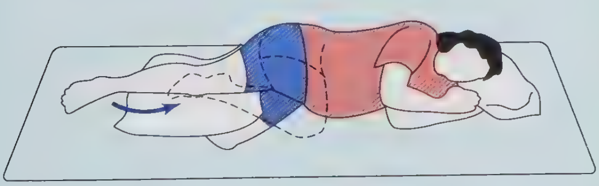


A

Knee flexion/extension with the hip flexed.



B Knee flexion/extension with the hip extended.



C Knee to chest.

Patient-Related Instruction 13-2

Bed Mobility

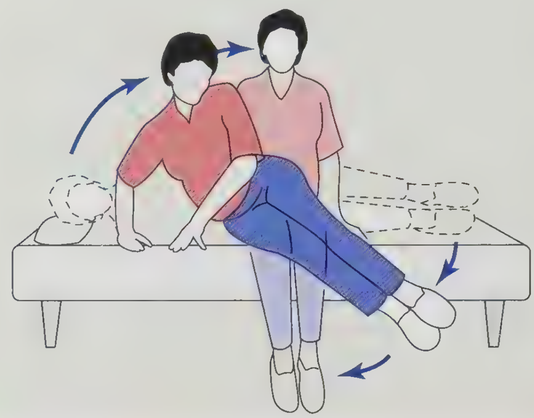
For moving from side to side:

1. Keep your head on the pillow.
2. Roll like a log, keeping your trunk and limbs in a line.

For moving from lying to sitting using the "bed rest push-up" (shown below):

1. Roll to one side.
2. Keeping your back straight, use your arms to push up to sitting while you swing your legs over the edge of the bed.
3. Reverse this to lie back down.

Be sure to breathe and keep your stomach muscles relaxed. This helps to avoid Valsalva maneuvers. Never jackknife to sit.



EVIDENCE and RESEARCH 13-7

One study reported noncompliance of 33.8% for bed rest in the high-risk antepartum women they studied.[135] Reasons for noncompliance included not feeling ill, childcare responsibilities, household demands, lack of support, having to work, and discomfort while on bed rest. Pregnancy outcomes were similar for women who did and did not adhere to bed rest recommendations. Further research is needed to address the validity of the practice of bed rest as treatment for high-risk pregnancies.[135–139]

Because many high-risk pregnancies end in cesarean section deliveries, it may be an appropriate time to prepare the patient for cesarean recovery and rehabilitation. A discussion of the cesarean section is provided later in this chapter.

Those women who have endured bed rest during their pregnancy may find that postpartum recovery is delayed. They may experience greater muscle soreness, slower muscle tone recovery, and may be more prone to musculoskeletal dysfunction.

Mobility

Circulation Exercises Supine or sidelying circulation exercises should be done every waking hour. If allowed, these exercises may be performed while sitting at the edge of the bed. This reduces the likelihood of lower extremity DVT. Ankle pumps and circles improve circulation by facilitating a pumping action in the muscles of the lower extremities. Gentle lower extremity isometrics may also help. However, the therapist must be extremely careful that the patient avoids increasing intra-abdominal pressure or blood pressure. Examples of lower extremity isometrics include quadriceps, gluteal, and adductor muscle exercises.

Pain (Stress)

Relaxation Exercises There are several ways of instructing relaxation exercises.[63,70,86] Two methods of relaxation both require conscious recognition and release of muscle tension. The Mitchell method involves contraction of the antagonist to release stress-induced tension in the agonist.[140] The Jacobson method, also known as progressive relaxation, involves alternately contracting and relaxing muscle groups progressively throughout the body[141] (**Evidence and Research 13-8**).

EVIDENCE and RESEARCH 13-8

Women with back pain during pregnancy are at high risk of back pain postpartum.[142–145] Studies suggest that attention be paid to muscles that influence spinal and pelvic stability including TA, pelvic floor, lumbar multifidus, hip rotators, and gluteus maximus[146–149] (see Chapters 17, 18, and 19). Although pregnancy itself may be a factor in the development of lumbar disc disease, second-stage labor may markedly increase intradiscal pressure.[49] A disc protrusion may develop, or a preexisting protrusion may be exacerbated. This is treated with postural education, body mechanics, exercise, manual therapies, and modalities as in the general population, keeping in mind that hormonal changes persist for several weeks after delivery. The prevalence for low back pain or PGP after delivery is 5% to 37%.[98]

Visualization techniques or meditation may be helpful as a way to withdraw from the stress-producing situation temporarily. Diaphragmatic breathing and body awareness during exercises or ADLs also improve relaxation.[70]

Biofeedback and stretching are more active forms of relaxation. The patient is required to be mentally attentive to purposefully reduce a state of tension and recognize a state of relaxation (see **Building Block 13-8**).

BUILDING BLOCK 13-8

You understand the detrimental effect of inactivity when bed rest is recommended for a high-risk antepartum patient. Describe what you might say to a patient on bed rest about the importance of performing bed mobility exercises.

Cesarean Recovery

A cesarean section (i.e., C-section) is the surgical delivery of the baby through the wall of the abdomen and the uterus after a horizontal (most preferred in the United States) or vertical incision has been made. The horizontal, or transverse, incision extends from side to side, just above the pubic hairline. This incision is preferred because there is less blood loss, it heals with a stronger scar, and it is less likely to result in complications in a subsequent vaginal delivery.[1–4,150] Vertical incisions are sometimes needed because of certain positions of the baby or placenta.

The rate for cesarean births in the United States is approximately 10% to 25%.[150] About 25% to 30% of these are performed because the pregnant woman has had a previous cesarean section.[151] Women may be encouraged to try a vaginal birth after cesarean (VBAC) delivery. Although controversial, reasons to consider VBAC are less risk, shorter recovery time, and more involvement in the birth process.[151,152]

The cesarean procedure may be planned for reasons such as placenta previa (placement of the placenta below the fetus and over part or all of the cervix), breech presentation (presentation of the buttocks or feet of the fetus in the birth canal), and maternal illness or emergently for reasons such as fetal distress (a condition of fetal difficulty in utero detected by electronic fetal monitoring and fetal scalp sampling), prolapse of the umbilical cord, or failure to progress in labor. In childbirth classes, all women should be prepared for the possibility of a cesarean section birth. Some health care facilities have group classes before delivery for patients undergoing a planned cesarean section. This class provides an excellent opportunity to educate and instruct patients in recovery after the procedure. They experience many of the same physical discomforts associated with major abdominal surgery but have the additional responsibility of caring for the newborn.

Exercises may begin within 24 hours after surgery but should be graded and based on the patient's comfort level.[70,153] Breathing exercises are important to keep lungs clear of mucus. Coughing may be painful, and "huffing" (by pulling the abdominals up and in) is recommended while splinting the incision. Pelvic rocking or bridging with a gentle twist from side to side may assist in alleviating discomfort from decreased intestinal motility. Lower extremity exercises help prevent DVT and orthostatic hypotension before early ambulation. Despite the absence of a vaginal delivery, the pelvic floor has undergone dramatic changes during the pregnancy, or from a lengthy and unproductive trial of pushing. Pelvic floor exercises should be continued or initiated immediately. Gentle activity of the abdominal muscles stimulates healing of the incision and facilitates the return of muscle tone. The patient can progress with abdominal exercises as tone increases and tissues tolerate added stress.

Scar mobilization after sutures are removed (usually 3 to 6 days), or as comfort allows, assists proper healing and reduces adhesion formation. It is important to monitor the patient's upright posture, because pain and discomfort at the incision may prompt a protective flexed posture. TENS may be helpful in alleviating incisional pain.

The breast-feeding mother requires adequate caloric intake, fluids, and plenty of rest to produce milk for lactation. Exercise is an efficient way for the postpartum woman to return to prepregnancy weight.[154] Exercise does not adversely affect breast milk as long as she has adequate energy reserves (metabolic need increases by 500 kcal per day with lactation).[154]

THERAPEUTIC EXERCISE INTERVENTION FOR COMMON IMPAIRMENTS

Nerve Compression Syndromes

Soft tissue edema is reported by 80% of pregnant women, usually in the last few weeks of pregnancy.[59] Nerve compression syndromes may arise during pregnancy because of fluid retention, edema, soft tissue laxity, and exaggerated postural changes. Special attention should be paid to blood pressure in these patients because these syndromes may be the first sign of increasing fluid resulting from preeclampsia (a condition of hypertension, edema, and proteinuria).

Intercostal Neuralgia

Intercostal neuralgia is the term used to describe unilateral, intermittent pain in the rib cage or chest from flaring of the rib cage. Exercises to relieve this discomfort include spinal elongation with arms overhead in supine, sitting, or standing positions and trunk side bending away from the pain.

Thoracic Outlet Syndrome

If muscle support is inadequate, spinal curves may become more pronounced as the center of gravity changes and the woman gains weight, especially in the breasts. The forward head and shoulder posture may lead to thoracic outlet syndrome (TOS), with compromise of the brachial plexus and subclavian vessels. A variant of TOS, called acroparesthesia, occurs when the neurovascular bundle becomes stretched over the first rib, which may be elevated in pregnancy. The woman may complain of pain, numbness, and tingling in the hand and forearm.[155]

Strengthening of the upper back and scapular muscles and lengthening of the pectoral muscles may assist in relieving symptoms (see Chapters 24 and 25). Support for the upper back and breasts in the form of a good brassiere and manufactured supports may be appropriate to decrease the load.[82] This is especially important after delivery for the nursing mother. In addition, mobilization of the first rib, postural correction, and neuromobilization of the median and ulnar nerves through sliding techniques may be of benefit.

Carpal Tunnel Syndrome

Carpal tunnel syndrome of pregnancy usually disappears after delivery but may persist or even develop in the postpartum phase in the lactating mother. Impairments related to carpal tunnel syndrome are addressed similarly as in the nonpregnant client (see Chapter 26). Patients are encouraged to decrease hand and wrist flexion activities, use resting splints at night and perform exercises to keep fingers mobile and improve movement of fluids. Unlike patients with carpal tunnel syndrome due to cumulative trauma, pregnant and breast-feeding clients typically have bilateral symptoms.

Lateral Femoral Cutaneous Nerve Entrapment

Lateral femoral cutaneous nerve entrapment (meralgia paresthetica) occurs in pregnancy when the nerve is compressed as it emerges from the pelvis at the inguinal ligament adjacent to the anterior superior iliac spine or where branches enter the tensor fascia lata. Adequate length in the tensor fascia lata, iliopsoas, and rectus femoris muscles is necessary to help prevent this condition. Exercises to balance the hip muscles may be appropriate (see Chapter 19). To test the patient for entrapment of the lateral femoral cutaneous nerve, the patient lies prone. Pillows and other supports are recommended to position the patient comfortably. The therapist stands on the side of the table opposite the affected side, reaches across the table, and passively flexes the knee. While stabilizing the lumbar spine to minimize sidebending, the therapist adducts and extends the hip across midline. A positive test is recreation of the patient's symptoms along the line of the nerve. Management of lateral femoral cutaneous nerve entrapment includes lying on the unaffected side, as this draws the uterus away from the compressed area. Neuromobilization may be performed in sidelying on the unaffected side. Lastly, soft tissue techniques to reduce stiffness of the iliotibial band may also be helpful.

Tarsal Tunnel Syndrome

Tarsal tunnel syndrome is compression of the posterior tibial nerve (a branch off the tibial nerve) posterior to the medial malleolus and occurs as a result of edema. Compression of this nerve produces numbness and tingling in the medial aspect of the foot and may also result in weakness of the intrinsic toe flexors.[7] Testing of the posterior branch of the tibial nerve can be performed either in supine or sidelying. The therapist passively dorsiflexes and everts the ankle, extends the knee, flexes the hip until slight tension is felt. The tension is released (slightly) and the great toe is passively extended. This positive is held for 5 to 10 seconds and should recreate the patient's symptoms. Management of tarsal tunnel syndrome includes elevation and active foot and ankle exercises help to decrease edema. Neuromobilization may be performed, and a posterior splint may be used to immobilize the ankle at night.

Peroneal Nerve Compression

The peroneal nerve wraps around the neck of the fibula and supplies the ankle dorsiflexors. Prolonged squatting may compress these nerves and cause foot drop.[7] To test for peroneal nerve irritation, the patient may be in supine or sidelying. The therapist dorsiflexes and inverts the ankle while passively performing knee extension and hip flexion. This position should recreate the patient's symptoms. Treatment of peroneal nerve irritation includes neuromobilization and soft tissue mobilization. In addition, pregnant women should be discouraged from prolonged squatting during exercise and delivery (see **Building Block 13-9**).

BUILDING BLOCK 13-9

Your pregnant patient complains of numbness, tingling, pain, and burning at the anterolateral thigh. What is your potential physical therapy diagnosis? How would you incorporate therapeutic exercises as an intervention for this condition?

Other Impairments

Other impairments that may result from pregnancy include temporomandibular joint dysfunction (TMD), patellofemoral dysfunction, weight-bearing joint discomfort or dysfunction, and varicosis. Although more detailed exercise interventions are presented in other chapters for some of these impairments, guidelines for pregnancy should be carefully followed.

Temporomandibular Joint Dysfunction

TMD may be related to pregnancy and caused by hypermobility resulting from increased laxity. In addition, it may appear after delivery because of excessive tension in the face during the "pushing" phase of delivery[63] (see Chapter 22). Differential diagnosis for TMD would include tests to rule out cervical dysfunction.

Patellofemoral Dysfunction

Patellofemoral dysfunction and pain may occur from the added stress of weight gain and fluid retention, especially with preexisting muscle weakness. Knee hyperextension and foot pronation are common in pregnancy, due to the change in the center of gravity. This results in additional stress on the knees. Kinematic studies show that patellofemoral force increases by 83% in a pregnant woman rising from a chair without the use of her upper extremities.[7] Enlargement of the uterus causes a reduction in hip flexion and repositions the center of mass farther from the axis of rotation. Greater muscular effort is therefore required to move from sit to stand, which translates into increased force across the joint. This muscular effort is reduced if the pregnant woman uses her arms to rise from a chair or avoids low seating (see Chapter 20). As such, improving the patient's upper body strength to assist with transfers may decrease patellofemoral pain. In addition, encourage the patient to avoid low seats and chairs without arm rests whenever possible.

Weight-Bearing Joint Discomfort or Dysfunction

Weight gain in pregnancy increases the stress on weight-bearing joints, causing discomfort in normal joints or potentially increasing dysfunction in joints with preexisting arthritis or instability. Stair-climbing produces forces of three to five times the body weight in the hip and knee joints. In a woman who increases her body weight by 20% in pregnancy, forces on her weight-bearing joints may increase by 100%[155] (see Chapters 19 and 20). Utilization of a hand rail when ascending and descending stairs may decrease some of the load.

Varicosis

Venous pressure in the lower body increases with advancing pregnancy. Venous distention and stasis contribute to varicosities of the lower extremities and vulvar region.[4] Frequent foot and ankle exercises help to alleviate edema and muscle cramps, especially if the patient is sedentary throughout the day. Ankle and foot active movements also help decrease the likelihood of lower extremity DVT. Patients should be advised to elevate the lower extremities higher than the heart to assist venous circulation (**Fig. 13-6**). The quadruped position reduces stress on the lower extremity vascular structures, and sidelying positions decrease compression of the inferior vena cava. Because long periods of static standing increase compressive forces of the weight of the fetus on the vascular system, the patient should sit instead of stand when she has the option. Immersion in water has also been shown to mobilize extravascular fluid and reduce edema.[156,157] Consider compression stockings to help manage fluid retention in the lower extremities.

FIGURE 13-6 Elevation of feet to reduce varicosis. Note: The feet are higher than the heart to assist venous circulation. Place a wedge under the right hip to prevent SHS.

THERAPEUTIC EXERCISE INTERVENTION FOR WELLNESS IN PREGNANCY

Every pregnant woman adapts differently to the physiologic changes in pregnancy, and for the same woman, every pregnancy is different. The physical therapist must consider age, level of fitness, previous and current exercise history, previous pregnancies and concurrent adaptations to the changes of pregnancy when designing a therapeutic exercise program for the childbearing client.

Research focused on recreational exercise during pregnancy indicates an overall positive impact on pregnancy outcome.[9,155,158] The interaction between the physiologic adaptations to exercise and pregnancy appears to improve maternal cardiovascular reserve, maternal heat dissipation, placental growth, and functional capacity.[9,155] Women who engage in active exercise during pregnancy have fewer of the common discomforts associated with pregnancy, such as swelling, leg cramps, fatigue, shortness of breath, somatic complaints, insomnia, and anxiety.[9,159,160] In low-risk pregnancies, there are no apparent adverse outcomes such as increased risk of miscarriage, preterm labor, preterm birth, or intrauterine growth restriction associated with exercise.[9] Preterm birth is a major determinant of neonatal mortality and morbidity and compared to sedentary pregnant women, women who exercise during pregnancy show significant reductions in preterm birth.[161] Other studies show a reduction in the duration of labor and incidence of obstetric complications during delivery in women who exercise during pregnancy[162–164] (see **Building Block 13-10**).

BUILDING BLOCK 13-10

Your patient/client is a 32-year-old pregnant woman who works as an engineer which requires extensive sitting and desk work. She complains of lower back pain and upper back and neck tension that builds up throughout the day. She would like to remain active throughout her day to help with pregnancy symptoms. Provide some suggestions on how to incorporate activity exercise into her day.

Studies on exercise during pregnancy vary regarding type, intensity, duration, and frequency of exercise and are therefore difficult to compare.[9,165] Current research, however, suggests that moderate aerobic exercise, carefully prescribed and monitored during pregnancy, is safe and beneficial for the mother (even if previously sedentary[166]) and the fetus.[6,7,9,33,155–160,162–164,166–175] Healthy, well-conditioned women can participate in a moderate- or high-intensity exercise program during pregnancy without adverse fetal or maternal outcomes.[176] A Cochrane review reported that regular aerobic exercise during pregnancy appeared to improve or maintain physical fitness.[177]

Concerns about exercise during pregnancy exist nonetheless (**Table 13-2**). Although many of these concerns are not substantiated by research, the guidelines for exercise err on the side of conservative management. Precautions and contraindications should be considered, and prudent guidelines should be followed when developing an exercise program for a pregnant woman.

TABLE 13-2

Exercise Risks During Pregnancy

MATERNAL	FETAL
Hypoglycemia	Hypoxia—possibility that blood flow will be shunted from the uterus in favor of exercising muscles
Chronic fatigue	Distress
Musculoskeletal injury from repetitive mechanical stress, changes in balance, and soft-tissue laxity	Intrauterine growth retardation from alterations in energy and fat metabolism
Cardiovascular complications	Malformations
Spontaneous abortion	Hyperthermia secondary to maternal hyperthermia, increasing risk of neural tube defects, and preterm labor
Preterm labor	Prematurity and reduced birth weight

Data from references 5–7, 40, 49, and 59.

Precautions and Contraindications

Pregnant and postpartum women should seek the approval of their health care providers (e.g., physician, midwife) before engaging in an exercise program. They should be screened for contraindications or risk factors for adverse maternal or perinatal outcome. Dietary intake, prepregnant BMI, and exercise history should be addressed.[178] **Displays 13-6** and **13-7** detail the absolute and relative contraindications to exercise during pregnancy. Limitations or modifications of the exercise program may be recommended at any time during the pregnancy.[6,7,155,167] For example, a pregnant woman with preexisting pulmonary disease may be able to exercise, but her intensity level may vary over time as pregnancy-induced changes affect the respiratory system. As another example, women with GDM benefit from exercise but should be educated in the signs of hypoglycemia. In the presence of a specific relative contraindication, decisions regarding exercise should be made in conjunction with the patient's physician and guidelines referenced in Displays 13-5 and 13-9.

Exercise Guidelines

ACOG and the Melpomene Institute for Women's Health Research have published guidelines for exercise both during pregnancy and after delivery (**Displays 13-8** and **13-9**).[7,47,94] Changing attitudes regarding exercise during pregnancy are reflected in ACOG's 2002 revision of its recommendations (reaffirmed in 2009). In this update, ACOG recommended moderate exercise, 30 minutes or more per day, on most days of the week. The guidelines recommend that previously sedentary women could start a new exercise program during pregnancy.

A gentle-paced water aerobics class may be an appropriate starting point for the first-timer exerciser. Exercise in water offers several physiologic advantages for the pregnant woman.[179–181]

DISPLAY 13-6

Absolute Contraindications to Aerobic Exercise During Pregnancy

- Hemodynamically significant heart disease
- Restrictive lung disease
- Incompetent cervix/cerclage
- Multiple gestation at risk for premature labor
- Persistent second- or third-trimester bleeding
- Placenta previa after 26 weeks of gestation
- Premature labor during the current pregnancy
- Ruptured membranes
- Preeclampsia/pregnancy-induced hypertension

Data from ACOG 2009 Guidelines. Available at: http://www.acog.org/Resources-And-Publications/Committee-Opinions/Committee-on-Obstetric-Practice/Exercise-During-Pregnancy-and-the-Postpartum-Period. Accessed May 18, 2015.

