CHAPTER 16

Aquatic Therapeutic Exercise

LORI THEIN BRODY

Although water has been used therapeutically for centuries, only recently has its use become widespread in the rehabilitation community. The unique buoyant and resistive properties of water make it a useful tool for therapeutic exercise, and the advantages of unloading and of immersion in a resistive medium are well recognized. As a result, the body of knowledge surrounding aquatic rehabilitation has expanded tremendously. As with land-based exercises, different techniques, schools of thought, and approaches have been developed. The Halliwick method, the Bad Ragaz Ring method, Watsu, and Ai Chi are all examples of approaches to rehabilitation in the water. Further information on resources for these techniques can be found in the Additional Resources section at the end of the chapter.

As with other approaches to therapeutic exercise, it is important to realize that water is a tool, with advantages and disadvantages. Not all patients are appropriate candidates for aquatic rehabilitation. The strengths and weaknesses of each treatment modality must be matched to the needs of the patient. Because water is such a unique environment, the clinician should get in the pool and experience the effects of different exercises before prescribing them for patients. Often, aquatic exercises that appear to be simple can be quite difficult, and exercises that are difficult on land are easy to perform in the pool. The trunk-stabilizing muscles are challenged with most arm and leg exercises and represent a very different task from the same activity performed on land.

Aquatic physical therapy can be defined as the use of an aquatic medium to achieve physical therapy goals. The purpose of this chapter is to acquaint the reader with the fundamental principles of therapeutic exercise in the water. It is intended to provide the framework for integration of water-based and land-based exercises to treat impairments, activity limitations, and participation restrictions.

PHYSICAL PROPERTIES OF WATER

The physical properties of water provide countless options for rehabilitation program design. Be familiar with these properties and the intended or unintended effects that may result from their interaction. For example, the effect of buoyancy on gait is that of unweighting, thereby reducing the amount of physical work of walking. However, this reduction may be offset by the frontal resistance encountered because of the water's viscosity. As such, the clinician and patient should clearly define the goals of any given exercise in the pool to ensure progress toward overall functional goals.

Buoyancy

Archimedes' principle states that an immersed body at rest experiences an upward thrust equal to the weight of the same fluid volume it displaces.[1] As such, rather than a downward force resulting from gravity and body weight, individuals in the pool experience an upward force (i.e., buoyancy) related to water depth and specific gravity. The specific gravity of an object (or an individual) is its density relative to that of water.[1] The density of water is almost exactly 1 g per cm^3; therefore, anything with a specific gravity >1 g per cm^3 sinks, and anything less than 1 g per cm^3 floats. This property forms the scientific basis for underwater weighing to determine body composition. The specific gravity of a person is determined by the relationship between lean body mass and body fat. Individuals with a higher relative lean body mass are more likely to sink, and those with a higher relative body fat have a tendency to float. These differences can be balanced by the appropriate use of water depth, flotation equipment, and waterproof weight equipment.

Buoyancy acts through the **center of buoyancy**, which is the center of gravity of the displaced liquid. If the body weight and the displaced fluid weights are unequal, a rotation about the center of buoyancy occurs until equilibrium is reached. The moment of buoyancy is the product of the force of buoyancy and the perpendicular distance from the center of buoyancy to the axis of rotation. As on land, the greater the distance, the greater is the force needed to move the limb.

Buoyancy is one property of water that can be used to progress therapeutic exercise. The four main variables that can be manipulated to alter assistance or resistance are

1. Position or direction of movement in the water
2. Water depth
3. Lever arm length
4. Use of flotation or weighted equipment

Position and Direction of Movement

As with gravity, patient position and direction of movement can greatly alter the amount of assistance or resistance. Activities in the water can be buoyancy assisted, buoyancy supported, or buoyancy resisted (**Fig. 16-1**).

- Buoyancy-assisted exercises are movements toward the surface of the water and are similar to gravity-assisted exercises on land. In the standing position, shoulder abduction and flexion, as well as the ascent phase of a squat, are considered buoyancy-assisted exercises. In a prone position, hip extension can be buoyancy assisted.
- Buoyancy-supported exercises are movements parallel to the bottom of the pool and are similar to gravity-minimized positions on land. These movements are neither resisted nor assisted by buoyancy. In a standing position, horizontal shoulder abduction is an example of such an activity. Hip and shoulder abduction in a supine position are also examples of buoyancy-supported activities.
- Buoyancy-resisted exercises are movements toward the bottom of the pool. In a supine position, shoulder and hip extension are buoyancy-resisted activities. The descent phase of a squat is resisted in a standing position and is another example of buoyance-resisted activity.

The ability to position the patient a number of ways allows for a multitude of assisted, supported, and resisted activities (see **Case Study 16-1** and **Building Block 16-1**).

Water Depth

The water's depth is another variable that can alter the amount of assistance or resistance offered. For example, performing a squat in chest-deep water is easier than in hip-deep water. The challenge of walking varies tremendously depending on the

FIGURE 16-1 **(A)** Buoyancy-assisted elbow flexion. In a standing position with the elbow at the side and a small buoyant cuff or noodle, elbow flexion is assisted by buoyancy as the triceps relax and allow flexion to occur. **(B)** Buoyancy-supported elbow flexion. In a standing position with the shoulder in abduction, elbow flexion is neither assisted nor resisted by buoyancy, but moves through a range perpendicular to buoyancy. **(C)** Buoyancy-resisted elbow extension. In a standing position, the motion from flexion to extension becomes resisted by the water's buoyancy.

CASE STUDY 16-1

HISTORY

The patient is a 57-year-old woman who fell 8 weeks ago and sustained a right bimalleolar fracture. She was treated with open reduction internal fixation and placed in a boot. Over the following 6 weeks, her weight-bearing status was gradually increased. She is now full weight bearing (FWB) and is instructed to wean herself from the walking boot. She is apprehensive about walking without the boot. She feels like her ankle is stiff and weak and that she has poor balance. She is otherwise healthy, although she has mild degenerative joint disease in both knees. She reports that her knees are bothering her more since walking in the boot and because she has been unable to exercise regularly. She hopes to return to walking 3 miles per day for routine exercise.

EXAMINATION

Patient 65-in tall, weighing 150 lb. Ambulates with a slight limp in walking boot. Unable to walk FWB without boot. AROM from 0- to 30-degree dorsi/plantar flexion and 10-degree eversion to 15-degree inversion. Decreased AP glide of talus in mortise. Joint stable. Significant atrophy and strength of 4/5 throughout with discomfort but no frank pain. No neurologic signs. Unable to single-leg balance on involved limb.

BUILDING BLOCK 16-1

Consider Case Study 16-1 given earlier. How might buoyancy be a useful tool for this patient?

individual's impairment or disability. For example, someone with pain because of degenerative joint disease may find walking in deeper water easier because of the additional unloading of buoyancy, while someone with muscular or cardiovascular weakness may find the additional viscosity-induced resistance of deeper water more difficult.

Estimates of percentage weight bearing at various depths have been obtained by Harrison et al.[2] While estimates have been given, the amount of weight bearing depends on the body composition of the patient, the water's depth, and the walking speed. Fast walking can increase the loading over the static condition by as much as 76%.[2] Occasionally, water-depth options are limited by the available facilities. Modifications can be made by adding buoyant equipment to unload or by adding resistive equipment to increase frontal resistance.

Lever Arm Length

Just as with exercise on land, the lever arm length can be adjusted to change the amount of assistance or resistance. Performing buoyancy-assisted shoulder abduction in a standing position is easier with the elbow straight (i.e., long lever) than with the elbow flexed (i.e., short lever). Conversely, buoyancy-resisted shoulder adduction is more difficult with the elbow extended because of the long lever arm (**Fig. 16-2**).

Buoyant Equipment

To further increase the amount of assistance or resistance, buoyant equipment can be added to the limb (**Fig. 16-3**). Similar to land, as the buoyancy of the equipment increases, the resistance also increases. However, the classification of "buoyancy assisted" and "buoyancy resisted" is not as straightforward as it seems. Just as the motion of lowering the arm on land is not a passive activity but rather an eccentric lowering action, similar effects occur in the water. A buoyant "bell" in the hand during shoulder abduction increases the "assistance" from buoyancy while increasing resistance to the adduction return motion. However, this is true *only* if the patient relaxes the shoulder during the abduction motion. If the patient controls the buoyant bell during the abduction motion, then the muscle activity becomes an eccentric resisted activity of the shoulder adductor muscles rather than a buoyancy-assisted exercise.

Buoyant cuffs can be added anywhere along the limb to adjust the quantity and location of assistance or resistance (**Fig. 16-4**). Buoyant equipment is also used to support individuals in supine or prone positions as they perform exercises.

Hydrostatic Pressure

The pressure exerted by the water at increasing depths (i.e., hydrostatic pressure) accounts for the cardiovascular shifts seen with immersion and for the purported benefit of edema control. Pascal's law states that the pressure of a fluid is exerted on an object equally at a given depth.[1] The pressure increases with

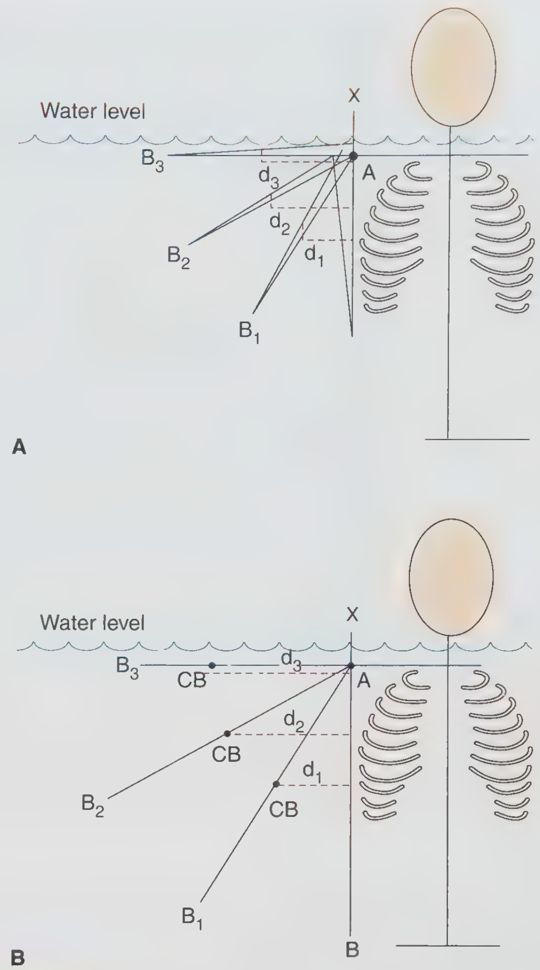

FIGURE 16-2 **(A)** The effect of buoyancy on shoulder abduction with a shortened lever arm (*elbow bent*). **(B)** The effect of buoyancy on shoulder abduction with a long lever arm (*elbow extended*). Increasing the lever arm increases the distance from the center of rotation, thereby increasing the resistance or assistance. (Adapted from Skinner AT, Thomson AM, eds. Duffield's Exercise in Water. 3rd Ed. London: Bailliere Tindall, 1983.)

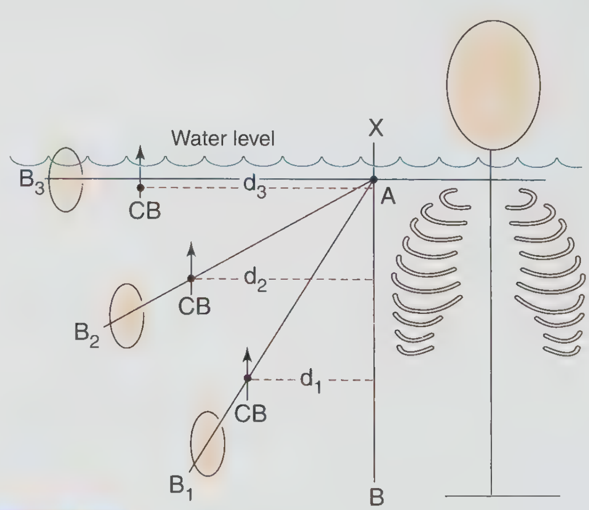

FIGURE 16-3 The effect of buoyancy with the addition of a float in the hand. The distance from the axis of rotation is further increased, thereby increasing the resistance or assistance. (Adapted from Skinner AT, Thomson AM, eds. Duffield's Exercise in Water. 3rd Ed. London: Bailliere Tindall, 1983.)

FIGURE 16-4 (A) Buoyant cuff added to the knee provides some assistance to hip flexion. (B) A buoyant cuff added at the ankle provides greater hip flexion assistance.

the density of the fluid and its depth. Hydrostatic pressure is greatest at the bottom of the pool because of the weight of the water overhead. As such, the pool may be a good exercise option for individuals with lower extremity edema or joint effusion. The hydrostatic pressure also produces centralization of peripheral blood flow, which alters cardiac dynamics. This is discussed later in this chapter under Physiologic Responses to Immersion.

Viscosity

The viscosity of a fluid is its resistance to adjacent fluid layers sliding freely by one another.[1] This friction causes a resistance to flow when moving through a liquid. Viscosity is of little significance when stationary. The viscous quality of water allows it to be used effectively as a resistive medium because of its hydrodynamic properties. Turbulent flow is produced when the speed of movement reaches a critical velocity.[3] Eddies are formed in the wake behind the moving object, creating drag that is greater in the unstreamlined object than in streamlined objects (**Fig. 16-5**). When using viscosity, consider several important factors:

- In turbulent flow, resistance is proportional to the velocity squared, and increasing the speed of movement significantly increases the resistance.
- When moving through the water, the body experiences a frontal resistance proportional to the presenting surface area, and so resistance can be increased by enlarging the surface area.

The clinician has two variables to alter resistance produced by viscosity: the velocity of movement and the surface area or streamlined nature of the object.

FIGURE 16-5 Using a plow while walking increases the surface area, creating eddies and drag.

Velocity of Movement

Turbulence and resultant drag are created when movement reaches a critical velocity. Slow movement through the water produces little drag, and resistance is minimal. When moving rapidly through the water, resistance is proportional to the speed of movement. Progress resistance incrementally by gradually increasing the speed of the exercise. This allows multiple gradations of an exercise rather than finite increases in weight, which is a common limitation in land programs.

Research into muscle activation patterns during shoulder elevation on land and in water highlights the relationship between viscosity and movement speed (**Evidence and Research 16-1**). When using viscosity as resistance, as the speed of movement through the water increases, so does the resistance. Slow movements produce muscle activation that is below those levels achieved against gravity on land, whereas fast movements exceed the muscle activation of comparably paced land-based movements.

EVIDENCE and RESEARCH 16-1

Research comparing shoulder muscle activation at 30, 45, and 90 degrees per second in the water and on land highlights the relationship between speed and muscle activation using viscosity.[4] The percent of maximal voluntary contraction of the shoulder muscles was consistently higher on land at 30 and 45 degrees per second, whereas those values were higher in water at 90 degrees per second (**Table 16-1**). These findings were replicated in additional research.[5]

Surface Area

In addition to altering the speed of movement, resistance can be modified by changing the object shape to provide more or less turbulence. The body can be positioned to alter turbulence, or equipment can be added. For example, less resistance is encountered in sidestepping than in forward or backward walking because of the more streamlined shape in frontal plane movement. Performing shoulder internal and external rotation with the elbows bent to 90 degrees with the forearms pronated ("slicing" the water) produces much less resistance than performing this exercise with the forearms in neutral (**Fig. 16-6A** and **B**). Adding resistive gloves further increases the resistance (Fig. 16-6C). Changing the pitch of the hand slightly between neutral and pronation alters the surface area and resultant resistance providing a multitude of resistive positions (**Evidence and Research 16-2**). Other equipment to increase the surface area and resultant turbulence are fins for the feet, resistive bells and boots, paddles or pinwheels, and a plow for resistive walking or other pushing and pulling activities (**Fig. 16-7**). A study using the Hydrotone (Hydro-Tone Fitness Systems, Inc., Huntington Beach, CA) boots showed increased drag compared with a barefoot condition[7–9] (see **Building Block 16-2**).

EVIDENCE and RESEARCH 16-2

A study of the Hydro-Tone (Hydro-Tone Fitness Systems, Inc., Huntington Beach, CA) resistive bells found that both their orientation and the velocity had a significant effect on force production.[6] Approximately 50% more force is produced when the bell is oriented at 45 degrees compared with 0 degrees at fast speeds. At slow speeds, the orientation made little difference in force production.

BUILDING BLOCK 16-2

The patient from the Case Study 16-1 is starting a walking program in the pool. Which walking movements will facilitate ankle mobility? What factors should be considered when determining the speed and depth for the walking exercise?

TABLE 16-1

Shoulder Muscle Activation (Electromyographic) During Arm Elevation in the Scapular Plane on Land and in Water

MUSCLE	TEST CONDITION	30 DEGREES/SECOND	45 DEGREES/SECOND	90 DEGREES/SECOND
Supraspinatus	Land	16.68	17.46	22.79
	Water	3.93	5.71	27.32
Infraspinatus	Land	11.10	10.76	15.03
	Water	2.28	2.89	21.06
Subscapularis	Land	5.96	6.83	7.45
	Water	1.49	2.26	10.73
Anterior deltoid	Land	15.88	18.82	22.09
	Water	3.61	43.49	32.83
Middle deltoid	Land	6.22	7.64	10.07
	Water	1.60	2.53	17.39
Posterior deltoid	Land	2.25	2.24	4.23
	Water	0.75	0.91	6.56

Data are mean percentage of maximal voluntary contraction.

DISPLAY 16-1

Physiologic Changes with Immersion to the Neck

1. Decreased:
   - Peripheral blood flow
   - Vital capacity by ~8%
2. Increased:
   - Heart volume by ~250 mL
   - Intrapulmonary blood volume from 33% to 60%
   - Right atrial pressure ~12 to 18 mm Hg
   - Left ventricular end-diastolic volume
   - Stroke volume ~35%
   - Cardiac Output ~32%
3. Decreased or unchanged heart rate

From Risch WD, Koubenec HJ, Beckmann U, et al. The effect of graded immersion on heart volume, central venous pressure, pulmonary blood distribution, and heart rate in man. Pflugers Arch 1978;374:115–118.

PHYSIOLOGIC RESPONSES TO IMMERSION

Significant physiologic changes occur with immersion at various depths. These responses may produce desirable effects (e.g., control of lower extremity edema) or undesirable effects (e.g., limitation of chest expansion). Choose the appropriate water depth on the basis of the specific health status of the patient and the patient's physical therapy goals.

Effects of Hydrostatic Pressure

Immersion alone is not a benign action. The hydrostatic pressure encountered results in changes in cardiovascular dynamics even before exercise is initiated (**Display 16-1**). Immersion to the neck results in centralization of peripheral blood flow.[10–14] The hydrostatic pressure creates a pressurized force increasing blood flow to the thorax, similar to how squeezing the bottom of a plastic bottle pushes the liquid to the top. The blood volume shift results in increased venous return to the heart, causing a cardiac preload.[11,12,14] The cardiac preload produces a stroke volume (SV) increase through the Frank-Starling reflex.[10,14] The heart rate (HR) remains unchanged or decreases because of the relationship of HR, SV, and CO such that HR × SV = CO. Risch et al.[13] demonstrated that raising the water depth from the symphysis pubis to the xiphoid process decreased the HR 15%. These HR changes depend on the depth of immersion, the individual's comfort level in the water, water temperature, and type and intensity of exercise. Heart volume–associated changes were similar between immersion to the diaphragm and supine positions.[13]

The disparity in HR changes with water exercise reported in the literature reflect the many variables impacting cardiopulmonary dynamics in the water. The cardiovascular changes resulting from centralization of blood flow are graded on the basis of the depth of immersion and body position, and they occur before the onset of exercise. The **hydrostatic indifference point** is located approximately at the diaphragm and represents the point at which the increase in hydrostatic pressure in the lower extremities and abdomen is precisely countered by the hydrostatic pressure of the water.[13] This principle can be used in a variety of clinical situations. For example, when the water level drops below the symphysis pubis, the positive effects of prevention of lower extremity edema are negated. The cardiopulmonary responses to the exercise program will more closely match that of land-based exercise. Exercise in deeper water will facilitate return of peripheral blood flow, which may be a desired outcome. A patient with no significant cardiac history and ankle swelling would benefit from immersion in deeper water, whereas a patient with known cardiac disease and no lower extremity edema should be treated in more shallow water. Be sure to match the needs of the patient (e.g., prevention of edema, cardiac history) with the risks and benefits of the various treatment modalities.

Effects of Water Temperature

Water temperature, as with hydrostatic pressure, alters the cardiovascular challenge to the immersed subject in a depth-related fashion. Water that is too warm or too cold can add a significant thermal load to the cardiovascular system. Choukroun and Varene[15] found cardiac output (CO) to be unchanged from 25°C to 34°C (77°F to 93°F) but significantly increased at 40°C (104°F); oxygen consumption was significantly increased at 25°C (77°F). Several studies have found a decreased HR in subjects exercising in cold water, and exercising in very warm water can increase HR.[16–20] Thermoneutral temperature is suggested to be approximately 34°C.[18–20] Most pool temperatures range from 27°C to 35°C (81°F to 95°F). Know the current pool temperature and potential effects on the patient before the onset of exercise.

PHYSIOLOGIC RESPONSES TO EXERCISE WHILE IMMERSED

In addition to the effects of immersion alone on cardiovascular dynamics, consider the combination of changes resulting from immersion combined with changes resulting from exercise. Training in water produces physiologic adaptations similar to training on land, and aquatic training can be used to increase or maintain cardiovascular condition in a variety of populations.[14,21–25] The aerobic and anaerobic benefits of deep- and shallow-water exercise have been verified in a number of populations.[26–29] The pool can be used as a cardiovascular training tool alone or in combination with land-based training, providing the individual recovering from injury with alternative training mediums.

When training in the pool, the cardiac preload resulting from central volume increases persists despite the vascular shifts known to occur with exercise.[11] Despite the increase in blood flow to the working muscles (i.e., peripheralization of blood flow), the increased cardiac load resulting from hydrostatic pressure (i.e., centralization of blood flow) still occurs. Most studies have found the HR to be lower or unchanged compared with similar cardiovascular activity on land[22,30–33] (**Evidence and Research 16-3**). The depth of immersion affects the degree of cardiac changes, with increasing depth producing greater cardiovascular changes (**Evidence and Research 16-4**). Running and jogging in waist-deep water produces the same HR and oxygen consumption changes as exercise on land.[39,40] However, exercise while immersed to the neck will produce an HR of 8 to 11 beats per minute lower than similar land-based exercise.[33,41]

EVIDENCE and RESEARCH 16-3

If working below the hydrostatic indifference point, exercise is more strenuous because of the increased resistance against the legs from viscosity. Subjects walking and jogging in ankle-, knee-, thigh-, and waist-deep water were found to work harder with increasing immersion up to the waist, at which point the increased resistance (resulting from increased surface area) was partially offset by buoyancy.[34] The cardiorespiratory changes due to buoyancy were not significant below waist level.

EVIDENCE and RESEARCH 16-4

Deep-water running has been shown to maintain an individual's maximum oxygen consumption and 2-mile run time over a 6-week training period.[25,27,35] Research has consistently shown a lower exercise heart rate with deep-water running compared with land-based running due to the water's hydrostatic pressure.[28,36,37] Similar results were found when comparing cardiorespiratory exercise immersed to the hip or to the breast when compared with land exercise.[38]

Both shallow-water running and deep-water running can be used for cardiovascular training. As with on land, a linear relationship between HR and cadence exists for deep-water running.[42] Mechanically, shallow-water running more closely resembles land-based running because of the foot contact on the bottom, but contact may also cause impact or friction problems. Muscle activation patterns will differ between shallow- and deep-water aerobic exercise because of the contact with the pool bottom.

When performing resistive exercise in the pool, be sure to realize that most muscle contractions are concentric because of the negation of gravity. Eccentric contractions can be generated if the water is shallow enough to minimize the effects of buoyancy, by manually resisting the force of buoyancy in an eccentric fashion, by using a lot of buoyant equipment or by direction changes requiring the person to slow, stop, and change directions. For example, performing a squat exercise in thigh-deep water requires eccentric contractions in the lowering phase, but performing the same exercise in waist-deep water negates most of gravity's effects. If enough flotation equipment is used, an exercise can require eccentric resistance against buoyancy. With large flotation devices in the hand, the motion of shoulder abduction becomes an eccentric contraction of the shoulder adductors, resisting the upward force of buoyancy.

EXAMINATION AND EVALUATION FOR AQUATIC REHABILITATION

Perform a complete land-based examination before initiating aquatic rehabilitation activities. This is the same evaluation the clinician performs when designing a land-based program. As always, choose tests and measures on the basis of the patient history and systems review. Additionally, be sure to consider the physical properties of the water and the physiologic effects of immersion when determining the appropriateness of aquatic physical therapy for the patient (see **Display 16-2**). Will the patient benefit from the properties of buoyancy or hydrostatic pressure (i.e., relief of weight bearing or swelling control)? Will the centralization of blood flow place the patient at risk? Look for impairments that might alter the patient's relative density and ability to float. For example, a patient with paraparesis may need flotation to keep his or her legs from sinking when supine. Identify pathology or impairments that might affect the patient's ability to tolerate the hydrostatic pressure against the chest wall. Patients with decreased lung capacity may have difficulty breathing resulting from this pressure. Watch for sensory impairments that might alter the patient's ability to tolerate the touch of the pool floor, walls, or water, or the visual or auditory sensory stimulation found in a pool.

Be sure to assess the patient's safety in the pool environment. Will the patient be able to traverse a wet shower room and pool deck? Will he or she be able to don and doff a swim suit? Are there safe mechanisms for transfer in and out of the pool, given the patient's physical capabilities? What is the patient's comfort level in the pool? Is he or she able to float and recover, blow bubbles, and immerse the face in the water? Is the patient able to regain balance comfortably if he or she loses it in the water? The patient's safety is paramount in the pool, just as on land (see **Building Block 16-3**).

DISPLAY 16-2

Patient Screen for Aquatic Rehabilitation

1. Basic safety
   - Ability to enter/exit the shower area, pool deck, and pool safely
   - Comfort in the water
   - Ability to put face in the water
   - Rhythmic breathing/bobbing
   - Ability to supine and prone float and recovery
   - Turning over when horizontal in the water
2. Precautions to aquatic environment
   - Cardiac history
   - Fear of the water
   - Any precautions to land exercise (i.e., diabetes)
   - Limited lung capacity
3. Contraindications to aquatic environment
   - Fevers, infections, rashes
   - Open wounds without Bioclusive dressing
   - Incontinence without protection
   - Unstable cardiac conditions

BUILDING BLOCK 16-3

What are the important aspects of the examination in terms of mobility and safety for the patient in Case Study 16-1?

THERAPEUTIC EXERCISE INTERVENTION

After determining the appropriateness of aquatic physical therapy with the patient, specific physical therapy goals must be developed. These goals should be written to address the specific impairments and activity limitations identified. Aquatic exercise has been shown to improve impairments and activity limitations in individuals with various diseases and to improve the fitness of older women[43,44] (**Evidence and Research 16-5**).

EVIDENCE and RESEARCH 16-5

Patients with rheumatic disease showed significant improvement in mean pre-test and post-test scores of active joint motion and the Functional Status Index.[43] The decreased pain and difficulty with daily activities contributed significantly to the overall increased functional status and active joint motion. Elderly women participating in a 12-week water exercise class demonstrated significant improvements in oxygen consumption, muscular strength, agility, skinfold thickness, and cholesterol as compared with a control group.[44] Aquatic exercise has been shown to improve gait stability in the elderly.[45,46] A group of patients with coronary artery disease improved stress test time, oxygen consumption, and muscle strength after a 4-month aquatic exercise program.[47] However, improvements were lost after a 4-month detraining period, suggesting the need for continued exercise through the lifetime.

Research in individuals with arthritis has shown aquatic rehabilitation to be efficacious and cost-effective. Significant reductions in pain along with improvements in strength and function have been noted in patients with osteoarthritis of the hip or knee.[48–50] Additionally, compliance with the water therapy tends to be higher than with land therapy.[49,51,52] Other research has found significant improvements in measures of range of motion (ROM), thigh girth, pain scales, and 1-mile walk test in patients with knee osteoarthritis, with the aquatic group showing significantly lower pain levels than the land group.[53] The results reinforce the notion that patients can improve strength and function effectively in either a land or aquatic environment. The key is the ability to provide a comprehensive program, whether on land, in the water, or some combination of both.

Pools are expensive to build, staff, and maintain. A study of the cost-effectiveness of water-based therapy for lower limb osteoarthritis found a favorable cost–benefit ratio as measured by a reduction in Western Ontario and McMaster Osteoarthritis Index (WOMAC) pain as the measure of benefit.[48] A Cochrane Review examining the effectiveness of aquatic physical therapy for the treatment of hip and knee osteoarthritis has shown the benefits of aquatic exercise in this patient group.[54] The Osteoarthritis Research Society International has recommended both land and water treatments for patients with knee osteoarthritis.[55] The following sections describe principles of aquatic physical therapy to treat common impairments.

Mobility Impairment

Exercises to improve joint mobility and ROM are easily performed in the water. The general muscular relaxation, support of buoyancy, and hydrodynamic forces occurring in water interact to provide an environment conducive to mobility activities. When designing a mobility program in the pool, the primary considerations are the following:

1. The force of buoyancy and its effect on the desired motion (assisting, supporting, or resisting)
2. The available ROM at the joint
3. The direction of the desired motion
4. The need for any flotation or weighted equipment

Avoid overstretching in the water; start with simple cardinal plane ROM exercises that address identified impairments. Progress to activities directed toward activity limitations and participation restrictions as tolerated. For example, progress exercises to increase hip and knee motion to normal ambulation as soon as possible.

Buoyancy is the physical property used most often to facilitate ROM. Use lever arm length and buoyant equipment to increase or decrease the amount of assistance from buoyancy. For example, hip flexion, shoulder flexion, and shoulder abduction are motions assisted by buoyancy in a vertical position. High marching steps can be performed with the knee flexed or extended, with or without flotation equipment to improve hip flexion ROM. As soon as motion and weight bearing allow, progress this activity to normal walking, running, or bicycling, depending on the patient's needs. Perform traditional stretching exercises using buoyancy or using static structures in the pool such as steps, pool sides, and bars (**Fig. 16-8**).

Be alert to the use of proper technique when performing any exercise in the pool. Because of the water's refraction, it may be difficult to see the patient's posture and mechanics during exercise. Maintain proper spine position and osteokinematics

FIGURE 16-8 Stretching exercises using **(A)** flotation equipment, **(B)** a railing or the pool edge, **(C)** a ladder for upper extremity stretching, and **(D)** a ladder for hamstring stretching.

during ROM activity to ensure that the mobility is occurring at the desired location. You may need to observe the patient's exercise mechanics on land to ensure proper performance before pool exercise. **Selected Interventions 16-1** and **16-2** present examples of aquatic exercises that may be prescribed for clients with mobility impairment (see **Building Block 16-4**).

Muscle Strength/Power/Endurance Impairment

Although buoyancy is the primary tool used to increase mobility, viscosity and hydrodynamic properties provide the greatest challenge to strength and endurance. These forces have been

SELECTED INTERVENTION 16-1

Aquatic Therapy to Improve Upper Extremity Mobility

See Case Study No. 4 in Unit 7.

ACTIVITY: Shoulder internal rotation stretching

PURPOSE: To increase mobility in internal rotation and extension

SUBSYSTEM OF THE MOVEMENT SYSTEM: Base

STAGE OF MOTOR CONTROL: Mobility

POSTURE: Standing in waist-deep water holding a buoyant barbell with both hands behind the back

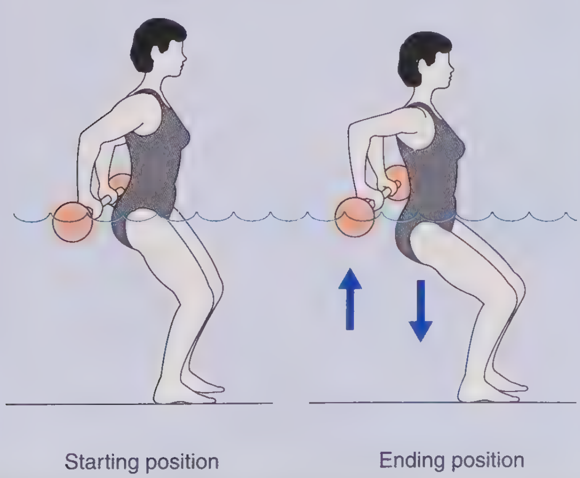
MOVEMENT: Squat slightly, bring the hands closer together, and allow buoyancy to passively slide the hands up the back to increase the stretch

SPECIAL CONSIDERATIONS: Substitution such as forward trunk flexion or scapular protraction must be avoided. The patient should feel a medium to moderate stretching sensation.

DOSAGE: The patient should hold stretch for 30 seconds.

EXPLANATION OF CHOICE OF EXERCISE: This exercise was chosen to increase shoulder mobility as one component of a comprehensive mobility, strength, and endurance program performed in the pool. This program is balanced with a home exercise program.

FUNCTIONAL MOVEMENT PATTERNS TO REINFORCE GOAL OF SPECIFIC EXERCISES: Reaching behind the back for hygiene, tucking in shirt, and hooking brassiere.



SELECTED INTERVENTION 16-2

Aquatic Therapy to Improve Lower Extremity Mobility

See Case Study No. 6 in Unit 7.

Although this patient requires comprehensive intervention as described in previous chapters, one specific exercise related to aquatic therapy will be described.

ACTIVITY: Lunge walking

PURPOSE: To increase mobility in the hip, knee, and ankle, and force or torque generation and endurance in the lower extremities

RISK FACTORS: No appreciable risk factors

STAGE OF MOTOR CONTROL: Controlled mobility

MODE: Mobility and resisted activity in a gravity-lessened environment

POSTURE: Maintain an upright trunk throughout the exercise

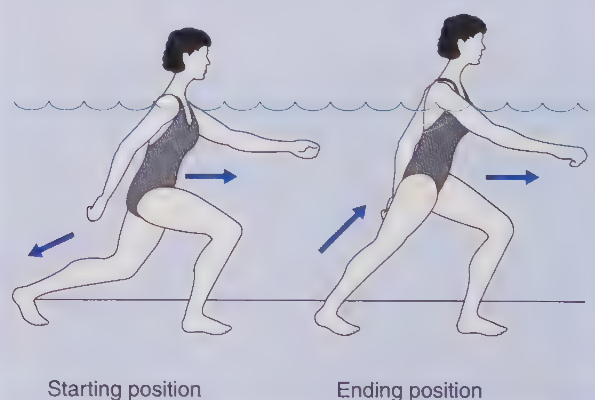
MOVEMENT: Walking in a normal heel–toe gait pattern, exaggerating the knee flexion of the loading response to 60 to 80 degrees of flexion, followed by full extension at midstance.

SPECIAL CONSIDERATIONS: Ensure an upright trunk avoiding forward lean. Avoid knee flexion beyond 80 degrees of flexion, and maintain a vertical tibia during the knee flexion component.

DOSAGE: Repetitions to form fatigue; performed two to three times per week

EXPLANATION OF CHOICE OF EXERCISE: This exercise was chosen to improve mobility at the hip, knee, and ankle, as well as dynamic muscular control at these joints. This movement was chosen to emphasize the knee flexion component in the loading response phase of gait.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Normal gait, ascending and descending stairs, and getting in and out of chair



BUILDING BLOCK 16-4

Describe an aquatic program to increase this patient's ankle mobility. Progress it from simple mobility exercises to more functional exercises.

proven to increase muscle performance following an aquatic resistive exercise program.[56–58] The turbulence created during motion produces resistance and is influenced by the surface area, object shape, and speed of movement. The strength training principles and progressions used in water-based activities are the same as those used on land. These include variables such as frequency, intensity, and duration. As with techniques to increase mobility, progress traditional strength and endurance training exercises to address activity limitations and participation restrictions as quickly as possible. For example, progress simple viscosity-resisted hip extension and knee extension exercises to land-based exercises, such as ascending or descending stairs or rising from a chair, as quickly as possible.

Because the patient is immersed in a resistive medium, exercise in any direction can be resistive if given a critical velocity. Calisthenics, open kinematic chain, closed kinematic chain, diagonal patterns, and motor control exercises can be performed effectively in the pool. A resistive motion in any direction requires a counterforce to stabilize against the turning effects of the center of buoyancy. For example, an individual standing in shoulder-deep water performing bilateral shoulder flexion from neutral to 90-degree flexion is pushed backward by the force generated with the arms (see **Self-Management 16-1**). The leg and trunk stabilizers must fire to counteract and keep the individual from falling over. This can be an effective technique to train trunk stabilization.

It is easy to overlook the additional muscular work necessary to provide stabilization against resistive movements in the pool, and this demand probably contributes to the overwork experienced by many patients. Be aware of which muscle groups are providing stability, the quantity of stabilization necessary, and the position or posture of the joints being stabilized. In the absence of external support (e.g., hand hold, wall support), nearly any upper or lower extremity exercise places significant demands on the hip and trunk stabilizers.

As with exercises to increase mobility, equipment can be used to enhance resistive exercise. Buoyant cuffs or bells can be used to increase the resistance against buoyancy, and paddles, gloves, and other surface area–enhancing equipment can increase the resistance resulting from turbulence. It is important that the quality of the exercise not be sacrificed for an increase in resistance (see **Self-Management 16-2**). As resistance is increased, patients may alter their technique or posture to accommodate the resistance change. For example, adding gloves to bilateral shoulder horizontal abduction and adduction can increase the postural sway so much that the patient cannot maintain balance.