DISPLAY 13-7

Relative Contraindications to Aerobic Exercise During Pregnancy

- Severe anemia
- Unevaluated maternal cardiac arrhythmia
- Chronic bronchitis
- Poorly controlled type 1 diabetes
- Extreme morbid obesity
- Extreme underweight (BMI <12)
- History of extremely sedentary lifestyle
- Intrauterine growth restriction in current pregnancy
- Poorly controlled hypertension
- Orthopedic limitations
- Poorly controlled seizure disorder
- Poorly controlled hyperthyroidism
- Heavy smoker

Data from ACOG 2009 Guidelines. Available at: http://www.acog.org/Resources-And-Publications/Committee-Opinions/Committee-on-Obstetric-Practice/Exercise-During-Pregnancy-and-the-Postpartum-Period. Accessed May 18, 2015.

DISPLAY 13-8

General Exercise Guidelines

Frequency/Intensity

- Exercise regularly, at least three times per week
- Strenuous activity should not exceed 30 minutes; 15 to 20 minute intervals are recommended to decrease the risk of hyperthermia. Ketosis and hypoglycemia are more likely to occur with prolonged strenuous activity
- Do not exercise to exhaustion or undue fatigue
- Postpartum progression into prepregnancy routines should be gradual

Nutrition

- Maintain metabolic homeostasis by maintaining adequate caloric intake
- Fluids should be taken before, during, and after exercise to avoid dehydration
- Eat meals 1½ hours before exercise to avoid digestive discomfort

Program Guidelines

- Avoid ballistic movement, rapid changes in direction, and exercises that require extremes of joint motion
- Include warm-ups and cool-downs
- Avoid overexertion in high heat and humidity, during high pollution levels, and during febrile illness
- Modify intensity according to symptoms and stage of pregnancy
- Low resistance and high repetition exercise is recommended; avoid Valsalva during exercise

Positioning

- Change of positions may help with SHS symptoms
- Avoid sudden changes in posture
- May need to adapt to non–weight-bearing exercise such as pool exercise instead of weight-bearing exercise

Data from references 1–4, 6, 7, 8, and 160.

The hydrostatic force of water, proportional to the depth of immersion, produces an increase in central blood volume by pushing extravascular fluid (edema) into the vascular spaces.[156] This may lead to increased uterine blood flow and serves to keep the maternal heart rate and blood pressure lower than with land exercise. Additionally, the buoyancy of water is supportive, and water is thermoregulating.[156,179–182]

The above guidelines are for the general population.[3,7,8,94,155,167,183–185] They differ from those given to the elite or professional athlete, whose risks and precautions are similar but whose training level may be more intense if closely supervised.[7,158,186,187] Healthy, well-trained pregnant athletes may benefit from training at vigorous levels while facilitating a more rapid return to competition postpartum.[188] However, certain activities should be discouraged or avoided during pregnancy.[6,7,155,167] For instance, the pregnant female should avoid participating in collision or contact sports. The following activities have the potential for high-velocity impact that may cause abdominal trauma and should be discouraged:

- Horseback riding
- Snow and water skiing
- Snow boarding
- Ice skating
- Diving
- Bungee jumping
- Heavy weight lifting
- High-resistance activities

In addition, pregnant females should avoid any hyperbaric conditions, as in scuba diving, and activities that may promote extreme Valsalva maneuvers, such as heavy weight lifting. The pregnant woman should not partake in activities that pose an increased risk of damaging joints, ligaments, and discs secondary to hormonal changes that have already increased joint laxity (e.g., positions in which free weights may put joints into traction or stress the ligaments). The shift in the center of gravity along with increasing weight gain puts the pregnant woman at a higher risk of injury in sports that require balance and agility.[94] The pregnant woman should avoid activities and exercises in which loss of balance is increased (e.g., mountain climbing, gymnastics, downhill skiing, sliding into base), especially in the third trimester. Use caution when exercising at high altitudes during pregnancy, regardless of the trimester.[5,189,190] Be aware of warning signs that exercise should be terminated (Display 13-9).

DISPLAY 13-9

Warning Signs to Terminate Exercise While Pregnant

Vaginal bleeding
Dyspnea prior to exertion
Dizziness
Headache
Chest pain
Muscle weakness
Calf pain or swelling (need to rule out thrombophlebitis)
Preterm labor
Decreased fetal movement
Amniotic fluid leakage

Data from references 1–4 6, 7, 8, and 160.

Exercise Intensity

For the general population, the Centers for Disease Control (CDC) and the American College of Sports Medicine (ACSM) define moderate exercise intensity as three to four METS or the equivalent of brisk walking. It is recommended to exercise at a moderate level most days of the week to maximize health benefits.[191,192]

This recommendation also applies to the pregnant patient (without medical or obstetric complication). Previously, pregnancy guidelines for exercise intensity were based on a heart rate limit of 140 bpm. However, measuring heart rate does not necessarily correlate with exercise intensity. In a recent meta-analysis, there were no significant adverse effects with pregnant women exercising at very high intensity, suggesting women may participate in challenging cardiovascular activities.[193]

Endurance exercise has the additional benefit for pregnant women of preparing them for the increased exertion of labor and delivery. In addition, with dramatic fluctuation in the hormonal milieu, aerobic exercise is an excellent mood elevator. However, pelvic floor laxity may require modifications or support for continuation of aerobic exercise throughout pregnancy. For example, the patient may benefit from use of a sacroiliac belt for support during walking, running, or stair-climbing. Water aerobics or bicycling is an appropriate form of cardiovascular fitness that may decrease stress on weak muscles and vulnerable joints.[179–181]

Exercise Classes

Prenatal wellness can be greatly enhanced by prenatal exercise classes. Physical therapists' understanding of the musculoskeletal system makes them ideal instructors. An individual approach with a focus on essential muscles affected by pregnancy makes these classes different from other community-based classes. Special certification is not required to teach classes, but continuing education in this area is recommended.

Prenatal exercise classes should address the physiologic changes that occur during pregnancy and the therapeutic exercises that prepare the body for these changes. Compliance with exercise improves when clients understand that musculoskeletal dysfunction and associated discomfort may be prevented. Since women who have had one or more vaginal deliveries are at increased risk of chronic back pain, classes that target back pain prevention might be a cost-effective way to reduce disability and health care costs in the future.[194,195] Many women return to these exercise classes after delivery for continued socialization, support, and recommendations on safe exercises to do postpartum. In addition, it may be helpful to offer programming for postpartum women that allows them to interact with their child such as mother/baby exercise or yoga classes (see Chapter 4).

KEY POINTS

- The many physiologic changes that occur during pregnancy affect a woman's ability and motivation to exercise.
- By following precautions, contraindications, and guidelines, a safe therapeutic exercise program may be established for pregnant women.
- Exercise during pregnancy has many benefits and may prevent or assist in the treatment of common impairments.
- Therapeutic exercise during pregnancy focuses on key postural muscles most affected by the biomechanical changes of pregnancy.
- A high-risk pregnancy may require bed rest; however, specific exercises may be performed and are beneficial.
- Therapeutic exercise is beneficial to postpartum recovery, regardless of the type of delivery.

CRITICAL THINKING QUESTIONS

1. The pregnant woman is positioned in supine for a manual therapy technique. Her face begins to lose color, and she complains of faintness.
   a. Should you continue with the technique but move very gently?
   b. Should you offer the patient a glass of water?
   c. Should you have her lie on her side until the symptoms resolve?
   d. Would you proceed with the technique after the symptoms resolved?
   e. What are some possible position changes you could make other than sidelying that could alleviate symptoms?
   f. Can you treat the patient in positions other than supine?
2. A 32-year-old woman, 6 weeks after delivery of her second child, experienced severe lower quadrant pain while lifting a stroller into the trunk of her car.
   a. List possible causes for her pain.
   b. What specific muscle groups would you assess, and what treatment options would you consider?
3. The pregnant patient is being instructed in an exercise program to improve her posture. She begins to experience contractions.
   a. Should you stop the exercise and send the patient home?
   b. Should you have the patient lie in left lateral recumbent position until the contractions stop? Would you then proceed?
   c. Should you call the patient's doctor immediately?
   d. What is your advice to the patient regarding performance of her exercise program?

LAB ACTIVITIES

1. Your patient is 20 weeks' pregnant and complains of sharp pain in the right SIJ with transitional movements. With your partner, perform tests and measures to assess her dysfunction.
   - Discuss modalities that may be appropriate and safe to use on this patient.
   - Demonstrate positioning for treatment and exercise. Make appropriate modifications if SHS is present.
2. With your partner, demonstrate evaluation of the abdominal muscles for a DRA and the appropriate corrective exercise for a patient who is postpartum. Discuss other treatment options for a DRA; discuss the advice you would give to the patient who is postpartum with a DRA regarding basic ADLs.
3. Discuss possible reasons for a pregnancy becoming high risk. Demonstrate exercises that could be taught to a pregnant woman on bed rest.
4. Design an exercise class for healthy pregnant women. Use the general exercise guidelines in Display 13-8.
   - Consider the safety of your class participants. How will you screen participants for possible contraindications or restrictions to exercise?
     i. Develop a screening tool utilizing the information in Displays 13-6 and 13-7.
     ii. Would you require participants to get a physician referral/approval before being allowed to participate in the class?

(continued)

LAB ACTIVITIES (continued)

- Identify barriers to exercise your class participants might encounter.
- Describe the possible physical and psychological benefits of exercise to your class participants. Use the information in Display 13-1 to guide you.
- Describe the possible benefits of exercise during pregnancy on future health.
- How will you motivate your class to participate in exercise?
- Simply describe the physiologic changes that occur in various systems of the body during pregnancy.
- Consider the musculoskeletal changes associated with pregnancy. What strengthening exercises might you want to include in your class to target key muscles?
- What flexibility exercises would you include?
- What precautions might you provide to your class regarding flexibility exercise/stretching?
- Include modifications in your class for a variety of complications that might occur. These include: SHS, DRA, pelvic floor muscle weakness, urinary incontinence, pelvic floor muscle tension, PGP, lower extremity edema, the different stages of pregnancy.
- How will you incorporate promotion of cardiovascular fitness into your class?
- Instruct your class in methods to monitor exercise intensity.
- What signs and symptoms should your class be aware of as a signal to stop exercising and contact their health care provider?
- How will you prepare your class for the postpartum phase of childbearing?

CASE STUDY 13-1

The patient is a 34-year-old married woman in her second trimester of pregnancy. She has a 3-year old and 6-year old at home and she works part-time as an administrative assistant. During the past few weeks, she has noticed the progressive onset of pelvic pain and subsequent limitation in ADLs.

PMH: coccyx injury from slipping on the ice during her teen years, mild LBP during her previous pregnancy

Obs: waddle gait, + modified Trendelenburg

IMPAIRMENTS

Pain in the right SIJ with radiation into the right posterior thigh, pain at the pubic symphysis, instability of pelvic girdle joints, antalgic gait

ACTIVITY LIMITATIONS

Walking long distances, stair-climbing, getting dressed, getting in and out of the car, bed mobility, sexual activity

PARTICIPATION RESTRICTIONS

Unable to participate in her pregnancy exercise class, unable to perform household chores and care for her two children at home in their two-story house, unable to drive children to sports activities, unable to drive to work

QUESTIONS

1. What is the most probable physical therapy diagnosis for this patient?
2. What immediate advice might you give to this patient regarding her ADLs?
3. The patient and her family live in a two-story house. What suggestions might you give to the patient regarding her functional independence in the home?
4. Describe the important muscle groups you would emphasize during exercise instruction with this patient.
5. What adjunctive interventions might you consider for this patient?
6. Using the list of limitations and restrictions, create some functional goals for this patient.

CHAPTER

14

Kinetic Chain Applications in Functional Movement

DANNY MCMILLIAN

Motor events are a long chain of cause and effect.
—Arthur Steindler, MD

The quote above captures the fundamental premise of this chapter. Movement has a complex series of both precursors and consequences, and rarely occurs in isolation. The purpose of this chapter is to identify the relationships that influence the kinetic chain (KC) of cause and effect.

The KC has been defined by Fonseca as mechanically coupled segments in which the forces arising in one segment are transferred to other segments, with the kinematic chain referring to the effect of mechanically coupled segments on motion.[1] In keeping with common usage in musculoskeletal medicine, this chapter will use the term KC to refer to both coupled forces and motions (**Evidence and Research 14-1**).

EVIDENCE and RESEARCH 14-1

Regional Interdependence

Kinetic chain effects are part of a larger concept and clinical model of interconnectedness, referred to as regional interdependence (RI)[2-5] The original RI concept[5] was directed primarily at the musculoskeletal system, but was expanded in 2013 to account for evidence that suggests a patient's primary musculoskeletal symptoms may be directly or indirectly related to or influenced by impairments from various body systems regardless of proximity to the primary symptoms.[4]

The revised RI model accounts not only for musculoskeletal interactions (active and passive subsystems), but also for the influence of neurophysiologic (neural subsystem), somatovisceral (support subsystem), and biopsychosocial effects (cognitive-emotional subsystem). Although such effects are important to movement and should not be underestimated,[6,7] the primary focus of this chapter is the KC and its role in functional movement and tissue stress.

Impairments within the KC commonly degrade movement elsewhere in the chain, often leading to injury or pain syndromes:

- In a prospective, cohort study, trunk displacement, proprioception, and history of low back pain (LBP) strongly predicted knee ligament injury in female athletes. Only a history of LBP was predictive in male athletes.[8]
- In another prospective study, acquired ligamentous laxity of a lower extremity joint predicted the risk of noncontact LBP.[9]
- Burkhart and colleagues have described the association of KC impairments and shoulder pathology. In throwing athletes with shoulder pathology, they have noted decreased mobility of the low back, decreased internal rotation of the contralateral hip (possibly limiting throwing follow through), and dysfunctional performance on single-leg stance tasks, with incidence of those impairments ranging from 39% to 48%.[10]

These examples demonstrate the effect of physical stress on musculoskeletal tissues. Through posture and alignment, muscle performance, and neuromuscular control, the KC heavily influences the degree of tissue stress incurred.[14] Those same factors are also key determinants of how effectively the KC creates functional movement and will frame the subsequent discussion. See **Building Block14-1** for a definition of functional exercise.

BUILDING BLOCK 14-1

Functional Exercise

Although functionality in rehabilitation and performance training is often contentiously debated, here it will be defined as any form of training that improves any relevant biomotor ability that is not detrimental to other biomotor abilities.[11] Such a broad interpretation of the concept of function is warranted based on the variety of interventions that have produced positive outcomes.[12,13] It is incumbent upon clinicians to justify the functionality of their interventions in relation to the patient's activity limitations and participation restrictions. How will you describe the concept of functionality in patient friendly language?

UNDERSTANDING THE KINETIC CHAIN

Biologic developmental and the childhood environment heavily influence characteristics of the KC. Maturation of the central nervous system alters motor patterns, which in turn influence structural development.[15] Developmental disorders or deprivation from normal stimuli during development might preclude optimal function of the KC. For example, Michaud has described how footwear and obesity during early childhood might alter formation of the sustentaculum tali, and subsequently diminish passive support for the medial longitudinal arch, possibly leading to a pathologic degree of pronation in some individuals.[16] Similarly, neurologic insult and musculoskeletal injury bring consequences for the KC, such as when anterior cruciate ligament (ACL) deficiency alters somatosensory input and the individual suffers a resulting decline in the KC's responsiveness.[17]

The neural subsystem orchestrates KC activity in large part by setting the conditions for responsiveness to the environment. Stergiou has described the role of rehabilitation in promoting responsiveness:

> Although our goals often do not explicitly target variability in movement, our implied expectation is that the functional movement that emerges will be adaptive and flexible enough to meet the everyday goals of our patients. To achieve this flexibility, our patients need adequate variability of the motor system. It follows that adequate variability should be a focal point of examination and intervention in order to achieve optimal function for the individual.[17]

The degree to which the KC's coupled segments are dependent upon one another is a key concern of KC analysis. When motion of one segment is independent of the motion of other segments, an open kinetic chain (OKC) is in effect. When motions of the segments are interdependent, a closed kinetic chain (CKC) is in effect.[1] For example, seated knee extension is an OKC event, given that the relationship of the femur and acetabulum is essentially independent of the movement occurring between the femur and tibia. In contrast, when rising from a seat or squatting, CKC mechanics are observed, with interdependent effects not only at the hip and knee, but also involve movements at the ankle, foot, pelvis, and low back.

CKC exercises began to gain favor in the 1980s, in response to evidence from the biomechanics literature demonstrating an increase in anterior shearing forces during the last 30 degrees of OKC knee extension.[18] Since anterior shearing had the potential to strain a healing ACL graft, clinicians desired a safer method to rehabilitate the quadriceps mechanism after ACL reconstruction. An influential in vivo study, measuring ACL strain during various exercises, found that isometric knee extension at 0 and 22 degrees placed more strain on the ACL than walking or stationary biking.[19] Subsequently, rehabilitation protocols shifted to emphasize CKC activities or use them exclusively.[20,21]

In addition to ACL graft concerns, analysis of forces at the patellofemoral joint showed that OKC knee exercises against resistance produce non-physiologic loading of patellar articular cartilage, because of decreasing contact surface between the joint surfaces that occurred as the moment increased from 30 to 0 degrees of knee flexion. The authors concluded that OKC extension exercises, even with the relatively small loads commonly used in knee rehabilitation, produce pressures far in excess of those produced in normal activities, such as stair-climbing or squatting.[22]

After those influential studies, CKC rehabilitation continued to gain in popularity as new investigations highlighted the ability of muscles to affect segments and joints far from their attachments.[23] For example, over 50% of the kinetic energy for a tennis serve was shown to be provided by the legs and trunk.[24] Similarly, for throwing, Burkhart has described force generation from the ground, legs, and trunk; force regulation from the shoulder; and delivery from the arm.[10]

The broad definition of function described in the introduction, together with more recent evidence, warrants utilization of both CKC and OKC exercises. Although some clinicians removed OKC exercise from their ACL rehabilitation protocols based on potential anterior shearing effects, Fitzgerald's 1997 review of the evidence called for a combination of OKC and CKC exercise when quadriceps femoris muscle function is a treatment goal.[25] Current evidence confirms that philosophy, with the caveat that OKC knee extension is restricted to 90 to 45 degrees.[26–28] Similar findings exist for treating patients with patellofemoral concerns, with recommendation that CKC exercises such as a squat should be performed from 45 to 0 degrees of knee flexion. Conversely, OKC movements can be performed from 90 to 45 degrees without a detrimental increase in patellofemoral joint reaction forces[29] (**Building Block 14-2**).

BUILDING BLOCK 14-2

Observation of a patient with the diagnosis of patellofemoral pain (PFP) syndrome during the gait cycle reveals an increase in the amount of frontal plane foot and limb motion.

1. Describe the relationship between the patient's diagnosis and limb mechanics
2. What posture should you exercise the hip and foot in to help decrease stress on the knee?
3. Describe a CKC exercise to eccentrically control hip internal rotation

Understanding OKC and CKC mechanics and, therefore, the degree to which the KC's coupled segments are dependent upon one another, aids in our understanding of energy flow and its potential effect on the movement system. Optimizing movement performance and tissue stress may be thought of as a matter of energy management. The efficacy with which the KC generates, transfers, and dissipates energy is critical to the effectiveness of the movement and the resulting stress on tissues.[1] An approach to energy flow and its effect on functional movement and tissue stress should consider the interrelated components of posture and alignment, muscle performance, and neuromuscular control.

Posture and Alignment

Posture and alignment are influenced by the active, passive, and neural subsystems. Sahrmann has stated "optimal alignment is the desirable if not the necessary requirement for optimal movement."[30] Alignment is particularly relevant to the KC during functional movement, and is supported by evidence that links kinematic variables with muscular activation,[31] joint kinetics,[32–36] and injury risk.[10,37–40]

Alignment and muscle performance interact reciprocally. Sahrmann has described how an anteriorly tilted pelvis might result from hypertrophy of back extensors and hip flexors in combination with relatively less passive tension in the abdominals.[30] In such a case, simply cueing a neutral pelvis or even strengthening the abdominals might not lead to a sustainable leveling of the pelvis if the relative tension of the anterior and posterior muscles is not also addressed.

Alignment also affects tissue stress.[14] For example, sitting with a posteriorly tilted pelvis will increase tensile stress to structures of the posterior spine, although it should not be assumed that such stress will necessarily lead to pain arising from those tissues. Conversely, alignment might be influenced by overstressed (and symptomatic) tissue, for example, when a patient assumes an unbalanced trunk posture to offload an irritated spinal nerve root (**Building Block 14-3**).

BUILDING BLOCK 14-3

Static and Dynamic Postures: Evaluation of static posture aids in understanding segmental relationship, but the degree of clinical relevance, if any, must be determined through a thorough evaluation that also includes movement analysis. Consider a patient presenting with persistent LBP who sits with a posterior tilt of the pelvis but stands with an anterior tilt. Do you expect that motor control of the pelvis and lumbar spine during functional movements will be adequate or impaired? If impaired, do you expect to find isolated motion and muscle performance impairments as well? Will you address those isolated impairments separately or in conjunction motor control training? Will posture and alignment need retraining?