Cardiorespiratory endurance can be increased in several ways, relying on the same principles of overload and progression used in land-based programs. The activity must be of sufficient intensity and duration, must use primarily large muscle groups, and should be performed three to five times per week. Deep-water activities are especially useful for individuals with weight-bearing limitations. Deep-water running, bicycling, cross-country skiing, and vertical kicking are only a few of the activities that can be performed continuously or as intervals. Traditional swimming strokes complement these lower-extremity–dominant exercises. Shallow-water running makes an excellent cardiovascular conditioning exercise if impact is tolerated. Appropriate aquatic footwear must be worn when shallow-water running for any length of time. This can include an inexpensive surf shoe or a more expensive aquatic exercise shoe. This minimizes the likelihood of impact injuries and friction injuries to the bottom of the foot (see **Building Block 16-5**).

SELF-MANAGEMENT 16-1
Bilateral Shoulder Flexion

Purpose: Increased muscular strength and endurance in shoulder flexors and extensors

Increased trunk stability

Position: Standing with the feet in stride, arms at the side, and palms facing forward

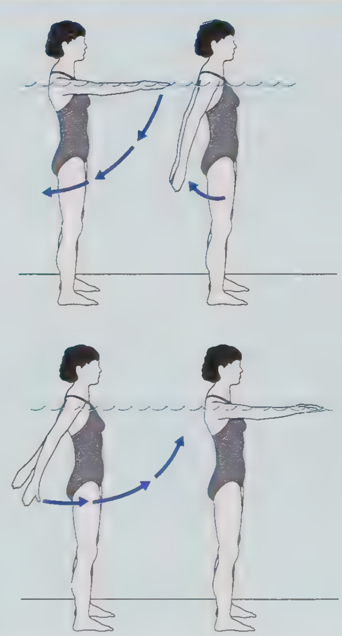
Movement Technique: Level 1: Bring arms forward together; then turn palms facing backward and push arms backward. Turn palms forward and repeat.

Level 2: As above, but with feet in stance

Level 3: As above, with addition of resistive equipment

Level 4: As above, but standing on one leg

Level 5: As above, with eyes closed



Dosage:

Repetitions: ____________________

Frequency: ____________________

SELF-MANAGEMENT 16-2
Bell Push-Downs

Purpose: Increased abdominal strength
Increased trunk stability
Increased shoulder and arm strength

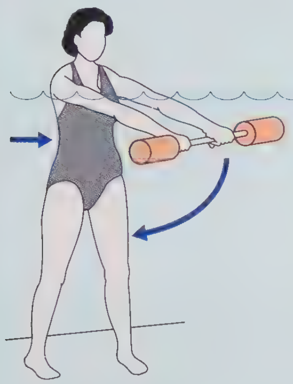
Position: Standing in chest-deep water, arms straight out in front with hands on a Styrofoam bell

Movement Technique: Level 1: Tighten abdominal muscles and pull bell straight down toward legs. Control the bell on the way back up.
Level 2: Move to deeper water.
Level 3: Increase size of buoyant bell.

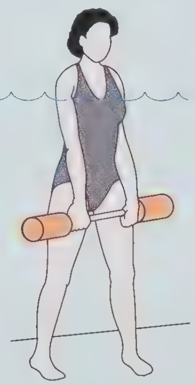
Dosage:

Repetitions: ______________________

Frequency: ______________________



Starting position



Ending position

SELF-MANAGEMENT 16-3
Single-Leg Lifts

Purpose: Increased hip mobility
Increased hip and knee muscle strength and endurance
Increased single-leg balance

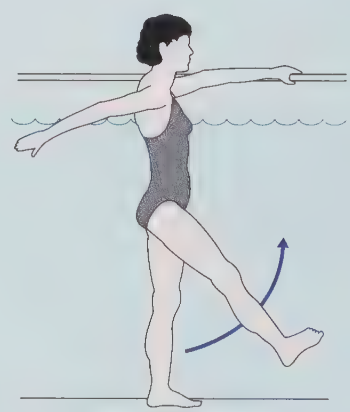
Position: Standing on one leg in a neutral spine posture with abdominal muscles tightened. The non–weight-bearing leg should be straight at the knee and flexed at the ankle. If working primarily on balance, stand near the edge, but do not hold on to steady yourself. Otherwise, hold on to the side for support.

Movement Technique: Level 1: Lift leg forward and back, ensuring proper spine position. Avoid arching your back as your leg comes back, and avoid letting your trunk sway. If the hip extends beyond its normal 15 degree range, low back pain may result.
Level 2: Add resistive equipment to foot or ankle.

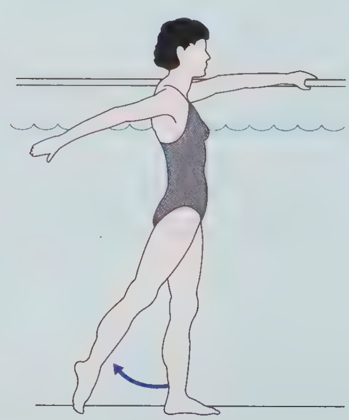
Dosage:

Repetitions: ______________________

Frequency: ______________________



Starting position



Ending position

BUILDING BLOCK 16-5

Design a beginning strengthening program for the case study patient, including activities that provide both direct resistance to the involved muscles as well as indirect challenges to the muscles.

Balance Impairment

The supportive medium of the water and its destabilizing forces provide an ideal environment for balance training. Other individuals in the pool create turbulence and destabilizing forces as well.[58] These forces can also be created by an individual's own movements. For example, lifting one leg forward produces a force pushing the individual backward (see **Self-Management 16-3**). The forward leg movement is countered with balance responses. The increased reaction time makes these types of training movements especially useful for individuals with poor balance. Movements occur more slowly in the pool because of the water's viscosity. As such, when balance is lost, the fall is slowed dramatically, giving the individual time to react and respond.

TABLE 16-2

Aquatic Balance Exercises

ACTIVITY	PROGRESSION ALTERNATIVES	COMMENTS
Bilateral shoulder flexion/extension	■ Narrow base of support ■ Single leg ■ Close eyes ■ Move head to engage vestibular system ■ Stand on immersible foam	Creates an anterior–posterior sway with sagittal plane motion ■ Add buoyant or resistive equipment to increase resistance
Bilateral shoulder horizontal abduction/adduction	■ Narrow base of support ■ Single leg ■ Close eyes ■ Move head to engage vestibular system ■ Stand on immersible foam	Creates an anterior–posterior sway with transverse plane motion ■ Add buoyant or resistive equipment to increase resistance
Bilateral reciprocal shoulder internal/external rotation	■ Narrow base of support ■ Close eyes ■ Move head to engage vestibular system ■ Stand on immersible foam	Creates rotation through transverse plane motion ■ Add buoyant or resistive equipment to increase resistance
Bilateral reciprocal shoulder abduction/adduction	■ Narrow base of support ■ Single leg ■ Close eyes ■ Move head to engage vestibular system ■ Stand on immersible foam	Creates frontal plane sway ■ Add buoyant or resistive equipment to increase resistance
Unsupported leg activities: ■ Knee flexion/extension ■ Hip abduction/adduction ■ Hip flexion/extension ■ Hip circles or figure 8s ■ Soccer kicks	■ Close eyes ■ Move head to engage vestibular system ■ Stand on immersible foam ■ Arms across chest ■ Arms overhead	■ Add buoyant or resistive equipment to increase resistance or challenge
Stepping activities: ■ Tandem walk ■ March in place and hold ■ Step and hold ■ 3-step stop	■ Close eyes ■ Arms across chest ■ Arms overhead ■ Move head to engage vestibular system ■ Increase speed of movement	Incorporating direction change increases the challenge because of the drag created by the movement through water
Hopping activities: ■ Hop in place with stable balance in between ■ Hop forward/back, side to side with stable balance	■ Close eyes ■ Arms across chest ■ Increased speed	Verbal cueing for movement direction can increase challenge by having the patient react to the therapist's instructions

A variety of balance activities performed on land can be adapted to the pool. Any single-leg stance exercise with concurrent movement of the arms, opposite leg, or both can provide a wealth of balance exercise. Single-toe raises, step-ups, and simple single-leg balance exercises can be performed with and without equipment (see **Table 16-2** and **Self-Management 16-4**). **Selected Intervention 16-3** presents a sample of an aquatic exercise that may be prescribed for the client with balance impairment. Research comparing the effects of balance training on land and in water found both mediums to result in improvements in the center of pressure variables, suggesting that balance training can be equally effective when performed in water[59] (**Evidence and Research 16-6**).

EVIDENCE and RESEARCH 16-6

The effects of a water-based program on balance, fear of falling, and quality of life was performed in community-dwelling older women with osteopenia or osteoporosis.[60] After a 10-week water-based and self-management program, the intervention group showed significant improvement over the control group in balance and quality of life, but not in fear of falling. In a similar study, 59 elderly individuals were randomly assigned to a land-based group, an aquatic-based group, or a control group; they exercised twice weekly for 6 months. The 8-foot-up-and-go test was improved in both groups, with the aquatic group showing significantly greater improvements than the land or control groups.[61]

SELF-MANAGEMENT 16-4
Three-Step Stop

Purpose: Increased dynamic balance
Increased trunk stability
Increased lower extremity strength
Increased single-leg balance

Position: Standing on both legs in a neutral spine posture, with abdominal muscles tightened. Take three steps forward beginning with your right leg, then stop and balance on your right leg. Step back with the left leg for three steps, stopping to balance on the left leg. After several repetitions, switch to stepping with the left leg first.

Movement Technique: Level 1: Use your arms as needed for balance.

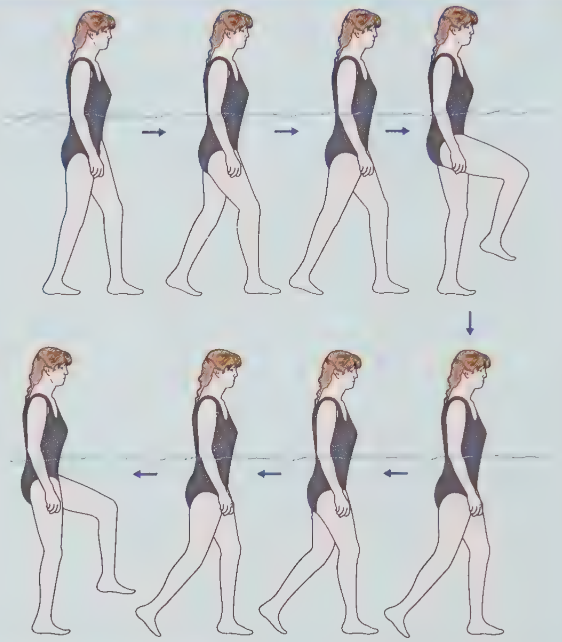
Level 2: Place your arms across your chest.

Level 3: Close your eyes.

Dosage:

Repetitions: ______________________

Frequency: ______________________



SELECTED INTERVENTION 16-3
Aquatic Therapy to Improve Balance

See Case Study No. 1 in Unit 7.

ACTIVITY: Single-leg balance in chest-deep water

PURPOSE: Train single-leg balance through entire lower extremity and trunk without full weight on the limb.

RISK FACTORS: No appreciable risk factors

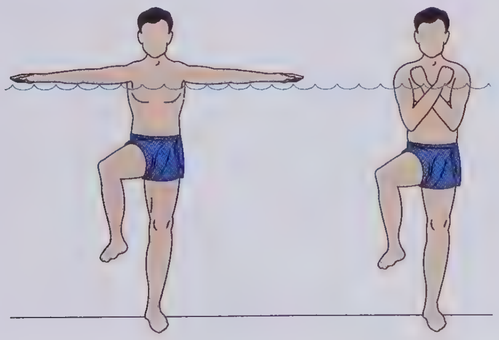
STAGE OF MOTOR CONTROL: Stability

POSTURE: Single-leg stance with arms in a comfortable position; lumbopelvic region in neutral and knee in slight flexion

MOVEMENT: None; simply maintain balance

DOSAGE: Repetitions to form fatigue or pain; attempt to hold as long as possible

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF SPECIFIC EXERCISE: Single-leg stance of gait cycle



AQUATIC REHABILITATION TO TREAT ACTIVITY LIMITATIONS

Activity limitations represent restrictions in performance at the level of the whole person. Impairments involve losses at the tissue, organ, or system level, but may or may not contribute to activity limitations. As the patient makes improvements in impairments, activities in the pool should be modified to emphasize the activity limitations. Activity limitations related to posture or position can be addressed in the pool. If prolonged sitting is a functional limitation, a variety of sitting activities can be performed in the pool. Many pools contain steps where the patient can sit with various levels of depth (i.e., unloading). Chairs can be submerged in the pool, and buoyant equipment for sitting is available (**Fig. 16-9**).

FIGURE 16-9 Posture exercises and reaching activities can be performed while sitting on flotation equipment.

As sitting tolerance increases, the depth of water should be decreased, thereby more closely representing land situations. This same principle may be applied to deficiencies in prolonged standing or other positional limitations, such as bending over a counter.

Activity limitations related to specific movement patterns (e.g., gait, forward reaching) respond well to aquatic rehabilitation. Unloading the lower extremity or spine alone may be adequate to normalize gait mechanics. Verbal or tactile cuing may be necessary if gait changes have existed for some time. Research has shown improvements in gait stability in the elderly following an aquatic exercise program (**Evidence and Research 16-7**). Underwater treadmill walking has been shown to improve pain and gait mechanics in patients with knee osteoarthritis.[45] As normal pain-free gait mechanics are achieved, the water depth should begin decreasing to replicate the land-based environment.

EVIDENCE and RESEARCH 16-7

Research comparing forward walking with backward walking on an underwater treadmill have produced a great deal of information about gait. Masumoto et al.[62] and others[63] found that stride frequency was increased and stride length decreased in backward walking compared with forward walking. Additionally, measures of exertion, oxygen consumption, and cardiac responses were all higher with backward walking. Paraspinal muscle activity was greater when walking backward against a current than when walking backward without a current or walking backward on land.[64] Walking backward in the water elicits greater muscle activation than does walking forward, and the heart rate increased with increased walking speed.[65]

Similarly, other activity limitations in movement can be addressed in the same manner. For the individual with difficulty performing forward reaching, this activity can be assisted by buoyancy, which is progressed to buoyancy-supported and to buoyancy-resisted activity. Repetitive trunk flexion and extension, lifting, pushing, pulling, and squatting can be progressed in the same fashion (**Fig. 16-10**). Components of basic activities of daily living and instrumental activities of daily living can also be reproduced in the pool.

COORDINATING LAND AND WATER ACTIVITIES

One of the questions frequently asked by clinicians concerns the integration of water- and land-based activities. How much activity should be performed in the water, and when should land-based activity be incorporated? The advantages and disadvantages of aquatic rehabilitation and land rehabilitation should be matched to the needs of the individual patient, keeping in mind that humans function in a gravity environment. Because it is difficult to reproduce lower extremity eccentric muscle contractions in the pool, progress the patient with quadriceps strength impairments to land-based activities as quickly as tolerated. Early on, the patient may tolerate minimal land-based activity because of pain. Aquatic rehabilitation occupies most of the program at this time. As the patient is able to tolerate land-based activity, incorporate a greater percentage of land-based exercises into the program. The quantity of water-based activity may remain unchanged, increase if tolerated, or decrease as the quantity of land-based exercise increases. The exact proportion and quantity of both land and water activity is determined by the needs and response of the patient. Occasionally, individuals respond better to alternate days in the pool, but others can progress to daily land-based exercises and discontinue pool exercise. The exercise program should be matched to the needs of the patient, with the goal of progressing to land-based exercise.

PATIENT-RELATED EDUCATION

As with land-based exercise, patient education is a key component of the aquatic physical therapy program. The education program begins before entry into the water with a discussion of the fundamental properties of the water and the patient's expectations. Ensure patient comfort in the water; this is enhanced by educating the patient about the anticipated experience in the water. Identify the areas of entry and exit from the pool, the water's depth, and any other important safety features (e.g., drop-offs, gutters, bars). Also familiarize the patient with the exercise program on land before entering the water to ensure proper exercise performance.

As the patient enters the water and the rehabilitation program proceeds, use this time as an opportunity to teach the patient about the expected benefits of the exercise. For example, when

A B

FIGURE 16-10 Work conditioning exercises such as **(A)** pushing and **(B)** lifting can be reproduced in the pool.

performing activities in single-leg stance, the patient frequently complains of an inability to maintain balance. Emphasize that developing balance is the purpose of the exercise and that any modification of the exercise to further destabilize the person is a progression of the exercise. When surface area–enhancing equipment is added, explain to the patient that it will increase the difficulty of the exercise. This also educates the patient on appropriate exercise program progression, and when the program is continued independently, the patient is able to self-manage and progress his or her own exercise program.

PRECAUTIONS/CONTRAINDICATIONS

Some absolute and relative contraindications to exercise in the water exist. Individuals with excessive fear of the water, open wounds, rashes, active infections, incontinence, or tracheostomy should not be admitted to the pool. However, some physicians allow patients with open wounds to participate in aquatic rehabilitation with use of a Bioclusive dressing. This is commonly seen in patients with postoperative incisions.

Be aware of precautions to exercising in the water. The cardiovascular changes occurring with immersion should be of concern for the patient with a cardiac history. The hydrostatic pressure also limits chest expansion in those immersed in neck-deep water. This can create breathing difficulties for patients with pulmonary impairments or activity limitations. The hydrostatic pressure against the chest wall also can cause a sensation of an inability to breathe in persons who are uneasy in the water. The hydrostatic pressure produces diuresis, which can be avoided by emptying the bladder before entry to the pool.

Be alert to medical emergencies in the pool. It may be more difficult to respond to an emergency in the water, and an action plan must be in place. Be sure to know and practice safe removal of the patient from the water, and know the guidelines for implementing cardiopulmonary resuscitation in the pool.

Because of the sense of mobility experienced when exercising in the pool, many patients tend to overwork. Overexercise may occur because of the reduced gravity environment, the support of buoyancy, and the muscular relaxation associated with immersion, hydrostatic pressure, and water temperature. Frequently, the signs and symptoms of overwork do not manifest until later in the day or the next day. It therefore is better to err on the conservative side and underestimate the appropriate amount of exercise rather than overestimate. Once a baseline aquatic exercise program that does not exacerbate symptoms is established, the exercises can be safely progressed by increasing intensity, frequency, or duration.

KEY POINTS

- The pool provides a unique environment for the rehabilitation of individuals with a variety of impairments, activity limitations, and participation restrictions.
- The properties of buoyancy and viscosity can be used in a number of ways to achieve physical therapy goals.
- The effects of hydrostatic pressure and water temperature on the physiologic responses to activity must be considered to ensure patient safety.
- The water's viscosity provides much resistance and can be fatiguing for deconditioned individuals.
- Because a range of activities, from mobility and stretching to resistive and cardiovascular exercise, can be performed in the pool, aquatic therapy can progress from the early stages of rehabilitation through functional progression.
- Balance is challenged with nearly every arm and leg movement in the pool, and the effects of exercises on the trunk and leg stabilizers must be considered when designing the exercise program.
- The pool program must be balanced by a well-designed land-based program to ensure proper transition back to the land environment.

CRITICAL THINKING QUESTIONS

1. How can the difficulty of the first selected intervention exercise (single-leg balance) be increased using the following?
   a. Arms
   b. Legs
   c. Equipment
   d. Other sensory systems
2. What factors might limit the patient's ability to perform this exercise? How would you modify the exercise program to adjust for these factors?
3. How is this exercise changed in different water depths?
   a. Waist deep
   b. Neck deep
4. How is the exercise in Self-Management: Bell Push-Downs changed in different water depths? How would the exercise differ if performed with resistive gloves with the thumbs up? Palms down?
   a. Chest deep
   b. Neck deep
5. How can mobility in internal rotation be improved while keeping the shoulders immersed?

LAB ACTIVITIES

Pool Activities

1. Upper extremity
   a. Using a variety of positions (e.g., supine, prone, standing) and equipment (e.g., buoyant, resistive, wall, railings), develop an exercise program to increase a patient's shoulder, elbow, forearm, and wrist ROM in all available ranges. Do this for a variety of motion limitations (i.e., minimal loss to significant motion loss).
   b. Using a variety of positions and equipment, develop an exercise program to increase a patient's shoulder, elbow, forearm, and wrist strength and function. Progress from isometric exercise through a functional progression to activities of daily living, work-related activities, or different sports. Perform open- and closed-chain exercises.
2. Lower extremity
   a. Using a variety of positions (e.g., supine, prone, standing) and equipment (e.g., buoyant, resistive, wall, railings)

LAB ACTIVITIES (continued)

develop an exercise program to increase a patient's hip, knee, and ankle ROM in all available ranges. Do this for a variety of motion limitations (i.e., minimal loss to significant motion loss). Consider patient-specific issues such as precautions following total hip arthroplasty or patients with weight-bearing restrictions.

b. Using a variety of positions and equipment, develop an exercise program to increase a patient's lower extremity strength and function. Progress from isometric exercise through a functional progression to activities of daily living, a variety of work activities, or various sports. Perform open- and closed-chain exercises.

3. Trunk
   a. In an upright position, establish a neutral spine position and ambulate forward, backward, sidestepping, and braiding patterns. Vary step length and observe resultant changes in ROM. Vary speed and note changes in muscle activation.
   b. In an upright position, perform a variety of upper extremity exercises and observe the challenges to the trunk stabilizers. Perform exercises with a wide stance, narrow stance, and standing on one leg. Perform these same exercises with your eyes closed.
   c. In an upright position, perform a variety of lower extremity exercises and observe the challenges to the trunk stabilizers. Notice the differences between sagittal plane and frontal plane motions. Perform with your eyes closed and on an unstable surface.

Land Activities

Develop land-based and aquatic rehabilitation programs for the following patient problems. Progress the program from the acute phase through to a functional progression.

Patient No. 1

A 54-year-old man has L4–L5 discogenic back pain. The patient has had recurrent episodes of pain over several years but has always been able to self-treat with a home exercise program designed by a physical therapist. Two weeks ago, the patient took a vacation requiring a long flight, followed by sleeping in a bed with a poor mattress. This patient has been unable to relieve the symptoms with self-treatment. His primary complaint is low back pain with occasional radicular pain to the left knee. Symptoms do not extend beyond the knee. The patient desires to return to walking as exercise and recreational golf. He works at a desk job.

Examination reveals an easily correctable lateral shift to the right, with decreased active and passive ROM in extension, left side-bending, and left rotation. Active motion is limited in flexion. Dural signs are positive for radicular symptoms, but deep tendon reflexes and sensation are intact throughout. The low back is diffusely tender, with a protective muscle spasm in the left erector spinae. Lower extremity strength is 5/5 to single repetition testing throughout.

Patient No. 2

A 60-year-old woman presents after a right proximal humeral fracture, which was cared for with sling immobilization for 6 weeks. She has a history of mild degenerative joint disease at the acromioclavicular joint. She is right-handed and complains primarily of an inability to perform her daily activities because of motion loss and shoulder pain. Her goals are to return to activities of daily living, golf, and gardening.

Examination reveals loss of motion in all shoulder motions in a capsular pattern. Elbow, wrist, and hand motions are normal. Strength tests are limited by shoulder pain. Accessory motion is slightly decreased compared with the left in anterior, posterior, and inferior directions. Strength and sensation are normal throughout the rest of the right upper extremity.

Patient No. 3

A 17-year-old girl is seen 6 weeks after abrasion chondroplasty for an acute osteochondral lesion on the weight-bearing surface of her right knee medial femoral condyle. Her goals are to return to basketball, softball, and volleyball. She is partial weight bearing (50%) and can be progressed by 25% every 2 to 3 weeks until full weight-bearing is achieved.

Active motion of the knee is S:0-10-90 and passive motion is S:0-5-100 with an empty end-feel. She maintains a 1+ effusion and has 4+/5 strength to manual muscle test, with visible atrophy of the quadriceps. Hamstring muscle testing is 4+/5, gluteus maximus is 4+/5, and gluteus medius 4/5. She ambulates with an antalgic gait pattern with bilateral axillary crutches. Overall, she has a varus knee alignment.

Functional Approach to Therapeutic Exercise of the Lower Extremities

UNIT 5

CHAPTER

17 The Lumbopelvic Region

CARRIE M. HALL

Low back pain (LBP) is among the most common reasons to visit a physician, and is a leading cause of disability in the western world, resulting in enormous personal, social, and economic burden.[1] It is estimated that approximately 60% to 80% of all people will suffer from LBP at some point in their lifetime.[2] A 2012 publication by the Centers for Disease Control and Prevention's National Center for Health Statistics reported that 28.4% of adults older than 18 years had experienced LBP in the previous 3 months,[3] with 24.7% reporting limitations in their physical functions,[4] translating to more than 7 million adults experiencing activity limitations because of low back-related conditions.[5] While the vast majority of LBP episodes resolve within 2 to 4 weeks (acute), 25% of patients will experience recurrent episodes within 1 year.[6,7] The prevalence of LBP has major socioeconomic impact with direct and indirect costs reported to be between $85 billion and $238 billion annually.[8–10] The cost to society as a result of LBP is greater than that for traumatic brain injury, arthritis, or stroke. This has led toward a push for evidence-based practice combined with a focus on the triple aim (see Fig. 2-1). This has prompted researchers to determine interventions that improve patient outcomes and reduce disability and work absenteeism at the lowest cost to the consumer and health care system.

LBP is usually defined as pain, muscle tension, or stiffness localized below the costal margin and above the inferior gluteal folds, with or without leg pain (sciatica) and classified as being "specific" or "nonspecific." Specific LBP refers to symptoms (such as herniated nucleus pulposus [HNP], infection, inflammation, osteoporosis, rheumatoid arthritis, fracture, or tumor) caused by a specific pathoanatomic or pathophysiologic mechanism. It is estimated that in only about 10% of the patients specific underlying pathoanatomic or pathophysiologic impairment can be identified.[11] The vast majority of patients (up to 90%) are labelled as having nonspecific LBP (NSLBP), which is defined as symptoms without a clear specific cause, that is, LBP of unknown origin. Spinal abnormalities on X-rays and magnetic resonance imaging (MRI) are not strongly associated with NSLBP, because many people without any symptoms also show these abnormalities.[12]

While management of LBP comprises a range of different intervention strategies, including surgery, drug therapy, cognitive-behavioral therapy, and nonmedical interventions; exercise therapy is probably the most widely used type of conservative treatment worldwide. Unfortunately, the results of clinical trials testing the value of exercise approaches relative to other interventions, including various forms of exercise, demonstrate that no management approaches are clearly superior.[13–15] The rationale for this may be due to the attempt to take a heterogenous population and study effects on the entire group. It is essential to identify and classify persons with LBP into specific and clinically relevant subgroups to match best practice with the patient-centered needs. This remains elusive to date due to the multidimensional nature of the condition and the various therapeutic models proposed.

General clinical guidelines have been established, primarily in the military settings, slowly making its way into civilian settings. Recommendations in clinical guidelines for acute and NSLBP in both military and civilian settings are to (1) avoid opioids as a first-line medication and (2) avoid advanced imaging procedures such as MRI or computed tomography (CT) scan.[16–20] However, research conducted mostly in civilian settings demonstrates that clinical practice remains inconsistent with these recommendations,[21] with excessive use of unendorsed care early in the treatment process contributing to the high costs of managing LBP, adverse negative psychologic effects, and increasing risk of chronicity.[6,21] Several guidelines suggest a delay in referral to physical therapy for 2 to 4 weeks to allow for spontaneous recovery,[16,19,20] but emerging research with civilian populations has found cost savings when referrals to physical therapy occur early in the care process for patients with acute LBP symptoms, particularly if the physical therapy care provided focus on active treatment approaches[22–24] (**Evidence and Research 17-1**).

EVIDENCE and RESEARCH 17-1

"Washout Effect" of Meta-Analysis on Effectiveness of Therapeutic Exercise Intervention with LBP

Therapeutic exercise is widely used as a treatment for LBP. The vast majority of patients with LBP fall into the nonspecific category; therefore, most research is based upon this group. A meta-analysis of the effectiveness of therapeutic exercise for reducing pain and disability in adult nonspecific acute, subacute, and chronic LBP compared with no treatment and other conservative treatments found exercise to be superior, but with a small effect size.[25] One of the criticisms of the standard meta-analysis is that treatment is not matched to specific subgroups of patient creating a "washout effect." The Cochrane Back Review Group proposed that identification of subgroups is a key priority of LBP management in order to address the problem of patient heterogeneity.[26] Recent research supports this claim, with evidence that subjects with NSLBP can be broadly classified based on psychologic factors,[27–29] movement and postural behaviors,[30–32] neurophysiologic factors,[33] and lifestyle behaviors (sedentary[34] vs. excessive activity[35]). Despite this knowledge, to date, the majority of studies that relate to the classification of back pain have focused only on a single dimension of the problem, rather than consideration being given to all dimensions of LBP.[36] What is clear from the scientific literature and clinical practice is that a multidimensional approach to dealing with LBP is required.[37,38] These dimensions consist of pathoanatomic, neurophysiologic, physical and psychosocial factors.[2] The relative contribution of the different dimensions and their dominance associated with a LBP disorder will differ for each patient and therefore trigger a truly patient-centered intervention.

Understanding the complexity of LBP, the role of the treating clinician is to consider all dimensions of the disorder based on an interview, thorough physical examination (assessing all subsystems of the movement system) combined with review of radiological imaging, medical tests, and screening questionnaires. A clinical reasoning process allows determination of which factors are dominant in the disorder and whether the patient has adjusted to the disorder in an adaptive (protective) or maladaptive (provocative) manner. Consideration of all the factors outlined allows for a diagnosis and mechanism-based classification guiding management of the disorder.

As physical therapists, our expertise typically falls under mechanically or symptom-driven causes, but we need to look beyond mechanical or chemical nociception and become aware of the cognitive/emotional aspects of LBP. Considered simplistically, the presence of localized and anatomically defined pain associated with specific and consistent mechanical aggravating and alleviating factors suggest that physical/mechanical factors are likely to dominate the disorder. This results in a primary peripheral nociceptive drive that will respond well to mechanical based classification models and interventions. Correlation between clinical examination of mechanical factors and pathoanatomic findings is useful to determine their significance and relationship to the disorder. If pain is constant, non-remitting, widespread, and is not greatly influenced by mechanical factors (or minor mechanical factors result in an exaggerated and disproportionate pain response), then inflammatory or centrally driven neurophysiologic factors (such as altered central pain processing) are likely to dominate the disorder. High levels of anxiety, hypervigilance, fear and emotional stress presenting as primary aggravating or precipitating factors in the disorder highlight the influence of psychologic and in some cases social factors indicating a dominant psychosocial driver of pain. In reality, all pain conditions have a combination of drivers and must be assessed not only on a case by case basis, but also one date of service at a time since some patients tend to fluctuate as to what factor is the primary driver at any given time.

Physical therapy interventions that are classification based and specifically directed to the underlying driving mechanism (cause) have the potential to alter these disorders and impact both the physical and cognitive/emotional drivers of pain. Exercise prescription should be based on individual and ongoing assessment of the activity and participation levels, multidimensional drivers, and associated body functions and structure. Despite the wide variety of exercises that are prescribed for the low back, evidence-based data to justify choices are not as complete as one may think or expect. Professional challenges regarding exercise prescription are based upon strong clinical decision-making processes built upon what we know about the multidimensional nature of LBP. This chapter will provide the tools for sound clinical decision-making with multiple examples of therapeutic exercise prescription to assist the practitioner as to why and when a specific targeted exercise may be useful.

REVIEW OF ANATOMY AND KINESIOLOGY

Prerequisite to sound clinical decision-making in the patient management process (see Chapter 1) is an extensive knowledge of anatomy and kinesiology. The anatomy and kinesiology of the lumbopelvic region have received considerable attention in the literature,[39–43] which has enhanced clinical understanding of the function of the lumbopelvic region and emphasized the integrated nature of normal movement between the trunk and extremities. To properly examine, evaluate, diagnose, and treat the lumbopelvic region, in-depth knowledge of all aspects of the movement system involved in LBP is essential. It is beyond the scope of this text to provide a complete review of the anatomy and kinesiology of the lumbopelvic region; thus, the review will be limited to myology. Further elaboration of anatomy and kinesiology can be found on thePoint.lww.com/BrodyHall4e.

Myology

Optimal function of the lumbopelvic region requires an integration of the musculature of the posterior and anterior aspects of the spine, pelvis, and hips. In addition, the latissimus dorsi influences lumbopelvic mechanics. Because of the integration of musculature spanning the lumbopelvic region, myology is addressed in an integrated format for the entire region.

Posterior Lumbopelvic Myology

The thoracolumbar fascia (TLF) and its powerful muscular attachments play an important role in stabilization of the lumbopelvic region.[44,45] Numerous muscular attachments into the TLF have been described, including attachments of transversus abdominis (TrA) and some fibers of the internal obliques (IO) into the lateral raphe portion of the TLF and attachments of gluteus maximus, latissimus dorsi, erector spinae, and biceps femoris into the posterior layer of the TLF (**Fig. 17-1**). This pattern suggests that the hip, pelvic, and leg muscles interact with arm and spinal muscles through the TLF.[44] The gluteus maximus and latissimus dorsi may conduct forces contralaterally through the posterior layer of the TLF, and the action of these two muscles may be linked to provide support to the sacroiliac joint (SIJ) and lumbar spine during gait and trunk rotation. This integrated system has also been proposed as a method of load transference between the spine and hips, in which the TLF is a centrally placed structure for the interaction of muscles from each region.

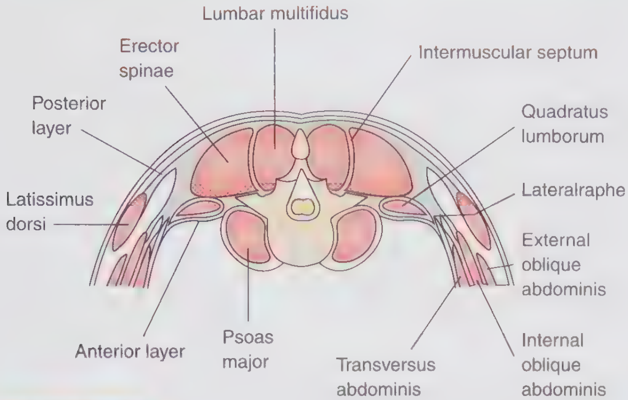

FIGURE 17-1 Cross section of the lumbar spine showing layers of the trunk musculature. (Adapted from Porterfield JA, DeRosa C. Mechanical Low Back Pain: Perspectives in Functional Anatomy. 2nd Ed. Philadelphia, PA: WB Saunders, 1998.)

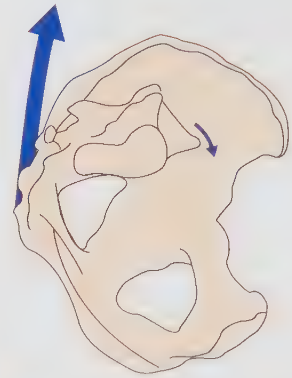

FIGURE 17-3 The attachment of the superficial erector spinae to the sacrum provides a potential force for sacral nutation (sacral flexion). Because nutation increases sacral stability, the superficial erector spinae may play a role in force closure of the sacroiliac joint. (Adapted from Porterfield JA, DeRosa C. Mechanical Low Back Pain: Perspectives in Functional Anatomy. 2nd Ed. Philadelphia, PA: WB Saunders, 1998.)

The spinal extensors may be broadly categorized as superficial muscles (i.e., iliocostalis), which travel the length of the spine and attach to the sacrum and pelvis, and deep muscles (i.e., longissimus and lumbar multifidus [LM]), which span the lumbar segments. Even though the superficial spinal extensors do not attach directly to the lumbar spine, they have an optimal lever arm for lumbar extension by virtue of their attachments (**Fig. 17-2**). By pulling the thorax posteriorly, they can create an extension moment at the lumbar spine. They function eccentrically to control descent of the trunk during forward bending and isometrically to control the position of the lower thorax with respect to the pelvis during functional movements.[46,47] The attachment of the superficial spinal extensors also influences SIJ mechanics. Because of the attachment of the erector spinae aponeurosis to the sacrum, the pull of the erector spinae tendon on the dorsal aspect of the sacrum induces a flexion moment (i.e., nutation) of the sacrum on the ilium (**Fig. 17-3**).

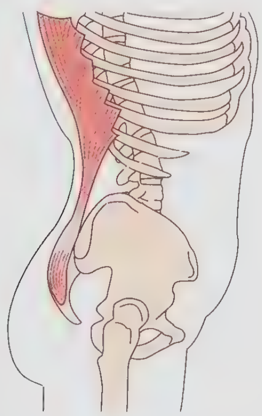

FIGURE 17-2 When viewed from the side, the superficial erector spinae can be seen to course superiorly and posteriorly from its point of origin at the pelvis to its attachment to the ribs. Elongation of the muscle occurs when the thorax (on the same side as the superficial erector spinae) is brought even further posterior, or the iliac crest on the same side is brought forward. Shortening of the superficial erector spinae occurs with thorax or pelvis movement opposite those just described. (Adapted from Porterfield JA, DeRosa C. Mechanical Low Back Pain: Perspectives in Functional Anatomy. 2nd Ed. Philadelphia, PA: WB Saunders, 1998.)