Postural variations from stated norms might be of no clinical consequence.[12,41,42] For example, if a patient presents with a slightly depressed and abducted scapular posture of their dominant upper extremity, but demonstrates effective and pain-free component motions for elevation of the arm, the postural variation might not require intervention. To confirm that hypothesis the clinician is obligated to further examine the patient with a relevant degree of loading to functional movements.

Of particular relevance to this discussion of the effect of posture and alignment on tissues is Dye's concept of the envelope of function, which defines a range of loading compatible with the overall tissue homeostasis of a given joint or musculoskeletal system.[12] The concept considers the magnitude and frequency of the applied stress. The upper limit of the envelope represents a threshold between loads that are compatible with tissue homeostasis and loads that initiate the "complex biological cascade of trauma-induced inflammation and repair."[43] The lower limit to the envelope of function represents loading of the minimal magnitude or frequency required to sustain tissue health (see **Building Block 14-4**).

BUILDING BLOCK 14-4

The envelope of function concept supports the notion that a wide range of postures might support function and tissue health, as long as the involved tissues are capable of tolerating or adapting to the imposed stress. Consider how thoroughly identifying a patient's injury and activity history might aid in understanding their tissue response to stress. Will a patient's history of upper body greater than lower body activity suggest different degrees of tissue resilience between those regions? Consider the likely tissue response to a novel weight-bearing exercise program for someone whose primary means of exercise has been swimming. Contrast the likely tissue response for someone who has primarily hiked over rough terrain for exercise.

Although it is difficult to predict who will develop symptoms because of malalignment, evidence has revealed some specific alignment patterns that suggest the need for further evaluation and intervention. For example, frontal plane malalignment of the knee is well established as a predictor of disease progression in knee osteoarthritis.[44] Other malalignment concerns will be identified throughout this and other chapters.

Muscle Performance

The ability of muscles to generate and dissipate energy is an important determinant of KC function. Muscle performance is primarily a product of interactions of the active and neural subsystems, but is also influenced by the other subsystems of movement. Muscle activation patterns and the inherent orientation of their fibers serve to modulate stiffness of the muscle-tendon unit, with subsequent effects on the KC. For example, in a KC environment, segments with less stiffness move before segments with greater stiffness.[1] When tissue stiffness is ideal, movement is energy efficient without excessive stress to any particular tissue. It is ideal to have sufficient stiffness to resist excessive deformation, but enough compliance to absorb some stress rather than passing too much along to other links in the KC. Although this section will highlight the effects of muscle performance on tissue stiffness, note that passive restraint to lengthening connective tissues also contributes to tissue stiffness.

Consider two examples that demonstrate the effect of stiffness on the KC: first, squatting to lift a box from the floor, then rising to place it on a shelf at shoulder height. The upper extremities stiffen to grasp and hold the box, and the lower extremities stiffen to rise out of the squat. However, consider the trunk. If it is the least stiff of the three segments, motion, under load, will occur there first, potentially creating an injurious transfer of energy to spinal tissues.[45] Now, consider a runner with abnormally high stiffness of the foot. The lack of foot compliance to ground reaction forces will transfer a greater amount of stress up the KC relative to runners with less stiffness at the foot. Such mechanics have been associated with skeletal injury.[46]

Muscle performance is significantly influenced by the muscle's length, and length will change in response to the nature of its use, or lack thereof. For example, muscles immobilized in a shortened position will lose sarcomeres, and, even though the remaining sarcomeres lengthen to enable the muscle to develop maximum tension in its immobilized position, peak tension is only attainable near the position of immobilization.[47,48]

Conversely, muscles in a chronically lengthened position will add sarcomeres in series. To adapt to the new length, individual sarcomeres will shorten in order to maximize potential for creating tension in the lengthened position. Such an adaptation will likely predispose the muscle to active insufficiency at specific ranges of motion.[1,30] For example, if the muscles of scapular adduction are adaptively lengthened because of a chronic posture of thoracic kyphosis and scapular abduction, those muscles will likely generate less than normal tension when the scapula is in a neutral or adducted posture.

The previous example has important implications for clinicians. If a muscle has adaptively lengthened, postural corrections and the therapeutic exercises to reinforce those corrections must be carefully chosen and progressed so that the patient is not asked to sustain postures or generate forces that are impractical because of active insufficiency (see **Building Block 14-5**).

BUILDING BLOCK 14-5

Depression of one or both shoulder girdles is a common observation among patients who report neck or shoulder pain. Consider the effect of this common posture on the length of the upper trapezius and serratus anterior. Would upward rotation of the scapulae be affected? If that is observed when the patient is asked to elevate the upper extremities, what are the implications for initial therapeutic exercise? If the elongated muscles are incapable of generating force in a shortened range, what are the initial steps to restore their force production through a functional range of motion? Would the expected rehabilitation duration be brief or lengthy and why? How important is correction of the habitual posture of shoulder girdle depression?

BUILDING BLOCK 14-6

Consider the patient in Case Study 14-1 to answer the following questions.

1. Given the history and examination findings what are some signs and symptoms that are compatible with abnormal closed chain function?
2. Does the pathology match his abnormal closed chain mechanics? Why or why not?
3. Write some possible short-term and long-term goals for this patient.

In addition to length, muscle performance is highly influenced by activation of other subsystems of the KC. This is a key principle of proprioceptive neuromuscular facilitation. This effect is demonstrated when activation of the serratus anterior is facilitated by simply activating the lower extremity and trunk muscles during specific functional tasks.[49] Therefore, in addition to other facilitation techniques that are common to rehabilitation, clinicians might elicit the desired muscle response by setting the KC conditions for synergistic activation (**Case Study 14-1** and **Building Block 14-6**).

Neuromuscular Control

Coordinated movement is a product of a complex interaction between sensory organs, the central and peripheral nervous system, and skeletal muscle.[50] As such, it is primarily a product of the neural and active subsystems, but is influenced by all the movement subsystems. The importance of neuromuscular control to the KC is highlighted by studies that show improving muscular performance in isolation might not improve common clinical movement impairments until optimal movement patterns are also reestablished.[36,51,52] For example, the consensus statement from an international PFP research summit stated

Case Study 14-1

Patient Case Study #1: Patient is a 28-year-old male roofing contractor with complaints of L medial shin pain and the diagnosis of posterior tibialis tendinitis. States pain is worse at work with climbing ladders and working on a steep pitched roof. Pain has been getting worse over the past month. Recreational activities include jogging three times weekly 30 to 40 minutes which he has been unable to do secondary to the pain. Pain is a 5 on a 0 to 10 scale. Rest and NSAIDs have not been helpful.

PMH: Hernia operation 4 years ago, intermittent LBP

Obs: Patient ambulates with a toe out position on the left, with a normal base of support. Additionally his gait reveals an inverted position of the heel at initial contact with subtalar joint eversion to vertical and prolonged subtalar joint pronation through early to mid midstance without midfoot collapse and with minimal lowering of medial longitudinal arch height. During the later part of the propulsive phase of gait, the patient demonstrates a medial heel whip.

Examination:

MMT: normal throughout except: L hip abd 4/5, hip er 4–/5, posterior tibialis 4–/5 +P

Range of motion (ROM): normal throughout except: B decreased talocrural joint dorsiflexion by 50%

Plantar callus pattern: lateral border of the heel, pinch on great toe

Weight-bearing alignment: external tibial rotation, vertical calcaneal position.

Weight-bearing examination: neutral (subtalar neutral) calcaneal position 10 degrees varus, relaxed calcaneal position vertical. Navicular drop (sit to stand) 7 mm.

Activity Limitations:

1. Patient unable to work safely on pitched roofs.
2. Patient unable to climb frequently up and down ladders.
3. Patient unable to run/walk for more than 10 minutes.
4. Patient unable to stand for more than 40 minutes.

Participation Restrictions:

1. Has been decreasing hours at work over the past month.
2. Unable to participate in recreational activities.

"increasing hip abductor and knee extensor muscle strength does not affect altered lower extremity kinematics associated with PFP."[13]

The fact that improvements in strength do not necessarily improve integrated movement patterns should not come as a surprise, given the fundamentally different effects on the central nervous system between isolated strength training (OKC) and movement skill training (CKC).[53] Clinicians should interpret with caution reports of improved movement patterns based solely on isolated strength or muscle performance training. It is not uncommon for studies to highlight improvements in strength at one region (e.g., the hip) leading to improved outcomes at another (e.g., the knee), even though interventions included integrated training (e.g., alignment during landing, single-leg stance). Consider that the improvements may be due to motor learning effects, and not due to isolated muscle training.[54,55]

Individuals with an ACL-deficient knee represent an interesting cohort with which to examine the effects of neuromuscular control on the KC. Despite the widespread advocacy for reconstructive surgery in the athletic, ACL-deficient population, a sub-cohort of copers (able to resume all pre-injury activities, including sports, without episodes of knee giving way) exists.[56] This group manages to resume athletic activities without reconstructive surgery,[57–59] suggesting that outcomes after an ACL injury are a product of much more than simple joint laxity. Notably, each of the research groups that have documented a cohort with effective resumption of activity without surgery has emphasized neuromuscular training during rehabilitation.[57–59]

Prevention of ACL injuries also benefits from neuromuscular training. A systematic review of clinical trials has shown that such training significantly reduced ACL injury incidence in young, female athletes when combined with strengthening and proximal control exercises.[60] The same review found that preventive programs using only one training mode did not reduce ACL risk; therefore, multimodal interventions that include neuromuscular training are recommended.

Because neuromuscular control of any particular segment of the KC is influenced by all components of the movement system, compromise of any subsystem might degrade movement and expose the individual to injurious tissue stress. For example, a significant increase in musculoskeletal injury risk has been noted for up to 1 year following concussion.[61,62] Similarly, fatigue might induce lower extremity biomechanics and postural control deficits that have been associated with ACL injury[1] (**Evidence and Research 14-2**).

EVIDENCE and RESEARCH 14-2

Selected KC Interactions and Implications

KC Interactions	Implications
Ankle dorsiflexion (DF) ROM may influence movement variables at the knee. For example, decreased DF may limit the ability to perform a squat.[63,64] In contrast to a non–weight-bearing (NWB) method of measurement, ankle DF ROM assessed with a weight-bearing lunge (WBL) differentiated lower extremity kinematics between the normal and limited groups.[65]	These findings and broader understanding of KC interactions suggest that the WBL is a preferred method for evaluating DF ROM, and is likely a more sensitive tool for identifying those with high-risk movement patterns compared to NWB techniques.
Pronation of the feet, and forefoot varus with which it is often associated, have been shown to significantly increase hip internal rotation during gait and a single-leg squat.[66,67] Hip internal rotation and adduction have been frequently associated with PFP and ACL injury risk.[13,38]	Given that excessive hip internal rotation has been associated with knee injuries,[13,37] clinicians should evaluate foot alignment in patients with lower extremity movement impairments. However, caution is recommended when interpreting the results of such evaluation, since there is conflicting evidence regarding the clinical importance of rearfoot kinematics.[13] It is likely that some individuals tolerate an above-average level of foot pronation and others do not.
Mounting evidence suggests that mechanics of the lower extremities are heavily influenced by proximal factors, to include deficient control of the hip, pelvis, and trunk.[13,68–70] Females are generally more affected by these factors than males.[13,70]	Evaluation of lower extremity injuries, pain syndromes, and injury risk must include consideration of mechanics at the hip, pelvis, and trunk. Correction of proximal, mechanical factors that might be associated with injury may, in many cases, occur during the early stages of rehabilitation, when clinicians must protect healing tissues from excessive stress. For example, in the first weeks of ACL reconstruction rehabilitation, the patient can be working on core strength and trunk control in addition to the "typical" early phase of ACL rehabilitation.
A recent biomechanical study found that walking in the swayback posture was associated with higher peak hip extension angle, hip flexor moment, and hip flexion angular impulse compared to natural posture. Walking in a forward flexed posture resulted in a decreased hip extension angle and decreased hip flexion angular impulse.[32]	The findings from this study provide a plausible, mechanical rationale for KC alignment factors that direct excessive forces to anterior hip structures, such as those associated with femoro-acetabular impingement or hip flexor strain. Clinicians should observe for the related gait alignment factors described in this study and consider relevant interventions.

KC, kinetic chain; ROM, range of motion; PFP, patellofemoral pain; ACL, anterior cruciate ligament.

EXAMINATION AND EVALUATION

Because childhood development, movement experience (e.g., sport/activity participation), and injury history heavily influence the KC, clinicians benefit from a thorough history and systems review, which often identify factors that guide the subsequent physical examination. Both qualitative and quantitative techniques are used to evaluate the KC. Observation of gross, functional movement patterns provides information about several important factors, including:

- The subject's willingness to move
- Spatial and temporal characteristics of the gross movement (e.g., base of support, excursion, and speed of movement)
- Spatial and temporal characteristics of directly linked segments (e.g., ankle and knee)

Qualitative Examination

Display 14-1 describes KC observations that provide qualitative information. From these observations, the clinician forms a hypothesis regarding the contribution of perceived movement impairments to the patient's presenting problem. The initial observations also guide the choice of isolated and quantitative examination techniques, which then further guide the examination.

A systematic approach to qualitative assessment that has gained popularity is the Selective Functional Movement

DISPLAY 14-1

Qualitative Examination of the KC

Movement	Criteria and Rationale
Gait	■ Gait provides an opportunity to observe the entire KC during a functional activity. Observe both spatial and temporal characteristics of the entire KC. ■ Although a full evaluation of the KC in gait is beyond the scope of this chapter (see, Gait Analysis: Normal and Pathological Function by Perry),[73] the following are examples of common deviations that compromise the KC and identify the need for a more focused examination. ▪ If during initial swing, the heel rapidly rotates medially (also referred to as medial heel whip or abductory twist), suspect that excessive transverse plane stress is occurring throughout the lower extremity. Prolonged pronation during stance is a common reason for this deviation, although restricted motion at the first MTP joint and impaired muscle performance at the hip might also cause or contribute to this problem. ▪ Limited ankle dorsiflexion might manifest during gait as decreased step length or early heel rise. ▪ Knee impairments might manifest during gait with reduced stance time, lack of knee extension at initial contact, lack of knee flexion during loading response, and circumduction or hip hiking during swing phase, in order to create clearance for a knee that does not flex adequately. ▪ Excessive movement of the knee in the frontal plane during stance suggests increased risk for knee injury as well as PFP syndrome and suggests the need to further evaluate not only the knee, but the hip, foot, and ankle function.[74] ▪ Excessive lowering of the contralateral pelvis (adduction of the stance hip) suggests impaired gluteus medius function on the stance side and might contribute to both trunk and lower extremity pathomechanics.
Breathing pattern	■ The diaphragm and transversus abdominus muscles continuously contribute to the sometimes competing interests of respiration and postural control.[75] ■ Specific loading of the inspiratory muscles impairs postural control by decreasing lumbar proprioceptive sensitivity,[76] and differs significantly in a lifting task for individuals with LBP. However, inspiratory muscle training has been shown to improve postural control in individuals with LBP.[77] ■ These findings suggest KC effects and the need to evaluate the functionality of breathing patterns. Frank and colleagues have suggested the following,[15,78] with the patient seated: ▪ Place the second and third fingers lightly on the patient's lower ribs to detect movement of the rib cage during respiration, while the thumbs on the thoracolumbar paraspinal muscles monitor the intensity of their contraction. ▪ The fourth and fifth fingers are placed lightly on the lateral abdominal wall to monitor the resistance (eccentric contraction) of the abdominal wall against IAP changes during respiration. As the patient breathes in and out, the clinician observes the global posture in addition to monitoring movements at the ribcage and abdominal wall. Although objective measures are limited, some common observable and palpable faulty movement patterns include: (1) cranial excursion of the rib cage or shoulder elevation secondary to compensation of accessory muscles of respiration to make up for inadequate diaphragm activity; (2) excessive contraction of paraspinal muscles; (3) inadequate lateral rib cage expansion or resistance of the abdominal wall against IAP changes; and (4) inability to maintain the upright spinal alignment (either into flexion or extension). These faulty patterns are often magnified if the patient is cued to lightly brace his or her abdominals.

(continued)

DISPLAY 14-1

Qualitative Examination of the KC (*continued*)

Hip hinge	■ This movement involves hip flexion while maintaining the neutral position of joints above and below (the knee should remain flexed 10 to 20 degrees throughout the hip hinge). The hip hinge is a component motion of squatting and, therefore, many common functional tasks. It is also a technique for lifting items when a squat is contraindicated (e.g., knee impairment) or impractical (e.g., lifting an object from a shopping cart). ■ Inability to keep either the spine or the knees in neutral suggests that the patient will transmit energy to those segments during similar functional movements, rather than using the large hip joint and surrounding musculature. Such a movement habit might overload tissues of the spine or lower extremities.
Squat	■ Ask the patient to assume the stance width and directional orientation of the feet that they normally use to squat. ■ To squat, the knees flex synchronously with the hip hinge described above. The heels remain on the floor. The feet remain aligned with the transverse plane position in which they started, but not necessarily in parallel with the sagittal plane. ■ If the heels do not remain on the ground, limited dorsiflexion of the ankle or hypertonicity of plantar flexor muscles is suspected. However, poor coordination of the squat pattern, with excessively forward weight distribution, might also be the culprit. ■ If the feet excessively pronate, with noticeable forefoot abduction during the squat descent, suspect compensation at the transverse tarsal joint for limited ankle dorsiflexion. ■ In addition to the spinal neutral checkpoint noted for the hip hinge, also observe for frontal and transverse plane deviations of the pelvis and trunk. Such deviations might indicate impaired segmental motion of the spine, poor coordination of the KC, or unequal weight bearing in response to pain or dysfunction. ■ Knee deviations in the frontal plane are common and linked to an increased risk for knee injury as well as PFP syndrome. ■ Consider the functionality of the depth of the squat relative to the individual's movement requirements.
Single-leg stance (SLS)	■ The trunk should demonstrate only minimal sway. Ensure that the first and fifth rays of the foot maintain contact with the ground. SLS reduces the normal standing base of support and thus challenges balance. ■ In the sagittal plane, the knee is straight but not hyperextended (a sign of reliance on passive stability). ■ Also observe the knee for frontal plane stability. Excessive movement suggests increased risk for knee injury as well as PFP syndrome. ■ In the sagittal plane, the hip should remain in neutral. Realize that anterior and posterior pelvic tilting create hip joint flexion and extension, respectively, and suggest poor pelvic stability. ■ In the frontal plane, observe for hip adduction or abduction (lowering or raising the contralateral pelvis, respectively). Lowering of the contralateral pelvis (adduction of the stance hip) suggests impaired gluteus medius function on the stance side. ■ If excessive sway precludes using the SLS to observe the KC relationships described above, consider using the balance measurement tools recommended in Chapter 8. ■ If indicated, add further movement challenges to the SLS (e.g., hip hinge, squat, upper extremity reaches, contralateral leg swings).
SLS with heel raise	■ During the SLS heel raise, the clinician should observe relative rearfoot inversion, while the first and fifth rays of the foot remain in contact with the ground. Inability to do so suggests impaired ability to optimally stabilize the foot for propulsion during gait or other dynamic activities. ■ KC relationships described above for SLS should remain the same.
Step up/down	■ This movement combines some of the demands of SLS and squatting; therefore, many of the criteria for optimal movement are described above. ■ Observe hip and knee control in the frontal and transverse planes. ■ Observe sagittal plane motion of the pelvis; anterior tilting suggests impaired performance of the gluteus maximus.
Overhead reach	■ This movement allows the observer to evaluate the individual's ability to maintain a relatively neutral position of the trunk while reaching with one or both arms (simulate a functional task). Begin with parallel stance, but add challenge as indicated by changing the base of support (e.g., staggered stance) or adding a concurrent task such as stepping and reaching. Modify the speed and excursion of the task as indicated. ■ Inability to achieve independent limb and trunk movement decreases efficiency and might contribute to pathomechanics of the trunk or extremities.

KC, kinetic chain; MTP, metatarsophalangeal joint; PFP, patellofemoral pain; LBP, low back pain; IAP, inter-abdominal pressure; SLS, single-leg stance.

Assessment (SFMA).[71] The assessment begins with 10 movement patterns that are scored either categorically (functional or dysfunctional; painful or not painful) or using a criterion checklist (34 factors total for the 10 movements). Dysfunctional or painful movements then prompt further examination (complete coverage of the SFMA is beyond the scope of this chapter). Reliability testing of the SFMA showed excellent intrarater reliability for categorical scoring, and poor to good reliability when using the criterion checklist. Interrater reliability of the categorical scoring tool was slight to substantial, but was unacceptable for the criterion checklist.[72] To date, the SFMA has not been validated for clinical use, and therefore it is uncertain if the systematic approach of the SFMA adds additional value to KC examination.