The deep erector spinae have a poor lever arm for spine extension but are aligned to provide a dynamic counterforce to the anterior shear force imparted to the lumbar spine from gravitational force (**Fig. 17-4**). The attachment of the LM to the spinous process provides a good lever arm for spinal extension (**Fig. 17-5**). During forward-bending motions, this muscle contributes to controlling the rate and magnitude of flexion and anterior shear.[48] Because of its deep location, short fiber span, and oblique orientation, the LM is thought to stabilize against flexion and rotation forces on the lumbar spine.[49,50] Several studies have illuminated its relationship with the vertebral segment.[51-53] In a study of normal subjects without LBP, it seems that the deep fibers of the multifidi, along with the TrA, are the first muscles to become active when a limb is moved in response to a visual stimulus and fire independent of limb movement direction to control intervertebral movement.[54] The superficial fibers are also activated before the muscles that move the limb.[54] The LM also contributes to dynamic stability of the SIJ. Because it is attached to the sacrotuberous ligament, tension on the ligament imparted as a result of LM muscle

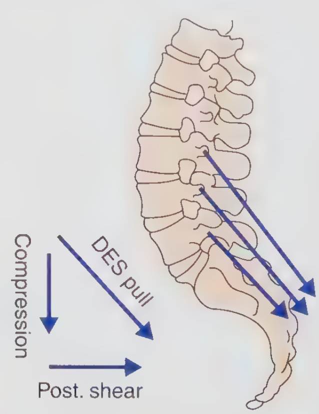

FIGURE 17-4 Because the deep erector spinae (DES) attach close to the axis of lumbar motion, the muscle group provides a dynamic posterior shear and compression force (*arrows*). This muscle can provide a force to prevent anterior translation. (Adapted from Porterfield JA, DeRosa C. Mechanical Low Back Pain: Perspectives in Functional Anatomy. 2nd Ed. Philadelphia, PA: WB Saunders, 1998.)

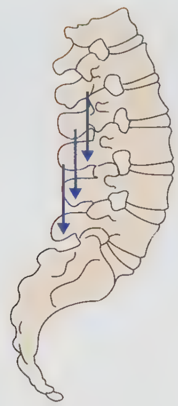

FIGURE 17-5 Because of lumbar multifidus (LM) insertion, there is a large vertical vector for extension, with a small horizontal vector indicating it is a stabilizer of rotation rather than horizontal rotation being its primary function. The primary vector is to provide posterior sagittal rotation. The primary rotators of the trunk are the oblique abdominals that, by virtue of their vertical vector, cause a flexion moment as well as rotation, which is stabilized by the LM. (Adapted from Bogduk N, Twomey LT. Clinical Anatomy of the Lumbar Spine. Edinburgh: Churchill Livingstone, 1987.)

contraction potentially increases the ligamentous stabilizing mechanisms of the SIJ (**Fig. 17-6**). The effect of dysfunction of this muscle, discussed in detail in a later section, further emphasizes its important role in spine stabilization.

Anterior Lumbopelvic Myology

One of the most important muscle groups contributing to mobility and stability of the lumbopelvic region is the abdominal wall mechanism. The abdominal wall consists of, superficial to deep, the rectus abdominis (RA), external oblique (EO), IO, and TrA. The RA, EO, and IO appear to serve a relatively more dynamic role than the TrA.

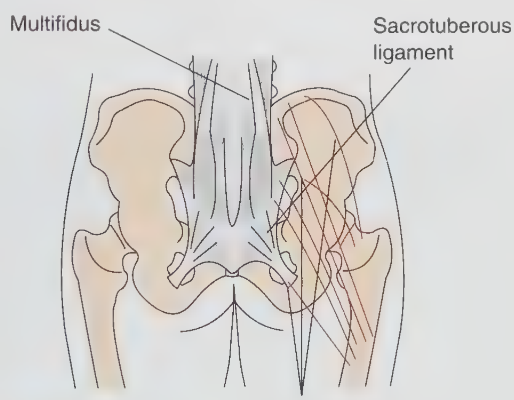

FIGURE 17-6 Anatomic relationship of lumbar multifidus (LM) to the sacroiliac joint, sacrotuberous ligament, and gluteus maximus. The LM attaches to the thoracolumbar fascia (TLF) primarily through a raphe separating the multifidus and gluteus maximus. The anterior border of the raphe is anchored to the sacroiliac joint (SIJ) capsule and the posterior border of the raphe becomes part of the TLF. Tendinous slips of the multifidus pass under the long dorsal SI ligament to join with the sacrotuberous ligament; these connections are thought to integrate the LM into the ligamentous support system of the SIJ. (Adapted from Porterfield JA, DeRosa C. Mechanical Low Back Pain: Perspectives in Functional Anatomy. 2nd Ed. Philadelphia, PA: WB Saunders, 1998.)

The TrA is circumferential, situated deeply, and has attachments to the TLF, the sheath of RA, the diaphragm, iliac crest, and the lower six costal surfaces.[55] The TrA has unique anatomic features, including its deep location, its link to fascial support systems, its fiber type distribution, and its possible activity against gravitational load during standing and gait. As a result, the TrA is an important stabilizing muscle for the lumbar spine.[56–64] The TrA activates before the onset of limb movement in persons without LBP, but this function is lost in those with LBP.[56,65] Current theory suggests that this muscle is a key background stabilizing muscle for the lumbar spine and that the emphasis of specific exercises for the abdominal wall should involve specific recruitment of the TrA instead of general strengthening or endurance. Exercises of this nature are described in detail in a subsequent section of this chapter.

The oblique abdominal muscles working synergistically provide an anterior oblique sling and, together with the posterior oblique sling (i.e., TLF and associated structures), they assist in stabilization of the lumbar spine and pelvis in an integrated system of myofascial support.[66,67] The right EO works synergistically with the left IO to produce rotation to the left and to prevent excessive rotation when necessary. The LM must synergically contract to prevent flexion imposed by the obliques so that pure rotation or transverse plane stabilization can occur. The inferior and medial directions of the fibers of the EO are positioned to prevent anterior pelvic tilt and anterior pelvic shear. With respect to the SIJ, the oblique abdominals provide compressive forces between the two pubic bones and at the SIJ posteriorly (**Fig. 17-7**).

Associated Pelvic, Hip, and Upper Extremity Myology

Twenty-nine muscles originate or insert into the pelvis. Twenty of these link the pelvis with the femur, and nine link the pelvis with the spine. This implies that significant forces can be generated through the pelvis and subsequently through the lumbar spine by various combinations of knee and hip muscle activity.

The iliacus and psoas major have significant attachments to the spine and pelvis. If not counterstabilized by the abdominal muscles, the iliacus can exert an anterior rotation force on the pelvis. If not counterstabilized by the deep erector spinae, LM,

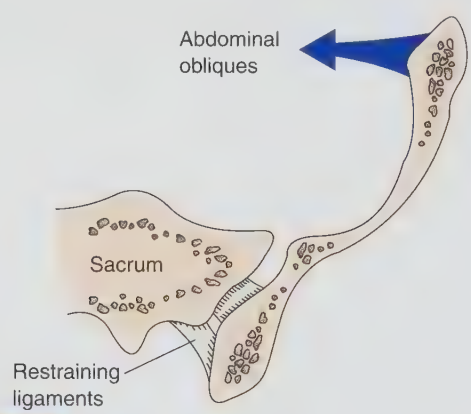

FIGURE 17-7 Contraction of the abdominal oblique muscles acting over the fulcrum of the interosseous ligament increases sacroiliac joint stability and pubic symphysis compression. (Adapted from Porterfield JA, DeRosa C. Mechanical Low Back Pain: Perspectives in Functional Anatomy. 2nd Ed. Philadelphia, PA: WB Saunders, 1998.)

and abdominal muscles, the psoas major can exert an anterior translational force on lumbar segments.

The fibers of the gluteus maximus muscle run perpendicular to the plane of the SIJ and blend with the TLF and the contralateral latissimus dorsi.[40] Compression of the SIJ occurs when the gluteus maximus and the contralateral latissimus dorsi contract. This oblique system crosses the midline and is believed to be a significant contributor to load transference through the pelvic girdle during rotational activities and during gait.[40,66] The TLF is tensed by contraction of gluteus maximus, latissimus dorsi, and erector spinae muscles.

In addition to the attachment to the ischial tuberosity, the long head of the biceps femoris attaches to the sacrotuberous ligament. Contraction of the biceps femoris increases tension of the sacrotuberous ligament and pulls the sacrum against the ilium, effectively increasing the stability of the SIJ.[60]

In standing and walking, the pelvic girdle is stabilized on the femur by the coordinated action of the ipsilateral gluteus medius and minimus and by the contralateral adductor muscles. Indirectly, by maintaining a relationship between the hip, pelvis, and lumbar spine in the frontal plane, the gluteus medius, gluteus minimus, and adductors contribute to lumbar spine stability. Although these muscles are not directly involved in force closure of the SIJ, they play a significant role in pelvic girdle function.

The piriformis is considered to be part of the deep hip lateral rotator group and pelvic floor. It appears to play a vital role in stabilization of the SIJ. The piriformis attaches to the sacrum, the anterior surface of the sacrotuberous ligament, and the medial edge of the SIJ capsule. This muscle anchors the apex of the sacrum and controls sacral nutation.

The link of pelvic floor function and lumbopelvic function should not be underestimated. The pelvic floor forms the base of the abdominal cavity, so pelvic floor muscles must contract during tasks that increase intraabdominal pressure to maintain continence. In subjects without LBP, strong voluntary abdominal muscle contraction caused pelvic floor muscle activity at the same intensity as maximal pelvic floor muscle effort. The pelvic floor does not simply respond to increases in intraabdominal pressure; instead, the pelvic floor muscles contract before the abdominal muscles.[68] One investigator found that some patients with chronic LBP (CLBP) were unable to recruit the TrA without prior contraction of the pelvic floor.[61]

Last, but certainly not least, is the importance of integrated function of the diaphragm. The diaphragm and deep stabilization muscles of the body have been described as an important functional unit for dynamic spinal stabilization.[69,70] In addition, proper use of the diaphragm assists with general relaxation of trunk muscle guarding patterns.[71] The diaphragm precedes any movement of the body by lowering and subsequently establishing abdominal pressure which helps to stabilize the lumbar part of the spine. Studies focused on diaphragm activation with the aim of posture stabilization have identified phase modulation which corresponds to the movement of the upper limbs.[72–75] Other studies show that healthy individuals have a bigger range of diaphragm motion with lower breathing frequency, better coordination within its movement, and better balanced postural and breathing components than those with LBP.[76] These factors are very important for maintaining intraabdominal pressure, which helps to support the spine in conjunction with the abdominal wall, posterior musculature, and pelvic floor. Studies support the difference in motor control of the respiratory and stabilization muscles in patients with and without LBP suggesting integrated motor control of the diaphragm, posterior, anterior, and pelvic floor muscles should be developed in patients with LBP.[72–77]

Gait

Gait is a vital functional activity. **Table 17-1** displays the biomechanics and muscle function of the gait cycle of the lumbopelvic region.

TABLE 17-1

Kinematics and Muscle Activity of the Gait Cycle in the Lumbopelvic Region

PHASES OF THE GAIT CYCLE	RANGE OF MOTION		MUSCLE ACTIVITY	
	LUMBAR SPINE	PELVIC GIRDLE[a]	LUMBAR SPINE[b]	PELVIC GIRDLE[c]
Initial contact	Sidebending ipsilateral/ rotation contralateral	Small cranial/caudal shear; ipsilateral innominate rotates posteriorly/contralateral innominate rotates anteriorly	Bilateral erector spinae	Hamstring (HS), gluteus maximus[d]
Loading response	As at initial contact			
Midstance	As at initial contact	Ipsilateral innominate rotates anteriorly toward neutral; contralateral innominate rotates posteriorly toward neutral		
Terminal stance	Preparing for initial swing	Ipsilateral innominate rotates anteriorly past neutral; contralateral innominate rotates posteriorly	Bilateral erector spinae[86]	
Preswing	Preparing for initial swing			
Initial swing	Contralateral side-bend/ ipsilateral rotation			

TABLE 17-1

Kinematics and Muscle Activity of the Gait Cycle in the Lumbopelvic Region (*continued*)

PHASES OF THE GAIT CYCLE	RANGE OF MOTION		MUSCLE ACTIVITY	
	LUMBAR SPINE	PELVIC GIRDLE[a]	LUMBAR SPINE[b]	PELVIC GIRDLE[c]
Midswing	As initial swing			
Terminal swing	As initial swing			

[a]The motion of the sacrum between the two innominates and adjacent fifth lumbar vertebra has been described as a complex, polyaxial, torsional movement that occurs about the oblique axes.[78,79]

[b]Discrepancy exists regarding activity of rectus abdominis and obliqui externus and internus, perhaps because of speeds of walking during testing conditions.[80,81] The transversus abdominis and lumbar multifidus appear to be linked with the control of stability of the spine against the perturbation produced by the movement of the limbs and should be considered as active during the gait cycle.[50]

[c]Much of the muscle activity occurring across the pelvic girdle during gait is discussed in Chapter 20. Additional information regarding the link between the hip, the lumbopelvic region, and the upper extremity is provided in this table.

[d]HS activity increases the tension in the sacrotuberous ligament and contributes to the force closure mechanism of the pelvic girdle with loading of the limb.[66,82,83] Gluteus maximus becomes active with counterrotation of the trunk and arm swing forward, resulting in lengthening of the contralateral latissimus dorsi muscle. Shortly thereafter, the arm swings backward, causing contraction of the contralateral latissimus dorsi. Lengthening and contraction of the latissimus dorsi contribute to increased tension in the TLF, thereby contributing to further force closure mechanism of the sacroiliac joint (SIJ).[84] Gluteus maximus activity is key to force closure stabilizing mechanisms within the pelvis; loss of function of the gluteus maximus can hinder stability of the SIJ.[85]

EXAMINATION AND EVALUATION

Patients suffering from spine pain can present with a wide spectrum of symptoms and examination findings, representing different degrees of clinical severity and pathological significance. In most people, LBP is benign and represents a simple back sprain or strain associated with a mechanical loading incident or a "pain flare" associated with psychosocial or lifestyle stresses. Serious etiologies of spine pain that include fractures, tumors, or infections are relatively rare, accounting for less than 1% of all medical cases seen during spine assessment.[87] However, because most spine pain patients present with a clinical picture that could be created by numerous different conditions,[87] it is imperative for clinicians to identify conditions or comorbidities that may deter a patient's recovery and function or place the patient at risk of serious medical consequences (red flags). A clinician must remain alert to potential clinical indicators that require more extensive testing, consultation, or referral (see **Table 17-2**).[88]

In approximately 5% to 10% of people with LBP, the pain may be associated with radicular features with or without neurologic deficit. This may be associated with compression of the nerve root, spinal cord, or cauda equina syndrome, which is linked to an underlying pathology, such as disk prolapse, lateral recess, and canal stenosis or advanced grade spondylolisthesis (discussed later in this chapter in more detail). A presentation of progressive neurologic deficits or signs of cauda equina syndrome (new urine retention, fecal incontinence or saddle anesthesia) warrants further investigation and referral to a medical specialist.[89]

As previously stated, 90% of patients with LBP do not have a specific pathoanatomic or pathophysiologic source and are considered to have NSLBP.[89] The goal of the physical therapy examination is to determine the multidimensional cause(s) of the patient's activity limitations and participation restrictions.

A multidimensional approach toward management of LBP combines a strong cognitive focus with an emphasis on reframing the persons' understanding of their back pain in a person-centered manner, with a simultaneous emphasis on changing maladaptive movement, as well as lifestyle behaviors

TABLE 17-2

Categorical Classification of "Red Flag" Findings During Medical Screening

Category I: Factors that require immediate medical attention

- Blood in sputum
- Loss of consciousness or altered mental status
- Neurologic deficit not explained by monoradiculopathy
- Numbness or paresthesia in the perianal region
- Pathological changes in bowel and bladder
- Patterns of symptoms not compatible with mechanical pain (on physical examination)
- Progressive neurologic deficit
- Pulsatile abdominal masses

Category II: Factors that require subjective questioning and precautionary examination and treatment procedures

- Age >50
- Clonus (could be related to past central nervous system disorder)
- Fever
- Elevated sedimentation rate
- Gait deficits
- History of a disorder with predilection for infection or hemorrhage
- History of a metabolic bone disorder
- History of cancer
- Impairment precipitated by recent trauma
- Long-term corticosteroid use
- Long-term worker's compensation
- Nonhealing sores or wounds
- Recent history of unexplained weight loss
- Writhing pain

Category III: Factors that require further physical testing and differentiation analysis

- Abnormal reflexes
- Bilateral or unilateral radiculopathy or paresthesia
- Unexplained referred pain
- Unexplained significant upper or lower limb weakness

Categorical Classification of "Red Flag" Findings During Medical Screening

Sizer PS Jr, Brismée JM, Cook C. Medical screening for red flags in the diagnosis and management of musculoskeletal spine pain. Pain Pract 2007;7:53–71.

contributing to their vicious cycle of pain. From a mechanical standpoint, targeting specific movement training is important to this approach in that it:

- Reveals to the examiner and the patient the type and direction of the mechanical stress that correlates with symptoms, empowering the patient with a sense of control
- Reveals potential physiologic impairments that contribute to the movement impairment
- Becomes the basis for a therapeutic exercise program and for posture and movement retraining

Patient History

To successfully manage a patient with LBP, it is imperative that the therapist has a clear understanding of the patient's medical history and current symptoms. In addition to the general data collected from a patient/client history as defined in Chapter 2, special questions regarding symptoms related to the low back and patient beliefs can begin the clinical reasoning process toward diagnosis. Research into the validity of history findings with respect to LBP generally uses a pathoanatomic classification system, but recently, emphasis on reflective interviewing has helped to understand psychosocial factors that are contributing to the experience of pain. **Display 17-1** presents examples of reflective interview questions for persons with LBP. The research presented in **Display 17-2** uses diagnostic labels of disk disease, zygapophyseal (ZJ) joint syndrome, SIJ syndrome, cauda equina syndrome, and stenotic syndrome. For detailed list of questions, please refer to Magee's text.[97]

DISPLAY 17-1
Reflective Interview Questions

- When did your back pain start?
- What do you think was the initial mechanism of injury?
- What are your beliefs about where the pain is coming from?
- What are you feeling in your body? Is there tension in your body? If so, where?
- Can you tell me about things that you are doing when your back feels better? Can you tell me about things you are doing when your back feels worse?

Additional Methods That Help Expand the Narrative

- Try to listen without interrupting or responding too quickly—if necessary, count to five slowly before making any comments and then see if the comment is necessary
- Invite elaboration and clarification (tell me more about. . .).
- Feel free to offer empathy if appropriate.
- Try not to comment, interpret, agree, disagree, or compare their views with yours or anyone else's; remember that this is not a conversation; the goal is to create a space for your patients' thoughts and not your own.
- Take notes so that you can reflect back on the major themes of the story.
- Paraphrase and summarize. For example, "Let me see if I have this correct. You said that. . ."
- If the patient has seen other health care providers, their care will be discussed as part of the history. Occasionally, the patient may be dissatisfied with their previous course of care, may appear frustrated over their lack of improvement, and may speak unfavorably of other health care providers. Listen without judging or making a comment regarding other health care provider's services.

DISPLAY 17-2
History Items in Patients with LBP

Disk Disease[90]

- LBP
- Burning, stabbing, "electrical" pain down the leg
- Numbness or paresthesia (sensitivity 30% to 74% for paresthesia)[91]
- Aggravated by increased intradiskal pressure or specific movements
- Substantial but not complete relief with rest
- Radicular distribution pain (sensitivity of 95% for sciatic distribution of pain)[11]
- Leg pain greater than back pain
- Pain superficial and sharp rather than less well-defined, dull, aching
- Sensitivity for sciatic distribution of pain of 79% to 95%[91]

Zygapophyseal (ZJ) Syndrome

- ZJs do not cause referred pain; pain is experienced exclusively in the central lumbar spine[92]
- ZJs may refer pain into the leg below the knee possibly due to segmental facilitation as a result of nociceptive input from a painful structure elsewhere in the affected segment[93]

Sacroiliac Joint (SIJ) Syndrome

- Groin pain[92]
- Pain inferior to the posterior superior iliac spine[94,95]
- Radicular symptoms may occur as a result of extravasation of inflammatory mediators through a capsular recess or tear to adjacent neural structures[95]

Cauda Equina Syndrome[96]

- Sensitivity of 95% for urinary retention[11]
- Sensitivity higher than 80% for motor weakness and decreased sensation in the legs[11]
- LBP
- Bilateral or unilateral sciatica
- Sensitivity of 75% for saddle area hyperesthesia[11]
- Sexual dysfunction (decreased sensation during intercourse, decreased penile sensation, and impotence)
- L5–S1 central disk herniation may cause no motor or reflex changes in the legs

Stenotic Syndrome[11]

- 60% sensitivity for neurogenic claudication
- 85% sensitivity for leg pain
- 60% sensitivity for neurologic abnormalities

Screening Examination

Symptoms originating in the lumbopelvic region often are experienced elsewhere in the lower quadrant and symptoms mimicking lumbopelvic origin dysfunction can originate in visceral tissues (see Appendix 1). It is for these reasons that a lumbopelvic screen is recommended before performing any lumbopelvic or lower quadrant examination. The purpose of the screening examination is to determine whether symptoms experienced in the lower quadrant are originating in the lumbopelvic region. If it is determined that symptoms are stemming from the lumbopelvic region, a more thorough lumbopelvic examination and evaluation is indicated. **Display 17-3** lists the tests that should be included in any lumbopelvic screening examination.

DISPLAY 17-3

Lumbopelvic Scan Evaluation

Observation: Posture scan in standing and sitting, local signs of skin color, texture, scars, soft-tissue contours

Active Range of Motion (with overpressure if indicated): In standing, flexion, extension, lateral flexion; in sitting, rotation

Stress Tests: Supine lumbar compression and distraction, supine sacroiliac joint compression and distraction, sidelying sacroiliac joint compression, prone lumbar torsion stress

Provocative Test: Prone posteroanterior pressure to the lumbar spine

Palpation: Palpate-related lumbar-pelvic-hip musculature, assessing for tone changes, lesions, and pain provocation

Dural Mobility Tests: Slump test, straight-leg raise, prone knee flexion

Neurologic Testing: Key muscle (see **Table 17-3**) reflexes, dermatomes

TABLE 17-3

Key Muscles and Corresponding Nerve Root and Peripheral Nerve in the Lumbopelvic Region

KEY MUSCLE	NERVE ROOT	PERIPHERAL NERVE
Psoas	L2 (3)	Femoral nerve
Quadriceps	L3 (4)	Femoral nerve
Tibialis anterior	L4 (5)	Deep peroneal
Extensor hallucis	L5 (S1)	Deep peroneal
Gluteus medius	L5 (S1)	Superior gluteal
Peronei	L5 (S1)	Superficial peroneal
Medial hamstring	L5 (S1)	Sciatic
Lateral hamstring	S1	Sciatic
Gastrocnemius	S1 (S2)	Tibial
Gluteus maximus	S2	Inferior gluteal
Bladder and rectum	S4	

Tests and Measures

The following sections describe, in alphabetical order, the tests and measures highlighted in any lumbopelvic examination/evaluation. The tests and measures must be individualized based on the data collected from the history, systems review, and screening examination. Additional tests and measures may be included on a case by case basis. The reader is referred to the *Guide to Physical Therapist Practice* for a detailed list of physical therapy tests and measures.[98]

Anthropometric Characteristics

Anthropometric characteristics may be of interest, whereas an individual's unique anthropometric characteristics can be a risk factor in developing certain types of lumbopelvic syndromes. For example, the anthropometric characteristics of a male with broad shoulders, narrow pelvis, and high center of mass promote lumbar flexion versus hip flexion during forward bend movements. This may pose as a risk factor in developing LBP.[99] In addition, if returning to a job requiring bending and lifting, he/she will need to pay attention to body mechanics limiting *excessive* or *highly repetitive* lumbar flexion forces—not necessarily avoiding them.

Ergonomics and Body Mechanics

An assessment of a patient's job-related duties and physical demands should include ergonomic and body mechanic assessment. This may include assessing material handling capabilities, such as lifting incrementally increasing weights at different heights. Assessment of non–material handling capabilities includes tasks such as sitting or standing tolerance, or work station ergonomics. These kinds of assessments are often termed functional capacity evaluations (FCEs). FCEs can be purchased or designed in the clinic and may use expensive mechanical devices interfaced with computers, or inexpensive handmade boxes, crates, and push/pull sleds. One important point to maintain concerning the validity of an FCE is that an FCE, conducted from 2 to 4 hours over 1 to 2 days of a person's life at a given point in time, cannot predict a person's capacity to work for 8 to 10 hours per day, 4 to 6 days per week, 52 weeks per year. At best, the FCE may simulate certain skills and capacities needed to perform the job. The FCE should be used as one aspect of the injured person's examination, not as a complete evaluation in and of itself.

Gait/Balance

Gait is a complex functional movement pattern that can indicate pathomechanical factors contributing to lumbopelvic signs or symptoms, particularly if the patient reports that walking increases or decreases symptoms. The relationship of other regions to the lumbopelvic region is important in ascertaining the mechanical stress imposed on the lumbar spine. For example, a hypomobile supinated foot that does not adequately pronate during the stance phase of gait may increase compressive stress on the lumbar spine, whereas a hypermobile pronated foot may induce a transverse plane stress on the lumbar spine by creating a short limb during the stance phase of gait. Even phones equipped with video applications can be used for full speed and slow motion video analysis. This can be an efficient tool to evaluate and provide patient feedback regarding the complex interaction of multiple regions on the lumbar spine during walking or running. Incorporating findings from a gait evaluation to other tests of measures can assist the practitioner in developing a specific exercise program to remediate the impairments related to gait deviation. Once quality of gait improves, it can be used as more effective activity to improve endurance and serve as a graded exercise to reduce fear-avoidance behaviors.[100]

Muscle Performance

The ability for the spine and pelvic girdle muscles to carry out functions of mobility and stability must be carefully assessed to ascertain the pathomechanics of the lumbopelvic region. Muscle performance testing includes tests of strength, power, and endurance adequate for each individual to carry out his or her desired controlled mobility (basic activities of daily living [BADLs]) and skill-level activities (instrumental activities of daily living [IADLs]).

Assessment of the force or torque-generating capability of the spinal extensor and abdominal muscle groups can be performed with traditional manual muscle testing procedures as described by Kendall et al.[101] Because of the numerous details regarding accurate assessment of the abdominal muscles, Kendall's work should be reviewed to ensure optimal manual muscle testing results.

Although objective information about muscle force or torque production can be gathered from isokinetic testing, gross strength testing by this method may not be sensitive to the function of the deeper musculature surrounding the spine. Whereas many studies demonstrate a relationship between impaired function of the deep abdominal and LM muscles and LBP, studies comparing gross trunk strength in normal subjects or patients with LBP have not consistently demonstrated such a relationship.[102–107] This difference may reflect the inherent limitations in conclusions that can be ascertained from studies examining maximal trunk strength in persons with LBP. For example, pain can hinder maximal effort, and a test of a patient with LBP may be more a test of the patient's tolerance to pain. This design problem may be responsible for the varied and seemingly contradictory results of trunk muscle strength reported in the literature. There is also growing evidence that altered movement patterns and increased trunk muscle cocontraction are associated with the recurrence and persistence of LBP, suggesting a need to think about excessive forces on the spine.[71]

Isokinetic testing of trunk muscle strength focuses largely on the assessment of muscles primarily involved in and capable of producing large torques about the spine (e.g., RA, thoracolumbar erector spinae) rather than on muscles considered to provide stability and fine control (e.g., TrA and LM).[108,109] Most studies focus on maximal voluntary contractions, which are rarely carried out during the ADLs. In the CLBP population, sudden, unexpected, and insignificant movement at low load can exacerbate symptoms just as commonly as tasks involving maximal exertion.[110,111] However, a recent investigation has shed light on the difference in torque production at various speeds between persons with and without herniated lumbar disks which may impact rehabilitation goals (**Evidence and Research 17-2**).

Isokinetic and traditional manual muscle testing may not be sensitive enough to assess the muscle performance of the deep trunk muscles (i.e., TrA and LM). Testing of trunk muscle strength should also consider the function of the deeper musculature. Tests that examine the ability of the deep trunk muscles to stabilize against various directional forces during active extremity movement can provide the clinician with an indication of their muscle performance.[36,113] When the spine is unable to remain stable against a specific direction of force, it can indicate a lack of motor control, force or torque production, or fatigue (depending on the focus of the test) of the associated trunk muscle(s). Additional methods of testing TrA muscle function involve palpation of the abdominal wall[114] and the use of a pressure cuff (pressure biofeedback unit, Chattanooga, USA) placed under the abdomen with the patient in a prone lying position.[115] This test represents an inner range concentric contraction of the TrA muscle to lift the abdominal contents and wall and thereby decrease the pressure in the pressure biofeedback unit. The multifidus muscle can be assessed by the palpation of muscle bulk and by the quality of voluntary contraction at each lumbar vertebral level.[115] The LM can be assessed using a biofeedback device as well. With the patient in supine hook-lying, the biofeedback device is placed under the lumbar spine; concentric contraction of the LM muscle increases the pressure in the biofeedback unit. Real-time ultrasound imaging is another method that is used in physical therapy clinical practice both for assessment of TrA and multifidus muscle function and size as well as for retraining purposes.[116,117] High repetitions of any test can provide an indication of the endurance of the trunk muscles.

In theory, resisted testing of the trunk muscles can also provide information about the integrity of the trunk muscles relative to imposed strain. However, resisted testing of the trunk muscles can also provoke other pain-sensitive structures and

EVIDENCE and RESEARCH 17-2

Isokinetic Testing of Extremity Muscles in LBP with Lumbar Disk Herniation

A cross-sectional study comparing normal subjects and patients with lumbar disk herniation (LDH) with sciatica was performed to simultaneously measure the isokinetic muscle strength of the trunk, knees, and ankles in both groups.[112]

Key Points

- Simultaneous trunk, knee, and ankle strengths were measured in patients with LDH with sciatica.
- In addition to decreased trunk strength, significant decrease in the knee flexion/extension and ankle plantar flexion strength, but not dorsiflexion strength, was demonstrated in the LDH group, regardless of the laterality of sciatica.
- At the test velocity of 180 degrees per second, knee extension torque was revealed to be significantly lower in the limb with sciatica than in the limb without sciatica in the LDH group.
- Reduction in knee torque at fast speeds may possibly be explained by the pain-related reduced walking activity of affected limbs associated with selective type II muscle fiber atrophy in the quadriceps muscles. Future histologic or morphologic studies are warranted.
- Results of the study provide clinical implications that a good and satisfactory rehabilitation/therapeutic program for patients with LDH or LBP should control the pain (back pain and leg pain) and that these patients should strengthen both the trunk and lower extremity muscles at different contraction speeds (especially the faster speeds) to ensure successful recovery.

result in a weak and painful test, making it difficult to use resisted testing as a differential diagnostic test for trunk muscle strain.

Muscle strength testing of pelvic girdle and pelvic floor muscles can provide pertinent information about factors that may contribute to lumbopelvic dysfunction. For example, weakness in the gluteus medius results in excessive hip adduction and pelvic drop in the single-limb support phase of gait, which can impose frontal or transverse plane stress on the lumbopelvic region and thereby contribute to lumbopelvic impairment or pathology. When healthy study participants performed sidelying hip abduction while concurrently performing lumbar stabilization, gluteus medius activity increased and quadratus lumborum activity decreased, causing a decrease in lateral pelvic tilt. The authors suggested that hip abduction with lumbar stabilization is useful to exclude substitution by the quadratus lumborum.[118] Chapters 18 and 19 respectively, provide recommendations for pelvic floor and pelvic girdle muscle performance testing.

Neurologic Testing: Tests for Motor Function and Sensory and Reflex Integrity

A thorough neurologic examination for the lumbopelvic region consists of three parts. An *upper motor neuron screening* is indicated when cord compression is suspected. An upper lumbar central herniation may result in spinal cord compression. A central herniation in the lower lumbar spine can cause compression to the cauda equina and therefore should not result in upper motor neuron signs.

Sufficient compression on the nerve root may result in decreased conductive function of the nervous system; *neuroconductive testing* may reveal segmentally related sensory changes, motor changes, and hypo- or hyperreflexia.[119] Testing motor function can indicate a pattern of muscle weakness from a specific nerve root level or peripheral nerve. Table 17-3 indicates the key muscles with the corresponding nerve root and peripheral nerve innervation.

The third part includes *neurodynamic tests* that examine the movement and tensile abilities of the nervous system. Examples of neurodynamic tests include the straight leg raise (SLR), femoral slump test (FST), and seated slump maneuver. The clinician administering these tests should be skilled in the specialized features of handling and sequencing the components of the test and must understand what is considered to be a normal or acceptable response. Butler[120] describes the technique and rationale for neurodynamic tests in the lumbopelvic region. Deyo et al.[121] noted a sensitivity of 80% and specificity of 40% for the SLR in the diagnosis of low LDH. The SLR test is most appropriate for testing the L5 and S1 nerve roots. Irritation of the higher lumbar roots is tested by the FST, which biases the femoral component of the nervous system.[122,123]

Pain

The clinician examines pain in the lumbopelvic region with respect to many variables:

- Measurement of pain with respect to the level of disability it imposes on an individual with LBP
- Screening for psychosocial prognostic factors for the development of CLBP following the onset of musculoskeletal pain
- Examination techniques used to diagnose whether the pain is originating in the lumbopelvic region and, when possible, determine the potential pathoanatomic source(s) of the pain
- Examination techniques to determine potential mechanical cause(s) of pain

Because the United States, in common with other western nations, is trying to restrain the costs of health care, it is more important than ever for clinicians to demonstrate that the care they deliver is both efficient and effective. Pain scales are a common method for assessing patient outcome in back pain. At least 22 scales have been reported in the literature.[124] However, the presence of pain alone is a narrow definition of health outcome that correlates poorly with physical function.[125] Waddell and Main[126] stated that in evaluating the severity of LBP, three recordable, clinical components must be differentiated: pain, physical impairment, and disability. (See "Work [Job/School/Play], Community, and Leisure Integration or Reintegration [Including IADLs]" for further discussion regarding measures of disability.)

Efficient allocation of health care resources can be augmented by an outcome measure that can predict those patients whose outcomes are likely to be poor. Those individuals can be redirected to more appropriate intervention. Waddell developed a list of nonorganic signs that can be used as a predictor of outcome for patients with lumbopelvic disabilities.[127,128] Waddell et al.[128] identified five nonorganic signs, and each can be detected by one or two tests. The tests assess a patient's pain behavior in response to certain maneuvers (**Table 17-4**). A patient presenting

TABLE 17-4

Waddell Signs

TEST	SIGNS
Tenderness	Superficial—the patient's skin is tender to light pinch over a wide area of lumbar skin
	Nonanatomic—deep tenderness felt over a wide area, not localized to one structure
Simulation tests	Axial loading—light vertical loading over patient's skull in the standing position causes lumbar pain
	Acetabular rotation—back pain is reported when the pelvis and shoulders are passively rotated in the same plane as the patient stands; considered to be a positive test result if pain is reported within the first 30 degrees
Distraction tests	Straight-leg-raise discrepancy—marked improvement of straight-leg raising on distraction compared with formal testing
	Double-leg raise—when both legs are raised after straight-leg raising, the organic response is a greater degree of double-leg raising; patients with a nonorganic component demonstrate less double-leg raise compared with the single-leg raise
Regional disturbances	Weakness, cogwheeling, or giving way of many muscle groups that cannot be explained on a neurologic basis
	Sensory disturbance—diminished sensation fitting a "stocking" rather than a dermatomal pattern
Overreaction	Disproportionate verbalization, facial expression, muscle tension and tremor, collapsing, or sweating

From Karas R, McIntosh G, Hall H, et al. The relationship between nonorganic signs and centralization of symptoms in the prediction of the return to work for patients with low back pain. Phys Ther 1997;77:356. Reprinted with permission of the American Physical Therapy Association.

with a high Waddell score (i.e., 3 to 5 of 5 positive nonorganic signs) is believed to have a clinical pattern of nonmechanical, pain-focused behavior. The patient has significant enough psychologic impairments that intervention focused on physiologic and anatomic impairments alone probably cannot produce a successful outcome. A high Waddell score can be used as a predictor of functional outcome, as indicated by a low rate of return to work.[129] However, the practitioner must interpret this finding with caution.[128] A high Waddell score only indicates a high degree of nonorganic or psychologic impairments. It does not signify malingering, which is a judgment, not a medical or psychologic diagnosis.[127,128] Patients with a high Waddell score may need to be referred to the appropriate mental health practitioner for treatment before or in conjunction with physical therapy intervention (**Evidence and Research 17-3**).

EVIDENCE and RESEARCH 17-3

Construct Validity of Waddell Score

In a 2012 study, researchers investigated the construct validity of the Waddell score.[130] Construct validity refers to the question whether the relationship between the Waddell score and scores for other factors is in agreement with theoretical expectations. The primary aim of this study was to examine the relationships between the Waddell score and factors measuring demographics, pain intensity, illness behavior, and physical and psychologic status. A wide range of factors can contribute to the expression of Waddell signs, such as illness worry, sick role, unemployment, hypochondriasis, depression, anxiety to examination, central sensitization, learned behavior, and the disease state. For example, recent research shows that in patients with CLBP, brain structure and function can alter[131] and the patient can display Waddell signs as a response to these changes.[132] Given the substantial interindividual variability of how people respond to health problems, the differences in social norms, cultural models, and health care systems, and the probably limited usefulness of the description of the Waddell score in traditional diagnostic domains, it is not very surprising that only weak relationships were found between the Waddell score and the domains measured. For clinical practice, the presence of Waddell signs does not indicate exactly what the specific problems are, and they must, therefore, be conceptualized and understood in the total clinical picture of the patient. It is evident that the Waddell score cannot be regarded as a straightforward psychologic "screener."[127] This research underscores the complexity of illness behavior as measured with the Waddell score.

In addition to measurement of pain in relation to outcome data, the clinician should also attempt to determine whether or not the lumbar spine or pelvis is indeed the source of nociception. After it has been determined that the lumbopelvic region is the region of origin, even if the exact source of the trigger cannot be diagnosed, attempts must be made to determine whether mechanical interventions can alter the experience of pain. During the examination process, the therapist can observe stabilization and movement patterns and correlate faulty patterns with pain provocation. If altering the pattern of stabilization or movement reduces or eliminates the pain, the specific faulty movement patterns responsible for the pain can be diagnosed and used as a platform for treatment.[31]

Posture

The therapist should perform a cursory evaluation of the patient's standing and sitting postures during the history portion of the examination. Posture also is examined formally as part of the evaluation process. During the examination, the patient may assume what he or she considers to be "proper posture" or a posture that depicts the painful or emotional state he or she wishes to portray. The posture portrayed during this examination may be unconscious or intentional, and the motivation is not always easily discerned. Observation of posture without the patient's knowledge can be more revealing of the true contribution of posture to his or her signs and symptoms.

More specific examination should include standing, sitting (supported and unsupported), and recumbent postures. Several things should be observed, including head position, shoulder girdle position, cervical, thoracic, and lumbar curves, and lumbopelvic, hip, knee, ankle-foot alignment; all should be examined in all three planes. In standing, the examiner is looking for asymmetry and possible relationships between segmental regions (e.g., foot pronation and genu valgum on the side of a low iliac crest and apparent short limb). Bony landmarks are assessed to visualize the position of the pelvis, including the iliac crest, posterior superior iliac spines (PSISs), anterior superior iliac spines (ASISs), and pubic symphysis. Ideal pelvic alignment is best visualized through the ASIS and pubic symphysis in the frontal plane.[101]

A hypothesis can be developed regarding the contribution of faulty lumbopelvic alignment to the pathomechanical cause of symptoms and the relationship of other body regions in perpetuating the faulty lumbopelvic alignment. Correction of alignment can reduce pathomechanical stress in the lumbopelvic region and therefore reduce or eliminate symptoms. This is an early step toward the diagnosis of a pathomechanical cause of lumbopelvic activity limitations and participation restrictions. However, static posture is not always a good indicator of the pathomechanical stress causing lumbopelvic symptoms. For example, a person with spinal stenosis may have a flat lumbar spine and yet incur symptoms with extension forces on the lumbar spine due to the narrowed spinal canal or lateral foramina.

Other hypotheses can be developed about muscle lengths. Assumptions can be made regarding muscle-fascial structures that are too long based on joint position, such as a long EO in an anterior pelvic tilt (**Fig. 17-8**). Muscle length testing is indicated to determine whether muscles are short because of joint position (e.g., specifically which hip flexors are short in anterior pelvic tilt). Additionally, the results of positional strength tests should correlate with muscle length hypotheses.

Posture can also indicate muscular holding patterns such as spinal extensor hyperactivity versus relaxed spinal extensors during sitting or standing. All of these observations can assist the practitioner in classifying patients into homogenous groups.

Range of Motion, Muscle Length, and Joint Mobility

Range of motion (ROM) tests of the lumbopelvic region should not only assess the ROM of the lumbar spine, but also the pelvic-femoral complex and the relationship between the ROM of the hip and lumbar spine. The interrelationship of ROM with other regions of the body (e.g., thoracic spine and upper extremity) is also of interest. Muscle length testing of the spine,

FIGURE 17-8 **(A)** Neutral spine and pelvic position and length of external oblique (EO). **(B)** The lordotic posture and anterior pelvic tilt elongate the EO.

upper, and lower quarters should also be included. Mobility tests of the lumbopelvic region determine the intervertebral mobility/stability (passive intervertebral motion [PIVM] testing) of the spine and mobility/stability of the SIJ.

Range of motion testing is performed in standing for flexion and extension, lateral flexion, and quadrant movements; it is performed in sitting for rotation. Overpressure can be used to reproduce symptoms. The intent of ROM testing is fourfold:

1. To determine the patient's willingness to move
2. To reproduce symptoms
3. To determine the quantity of motion in the lumbar–pelvic–hip complex
4. To determine the quality of movement by assessing the relationship between the various regions of the spine and the pelvic–hip complex

Chapter 19 describes hip ROM testing. The purpose of hip ROM testing is to determine reduced ROM in the hip that may contribute to compensatory spine motion, thereby imposing a pathomechanical stress on the lumbar spine. For example, a hip that has reduced ROM in extension may cause compensatory lumbar spine extension, particularly during the terminal stance phase of gait or in the final phase of return from a forward bend.

Active hip ROM testing can be used to assess movement patterns of the hip and stabilization patterns of the lumbopelvic region.[31] Faulty patterns can induce a pathomechanical stress on the lumbar spine and provoke symptoms. Correction of faulty patterns of lumbopelvic stabilization should reduce symptoms if the faulty pattern is contributing to pathomechanical stress on the affected structures. In this way, these tests can also be used to clear the hip joint of any possible involvement. If correction of lumbopelvic stabilization reduces symptoms, it is unlikely that the hip is the source of symptoms.

Thoracic ROM testing is described in Chapter 24. The purpose of thoracic ROM testing is to determine whether reduced ROM of the thoracic spine is contributing to compensatory motion in the lumbopelvic region (e.g., reduced or stiff thoracic spine rotation could induce increased stress to the lumbar spine during transverse plane movement patterns).

Tests of muscle extensibility across the pelvis and hip are described in Chapter 19. Data obtained from these tests provide the clinician with additional information about potential causes of pathomechanical stress on the lumbar spine. For example, during forward bending, stiff hamstrings (HSs) can restrict pelvic forward rotation, resulting in flexion stress (**Fig. 17-9B**) on the lumbar spine.

Although not direct measures of trunk muscle extensibility, lumbopelvic forward bending, backward bending, and lateral flexion can test for posterior, anterior, and lateral trunk extensibility, respectively. Assessment of postural alignment can lead

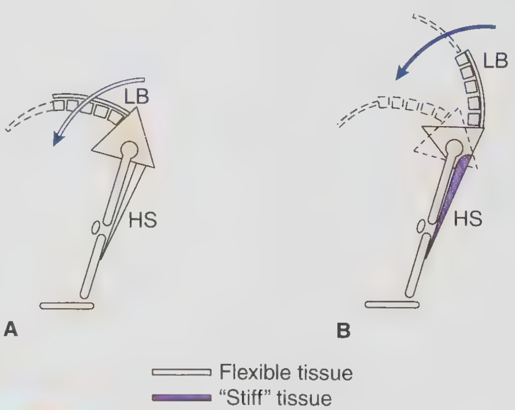

FIGURE 17-9 **(A)** Normal lumbopelvic rhythm. **(B)** Reduced extensibility of the hamstrings (HSs) can alter lumbar-pelvic range of motion. Stiffness from the HSs slows the rate and can potentially restrict the range of pelvic motion, resulting in excessive flexion stress of the lumbar spine. (Adapted from Calliet R. Low Back Pain. 3rd Ed. Philadelphia, PA: FA Davis, 1981.)

to a hypothesis about excessive trunk muscle length (see the "Posture Examination" section).

One type of ROM testing unique to the lumbar region was developed by McKenzie.[133] This method is based on the assumption that sustained or repeated movements may affect nuclear position, resulting in centralization or peripheralization of symptoms. McKenzie defined the centralization phenomenon as "the situation in which pain arising from the spine and felt laterally to the midline or distally, is reduced and transferred to a more central or near midline position when certain movements are performed."[133] Peripheralization is the opposite phenomenon whereby pain arising from the spine and felt proximally and to the midline is increased and transferred laterally and distally when certain movements are performed. McKenzie's theory presumes that as long as the annulus and disk are intact, an offset load on the disk in a lesion-specific direction of spinal movement may apply a reductive force on a displaced nuclear fragment, directing it toward a more central location (i.e., "centralization"), thereby reducing symptom-generating stress on neural or other nociceptive structures.[133]

Joint mobility tests of the lumbar region come in three categories: passive physiologic intervertebral motion (PPIVM), passive accessory intervertebral motion (PAIVM), and segmental stability tests. PPIVM testing is used to determine relative physiologic mobility (e.g., hypermobility versus hypomobility) and to stress the related spine and pelvic joints in an attempt to determine end-feel, assess irritability, assess stability, and provoke symptoms. PAIVM is defined as the passive assessment of accessory intervertebral joint through its glides (e.g., posterioanterior [PA] glide), whereas stability tests attempt to examine segmental translatory mobility that is excessive[119] (see **Evidence and Research 17-4**). Research shows at best moderate intrarater reliability and poor interrater reliability.[137] Reliability improves when a positive response includes both perceived changes in ROM and provocation of symptoms rather than just decreased mobility.[137,138] A combination of PPIVM and PAIVM tests correctly identified dysfunctional levels diagnosed with intraarticular infiltration.[139]

Regarding the SIJ, a battery of tests has been suggested to rule out or confirm a suspected diagnosis of SIJ dysfunction.[140] A criteria of at least three of four tests with positive results is required to determine the presence of SIJ dysfunction: standing flexion, prone knee bend, supine-to-long sitting, and palpation of the PSIS in sitting. Passive physiologic motion tests of the pelvis include anterior and posterior innominate rotation.[141] Passive accessory motion tests refer to the passive assessment of a joint by way of glides and in the SIJ can be used to test stability.[141]

All ROM, muscle length, and mobility/stability tests should assess the effect that altered motion or stabilization strategies of the examined region have on symptoms. For example, an increased extension moment may be imposed on the L5 segmental level during prone hip extension because of relatively less extension mobility available at the hip. By determining the spinal segmental levels (e.g., L5), the associated anatomic regions (e.g., the hip), and the sources of structural limitation (e.g., muscle, capsule, bone), a specific intervention plan can be developed to address the related physiologic impairments. Addressing the impairments associated with lumbar extension can improve the patient tolerance to walking or running (activity limitations and participation restriction).

EVIDENCE and RESEARCH 17-4

Prone Stability Test

The prone stability test uses the PA glide to assess segmental stiffness and pain provocation with muscles in a resting state and during an active contraction.[134] The first portion of the test is performed with the patient in prone with the lower extremities in contact with the ground while a PA glide is performed at each lumbar segment to see if pain is produced at that segment. If a painful segment is identified, the second half of the test is performed at that segment in conjunction with active lumbar and hip extension to lift the legs from the ground. The prone instability test is considered positive if pain is provoked in the resting state and eliminated during active muscle contraction. Reliability of the prone instability test has been described as high ($\kappa = 0.87$).[134] Recently, spinal stiffness was measured during the application of a PA force when doing either the abdominal drawing in maneuver or abdominal bracing in individuals without lumbar spine pathology.[135] Both instances increased spinal stiffness greater than resting, but the abdominal brace increased spine stiffness greater than the abdominal drawing in maneuver. These findings are consistent with modeling of lumbar spine function during muscular contraction.[136]

Work (Job/School/Play), Community, and Leisure Integration or Reintegration (Including IADLs)

This category of tests and measures includes the measurement of participation restriction. Waddell and Main[126] proposed that in evaluating the severity of LBP, three recordable clinical illness components must be differentiated (see "Pain" category), one of those being disability. The following list is limited to validated functional questionnaires that were designed by selecting items relevant to back pain:

1. Oswestry Low Back Disability Score[142]
2. Million Visual Analogue Scale[143]
3. Roland Morris Disability Questionnaire[144]
4. Waddell Disability Index[126]
5. Clinical Back Pain Questionnaire (Aberdeen Low Back Scale)[124]
6. Lumbar Spine Outcomes Score (LSOQ)[125,145,146]
7. STarT BackScreening Tool (see http://painhealth.csse.uwa.edu.au/pain-self-checks. html)
8. Short Form Orebro Musculoskeletal Pain Screening Questionnaire (https://www.aci.health.nsw.gov.au/__data/assets/pdf_file/0003/212907/OMPSQ-10.pdf)

Descriptive information for the selected measures is given in **Table 17-5**. Problems in the assessment of outcome for patients with LBP have been subject to considerable recent investigation with little agreement in the literature concerning which outcome measure to use, with few reports using the same criteria for assessing patients.[147,148] The LSOQ appears to be acceptable to patients, easy to administer, highly reliable, valid, and responsive (see **Display 17-4**). It provides information on demographics, pain severity, functional disability, psychologic distress, physical symptoms, health care utilization, and satisfaction. It should be considered for use in both clinical and research applications as well as regulatory review involving patients with LBP complaints. The STarT Back Screening Tool is designed for use in a primary care setting and is a validated tool that stratifies patients into

TABLE 17-5

Descriptive Information for Selected Back-Specific Functional Instruments

INSTRUMENT	CONTENT	SCORING	COMPLETION TIME (min)
Oswestry Low Back Disability Score	Pain intensity, interference with sleep, self-care, walking, sitting, standing, lifting, sex life, traveling, social life.	0–100	5
Million Visual Analogue Scale	Pain intensity, interference with physical activities, interference with work, overall handicap.	0–100	5–10
Roland Morris Disability Questionnaire	Physical activities, housework, mobility, dressing, getting help, appetite, irritability, pain severity.	0–24	5
Waddell Disability Index	Heavy lifting, sitting, walking, standing, social life, travel, sex life, sleep, footwear.	0–9	5
Low Back Outcome Score	Current pain, employment, domestic and sport activities, use of drugs and medical services, rest, sex life, five daily activities.	0–75	5

DISPLAY 17-4

The Low Back Outcome Score

Please mark on the line below how much pain you have had from your back on average over the past week.

0 1 2 3 4 5 6 7 8 9 10

No pain at all — Maximum pain possible

Please tick the answer which most closely describes you on each of the following six sections.

At present are you working

Full time at your usual job	☐ 9
Full time at a lighter job	☐ 6
Part-time	☐ 3
Not working/unemployed	☐ 0
Disability benefit	☐ 0
Housewife/student/retired	☐ score as for chores

At present can you undertake household chores or odd jobs

Normally	☐ 9
As much as usual but more slowly	☐ 6
A few, not as many as usual	☐ 3
Not at all	☐ 0

At present can you undertake sports or active pursuits (e.g., dancing)

As much as usual	☐ 9
Almost as much as usual	☐ 6
Some, much less than usual	☐ 3
Not at all	☐ 0

Do you have to rest during the day because of pain?

Not at all	☐ 6
A little	☐ 4
Half the day	☐ 2
Over half the day	☐ 0

How often do you have a consultation with a doctor or have any treatment (e.g., physiotherapy) for your pain?

Never	☐ 6
Rarely	☐ 4
About once a month	☐ 2
More than once a month	☐ 0

How often do you have to take painkillers for your pain?

Never	☐ 6
Occasionally	☐ 4
Almost every day	☐ 2
Several times each day	☐ 0

Please tick the box that best describes how much your back pain affects the following activities.

	No Effect	Mildly/Not Much	Moderately/ Difficult	Severely/ Impossible
Sex life	☐ 6	☐ 4	☐ 2	☐ 0
Sleeping	☐ 3	☐ 2	☐ 1	☐ 0
Walking	☐ 3	☐ 2	☐ 1	☐ 0
Traveling	☐ 3	☐ 2	☐ 1	☐ 0
Dressing	☐ 3	☐ 2	☐ 1	☐ 0

Pain scale readings are equivalent to the following scores: 0–2 = 9; 3–4 = 6; 5–6 = 3; 7–10 = 0. Patients are placed in one of four outcome categories based on overall scores: 65 or higher (excellent), 50 or higher (good), 30 or higher (fair), and lower than 30 (poor).

Adapted from Holt AE, Shaw NJ, Shetty A, et al. The reliability of the Low Back Outcome Score for Back Pain. Spine. 2002;27:206–210.

risk groups: low-risk (LBP with little distress), medium-risk (moderate levels of pain, disability, and distress), and high-risk patients (high levels of pain, disability and distress). These risk groups are predictive of chronicity, disability, and work absenteeism, providing a basis for targeted stratified care.[149] The Short Form Orebro Musculoskeletal Pain Screening Questionnaire also identifies people with high psychosocial risk status.[150] As this questionnaire includes occupational risk factors, it may be more suited to use for work-related LBP.

THERAPEUTIC EXERCISE INTERVENTION FOR COMMON IMPAIRMENTS OF BODY FUNCTIONS

The evidence supports a patient-centered approach to LBP care that addresses the multidimensional influences on the disorder and empowers patients to self-manage. Therapeutic exercise as an intervention is a powerful tool to empower patients to treat, manage, and prevent, or lessen the impact of future exacerbations. The heterogenous nature of the underlying drivers of LBP makes it impossible to provide a one-size-fits-all exercise regimen for the treatment of LBP. What we do know is that early intervention that fits the right treatment to the underlying drivers can reduce symptoms, improve function and participation, and reduce cost. Therapeutic exercise intervention must be prescriptive and based upon each individual's unique combination of systems and subsystems affected, staging of the condition, and functional and participation restrictions. As a general philosophical approach, acute LBP should follow basic principles of intervention (see **Display 17-5**).

Because this text is not presenting a treatment approach related to a specific classification system, the exercises are based on the impairments of body functions detailed in Unit 2 and are presented in alphabetical order. Impairments of body functions have been separated for clarity of presentation, though, in reality, patients most often present with a complex interaction of pathology and structural, physiologic, and psychologic impairments. The exercise examples are not meant to demonstrate a comprehensive approach to the treatment of physiologic impairments; they were chosen to illustrate principles and a reasonable approach to the use of exercise for the lumbopelvic region. Principles related to work-conditioning programs, although often used in addressing lumbopelvic dysfunction, are not covered in this text.

Aerobic Capacity Impairment

Aerobic capacity impairment can be considered a secondary condition resulting from the incapacitation associated with CLBP or a lifestyle risk factor contributing to the development of CLBP. Research supports the fact that aerobic exercise alone is not enough to prevent recurrence of LBP, although aerobic exercise is beneficial for patients with lumbopelvic syndromes.[57] Aerobic exercise enhances healing, assists with weight loss, and has favorable psychologic effects, such as reduction in anxiety and depression.[151]

Typically, the patient is limited by musculoskeletal pain in working at the optimal target heart rate necessary for producing aerobic gains. Aerobic exercise is initially prescribed "to tolerance" and is progressively increased as the patient's signs and symptoms improve. The goal is to exercise at 60% to 80% of age-predicted maximal heart rate (220—age) for 30 to 50 minutes, three to five times per week. The mode of exercise (e.g., biking, swimming, walking, jogging) should be based on the patient's desires and the postures and movements that do not aggravate symptoms. For example, if walking does not increase or relieve pain, but sitting increases pain, walking should be encouraged and biking should be discouraged. If weight-bearing aerobic exercise is chosen, the physical therapist may need to counsel the patient in choosing proper footwear to ensure the best weight-bearing dynamics possible. Orthotic prescription may be necessary to optimize ground reaction forces (see Chapter 21). If weight-bearing exercise is unbearable, water is often a well-tolerated medium for aerobic exercise by a person with lumbopelvic dysfunction (see Chapter 16). Another option is to walk with some type of unloading mechanism either through harness apparatus or the use of crutches, walker, grocery cart, or stroller.

DISPLAY 17-5

Activities and Exercises to Recommend to Patients with Acute LBP

Advice for Patients

"Pain with movement does not mean you are doing harm"
"Gradually increase your activity levels to build tissue tolerance and allow time for tissue adaptation"
"It is safe to exercise and work with back pain—you may just have to modify what you do based on aggravating factors in the first several weeks"

The Guidelines Below May Assist This Process

Relaxation

Encourage diaphragmatic breathing (see Chapter 24)
Facilitate awareness of tension in the muscles of the trunk and encourage mindful relaxation

Mobility Exercises

Encourage gentle flexibility-based exercises for spine and hips progressing from non-weight-bearing to weight-bearing (e.g., hip and back stretches lying down, progress to sitting and standing)

Functional Movement Training

Encourage relaxed movements and avoidance of guarded movements
Discourage breath-holding and propping with the hands during load transfer
Encourage patients to incorporate movement training into their usual daily activities (e.g., walking, bending, twisting) and strengthening and conditioning if relevant to the patient (e.g., squatting for someone who is involved in manual work)

Physical Activity

Aim for patients to undertake aerobic exercise for 20 to 30 minutes each day that does not excessively exacerbate pain (e.g., walking, cycling [leg or arm cycling] or swimming based on comfort and preference)
Explain to patients that they may need to exercise for a shorter duration initially, or exercise for short periods throughout the day to build exercise tolerance
Advise patients to increase activity gradually (e.g., 10% per week)

Balance and Coordination Impairment

The human postural system operates on the basis of integrated information from three independent sources: vestibular, visual, and somatosensory. It is conceivable that a derangement of any of these systems will influence the overall control of the postural system. Healthy persons have control of sufficient variability in motor learning and balance strategies, enabling adaptation to altered postural demands without running the risk of jeopardizing performance.[152,153] There is evidence that LBP patients may be prone to excessive postural sway, poor balance reactions, and altered strategies for balance.[154–159] Patients with LBP have been shown to display increased visual dependence, reduced hip and increased ankle strategy for postural control in quiet standing, and altered postural control in single limb stance[154–159] (**Evidence and Research 17-5**).

EVIDENCE and RESEARCH 17-5

Visual Dependence and Postural Control in LBP

A study by Lee et al.[160] evaluated standing stability in subjects with and without recurrent LBP during single limb stance for 25 seconds and visual condition (eyes open vs. eyes closed). Twenty-seven subjects without LBP and 15 subjects with LBP participated in the study. Participants with LBP were able to balance on their dominant leg for less time with their eyes closed compared to the healthy subjects (0.68 ± 0.30 for control vs. 0.37 ± 0.32 for LBP, $T = -3.23$, $P = 0.002$). This sensitive detection of imbalance with postural stability is important to understand compensatory mechanisms and for effective rehabilitation strategies in patients with LBP.

In addition, it has been shown that patients with LBP seem to adopt a body stiffening strategy when balance is challenged.[161] The question arises whether, and to what extent, mechanisms associated with pain, fear, and altered lumbosacral proprioceptive acuity alter postural control in anticipation of postural instability. This stiffening strategy (e.g., cocontraction of trunk muscles) when postural instability is anticipated could lead to more compressive forces on the spine.[162]

Authorities acknowledge the necessity of balance work in the rehabilitation of lumbopelvic patients.[163] Gym balls, wobble boards, slide boards, and foam rolls can be used to enhance proprioception and teach optimal balance strategies (e.g., use of intrinsic and superficial muscles as needed versus superficial only, improved use of hip strategy, decreased reliance on visual feedback). Aspects of proprioceptive training can be incorporated at any stage of rehabilitation, as illustrated by examples focusing on balance and coordination discussed in other sections of this chapter. After an activity is performed correctly on a stable surface, the patient can be positioned on a moving base of support, such as a gym ball (**Fig. 17-10**) or foam roll (**Fig. 17-11**) and progressed from double limb to single limb support. Any activity challenging balance and proprioception must be performed with confidence and without guarded, splinting, or overactive strategies, emphasizing correct body position and shaping toward a more nuanced strategy as balance control is achieved. Over time, the rate of movement is progressed while accuracy is maintained.

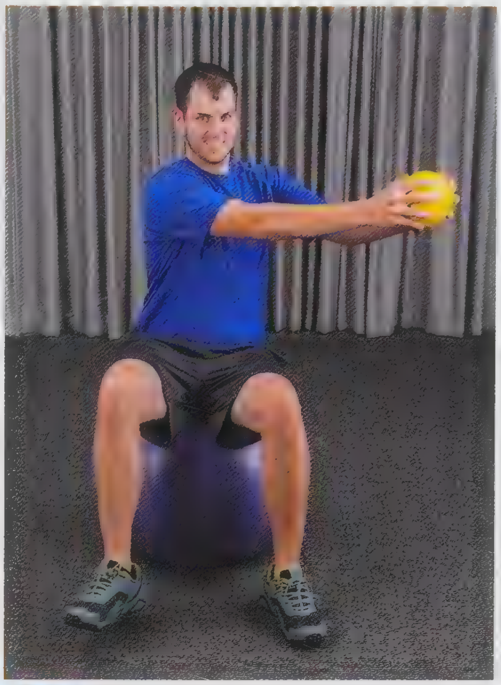

FIGURE 17-10 Sitting on a gym ball can add an element of difficulty to the stability phase of lumbopelvic exercise. Care must be taken to ensure quality of recruitment strategy as dominant strategies may emerge on the unstable surface.

FIGURE 17-11 Standing on two foam rolls is easier than standing on one foam roll. For the stability phase, the goal is to reach to the side through rotation of the feet and hips with the spine in neutral. For controlled mobility, the goal is to move the feet, hips, thoracic, and lumbar spine in a combined rotational movement pattern. However, movement should be emphasized at the feet, hips, and thoracic spine, with very little rotation occurring in the lumbar spine.

Muscle Performance Impairment

Treatment of general muscle performance impairments in the lumbopelvic region has limitations. Evidence suggests that muscular dysfunction in the presence of lumbopelvic syndromes does not so much affect the strength of the trunk musculature as it influences the patterns of trunk muscle recruitment.[164–167] Several electromyographic (EMG) studies have reported increased activation of the erector spinae muscle in study participants with LBP during tasks such as trunk flexion,[168–172] and the absence of relaxation of the erector spinae at the end of range of trunk flexion (the "flexion-relaxation" phenomenon) has been shown to be associated with reduced intervertebral motion.[169] In contrast to the increased activation of the superficial trunk muscles, activity of the intrinsic spinal muscles has been found to be either increased,[173,174] decreased,[175,176] similar,[175,177] or delayed[178,179] in patients with LBP. Similarly, activity of the deep abdominal muscle, transversus abdominis, has been found to be delayed in study participants with LBP.[50,129,180] Subtle shifts in the patterns of muscle recruitment result in some muscles being relatively underused in the force couple, whereas other muscles relatively dominate the force couple.[31] The cause and effect relationships of these subtle shifts in muscle recruitment patterns cannot be determined and should be thought of as part of a continuous cycle of altered recruitment strategies and movement patterns. In the presence of trunk muscle guarding and stiffness, which paradoxically increase spinal loading and pain,[71] performing relaxation of trunk muscles incorporated with graded movement training can be helpful to unload sensitized spinal structures and allow normal movements to occur.

Lack of muscle endurance has been shown to also be a prime impairment in muscle performance. Many investigators have reported diminished trunk muscle endurance and increased rates of muscular fatigue in patients with LBP compared with healthy individuals, even when strength measures testing results are within normal limits.[106,107,165,181] Sophisticated EMG testing using a technique called power spectrum analysis has identified that the LM is the back extensor most susceptible to endurance changes.[166,182] These studies indicate the need to provide an endurance training component in the course of a total rehabilitation program. No special exercise recommendations are needed, because the dosage can be modified for exercises prescribed for force or torque production to satisfy endurance goals (i.e., higher repetitions with lower loads).

Mechanisms such as muscle strain, pain, inflammation, neurologic pathology, or general deconditioning can contribute to muscle performance impairment. The clinician must consider the possible mechanisms contributing to the more dramatic as well as subtle changes in muscle recruitment patterns to develop the appropriate exercise intervention. After the underlying mechanism(s) are identified, precise exercise can be prescribed to activate, restore, or improve muscle control and performance of the trunk muscles. The following section describes exercises to establish control over specific trunk muscles. Subsequent sections investigate the various causes of reduced muscle performance around the lumbar spine and recommend activities and techniques to alleviate individual causes of muscle performance impairment.

Exercise for Motor Control

As already stated, research has established a link between lumbar dysfunction and altered muscle performance and neuromuscular control of the *intrinsic or deep trunk muscles* defined to include the TrA, LM, pelvic floor, and diaphragm.[164,183]

General strengthening programs for the trunk muscles may not adequately recruit or improve the muscle performance of the deep and often underused trunk muscles. Localized and specific exercise aimed at training neuromuscular control of the intrinsic spinal muscles may be critical to improving subtle patterns of muscle recruitment necessary for optimal segmental stability in the lumbar spine.[70,184,185] Similarly, specific exercises aimed at training neuromuscular control and muscle performance of the intrinsic spinal muscles plus the gluteus medius, gluteus maximus, biceps femoris, deep hip lateral rotators, and latissimus dorsi may be critical for optimal SIJ stability and load transference from the upper and lower quarter to the low back.[186,187] A pelvic floor contraction, in particular (see Chapter 18), is indicated for the chronic, hypermobile SIJ because of the shared muscle of the piriformis and obturator internus and the important supportive function of the pelvic floor to the pelvic girdle.[188]

Before presenting the exercise recommendations for the intrinsic spinal muscles, three additional concepts must be addressed:

1. Exercises chosen should promote optimal length–tension properties of the trunk and pelvic girdle muscles. The affected muscles should be trained at the length desired for function. Too often, the lumbar spinal muscles are strengthened in the lengthened range because of use of a Valsalva maneuver, resulting in abdominal distension or "pooching," lumbar flexion, and bearing down on the pelvic floor (see **Fig. 17-12**). A disadvantage to strengthening the muscles in a lengthened range is the contribution this may have toward altered length–tension properties. The lumbar spinal muscles need to be of the right length to support the spine and pelvis in good static alignment and have the correct length–tension properties to continue to support the spine and pelvis during dynamic activities.
2. A second important principle is specificity of training or the principle of specific adaptation to imposed demands (SAID principle). For example, although a sit-up is a functional activity, it is not the primary function of all the abdominal muscles for BADLs and IADLs. It has been proposed that the intrinsic spinal muscles are linked with the control of stability of the spine against the perturbation produced by movement of the limbs.[50] The primary role for the deep trunk muscles is to provide static stability via isometric contraction to the trunk during movements of the extremities. In addition, they also offer dynamic stability during trunk movements. It is important to realize that all the trunk muscles play a role in static and dynamic control of the trunk dependent on the demand placed on the spine and the level of skill involved in performing the activity.
3. A third principle governs exercise progression. The stages of motor control (i.e., mobility, stability, controlled mobility, and skill) can be used to progress lumbopelvic exercise. Mobility and stability usually occur together in the lumbopelvic region. Stability is often a problem at the dysfunctional segmental level, and mobility is more likely to be a problem at an adjacent

A B

FIGURE 17-12 **(A)** Use of the abdominal muscles in a lengthened range. Note protrusion of the umbilicus. **(B)** Use of the oblique abdominal muscles and transversus abdominis (TrA) in the short range.

lumbar level or in some associated region (e.g., hip, thoracic spine, shoulder girdle). To be most effective, simultaneous reconciliation of mobility and stability impairments is desired. When developing a program focusing on stability, the chosen direction of force must be based on the directions in which the spine is most susceptible to motion and the directions most correlated with symptom reproduction.[31,188,189] After adequate mobility and stability are achieved, the patient is progressed to controlled mobility (BADLs) and then to skill-level activities (IADLs). According to a study by Richardson and Jull,[57] patients who followed a graded program of exercise to improve the muscle performance and neuromuscular control of the intrinsic spinal muscles experienced pain resolution within 4 weeks, with only a 29% recurrence rate at 9 months. These results were compared with a control group of patients with LBP who exercised aerobically by jogging and swimming. They too were pain-free at 4 weeks, but they had a LBP recurrence rate of 79% at 9 months. With certain subgroups of patients, specificity seems to be the key to the proper prescription of the exercises that correspond with improved neuromuscular control and muscle performance of the deep trunk muscles. This treatment approach demands a high level of skill by the instructor in teaching the exercise and a high level of patient adherence and attention to detail. Continual reassessment of muscle recruitment capabilities and muscle performance is necessary to progress or modify the exercise for optimal results.

Patient-related instruction is the first step to establish awareness over the individual intrinsic spinal muscles. **Display 17-6** contains specific instruction for the clinician as to how to train the intrinsic spinal muscles. **Patient-Related Instruction 17-1** describes in patient terms, techniques to activate the intrinsic spinal muscles.

Self-Management 17-1 describes a series of exercises in the supine position to progressively challenge the intrinsic and global spinal muscles. Beyond level I, most individuals will require recruitment of global muscles for stabilization in addition to the recruitment of the intrinsic muscles. The exercise is progressed from level I to level V through a combination of progressively longer lever arms and increased loads. The direction of forces imposed on the spine also must be considered in advancing the

DISPLAY 17-6

How to Teach the Components of the Intrinsic Spinal Muscle Group Synergy

- The clinician must first determine the presence or absence of the intrinsic spinal muscles synergy by palpating the TrA, LM, and external palpation of the pelvic floor if necessary (see Chapter 18). Although it is not necessary to facilitate the intrinsic spinal muscles in this manner, often the easiest component of the intrinsic spinal muscles to activate is the pelvic floor (see Chapter 18 and Patient-Related Instruction 17-1). After the patient has contracted the pelvic floor, the therapist can palpate other components of the intrinsic spinal muscles.
- The **TrA** can be palpated medially and deep to the ASIS. Contraction of the TrA should feel like taut fascia under the fingertips, whereas contraction of the IO will push the fingertips out superficially. Toning down the force of contraction will assist in isolating the TrA. Another indication that the TrA has contracted is that the waist will pull inward laterally like the function of a girdle, and the umbilicus will be gently pulled in toward the spine. The umbilicus pulled upward toward the ribs coupled with rib cage depression indicates dominance of the RA and is a common mistake.
- The **LM** can be palpated best at the L5 level just medial and deep to the spinous process. If the LM is not contracting, the therapist can provide an explanation to the patient as to the function of this muscle with respect to sacral nutation, lumbar extension, and stabilization against rotational forces. Visually, show the patient models and pictures of the region and LM muscles. Cue for tactile input by palpating directly over the LM at the affected level. Key to isolation of the LM is to facilitate a submaximal isometric contraction. Patients often have initial difficulty in facilitating a LM contraction in a home exercise program. This is particularly true for patients with a chronic condition and for postoperative patients. Manual techniques can be used to help facilitate recruitment in the early stages of neuromuscular training. Figure A illustrates a manual technique for facilitating recruitment of LM musculature. Another technique is to use isometric hip lateral rotation (see Patient-Related Instruction 17-1). After a consistent

(continued)

DISPLAY 17-6

How to Teach the Components of the Intrinsic Spinal Muscle Group Synergy (*continued*)

LM contraction can be elicited, ask the patient to perform a body check and determine whether focusing on contraction of the LM facilitated a pelvic floor contraction. The clinician can palpate the TrA to determine whether it has contracted in synergy with the LM and pelvic floor. The clinician can ask the patient to vary the initial muscle activation focus from the pelvic floor, to the LM, to the TrA to ensure the synergy is intact.

- Contraction of the intrinsic spinal muscles should occur in conjunction with good breathing habits. Ask the patient to perform a deep diaphragmatic breath and assess the quality of the inhalation and exhalation technique. If the quality is poor, teach the patient diaphragmatic breathing as discussed in Chapter 24. Next, ask the patient to take a deep diaphragmatic breath with a relaxed, not forced, exhalation. Before the next breath, ask the patient to slowly and gently contract the intrinsic spinal muscles synergy, then resume normal relaxed breathing. After relaxed breathing can be performed while sustaining an intrinsic spinal muscles contraction, the intrinsic spinal muscles supine progression (see Self-Management 17-1) and intrinsic spinal muscles series (Self-Management 17-2) can be prescribed.

FIGURE A Sidelying manually resisted lumbar multifidus exercise. Restoration of lumbar multifidus activity may need to begin by facilitating the muscle at the specific level of spinal pathology with a manual technique. Low-load rotary resistance is applied to the affected segment in a sidelying position as if testing for passive physiologic intervertebral movement. The patient is encouraged to maintain submaximal contraction against the therapist's resistance into rotation. The therapist palpates the segmental level to ensure multifidus activity. EMG reveals that the multifidus is active in rotation both ipsilateral and contralateral as a stabilizer.[190] The primary role of the multifidus is to oppose the flexion moment associated with rotation.

Patient-Related Instruction 17-1

How to Activate Your Intrinsic Spinal Muscles

What are the Intrinsic Spinal Muscles?

The intrinsic spinal muscles refers to a group of deep muscles that, under normal circumstances, work together to provide stability to the lower back and pelvis. In normal function, they should contract automatically and simultaneously before any upper extremity, lower extremity, or trunk movement—in effect, before any movement you make. The intrinsic spinal muscles include

- The diaphragm—your primary breathing muscle
- The pelvic floor—attached to the bony ring of the pelvis from the tailbone to the pubic bone
- The lumbar multifidus—the deepest layer of the back muscles
- The TrA—the deepest layer of the abdominal muscles

How Do You Activate Them?

This section describes intrinsic spinal muscle awareness activities. These activities must be mastered before using the intrinsic spinal muscles with more advanced self-management activities and activities of daily living. NOTE: Your physical therapist will work with you individually to identify the best strategy to initiate your intrinsic spinal muscles.