Quantitative Examination

Observation of impaired KC function normally requires further examination of discrete segments of the musculoskeletal system. That examination will usually include both qualitative factors (e.g., determining the end-feel of a synovial joint) and quantitative measurements such as ROM or instrumented laxity measurements. The gross function of the KC may also be measured.

The most commonly used clinical tools for measuring KC function are hop tests and balance reach tests. Although products are available to enhance the measurement of such tests, this descriptions here will be limited to test that do not require equipment.

- Hop tests are primarily used to establish a limb symmetry index (LSI). To calculate the LSI, divide the distance hopped on the involved side by the distance hopped on the uninvolved side, and then multiply by 100. For timed hop tests, calculate the LSI by dividing the time to completion of the uninvolved limb by the time to completion of the involved limb, and then multiply by 100. Evidence has shown that for the single-leg hop, 93% of normal individuals have greater than 85% LSI, and 100% have LSI greater than 80% Therefore, most clinicians and researchers support the use of LSI return-to-play criteria ranging from 80% to 90%.[79,80]
    - The most well established hop tests have been used to measure readiness for return to full activity after ACL reconstruction. Reid reported that four hop tests—single hop, triple hop, crossover hop, and the 6-m timed hop—originally described by Noyes provided reliable and valid outcome measurement for rehabilitation and return to sport after ACL reconstruction.[80] Therefore, those specific hop tests can be used to inform return-to-play decisions.
    - Logerstedt reported that hop tests conducted 6 months postoperatively predicted self-reported knee function at 1 year, with the 6-m timed hop and crossover hop tests being most predictive. Using receiver operating characteristic curves to determine the overall discriminative accuracy of each single legged hop test, the optimal LSI was 88% and 95% for the 6-m and crossover hops, respectively.[81]
    - Since LSI could improve because of unwanted decrements in performance of the uninvolved limb, absolute gains are important to document. Rohman studied such potential effects and reported no performance decrement in the uninvolved limb of a large cohort, indicating the improvements seen in LSI were reflective of valid improvement in performance of the involved limb.[80]
    - In a systematic review of the literature, Hegedus has urged caution when using hop tests to evaluate knee function, because of conflicting or unknown evidence regarding their measurement properties.[82] In the same study, it was noted that the single-leg hop for distance is discriminative in males with ACL tears and that it is responsive to rehabilitation after ACL tear.[82]
    - Single-limb hop tests have also been used to evaluate the functional performance for patients with functional ankle instability (FAI), with conflicting evidence as to whether such tests are valid indicators of dysfunction.[83,84] As a result, Caffrey proposed four novel hop tests (figure-of-8 hop, side hop, 6-m crossover hop, and square hop) designed to better challenge ankle function relative to traditional hop tests designed to evaluate knee function.[85] Results from the original cross-sectional study showed that for subjects with FAI who reported giving way with activity, performance deficits were noted relative to both a control group and the uninvolved limb.
    - It is important to note that hop tests are not designed to evaluate movement quality. Though many clinicians note qualitative factors such as movement into knee valgus upon landing, as designed, the hop tests noted here are strictly quantitative evaluation tools.
- Star Excursion Balance Test (SEBT)
    - First described by Gray,[86] the SEBT is a practical tool for examining an individual's ability to maintain SLS while maximally reaching in various directions with the non–weight-bearing foot.
    - A systematic review by Gribble reported that the SEBT is a "highly representative, non-instrumented dynamic balance test for physically active individuals."[87] Reliability for the SEBT is good, with validity to predict lower extremity injury risk, identify dynamic balance deficits, and to be responsive to training in both uninjured and injured populations.[87,88]
    - Clinicians should note that only the anterior, posteromedial, and posterolateral reaches have been associated with injury risk.[89]
    - Like the hop tests, the SEBT is not designed to evaluate movement quality. Although it is useful for quantifying lower extremity reach excursion, the test itself does not have a means for evaluating movement quality.[90]
- The Landing Error Scoring System (LESS) was designed as a clinical tool for identifying movement patterns associated with lower extremity injury risk during landing.[91] The LESS requires a box with a height of 30 cm, two cameras, and a video analysis equipment. Because the LESS requires such equipment, the developers sought to enhance clinical utility by modifying the test to allow for analysis in real time, thus the LESS-RT, which appears to have comparable interrater reliability and precision.[92] Both the LESS and LESS-RT evaluate qualitative jump-landing performance factors such as knee valgus, lateral trunk flexion, and knee flexion

displacement Although the LESS has established reliability and correlation with three-dimensional laboratory analysis of landing kinematics,[91] it was unable to predict injury risk in a large, case–control study.[93] Such findings highlight the complexity of the KC and injury mechanisms, and should serve as a caveat to clinicians attempting to predict injury from biomechanical findings.

- The tuck jump assessment (TJA) was also designed to identify biomechanical deficiencies that predict risk for ACL injury.[94] Among those deficiencies described by Hewett and colleagues are ligament dominance, quadriceps dominance, leg dominance/residual injury deficits, trunk dominance, and technique deficits.[38] The tuck jump test requires the individual to perform as many jumps as possible in 10 seconds. Tuck jumps are defined by movement of the thighs to parallel with the ground at the highest point of the jump. Six common errors that suggest the biomechanical deficiencies noted above are: (1) medial knee collapse, (2) knees not reaching parallel to the ground, (3) asynchronous lower limb positions during flight, (4) landing with the feet too close together, (5) landing in an staggered stance position, and (6) failure to land with both feet at the same time. In addition to those faults, other factors noted are pausing between jumps, excessive noise upon landing, inconsistent landing footprint, and degraded movement within 10 seconds. The developers of the TJA have suggested that six or more faults (out of 10 total factors assessed) indicates a need for further technique training.[94]
- To date, the TJA tool has not been tested for predictive value, but Myer has shown that augmented feedback based on TJA faults improved landing performance on a separate vertical jump task, suggesting that motor learning of improved landing technique had occurred.[94]
- It is important to note that the TJA and LESS take into consideration the quality of movement, something the SEBT and hop tests do not.
- Close Kinetic Chain Upper Extremity Stability Test (CKCUES)
  - Reflecting the nature of the KC, most KC tests challenge the lower extremities to a greater extent than the upper extremities, but the CKCUES might be a useful evaluation tool for individuals whose upper extremity functional activities include CKC activities. For example, a carpet layer, who works on his hands and knees, may benefit from assessment via CKCUES. Although reliability[95–97] and reference values[98,99] have been published, the functionality of the test has been questioned and its possible inherent risk noted.[97]
  - The CKCUES test is performed from the push-up position, with the hands at 36 inches apart (a 1.5-inch strip of athletic tape normally serves as the reference point). To perform the test, use one hand to reach across and touch the tape under the opposing hand. After touching the tape, the hand is taken to the original starting position and the movement is repeated with the other hand. The score is the number of touches within 15 seconds. Note that the published performance standard to date has been the same for men and women.

CHOOSING THERAPEUTIC MOVEMENTS TO ENHANCE KINETIC CHAIN FUNCTION

Effective function of the KC requires effective performance of its components. When impairments of KC segments preclude optimal integrated movement, then interventions should target those impairments. As discussed previously, both OKC and CKC activities have a role in rehabilitation, with OKC exercise generally most appropriate to target isolated impairments in the stability stage of motor control. However, different stages of motor control can be addressed with the concurrent use of OKC and CKC exercise (**Building Block 14-7**).

BUILDING BLOCK 14-7

A patient with a quadriceps strength deficit may perform CKC activities in conjunction with their OKC activities as long as the demands of the CKC activities do not exceed their capabilities and render a faulty movement pattern in the patient. Describe some possible program modifications to CKC activities in such a patient.

Clinicians should note that discrete impairments of KC segments vary in their effect on other segments. A kinematic study of female runners with PFP found that rearfoot kinematics did not differ between the PFP and control groups.[68] However, the PFP group demonstrated greater hip internal rotation and adduction, as well as greater shank internal rotation, suggesting that pathomechanics at the knee and shank were driven more by proximal rather than distal factors.[68] These findings are consistent with reports from the two most recent international PFP research retreats.[13,100] This does not suggest that interventions directed at segments distal to the knee should be discounted for patients with PFP, but rather that clinicians should seek to prioritize, through research evidence and examination of the individual, those factors that are most relevant to a particular patient's clinical problem. For a more complete explanation of the factors that influence patient management, the reader is referred to Chapter 2.

As the patient advances through the stages of motor control, skill training addressing activity limitations and participation restrictions must be considered. In many cases, that will require rehabilitation tasks with higher energy demands and greater tissue risk. See **Display 14-2** for a discussion of factors that guide exercise prescription and progression.

The individual requirements for each of the factors discussed in Display 14-2 vary widely across occupational, recreational, and sports tasks. For example, a patient who wishes to return to participation in gardening (participation restriction) might benefit most from interventions that improve movement excursion, load carriage, and endurance. For the gardener, the speed and complexity of movement are likely less important and would not be rehabilitation priorities. In contrast, a patient who wants to resume playing tennis requires complex movements involving speed. Clinicians must carefully select interventions that best target impairments related to the patient's activity limitations and participation restrictions. This may prove challenging in an environment in which rehabilitation time is constrained (**Evidence and Researches 14-3** and **14-4**).

DISPLAY 14-2

Factors that Guide Exercise Prescription and Progression with Clinical Application

Factor of KC Exercise Selection and Progression	Clinical Application
Excursion	■ Training for control of movement normally starts with restricted motion, then, as stability through the restricted range is demonstrated, that range can be expanded incrementally through controlled mobility and skill. ■ Excursion refers to the functional ROM through which an integrated KC exercise is performed. In this context, it does not include isolated stretching or joint mobilization, although those modalities might be complementary. ■ Maximal excursion must be both consistently controlled and relevant to the movement demands of the patient.
Speed, acceleration, and deceleration	■ Training for control of movement normally starts with a slow speed. Slower speeds initially might promote better movement awareness for the patient, as well as afford the clinician a better opportunity to evaluate alignment and control. ■ Excessively slowing a movement might degrade it. Therefore, as long as tissue safety is ensured, clinicians might consider adding some speed in an attempt to elicit a better movement pattern. ■ Even activities of daily living involve substantial KC segment speeds, if not the entire KC. This suggests that clinicians should routinely add speed of movement to some degree for all patients. ■ For many occupational, recreational, and sports tasks, the speed demands are obvious. If rehabilitation is to ensure the restoration of function, training those tasks at progressive speeds, in a controlled environment, is imperative.

Complexity	■ Clinicians seeking to promote motor learning of integrated KC tasks may easily manipulate several variables that contribute to the complexity of a movement. Among these are:
	  ■ Base of support: Decreasing the base to increase the complexity.
	  ■ Number of planes in which movement must be controlled: Increase the number of planes to increase the complexity. The easiest plane in which to move is the sagittal, followed by the frontal, and lastly, the transverse plane.
	  ■ Surface: Unstable surfaces create greater complexity for movement control. However, somatosensory input to the central nervous system becomes, in effect, less reliable; therefore, visual and vestibular pathways are used for movement control to a greater degree than they would if the movement occurred on a stable surface. When selecting the surface, clinicians should consider both the objectives of the movement and the surfaces on which the patient will perform their goal activities.
	  ■ Environment. An open, changing environment increases complexity. For example, stepping and reaching movements are made more complex by manipulating an object, reacting to visual or verbal cues, or cognitive problem-solving.

Load	■ Training for control of movement normally starts with a low degree of loading, and then incrementally adds loads until a functionally relevant degree of loading has been applied and the patient has maintained the quality of the movement. ■ For integrated KC training, it is assumed that isolated strength deficits or imbalances have been resolved by resistance training earlier in rehabilitation. Therefore, for this discussion, it is assumed that the stress of progressive loading is shared throughout the KC and that all segments of the chain are unimpaired. ■ Progressive loading is achieved in a variety of ways. In addition to the obvious effects of external loading, note that increasing acceleration/deceleration (e.g., plyometrics, agility training) also increases loading.
Volume (endurance)	■ For movement control training, volume reflects the total number of repetitions for a given period of time. For conditioning exercise (e.g., running, swimming), distance or time may be used to measure volume. ■ The volume of activity (inclusive of rehabilitation and other activity) is an important determinant of the viability of the support subsystem. ■ Increasing the volume of training, along with increasing strength and movement control, will lead to a greater work capacity.

KC, kinetic chain; ROM, range of motion.

EVIDENCE and RESEARCH 14-3

Evidence for KC Exercise Interventions Based on Clinical Objectives

Objectives	Interventions and Effects
Type of Analysis	
Modify factors related to PFP *Consensus statement based on review of the literature*[13]	■ Strengthening posterolateral hip muscles reduces pain and improves function when performed alone, or in combination with multimodal therapy. ■ A dynamic warm-up including CKC quadriceps and gluteal strengthening exercises may prevent the development of PFP for active individuals. ■ Because pathomechanics differ between men and women, rehabilitation goals might need to be sex-specific.
Reduce risk of ACL injury for female athletes *Meta-analysis with subgroup analysis for exercise interventions categorized as balance, plyometric, strength, and proximal control*[60]	■ The greatest prophylactic effect was seen with strengthening and proximal control exercises. ■ Plyometric exercises reduced ACL injury incidences, but were not statistically significant. ■ Balance exercises alone did not demonstrate ACL injury reduction; however, this may be related to the number of exercises incorporated rather than the actual balance exercises. ■ Two studies that incorporated only a single exercise mode did not reduce ACL injuries. Studies that combined multiple exercise modes including plyometrics, strengthening, trunk and balance exercises demonstrated greater ACL injury reduction.
Modify factors related to hamstring strain *Clinical trials*	■ Progressive agility and trunk stabilization is associated with a decreased risk of reinjury.[101] ■ Training programs with an eccentric emphasis, have similar effects as progressive agility and trunk stabilization programs.[102] ■ Training that exposes the hamstring and KC to high loads at long muscle-tendon lengths enhances return to sport.[103]
Improve outcomes and prevent recurrence after ankle sprain *Systematic reviews*	■ Limited to moderate evidence suggests that functional training programs reduce chronic ankle complaints, and might prevent recurrence.[104] ■ After acute ankle sprain, balance and coordination training of at least 6 weeks resulted in a 20% to 60% relative risk reduction for lateral ankle sprain for up to 1 year.[105]
Retrain gait for injured and healthy runners *Systematic review*[106]	■ Real-time feedback was effectively used to (1) reduce variables related to ground reaction forces, and (2) positively modify lower extremity kinematic patterns associated with injury risk. ■ Both healthy runners and those with PFP or chronic exertional compartment syndrome might benefit from such real-time feedback. ■ No one method of feedback was identified as being superior. Mirror and two-dimensional video feedback were identified as potential methods for running gait modification in a clinical setting.
Reduce pain and disability associated with LBP *Systematic review with meta-analysis*[107] *Systematic review*[108]	■ Strong evidence that stabilization exercises are not more effective than any other form of active exercise in the long-term.[107] ■ Studies specifically compared isolated motor control exercise (generally targeting the transversus abdominus and multifidi) with a general core strengthening exercise intervention. Two studies documented better outcomes with the general exercise program, and the other four studies reported no significant differences between the two. The authors concluded that "it may be unnecessary to prescribe therapeutic exercises that are purported to selectively activate the local muscles."[108] That conclusion is supported by McGill's analysis that stability is generally not enhanced by attempted isolation of deep trunk muscles.[45]

EVIDENCE and RESEARCH 14-4

Evidence for Specific KC Exercises to Target Specific Muscles

Targeted Muscles	Exercises and Selection Factors
Quadriceps and hamstring co-activation	■ Quadriceps-dominant activation has been associated with ACL injury risk.[38] ■ Exercises that balance quadriceps and hamstrings activation are valued in ACL rehabilitation and injury prevention programs. ■ In one study, the most balanced quadriceps-to-hamstrings co-activation ratios were produced during the single-limb dead-lift, lateral-hop, transverse-hop, and lateral band-walk exercises.[109] Note that hops involved a single-limb landing. ■ Although the forward lunge with an upright trunk was not among the best exercise at balancing the ratio in that study, the exercise is heavily influenced by trunk position. Performing the lunge with a forward trunk lean increases activation of the hamstrings and improves the ratio.[110]
Gluteus maximus activation[111]	■ In a systematic review of the literature, Reiman analyzed the factors that influenced gluteus maximus activation, and suggested that clinicians consider trunk position relative to the base of support and the direction of movement as key factors. ■ The exercise with the highest gluteus maximus activation was the forward step up, with very high activation (>60% of maximal voluntary isometric contraction [MVIC]) (**Fig. 14-1**). ■ Variations of the lunge (except the lunge with backward trunk lean), squat, and dead-lift had moderate (21% to 40% MVIC) to high (41% to 60% MVIC) levels of gluteus maximus activation.
Gluteus medius activation	■ As part of Reiman's systematic review of the literature, gluteus medius activation was also analyzed. The exercises with very high gluteus medius activation were the side-bridge to neutral spine position and the single-limb squat.[111] ■ In a laboratory study, Distefano reported that the single-leg squat and single-leg dead-lift strongly activated both the gluteus maximus and medius.[112]

APPLYING THERAPEUTIC MOVEMENT

In general, biological systems, including humans, are complex, nonlinear systems with inherent variability in all healthy organisms.

—*Jan Walleczek*[113]

The quote above underscores the need for clinicians to not only treat individuals rather than generic pathologies, but also to ensure that intervention choices and application of therapeutic movements will facilitate a KC that addresses activity limitations and participation restrictions. The practical implication is that the exercises described in the following exercises serve as a starting point for exploration between clinician and patient. The patient's unique capabilities and goals guide the process, but clinicians that promote KC responsiveness to a wide-range of movement environments will add value (see **Case Studies 14-2**, **14-3**, and **Building Block 14-8**)

Selected KC exercises techniques are presented in this section to highlight key factors of execution and provide a theoretical framework for progression. The series of exercises begins with the hip hinge (**Self-Management 14-1**), an important component of squatting. From the squat in parallel stance, among the most functional of movements, the progression incorporates asymmetric stance activities (**Self-Managements 14-2** to **14-4** starting on page 372). Those exercises provide an opportunity for the clinician to manipulate each of the factors of progression discussed in Display 14-2.

CASE STUDY 14-2

Patient Case Study #2: Patient is a 60-year-old female who complaints of bilateral medial plantar heel pain L > R. The patient complains of significant heel pain the first thing in the morning or when she arises in the middle of the night requiring her to "shuffle to the bathroom." Once she is up and moving her heel pain subsides unless she is on her feet for sustained activities or for a prolonged amount of time. Pain is rated at a 6 on a 0 to 10 scale. Footwear includes 3-year-old casual shoes, open toe sling back sandals with a 1-inch heel, "unbranded" 2-year-old walking shoes.

PMH: Type II diabetic ×5 years controlled by diet and exercise. L bunionectomy ×2 years ago; high blood pressure which is controlled with medication.

Obs: Mild truncal obesity. Patient demonstrates a bilateral Trendelenburg gait pattern, with a wide base of support and an increase in the toe out angle of her gait. Additionally her gait reveals excessive and prolonged subtalar joint pronation with midfoot collapse throughout stance resulting in abduction of the forefoot on the rearfoot and loss of medial longitudinal arch height. During the later part of the propulsive phase of the gait cycle the patient demonstrates a medial heel whip thus shifting her weight to the lateral aspect of her foot.

MMT: Normal throughout except: B hip abd 4–/5, hip er 3+/5, hip ext 4–/5

ROM: Normal throughout except: B decreased talocrural joint dorsiflexion by 50% and decreased hip internal rotation and extension by 50%.

Non–weight-bearing FF to RF foot alignment: perpendicular

Weight-bearing alignment: B anterior pelvic tilt, with slight hip flexion, internal medial femoral rotation, knee valgus, external tibial rotation, calcaneal eversion, and lowered medial longitudinal arch.

Weight-bearing examination: neutral (subtalar neutral) calcaneal position 2 degrees varus, relaxed calcaneal position 10 degrees everted. Navicular drop (sit to stand) > 10 mm.

Activity Limitations:

1. Very painful first few steps in the morning
2. Patient unable to walk more than ¼ mile without stopping to rest.
3. Patient unable to be weight bearing longer than 20 minutes.

Participation Restrictions:

1. Patient unable to maintain household and perform gardening activities and volunteer activities.
2. Patient unable to participate in her regular exercise program, both a primary social outlet and necessary to control her type II diabetes.

CASE STUDY 14-3

Patient Case Study #3: Patient is a 17-year-old female high school soccer player who complains of R posterior lateral hip pain ×2 weeks, diagnosed withgreater trochanteric bursitis. The patient complains of hip pain while running which is worse when she begins running. Once she is warmed up and moving her hip, pain subsides unless she's on her feet for sustained activities or for a prolonged amount of time. Pain is rated at a 6 on a 0 to 10 scale. She is pain-free with NWB activities. She is trying to win a college scholarship in soccer.

PMH: Unremarkable, tonsillectomy age 5-year old.