- To contract the pelvic floor:
  Think of slowly and gently pulling the tip of your tailbone toward your pubic bone. Try not to contract the rectal portion of your pelvic floor, but rather more of the portion closer to your pubic bone. To see if you are using the correct muscles, the next time that you urinate, let out half the volume of your bladder and then stop the flow of urine with the least amount of effort possible. Be aware of which muscles you are using. *Note*: This *test* is not to be used as a daily exercise. It is simply a method for you to identify which muscles make up the pelvic floor. Another image is to think about an elastic cord anchored between your feet and extending up toward your umbilicus. Think about pulling the cord tight from the anchor point upward toward your umbilicus. Monitor your seat and inner thigh muscles to be sure you are relaxed in these muscle groups.
- To contract the lumbar multifidus
  Think of initiating a *very tiny* tilt of the sacrum (moving the tailbone away from your body as if to arch your back). The contraction should be isometric (the muscle contracts but the joint does not move). Another image is to think about an elastic cord running between your "dimples" in your low back. Think about tightening the cord between your dimples. This may help you to feel the contraction of the lumbar multifidii.
  Another method to begin to feel your lumbar multifidus is to lie on the floor with your knees bent and your heel pressing into the leg of a table (pictured). Press your heel *gently* (about 10% effort) into the leg of the table. Think about contracting your "dimple" muscle as you perform the push. Hold for 10 seconds. Repeat four times each leg.
- To contract the TrA
  Slowly and gently pull your lower abdomen inward. Imagine trying to "zip up" a slightly tight pair of pants. You can feel the tension in the muscle under a finger placed 1 in inward from

Patient-Related Instruction 17-1 (*continued*)

the front pelvic bones. You should feel a tensing of the deep muscle, not a bulging of the more superficial muscles. Another image is to think about an elastic cord running between the two prominent pelvic bones (called the *ASIS*). Think about tightening the cord between these two bones. This may help you to isolate your TrA from the other abdominal muscles. Another option is to try humming. Hum at a low level, and palpate 1 in inward from your pelvic bones. You should feel the deep muscles tense, but the superficial muscles should stay relaxed.

- To activate the intrinsic spinal muscles synergy
  Your physical therapist will help you to identify which intrinsic spinal muscle best activates the entire intrinsic spinal muscle group. Next, take a deep diaphragmatic breath, allowing your ribs to expand to the front, sides, and back. Allow the air to exhale naturally. Before you take another breath, *slowly and gently* contract your intrinsic spinal muscles. Next, resume normal breathing while maintaining contraction of your intrinsic spinal muscles. Your physical therapist will instruct you how to proceed from this step.

- Positions to activate your intrinsic spinal muscles:

___ back lying	___ stomach lying
___ sidelying	___ quadruped
___ sitting	___ standing
___ squatting	___ walking

SELF-MANAGEMENT 17-1
Supine Intrinsic Spinal Muscle Progression

Purpose: A back lying activity to strengthen and improve muscle control over your deep trunk muscles including your LM, TrA, and pelvic floor. Use of progressively more difficult leg movements challenges your intrinsic spinal muscles. Higher levels will require use of more superficial muscles, but the intrinsic spinal muscles should still be activated as the local stabilization strategy. You can think of this progression as strengthening from the "inside out."

Starting Position: Lie on your back on a firm surface, such as the floor, with knees bent, feet flat on the floor, and shoes off. To feel the TrA, place your fingertips deep to the inside of your front pelvic bones (your physical therapist will show you the exact location). Refer to the Patient-Related Instruction sheet that teaches how to contract each muscle of the intrinsic spinal muscles. Take a deep diaphragmatic breath in (your physical therapist will teach you the correct technique for diaphragmatic breathing). Allow the exhalation to occur naturally; do not force the exhalation. Before you take your next breath, activate your intrinsic spinal muscles. Resume normal breathing. After normal breathing has been established, you can begin the prescribed level of this exercise.

TIP:

- The abdominal muscles must be pulled in, not ***pooched out*** or distended. The pelvic floor must be pulled up, not pushed downward. These errors in strategy often occur as increased strain is placed on the abdominal and pelvic floor muscles from the progressively difficult leg movements.
- The lumbar spine must remain in a neutral position with a ***slight*** forward curve—just enough to fit your hand between your back and the floor—and not move into further forward curve or excessively flat. If needed, you may use a small hand towel rolled under the small of your back to provide feedback as to the position of your spine.

Movement Technique: Your physical therapist will check off the level(s) you are to perform with the appropriate dosage.

Level I: While keeping your intrinsic spinal muscles activated, *slowly* slide one leg down to a straight position followed by sliding the other leg down so that both are in a straight position. If your back is arched, you may need to limit your heel slide so that your pelvis is not pulled out of a neutral position. Next, slide one leg up the table to a flexed hip and knee position. After you have completed this movement, slide the same leg back to a straight position. Repeat with the opposite limb.

TIP: The pelvis must remain in neutral and not rotate. The spine must remain in neutral and not flatten, arch, or rotate. To keep your spine and pelvis stable you must be sure to keep your intrinsic spinal muscles activated, especially during the initiation of the heel slide because this is the moment when the neutral position is often lost.

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________

(*continued*)

SELF-MANAGEMENT 17-1

Supine Intrinsic Spinal Muscle Progression (*continued*)

Level II: Assume the start position. Lift one leg off the floor until your hip is at a 90-degree angle with the floor. Next, slide the other leg down to a fully extended position while keeping the opposite leg elevated off the floor. Slide the leg back to the same position as the nonmoving limb. Repeat with the other leg.

TIP: As soon as you are unable to stabilize the pelvis and lumbar spine with your intrinsic spinal muscles, stop and rest for a minute before continuing. If your hip flexors (front thigh muscles) are short, you will not be able to fully extend your leg without moving your spine or pelvis out of neutral. In this case, stop sliding your leg when you notice your spine or pelvis moving from the neutral position. Eventually, your hip flexor muscles will lengthen as your abdominal muscles shorten and become stronger.

Dosage:

Sets/Repetitions: ______________________________

Frequency: ______________________________

Level III: Repeat level II, but instead of sliding your leg down and back, glide your leg down and back. The nonmoving leg should remain in a flexed position off the floor.

TIP: It is easy to transition from a flat abdomen to a pooched abdomen and from keeping the pelvic floor pulled upward to pushing it downward at this level. Keep the intrinsic spinal muscles activated and continue to breathe.

Dosage:

Sets/Repetitions: ______________________________

Frequency: ______________________________

Level IV: Begin from the starting position, and lift both legs off the floor at the same time to the 90-degree position. Return to the start position by lowering both legs at the same time. Slide both legs simultaneously to the fully extended position, and slide both legs back to the start position.

Dosage:

Sets/Repetitions: ______________________________

Frequency: ______________________________

Level V: Repeat level IV, but glide both legs down and back to the start position.

Dosage:

Sets/repetitions ______________________________

Frequency ______________________________

exercise, and levels may be interchanged depending on which direction of force the patient has most difficulty controlling.

It is important that the exercise is not progressed to the next level unless the prescribed number of repetitions of the previous level can be achieved *and* the following criteria have been met:

- The lumbar spine should minimally deviate from the initial starting position, which should be in a neutral spine position (**Table 17-6**).
- The trunk muscles should be functioning at optimal lengths (i.e., not lengthened).
- The RA should not be dominating the synergy.
- Valsalva maneuver is discouraged.

Self-Management 17-2 challenges the intrinsic spinal muscles in a variety of positions and motor control levels. As the exercises become more difficult, superficial muscles will contract concurrently with the intrinsic spinal

TABLE 17-6

Neutral and Functional Spine Positions

SPINE POSITION	DEFINITION	CLINICAL JUDGMENT OF POSITION
Neutral	Lumbar spine in slight extension. Anterior superior iliac spine and pubic symphysis in the same vertical plane[a]	In supine, enough lumbar extension curve that the clinician can palpate the lumbar spinous processes, but not so much lumbar extension so as to pass hand through to the other side
Functional spine	Position of greatest stability, least stress, fewest symptoms for an individual for any given activity	Varies with pathology, activity, and symptoms

[a]Maitland GD. Vertebral Manipulation. 4th Ed. London: Butterworth, 1977.

SELF-MANAGEMENT 17-2
Intrinsic Spinal Muscle Series

Purpose: The purpose of this series of activities is to progressively recruit your intrinsic spinal muscles, aided by your more superficial trunk muscles as needed, in a variety of positions. Be sure to activate your intrinsic spinal muscles prior to and during these various activities to strengthen "from the inside out." Your physical therapist will check off the positions you are able to perform with good technique and will teach you appropriate variations and progressions of these activities.

Back Lying: You can perform the back lying intrinsic spinal muscle progression in this position. Refer to the back lying intrinsic spinal muscle progression handout.

Sidelying:

Start Position: Lie on your side with your hips and knees bent about 45 degrees. Place one or two pillows between your knees. You may need to place a small towel under your waist.

Movement Technique: Slowly rotate your hip so that your kneecap rotates slightly upward. Do not allow your pelvis to move.

TIP: You can advance this activity to a straighter hip position and add a lifting movement with your thigh. Your physical therapist will teach you this progression and provide you with a more detailed handout.

Dosage:

Repetitions: ______________________________

Frequency: ______________________________

Stomach Lying:

Start Position: Lie on your stomach with a pillow positioned vertically under your chest and hips. Bend your elbows and rest your hands on the back of your head.

Movement Technique: Lift your elbows only about 1/2 in off the surface. Hold the position for 5 to 10 seconds. Return your elbows to the start position.

TIP: You can advance this exercise by changing your arm positions and movements or by adding leg movements. Your physical therapist will teach you the appropriate progression and provide you with a more detailed handout.

Dosage:

Repetitions: ______________________________

Frequency: ______________________________

Quadruped:

Start Position: Assume a position on your hands and knees, centering your hips over your knees and your shoulders over your hands. Rotate your pelvis so that your hips are at a 90-degree angle with your thigh, spine straight, and head in line with the rest of your spine.

TIP: Do not round your spine upward, drop your head, or arch your low back excessively.

Movement Technique: Lift one arm off the table top surface. It is not important to lift the arm fully overhead. Return your hand to the supporting surface.

TIP: Do not let your spine and pelvis move from the start position when lifting your hand. Your physical therapist will teach you how to advance this exercise with variations in the start position or by adding arm and leg movements together.

Dosage:

Repetitions: ______________________________

Frequency: ______________________________

Sitting:

Start Position: Sit on a chair with a straight seat pan and straight back. Hips and pelvis should be at a right angle with the seat pan. Shoulders should be centered over hips.

Movement Technique: Slowly straighten one leg as far as possible without letting your spine or pelvis move out of the start position. Return to the start position and repeat with the other leg.

TIP: Do not let your spine or pelvis move backward (slump) or rotate. Your physical therapist can advance this exercise with combined arm and leg movements.

Dosage:

Repetitions: ______________________________

Frequency: ______________________________

Activities of Daily Living: Your physical therapist will teach you how to engage your intrinsic spinal muscles with various movements used in your daily activities such as squatting, stair stepping, lifting, reaching, or walking.

muscles. Strengthening should continue to occur "from the inside out."

Another exercise focusing on the ability of the intrinsic spinal muscles to stabilize the spine and pelvis is illustrated in **Self-Management 17-3**. This exercise challenges the ability of the intrinsic spinal muscles to stabilize against extension and rotation torques. The introduction of rotational torques requires the synergy of abdominal obliques to control the rotational torques. For example, if the patient is having difficulty controlling right pelvic rotation with a right hip abduction/extension/lateral rotation movement, the patient is cued to recruit the left external oblique and right internal oblique to control the rotation.

An increased measure of difficulty can be introduced to any of these exercises by using half or full foam rolls or gym balls. An unstable surface is believed to facilitate recruitment of the deep trunk muscles and stimulate the proprioceptors and balance reactions that are necessary for function.[154,191–194] Care must be taken to introduce this variation when the patient is capable of using subtle recruitment patterns and does not use excessive superficial muscle cocontraction to balance on the roll or ball.

As shown in the deep trunk muscle progressions, exercises emphasizing stability can be progressed to sitting or standing. In sitting, extremity movements can be used in much the same way as in supine positions to challenge the spine to stabilize against various directional forces, with the emphasis on using the entire lumbopelvic stabilizing system in a synergistic manner. For example, sitting while raising the arms in the sagittal plane can challenge the spine to stabilize against sagittal forces, and changing the movement to a unilateral arm raise or to a diagonal direction challenges the spine to stabilize against a transverse plane force. Sitting on a gym ball (Fig. 17-10) making the base of support unstable can further challenge sitting. The patient is encouraged to preset the intrinsic prior to beginning arm or leg movements. Stabilization progressions can also be developed in standing. Standing on a half or full foam roll can further challenge a standing progression (Fig. 17-11).

After neuromuscular control and adequate muscle performance are established, higher forces are required than can be supplied by the extremities alone. Dumbbells, weighted balls, and ankle weights can be used to progress the previously described exercises. Pulleys or elastic tubing can also be used to increase the force requirements of the trunk musculature to stabilize the spine. For example, the patient can be challenged to maintain trunk stability with an isometric contraction while pulling the weight up or down (**Fig. 17-13A**), side to side, or in a rotary motion. The emphasis initially is on dynamic motion at the hips (Fig. 17-13B), while avoiding motion through the trunk (i.e., stability level of stages of motor control). This exercise requires recruitment of the intrinsic as well as the more superficial trunk muscles and latissimus dorsi, gluteus maximus, gluteus medius, HSs, adductors, and hip rotators. All of these muscles are important in stabilization of the lumbar spine and pelvic girdle through the posterior, anterior, and oblique muscular systems. The load is increased as tolerated, and the speed is maintained at a low level.

Preparation for high-level functional return requires more advanced strength training that incorporates spine motion as part of the total movement pattern (i.e., controlled mobility and skill stages of motor control). Programs of this nature may include spine motions involving concentric and eccentric work with variable resistance in all planes (**Fig. 17-14**). At this stage, the various isokinetic machines (e.g., MedX, MET [Medical Exercise Therapy] rotation trainer) and any pulley apparatus or elastic resistance can be useful. The chosen movement pattern should be tailored to address the patient's activity limitations and participation restrictions.

One precaution to strength training involving spinal motion is in the presence of true articular instability. Rotation is often not well tolerated by those with a true articular instability of the lumbar spine or SIJ, particularly when the pelvis is fixed, as when sitting. Patients with true articular instability should avoid motion in the affected region and should train strictly in isometric modes. Vocational counseling or recreational modification may be necessary for those with true articular instability. In cases where lumbopelvic joint dysfunction fails to respond to physical therapy modes of stabilization, a trial of prolotherapy may be considered.

SELF-MANAGEMENT 17-3
Bent-Knee Fall-Out

Purpose: To train you to move your thigh independently of your pelvis, lengthen your inner thigh muscles, strengthen and shorten weak and overstretched abdominal muscles, and train your intrinsic spinal muscles to stabilize against rotational forces

Starting Position: Back lying with one leg straight and the other hip and knee bent with the foot flat on the floor. Place your hands on your pelvis as indicated by your physical therapist to monitor pelvic motion. Your physical therapist may ask you to place ____ pillows under the outside of the bent knee to let the knee fall into something.

TIP: Before beginning the movement, engage your intrinsic spinal muscles. Be sure to keep it engaged throughout the entire movement and continue to breathe in a relaxed manner.

Movement Technique: Let the bent knee fall out to the side. Do not allow motion to occur in the pelvis. Relax the inner thigh muscles completely before returning to the start position.

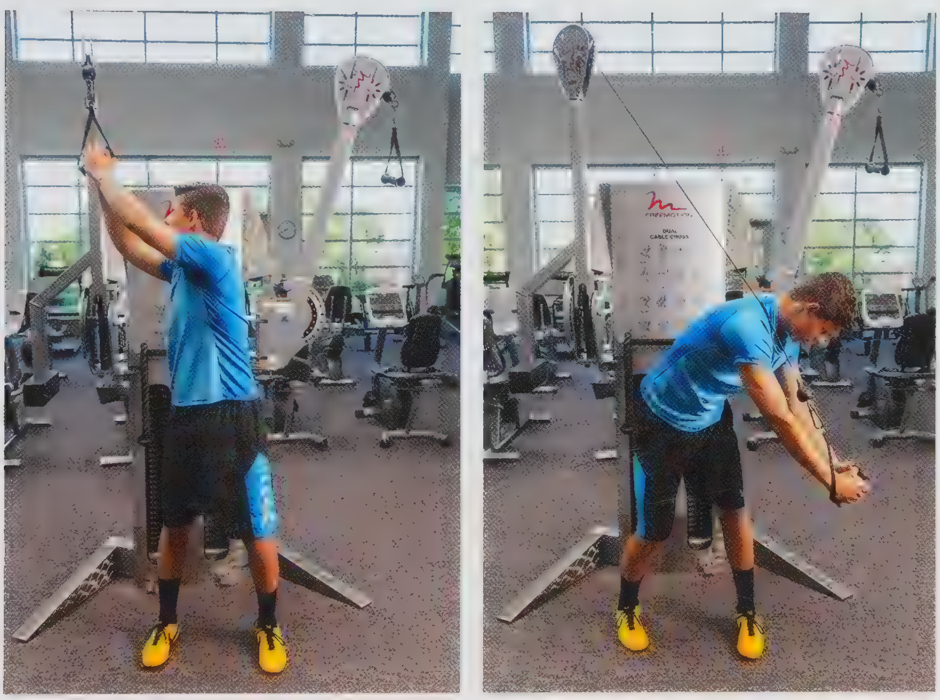
Dosage:

Repetitions: ______________________

Frequency: ______________________

A B

FIGURE 17-13 Tubing or pulleys can be used to add isometric resistance to create an upright stability activity. The goal is to maintain the spine in neutral through isometric contractions of the trunk musculature while the upper quarter, trunk, or lower quarter is moving in sagittal or transverse planes. In this example, the primary motion is occurring at the hips in the **(A)** sagittal or **(B)** transverse plane while the trunk remains in neutral alignment via isometric contractions of the intrinsic spinal muscles and more superficial trunk muscles.



A B

FIGURE 17-14 A progression from Figure 17-13 is controlled mobility. Instead of holding the trunk in neutral alignment, the lumbar spine is incorporated into combined movement patterns. Controlled mobility activities can be performed about separate planes of movement (e.g., sagittal, transverse, frontal plane). This figure demonstrates spine motion across all planes of motion. **(A)** start position and **(B)** end position. Caution must be practiced when moving in multiple complex planes of movement. Resistance can be applied through pulleys, elastic tubing, or weighted balls. The patient can perform these activities on an unstable surface such as foam rolls or high-density foam squares.

Dorman and co-workers observed in vitro that injecting chemical irritants into ligamentous tissue incites collagen proliferation.[195] Theoretically, scarring and tightening of the ligaments results in stabilization of the joint. Present studies provide no evidence that prolotherapy injections alone have a beneficial role in the treatment of CLBP. However, repeated ligament injections, irrespective of the solution used, may give prolonged partial relief of pain and disability as part of a multimodal treatment program, including exercise.[196] If injury to specific structures, such as ligaments or fascia, can be related to a specific clinical presentation and subsequent loss of function associated with pain, a case could be made for the use of prolotherapy.

As with all resistive exercise, after the muscle performance has reached a functional level, functional activities must be added to the program. However, it is unnecessary to wait until the end of the rehabilitation program to train functional activities. These should be considered from the beginning in designing the plan of care. For example, a minimal expectation for a patient in acute pain is to perform hip and knee flexion (see Self-Management 17-1, Level I) and bent-knee fall-outs (see Self-Management 17-3) in a supine position without pain. These duplicate movements which are necessary for pain-free bed mobility.

The definition of a successful functional outcome varies. Success for one person may be to perform light housework; for another, success may mean resuming heavy lifting in a job, playing a racket sport, or running a marathon. The ability to return to desired functional activities, regardless of the level, requires neuromuscular skill to control motion of the trunk and pelvic girdle in relation to the other extremities. Exercises addressing force or torque generation of the trunk muscles should be part of a comprehensive rehabilitation program. To achieve the neuromuscular skills necessary to return to activity at any level, functional exercises must be practiced with precise movement and recruitment patterns and for many repetitions frequently throughout the day. The exercises used to progress to a functional outcome are based on the postures and movement patterns unique to the patient. As such, no two functional retraining programs should be the same. Examples of functional activities are provided in the "Posture and Movement Impairment" section.

Neurologic Impairment and Pathology Mechanical (e.g., compression, traction) and biochemical (e.g., inflammatory response) factors arising from lumbopelvic dysfunction can result in nerve root pathology. For example, a herniated nucleus pulposus (HNP) at the L5–S1 level can cause mechanical and biochemical irritation to the L5 nerve root and medial branch of the dorsal rami, resulting in weakness in the gluteus medius and same-level LM, respectively.[197] The underlying pathology or impairment causing the mechanical or biochemical irritation must be treated, if possible, to affect the efferent input into the corresponding musculature. Exercise to improve force or torque capability of the affected musculature without treating the underlying neurologic dysfunction will prove futile. Nonetheless, exercise may be a large part of the solution. For example, excessive mobility at a segmental level can lead to degenerative disk disease,[198] which can result in nerve root compression and reduce efferent input into the associated musculature. Exercises to improve the stability of the offending segment coupled with exercises to improve the mobility of other segments or regions (e.g., thoracic spine rotation, hip joint flexion) can reduce the mechanical stress on the nerve root, thereby contributing to restoration of neurologic input into the affected musculature. Appropriate strengthening exercises for the affected musculature (see **Display 17-7**) can be more effective after the neurologic compromise is resolved.

Another neurologic cause of impaired muscle performance is nerve injury resulting in muscle paresis or paralysis, which can occur as a complication of surgery or from a traction injury to the nerve. LM segmental atrophy at the surgical site has been reported in the CLBP population after surgical intervention.[198,199] It is thought to be the result of iatrogenic lesions of the dorsal rami and innervation failure of the low back muscles after surgery. This finding is highlighted as a possible cause of "postoperative failed back syndrome" and is supported by histologic evidence.[198,199] Other investigators have reported denervation of segmental paraspinal musculature in patients with the radiologic diagnosis of segmental hypermobility.[200] These changes were thought to result from traction injury of the posterior primary rami segmentally supplying the muscle at the hypermobile segment. The ability for exercise to reverse the effects of denervation is related to the neurophysiologic recovery of the damaged nerve. Nonetheless, sustained mechanical stress from segmental instability delays or inhibits healing, and exercise targeted toward increasing segmental stability can reduce mechanical stress on the segment and augment healing. If nerve regeneration occurs, specific exercises focused on improving force or torque generation are necessary to "reeducate" the previously denervated muscle.[200] Specific exercise recommendations will be discussed subsequently.

Muscle Strain Muscle strain can result from a variety of mechanisms:

- Trauma (e.g., spinal extensors and LM after a motor vehicle accident)
- Overuse (e.g., one diagonal EO and IO muscles in a competitive rowing team member)
- Gradual continuous stretch (e.g., EOs in a swayback or lordotic posture)

Strain to lumbopelvic musculature, particularly if caused by trauma, is difficult to diagnose, because it often occurs with injury to other tissues in the motion segment. If a strain is suspected, the exercise and dosage depend on the severity of the strain, the stage of healing, and the mechanism of injury. Severe strains in early stages of recovery and chronic strains with long-term disuse must start with low-intensity isometric exercises. Strains resulting from chronic stretch must be supported in a short range and exercised with low initial loads with a focus on generating tension in the short range. For example, in the case of an EO strain resulting from marked lordosis and anterior pelvic tilt, use of an abdominal binder combined with low-load exercises in a neutral spine and pelvis position may be indicated in the early stages of recovery (see Patient-Related Instruction 17-1 and Self-Managements 17-1 and 17-2).

If the strain is the result of overuse, ultimate recovery must involve improving the force or torque production and recruitment patterns of the underused synergist(s). For example, strain to one diagonal oblique abdominal muscle is a common injury among members on a rowing team who only row either port or starboard. It is caused by repetitive flexion and unilateral rotation. Changing the movement pattern to greater flexion and rotation occurring at the hips, and improving the force and torque capability of the posterior spinal muscle group (to minimize the flexion component during unilateral rotation) and opposite oblique abdominal muscle group, may be indicated.

Rarely does a patient progress from a trunk muscle strain in the expected time frame, primarily because of frequent reinjury of the muscle. Reinjury is most likely a result of poor protection of the injured area during postures and movement patterns the patient is unaware he or she is performing. It is the responsibility of the therapist to educate the patient to avoid postures and movement patterns most likely contributing to delayed healing and to use improved postures and movement patterns to promote the healing process.

General Disuse and Deconditioning General disuse and deconditioning of the trunk and pelvic girdle muscles can result from the previously described causes. However, the trunk and pelvic girdle muscles also are susceptible to deconditioning as a result of general decreased activity level. Trunk and pelvic girdle deconditioning may be a leading cause of lumbopelvic

DISPLAY 17-7
Resisted Exercises for the Lumbopelvic System

Stability Activities for the Anterior Aspect

- Intrinsic spinal muscle activation (see Patient-Related Instruction 17-1)
- Leg slides (see Self-Management 17-1)
- Prone knee bend (see Self-Management 17-5)
- Hip and knee flexion, hip abduction, and lateral rotation (see Self-Management 17-3)

Stability Activities for the Posterior Aspect

- Intrinsic spinal muscle activation (see Patient-Related Instruction 17-1)
- Manual lumbar multifidus facilitation (see Fig. A in Display 17-5)
- Sidelying small-range hip abduction
- Prone small-range hip extension (see Self-Management 19-1 in Chapter 19)
- Prone neutral spine isometric

Stability Activities for Lumbopelvic Synergy

- Intrinsic spinal muscle activation (see Patient-Related Instruction 17-1)
- Sitting upper extremity abduction (**Fig. A**), flexion (**Fig. B**), rotation (not pictured)
- Quadruped arm lift (**Fig. C**)
- Intrinsic Spinal Muscle Series: Self-Management 17-2

Controlled Mobility Activities for Lumbopelvic Synergy

- Trunk curl sit-up (see Self-Management 17-4)
- Trunk sagittal and transverse plane motion in standing (see Fig. 17-14)

Skill Activity for Lumbopelvic Synergy

- Monitor performance of recreational or occupational skills

syndromes and therefore are critical areas to address in prevention. Individuals with general deconditioning require a careful examination so that a graded conditioning program is focused on the specific muscles in need of strengthening and that the program is initiated at the appropriate level of difficulty. The dilemma with most trunk-strengthening exercises performed to improve fitness (e.g., bent-knee sit-ups, crunches, Roman chair hyperextensions, abdominal or back strengthening machines) is that the exercise is often performed at a higher level than that at which the muscles can safely and precisely execute the movement. When one synergist of a group is relatively weak, the other synergists often produce the necessary force or torque required to perform the desired movement, thereby reinforcing muscle imbalance and increasing the risk of injury to the lumbopelvic region.

It is beyond the scope of this text to analyze all the common fitness exercises used to strengthen the trunk muscles. Because the ability to curl up to a sit-up should be considered a normal ADL and because various forms of the sit-up are still commonly performed, a concise analysis of this exercise is provided.

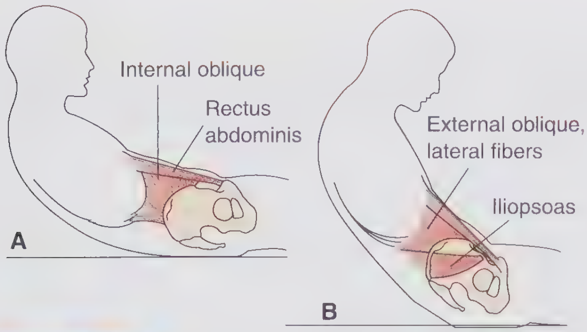

FIGURE 17-15 The sit-up can be considered a two-phase activity. **(A)** The first phase is the trunk curl. Trunk flexion is slowly initiated by raising the head and shoulders, with the pelvis tilting posteriorly simultaneously. **(B)** As the trunk is raised in flexion on the thighs, the hip flexors exert a strong force to tilt the pelvis anteriorly, the external oblique (EO) maintains the spine in flexion and the pelvis in posterior rotation. (Adapted from Kendall FP, McCreary EK, Provance PG. Muscles Testing and Function. 4th Ed. Baltimore, MD: Williams & Wilkins, 1993.)

The sit-up can be considered as two distinct phases of one movement: trunk flexion followed by hip flexion (**Fig. 17-15**). The RA and IO produce the trunk flexion phase, as indicated by rib cage depression (RA) and rib angle widening (IO), and the hip flexors produce the hip-flexion phase.[101] The role of the EO is to offset the anterior force on the pelvis and lumbar spine exerted by the hip flexor muscles.[101]

Although hip flexors may exhibit some weakness associated with postural problems (e.g., weak hip flexors in the swayback posture), it rarely interferes with performing the hip-flexion phase of the sit-up. The problem in accurately performing a straight leg sit-up is usually weakness of the abdominal muscles, causing the lumbar spine to be vulnerable to the extension forces exerted by the hip flexor muscles lifting a longer lever arm.

Instruction in proper execution of the sit-up requires a complex level of analysis and decision-making considering the performance of the abdominal muscles in relation to the hip flexor muscles and structural factors. **Self-Management 17-4** offers a detailed description of the sit-up. It is important to

SELF-MANAGEMENT 17-4
Sit-Up

Purpose: To strengthen the abdominal muscles and hip flexor muscles necessary to sit up from a supine position

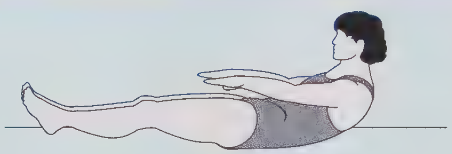
Starting Position: Back lying with hips and knees straight. Your physical therapist will determine if you are to begin this exercise in a supine position with hips and knees straight or with pillows under your knees. Your physical therapist will also determine if you will require fixation of your feet during the sit-up phase of this exercise.

TIP: To perform this exercise with proper technique, follow the tips listed:

- Start with an intrinsic spinal muscle contraction and hold this contraction throughout the entire sit-up and return to the start movement.
- Curl your trunk to the same spine level with the selected arm position.
- Maintain lumbar flexion and posterior pelvic tilt during the hip flexion phase.
- If you require fixation for your feet, do not use the fixation until the sit-up phase.
- If you did not require fixation for level I, you should not require fixation at any level of the exercise. Premature lifting of your feet can be an indication of abdominal fatigue.

Movement Technique:

Level I: With your arms in front of your body, bring your chin to your chest, and slowly curl your trunk as you come to a full sitting position. Slowly reverse the curl and resume the start position.

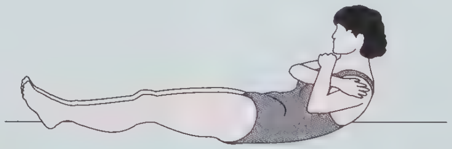


Dosage:

Sets/Repetitions: ____________

Frequency: ____________

Level II: Perform as in level I, but place your arms folded across your chest.

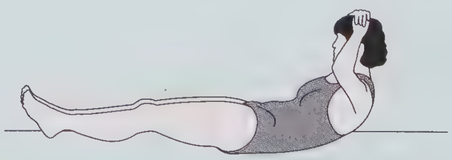


Dosage:

Sets/Repetitions: ____________

Frequency: ____________

Level III: Perform as in level I, but place your hands on top of your head with your elbows open.



Dosage:

Sets/Repetitions: ____________

Frequency: ____________

teach the client to complete the trunk-curl phase before the sit-up phase for proper execution of this exercise.

The lower extremities constitute about one-third of the body weight.[201] This means that the force exerted by the trunk in the supine position is greater than that of the lower extremities, and the feet need to be held down during the hip-flexion phase. However, if the spine flexes sufficiently as the trunk raises and the center of mass moves downward toward the hips, the trunk can be raised in flexion without having the feet held down. Most adolescents and women can perform the sit-up without having their feet held down because of a combination of body proportion (e.g., upper body less mass relative to lower body) and segmental trunk flexion lowering the center of mass. In contrast, many men may need to have some added force applied (usually very little) at the point where the trunk curl is completed and the hip flexion begins because mass of the upper body is greater than that of the lower body. This may also be true for women with a stiff trunk because of the inability to segmentally flex the spine, which creates a longer lever arm and may require the feet to be held down during hip flexion. If it is necessary to stabilize the feet during the hip-flexion phase, the feet should be held down *only during the hip-flexion phase* to ensure full trunk flexion before the hip-flexion phase begins. If the feet are held down prematurely or throughout the sit-up, the hip flexors are given fixation, and the trunk can be raised by hip flexion instead of trunk flexion.

Elevation of the feet during the sit-up can indicate abdominal muscle fatigue, as the abdominal muscles are no longer producing enough torque to flex the trunk through the specified arc of motion. Therefore, the hip flexors act earlier in the range to raise the trunk, with the feet rising as a result.

The bent-knee sit-up has long been advocated as a means of minimizing or eliminating the action of the hip flexors, placing them "on slack" during the sit-up. This idea is false and misleading. The abdominal muscles do not cross the hip joint and can therefore only flex the trunk. Regardless of hip position, the sit-up is a strong hip flexor exercise; the difference is the arc of hip joint motion through which the hip flexors act (i.e., hips extended: 0 to 80 degrees flexion; hips flexed: 50 to 125 degrees flexion). Because the hip joint moves to completion of hip flexion ROM with the hips and knees flexed, high repetitions of this type of sit-up may be more conducive to the development of short hip flexors than the sit-up with the hips extended.

Although normal flexibility of the back is desired, excessive flexibility is not. A contraindication to performing a bent-knee sit-up is excessive flexibility of the lumbar spine. With the hips extended, the center of mass is slightly anterior to the first or second sacral segment. With the hips and knees bent, the center of mass moves cranially. The lower extremities exert less force in counterbalancing the trunk during the sit-up with the hips and knees flexed than with the hips extended. To sit up from the bent-knee position, the feet must be held down, or the trunk must flex excessively to move the center of mass downward. As the curl progresses, the center of mass moves distally toward the hip joint. In the hip-extended position, by the time the hip-flexion phase arrives, the center of mass has moved toward the hips, which encourages the hips (not the lumbar spine) to flex during the sit-up phase. With the hips flexed, the center of mass may not reach the axis of motion of the hips by the hip-flexion phase, thereby imposing a flexion moment on the lumbar spine versus the hip joints. The persons most in danger of being adversely affected by repeated bent-knee sit-ups are children and young adolescents because of their tendency toward excessive flexibility. Adults with LBP associated with excessive flexion flexibility of the low back may also be adversely affected by this exercise.

A precaution to performing a straight-leg sit-up is short hip flexors. In the supine position with the legs straight, a person with short hip flexors lies in anterior pelvic tilt and lumbar extension. The danger with performing the sit-up from this position is that the multijoint hip flexors (i.e., tensor fascia lata [TFL] and rectus femoris) pull the pelvis into more anterior pelvic tilt and subsequently the spine into further extension during the hip-flexion phase. The bent-knee position releases the downward pull of the short hip flexors, allowing the pelvis to tilt posteriorly and the lumbar spine to relatively flex. The hips and knees should be bent only as much as needed to allow the pelvis to reach neutral in the supine position. This position should be maintained passively by using a large enough roll or pillow under the knees. Prescribing bent-knee sit-ups (even in a partially bent-knee position) to individuals with short hip flexors is not the final solution, and this position should not be used indefinitely. Short hip flexors often accompany lengthened EO muscles because of the anterior pelvic tilt posture induced by the short hip flexors. The bent-knee sit-up neither addresses the short hip flexors nor the lengthened EOs. Consequently, it is important to perform exercises to stretch the short hip flexors (see **Self-Management 17-5**), to strengthen and shorten the EO muscles (see Self-Management 17-1), and to attend to undesirable postural habits (e.g., avoiding excessive anterior pelvic tilt and lumbar lordosis).

A contraindication to either bent-knee or straight leg sit-up techniques is concern about compressive loading of the spine. Lumbar compressive loads >3,000 N were predicted for both sit-up techniques.[202] In the presence of an HNP, for example, the issue of using straight-leg or bent-knee sit-ups is not as important as the issue of whether or not to prescribe sit-ups at all.

A trend in abdominal strengthening is a trunk curl or "crunch" performed without the hip-flexion phase. Performance of only the trunk-curl phase should be safe and effective for strengthening the abdominal muscles. There is less intradiskal pressure in performing the trunk curl than in a full sit-up.[203] However, the trunk curl focuses primarily on producing torque for movement rather than force or torque for stabilization of lumbar segments. This preferentially recruits the RA and IO over the EO. Moreover, the trunk curl is contraindicated for any person with a thoracic kyphosis because of the stress thoracic flexion exerts on the kyphosis. Alternative exercises should be suggested for persons with poor lumbar stabilization and thoracic kyphosis (see Self-Managements 17-1 and 17-2).

If the trunk curl is chosen, the therapist should determine the position in which the patient should start—a small towel roll under the knees, a wedge-shaped pillow under the head and shoulder, or a pillow under the knees. Before any trunk movement, an intrinsic spinal muscle contraction should be initiated (see Patient-Related Instruction 17-1). With the arms extended forward, the patient should flex the chin toward the chest and continue to curl the upper trunk as far as the spine can flex (see Self-Management 17-4). If the subject cannot perform the curl to completion of his or her spine flexion because of abdominal weakness, a wedge-shaped pillow can be placed behind the

SELF-MANAGEMENT 17-5
Prone Knee Bend

Purpose: To lengthen the hip flexors and quadriceps, improve the strength of the intrinsic spinal muscles, and train the pelvis and spine to remain still during knee bending movements

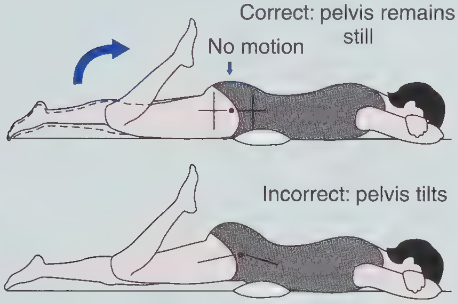
Starting Position: Facelying with both lower limbs straight and knees together.

Options: You may need _______ pillows under your hips, as indicated by your physical therapist.

You may need to position your thigh out to the side.

Movement Technique: Before moving your legs, engage your intrinsic spinal muscles. Maintain this contraction as you bend one knee as far as possible *without movement in the pelvis or spine*

Options: Bend both knees at the same time while keeping knees and ankles together.



Dosage:

Repetitions: ________________________________

Frequency: ________________________________

head and shoulders to limit the range and decrease the effect of gravity. As abdominal muscle strength improves, smaller pillows can be used. If the hip flexors are short, temporary use of a pillow under the knees can decrease the pull of the hip flexors on the spine and allow the individual to lie in supine with the pelvis and spine in neutral. **Table 17-7** summarizes features related to the prescription of the sit-up and its variations.

Range of Motion, Muscle Length, and Joint Mobility

Clinical decisions regarding exercise prescription for ROM, muscle length, and joint mobility must be considered in relation to other regions of the spine, upper quarter, and lower quarter.

Hypermobility

Diagnosis of hypermobility and true articular instability can be made from careful clinical examination.[119,141] The examiner should also seek to discover the impairments contributing to the hypermobility or articular instability.[31] Four factors can be responsible for the development of a hypermobile segment: trauma (e.g., motor vehicle accident resulting in an acceleration injury), pathology (e.g., rheumatoid arthritis, degenerative joint changes), structural impairment (spondylolisthesis, HNP, asymmetric trophic changes in the ZJ), or chronic repetitive movement patterns. With repetitive movement, hypermobility can develop within the lumbopelvic region in response to a relatively less mobile segment or region. Theoretically, in a multijoint system, any given movement follows the segments providing the least resistance, resulting in abnormal or excessive movement of segments with the least amount of stiffness.[31] With repeated movements over time, the least stiff segments increase in mobility, and the more stiff segments decrease in mobility.

Sahrmann has termed the site of abnormal or excessive motion *the site of relative stiffness or flexibility*.[31] The term *relative* is key to this concept. For example, the fifth lumbar vertebra, because of its biomechanical and anatomic properties, is more adapted to produce rotation than any other lumbar segment. It is therefore *relatively* more flexible in the direction

TABLE 17-7

Summary of Indications, Contraindications, and Precautions in Prescribing Sit-Ups and Sit-Up Variations

EXERCISE	INDICATIONS	CONTRAINDICATION AND PRECAUTIONS
Bent-knee sit-up	Lordosis	Short hip flexors, excessive trunk flexion range of motion, thoracic kyphosis
Temporary use of pillows under knees for sit-up	Short hip flexors	
Straight leg sit-up	At least 3+/5 strength of all abdominal muscles and hip flexors	Acute or subacute disk pathology
Trunk curl (only)	Weak external oblique, acute or subacute disk pathology	Thoracic kyphosis
Temporary use of wedge under spine	<3/5 in lower fibers of abdominals, stiff lumbar region (restricted in flexion)	

of rotation. This becomes a clinical problem or impairment only if the segmental motion becomes excessive due to relative stiffness elsewhere along the kinetic chain. For example, playing golf involves a significant amount of total-body rotation. If the hips or feet are relatively stiff in rotation, the spine may incur excessive rotational stress. If the thoracic spine or upper lumbar segments are stiff in rotation, this pattern may impose excessive rotation on the L5 segment.

The cause and effect relationship of relative flexibility can be addressed through a comprehensive program of improving mobility at the relatively more stiff segments or regions and improving stiffness at the relatively more mobile segment. Stiffness should be increased at the site of relative flexibility by improving neuromuscular control, muscle performance (i.e., hypertrophic changes), and length–tension relationships of the stabilizing muscles (see the "Muscle Performance Impairment" section). According to a study by Shirley et al.,[204] voluntary submaximal contractions as low as 10% maximum voluntary contraction (MVC) demonstrated an increase in lumbar stiffness. This conclusion points to the importance of motor control and simply teaching the patient to activate the spinal muscles at low levels to increase segmental stability.

Exercises to reduce hypermobility at a segmental level or within the pelvis can be progressed according to traditional stages of motor control: mobility, stability, controlled mobility, and skill. The stage of mobility can be thought of as improving mobility at relatively stiff or hypomobile segment(s) or region(s) in the specific direction(s) desired to reduce the stress at the associated hypermobile segment. Activities and techniques to improve mobility are presented in the "Hypomobility" section.

The stage of stability can be thought of as improving motor control, muscle performance (particularly hypertrophic changes), and length–tension properties of the affected muscles. Specific activities and techniques chosen to promote stiffness and stability should be based on the direction the segment is susceptible to motion. The patient must be educated to avoid habitual postures that place a lengthening stress on the muscle (e.g., avoid standing in a swayback in the presence of lengthened EO). In some cases, immobilization in the short range (e.g., use of an abdominal binder or taping) may be necessary to facilitate adaptive shortening. To stimulate hypertrophic changes that lead to increased muscle stiffness, prescribe exercises for specific muscles dosage levels for hypertrophy (i.e., 10 to 12 repetition max sets).

Controlled mobility focuses on the ability of the lumbopelvic region to move dynamically in all three planes with appropriate distribution of movement throughout the lumbar region, the thoracic spine, the SIJ, and the extremities. Skill is reached when the patterns of muscle activation become automatic and internalized by the patient during functional activities. Display 17-7 provides recommendations for exercises to develop stability through the stages of motor control.

To be most effective in reducing hypermobility with exercise, the therapist should educate each patient to use appropriate spine positions during all exercises and activities. There is no particular lumbopelvic functional position that is best for all patients and for all activities. Although the standard is the neutral position (see Table 17-6), it may not be achieved by all patients and for all activities, in which case the functional position of the spine should be used. The functional position (see Table 17-6) varies with physiologic status and stresses from BADLs and IADLs. For example, to avert exacerbation of symptoms, patients with spinal stenosis must avoid extension. The functional position may vary with the patient's activity. For example, flexion should be avoided during heavy lifting from the floor to the waist, whereas end-range extension should be avoided during lifting from waist level to overhead. Functional spinal posture may also vary with the patient's behavior of symptoms. The more severe, irritable, and acute the condition, the more limited the functional position of the spine becomes to avoid symptoms.

Hypomobility

To be most effective, activities or techniques to reduce hypermobility must occur simultaneously with activities or techniques to increase hypomobility in related regions. Many activities or techniques can be used to increase mobility, such as manual techniques (e.g., articular joint mobilization, muscle energy techniques, soft-tissue mobilization); passive self-stretch or self-mobilization; or active assisted, active, and resisted exercise.

There are multiple justifications for the use of manual therapy including (see Chapter 7):

- Psychologic effects as a result of patient–therapist interaction[205]
- Mechanical effect (e.g., altering positional relationships or mobilizing joints through stretching or rupturing restrictive structures)[206]
- Neurophysiologic effect (e.g., activation of the gate control mechanism, reflexogenic decrease of muscle hypertonicity)[206]

Research does not support the use of rotatory manual techniques for reduction of herniations in contained or uncontained disks.[207–209] These techniques seem contraindicated in diskogenic dysfunctions because they cause tensile strain to annular fibers which further weaken nuclear containment.[210] Research also does not support the rationale that manual therapy can affect the positional relationship in the SIJ and thus decrease complaints.[140] Neurophysiologic mechanisms may offer a better explanation of the effects of manual therapy. Clinical outcome studies demonstrate better results with manual therapy techniques when patients with NSLBP are classified using clinical guideline indices.[211]

Passive intervention in the form of manual therapy or manual exercise without some form of follow-up active exercise is discouraged. One potential hazard in providing purely passive intervention is that the patient may not participate *actively* in the rehabilitation process. Whenever possible, active participation in the form of patient-related education and self-management exercise is encouraged.

Active assisted ROM, active ROM, proprioceptive neuromuscular facilitation techniques (see Chapter 13), and passive stretching can also be used to increase mobility (see Chapter 7). This discussion focuses on self-management exercises, emphasizing passive and active stretching.

Passive stretching may be necessary, particularly for muscle groups with adaptive shortness. Careful muscle length testing determines which trunk and pelvic girdle muscles require stretching. Superficial trunk muscles, such as the RA, quadratus lumborum, and lumbar erector spinae, and multijoint hip muscles, such as TFL/iliotibial band, HSs (semitendinosus or semimembranosus [medial HSs], biceps femoris [lateral HSs]), hip adductors, and rectus femoris, are susceptible to adaptive shortening.

Care must be taken when stretching muscles crossing the hip joint in individuals with lumbopelvic dysfunction, because the SIJ or lumbar spine often becomes the site of relative flexibility when the hip becomes hypomobile. Appropriate stabilization at the pelvis while the distal attachment moves is essential. Otherwise, the spine or SIJ becomes the path of least resistance and therefore easily moves before the feeling of a stretch.

An example of proper stabilization for a diarthrodial muscle with attachments on the pelvis is the supine passive HS stretch. The HSs may be passively stretched in supine with one hip flexed and the ipsilateral knee extended (to the point of mild HS tension) and the foot against a wall while the contralateral hip and knee are extended. The lumbopelvic region is stabilized by appropriate recruitment of the intrinsic spinal muscles and by the surface supporting the patient. The length of the HSs determines the distance from the wall and angle of SLR. Certain criteria are used for proper stabilization to facilitate the optimal stretch (see **Building Block 17-1**).

BUILDING BLOCK 17-1

With regard to supine passive HS stretch:

1. Provide specific criteria for positioning for the:
   - Contralateral limb
   - Spine and pelvis
   - Ipsilateral limb
2. How could you isolate medial versus lateral HSs?
3. Based on your knowledge of the dosage for stretching, prescribe specific duration and repetitions for an effective stretch.

Neuromeningeal Hypomobility

Loss of mobility of the nervous system can occur as a result of congenital disorders, trauma, surgical complications, or degenerative changes.[120,133,212] There are two types of neuromeningeal hypomobility: the tethered cord syndrome and the nerve root and dural movement dysfunction. The tethered cord syndrome forms a contraindication to physical therapy intervention; however, nerve root and dural movement dysfunction can respond quite well to neural mobilization techniques.[120] Before intervention, neuromeningeal mobility should be assessed and its influence determined. Specific exercises may be prescribed that are designed to improve mobility of the neural system (see **Self-Management 17-6**). The related anatomy, physiology, and application principles must be well understood for the effective and safe use of this type of treatment. This topic is worthy of more extensive coverage. Detailed information is provided by Butler.[120]

Pain

LBP is the most common type of pain reported by adults in physician offices.[213] The well-meaning clinician desires to identify and explain the source of pain to a patient. Of frustration to the clinician is the difficulty associated with identifying the pathoanatomic cause for most cases of LBP due to the complex interaction of peripheral and central mechanisms responsible for the pain experience. The physiologic and psychologic impact that lumbopelvic pain has on the person can create profound participation restriction. The experience of musculoskeletal origin pain is a complex process involving both the peripheral nervous system and the central nervous system and is beyond the scope of this chapter. The reader is referred to Chapter 10 and additional reading on the topic.[214–216] This section addresses the treatment of pain based solely on body function and structures.

There is growing evidence that factors such as sleep disturbance, sustained high stress levels, depressed mood, and anxiety are strong predictors of persistent LBP.[217] This highlights the role that cognitive/affective subsystem components such as lifestyle and negative emotional factors play in sensitizing spinal structures.[217] This may reflect clinically as a patient presenting with acute LBP, reporting high levels of pain, distress, and muscle guarding associated with a "minor" mechanical trigger. Identifying this pattern in the acute phase may prevent the slide into CLBP. It is also important to note that negative beliefs about LBP are predictive of pain intensity, disability levels, and work absenteeism.[218] Unfortunately, many beliefs such as a negative future outlook, believing that "hurt equals harm" and that "movements that hurt should be avoided" because of fear of pain gain their origins from health care practitioners.[219,220] What we say to our patients matters. Inadvertent comments from a well-meaning practitioner can affect the long-term recovery of a patient experiencing pain, highlighting the critical role of communication in the acute care of people with LBP (see **Patient-Related Instruction 17-2**).

There is also evidence that, in the absence of a clear traumatic injury, pain behaviors, such as limping, protective muscle guarding, and grimacing, are more reflective of catastrophic thinking (e.g., "my back is damaged," "I am never going to get better" and "I am going to end up in a wheel chair"), fear and distress.[221] These behaviors can result in abnormal loading of sensitized spinal structures, feeding a vicious cycle of pain. They are also linked to poor coping skills, such as avoidance and excessive rest, and leave the person feeling helpless and disabled. In contrast, people who have positive beliefs about LBP and its future consequences are less disabled.[218]

Treatment of the physiologic musculoskeletal component of pain can include a variety of interventions, ranging from pharmaceutical interventions (oral medications or injections) to physical therapy, to surgery—applied individually or in any combination. The choice of intervention must be tailored to each case, ideally with input from all involved practitioners. This section discusses therapeutic exercise as one type of intervention for the treatment of musculoskeletal lumbopelvic pain. Although the exercises suggested in this section were chosen to demonstrate activities or techniques to treat different underlying causes of pain, many are used to treat associated impairments, such as those of mobility, muscle performance, posture, and motor control. Consequently, they may be referred to in other sections of this chapter, illustrating the complex interaction of impairments and the diversity and versatility of the exercises. To make informed decisions about the exercises chosen to treat pain, the clinician should understand the physiologic impact that pain has on the structures of the lumbopelvic region. There is evidence of segmental changes within the deep low back muscles in the presence of LBP.[51,200,216,222–225] Atrophy has been found at the corresponding level of symptoms in the LM.[51,226] Histologic changes have been found in type I fibers of the LM in patients with herniated intervertebral discs (IVDs) and CLBP.[223,227–230]

SELF-MANAGEMENT 17-6
Neuromeningeal Mobilization

Purpose: To improve the mobility of your sciatic nerve and its branches into the calf and foot and to reduce the pain coming from a loss of mobility in the sciatic nerve

Assessment: Before beginning this exercise, you must first assess the status of your neural mobility.

While seated, slump in your low back and pelvis as far as possible.

Bring your chin toward your chest.

Flex your foot as far as possible.

Slowly extend the knee on the side of symptoms as far as possible.

Stop at the onset or worsening of symptoms.

Notice the angle of your knee. You will recheck this angle after performing the exercise. You should be able to extend your knee further if you are successful with mobilizing your nerve.

If the angle is less, you have exacerbated your nerve and should repeat the series, reducing the range of motion of each movement in the series. Recheck the knee angle. It should be back to the original assessment position or may be improved.

Starting Position: Slump in your low back, and roll your pelvis back as far as possible. *Slightly* flex your neck to take the stress off the forward head position the slumped posture placed your head in.

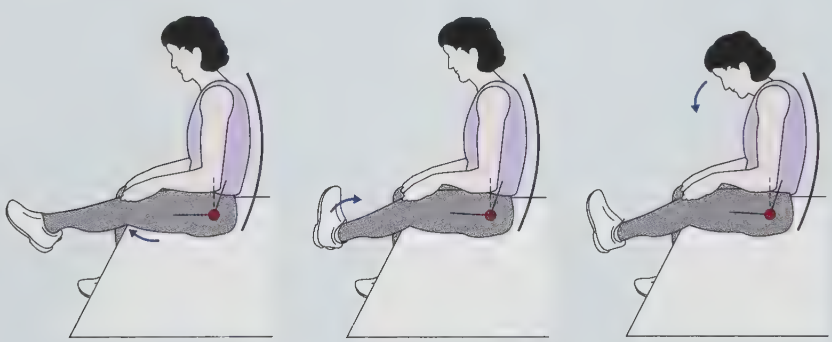
Movement Technique: Repeat each activity up to 15 times.

Knee Mobilization: Keeping your ankle relaxed, extend your knee until you feel *mild* tension behind your knee. Relax back to the start position.

Ankle Mobilization: Extend your knee about three-fourths of the distance you found during the assessment. Flex and extend your ankle.

Neck Mobilization: Extend your knee three-fourths of the distance you found during the assessment. Flex your ankle toward your head about three-fourths of the distance of its full range of motion. Actively flex your chin toward your chest and release to the start position.

Reassess after the first cycle. If you have been successful as described under the assessment, repeat the cycle ________ times.



Knee mobilization   Ankle mobilization   Neck mobilization

Patient-Related Instruction 17-2

Messages that can Harm People with NSLBP

Promote Beliefs About Structural Damage/Dysfunction

- "You have degeneration/arthritis/disk bulge/disk disease/a slipped disk"
- "Your back is damaged"
- "You have the back of a 70-year-old"
- "It's wear and tear"

Promote Fear Beyond Acute Phase

- "You have to be careful/take it easy from now on"
- "Your back is weak"
- "You should avoid bending/lifting"

Promote a Negative Future Outlook

- "Your back wears out as you get older"
- "This will be here for the rest of your life"
- "I wouldn't be surprised if you end up in a wheelchair"

Hurt Equals Harm

- "Stop if you feel any pain"
- "Let pain guide you"

(continued)

Patient-Related Instruction 17-2 (*continued*)

Messages that can Reduce Pain in People with NSLBP

Promote a Biopsychosocial Approach to Pain

- "Back pain does not mean your back is damaged—it means it is sensitized"
- "Your back can be sensitized by awkward movements and postures, muscle tension, inactivity, lack of sleep, stress, worry, and low mood"
- "Most back pain is linked to minor sprains that can be very painful"
- "Sleeping well, exercise, a healthy diet and cutting down on your smoking will help your back as well"
- "The brain acts as an amplifier—the more you worry and think about your pain the worse it gets"
- "Pain with movement does not mean you are doing harm"

Promote Resilience

- "Your back is one of the strongest structures of the body"
- "It's very rare to do permanent damage to your back"

Encourage Normal Activity and Movement

- "Relaxed movement will help your back pain settle"
- "Your back gets stronger with movement"
- "Protecting your back and avoiding movement can make you worse"
- "It is safe to exercise and work with back pain—you may just have to modify what you do until the sensitivity is reduced"

Address Concerns About Imaging Results and Pain

- "Your scan changes are normal, like gray hair"
- "The pain does not mean you are doing damage—your back is sensitive"
- "Movements will be painful at first—like an ankle sprain—but they will get better with time and as you get active"

Encourage Self-Management

- "Let's work out a plan to help you help yourself"
- "Getting back to work as you're able, even part-time at first, will help you recover"
- "Gradually increase your activity levels based on time rather than pain levels"

These changes may result from pain-provoked, low-tension muscle contraction, which is not strong enough to stimulate type II fibers.[52] Others have hypothesized that the atrophy is consistent with pain-induced disuse.[224] Although the physiologic changes are not well understood, they do occur and contribute to a decline in muscle performance and neuromuscular control, particularly in the LM.

Most structures in the lumbar spine can be a source of pain at some time under the right circumstances, making it difficult or impossible to diagnose a specific pathoanatomic cause of pain. The nerve root, disk, annulus, facet joint, and muscle seem to be the most acceptable candidates for sources of pain.[231] The mechanisms of pain production are described as a combination of mechanical and chemical irritation of the nociceptive receptors within the tissues. It is not clear whether mechanical stresses lead to chemical irritation, which sensitizes the tissue, or chemical irritation makes tissue more sensitive to mechanical stress. The two mechanisms most likely coexist in the vast majority of cases.

In the spinal canal, the HNP is a strong candidate for the cause of inflammation and irritation of nerve roots and nerve endings. Because of the juxtaposition of disk and nerve roots in the spinal canal, sciatica (i.e., pain radiating from the low back into the buttock, posterior thigh, and leg) is likely to rise from compression of the dorsal root ganglion and inflamed nerve roots. When a painful condition is set in the peripheral tissue, the consequent barrage of noxious signals into the spinal cord can sensitize somatosensory neurons in the dorsal horn. These sensitized neurons can contribute to a condition of CLBP.[133]

The physical therapist is most interested in the mechanical cause of pain as it relates to movement. A systematic physical examination can reveal postures, stabilization, and movement strategies that contribute to the onset of pain, worsen existing pain, or conversely, reduce or abolish pain.[189,232]

One philosophical approach to treating mechanical causes of pain related to posture or movement is to teach the patient to modify postures or movements that aggravate pain.[31,189,232,233] Based upon examination findings, the therapist instructs the patient in strategies to modify aggravating movements and postures and treats the aggravating physiologic impairments (e.g., ROM, joint mobility, muscle performance, neuromuscular control). This approach is believed to intervene mechanically by avoiding aggravating postures and movements, therefore allowing the painful structures to "rest" which will decrease the inflammatory process. For example, in the patient who reports worsening of pain during forward bending, the lumbar-pelvic relationship is faulty, with excessive motion in the low back relative to the hips.[234] If the pain is reduced or abolished when the patient is instructed to bend with a greater contribution of movement from the hips and less movement from the low back, this information can be used to devise an exercise intervention. Examples of exercises to include in such a program are listed in **Display 17-8.**

In many cases, reducing the mechanical stress on the affected structures by improving mobility in adjacent regions, improving stability in the affected region, and making associated changes in posture and movement patterns are sufficient steps to resolve the episode of pain without need for other interventions. In other instances, short-term use of complementary interventions (e.g., joint mobilization or manipulation, traction, physical agents, pharmaceutical intervention, psychologic counseling) by the physical therapist or other practitioners involved in the case may be necessary to treat additional mechanical, chemical, or psychologic contributions to pain. It is important for the clinician to be mindful of what is said during this period regarding the underlying causes of pain and the steps necessary to reduce pain (see Patient-Related Instruction 17-2).

McKenzie developed another therapeutic exercise approach for the treatment of pain.[235,236] A simplified example of this approach is the use of movements that reduce or abolish symptoms. Self-reports of postures related to pain, observation of posture, and

DISPLAY 17-8

Exercises to Improve Hip Flexion Mobility and Decrease Lumbar Flexion Mobility

- Exercises to improve hip flexion mobility
  - Hand-knee rocking (see Self-Management 19-7 in Chapter 19)
  - Supine hip flexion without lumbar flexion or rotation (**Fig. A**)
- Exercises to reduce lumbar flexion mobility
  - Seated knee extension (see Self-Management 19-8 in Chapter 19)
  - Standing hip flexion (**Fig. B**)
  - Instruction to alter posture and movement patterns
  - Corrected sitting posture (see Patient-Related Instruction 18-4 in Chapter 18)
  - Improved lumbar-pelvic movement (see Patient-Related Instruction 17-3)

A

B

uniplanar movements (e.g., flexion, extension, lateral flexion) are used to assess the effect of posture and movement on symptoms. During the examination, each movement is rated according to terms used to describe a change in status (e.g., improve, worsen, status quo). After the movement, or repeated movements, the patient is asked to compare his or her symptoms with the baseline.

The concepts of *peripheralization* (i.e., pain or paresthesia that moves distally away from the spine) and *centralization* (i.e., pain or paresthesia that is abolished or moves from the periphery toward the lumbar spine) are used to determine which movements should be used in self-treatment. For example, if repeated forward bending peripheralizes symptoms and extension centralizes symptoms, extension-related exercises would be used in self-management to modulate symptoms (see **Self-Management 17-7**). This approach to the treatment of acute LBP has been effective in restoring function,[236] particularly if used in conjunction with a treatment-based classification approach to low back syndrome.[237] In a retrospective study of 87 patients with leg and LBP, Donnelson et al.[238] found that all patients with excellent outcomes of McKenzie-based diagnosis and treatment showed centralization during the initial evaluation.

McKenzie's conceptual model for treatment of diskogenic dysfunction theorizes that when the annulus is intact, it will force the NP to move posteriorly during flexion and anteriorly during extension.[6,77] Other rationale includes effects related to activating gate control mechanisms, neural tissue relaxation, decreasing mechanical stimulation of nerve roots and other nociceptive tissues, and disk hydration.[133,239-243]

Positional techniques can also be used to modulate pain. For example, a patient can be taught to use positional traction if the goal is to separate joint surfaces to expedite relief of pain (**Fig. 17-16**). The theory behind positional traction is similar to that for other types of traction (see "Traction" in a later section of this chapter) in that the technique is used to affect the mechanical causes of pain.[244]

Self-mobilization can be prescribed to correct articular dysfunction, particularly that which relates to the SIJ. For example, a patient who presents with recurrent iliosacral dysfunction (e.g., anterior innominate rotation) should be able to self-treat the articular dysfunction rather than relying solely on the therapist to restore articular function.[245] An example of a prescriptive articular exercise is illustrated in **Self-Management 17-8**. For this type of technique to be successful, the patient must learn to evaluate his or her dysfunction and to perform the appropriate technique with precision only until correction is achieved. It also must be emphasized to the patient that these techniques are not considered part of the regular exercise regimen; they should be used only for articular dysfunction that contributes to the patient's symptoms. Although pain is the most common symptom, limited ROM, stiffness, paresthesias, and weakness are also symptoms related to articular dysfunction, and should be used as indications for this treatment technique. A relative contraindication for this technique is a hypermobile hip joint. Repeated use of this technique in the presence of a hypermobile hip may cause further increases in hip laxity and subsequent pain. **Self-Management 17-9** can be used if the specific dysfunction is a sacral torsion in which the sacrum is rotated causing a unilateral counter-nutation. This technique activates both piriformis and LM to restore sacral nutation. From a sequencing standpoint, a technique to correct an articular dysfunction should be performed before any other exercise. Once articular alignment is restored, the patient should perform intrinsic stabilization exercises.

For patients with nonspecific CLBP, there is compelling evidence that active rehabilitation that is directed toward return to normal activity and work can reduce absence from work more than traditional care.[246] Interventions such as physical exercise, application of operant-conditioning behavioral principles, and promotion of improved functioning and safe return to work despite pain are recommended.

In an acute onset of LBP, inflammation often dominates the clinical picture, and attempts at altering mechanical causes may not substantially decrease pain. The clinician must treat inflammation with the appropriate adjunctive modalities (e.g., cryotherapy, electrotherapy), protective measures (e.g., corset,

SELF-MANAGEMENT 17-7
Prone Press-Up Progression

Purpose: To improve the mobility of your low back into backward bending, stretch the front trunk muscles, move your leg pain toward your back or abolish it completely, and/or progressively relieve the pressure on your lumbar disk

TIP: Your physical therapist may ask you to perform special exercises to reduce any shift you exhibit in your spine before the execution of this exercise.

Starting Position: Face lying with legs straight.

Movement Technique: Your physical therapist will inform you of the levels of this exercise you are to perform and the duration of time you should spend at each level.

TIP: You should ***not*** progress to the next level if your pain does not move toward your spine. Occasionally, your LBP may increase in intensity. This is normal and should return to baseline quickly.

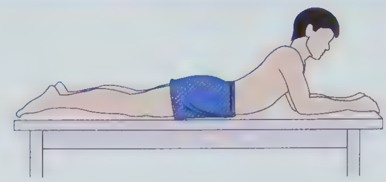
Level I: Remain on your stomach with your hands supporting your forehead.

Dosage:

Repetitions: ______________________________

Frequency: ______________________________

Level II: Prop up onto your forearms. Exhale and relax the muscles in your back.



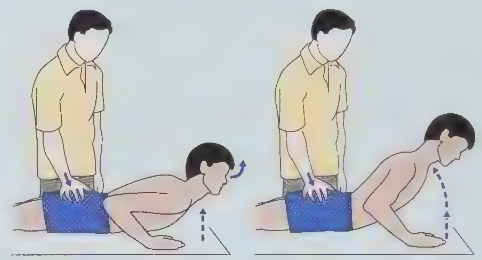
Dosage:

Duration: ______________________________

Sets/Repetitions: ______________________________

Frequency: ______________________________

Level III: Place your hands next to your shoulders. Press your upper trunk upward with your arms through the prescribed range of motion. Be sure the muscles in your back are fully relaxed.



Dosage:

Range of motion: ______________________________

Sets/Repetitions: ______________________________

Frequency: ______________________________

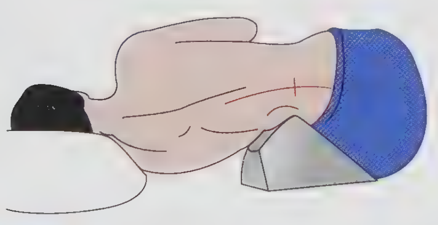


FIGURE 17-16 Positional traction. The use of a foam wedge allows maximal lateral flexion at a desired segmental level because of its sharp apex and ability to accommodate to the bony pelvis. The wedge easily can be made at a business that specializes in the manufacturing or design of foam products. The recommended density is CD-80. The preferred dimensions are 0 × 8 × 8 × 18 in (small) and 0 × 10 × 10 × 18 in (large).

SIJ belt), and controlled rest, but strict bed rest should be avoided (see Chapter 7). Moreover, the patient's physician should be alerted so that, if necessary, appropriate pharmacologic agents may be prescribed or modified.

Exercise is not contraindicated when an inflammatory response dominates the clinical picture. Although the primary goal is to reduce the inflammatory process, exercises encouraging controlled rest are prescribed to enable the patient to perform basic movements without aggravating pain. To move without inducing an increase in baseline pain, motion must be prevented at the affected lumbar spine segment or SIJ. Patient education is critical to teach the patient what postures and movements to avoid to reduce mechanical stress. Exercise may involve low-intensity isometric recruitment of the stabilizing muscles of the lumbar spine and SIJs with simultaneous small-range movements of the extremities. Altering the length of lever arms, limiting the ROM, and adjusting the position of the exercise to a gravity-lessened position are examples of altering the exercise to reduce the stress on the inflamed segments. Prophylactic ROM exercises for associated regions and neuromeningeal mobility exercises[120] (see Self-Management 17-6) also may be used to prevent unnecessary loss of movement.

As the acute pain subsides and functional movement improves, more advanced exercises may be introduced, focusing on impairments in muscle performance, ROM, muscle extensibility, joint mobility, and balance. Transition to more advanced stages of care is rarely simple; if a dosage stresses any given subsystem of the movement system beyond its tolerance, the result will be an increase in pain and inflammation. Therefore, exercise gradation should err on the conservative side to avoid exacerbation of symptoms.

SELF-MANAGEMENT 17-8
Self-Mobilization for an Anterior Innominate Dysfunction

Purpose: To normalize the position and motion of your pelvis

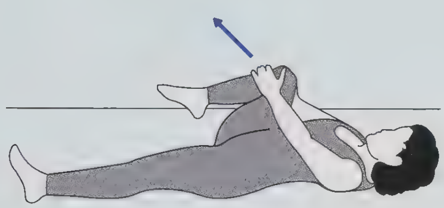
Starting Position: Back lying on a firm surface.

Movement Technique: Keep your ___ hip and knee straight. Pull your ___ knee toward your chest until you feel a mild barrier. Gently squeeze your ___ gluteal muscles against an unyielding force exerted by your hands keeping your knee to your chest. Hold your contraction for 8 to 10 seconds. On relaxation, flex your hip and rotate your pelvis posteriorly until you feel a new barrier. Repeat this process three to four times.

Dosage:

Repetitions: ______________________________

Frequency: ______________________________



SELF-MANAGEMENT 17-9
Self-Management for a Sacral Dysfunction

Purpose: To restore normal position and movement of your sacrum

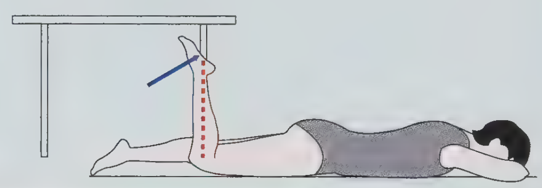
Starting Position: Lie on your stomach on the floor with your legs on either side of a table leg or door. Bend your ___ knee to 90 degrees and position your heel against the table leg or door.

Movement Technique: First, activate your pelvic floor muscles, transverse abdominis, and LM. *Gently* (about 10% maximum pressure) press your heel into the table leg or door. *Use your deep hip muscles (not your thigh muscles). Hold the contraction for 10 seconds.*

Dosage:

Repetitions: ______________________________

Frequency: ______________________________



Patients should be educated about when to modify or stop exercise in light of increased symptoms (e.g., numbness, paresthesia, pain) beyond acceptable time frames (e.g., if symptoms are increased for more than 24 hours). Continuing to exercise duration these situations can be counterproductive to progress. Educating the patient to respond to their body's response to exercise and to modify exercises appropriately (e.g., decrease lever arms, work in gravity-lessened position, decrease repetitions, decrease frequency, longer rest periods) can prevent excessive stress on healing tissues. Conversely, fear-avoidance behaviors should be circumvented with encouragement that pain does not always mean harm and carefully prescribed exercise will induce healing and adaptation.

The muscular changes that occurred as a result of lumbopelvic pain (e.g., muscle performance capabilities, cross-sectional area, neuromuscular control) may not improve naturally after the pain has ceased and the patient resumes functional activities.[179] Specific localized exercises as described in this chapter can restore the ideal lumbopelvic muscle control and performance (see **Building Block 17-2**).

An earlier section (see "Myology" and "Muscle Performance Impairment") discussed the role of the TrA, LM, and pelvic floor in the stabilization of the lumbopelvic region. Specific stabilization exercises aimed at improving motor control and muscle performance of the intrinsic spinal muscles appear effective in reversing atrophic changes in the LM muscles in patients with acute LBP[179] and may reduce recurrence rates

BUILDING BLOCK 17-2

1. A clinical example may provide insight into the complex relationships between pain and the development of hypermobility in the lumbopelvic region. A 45-year-old male presents with LBP. He has a flat back, a slight pelvic shift in standing, and increased foot pronation and foot abduction on the right. During the examination, the physical therapist notices that the pelvis and lumbar spine rotate during the initiation of active hip flexion in the supine position and that this movement provokes LBP. When the patient is properly cued to recruit the intrinsic spinal muscles, pelvis and spine rotation is reduced, and symptoms are eliminated. Other tests throughout the examination confirm that the L5–S1 segmental level is the site of relative flexibility in the direction of flexion and rotation. The examination should determine all contributing physiologic impairments. What examination findings would you expect in relation to key muscle testing, motor control over intrinsic spine muscles, and muscle flexibility?
2. To develop a program to improve the stability at the site of relative flexibility, each of the correlating impairments must be addressed. The program emphasizes achieving local spinal control over flexion and rotation stresses, improving quality of body movement, and training kinesthetic awareness to control spinal postures and movements in the direction associated with symptoms. Given this case study, develop an exercise program that addresses all relevant impairments. Provide at least one exercise progression or functional transition for each exercise. Be sure to include dosage information.

after the first episode of acute LBP.[113] In a subgroup of patients with structural abnormalities predisposing them to segmental instability, specific stabilization exercises reduced long-term pain and disability levels when compared with general exercise.[247]

Posture and Movement Impairment

Effective education in the area of posture and movement is essential to recover from and prevent recurrence of lumbopelvic syndromes. Education regarding posture and movement should be initiated at the first visit. By the end of the initial examination, the clinician should have identified aggravating postures and movements[248] and instructed the patient in recommendations regarding sitting, standing, and recumbent postures. Basic movement patterns, such as bed mobility (see **Patient-Related Instruction 17-3**), sit to stand, and bending (see **Patient-Related Instruction 17-4**) and lifting maneuvers can be taught to the patient. The specific postures and movement patterns should reflect the patient's impairments, activity limitations, and participation restrictions. For example, a person with a diagnosed HNP at L4 may have different sitting recommendations than a person with spinal stenosis. The former is advised to avoid sustained end-range flexion, while the latter is advised to avoid sustained, end-range extension. The bottom line is that patients need to understand why, not just what to do, to facilitate empowerment and commitment to change.[249,250] They must play an active role in their treatment to obtain optimum benefit.[251–254]

In addition to education regarding posture and movement during ADLs, the clinician must consider specific posture and movement patterns for each prescribed exercise to be most effective. For example, allowing a patient with disk pathology to sit or move in lumbar flexion during a sitting HS stretch not only reduces the

Patient-Related Instruction 17-3

Bed Mobility

To reduce the stress on your low back, your physical therapist may ask you to get out of bed in a specific manner. The following instructions pertain to safe bed mobility.

- Activate your intrinsic spinal muscles and slide one foot at a time up the bed until your knees are flexed and your feet are flat on the bed. Be sure to prevent your back from arching or rotating by using your intrinsic spinal muscles.
- If you are not close to the side of the bed, you must bridge and slide until you are close to the side of the bed. Be sure to keep your intrinsic spinal muscles activated while bridging and sliding.
- Roll your body as one unit until you are lying on your side. Do not lead with your upper body or pelvis because this will result in a rotational stress on your spine that is detrimental to the healing process.
- Gently let your feet slide off the bed while simultaneously pushing yourself into the upright position with your hands.
- *TIP*: Be sure to maintain an intrinsic spinal muscle contraction during all components of this maneuver. You should be able to perform this skill without increase in symptoms. Talk to your physical therapist if you are unable to transfer from back lying to sitting without increased symptoms.

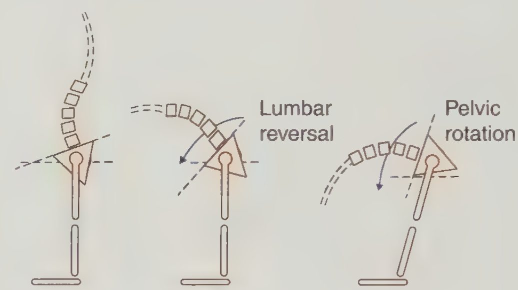
Patient-Related Instruction 17-4

Lumbar-Pelvic Movement

When you bend forward to pick up a light object, such as a shirt or a pencil, you can practice moving with the appropriate relationship between your low back and pelvis. The following are key points to keep in mind while bending forward:

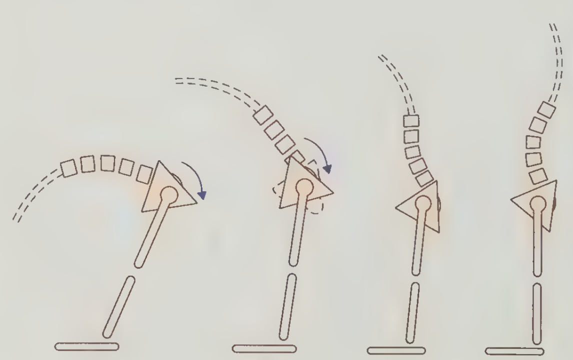
Bending Forward (Figs. A to C)

- Leading with your head, slowly curl your spine as you bend forward.
- Think about relaxing at each vertebral segment.
- Try to keep your knees straight and minimize the backward shift of your hips.
- After you have reached the level of your low back in your forward bend, try to rotate your pelvis.
- Do not flex your low back further after your pelvis has stopped rotating.
- If you need to bend more to reach the desired distance, bend your hips and knees instead of flexing your low back beyond the rotation of your pelvis.
- At the end of the forward bend, relax your low back.