Obs: Patient demonstrates a bilateral Trendelenburg gait pattern, with a wide base of support and an increase in the toe out angle of her gait. Additionally her gait reveals excessive and prolonged subtalar joint pronation with midfoot collapse throughout stance resulting in abduction of the forefoot on the rearfoot and loss of medial longitudinal arch height. During the later part of the propulsive phase of gait the patient demonstrates a medial heel whip thus shifting her weight to the lateral aspect of her feet.

MMT: Normal throughout except: B hip abd 4–/5, hip er 3+/5, hip ext 4–/5

ROM: Normal throughout except: B decreased talocrural joint dorsiflexion by 50% and decreased hip internal rotation and extension by 30%.

Non–weight-bearing FF to RF alignment FF varus 10 degrees

Weight-bearing alignment: B anterior pelvic tilt, with slight hip flexion, internal medial femoral rotation, knee valgus, external tibial rotation, calcaneal eversion and lowered medial longitudinal arch.

Weight-bearing examination: neutral (subtalar neutral) calcaneal position vertical, relaxed calcaneal position 10 degrees everted. Navicular drop (sit to stand) >10 mm.

Activity Limitations:

1. Patient unable to walk/run more than 10 minutes without stopping to rest.
2. Patient unable to be weight bearing longer than 20 minutes.

Participation Restrictions:

1. Patient unable to participate in her regular exercise program, both a primary social outlet and possible scholarship for college soccer.

BUILDING BLOCK 14-8

Consider the patients in Case Studies No. 2 and No. 3 to answer the following questions.

1. What are the common examination findings between both case studies?
2. What examination findings are different and significant to abnormal gait?
3. Using the principles of CKC function, how does the influence of the weak hip musculature in Case Study No. 2 contribute to her pathology? Does the pathology match her abnormal closed chain mechanics?
4. Using the principles of CKC function, how does the influence of the forefoot varus alignment in Case Study No. 3 contribute to her pathology? Does the pathology match her abnormal closed chain mechanics?
5. Describe two hip CKC exercises in the frontal plane to improve the valgus position at the knee.

SELF-MANAGEMENT 14-1
Hip Hinge to Squat

Purpose: To promote good alignment and neuromuscular control of the spine by using the hips to initiate movement. As the exercise progresses to a squat, it also serves to strengthen the legs.

Precautions and Contraindications: Limited weight-bearing status; pain on exertion.

Position: Stand in a tall posture with the feet wide enough to allow comfortable squatting. The feet may be directed straight ahead or rotated out for comfort. Initially, the buttocks are a few inches from the wall, trunk muscles are lightly engaged, the pelvis is in neutral, and the knees are straight but not locked backward.

Movement Technique:

- Direct the buttocks backward to lightly touch the wall, allowing the trunk to angle slightly forward.
  - To keep the trunk straight, pretend there is a stick connecting the back of the head, spine, and tailbone.
- Return to the starting position and repeat. Gradually step further from the wall.
- Progress to a squatting movement that includes flexing of the knees. You may use a chair to serve as a target for the squat depth.
- Alternately, you may use weights in the hands to simulate lifting of an object from the floor.
  - During the squat, pretend the knee caps are flashlights and your control of the movement keeps them shining in line with the direction the feet are pointing.
- Maintain rhythmic breathing and fluid movements.

Dosage:

Repetitions: ______________________

Frequency: ______________________

SELF-MANAGEMENT 14-2
Split Squat to Runner's Pose

Purpose: To promote good alignment and neuromuscular control of the spine and lower extremities; enhance balance and coordination; and promote leg strength/power.

Precautions and Contraindications: Limited weight-bearing status; impaired balance; pain on exertion.

Position: Split stance with the trunk muscles lightly engaged, the spine aligned, and the pelvis in neutral as well as squared to the front. The front foot is flat, with the rearward heel off the ground. Width of the foot placement should promote a balanced stance. Hands may be on the hips, at the side, or overhead (most challenging variation).

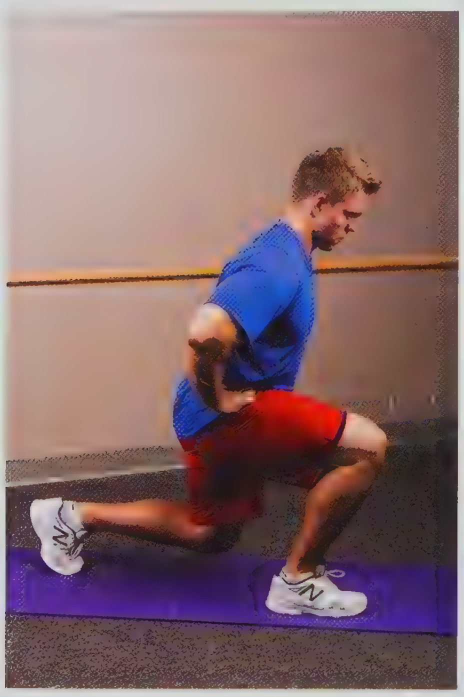
Movement Technique:

- Lower the body to a comfortable depth.
  - Pretend there is a stick connecting the back of the head, spine, and tailbone. The stick/trunk tilts slightly forward to maintain the majority of body weight on the front leg.
  - Pretend the front-leg knee cap is a flashlight and your control of the movement keeps it shining straight ahead.
- Return to the starting position by pressing through the entire foot of the forward leg.
- To progress this exercise, raise out of the split squat directly into a SLS on the front leg (runner's pose), pause for 1 to 3 seconds, then return to the split squat all in one motion.
  - Note the change in arm position
- Maintain rhythmic breathing and fluid movements.

Dosage:

Repetitions: ____________________

Frequency: ____________________



SLS, single-leg stance.

SELF-MANAGEMENT 14-3
Forward and Diagonal Lunge

Purpose: To promote good alignment and neuromuscular control of the spine and lower extremities; enhance balance and coordination; and stimulate leg strength/power.

Precautions and Contraindications: Limited weight-bearing status; impaired balance; pain on exertion.

Position: Stand in a tall posture with the trunk muscles lightly engaged, the pelvis in neutral, and the knees straight but not locked backward. Hands may be on the hips, at the side, or overhead (most challenging variation).

Movement Technique:

- Step forward and lower the body to a comfortable depth (**Fig. A, B**).
  - Pretend there is a stick connecting the back of the head, spine, and tailbone. The stick/trunk tilts slightly forward to maintain the majority of body weight on the front leg.
  - Pretend the front-leg knee cap is a flashlight and your control of the movement keeps it shining straight ahead.
- Return to the starting position by pressing through the entire foot of the forward leg and springing backward.
  - The stick/trunk remain tilted slightly forward throughout the movement.
- Alternatively, perform a walking lunge by stepping forward with the back leg.
- For the diagonal lunge, step forward and laterally (about 45 degrees), keeping the front foot entirely on the ground and pointed forward (**Fig. C**).
  - Allow the rearward foot to pivot naturally as the arm reaches across the body.
- Increase the challenge by adding trunk rotation and/or additional load such as a weighted ball (**Fig. D, E,** and **F**).
- For each of the lunges, maintain rhythmic breathing and fluid movements.

SELF-MANAGEMENT 14-4
Single-Leg Run and Reach

Purpose: To promote good alignment and neuromuscular control of the spine and extremities; enhance balance and coordination

Precautions and Contraindications: Limited weight-bearing status; impaired balance; pain on exertion

Position: Stand in a tall posture on the right leg, with the trunk muscles lightly engaged, the pelvis in neutral, and the stance knee straight but not locked backward. The left leg is flexed to 90 degrees at the hip and knee. The left hand is at the side, whereas the right hand is at chin level. Both elbows are bent to 90 degrees

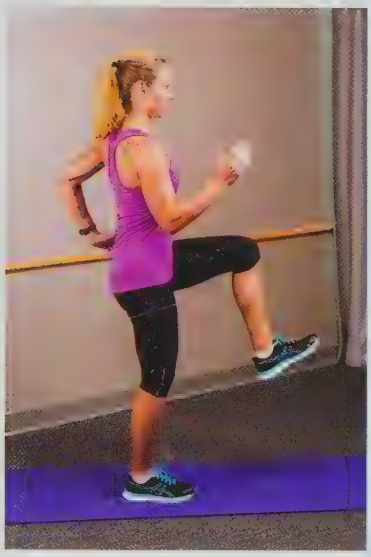
Movement Technique:

- Extend the left leg behind you while allowing the trunk to lean forward. As the trunk leans forward, reach forward/overhead with the left arm while the right arm reaches rearward to come in line with the trunk and left leg.
  - Pretend there is a stick connecting the back of the head, spine, and tailbone.
  - Gaze to a point on the floor that is 2 to 3 inches forward of your stance foot.
  - At the end of the reach, the pelvis is squared with the floor (a stick laying across the lower back would be parallel with the floor) and the elbows are straight.
- Hold the end range for 1 to 3 seconds, then return to the starting position. Perform the prescribed number of repetitions, then repeat on the opposite leg.
- Maintain rhythmic breathing and fluid movements.
- Extend the left leg behind you while allowing the trunk to lean forward. As the trunk leans forward, reach forward/overhead with the left arm while the right arm reaches rearward to come in line with the trunk and left leg.

Dosage:

Repetitions: ____________________

Frequency: ____________________



A series of exercises that place additional demands on the trunk and upper extremities are included in **Self-Managements 14-5** to **14-7** and **Figure 14-2A** and **B**. The KC exercise examples then conclude with a selection of plyometric and agility exercises (**Fig. 14-3A** and **B**; **Self-Managements 14-8** and **14-9**). Even though plyometric and agility exercises place high demands on movement control and high levels of tissues stress at various regions of the KC, they also offer the clinician the opportunity to promote motor learning through the skillful use of feedback.

SELF-MANAGEMENT 14-5
Wall Plank with Leg Raises

Purpose: To promote good alignment and neuromuscular control of the spine and extremities; strengthen lower leg muscles.

Precautions and Contraindications: Limited weight-bearing status; pain on exertion.

Position: Stand facing a wall with the trunk muscles lightly engaged, the pelvis in neutral, the spine and lower extremities aligned, and the stance knee straight but not locked backward. The arms are extended to support leaning into the wall.

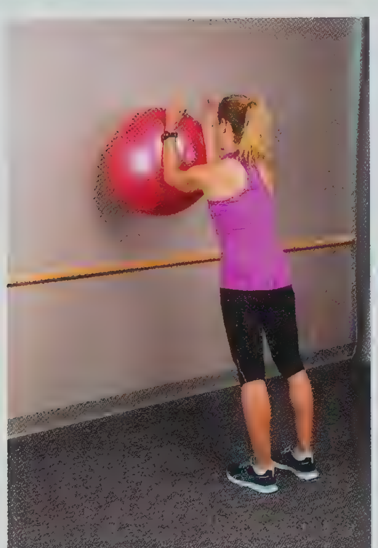
Movement Technique:

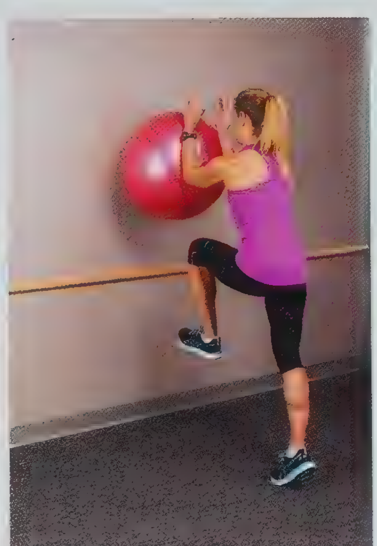
- Lift one knee toward the wall to about hip level while the heel of the stance leg raises off the ground. Hold for 1 to 3 seconds, then return to the starting position.
- Pretend there is a stick connecting the back of the head, spine, and tailbone.
- Perform the prescribed number of repetitions, then repeat on the opposite leg.
- To increase the stability requirement, lean into an exercise ball placed against the wall at about shoulder height, (contacting the ball with your forearms).
- Maintain rhythmic breathing and fluid movements.
- Lift one knee toward the wall to about hip level while the heel of the stance leg raises off the ground. Hold for 1 to 3 seconds, then return to the starting position.

Dosage:

Repetitions: ____________________

Frequency: ____________________





SELF-MANAGEMENT 14-6
Resisted Side Step and Reach

Purpose: To promote neuromuscular control of the spine and shoulder girdle.

Precautions and Contraindications: Limited weight-bearing status; pain on exertion.

Position: Stand facing along a wall from which an elastic band is anchored. Hold the other end of the band with both hands at the middle of the chest. The trunk muscles are lightly engaged and the pelvis is in neutral.

Movement Technique:

- Crouch slightly, then side step away from the wall.
  - Pretend there is a stick connecting the back of the head, spine, and tailbone.
  - Pretend you have lights on your knee caps and center of the chest, with all lights shining directly ahead.
- When you feel significant resistance from the band, stop and straighten the elbows, maintaining the hands directly forward.
- Hold for 1 to 3 seconds, slow side step back to the wall, then rise out of the crouch to return to the starting position.
- Perform the prescribed number of repetitions, then repeat in the opposite direction.
- Maintain rhythmic breathing and fluid movements.

Dosage:

Repetitions: ______________________

Frequency: ______________________

SELF-MANAGEMENT 14-7
Diagonal Ball Swings

Purpose: To promote good alignment, neuromuscular control, strength, and coordination of the spine and extremities.

Precautions and Contraindications: Limited weight-bearing status; pain on exertion.

Position: Stand in a tall posture with the trunk muscles lightly engaged and the pelvis in neutral. With both hands, hold a medicine ball or other appropriately weighted object above the right shoulder. The right foot is flat and supporting most of the body weight; the right knee is straight but not locked backward; the left heel is off the ground.

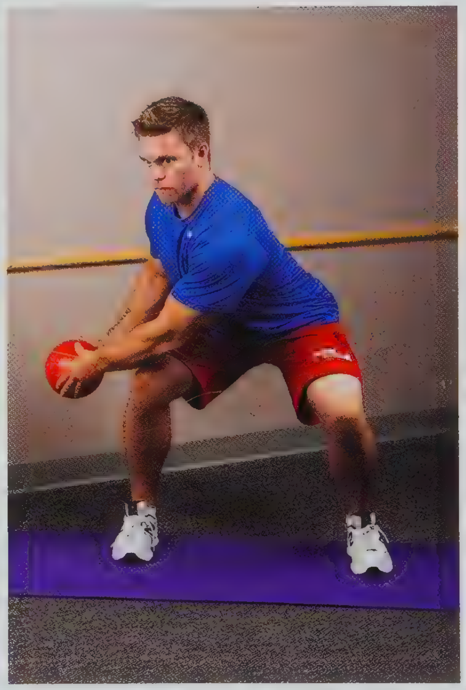
Movement Technique:

- In one motion, swing the ball down and across the body to end just outside the left thigh.
  - Allow your body to crouch as you break the momentum of the ball.
- Return to the starting position and a tall posture.
- Perform the prescribed number of repetitions, then repeat in the opposite direction.
- Maintain rhythmic breathing and fluid movements.
  - Stiffen the body to brake the momentum of the ball at both end range positions, but allow flowing movements during the ball swing.

Dosage:

Repetitions: ____________________

Frequency: ____________________



A B

FIGURE 14-2 **(A)** and **(B)** Reciprocal, rotational push pull with cables reinforces trunk stability with upper extremity functional movement patterns.

A B

FIGURE 14-3 **(A)** and **(B)** Agility drills focusing on proper landing within a specified target.

SELF-MANAGEMENT 14-8
Jump and Reach

Purpose: To promote good alignment, neuromuscular control, power, and coordination of the spine and extremities.

Precautions and Contraindications: Limited weight-bearing status; pain on exertion; insufficient strength to manage the high landing forces associated with this exercise.

Position: Stand in a tall posture with the trunk muscles lightly engaged, the pelvis in neutral, and the knees straight but not locked backward.

Movement Technique:
- Quickly crouch, then jump high while reaching overhead.
- Upon reaching maximum jump/reach, quickly bring the arms back down while preparing the legs to absorb the landing like springs.
  - During the landing and preparation to jump, pretend the knee caps are flashlights and your control of the movement keeps them shining straight ahead.
- Return to the starting position and perform the prescribed number of repetitions. Alternatively, your therapists may ask you to perform a continuous series of jumps without pause.

Dosage:

Repetitions: ______________________

Frequency: ______________________

SELF-MANAGEMENT 14-9
Lateral Hops

Purpose: To promote good alignment, neuromuscular control, power, and coordination of the spine and extremities.

Precautions and Contraindications: Limited weight-bearing status; pain on exertion; insufficient strength to manage the high landing forces associated with this exercise.

Position: Stand in a tall posture with the trunk muscles lightly engaged, the pelvis in neutral, and the knees straight but not locked backward.

Movement Technique:

- Step to your right side and quickly crouch on the right leg, with the left arm reaching across the body and the left leg lifted to the rear.
- Without pause, quickly hop to the left, landing in a crouch on the left leg, with the right arm crossing the body to the front.
  - During the landing and preparation to jump, pretend the leg is a shock-absorbing spring and the knee cap is a flashlight shining straight ahead.
  - Think of the landing spots as boundaries, and your body as staying within those boundaries.
- Perform the prescribed number of repetitions without pausing between hops.

Dosage:

Repetitions: ____________________

Frequency: ____________________

Most neuromuscular training programs designed to prevent ACL injury risk have used plyometric exercises, with verbal or visual feedback. Despite the fact that these programs have been effective to at least some degree in altering landing patterns in the frontal plane,[55,95,114] ACL injury incidence remains high.

Some researchers have expressed concern that techniques learned in rehabilitation or training program might not transfer well to the highly variable events that occur during athletics, and that improvements in feedback methods might facilitate better carryover effects.[115] Traditionally, internal feedback (focus on the movement) has been used more than external feedback (focus on the effect of the movement). However, an internal focus on the movement might constrain the motor system by disrupting automatic control processes.[116] To improve feedback during motor control training, Benjaminese and colleagues have suggested increased use of externally focused feedback.[115] Although much of their novel work has used technologies that might be cost prohibitive for many clinicians, dyad training using peers or a rehabilitation specialist to demonstrate the desired movement pattern has been suggested as a low-cost alternative.[117] During such training, clients observe effective execution of the goal movement, then attempt to mimic the movement with minimal if any instruction, though feedback is offered afterward (see Chapter 3 and **Self-Management 14-10** to **14-15**).

SELF-MANAGEMENT 14-10
First Ray Stability–Windlass Mechanism

Purpose: To strengthen the muscles supporting the arch of your foot.

Precautions and Contraindications: Pain on exertion, acute injury.

Position: Begin seated, progress to normal walking stride

Movement Technique: Maintain arch height.
Extend *only* the hallux.

Gently push the knuckle of your big toe into the floor.

Hold for ___ seconds.

Dosage:

Repetitions: ______________________

Frequency: ______________________

Starting position

Ending position

SELF-MANAGEMENT 14-11
Subtalar Joint and Midtarsal Joint Pronation

Purpose: To improve controlled movement of your heel and the arch of your foot.

Precautions and contraindications: Pain on exertion, acute injury.

Position: Begin seated, progress to normal walking stride.

Movement Technique: Extend *only* the lateral four toes in a smooth and controlled manner.

Gently try to lift the lateral border of your foot off the floor.

Take ___ seconds to complete this exercise.

Dosage:

Repetitions: ______________________

Frequency: ______________________

Starting position

Ending position

SELF-MANAGEMENT 14-12
Controlled Subtalar Joint Pronation

Purpose: To promote controlled movement of your heel and improve your balance.

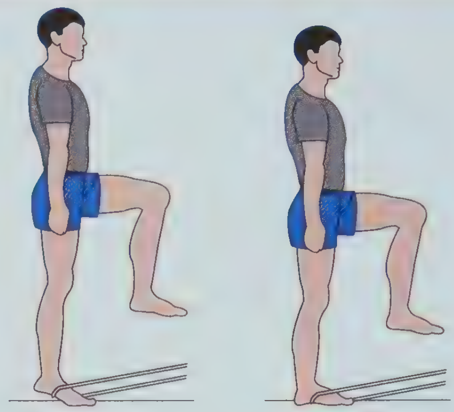
Precautions and Contraindications: Pain on exertion, acute injury, severe balance disorder.

Position: SLS

Movement Technique: Place the elastic band around the mid-foot or leg and anchor it medially to an immovable object. Ensure sufficient tension in the elastic to pull the foot toward pronation/lowering of the arch.

Perform heel raising and lowering with the knee straight but not locked and aligned with the 2nd/3rd toes.

Maintain the arch of the foot and ensure all toes remain on the ground throughout the movement.



Starting position *Ending position*

Dosage:

Repetitions: ______________________

Frequency: ______________________

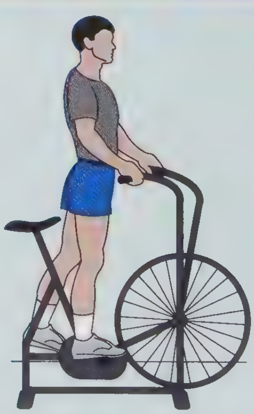
SELF-MANAGEMENT 14-13
Quadriceps Strengthening 0 to 30 Degrees (Standing Stationary Cycling)

Purpose: To strengthen the muscles around your knee and in the front part of your thigh.

Precautions and Contraindications: Pain on exertion, acute injury, balance difficulties.

Position: Standing on the pedals of the bike.

Movement Technique: Begin pedaling in an upright position. Use the quadriceps muscle to control the knee as it moves into extension.



Dosage:

Repetitions: ______________________

Frequency: ______________________

SELF-MANAGEMENT 14-14
Glenohumeral Dynamic Stability

Purpose: To stabilize the muscles around your shoulder as your shoulder pain lessens

Precautions and Contraindications: Pain on exertion, acute injury

Position: Quadruped injured hand weight bearing on soft 6-inch ball

Movement Technique: Weight shift on to injured arm and move ball in sagittal, frontal, and transverse planes

Enhance dynamic stability with controlled mobility by using axial compression and a moveable boundary

Dosage:

Repeat: ______________ seconds per minute

Frequency: ______________

Starting position

Ending position

SELF-MANAGEMENT 14-15
Thoracic Spine Extension Glenohumeral Joint Stability

Purpose: To improve the mobility of your thoracic spine and stability of your shoulder to improve your posture

Precautions and Contraindications: Pain on exertion

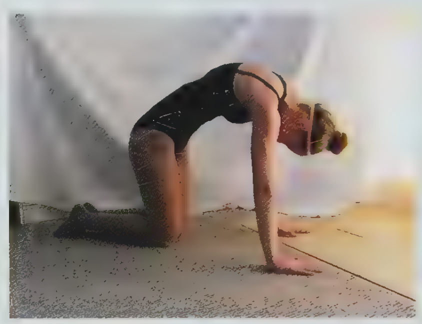
Position: Quadruped

Movement Technique:
Tighten abdominal muscles
Push into the floor spreading the area between your shoulder blades
Bring the top of your head and tailbone toward each other
Hold for 15 to 30 seconds
Reverse the movement squeezing the shoulder blades together sinking in the area between your shoulder blades
Lengthen through the top of your head and tailbone
Hold for 15 to 30 seconds
Repeat the exercise trying to move one vertebra at a time

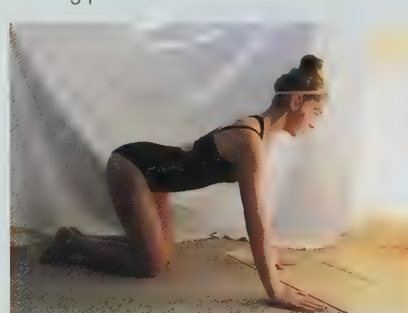
Dosage:

Repetitions: ______________

Frequency: ______________



Starting position



Ending position

LAB ACTIVITIES

1. The patient's base of support in any posture influences movement proficiency. Modify the base of support in various postures (e.g., quadruped, seated, standing) and observe the effect on movements.
2. The degree of neuromuscular activation also influences movement proficiency. Consider verbal, visual, and tactile cues to alter your patient's neuromuscular activation for more proficient execution of the following tasks:
   a. During an overhead reach, you notice that your patient moves from pelvic neutral into excessive anterior pelvic tilt.
   b. Your patient's split squat includes excessive knee valgus of the forward leg.
   c. Gait evaluation reveals that your patient fails to achieve hip extension or ankle dorsiflexion in terminal stance, despite adequate active and passive motion demonstrated previously at those joints.
3. To promote an external focus of attention, simply cue your client to objects in the environment (e.g., "as you step, direct your knee toward the cone) or prompt imagery that promotes the intended performance (e.g., "land as light as a feather"). Develop verbal or visual prompts that promote an external focus of attention to enhance the patient's motor learning of the following movements:
   a. Quadruped, reciprocal arm and leg lift
   b. Sit-to-stand-sit
   c. Diagonal step and cross-body arm reach
4. Using the factors of exercise selection and progression in Display 14-2, evaluate the relative need for each of those factors for:
   a. A gardener
   b. A tennis player
   c. A soldier
5. Consider the plane in which you will start activities and rehabilitation exercises for patient's recovering from the conditions listed below. Identify exercises that will provide low, medium, and high stress to the injured tissue. For the most challenging movements in your exercise progression, consider how you will mitigate the risk for reinjury.
   a. Inversion ankle sprain
   b. Medial collateral ligament injury of the knee
   c. L5 pars defect with anterior spondylolisthesis

KEY POINTS

- Kinetic chain (KC) performance is a product of all movement subsystems.
- The functionality of the KC must be considered in light of the physical demands of the patient's environment and their activity limitations and participation restrictions.
- Evaluation of the KC as whole, together with evaluation of its components, informs the assessment of the patient's problem and guides interventions.
- Kinetic chain interventions that include significant variety and focus on the effect of the movement rather than the movement itself are likely to offer the best outcomes.

CRITICAL THINKING QUESTIONS

1. Consider Case Study 14-1 on page 361.
   a. Describe the relationship between this patient's foot posture in weight bearing and during gait to theorize the cause of his symptoms.
   b. Given the concept of musculoskeletal regional interdependence, how might proximal factors influence or be associated with the findings at this patient's foot?
   c. Describe the first phase of the rehabilitation program for this patient. Where would your attention be directed first and why?
   d. Assuming that the patient improves in a linear fashion, how would you progress him back to work and recreational activities? How would you prioritize these and incorporate these goals into his treatment program?
2. Consider Case Study No. 4 in Unit 7.
   a. Describe the relationship between his shoulder and neck symptoms from a regional interdependence perspective. Would you prioritize neck or shoulder intervention or treat them simultaneously? Why?
   b. Design three exercises that the patient can do at home to improve mobility for:
      1. primarily shoulder
      2. primarily neck
      3. integrated neck and shoulder together
   c. When would you start strengthening exercise for the neck, shoulder, or both? Describe three beginning exercises for each key area.
3. Consider Case Study No. 6 in Unit 7.
   a. Describe the relationship between this patient's knee mobility impairment and its effect on the ipsilateral hip, ankle, and subtalar joints.
   b. Choose one of this patient's short- or long-term goals and design three different exercises you might use to address this goal.
   c. Design a return to activity progression.

CHAPTER 15

Proprioceptive Neuromuscular Facilitation

KYLE M. YAMASHIRO • RAFAEL F. ESCAMILLA

HISTORY AND BACKGROUND

The foundation for proprioceptive neuromuscular facilitation (PNF) was initially established by neurophysiologist Sir Charles Scott Sherrington in the early 20th century in his published work "On Plastic Tonus and Proprioceptive Reflexes,"[1] which delineated inhibitory and excitatory neurophysiologic properties of the neuromuscular system. These principles were further developed by neurophysiologist Dr. Herman Kabat near the mid-1940s, who at that time called it "proprioceptive facilitation" and published his initial papers using this term.[2] In 1946, Dr. Kabat began to look for natural movement patterns for rehabilitating the muscles of patients affected by polio and soon thereafter discovered that typical human movement patterns involved diagonal patterns employing multiple muscles and joints. Prior to "proprioceptive facilitation," rehabilitation was typically done one joint and one muscle at a time.

Around 1946, Dr. Kabat joined Henry J. Kaiser, an American Industrialist, in forming the Kaiser-Kabat Institute in Washington, DC, and around that same time joined with physical therapist Maggie Knott to work with him using his "proprioceptive facilitation" principles with patients with neurologic disorders such as cerebral palsy and hemiparesis. In 1948, the Kaiser-Kabat Institute opened in Vallejo, CA, now known as the Kaiser Foundation Rehabilitation Center, and Dr. Kabat and Maggie Knott moved westward to work at the Kaiser-Kabat Institute in Vallejo. That same year Maggie Knott began to teach other physical therapists about the neuromuscular principles involving "proprioceptive facilitation" and postgraduate training began with therapists coming from all over the world to learn these new principles and training techniques. Dorothy Voss was one of the first students to be trained and then joined Dr. Kabat and Maggie Knott at the Kaiser-Kabat Institute. In 1954, Dorothy Voss and Maggie Knott published the first paper in the scientific literature that used the term "proprioceptive neuromuscular facilitation" (PNF),[3] and the term PNF continues to be used to the current day.

Dr. Kabat and physical therapists Maggie Knott and Dorothy Voss continued to develop and refine the PNF principles we know today. In 1956, Maggie Knott and Dorothy Voss wrote and published the first edition of their textbook entitled "Proprioceptive Neuromuscular Facilitation". With a PNF textbook available, United States-based physical therapy programs began teaching PNF principles and techniques to their students in the 1960s. Today, PNF concepts, principles, and procedures continue to be taught to physical therapy students. Moreover, PNF is required to be taught in all Physical Therapy Education programs in the United States, as it is included in the Normative Model, established by the Committee on Accreditation of Physical Therapy Education.

Scientific publications related to PNF were first published in the 1950s.[2–9] Although PNF techniques were used to assess joint range of motion (ROM), reaction and response times, and muscle flexibility and strength, throughout the 1970s,[10–12] there were few research papers published in the scientific literature related to PNF. Therefore, even though some 30 years had passed since the advent of PNF, less than 20 papers were published in a handful of peer-reviewed scientific journals, so the evidence for the efficacy of using PNF for patients was quite limited. As such, PNF was considered much more of an art than a science.

There were as many PNF papers published in the scientific literature in the 1980s as there were in the previous 30 years combined. Many of these papers focused on improving ROM and muscle length using PNF stretching techniques.[13–18] For the first time, PNF techniques were appearing in sports physical therapy and sports medicine journals and being compared to traditional weight training for enhancing strength and athletic performance and minimizing sports injuries.[15,19] For example, Nelson et al.[19] reported that PNF resistance training resulted in greater gains in knee and elbow extensor strength, throwing distance, and vertical jump when compared to weight training.

PHILOSOPHY AND PRINCIPLES OF PNF

Proprioceptive neuromuscular facilitation uses proprioceptive input (sensory receptors found in muscles, tendons, joints, and the inner ear that detect body and limb motion or position) to improve (facilitate) neuromuscular function during human movement.[2,5] Neuromuscular function is enhanced by providing resistance during concentric, eccentric, and isometric muscle actions, thereby enhancing muscle strength and endurance, balance, posture, stability, and mobility. Neuromuscular function is also enhanced during stretching techniques, thus improving joint ROM and muscle length (flexibility).

The basis of the PNF philosophy is the idea that all individuals, regardless of their disease and disabilities, have untapped existing potential.[5] The treatment approach is always positive and focuses on what the patient can do, on a physical and psychologic level. The PNF approach is holistic, integrating sensory, motor, and psychologic inputs to ensure every treatment is directed toward the individual, not a specific problem. PNF attempts to provide a maximal response for increasing muscle performance, flexibility, balance, coordination, functional mobility, and functional performance. PNF patterns are more concerned with movements that require use of multiple muscles and joints as opposed to specific, isolated muscle actions. These patterns are composed of both diagonal and rotational exercise patterns that are similar to the motions required for activities of daily living (e.g., eating, rolling, scooting), functional mobility, and even athletic performance (e.g., using D1 and D2 diagonal patterns to enhance baseball pitching).

Although there are over 100 different PNF patterns, handholds, variations, and modifications as well as terminology, the most important thing is to understand the use of the appropriate procedures and basic techniques. This chapter discusses how to utilize PNF patterns in a simplified form to allow the learner to practice utilization of manual therapy. For further refinement of PNF skills, the learner is encouraged to pursue postgraduate continuing education.

PNF PHYSIOLOGY AND APPLIED CONCEPTS

A number of physiologic principles underlie the theory and application of PNF. These include principles to increase muscle performance (i.e., irradiation), muscle length (i.e., autogenic inhibition, reciprocal inhibition, stress relaxation), and pain (gate control theory of pain).

Irradiation refers to the overflow of response to a stimulus. This response can facilitate or inhibit a contraction in the synergistic muscles and patterns of movement; the muscular response will increase as the intensity and duration increase[1,4,5] (**Table 15-1**). Therefore, in theory, weaker muscle groups may gain strength from stronger muscles while working synergistically in muscle groups or movement patterns. For example, while performing a lower extremity diagonal PNF resistance pattern that involves hip flexion and ankle dorsiflexion, stronger hip flexors may facilitate weaker ankle dorsiflexors as overflow proceeds from proximal to distal. An overflow of response to a stimulus has also been investigated on the uninvolved contralateral side.[20–22] Gontijo and colleagues[22] demonstrated that trunk flexion and extension motions generate irradiated strength in the ankle dorsiflexors and plantar flexors, *respectively*. This technique may be helpful in certain patient populations (e.g., patients with hemiparesis) who cannot activate the dorsiflexors or plantar flexors directly. Cross education effects have also been demonstrated using PNF techniques in which activating muscles as a limb (e.g., right upper extremity) moves against resistance also activates muscles in the contralateral nonworking limb (e.g., left upper extremity).[20,21] This may facilitate healing or strengthening in limbs that cannot (hemiparetic) or should not (injury) work directly against resistance.

Four theoretical physiologic mechanisms for increasing ROM and muscle length with PNF stretching are (1) autogenic inhibition, (2) reciprocal inhibition, (3) stress relaxation, and (4) the gate control theory (via pain mechanisms).[23,24]

Autogenic inhibition is a decrease in a muscle's excitability because of inhibitory signals sent from the golgi tendon organ (GTO) of the muscle because of muscle contraction. The higher the muscle's tension the greater the inhibition. For example, contracting the hamstrings isometrically prior to stretching stimulates the GTOs in the hamstrings, causing inhibition of the hamstrings. This results in enhanced relaxation in the hamstrings during the subsequent hamstrings stretch. Hold-relax (HR) is based upon the theory of autogenic inhibition.

Reciprocal inhibition is a neurophysiologic phenomenon in which the contraction of agonist muscles causes a concurrent inhibition of their antagonist muscles. For example, when the knee flexors (agonists) actively flex the knee, the knee extensors (quadriceps) are reciprocally inhibited. This causes decreased activity in the quadriceps that are being stretched. When alpha motor neurons are provided excitatory stimulation in the agonists, the alpha motor neurons that control the antagonistic muscles are concurrently inhibited. Another example is stretching the left upper trapezius. When the neck is actively sidebent to the right (via the right upper trapezius), the right upper trapezius sends inhibitory signals to the left upper trapezius, fostering relaxation of the left upper trapezius.

TABLE 15-1

Summary and Examples of Physiologic Basis for PNF

PNF TECHNIQUE	DEFINITION	EXAMPLE
Irradiation	Overflow of the response to the stimulus to synergists.	The clinician resists submaximal dorsiflexion to enhance quadriceps contraction prior to performing a straight leg raise in a patient status post ACL reconstruction who is having difficulty performing a QS/SLR.
Reciprocal Inhibition	Contraction of the agonist results in a concurrent inhibition of the antagonist.	Contraction of the middle and lower trapezius causes a concurrent inhibition of the pectoralis major and minor muscle groups. Therefore, cueing a patient to perform gentle, isometric shoulder blade squeezes to address postural impairments results in inhibition of the pectoral muscles.
Autogenic Inhibition	The agonist (the muscle of interest) is inhibited during agonist contraction.	Contraction of the hamstrings immediately prior to stretching it will cause an inhibitory response, resulting in increased muscle length.

PNF, proprioceptive neuromuscular facilitation; ACL, anterior cruciate ligament; QS, quadriceps set; SLR, straight leg raise.

Additionally, reciprocal inhibition can be used in combination with autogenic inhibition. This is the theory behind hold-relax with agonist contraction (HR-AC). For example, to employ HR-AC for the gastrocnemius muscle, the patient would perform an isometric contraction of the gastrocnemius against resistance followed by an immediate isotonic contraction of the dorsiflexors to further lengthen the gastrocnemius. The isometric contraction of the gastrocnemius utilizes autogenic inhibition, while the active contraction of the dorsiflexors employs the theory of reciprocal inhibition.

Stress relaxation occurs when the musculotendinous unit is under a constant stretch (deformation). When held for a prolonged period of time, the stress within the tissue gradually decreases secondary to the viscoelastic properties of the musculotendinous unit, increasing the extensibility of the musculotendinous unit. A prone hang to increase knee extension following knee surgery utilizes the concept of stress relaxation. The position is held for 10 minutes or more, employing stress relaxation. Many dynamic splints utilize this theory to promote tissue elongation.

Finally, the *gate control theory* proposes that nociceptive and nonnociceptive signals are summated at the same interneuron in the spinal cord. Peripheral pain receptors have unmyelinated or small myelinated afferent fibers, while pressure receptors have larger, myelinated fibers. Since both afferent fibers connect to the same interneurons in the spine, the larger pressure afferent fibers arrive at the interneurons prior to the smaller pain fibers. This leads to inhibition of the pain signal. A classic example is stubbing your toe; pain travels on the small fibers and sends a pain signal. A natural response is to rub the affected area. Pressure and compression travel on large diameter fibers, and ultimately arrive at the interneurons prior to the pain signals traveling on the small fibers. The pain signal is masked, and the sensation of pressure is felt instead. As such, there is a scientific basis for rubbing an injured body part. This is also one theory behind patient reports of decreased pain when wearing compression sleeves for knee pain. In PNF stretching, muscles are stretched, but they also contract as part of the PNF technique. This causes a decrease in pain that is sensed which ultimately causes inhibition, produced by the GTOs. The GTOs adapt to the increase in length and force threshold, which allow for greater force production, enhancing the effectiveness of PNF stretching.[24] Although research does not directly support these four theoretic physiologic mechanisms for increasing ROM and muscle length, these theories haven't been disproven. However, there are limited data to suggest there may be additional physiologic mechanisms responsible for increasing ROM and muscle length when using PNF techniques. For example, decreases in the response amplitude of muscle stretch reflexes following a contraction of a stretched muscle may not be due to the activation of GTOs, as commonly believed, but instead may be due to presynaptic inhibition of the muscle spindle sensory signal.[25] Further research is warranted.

Research in PNF to Increase Muscle Length

Early research papers published in the 1990s related to PNF focused on stretching techniques, and successfully demonstrated that these techniques were as effective or more effective than static and ballistic stretching in increasing both passive and active joint ROM.[13,15,16,23,26–33] The concepts of contract-relax (CR), HR, and HR-AC were all reported to be effective in improving joint ROM.[13,15,16,23,28] and are defined in **Table 15-2**.

TABLE 15-2

Definitions of Classic PNF Terms

TERM	DEFINITION	EXAMPLE
Hold-Relax (HR)	The agonist is taken to its end-range position and this position is held for 10 s. The patient then performs an isometric contraction of the agonist against resistance provided by the clinician for 5–10 s. Immediately upon relaxation of the contraction, the muscle is taken further into end range.	To stretch the hamstrings, the patient lies supine, the clinician places the hip (with the knee extended) at end-range flexion (until a resistance in the hamstrings is felt). This is held for 10 s, followed by the patient contracting their hamstring for 5–10 s against resistance. When the patient relaxes, the clinician takes the leg further into hip flexion.
Contract-Relax (CR)	Similar to HR, with the exception of the rotation component. The rotators contract concentrically during this technique. The muscle is taken to a lengthened position and held for 10 s. This is followed by a concentric contraction of the rotation, followed by an isometric contraction for 5–10 s. Upon relaxation, the clinician passively moves the patient into the newly acquired length. This movement is multiplanar.	If we use the example of the hamstrings again, the patient's hamstrings (semimembranosus and semitendinosus) are biased. The leg, with the knee extended, is placed at end-range hip flexion with the hip in external rotation. This position is held for 10 s. This time, when asked to perform a contraction, the patient performs a concentric contraction, resisting rotation. This is achieved by having the patient fire the semimembranosus and semitendinosus, resulting in internal rotation of the hip. Once the hip has reached end-range internal rotation, an isometric contraction of the hip extensors as a group is performed for 5–10 s. This is followed by relaxation, where the clinician passively moves the leg into more hip flexion and external rotation.
Hold-Relax with Agonist Contraction (HR-AC)	Performed similar to HR, the patient isometrically contracts the agonist for 5–10 s against the resistance supplied by the clinician. Upon relaxation of the agonist, the patient actively contracts the antagonist isotonically to lengthen the agonist.	To stretch the hamstrings, the patient lies supine, the clinician places the hip (with the knee extended) at end-range flexion (until a resistance is felt). The patient fires their hamstrings for 5–10 s against resistance. The patient then immediately contracts their hip flexors isotonically to move the limb into more hip flexion, thereby increasing the length of the hamstrings. The clinician assists with the movement into hip flexion.

From Voss DE. Proprioceptive neuromuscular facilitation. Am J Phys Med 1967;46(1):838–899.