Return from Forward Bend (Figs. D to G)

- Lead with your hips and pelvis by contracting your gluteal muscles.
- Your low back should only extend after your pelvis has achieved its neutral position.
- At the end of the range, you may need to pull in with your abdominal muscles to achieve your neutral pelvic position.



Adapted from Calliet R. Low Back Pain. 3rd Ed. Philadelphia, PA: FA Davis, 1981.

BUILDING BLOCK 17-3

The following are examples of movement patterns used in ADLs that require education and training in proper performance:

1. Simple bed mobility and sit-to-stand transfers
2. Small bends and squatting maneuvers
3. Gait (**Fig. A**) and stair stepping (**Fig. B**)
4. Occupational activities, such as lifting mechanics
5. Recreational activities, such as baseball (**Fig. C**)

Teach a partner safe patterns of movement during bed mobility, sit-to-stand transfers, small knee bends, and squatting maneuvers. Teach a partner how to lift from floor to waist, then from waist to shoulder height. Consider what region of the body you would teach a baseball pitcher to emphasize in movement during a pitch.

A B C

effectiveness of the stretch, but also places additional stress on the disk. The posture of the spine and pelvis throughout the exercise must be emphasized. Attention to posture and movement during *all* exercises prescribed enhances their effectiveness. This requires a high level of supervision by the physical therapist. Research has shown that higher levels of supervision are associated with better outcomes with individuals with CLBP.[255]

The ultimate goal of each individual seeking treatment is to achieve a desired functional outcome. This involves skill in total-body posture and movement patterns that use optimal dynamic stabilization and recruitment strategies. To achieve this, the individual must pay close attention to precision of movement during specific functional exercises (e.g., heel slides to improve bed mobility skills), during BADLs (e.g., squatting maneuvers), and during IADLs (e.g., playing golf). The clinician should instruct the patient in proper stabilization and movement strategies using the foundation of neuromuscular control, muscle performance, mobility, and proprioception that the impairment-based exercises have provided.

Aspects of posture and movement retraining can be incorporated into any stage of rehabilitation. Training begins by breaking complex movements into a number of simple components. For example, an introductory postural strategy may be to teach the individual to sit properly in an ergonomic chair. Later, the patient may be progressed to sitting in a standard chair or on a soft surface such as a gym ball.

The more advanced the movement pattern, the more the task needs to be broken into simplified components to ensure that the proper amount of movement and stabilization occur in the desired segments. After skill is achieved at each simplified component, the components are linked together to form the complete activity sequence. Teaching skill in movement requires high levels of motivation and adherence from the patient and in-depth knowledge of concepts of motor learning and movement analysis by the clinician. Chapter 9 further addresses exercise prescription for the treatment of posture and movement impairments (see **Building Block 17-3**).

Specific exercises may be linked together in a circuit-training format. The circuit may include a variety of manual handling procedures, such as single- and double-handed lifts with a variety of different shapes and weights, pushing and pulling activities, and reaching high and low levels. In addition, almost any piece of equipment, whether designed for a specific exercise, sport, or work activity, can be utilized for movement retraining. Exercises should be adapted to meet the demands of the patient's work and recreation. The clinician must be careful not to progress the patient faster than he or she can learn to control motion with the optimal strategies. Diligence displayed by the patient and clinician is rewarded with fewer setbacks and higher gains in functional return (see **Building Block 17-4** and **Case Study 17-1**).

BUILDING BLOCK 17-4

Develop a sport-specific circuit for a soccer player with LBP. Bias your cues based upon sensitivity toward flexion postures/movements; and then with extension postures/movements.

CASE STUDY 17-1

HISTORY

The patient was a 54-year-old female with a 10+ year history of LBP. The pain had an insidious onset, but has gotten worse in the past year. Pain intensity, using a numeric pain rating scale, is 5/10 on average and 7/10 at worst. Standing, lifting, and walking more than 20 minutes made symptoms worse; sitting and lying with a pillow under the knees alleviates the pain. She estimates her sleep is disrupted about 30% to 40% of the time. Associated symptoms included an intermittent ache along the paraspinal musculature and a throbbing pain radiating into the buttock and posterior thigh. The patient reported having no saddle paresthesia, change in bowel and bladder function, or generalized weakness or incoordination of her lower extremities.

Other medical history included an appendectomy, tonsillectomy, hysterectomy, hypertension, hypercholesterolemia, and depression. Her depressive symptoms were being treated with bupropion hydrochloride. Other current medications included lisinopril and hydrochlorothiazide for hypertension, metoclopramide for gastroesophageal reflux, and lamotrigine for stabilizing mood. The patient's work activities included lifting and carrying boxes of files and sitting at a computer. Her hobbies included gardening. The patient's goals were to garden and perform all work duties with a pain level of 4/10.

EXAMINATION

At intake, the patient's Oswestry Low Back Disability Questionnaire (ODQ) score was 18/50, her Beck Depression Index (BDI) was 8/63, indicating minimal depressive symptoms; and her Fear-Avoidance Belief Questionnaire (FABQ) work subscale score was 38/42, indicating high fear-avoidance behavior concerning work activities. However, her FABQ physical activity subscale score was 10/24, indicating minimal fear-avoidance behavior concerning physical activity outside of work.

Her posture included increased thoracic kyphosis and lumbar lordosis with anterior pelvic tilt and iliac crest asymmetry with right ilium high. During the stance phase of gait, it was observed that her lumbar spine moves excessively into extension and rotation instead of the stance hip moving into extension. Patellar reflexes were 1+ bilaterally, and Achilles reflexes could not be elicited. Dermatomal function was normal, but there was a slight reduction in anterior tibialis force production on the right. Standing lumbar active range of motion revealed non-reversal of lumbar extension, but no pain during flexion. Slight pain was elicited upon return from flexion. Passive range of motion during a right SLR, as measured with bubble inclinometry, was 52 degrees, with reproduction of right gluteal pain, but sensitizing using dorsiflexion was negative. Left SLR was positive at 60 degrees for familiar back pain, and sensitizing with dorsiflexion was also negative. Muscle length testing in the Thomas test position with the knee flexed revealed right hip extension lacking 18 degrees and left hip extension lacking 15 degrees. Manual muscle tests of the hip revealed right gluteus medius muscle strength was 3/5, left 3+/5, and gluteus maximus muscle strength was 3+/5 bilateral. Abdominal performance testing, which was conducted as described by Sahrmann, showed inability to perform level 1 correctly. Palpation assessment of transverse abdominis and LM demonstrated poor activation with verbal cueing. Passive intervertebral testing revealed guarding with posterior/anterior pressure at L4/L5 and a positional fault in extension and rotation.

EVALUATION

Based on the initial examination data, the mediators influencing the patient's chronic LBP were categorized using the WHO-ICF model (see **Case Table 17-1**). It is hypothesized that the listed impairments contribute to the relative flexibility of the lumbar spine in the direction susceptible to motion (DSM) of extension and rotation include poor muscle performance of the intrinsic spinal muscles combined with short hip flexors.

INTERVENTION

The patient was educated on her physical therapist's diagnosis, prognosis, and plan of care. She was seen for 10 visits over 12 weeks. Patient education, specific exercise for associated impairments, and graded exercise were used to address her avoidance of physical activity, especially at work. Specifically, she was educated during the initial visit that pain did not signal harm, but that by moving with improved patterns of movement and using improved posture habits, it would be possible for her to perform more work-related duties and leisure activities with less pain. It was explained, however, that she needed to maintain a consistent activity pace, and to stay as active as tolerable. This was reinforced during discussions in subsequent visits.

Two examples of exercises to address specific impairments in motor control and muscle performance are listed below.

Self-Management 17-1 demonstrates an exercise progression targeting the impairments in the intrinsic spinal muscles simultaneous with lengthening the hip flexors. While the intrinsic spinal muscles contract in the short range, the hip flexor muscles elongate. If the patient allows the hip flexors to pull the pelvis and spine out of alignment, the exercise becomes detrimental to altering the site of relative flexibility. The patient can be taught to control the specific spine stabilization strategy with targeted muscle activation patterns.

In conjunction with this exercise, the patient can work on the same relationship in other positions, such as prone (see Self-Management 17-5). The lumbopelvic region is stabilized through appropriate intrinsic spinal muscle recruitment, and the knee is flexed to the point of mild tension and before the loss of lumbopelvic stabilization. Emphasis is placed on relaxation of the rectus femoris and TFL simultaneously with stabilization of the spine against the extension force imposed by the short hip flexors. Eventually, the patient can progress to the closed chain and the walk stance progression (see Self-Management 19-2) with emphasis on controlling lumbopelvic position in relation to the extending hip. These active movements prepare the patient for the ultimate goal of stabilizing the lumbar spine during standing tasks and during the stance phase of gait. The therapist will most likely need to guide the patient in the proper stabilizing strategies during gait.

CASE STUDY 17-1 (continued)

OUTCOME

At 12 weeks, the patient reported that she was able to bend and carry charts at work for a full day without increased pain. She regularly sat and stood at work for 30 minutes without pain. Her worst pain was reported as 3/10. Her ODQ score was 6/50. Hip flexion combined with knee flexion in the Thomas test position was 6 degrees on the left and 10 degrees on the right. Abdominal strength was graded as level 2 and she could demonstrate activation control over transverse abdominis and LM at L4 and L5 levels. The patient cancelled a follow-up appointment at 14 weeks and subsequently was contacted by telephone. Final questionnaires revealed an ODQ score of 2/50, a BDI of 4/63, an FABQ work subscale score of 0/42, and an FABQ physical activity subscale score of 0/24. Pain intensity, as measured with a numeric pain rating scale, was 2/10 at worst. The patient stated that she was "much improved."

CASE TABLE 17-1 The World Health Organization's International Classification of Functioning, Disability and Health (WHO-ICF) Model Applied to the Evaluation of Patient with CLBP

	BODY STRUCTURES AND FUNCTIONS	ACTIVITIES	PARTICIPATION
Patient's perspective	Pain in back and back of thigh	Standing	Unable to garden
		Lifting	Decreased work tolerance
		Walking 20 min	Interrupted sleep
Physical therapist's perspective	Reduced muscle power functions (b730)	Lifting and carrying objects (d430)	Remunerative employment (d850)
	Reduced mobility of joint functions (b710)	Maintaining body positions (d410)	Recreation and leisure (d920)
	Gait pattern functions (b770)		
	Neuromusculoskeletal and movement-related functions, other specified (b798)

THERAPEUTIC EXERCISE INTERVENTION FOR COMMON DIAGNOSES

The following section discusses three of the most common diagnoses of the lumbopelvic region. Although SIJ syndrome is not discussed, it should be evaluated and treated combining concepts related to both the lumbopelvic region and hip joint (see Chapter 19). The reader is challenged to develop a comprehensive lumbo-pelvic-hip therapeutic exercise prescription for each individual SIJ syndrome patient encountered.

Lumbar Disk Herniation

Disk degeneration involves structural disruption and cell-mediated changes in composition. Traditionally, disk degeneration has been linked to mechanical loading. The importance of mechanical factors has been emphasized by experiments on cadaver spines with both a severe single event as well as relentless loading.[256–260] Failure of the disk is more common in the areas with the heaviest mechanical stresses, such as the lower lumbar region. It has been suggested that mechanical factors produce endplate damage, the antecedent to disk degeneration[261] (**Evidence and Research 17-6**).

EVIDENCE and RESEARCH 17-6

Degeneration Versus Aging Changes to the Spine

Conventional theory would imply that degeneration and aging are very similar processes, albeit occurring at different rates. Resnick and Niwayama[262] emphasized the differentiating features of two degenerative processes involving the intervertebral disk.[263] These include *spondylosis deformans*, which affects essentially the annulus fibrosus and adjacent apophyses, and *intervertebral osteochondrosis*, which affects mainly the nucleus pulposus and the vertebral body endplates. Studies suggest that spondylosis deformans is the consequence of normal aging, whereas intervertebral osteochondrosis results from a clearly pathologic, though not necessarily symptomatic, process.[260–268] Anterior and lateral marginal vertebral body osteophytes have been found in 100% of skeletons of individuals over 40 years of age, and therefore are consequences of normal aging, whereas posterior osteophytes have been found in only a minority of skeletons of individuals over 80 years, and therefore are not inevitable consequences of aging.[264] Endplate erosions with osteosclerosis and chronic reactive bone marrow changes also appear to be pathologic.

Nutritional[269,270] and genetic[271,272] factors may also play a role in the cascade of disk degeneration, albeit to variable degrees in different individuals. The presence of degenerative change is by no means an indicator of symptoms, and there is a very high prevalence in asymptomatic individuals.[273] The etiology of pain as the symptom of degenerative disease is complex and appears to be a combination of mechanical deformation and the presence of inflammatory mediators. Regardless of the etiology of disk degeneration, by the age of 50 years, 85% to 95% of adults show evidence of degenerative disk disease at autopsy[274] with the peak incidence of herniated lumbar disks in adults between the ages of 30 and 55 years.[275]

The underlying mechanism of internal disk disruption is theorized as follows[261]: The damaged endplate deforms more when under load,[276] allowing more space for the hydrated nucleus pulposus, or allowing some nucleus tissue to pass through it. The nucleus therefore experiences a reduction in pressure,[277] which is similar in amount to the reduction seen in degenerated disks.[278,279] The decompressed disk bulges more and loses height.[280] This process is intensified by water loss after sustained loading.[281] Less of the applied compressive force is resisted by the decompressed nucleus, so more must be resisted by the surrounding annulus (and apophyseal joints). High stress gradients in the annulus then force the inner lamellae inward toward the decompressed nucleus[282] and the outer lamellae outward. The buckling of the lamellae is encouraged by the accompanying loss in disk height. The effects are greater in older disks because their tissues are less hydrated, and therefore less able to deform sufficiently to reduce steep stress gradients. Nucleus pulposus material can move into the disrupted annulus during repetitive loading, but bulk extrusion of nucleus pulposus from the disk can be achieved (in vitro) only if the motion segment is heavily loaded in flexion or hyperflexion.[257,259,283] With a disk protrusion, the NP does not herniate from the disk; it is confined by the annular fibers. This may be the typical "back sprain" that results from bending, lifting, and frequent twisting. It often gives a person LBP with little or no pain radiation into the legs. The pain is usually relieved quite rapidly with rest or curtailment of most bending or lifting activities for several days. Patients are usually fairly comfortable when on their feet, but when they change from a lying to a sitting position or from sitting to standing, the pain can be acute and disable them from fully standing. The probable cause of the pain is the flexion or torsion forces imposed on the disk during these movements. These episodes, if not treated appropriately, can recur and become more frequent as time progresses. Eventually, they can lead to the more disabling disk herniation.

If the annular tear progresses to full annular disruption, a HNP results. Penetration of the nuclear material into peripheral areas that are highly sensitive to mechanical and chemical stimulation may be the source of the disabling pain felt in disk herniation. Clinically, disk herniation can be divided into the following subsets:

- HNP without neurologic deficit
- HNP with nerve root irritation
- HNP with nerve root compression

HNP without neurologic deficit has signs and symptoms similar to those of an annular tear but is slower to recover and imparts slightly more disability. No encroachment on the nerve root has occurred with this condition. HNP with nerve root irritation has signs and symptoms, including sciatica, paresthesias, and positive SLR, but no neurologic deficit is diagnosed. HNP with nerve root compression has signs of nerve root irritation plus neuroconductivity changes. A massive midline disk herniation may cause spinal cord or cauda equina compression, requiring immediate surgical referral. Fortunately, the cauda equina syndrome occurs in only 1% to 2% of all LDHs that result in surgery.[284]

Regular physical activity appears to reduce or increase the risks of disk degeneration, depending on how severe the degenerative changes are.[261] This complication probably is caused by the ability of skeletal tissues to strengthen with regular moderate exercise[285] but to experience (fatigue) failure if the loading is too severe[286] (**Evidence and Research 17-7**).

EVIDENCE and RESEARCH 17-7

Physical Stress Theory and Disk Degeneration

"Adaptive remodeling" in response to controlled exercise explains why professional tennis players have 30% more bone in their racquet arm,[287] and why physically active individuals have extremely strong vertebrae[288,289] and disks.[290] Conversely, a lack of exercise leads to tissue weakening, and this may explain why some sedentary occupations increase the risk of disk prolapse.[291] The weakened spinal tissues would be vulnerable to accidental injury during slips and falls. Physical stress theory proposed by Mueller[292] summarizes the importance of optimal stress to tissues to sustain health (see **Fig. 17-17**).

Examination and Evaluation Findings

Sciatica is a symptom of nerve root irritation and is a form of neuropathic pain (NeP). Sciatica is defined as a sharp or burning pain radiating down the posterior or lateral aspect of the leg, usually to the foot or ankle, often associated with numbness or paresthesia. Coughing, sneezing, or the Valsalva maneuver often aggravates the pain. Sciatica caused by disk herniation is worsened by prolonged sitting and improved by walking, lying supine, lying prone, or sitting in a reclined position.[293] The absence of sciatica makes a clinically important LDH unlikely.[90,91,275,293,294] The estimated incidence of disk herniation in a patient without sciatica is 1 in 1,000.[11]

The International Association for the Study of Pain has defined NeP as "pain caused by a lesion or disease of the somatosensory system."[295–298] It has been estimated that 2% to 4% of the general population have some form of NeP with substantially higher rates in those with CLBP.[299–303] Importantly, the presence of NeP has been linked with poor recovery along with higher health care costs and lower quality of life.[297,298,304,305]

Neurodynamic tests are a series of multijoint movements of the limbs and/or trunk that produce mechanical and physiologic events in the nervous system and can detect NeP.[122,306,307] One of these mechanical events is an increase in tension in the nerve being tested.[308–312] The SLR test is the most commonly used neurodynamic test for the lower extremity. In the supine SLR test, tension is transmitted to the nerve roots after the leg is raised beyond 30 degrees, but after 70 degrees, further movement of the nerve is negligible.[312] A typical SLR sign is one that reproduces the patient's sciatica between 30 and 60 degrees of elevation.[275,313] The lower the angle producing a positive result, the more specific the test becomes, and the larger is the disk protrusion found at surgery.[314,315] The SLR test demonstrated 100% specificity in patients clinically diagnosed with NeP.[316] In addition, the rate of NeP was more than 14-fold higher in

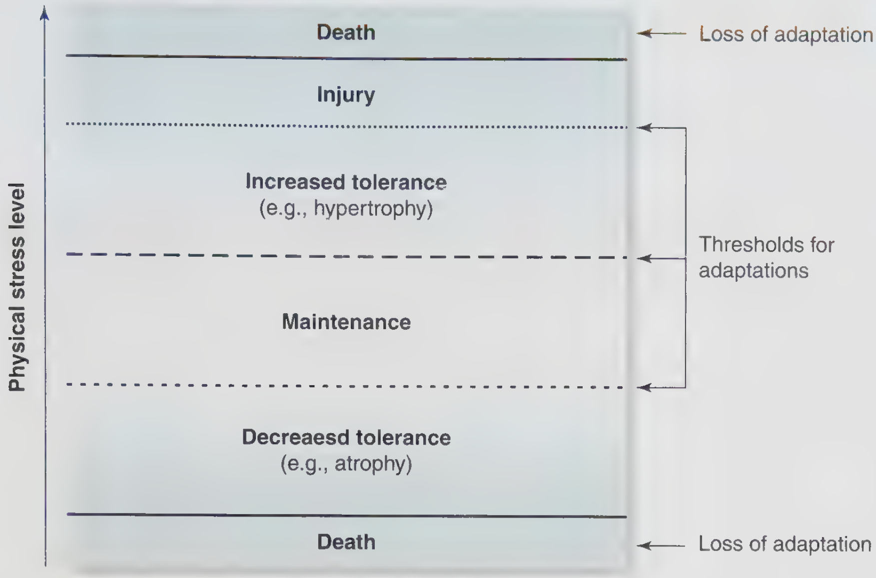

FIGURE 17-17 Effect of physical stress on tissue adaptation. Biological tissues exhibit five adaptive responses to physical stress. Each response is predicted to occur within a defined range along a continuum of stress levels. Specific thresholds define the upper and lower stress levels for each characteristic tissue response. The relative relationship between these thresholds is fairly consistent between people, whereas the absolute values for thresholds vary greatly.

those with a positive SLR test.[317,318] Care must be taken to differentiate HS tension from sciatica. Sensitizing techniques (e.g., neck flexion, ankle dorsiflexion) can be used to determine whether the pain experienced is originating from HS tension or nerve irritation. Straight-leg raising is most appropriate for testing the lower lumbar nerve roots (L5 and S1), where most disk herniations occur.[275] Irritation of higher lumbar roots is tested with femoral nerve stretch. The femoral nerve stretch, which is passive knee flexion, can be performed in prone with the spine in a neutral position. Alternately, the spine can be biased into flexion with the test performed in sidelying.

The slump test is another neurodynamic test which differs from the SLR test in that it incorporates spinal flexion and can therefore potentially generate greater overall neural tension and detect NeP in patients with more mild symptoms. The slump test also incorporates knee extension as a sensitizing maneuver which can be used to modulate the mechanical strain on the nervous system,[122] thereby confirming nervous tissue as the source of symptoms during the test. Accepting that neurodynamic tests increase tension in nerves and that NeP is associated with lowered mechanical thresholds, it would be expected that a positive outcome on a neurodynamic test would be highly associated with NeP. A variation of the slump test accurately identified patients with upper/mid lumbar nerve root compression[328] (**Evidence and Research 17-8**).

About 98% of clinically important LDHs occur at the L4–L5 or L5–S1 intervertebral level,[314,315,320] causing neurologic impairments in the motor and sensory regions of the L5 and S1 nerve roots. The most common neurologic impairments are weakness of the ankle and great toe dorsiflexors (L5) or ankle and foot plantar flexors (S1), diminished ankle reflexes (S1), and sensory loss in the feet (L5 and S1).[314,315,320] In a patient with sciatica and suspected disk herniation, the neurologic examination can be concentrated on these functions. Among patients with LBP alone (no sciatica or neurologic symptoms), the prevalence of neurologic impairments is so low that extensive neurologic evaluation is usually unnecessary.[121]

EVIDENCE and RESEARCH 17-8

Sensitivity and Specificity of the Slump Test

A 2015 study investigated the ability of a neurodynamic test to independently detect NeP in individuals with low to moderate levels of CLBP.[319] The neurosensory examination designated 11 of the 21 participants with LBP/sciatica as having NeP. The slump test displayed high sensitivity (0.91), moderate specificity (0.70), a positive likelihood ratio of 3.03, and a negative likelihood ratio of 0.13. Adding the criterion of pain below the knee significantly increased specificity to 1.00 (positive likelihood ratio = 11.9). Pain quality descriptors did not improve diagnostic accuracy. The authors concluded that the slump test was highly sensitive in identifying NeP within the study sample. Adding a pain location criterion improved specificity. Combining the diagnostic outcomes was very effective in identifying all those without NeP and half of those with NeP. Limitations arising from the small and narrow spectrum of participants with LBP/sciatica sampled within the study prevent application of the findings to a wider population.

Higher lumbar nerve roots account for only about 2% of LDHs.[314,315,320] They are suspected when numbness or pain involves the anterior thigh more prominently than the calf. Testing includes patellar tendon reflexes, femoral nerve neurodynamic testing, and assessment of quadriceps strength, and psoas strength.[275,315,320] Quadriceps weakness is virtually always associated with impairment in the patellar tendon reflex.[321]

The most consistent finding with a low lumbar midline disk herniation, called *cauda equina syndrome*, is urinary retention.[11,96,321–324] Unilateral or bilateral sciatica, sensory and motor deficits, sexual dysfunction (i.e., decreased sensation during intercourse, decreased penile sensation, and erectile dysfunction), and abnormal SLR also are common examination findings.[96,323,324] The most common sensory deficit (i.e., hyperesthesia or anesthesia) occurs over the buttocks, posterosuperior thighs, and perineal regions.[96,322,324] Finally, decreased anal sphincter tone can be a neurologic sequelae of cauda equina syndrome.[96] Kostuik et al.[96] warn that a central disk lesion, especially at the L5–S1 disk, can pose a diagnostic challenge because it affects only the lower sacral roots and causes no motor or reflex changes in the legs.

As has already been presented, radiological imaging for LBP, in the absence of red flags, progressive neurologic deficits or traumatic injury, is not warranted and may in fact be detrimental. The Quebec Task Force on Spinal Disorders suggests that early roentgenography is necessary only under the following conditions:

- Neurologic deficits
- Patient older than 50 or younger than 20 years of age
- Fever
- Trauma
- Signs of neoplasm[325]

Magnetic resonance imaging and CT can be used even more selectively, usually for surgical planning.[11] The finding of herniated disks and spinal stenosis in many asymptomatic individuals[326,327] indicates that imaging results alone can be misleading. There is strong evidence that unwarranted imaging makes patients worse; MRI scans for nontraumatic LBP lead to poorer health outcomes, greater disability and work absenteeism due to the pathologizing of the problem.[328]

Treatment

For the small group of patients (5%) who present with LBP due to disk herniation and associated radicular pain with or without neurologic deficit, the natural history is very good. Prospective studies demonstrate high recovery rates (over 80%) and reduction of the herniation in most of these patients at 12 months of follow-up when managed conservatively. Only in people with progressive neurologic changes and cauda equina symptoms is a surgical opinion immediately warranted. There is no "cookbook" approach toward the exercise management of LBP, even if a specific structural diagnosis, such as HNP with nerve root irritation, is offered. Determining which interventions to use depends on the pathoanatomic process, the identified impairments, and the patient disability profile, including the desired "return to" activities and participations. The following concepts of care for specific stages of disk herniation can guide patient management.

Acute Stage In the acute stages of any injury, the immediate goals are often to relieve pain and to reduce or halt the inflammatory process so that the healing process can occur unimpeded. Investigations into the biochemistry of disk degeneration and herniation indicate that intraspinal inflammation is a major cause of radicular pain.[329] A neurotoxic, inflammatory mediator phospholipase is contained within the disk nucleus and is released after annular injury. Early intervention and patient adherence to the recommendations addressing pain and inflammation in the case of HNP are essential for achieving a rapid recovery and for preventing chronic pain and disability.

Along with physical therapy intervention, the patient's physician usually prescribes steroidal or nonsteroidal anti-inflammatory medications and may suggest epidural steroid injection. Corticosteroids have powerful anti-inflammatory effects. The use of epidural steroid injection, performed by experienced physicians who have shown competence in the technical aspects of this procedure, has produced favorable outcomes, particularly if used in conjunction with physical therapy[330] (**Evidence and Research 17-9**).

EVIDENCE and RESEARCH 17-9

Evidence for Use of Epidural Steroid Injections in Conjunction with Physical Therapy

Intervertebral disk herniation, spinal stenosis, intervertebral disk degeneration without disk herniation, and post lumbar surgery syndrome are the most common diagnoses of chronic persistent low back and lower extremity symptoms, resulting in significant economic, societal, and health care impact. Epidural injections are one of the most commonly performed interventions in the United States in managing CLBP. However, the evidence is highly variable among different techniques utilized as well as for the conditions treated.

The available literature on epidural injections with or without steroids in managing various types of CLBP with or without lower extremity pain was reviewed and methodically analyzed.[331] The primary outcome measure was pain relief (short-term relief = up to 6 months and long-term >6 months). Secondary outcome measures of improvement in functional status, psychologic status, return to work, and reduction in opioid intake were utilized. There was good evidence for short- and long-term relief of chronic pain secondary to disk herniation or radiculitis with local anesthetic and steroids and fair relief with local anesthetic only. Further, this systematic review also provided indicated evidence of fair for caudal epidural injections in managing chronic axial or diskogenic pain, spinal stenosis, and post surgery syndrome.

While attempting to halt the inflammatory process, the primary role of the physical therapist may be to promote the concept of "controlled rest." This intervention may take the form of posture and activity modification (i.e., avoidance of flexed postures, sitting, and bending or lifting activities), pacing activity and rest, positions for pain relief, and most importantly, guiding the patient through this phase to avoid developing fear-avoidance behaviors. It is important to teach the patient to temporarily avoid flexed and asymmetric postures, flexion and rotation movements (especially under load), and sitting (which elevates disk pressures) to enhance healing and prevent reinjury. The clinician also can teach the patient how to use cryotherapy at home to control inflammation and reduce pain levels. Traction can be a useful adjunctive modality in the acute phase. Similar to the recommendations of Delitto et al.,[238] the most common examination criterion cited by clinicians as an indication for traction is the presence of signs of nerve root compression[332] (see the "Adjunctive Interventions" section).

Exercise can play a vital role in the treatment of pain and inflammation. For example, careful prescription of exercises based on the McKenzie diagnostic classification system may be useful in the early treatment of disk-related signs and symptoms (see Examination and Evaluation: Range of Motion, Muscle Length, and Joint Mobility and Therapeutic Exercise Intervention for Common Physiologic Impairments: Pain and Self-Management 17-7).[133,236,333]

As with any mechanically induced injury, the underlying causes of muscle or soft-tissue injury must be avoided. In the acute phase of disk herniation, due to altered movement patterns from the pain, it is often difficult to determine the postures and movements associated with the development of segmental dysfunction (see **Building Block 17-5**).

BUILDING BLOCK 17-5

In the acute phase of managing a herniated disk, it is useful to teach the patient basic bed mobility movements. Name two exercises you have learned in this chapter that would help a patient move in bed with less pain.

In the acute phase of disk herniation, the patient is often susceptible to the effects of immobilization as a result of the protective nature of this phase of care. Treatment to maintain or improve mobility of adjacent segments within the lumbar spine and thoracic spine and the extensibility of lower extremity muscles is vital for reducing stress on the injured segment and reducing the negative effects of immobilization that may play a role in recurrence of the condition. For example, joint mobilization of the thoracic spine and segments above and below the affected segmental level, along with soft-tissue mobilization of the erector spinae group, can maintain joint mobility during the acute phase. Piriformis spasm is a common secondary effect of lower LDH. Soft-tissue mobilization and passive stretching to this muscle can decrease pain associated with the spasm (see **Building Block 17-6**).

BUILDING BLOCK 17-6

Devise a safe stretch to the piriformis that will not place torsional stress on the sacrum or lumbar spine.

Treatment to maintain or improve mobility in the neural tissues also is critical in the acute stages. Decreased neuromeningeal mobility is a common sequel of HNP and can affect muscle performance and lumbopelvic mobility. Neuromeningeal mobility should be assessed and, if indicated, specific exercises to improve mobility of the neural system may be prescribed (see Self-Management 17-6). Initially, tolerance is usually very low, and neuromeningeal mobility exercises must be performed with caution, usually in recumbent positions to prevent exacerbating symptoms. Neuromeningeal mobility exercises performed during the acute stage may prevent chronic complications from increased neural tension. The related anatomy, physiology, and application principles must be well understood for the effective and safe use of this type of treatment. This topic is worthy of more extensive coverage; further guidance in prescribing these exercises has been provided by Butler.[122]

The clinician should encourage the patient to maintain some activity level, such as swimming or walking, during the acute stage. Swimming can be employed with the use of a kick board to minimize unwanted spinal motion while promoting aerobic fitness and lower extremity motion. Walking with a corset, wearing good shock-absorbing shoes, and walking on a soft surface (e.g., gravel) may reduce disk pressure enough to tolerate the stress of walking. In addition to the benefits of movement, the benefits of low-level aerobic exercise are gained.

Subacute and Chronic Stages After the acute pain has subsided and the patient has more freedom of movement, the treatment should focus on altering postures and movements and the associated impairments that produce symptoms. The ultimate goal is the return to the highest possible level of function with the safest and most desirable postures and movement patterns possible.

Review the sections on treatment of impairments to understand the concept of exercise intervention for mobility, muscle performance, balance, coordination, posture, and movement impairments and the progression through traditional stages of motor control. This information provides the basis for developing a progressive program of intervention for a patient with disk pathology beyond the acute stages of care.

Patient education is the most important intervention to protect against developing chronic disability. The patient must be taught self-management techniques to gain control over the pathology and remain less reliant on the health care system for ongoing treatment. The clinician must teach the patient to temporarily manage acute exacerbations with cryotherapy, positional techniques, or repeated shift correction and extension movements.[133] Instruction in body mechanics, ergonomics, and ongoing fitness activities is equally important in preventing recurrence. Evaluation of the home and work environment, work-station ergonomics, and the development of fitness programs are preventive strategies the clinician should implement. Perhaps the most important outcome of patient education is the sense of confidence gained by the realization that back problems can be managed while the patient continues to function and lead a productive life.

Spinal Stenosis

Spinal stenosis is defined as an abnormal narrowing of the spinal canal (central) or the intervertebral foramen (lateral or foraminal).[334] Central stenosis can result from osteophyte enlargement of the inferior articular process or vertebral bodies, congenitally decreased anteroposterior or mediolateral diameters of the spinal canal, hypertrophy of the ligamentum flavum, spondylolisthesis, or neoplasm that impinges on the cauda equina. Lateral or foraminal stenosis is typically caused by subluxation of the facets as a result of disk narrowing. Extension and rotation positional faults of the segment produce further narrowing. Symptoms are usually segmental because of entrapment of the nerve root.

Examination and Evaluation Findings

The characteristic history of persons with spinal stenosis is that of neurogenic claudication (i.e., pain in the legs) and, occasionally, neurologic deficits that occur after walking. In contrast to arterial ischemic claudication, neurogenic claudication can occur on standing (without ambulation), may increase with cough or sneeze, is associated with normal arterial pulses,[335] and is relieved by flexion of the lumbar spine. One often-used test to discriminate between ischemic and neurogenic claudication is stationary biking.[336] The patient is positioned in lumbar flexion and asked to pedal. This test will likely reproduce symptoms if the source is ischemic claudication, whereas with the spine positioned in flexion, neurogenic claudication is less likely.

Increased pain on spine extension is typical of stenosis. Although flexion is usually painful with herniated disks, it can be a position of relief for patients with spinal stenosis. Patients feel more comfortable walking in a stooped position, cycling, walking behind a shopping cart or lawn mower, or walking up an incline or stairs, rather than walking on a flat surface, down an incline, or downstairs.[337,338]

Treatment

Recently, the published surgical literature is sending a message to look for new strategies in the field of rehabilitation and conservative treatments before considering decompressive, instrumented surgery, or minimally invasive techniques that are presently offered.[339] This is great news for physical therapists who can provide much insight and rehabilitative skill into conservative treatment of spinal stenosis. Treatment of spinal stenosis is based on symptoms related to postures and movements. If the patient has mild symptoms that fluctuate with mechanical, postural, and movement changes, he or she can be accommodated with appropriate patient-related education, exercise, external lumbar support, (i.e., corset), and nonsteroidal anti-inflammatory medication. Although nonoperative measures cannot reverse a true anatomic impairment, they can accommodate it by increasing the foraminal or spinal canal diameter.

Exercise should focus on physiologic impairments that may contribute to foraminal or spinal canal narrowing:

- Poor muscle performance from the intrinsic spinal muscles (TrA, LM, diaphragm, and pelvic floor) resulting in insufficient support to the lumbar spine
- Short hip flexors, hypertrophied erector spinae, and long EO contributing to anterior pelvic tilt and lumbar lordosis
- Thoracic kyphosis with overstretched and weak thoracic erector spinae accompanying lumbar lordosis
- Asymmetry of pelvic girdle and lower extremity muscle length and strength resulting in lumbar scoliosis and lateral foraminal narrowing

Canal or foraminal narrowing is typically associated with spine extension, combined extension and rotation, or anterior translation. Postures associated with relative extension (i.e., kyphosis and lordosis), combined extension and rotation (i.e., kyphosis and lordosis and functional/structural limb length discrepancy), or anterior translation (i.e., swayback) should be avoided, and the patient should be instructed in postural correction to remedy these postural habits.

The clinician should teach the patient to avoid movement patterns that require repeated extension, rotation, or shearing and to develop control over these forces when unavoidable (see **Building Block 17-7**).

BUILDING BLOCK 17-7

Name at least three ADLs that require movement into extension that you will examine and retrain if faulty or too provocative for your patient's current status.

Limited ambulation is a frequent functional limitation among patients with spinal stenosis. Harness-supported treadmill ambulation or use of a walker, crutches, or a cane for patients with leg pain brought on by walking can be used as a progressive return to walking without symptoms. The amount of unloaded force can be progressed until unloading force is no longer required to relieve pain during ambulation.[340]

Patients should be instructed in recreational activities that do not produce symptoms. Exercise biased toward flexion should be encouraged, such as walking on a treadmill with a slight incline, cycling, or walking while pushing a stroller. Exercise biased toward extension should be discouraged, such as walking on a flat surface, walking downhill, or swimming.