With each of these techniques, a contraction of the muscle of interest is performed by the patient. The intensity of this contraction does affect outcomes. In addition to improving muscle length, employing a higher intensity static contraction (e.g., 80% to 100% of maximum contraction) for 5 to 10 seconds has been shown to also result in greater muscular strength and power and improved stiffness in the musculotendinous unit.[13,15,16,23,28] Muscle length has been shown to improve with contraction durations between 3 and 15 seconds, although longer contraction durations (e.g., 10 to 20 seconds) have been shown to result in greater flexibility gains.[13,15,16,23,28] The greatest changes in flexibility generally occur after the first repetition; in order to achieve more lasting changes, PNF stretching needs to be performed at least once or twice per week.[13,15,16,23,28] It has been suggested that the increases in flexibility seen after PNF stretching may be due to increased stretching tolerance rather than actual changes in muscle length (**Evidence and Research 15-1**).

EVIDENCE and RESEARCH 15-1

Mahieu et al.[34] reported that the increased mobility observed after PNF stretching could not be explained by changes in the musculotendinous tissue that was stretched; rather, they believed the increased mobility was due to an increase in stretch tolerance. This theory was further supported by Mitchell et al.,[35] who demonstrated that an increase in stretch tolerance occurred after employing the CR PNF stretching technique. Moreover, these authors suggested that at least four repetitions of CR stretching are required to obtain the greatest gains in mobility.

Research has shown that performing PNF stretching techniques over time acutely enhances muscle length. In addition, some studies suggest that joint motion and muscle length improvements are greater with PNF stretching compared to static or dynamic stretching, whereas others show similar results.[23,24,34,36–38,39–76] Possible mechanisms for improved joint ROM and muscle length include changes in the ability to tolerate stretch and changes in the viscoelastic properties of the stretched muscle.

Most recently, a surge in performance-based PNF studies has occurred due to the interest of many strength and conditioning specialists, coaches, and athletes on the effects of static and dynamic stretching on sports performance.

In the sports environment, dynamic stretching and dynamic warm-up has replaced static stretching as a means of an athlete to warm up prior to competition. A review of the literature on the effects of stretching on performance addressed the impact of both static and dynamic stretching (**Evidence and Research 15-2**). And although dynamic stretching appears to be more beneficial than static stretching immediately prior to performance, this does not prove that static stretching is an ineffective intervention. This research simply does not recommend static stretching as an initial warm-up immediately prior to athletic competition (See Chapter 7).

EVIDENCE and RESEARCH 15-2

In a recent systematic review by Peck et al.,[77] the authors summarized the literature related to the use of static and dynamic stretching immediately prior to performance. Based upon the review of the 62 papers that met inclusion criteria, the authors made the following recommendations:

1. It is reasonable to recommend against static stretching immediately prior to strength and power activities. However, if the static stretching is followed by a general warm-up or some dynamic stretching, any negative effect on strength and power performance may be reversed, although this contention has been disputed.
2. The evidence indicates that dynamic stretching prior to a strength- and power-dominant activity is beneficial.
3. The majority of the literature suggests that static stretching prior to speed- and agility-dominant activities is detrimental to performance; however, an intervening period of a general warm-up or dynamic stretching may reverse this negative effect, similar to that seen with strength and power activities.
4. There is insufficient evidence to recommend for or against PNF stretching prior to speed- and agility-dominant activities.
5. The available evidence shows static stretching to have either no effect or a detrimental effect on endurance performance.

Because PNF stretching largely involves static stretching, it is plausible to expect the acute effects of PNF stretching on performance to at least have some similarities to the acute effects of static stretching on performance. Although increases in joint ROM and muscle length have been found, the duration of these benefits once stretching is concluded is unknown. In addition, the relationship between improvements in ROM and muscle length and stretching dosage parameters has not been established.

Research in PNF to Improve Muscle Performance

Employing PNF resistance techniques has been shown to be effective in enhancing the neuromuscular system.[78–95] Performing a reciprocal concentric contraction of a diagonal pattern such as D1 may increase the rate of force development in older individuals, which may in turn improve performance in functional activities such as stair negotiation.[95] In addition, this training may reduce the risk of falls.[95] Other PNF techniques, such as D1 and D2 (see **Tables 15-3** and **15-4** for a description of these patterns) lower and upper extremity diagonal patterns, with or without PNF stretching, have also shown to be effective in treating numerous health- and disease-related variables (**Evidence and Research 15-3**).

TABLE 15-3

PNF Summary of Upper Extremity D1 and D2 Diagonal Patterns

UPPER EXTREMITY PATTERN	D1 FLEXION	D1 EXTENSION	UPPER EXTREMITY PATTERN	D2 FLEXION	D2 EXTENSION
Scapula	Anterior elevation	Posterior depression	Scapula	Posterior elevation	Anterior depression

EVIDENCE and RESEARCH 15-3

The utilization of PNF resistance techniques has been documented in the literature to show effectiveness in treating numerous impairments related to many common diseases seen across the lifespan. Specifically,

- PNF stretching combined with lower extremity PNF diagonal patterns resulted in increased postural stability and balance.[96–98]
- PNF stretching both with and without aerobic exercise has demonstrated decreased pain and increased function in patients with patellofemoral pain syndrome.[99,100]
- PNF muscle relaxation and stabilization exercises decreased pain and increased function in patients with myofascial pain syndrome.[101]
- PNF pelvic patterns have resulted in decreased low back pain in obese patients.[102]
- PNF pelvic and scapular patterns resulted in increased motor function and gait symmetry during hemiparetic gait[103] and increased motor recovery in patients with chronic poststroke hemiparesis.[104]
- PNF respiratory exercises improved pulmonary function of normal adults and in patients after vertebral vascular accident.[105,106]
- PNF integration pattern exercises were more effective compared to general exercises in enhancing fall efficacy and gait ability in elderly who previously experienced injuries secondary to a fall.[107]
- PNF lower extremity techniques have been shown to increase lower extremity strength,[108–110] whereas PNF upper extremity patterns have been shown to increase the functionality of the supraspinatus.
- Compared to weight training, PNF resistance training resulted in greater gains in knee and elbow extensor strength, throwing distance, and vertical jump.[19]
- Aquatic PNF lower extremity patterns have been shown to enhance balance and activities of daily living in patients with a cerebral vascular accident.[111]

As such, incorporating appropriately applied PNF resistance techniques can be effective in improving strength, pain, postural stability and balance, motor function and gait symmetry, fall risk, performance, and patient function.

PNF PROCEDURES

The premise underlying basic PNF procedures is enhancing the patient's postural responses or movement patterns. The goal of each treatment is to facilitate or enhance a movement or posture. These procedures can be utilized with most patients regardless of medical diagnosis. The examination and evaluation will determine the specific procedures utilized as well as any necessary modifications.

Manual Therapeutic Exercise Using PNF Procedures

The clinician must utilize correct manual contacts, body positioning, verbal cues, and visual cues during PNF applications. One advantage of manual therapeutic exercise is the ability to continuously assess the patient's movement or posture. This ongoing assessment allows for immediate modification of the activity. During a treatment session, the clinician can influence the following:

- The magnitude of resistance
- The type of muscle contraction
- Traction (distraction) or compression (approximation) to a joint, promoting movement or stability, *respectively*
- The direction of the movement or pattern
- Whether the treatment is direct or indirect

Manual Contacts

The patient's response to the PNF intervention can vary based upon manual contacts and body position. Motor responses are often influenced by stimulation of skin and other peripheral receptors. The therapist can enhance the appropriate motor response through the proper use of manual contact. The patient's position must also be considered in an effort to avoid postural positions that may conflict with the desired movement (e.g., a patient with extensor tone may be placed in sidelying instead of supine when facilitating hip flexion). A few considerations regarding manual contacts:

- Strength or power: When the therapist applies proper contact to the segment being facilitated, the patient often demonstrates increased strength of contraction.
- A common grip to use is the *lumbrical grip*; this allows a broad surface of contact which controls motion, and avoids squeezing the patient (see **Fig. 15-1**).

FIGURE 15-1 Lumbrical grip.

Body Position and Mechanics

The clinician's body position and the use of good body mechanics are essential when using PNF. The clinician's body should be positioned at either end of the desired movement, and with the shoulders and hips facing in the direction of the movement. In other words, the clinician should place themselves "in the diagonal pattern." The clinician's forearms should always be pointed in the direction of the desired movement. The following key points on the use of proper body mechanics are important to provide an effective treatment and to prevent injuries to the clinician:

- The movement of the therapist must be a mirror image of the patient's movement.
- The clinician should maintain a neutral spine with movement occurring from the hips and legs.
- Weight shift should be in the direction of the movement.
- The resistance should come from the trunk and pelvis, not the extremities.

Verbal Cues

Verbal cues should be brief, clear, concise, use nontechnical jargon, and appropriate for patient comprehension. The volume of the command is dependent on the intent of the movement; the therapist should use louder commands for stronger contractions and softer commands for stability or relaxation. The timing is very important with the command usually given just before the movement takes place or repeated as needed to facilitate a weak component or for emphasis.

Visual Stimulus

Visual input increases motor neuron excitability in the muscles which are responsible for the movement. Vision facilitates coordination of the head and in turn will facilitate a stronger contraction from the trunk and extremity musculature (e.g., resisted shoulder abduction from 0 to 90 degrees will be stronger with more trunk activity when the subject is looking at and following the movement of the tested arm compared to when he or she looks away from the arm).

Appropriate Resistance

The most important fundamental basis when applying manual therapeutic exercises is the use of *appropriate resistance*. When asked how much resistance should be given, the answer is "just enough" to accomplish the desired movement pattern and training goal (e.g., strength, power, endurance, etc.) without overpowering the patient, resulting in faulty movement patterns.

Resistance is used to facilitate muscle contraction to improve motor control and strength. The magnitude of the facilitation is directly related to the amount of resistance applied. Facilitation of the agonist will increase the response of the specific muscle and synergistic muscles at the same joint and adjacent joints. When using minimal resistance, the antagonists are usually inhibited. Increasing the resistance in the agonist will cause muscle activity to increase in the antagonist groups as well, resulting in a cocontraction.

Manual therapeutic exercise allows the therapist to determine the amount of resistance that demands maximal effort from the patient without compromising the intent of the activity. The levels of resistance include passive range of motion (PROM), active assisted range of motion (AAROM), active range of motion (AROM), and resistive ROM which can be applied with graded resistance from minimal to maximal resistance; in addition, resistance can be applied to inhibit the antagonist (reciprocal inhibition). The advantage of manual resistance is that the clinician can assess and then vary the resistance throughout the range of movement depending on the patient's ability. In other words, the patient may require assistance or light resistance at the initiation of movement while resistance can increase in the mid-range followed by less resistance again at the end range. This is referred to as *accommodating resistance*.

The clinician can also select a specific range to emphasize volitional control of the patient. For example, in a patient with incomplete paraplegia, the therapist may choose to treat volitional control of hip extension from 70 to 30 degrees of flexion, knowing that at 15 degrees spasticity of the hip extensor muscles will occur.

Muscle Actions

Isotonic (dynamic) implies movement resulting from muscle contractions either from muscle shortening (concentric muscle action) or muscle lengthening (eccentric muscle action). With concentric action, the patient may be instructed to push against the clinician's hand to produce motion, resulting in shortening of the muscle. The greater the resistance applied, the greater the concentric muscle force generated. With an eccentric contraction, the patient begins with an isometric contraction in a shortened position and then controls the rate of motion, with the muscle lengthening as the therapist pulls or pushes to move the limb. The more the patient resists the therapist, the greater an eccentric muscle force is generated. Isotonic (dynamic) muscle actions produce active voluntary movement. The resistance must be applied so that the motion can occur in a smooth and coordinated manner.

Isometric implies a muscle contraction with no joint movement. The amount of resistance applied matches the force of the muscle contraction such that no joint motion occurs.

Traction and Approximation

Traction and approximation stimulate joint receptors and should be used with directional resistance. *Traction* is a manual distraction of the joint surface which promotes movement and is useful with pulling and reaching motions. *Approximation* is a manual compression of joint surfaces, facilitates cocontraction, which promotes stability; it is often used with pushing activities. Traction should be applied throughout the entire range of the agonist. Compression should be applied lightly, then progressively heavier to enhance stability.

Patterns of Facilitation

The brain generates and organizes mass movement patterns rather than individual muscle contractions. PNF utilizes mass movement patterns. Human motion is patterned and rarely involves straight plane movements because all muscles are oriented in a diagonal and spiral direction. Therefore, most human movement involves three planes of motion occurring at all joints:

- Flexion or extension: Major excursion of range
- Abduction or adduction: Medium excursion of range
- Rotation: Smallest excursion of range but the most important

With all extremity movement, whether unilateral or bilateral, there is at least a minimum amount of rotation of the trunk or pelvis. Rotation of the trunk in the spiral and diagonal pattern will produce greater strength and a longer lever arm than in the straight plane pattern. The longer the lever arm, the more efficient the movement pattern.

Quick Stretch

A quick stretch facilitates the muscle's ability to contract with greater force. The stretch reflex is evoked by a gentle but quick stretch to a muscle under tension (stimulating muscle spindles). A quick stretch can be applied in two ways. First, a quick stretch is applied to all components simultaneously of the entire pattern in its lengthened position to initiate the movement (e.g., wind-up of a pattern such as D1 extension, starting in flexion and moving into extension—hip: extension, abduction, internal rotation; knee: extension; ankle: plantarflexion, eversion, and toe plantarflexion). Alternatively, a quick stretch can be applied to a muscle that is already contracting in an effort to strengthen or evoke a response. For example, the clinician might be resisting D1 flexion in the upper extremity via slow reversal when the clinician feels the patient starts to decrease his force production. The clinician can offer a quick stretch in the middle of the movement pattern to facilitate contraction. It is important to maintain resistance immediately following the quick stretch to heighten the response. Quick stretch is a key component to PNF; however, it can be a difficult skill to master. The clinician should know the integrity of the joint capsule, ligaments, and nervous system prior to performing a quick stretch at the end ROM. If the practitioner performs quick stretch incorrectly, it may cause damage to other structures that are also on tension. As such, the clinician should only perform a quick stretch at end range once the skill is mastered as a mid-range intervention.

EVALUATION AND TREATMENT IMPLEMENTATION

Working within the PNF philosophy, the first emphasis is on what the patient *can do* in order to facilitate the functional goals. In other words, for a patient with a right hemiparesis, the clinician can utilize the strength and movement available in the left upper and lower extremity to facilitate movement, such as rolling to the right.

Be sure to note whether the patient's functional problem is *static* (inability to maintain position) or *dynamic* (loss of ability to initiate or control motion). Finally, identify the specific reason for the functional loss; that is, pain, immobility, weakness, loss of sensation, or lack of motor control. After identifying the patient's goals, determine whether treatment sessions should emphasize direct treatment or indirect treatment.

Direct Treatment

Direct treatment utilizes techniques on the affected limb, muscle, or motion (e.g., to increase right hip flexion strength the therapist may apply resistance directly on the right thigh, resisting hip flexion).

Indirect Treatment

Indirect treatment consists of the use of techniques on the unaffected limbs and muscles to facilitate the affected limbs and muscles (refer to the concept of irradiation). The literature has confirmed the effectiveness of indirect treatment initiated on the strong and pain-free part of the body to increase muscle tension and electromyographic activity on the affected parts of the body.[1,5,21–22,112] Therefore, the clinician can use techniques on the unaffected parts of the body to guide irradiation to the affected parts of the body (e.g., the patient with right hip flexor weakness, the therapist may involve the left lower extremity and resist bilateral hip flexion thereby facilitating right hip flexor activity).

MANUAL THERAPEUTIC EXERCISE USING PNF TECHNIQUES

The goals of the PNF techniques are to promote movement, facilitate stability, or to gain joint ROM and muscle flexibility. These techniques are grouped into movement, stability, and flexibility.

FIGURE 15-2 Replication (repeated contractions)—end range: elbow flexion. Command: "Hold." The elbow is then moved to mid-range (actively or passively). The patient then actively flexes the elbow to the start position.

Movement

Replication (Repeated Contractions)

The intent of replication (repeated contractions) is to teach the patient the expected outcome of the activity or movement; this technique may be helpful as part of a patient's reeducation after an injury (e.g., hemiparesis). It is also utilized as an excellent assessment tool for the clinician to "feel" the patient's ability to isometrically "hold" at the end ROM. The patient is placed in the end position (agonist muscle in its shortened length) and asked to hold while the therapist applies "demand" to all the components of desired direction resulting in simultaneous joint stimulation (see **Fig. 15-2**). The joint or extremity is then moved (either passively or actively) closer to mid-range of the diagonal and asked to actively return to the end position. This technique is repeated with the movement starting progressively closer toward the beginning of the pattern of movement to challenge the patient through a larger range of movement (see **Building Block 15-1**).

BUILDING BLOCK 15-1

Replication (Repeated Contractions)

Mr. Jones suffered a cerebral vascular accident and is having difficulty with eating using his right hand secondary to weakness in the right upper extremity, especially the hand. He often drops his eating utensils. Note his strength for performing the activity: shoulder flexion = 3-/5; elbow flexion = 3-/5; wrist flexion = 2+/5; he is able to close his grip and make a fist, but it is very weak. Create a strategy to improve this functional activity using replication.

Rhythmic Initiation

The purpose of rhythmic initiation is to teach the patient a movement pattern using passive, active-assistive, active, and resistive ROM. This is primarily used to enhance the patient's ability to initiate movement; it is also used during complex multi-joint movement patterns. In addition, it can be a useful tool when motor learning or communication problems exist by allowing the patient to visually observe as well as receive sensory input regarding the desired movement, thereby increasing understanding of the movement technique. This technique is also beneficial for patients who have a fear of moving because of pain. Rhythmic initiation allows the clinician to evaluate the patient's ability and willingness to be moved. This technique was originally developed to focus on the agonist muscle group only during unidirectional movement (see **Building Block 15-2**), but can be modified to use in teaching complex multi-joint diagonal movement patterns. Commands may progress as follows; "Let me move you," (PROM) "Help me move you," (AAROM) "Now, you do it" (AROM), "Now move against resistance" (RROM) (see **Fig. 15-3**).

BUILDING BLOCK 15-2

Rhythmic Initiation

Mr. Jones has right upper quadrant hemiparesis and is having difficulty rolling to his left. In assessing his rolling movement, the therapist noted that he is able to use his pelvis and lower body efficiently. However, his right upper extremity and his upper quadrant are lagging behind and his trunk is unable to engage in flexion. Describe how rhythmic initiation can be used to facilitate rolling in this case.

Combination of Isotonics

The intent of isotonic contractions is to emphasize control and quality of movement of the agonists by changing the muscle dynamic contraction intent (see **Display 15-1**). The intention of isotonic contractions is to employ combinations of concentric and eccentric muscle actions, without any relaxation, to promote smooth, coordinated functional movement (see **Fig. 15-4**).

Slow Reversals

The intent of a slow reversal is to facilitate dynamic movement by alternating between agonist and antagonist muscle contractions through a full ROM, thereby improving muscular strength and endurance. These reversals may or may not involve an initial "quick stretch" from elongated muscle tissue at beginning range. The patient is asked to dynamically move through a pattern to end range through a concentric muscle action from the agonist muscle group and then reverse and move in the opposite direction to end range through a concentric muscle action from the antagonist muscle group. The end of one pattern is the beginning of the other pattern (see **Fig. 15-5**). The movement can also be performed utilizing eccentric contractions in both directions. Each directional movement can be initiated by the clinician's command or "quick stretch" (see **Display 15-2**).

DISPLAY 15-1

Combination of Techniques: Rhythmic Initiation, Agonist Reversal with Isometric Hold

John is an 18-year-old baseball player who is at the end stages of his shoulder labral repair rehabilitation. He is now ready to begin a throwing program. Prior to surgery, his pain occurred during the deceleration and follow-through phases of pitching.

- Assess his throwing motion: His wind-up phase and acceleration phases are good, but during the deceleration and follow-through phases, he has inadequate elbow extension, shoulder extension, and shoulder horizontal flexion. This is producing decreased velocity and inefficiency.
- Position the player supine to the start of the upper extremity D2 flexion pattern: shoulder extended, adducted, and internally rotated, elbow extended (see Table 15-1 for upper extremity D2 flexion diagonal pattern).
- Move the patient through the pattern to the end position (shoulder flexion, abduction, and external rotation with the elbow still in extension), then return to the start of the pattern. Have the patient help perform the movement pattern as the clinician assists with the movement. The purpose is to teach the patient the D2 flexion movement pattern employing rhythmic initiation.
- At the starting position, give the command "Pull up!" (loud voice). This is the concentric phase while the muscles are shortening.
- At the end of the D2 flexion, give the command "Now Hold!" (normal voice) Isometric phase: muscles are contracting but there is no change in muscle length. This is the transition between the previous concentric phase and the subsequent eccentric phase.
- Now give the command "Let me bring you down slowly!" (a little softer tone) and return the patient to the D2 flexion starting position. In this eccentric phase, the muscles are contracting while lengthening similar to the decelerating and follow-through phases of throwing.
- Repeat six to eight repetitions, or until the patient loses form.
- Now reassess his throwing.

DISPLAY 15-2

Slow Reversal

Larry had a total knee replacement 3 months ago and he is still walking with a slow cadence and a stiff legged gait. He has full knee ROM, good strength in both quadriceps and hamstrings, and has no pain.

- Assess his knee movement in sitting and note that he slowly moves his knee into extension and returns into knee flexion slowly.
- Position him sitting on the table facing you.
- To facilitate knee extension, one hand will be on his anterior distal tibia; to facilitate knee flexion, one hand will be on the posterior distal tibia.
- Ask Larry to "kick up" and "pull back." Progressively increase resistance for strength and progressively increase movement speed for power. Employ lighter resistance and greater repetitions for muscle endurance.
- Reassess his walking.

Agonist Reversal

The purpose of agonist reversal is to require the agonist muscle groups to contract concentrically, followed by an eccentric contraction of the same muscle group. This is the theory behind most weight machines. For example, when performing resisted knee extension in the seated position on a weight machine, the patient contracts the knee extensors concentrically as the knee extends. This is immediately followed by an eccentric contraction of the knee extensors as the weight is lowered back to the starting position. This can be applied to PNF diagonal patterns via manual resistance. To enhance force in the posterior deltoid, middle, and lower trapezius muscles, the patient can resist (concentrically) the movement from D2 extension to D2 flexion. This is followed by the patient returning to the start position (D2 extension) while resistance is applied by the clinician to achieve an eccentric contraction of the same muscle group.

D1 and D2 Diagonal Patterns for the Upper and Lower Extremities

The purpose of using diagonal patterns is to facilitate functional movement patterns for the lower extremity (e.g., scooting, rolling, kicking, swing phase of gait) and upper extremity (e.g., eating, rolling, arm cocking in throwing, arm deceleration in throwing). There are primarily two diagonal movement patterns of motion for both the upper and lower extremities and they are antagonistic to each other, with each pattern having a major component of flexion or extension. Each diagonal involves movement toward and across the midline or movement across and away from the midline, and each diagonal also includes rotational components. Treatment techniques may be implemented with these diagonals to increase muscle activation or ROM. Sensory input, including manual contacts, is used to facilitate the diagonal patterns.

A summary of the upper extremity D1 and D2 diagonal patterns is shown in Table 15-3 and illustrated in **Figures 15-6** to **15-9**. The patterns are named for the ending position; for example, D1 flexion starts in extension and ends in flexion. The movements shown in Table 15-3 provide insights into the muscle groups recruited. For example, for D1 flexion, the scapula elevates in the anterior direction (protraction), thus recruiting the scapular elevators (e.g., upper trapezius, levator scapula) and protractors (e.g., serratus anterior). The glenohumeral joint flexes, adducts, and externally rotates, thus recruiting the glenohumeral flexors (e.g., anterior deltoid, clavicular pectoralis major), adductors (e.g., latissimus dorsi), and external rotators (e.g., infraspinatus). The forearm supinates and the wrist and fingers flex, recruiting the supinators (e.g., biceps brachii), wrist flexors (e.g., flexor carpi radialis and ulnaris), and finger flexors (e.g., flexor digitorum superficialis and profundus). Finally, the elbow is variable during the motion and may flex, thus recruiting the elbow flexors (e.g., biceps brachii), or may stay extended throughout the movement. Muscle recruitment patterns can similarly be assessed during the remaining three upper extremity diagonal patterns.

A summary of the lower extremity D1 and D2 diagonal patterns is shown in Table 15-4 and illustrated in **Figures 15-10** to **15-13**. The patterns are named for the ending position, so D1 flexion starts in extension and ends in flexion, and so forth. The movements shown in Table 15-4 provide insights into the muscle groups recruited. For example, for D1 flexion, the pelvis elevates in the anterior direction, recruiting the pelvic elevators (e.g., quadratus lumborum). The hip joint flexes, adducts, and externally rotates, thus recruiting the hip flexors (e.g., iliopsoas, rectus femoris), adductors (e.g., adductor longus), and external rotators (e.g., six deep external rotators, sartorius). The ankle

dorsiflexes, the foot inverts, and the toes extend, recruiting the ankle dorsiflexors (e.g., tibialis anterior), foot invertors (e.g., tibialis posterior), and toe extensors (e.g., extensor digitorum). Finally, the knee is variable during the motion and may flex, thus recruiting the knee flexors (e.g., biceps femoris), or may stay extended throughout the movement. Muscle recruitment patterns can similarly be assessed during the remaining three lower extremity diagonal patterns.

Scapular Patterns

The intent of the scapular patterns is to assess and treat stability, mobility, and coordination of the shoulder girdle, to facilitate upper extremity function, and to facilitate rolling. Scapular movement patterns are often performed in sidelying, but can also be adapted to prone, prone on elbows, sitting, or other positions. The four patterns are anterior elevation and posterior depression, which are performed in opposite directions, and posterior elevation and anterior depression, which are also performed in opposite directions (see **Fig. 15-14** to **15-17**). All the various PNF techniques previously discussed can be applied to these patterns. For example, to encourage improved postural awareness, repeated contractions can be utilized. With the patient in sidelying, the clinician can passively place the scapula in posterior depression, and ask the patient to isometrically hold that position. The clinician can then passively move the scapula into the direction of anterior elevation. The patient then actively moves the scapula back into the start position of posterior depression. This can be repeated, having the patient move through greater portions of the diagonal.

FIGURE 15-14 Scapular anterior elevation (*unidirectional arrow*).

FIGURE 15-15 Scapular posterior depression (*unidirectional arrow*).

FIGURE 15-16 Scapuar posterior elevation (*unidirectional arrow*).

FIGURE 15-17 Scapuar anterior depression (*unidirectional arrow*).

Pelvic Patterns

The purpose of pelvic patterns is to examine and treat stability, mobility, and coordination of the pelvis, to facilitate lower extremity function, and to facilitate rolling and scooting. These techniques are frequently performed in sidelying, but can also be adapted to prone, prone on elbows, sitting, tall kneeling, half kneeling or other positions. The two patterns are anterior elevation and posterior depression, and posterior elevation and anterior depression, which are performed in opposite directions (see **Fig. 15-18** to **15-21**).

FIGURE 15-18 Pelvic anterior elevation (*unidirectional arrow*).

FIGURE 15-19 Pelvic posterior depression (*unidirectional arrow*).

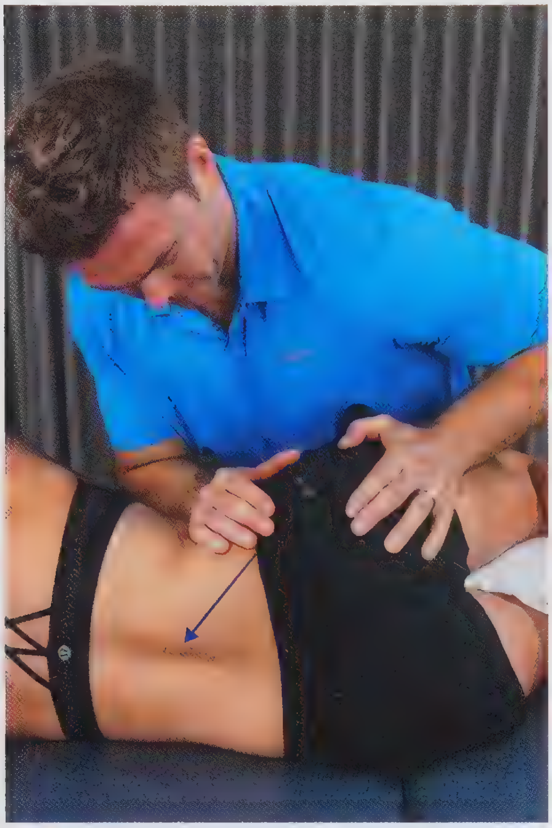

FIGURE 15-20 Pelvic posterior elevation (*unidirectional arrow*).

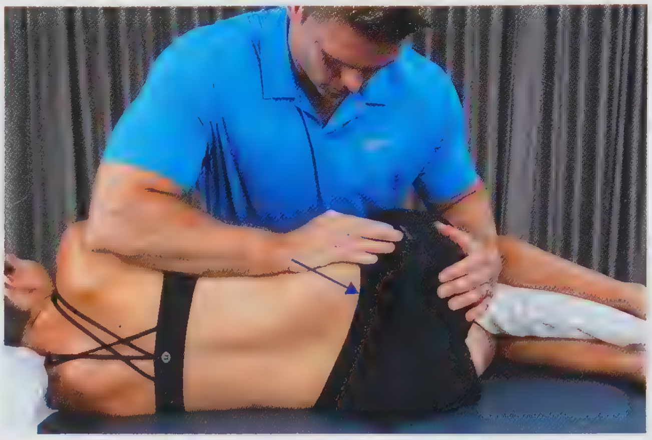

FIGURE 15-21 Pelvic anterior depression (*unidirectional arrow*).

Pelvic and scapular patterns can be combined. One combination is a reciprocal trunk pattern which involves scapula posterior depression combined with pelvis anterior elevation, and scapula anterior elevation combined with pelvis posterior depression. Examples of commands used during this technique are "scrunch" and "lengthen." To facilitate rolling, mass flexion (anterior depression of scapula combined with anterior elevation of pelvis) and mass extension (posterior elevation of scapula combined with posterior depression of pelvis) can be employed.

Stability

Alternating Isometrics

The intent of alternating isometrics is to promote stability of a body part in a specific ROM or position. Isometric holding is facilitated first in the agonist acting on one side of the joint, followed by isometric holding of the antagonist. No movement occurs while the patient tries to maintain body position. Muscle demands must be very slow and specific. For example, a physical therapist may apply simultaneous resistance to the anterior left and right shoulder for a few seconds before switching the resistance to the posterior left and right shoulder. The clinician's movements should be smooth, fluid, continuous, and predictable. The clinician may also provide traction or approximation, particularly when making rotational demand switches (see **Fig. 15-22**).

A B

FIGURE 15-22 Alternating isometrics for trunk rotational stability. **(A)** Resisted trunk rotation to the right; **(B)** resisted trunk rotation to the left.

BUILDING BLOCK 15-3

Approximation and Cocontraction

Wendy is a 14-year-old volleyball player with pain in the right shoulder and scapular winging. Assess her movement in shoulder elevation. Throughout the ROM, her scapula is unstable with "winging" and does not upwardly rotate adequately. Design an exercise to improve this problem using approximation and cocontraction.

SELF-MANAGEMENT 15-1

Improve Scapular Stabilization Progression

Purpose: To enhance the stability of the scapula by applying rhythmic stabilization for a home program to strengthen the upper and lower fibers of the serratus anterior and to improve scapular stability for upper extremity functional activities.

Position: Place the hands on the floor and get into a push-up plus (scapular protraction), neutral spine position with your feet in a wide base position

Movement Technique: Level 1: Maintain scapular protraction, neutral spine, and both hands on the floor, weight shift from right to left upper extremity. Perform the weight shifts 10 times to each arm without rest, or until fatigue sets in and you lose form.

Level 2: Using the same position as above, now use a narrow base with ankles touching. Perform the weight shifts 10 times to each side, or until fatigue sets in.

Level 3: Start in the same position as Level 2.

Lift one leg at a time approximately 3 inches off the floor. Perform alternate leg lifts 10 times each leg, or until fatigue sets in.

Level 4: Now place hands on a basketball, maintain the push-up plus position, and close your eyes. Perform alternate leg lifts 10 times each leg, or until fatigue sets in.

At no time between the changing muscle contractions is there relaxation of the body part being addressed (see **Building Block 15-3** and **Self-Management 15-1**).

Rhythmic Stabilization

The intent of rhythmic stabilization is also to promote stability of a body part in a specific range or position. This technique uses continuous alternating demands to isometric contractions and cocontractions, but emphasizes rotational stability control. Similar to alternating isometrics, the technique is performed without relaxation. For example, a physical therapist may apply simultaneous resistance to the anterior left shoulder and posterior right shoulder for a few seconds before switching the resistance to the posterior left shoulder and the anterior right shoulder.

Flexibility

Proprioceptive neuromuscular facilitation techniques are frequently used to increase muscle length and flexibility, utilizing the physiologic principles discussed previously (see Tables 15-1 and 15-2). These techniques rely on muscle contraction and relaxation to produce changes in muscle length and mobility.

Contract-Relax

The purpose of CR is to relax tight musculature that is inhibiting ROM (see **Display 15-3** and **Fig. 15-23**).

Hold-Relax

The intent of HR is to relax tight musculature that is inhibiting ROM. The stretching technique begins with a continuous static stretch (typically 15 to 30 seconds in duration) of an antagonist muscle group followed by a resisted isometric contraction (typically 5 to 10 seconds of moderate intensity) of the same antagonist muscle group (see **Display 15-4** and **Fig. 15-24**).

DISPLAY 15-3

Contract-Relax

Fred is a football player who suffered a moderate right ankle sprain about 6 weeks ago and has limited dorsiflexion on the right. He is ready to return to practice but you notice as he is running he has a short right step length.

- Position him supine on the table.
- The therapist stands at the foot of the table and dorsiflexes the right ankle to hold the Achilles on stretch for 10 to 15 seconds.
- At end of stretch, the therapist instructs the patient to contract his Achilles musculature by "pushing into my hands for 5 to 10 seconds" against moderate intensity resistance so that the ankle slowly plantar flexes via a concentric muscle action from the Achilles musculature.

When the patient relaxes after the 10-second contraction, the therapist passively moves the ankle into dorsiflexion combined with knee extension to lengthen the Achilles musculature. This new lengthened position is held for 10 to 15 seconds.

- This CR stretching process is related typically for three to four repetitions.
- Reevaluate his running.

A B

FIGURE 15-23 Contract-relax of a shortenend latissimus dorsi in a swimmer. **(A)** Therapist concentrically resists internal rotation of the shoulder followed by an isometric contraction of shoulder extension, held for 10 seconds. **(B)** As the patient relaxes the therapist passively moves the shoulder into external rotation and flexion.

DISPLAY 15-4
Hold-Relax

Julie is a sprinter on her track team who suffered a moderate left hamstring strain about 6 weeks ago. She is ready to return to practice but you notice as she is running with a short left step length.

- Position her supine on the table.
- Therapist stands at the foot of the table and raising her left leg in the straight leg position to end range and holding hamstring stretch for 10 to 15 seconds.
- At end of stretch instruct patient to contract her hamstrings by "pushing into my hands for 5 to 10 seconds" against moderate intensity resistance so that the hip stays in a fixed position via an isometric muscle contraction of the hamstrings.
- This HR stretching process is repeated three to four times.
- Reevaluate her running.

A B

FIGURE 15-24 Hold-relax stretching of the quadriceps. In prone, **(A)** the knee is taken to end-range flexion, and **(B)** the quadriceps contract isometrically, followed by further knee flexion.

Hold-Relax with Agonist Contraction

The purpose of using HR-AC is to relax tight musculature that is inhibiting ROM. The technique is the same as the HR technique, except the agonist muscle contracts to aid in the stretch of the antagonist muscle (see **Display 15-5**, **Building Block 15-4**, and **Fig. 15-25**).

BUILDING BLOCK 15-4

Improving Flexibility

Ms. Smith is a 50-year-old female who has a right shoulder adhesive capsulitis. She is improving with shoulder elevation and is now able to elevate her arm actively to 100 degrees and her end ROM is 105 degrees passively. Describe exercises for her using activities to increase flexibility.

DISPLAY 15-5

Hold-Relax with Agonist Contraction

Elisabeth is a 70-year-old woman who was immobilized with her right elbow in 45 degrees flexion following a radial head fracture. She now has shortening of her biceps muscles. She is having difficulty restoring full elbow extension.

- Position her supine on the table.
- Therapist stands next to the patient with her right elbow in end-range extension, holding for 10 to 15 seconds while the patient contracts her triceps muscles (agonist muscle group) to assist in the biceps stretch.
- At the end of the stretch, instruct the patient to contract her biceps by "pulling into my hands for 5 to 10 seconds" against moderate intensity resistance so that the elbow stays in a fixed position via an isometric contraction of the biceps.
- This stretching process is related typically for three to four repetitions.
- Reevaluate her elbow ROM.

A B

FIGURE 15-25 Hold-relax with agonist contraction to increase length of the wrist flexors. **(A)** The patient is taken to the end of range of the wrist flexors, asked to isometrically contract the flexors against resistance. **(B)** This is immediately followed by concentric contraction of the wrist extensors (*unidirectional arrow*).

LAB ACTIVITIES

Manual Contacts

DIRECTION OF MOVEMENT

1. Have your partner in the supine position with eyes closed.
2. Raise the right forearm to 90 degrees of elbow flexion and supination
3. Manual contact no. 1: Wrap entire hand around the forearm: Command: "Hold that position"
4. Manual contact no. 2 using a lumbrical grip on flexor surface only:
   Command: "Hold that position". . . now pull up!
5. Manual contact no. 3 using a lumbrical grip on the extensor surface only:
   Command "Hold that position. . . now push down!"
   a. Which manual contacts facilitated specific muscle activity?
   b. Which manual contact was difficult to facilitate the direct line of movement?

STRENGTH OF CONTRACTION

1. Use manual contact no. 2: apply light pressure and then slowly increase the pressure.
2. Repeat elbow flexion five times; start with a soft voice and raise your voice with each repetition.
   a. Does the patient respond to the pressure of the manual contact?
   b. Does the voice of the therapist facilitate the patient's contraction?
3. Now have the patient hold at 90 degrees of elbow flexion.
   a. Begin with light resistance to the biceps. Note biceps and triceps muscle tension.
   b. Now increase to maximal resistance. Note that although resisting elbow flexion, irradiation occurs into the triceps muscle as well.

APPROPRIATE RESISTANCE AND SPEED OF CONTRACTION

1. Try the following resistance guide to facilitate elbow flexion. Perform:
   a. PROM, AAROM, light resistance, medium resistance, and finally maximal resistance.
   b. Now control the speed of contraction from slow to medium speed to fast speed.

The result of each resistance should be a smooth and coordinated movement.

Irradiation

1. The clinician stands in front of a patient who is sitting at the edge of a table. Have the patient raise their arms to 90 degrees of shoulder flexion, elbows extended and fingers interlocked (in a "prayer" position—see figure).
2. The clinician provides resistance to both of the patient's arms and increases the static resistance and duration.
   a. Note the irradiation occurring in the hip flexors.
   b. Note the irradiation into the trunk.
3. Try resisting just one arm in the same position.
   a. Is there more or less trunk activity with one arm compared to both arms?
   b. Irradiation through the trunk will increase when involving two extremities.

Mass Movement Pattern

1. Stand facing your partner, throw a ball and follow through to the same side hip.
2. Throw the ball and follow through to the contralateral hip.
   a. Compare: Ball velocity of the throw.
   b. Compare the mass movement pattern from the feet, knees, hip, trunk, shoulders, and neck.

Manual Therapy

1. List the advantages of manual therapeutic exercises.
2. List the disadvantages of manual therapeutic exercises.

Patient Problem

Ms. Spock is a 54-year-old lady who suffered a CVA with mild to moderate right-sided hemiparesis. She is having difficulty with sit to stand.

Evaluation

- She has good ROM in all extremities.
- Upper body strength is 5/5 on the left, 4/5 on the right, weak grip
- Lower body strength is 5/5 on the left, 3+/5 on the right
- Balance: sitting: good slight lean to the right
- Balance: standing: fair +: leans to the right, and center of gravity is behind base of support. Requires a walker for

LAB ACTIVITIES (continued)

independent standing and gait. Requires stand by assist without walker

Functional Assessment: Sit to stand and return

- It takes approximately 10 seconds to sit to stand from a chair.
- She has a tendency to lean to the weak side as she is standing but is able to maintain balance.
- Weight is through the heels not the forefoot.
- Inadequate forward trunk lean.
- She uses a walker for gait.
- Return to sitting you note she "plops" back into the chair.

Goal: Safe and efficient sit to stand and return. Design a treatment plan and progression.

- What techniques would you apply in the treatment?
- How would you facilitate the progression: sitting forward trunk lean, sit to stand, weight shift to the forefoot, return to sitting with a controlled movement to the chair?
- Design a safe home program she can do independently.

KEY POINTS

- The advantage to manual therapeutic exercise is the ability to constantly assess the patient's movement or posture which allows for immediate modification of the treatment or resistance.
- The clinician can influence variables such as the magnitude of resistance, type of contraction, joint compression or distraction, movement or stability emphasis and the direction of the movement or pattern.
- Proprioceptive neuromuscular facilitation (PNF) is a manual therapy approach that attempts to provide a maximal response for increasing strength, flexibility, coordination, and functional mobility. PNF patterns are more concerned with mass body movements as opposed to specific muscle actions.
- These patterns are composed of both diagonal and rotational exercise patterns that are similar to the motions required for activities of daily living, functional mobility, and even athletic performance.

CRITICAL THINKING QUESTIONS

1. How does the clinician know they are applying too much resistance?
2. Which technique should always be utilized when facilitating movement?
3. Which technique should be applied when attempting to gain ROM?
4. Which technique should be applied to improve sitting balance?
5. Give an example of how to apply a direct treatment and an indirect treatment to facilitate trunk flexion.
6. What are two advantages to using manual therapeutic exercise?
7. What are two disadvantages of manual therapy exercise?