Spondylolysis and Spondylolisthesis

Spondylolysis, a bilateral defect in the pars interarticularis, occurs in 58% of adults.[341] Approximately 50% of those never progress to any degree of spondylolisthesis, a condition of forward subluxation of the body of one vertebrae on the vertebrae below it.[341] Spondylolisthesis is not limited to any specific segment of the spine, but is most often seen at L4/L5 or L5/S1.[342] Defects or impairment of any of the supporting structures can lead to subluxation of the superior segment on the inferior segment. Spondylolisthesis has been classified[343] by cause into five types:

1. Type I, isthmic: A defect in the pars interarticularis may be caused by a fracture or by an elongation of the pars without separation.
2. Type II, congenital: The posterior elements are anatomically inadequate because of developmental deficiency. This occurs rarely.
3. Type III, degenerative: The facets or the supporting ligaments undergo degenerative changes, allowing listhesis. There is no pars defect, and the condition worsens with age.
4. Type IV, elongated pedicle: The length of the neural arch elongates to allow listhesis. This is essentially an isthmic type. Traction forces are apparently contributory.
5. Type V, destructive disease: Metastatic disease, tuberculosis, or other bone disease may change the structure of the supporting tissues. This is rare.

Examination and Evaluation Findings

The patient may complain of backache, gluteal pain, lower limb pain or paresthesias, hyperesthesia, muscle weakness, intermittent claudication, or bladder and rectal disturbances. The physical examination may reveal that symptoms worsen on return from forward bending that is accompanied by lumbar extension. If the patient is cued to lead with the gluteal musculature and recruit the intrinsic spinal muscles, symptoms are reduced. The clinical diagnosis is suspected if this finding is accompanied by inspection and palpation of the spine in which a depression at the listhesis level is noticed. Percussion over the segment may elicit pain. Radiologic confirmation can be made by an oblique view of the lumbosacral region. A roentgenogram can diagnose spondylolysis or spondylolisthesis and the degree of subluxation, which can be graded.

Treatment

In general, treatment of spondylolysis or spondylolisthesis is nonsurgical.[344] Surgical treatment of this condition varies depending on patient age, degree of slip, presence of neurologic findings, and degree of deformity. Pediatric and adolescent patients with a low-grade slip that is asymptomatic only need observation. Nonsurgical treatment includes bracing, exercise, and nonsteroidal anti-inflammatory medications. In children and adolescents, immobilization in a thoracolumbosacral brace, activity modification, and exercise expedite healing of the defect.[343,345] It may be advisable to avoid contact sports and sports that require lumbar hyperextension, such as gymnastics, in patients with a Grade II slip (**Evidence and Research 17-10**).

EVIDENCE and RESEARCH 17-10

Surgical Versus Conservative Management of High-Grade Slips in Spondylolisthesis

Symptomatic high-grade isthmic spondylolisthesis in children and adolescents has an unfavorable natural history with high risk of progression and low likelihood of symptomatic relief. Conservative treatment is generally not recommended in symptomatic patients who constitute the majority of patients with high-grade slips in this age group[346-347] Pizzutillo et al.[346] found that only 1 of 11 symptomatic patients treated conservatively had significant pain relief at long-term follow-up. Asymptomatic patients can be treated with observation, and if symptoms do develop, surgery is considered. Some authors[348] have recommended surgical treatment for these patients regardless of symptoms because of the high risk of progression.[347] However, Harris and Weinstein[349] reported that 10 out of their 11 patients with high-grade slips who were treated nonoperatively remained active and required only minor modifications in activity. At a mean of 18-year follow-up, only one patient had significant symptoms, and all patients led an active life. Five patients had one or more neurologic findings, but none were incontinent. Adults with high-grade slips have often reached a stable position and typically do not experience progression. Autofusion or ankylosis of the slipped level can occur. Some of these patients are asymptomatic or minimally symptomatic and can be successfully treated with physical therapy and selective nerve root injections if radicular symptoms are present. If conservative treatment fails, surgery is recommended in adult patients with high-grade slips with back pain and/or radicular symptoms.[349]

Exercise, posture and movement retraining, and activity modification are the cornerstones of the rehabilitation program. As for the patient with spinal stenosis, lumbar extension and shearing forces should be avoided. Exercises focused on resolving the impairments associated with extension or shearing forces should be prescribed, and strong emphasis should be placed on intrinsic spinal muscle control and strengthening, and posture and movement retraining. **Figure 17-18** is a good position to activate the intrinsic spinal muscles without the anterior force from the hip flexors (Self-Management 17-1). Self-Management 17-2 provides examples of initial exercises to stimulate the stability necessary for recovery from

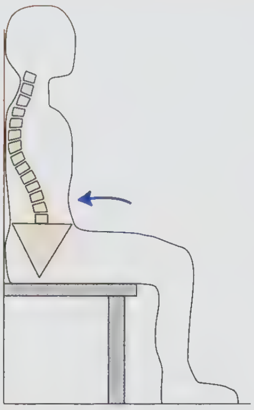

FIGURE 17-18 Sitting posterior pelvic tilt. This activity can be used by individuals with lordosis, anterior pelvic tilt, weak and overstretched abdominal muscles (particularly external oblique [EO] and transversus abdominis [TrA]), and short hip flexors. The supine intrinsic spinal muscle progression is often contraindicated for this type of patient due to the anterior translation force exerted by the iliopsoas and anterior pelvic tilt force exerted by the TFL and rectus femoris. The patient sits with her back against a wall and is instructed to pull the umbilicus toward the spine to reduce the lordosis. Sitting takes the stretch off the hip flexors, and the pelvis should be able to move posteriorly with greater ease than in standing with the hip flexors on relative stretch. Use of a gluteal contraction over an abdominal contraction is discouraged. This exercise can be progressed to standing in slight hip and knee flexion (to release tension on the hip flexors) and then to standing upright once the abdominal muscles are strong enough and the hip flexor muscles are of sufficient length to attain a neutral pelvic position. The advantage of this exercise is that it can be performed frequently throughout the day.

spondylolisthesis. If a brace is used in conjunction with physical therapy, the physical therapist should communicate with the physician regarding the prescribed immobilization period and weaning program. Most often, the patient can continue to participate in certain sports during the immobilization period and is encouraged to do so. However, contact or collision sports should be avoided. In addition, activity modifications may be warranted. For example, volleyball requires a great deal of extension movements and shearing forces when hitting. An athlete may avoid hitting during practice and focus more so on serving and defense. If movement patterns cannot be modified enough to reduce symptoms during these activities, the patient may need to be counseled to seek another form of recreation or athletic endeavor.

KEY POINTS

- A thorough understanding of the anatomy and biomechanics of the lumbopelvic region is prerequisite to appropriate therapeutic exercise prescription for this region.
- Exercise must be based on a thoughtful and systematic examination process identifying the physiologic and psychologic impairments most closely related to the individual's activity limitations and participation restrictions.
- Therapeutic exercise intervention for common physiologic impairments must be coordinated to address associated

impairments and prioritized to address those most closely related to activity limitations and participation restrictions.

- Exercise management of common pathoanatomic diagnoses must not follow a "cookbook" approach, but rather be highly prescriptive and relate to the patient's unique impairments, activity limitations, and participation restrictions.

CRITICAL THINKING QUESTIONS

1. Prioritize postures from the most to the least stressful on the lumbar spine.
2. Describe the principles for the use of optimal body mechanics during lifting.
3. Describe the biomechanical differences between the bent-knee and straight-leg sit-up. What would be the best abdominal exercise for an individual with a HNP? Spinal stenosis or spondylolisthesis? How would you modify the sit-up for a person with a kyphosis/lordosis posture type?
4. How can exercise impact chemical sources of nociception?
5. What postures place the EO in a lengthened position, making it susceptible to strain resulting from overstretch?
6. Given the following activities: flexion phase of forward bending, sidelying hip abduction, and seated rotation. Describe the optimal site and direction of relative flexibility during these movements. (Hint: during the return from forward bending, the optimal site of *relative* flexibility is the hip in the direction of extension versus the lumbar spine in the direction of extension.)
7. What is the conceptual basis for treatment of a relative flexibility or stiffness problem?
8. Define the anatomic injury that occurs with disk prolapse and the three subsets of disk herniation.
9. Define the three clinical categories of signs and symptoms associated with HNP.
10. Define the broad category of spinal stenosis and the two types of stenosis.
11. Discuss the difference between spondylolysis and spondylolisthesis.
12. What spine position and movement should a person with stenosis avoid? Same question with respect to spondylolisthesis?
13. What intrinsic muscle group would you target in a patient with stenosis or spondylolisthesis? (Hint: you want to avoid forces that produce extension or anterior translation on the lumbar spine.)
14. Discuss the musculature involved in force closure of the SIJ.
15. Refer to Case Study No. 5 in Unit 7.
    a. Based on her history and physical examination findings, what is the likely medical diagnosis for this patient?
    b. What are the faulty posture and movement patterns associated with the onset of her symptoms?
    c. What are the correlating physiologic impairments? List them under the headings used in this chapter (e.g., mobility, muscle performance).
    d. Develop an exercise program addressing all pertinent impairments related to her activity limitations and participation restrictions.
    e. Be sure to include patient-related instruction tips.

CHAPTER

18 The Pelvic Floor

ELIZABETH R. SHELLY • SHERRI S. HOLT

Pelvic floor dysfunction refers to dysfunction of the entire pelvis including impairments of the gynecologic, urinary, and gastrointestinal systems, as well as neuromusculoskeletal impairments. Physical therapists are often involved in the rehabilitation of patients with the following diagnoses:

- Urinary incontinence (UI)
- Fecal incontinence
- Pelvic organ prolapse
- Urinary retention
- Pelvic pain
- Painful penetration

The *PFMs* refers collectively to a group of skeletal muscles under voluntary control that span from the pubic bone to the coccyx. PFM rehabilitation utilizes the same training techniques as other skeletal muscles in the body and can prevent or reverse pelvic floor dysfunction[1] (**Evidence and Research 18-1** and **18-2**).

EVIDENCE and RESEARCH 18-1

A recent study investigated the prevalence of stress urinary incontinence (SUI) in a sample of 408 subjects age 30 to 50, attending a public well women clinic. SUI was reported in 37.5% of the women and 30.7% of those women reported impaired quality of life. In addition, 52.9% of the women with SUI believed that this was "inevitable with age"; 13.7% thought there was no treatment available.[2]

In a retrospective study of 778 women with pelvic floor dysfunction, including UI, defecatory dysfunction, and pelvic pain, 80% of the patients reported improvement in symptoms upon completion of five pelvic floor rehabilitation sessions.[3]

Fan et al.[4] investigated the effect of pelvic floor muscle (PFM) training on symptoms of UI and quality of life. The authors reported that 65% of the subjects had improvement in symptoms of incontinence and quality of life.

EVIDENCE and RESEARCH 18-2

Clinical audit in the United Kingdom showed that 79% of patients receiving PFM training improved sufficiently to avoid urological surgery.[5]

This chapter introduces students to the following concepts:

- Anatomy and kinesiology of the PFMs
- Physiology of micturition
- Screening for pelvic floor dysfunction
- Examination of the PFMs
- Management of common physiologic impairments of the PFM
- Relationship of the PFM to other body regions, particularly the lumbo-pelvic-hip complex (see Chapters 17 and 19)
- Clinical application through case studies

This chapter provides screening and examination tools that do not require internal vaginal evaluation or surface electromyography (EMG) of the pelvic floor and explains how to teach pelvic floor exercises (PFEs). These exercises, commonly referred to as Kegel (pronounced "kagel") exercises, strengthen the PFMs and specifically address impaired muscle performance. Arnold Kegel was an obstetrician who pioneered PFM strengthening in the 1940s.[6]

Postgraduate study is recommended for therapists interested in the specialized practice of pelvic floor rehabilitation. A complete evaluation of this area often requires intravaginal or intrarectal palpation and surface EMG evaluation, which are usually not considered entry-level skills.

REVIEW OF ANATOMY AND KINESIOLOGY

This section outlines the terminology used by most clinicians for structures of the pelvic floor.[7,8] Because most patients with PFM dysfunction are female, female anatomy is discussed in this chapter, but the pelvic diaphragm layers and intrapelvic hip rotators are essentially the same in both sexes.

Skeletal Muscles

Currently, the term "pelvic floor" refers to all the structures of the lower pelvis including the boney pelvis, viscera, fascia and ligaments, and PFMs. The skeletal muscles of the pelvic floor (**Fig. 18-1**) are specifically called "pelvic floor muscles"[7] and can be divided into four layers, from superficial to deep: (a) the anal sphincter, (b) superficial genital muscles, (c) perineal membrane, and (d) the pelvic diaphragm.[8]

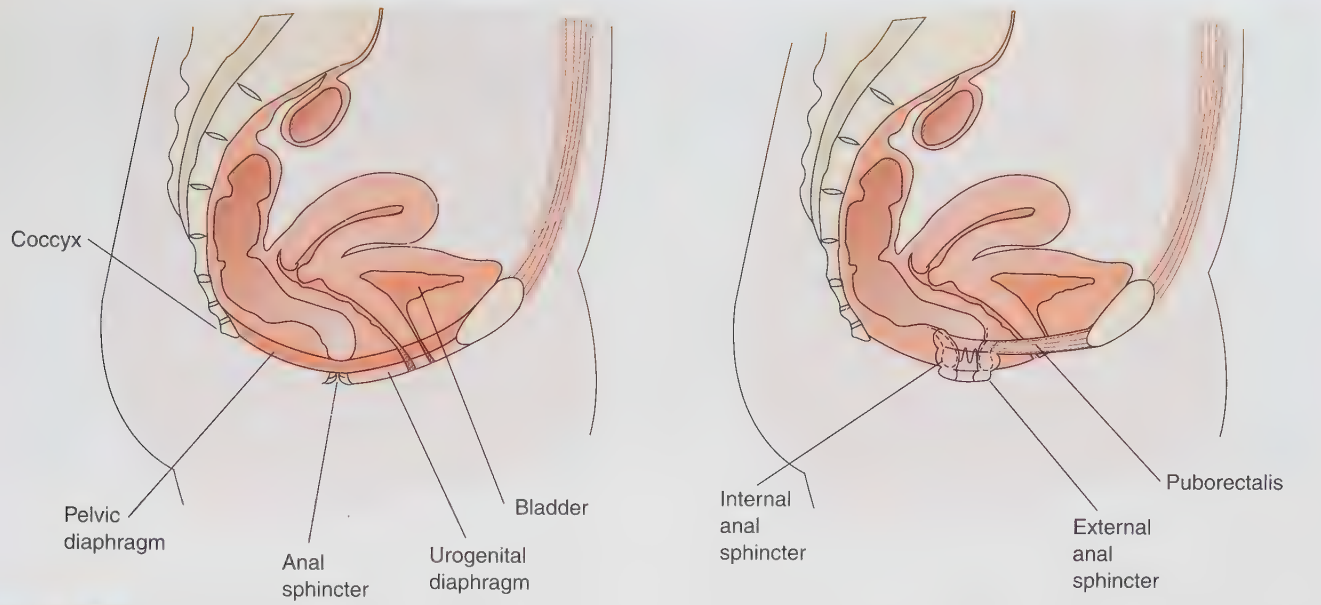

FIGURE 18-1 PFM layers.

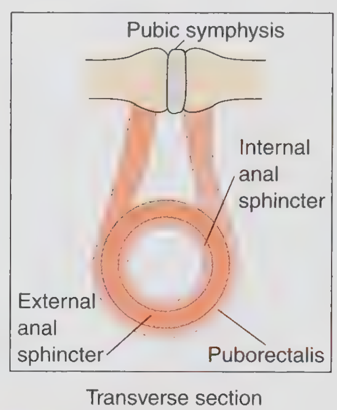

FIGURE 18-2 Anal sphincter.

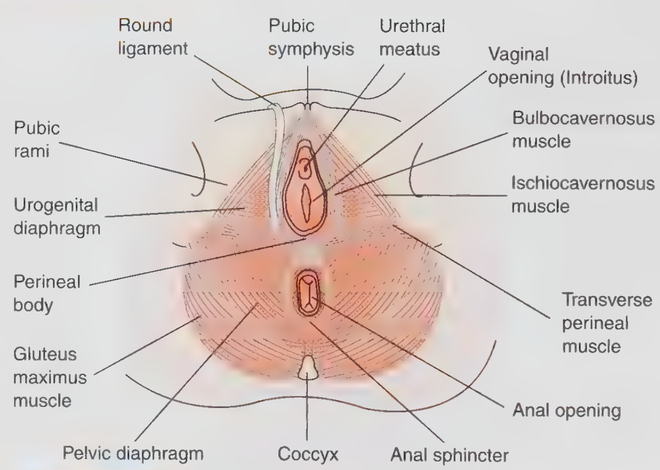

FIGURE 18-3 Female PFMs—inferior view.

The *anal sphincter* (**Fig. 18-2**):

- Most superficial skeletal muscle
- Includes internal anal sphincter (i.e., smooth muscle) and external anal sphincter (i.e., skeletal muscle)
- Internal and external anal sphincters fuse superiorly with the puborectalis (pelvic diaphragm muscle)
- Function is to provide fecal continence
- Innervated by S4 and the inferior branch of the pudendal nerve.

The *superficial genital muscles* (**Fig. 18-3** and **Table 18-1**[9–12]):

- Aid in sexual function of the pelvic floor
- Muscles include the bulbocavernosus, ischiocavernosus, superficial transverse perineal

The perineal membrane (**Fig. 18-4** and Table 18-1[9–12]):

- Part of the continence mechanism
- Muscles include the urethrovaginal sphincter, compressor urethrae (formerly known together as the deep transverse perineal), sphincter urethrae

Pelvic Diaphragm Muscles

The pelvic diaphragm (**Fig. 18-5**) contains the largest skeletal muscle group in the pelvic floor, the levator ani muscles. The four muscles of the levator ani are the coccygeus, iliococcygeus, puborectalis, and pubococcygeus (**Table 18-2**). These muscles function as a group to provide the following:

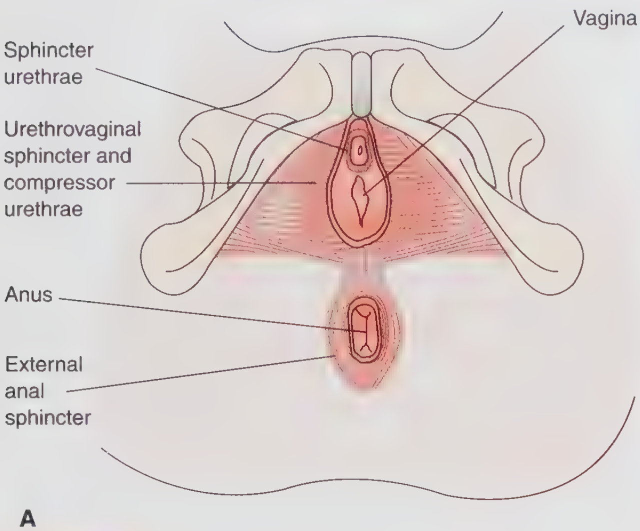
- Support pelvic viscera
- Maintain continence
- Postural stabilization
- Sexual function

The pelvic diaphragm muscles are approximately 70% slow-twitch muscle fibers (type 1) and 30% fast-twitch muscle fibers (type 2).[10] Both types of muscle fibers have specific functions in the pelvic floor, and therefore, a complete exercise program should train both types of muscle fibers. Impairments of the PFM can occur in a single layer or throughout the entire skeletal muscle layers. The PFMs contract as a unit to achieve various functions. Sensation in the region is limited and may be decreased with

TABLE 18-1

Muscles of the Female Urogenital Triangle

MUSCLE	ORIGIN	INSERTION	INNERVATION	FUNCTION
Superficial Perineal				
Bulbocavernosus	Corpus cavernosum of the clitoris	Perineal body	Perineal branch of pudendal S2–S4	Clitoral erection
Ischiocavernosus	Ischial tuberosity and pubic rami	Crus of the clitoris	Perineal branch of pudendal S2–S4	Clitoral erection
Superficial transverse	Ischial tuberosity	Central perineal tendon	Perineal branch of pudendal S2–S4	Stabilizes perineal body
Perineal Membrane				
Urethrovaginal sphincter	Vaginal wall	Urethra	Perineal branch of pudendal S2–S4	Compression of urethra
Sphincter urethra	Upper two-thirds of urethra	Trigone ring	Perineal branch of pudendal S2–S4	Compression of urethra
Compressor urethra	Ischiopubic rami	Urethra	Perineal branch of pudendal S2–S4	Compression of urethra



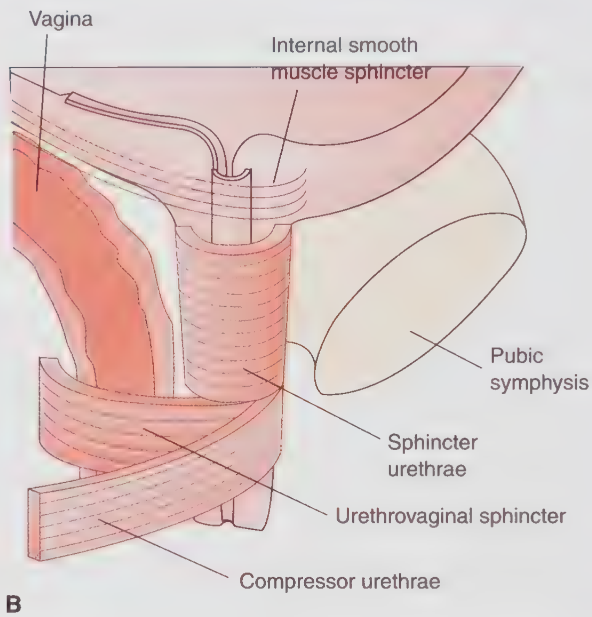


FIGURE 18-4 Female urogenital diaphragm—**(A)** inferior view, **(B)** side view. (From Schussler B, Laycock J, Norton P, et al, eds. Pelvic Floor Re-education Principles and Practice. New York, NY: Springer-Verlag, 1994.)

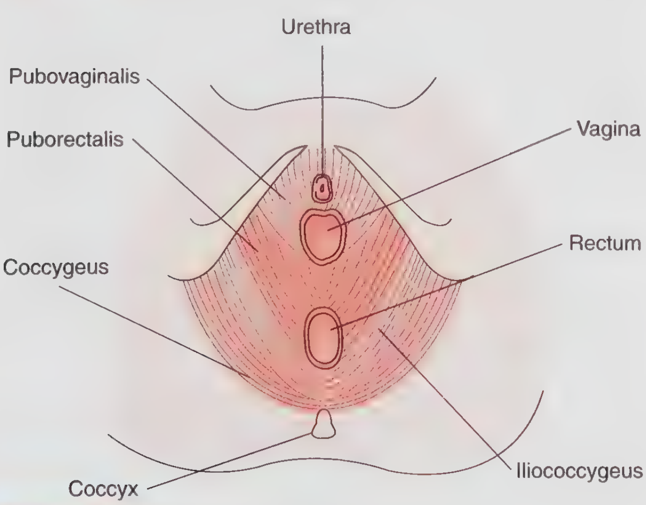

FIGURE 18-5 Female pelvic diaphragm—superior view.

surgery or childbirth making awareness of PFM contraction difficult. The PFM has extensive fascia throughout the muscle layers (see Table 18-2).

There is a very close anatomic relationship between the PFM and some hip muscles (**Fig. 18-6**).[13,14] The inferior border of the piriformis is close to the superior border of the coccygeus muscle, and the levator ani muscles attach to an extension of the obturator internus fascia (i.e., the arcus tendinous levator ani) (**Fig 18-7**). Clinically, it appears that impairments in length, strength, endurance, and patterns of recruitment of the piriformis and obturator internus muscles can contribute to PFM impairments and vice versa.[15]

The adductor muscle group also may contribute to PFM pain syndromes and overactive bladder. Adductor fascia at the pubic rami is in close proximity to the superficial perineal muscle fascia. The psoas minor and major muscles, iliacus, and quadratus lumborum are key muscles to treat in lumbopelvic dysfunctions including PFM pain syndromes.

TABLE 18-2

Levator Ani Muscles

MUSCLE	ORIGIN	INSERTION	INNERVATION	FUNCTION
Coccygeus	Spine of the ischium	Anterior portion of the coccyx and S4	Ventral rami, S4, and S5	Flex the coccyx
Pubococcygeus	Posterior os pubis	Perineal body, vaginal walls	Inferior rectal branch of the pudendal nerve, S2–S4, and ventral rami, S2–S4	Support of the pelvic viscera Compression of the vagina
Puborectalis	Pubic bone, arcus tendineus	Anterior coccyx, lateral rectum	Inferior rectal branch of the pudendal nerve, S2–S4, and ventral rami, S2–S4	Support of the pelvic viscera Compression of the rectum
Iliococcygeus	Pubic rami, arcus tendineus	Coccyx	Inferior rectal branch of the pudendal nerve, S2–S4, and ventral rami, S2–S4	Support of the pelvic viscera

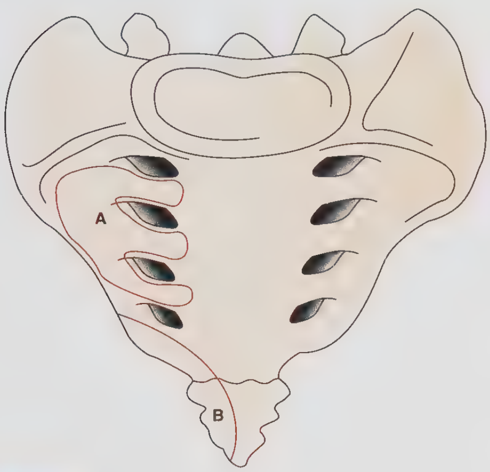

FIGURE 18-6 The anterior sacrum. Origin of the piriformis **(A)** and coccygeus **(B)**.

Pelvic Floor Function

Organ Support Function

The PFMs provide support to the pelvic organs against the forces of gravity and increased intra-abdominal pressure (e.g., laugh, cough, sneeze, vomit, lift, strain). This supportive function is primarily performed by the tonic, slow-twitch muscle fibers of the PFMs to maintain a minimal resting tone. Wei stated that normal pelvic organ support is achieved by ligamentous support from above, PFMs function from below, and the structural geometry achieved by normal function of both.[8] Recovery of organ support requires attention to restoring PFM function (i.e., PFM rehabilitation) firstly and in some cases restoring ligament support (i.e., surgery).[16] Women with pelvic organ prolapse, or protrusion of the pelvic organs, more often have defects in the levator ani and generate less vaginal closure force than women with good organ support.[17]

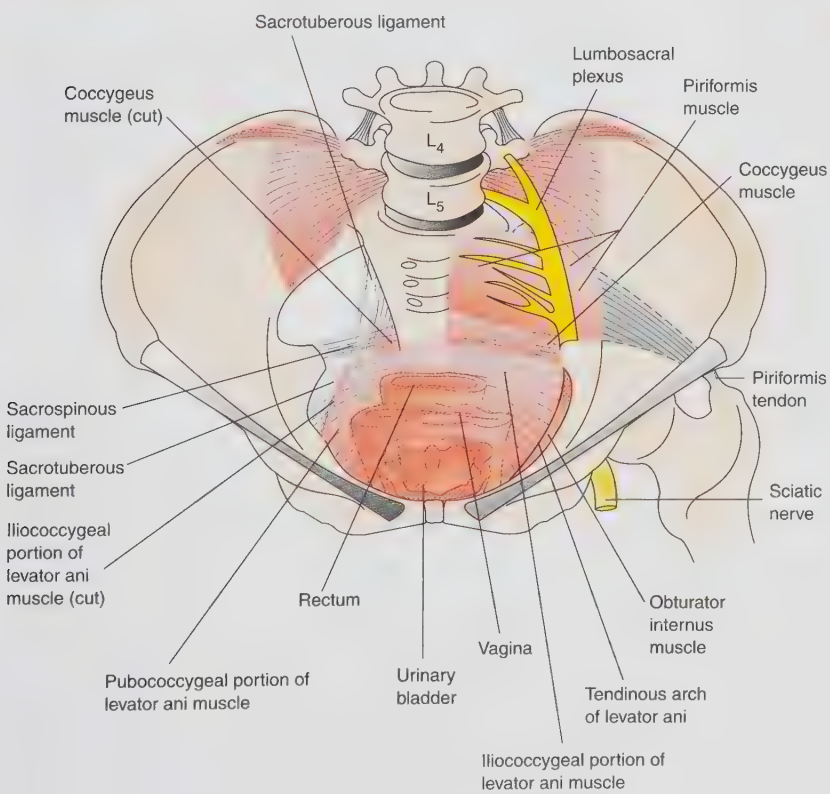

FIGURE 18-7 Piriformis and pelvic area—superior view.

Trunk Support Function

The PFM, transversus abdominis, deep multifidi, and diaphragm work together to enhance trunk stability.[18–21] There is cocontraction of the PFM and transversus abdominis muscles. The PFMs contract before movement to assist the abdominals in stabilizing the trunk.[22] Current research results support the role of the PFM in orthopedic conditions. It is essential that all physical therapists understand the role of the PFM, symptoms, and possible treatments (**Evidence and Research 18-3**).

EVIDENCE and RESEARCH 18-3

Many studies have documented bladder dysfunction in association with low back pain (LBP).[23] One study showed 78% of 200 women reporting to a physical therapy (PT) clinic with a chief complaint of LBP had UI.[24] Smith et al.[25] have documented decreased balance ability in women with SUI (a condition related to PFM weakness) compared to continent women.

Stuge et al.[26] documented an automatic PFM contraction with active straight leg raise in patients with pelvic girdle pain and in controls. This automatic PFM contraction was reduced by 62% to 66% when manual compression to the pelvis was provided.

Sphincteric Function

The PFMs provide closure of the urethra and rectum for continence. During normal function, quick closure of the orifices is provided by the phasic, fast-twitch fibers. Closure during rest (i.e., static resting tone) is provided by the slow-twitch muscle fibers. Continence is preserved when the pressure in the urethra (provided by several structures including the PFMs) is higher than the pressure in the bladder. Loss of sphincteric function may lead to incontinence. The medical literature commonly points out that incontinence is a symptom and not a disease; based on the terminology used in this book, incontinence results from impairments not a pathologic condition. Intervention should be aimed at the impairments that contribute to the syndrome of incontinence.

Sexual Function

The vagina has very few sensory nerve fibers.[27] The PFMs provide proprioceptive sensation that contributes to sexual appreciation. Hypertrophied PFMs create a smaller vagina and more friction against the penis during intercourse. This results in the stimulation of more nerve endings and provides pleasurable sensation during intercourse. Strong PFM contractions occur during orgasm. Patients with weak PFMs often cannot achieve orgasms.[27] In men, the PFMs assist in achieving and maintaining an erection.[28,29]

Physiology of Micturition

Micturition refers to the physiologic process of urination and involves a complex set of somatic and autonomic reflexes. An explanation of micturition is provided in **Display 18-1**. This information is included, so the therapist can explain the basics of normal bladder function to the patient and assist with basic bladder retraining.

Urine is produced steadily at about 15 drops per minute. Bladder filling is constant and urine production increases in the presence of bladder irritants. As the bladder fills, it passively expands until approximately 150 mL of fluid is collected. Stretch receptors in the bladder then signal the brain that it may be necessary to get to the bathroom soon. This is called the first sensation to void. The detrusor muscle (i.e., muscle of the bladder) remains quiet, and the PFMs maintain normal resting tone. Filling continues until 200 to 300 mL, when a stronger sensation of urgency is felt from increased activation of stretch receptors. The detrusor and PFMs remain unchanged. A strong urge to void usually occurs at 400 to 550 mL.[12,30] The brain eventually directs the person to a toilet and the person voids. The PFMs relax, the detrusor contracts, and urine flows out.[31] The PFMs return to resting tone when the urine flow stops. Normative values vary, but most practitioners consider it normal to have 5 to 50 mL of urine left in the bladder after a normal urination. It is neither necessary nor desirable to increase intra-abdominal pressure (i.e., bear down) at any time during urination.[11]

DISPLAY 18-1
Micturition Facts

- The bladder's job is to store urine and empty fully at the appropriate time and place.
- It is necessary to allow normal filling of the bladder for normal bladder function. Voiding "just in case" may contribute to urinary dysfunction.
  - Normal voiding frequency in a 24-hour period with normal fluid intake:
  - 6 to 8 times
  - >8 times is called *urinary frequency*
- Normal day time voiding interval: 2 to 5 hours
- Normal nocturnal voiding frequency (after the patient has gone to bed for the evening):
  - 0 to 1, children and adults <65 years
  - 1 to 2, adults >65 years
  - Normal volume for urination: 8 to 10 oz
- Recommended fluid intake per day: 6 to 8 oz glasses. Decreasing fluids does not decrease incontinence and may make urgency worse because concentrated urine is a bladder irritant.[32]
- Many fluids or substances are bladder irritants, causing urgency and increasing urine production:
  - Caffeine (e.g., coffee, tea, cola, medications, chocolate)
  - Alcohol
  - Carbonated beverages
  - Nicotine
  - Artificial sweeteners
  - Acid-containing foods (citrus, tomatoes, coffee, soda)
  - Some over-the-counter and prescription medications

Eliminating or limiting bladder irritants decreases symptoms of urgency and urge incontinence.

- Hovering over the toilet may result in incomplete emptying of the bladder due to increased PFM tone and decreased urine output.
- Toileting recommendations for women:
  - Wipe from front to back to ensures that fecal matter is not introduced into the urethra and decreasing the incidence of infection

Dysfunctions of micturition are complex. The screening questionnaire in Display 18-5 can help identify patients with dysfunctions of micturition who may need further medical intervention and who should be referred to the physician.

IMPAIRMENTS OF BODY STRUCTURES

Many factors contribute to normal function of the PFMs. Some of these factors cannot be changed by PT interventions. The two major causes of structural impairments are birth injury and neurologic dysfunction.

Birth Injury

Vaginal delivery may result in tears, overstretching, or crush injury of the PFMs (i.e., between the baby's head and the pubic rami) or may cause complete or partial denervation of unilateral or bilateral pudendal nerves (i.e., stretch injury or avulsion of the nerve) (**Evidence and Research 18-4**).

EVIDENCE and RESEARCH 18-4

Dollan et al.[33] found 80% of vaginal deliveries showed evidence of pudendal nerve reinnervation indicating trauma to the nerve. This occurrence was associated with longer pushing and larger babies.

Mild and moderate injuries can be effectively treated with behavioral interventions (see the "Impaired Muscle Performance" section). However, severe trauma may result in severe muscle damage (usually unilateral) and decreased sensory or motor innervation sufficient to render the muscle ineffective. This type of trauma occurs in a very small percentage of births. However, most women with vaginal deliveries sustain only minor, temporary dysfunctions and recover fully. To maximize birth recovery, all women of childbearing age should receive accurate preventative education on PFM health.[34]

Delivery Factors That May Contribute to PFM Injury[35–37]

■ Pushing phase >2 hours	■ Larger size of the baby's head
■ Forceps-assisted delivery	■ Medical interventions
■ Woman's position—supine	■ Medications administered
■ Use of episiotomy	■ Very fast deliveries

Neurologic Dysfunction

Many central and peripheral nervous system (PNS) dysfunctions affect PFM and bladder function.[38] PNS conditions, such as disk herniation and spinal cord injury, may result in sensory or motor denervation of the PFMs. Diabetes may result in sensory or motor denervation of the PFMs and autonomic neuropathy with disruption of bladder function. The pelvic plexus includes many small nerves that are often not visible during surgery. These nerves are not located in a consistent pattern in all patients. Radical pelvic operations, such as total hysterectomy[39] and radical prostatectomy,[40] may result in inadvertent disruption of the sensory and motor nerves to the bladder and PFMs. Patients may be able to strengthen the remaining innervated muscles to achieve full supportive and sphincteric function. Central nervous system (CNS) diseases such as cerebrovascular accidents,[41] multiple sclerosis,[42] and Parkinson disease may affect cognitive control of the bladder and PFMs. These conditions may also affect the patient's ability to get to the toilet or to recognize the toilet and may affect the patient's social awareness of continence. In these patients, UI is associated with eventual functional dependence and poor survival.[43] Maintaining functional independence should include treatment of PFM dysfunction and continence.

IMPAIRMENTS OF MENTAL FUNCTIONS

Motivation

PFM strengthening requires motivation and persistence. Improvement in muscle function with PFM therapy can be quick and dramatic, but it is more often slow and gradual. Some patients do not have enough motivation to complete therapy and find it easier to wear incontinence pads. Incontinence affects patients' lives differently. Some patients are devastated and severely limited by a small amount of urine leaking two or three times per week. Other patients view large leaks two or three times per day as a mild inconvenience. The perceived severity of the condition helps determine motivation. Ask the patient, "On a scale of 0 to 10, how severely does your condition affect your life (0 = no effect; 10 = severely limiting)." Therapists must strongly encourage patients throughout the therapy to maintain motivation. Depression and poor motivation may limit a patient's progress with pelvic muscle exercise (PME) (**Evidence and Research 18-5**).

EVIDENCE and RESEARCH 18-5

Adherence to PFM exercise programs has been shown to be predictive of positive outcomes.[44–46] Several factors limiting full participation in PFM exercises have been identified. These include lack of time and motivation, inconvenience, poor social support, and cultural beliefs.[47]

A prospective observational study investigated the effect of depression and anxiety on the success of PFM training in 108 subjects with pelvic floor dysfunction. The results revealed that subjects with no or mild depression or anxiety "benefited most" from PFM training.[48]

Vella et al.[49] investigated the effect of self-motivation on the success of PFM training for UI. The authors found that three of the five domains (positive attitude for treatment, frustration of living with incontinence, desire for treatment) of the Incontinence Treatment Motivation Questionnaire correlated significantly with outcome.

Sexual Abuse

All therapists should be aware of symptoms of sexual abuse (**Display 18-2**) and should have some exposure to techniques to facilitate rehabilitation of these patients (**Display 18-3**). It is especially important to be sensitive to these issues when treating PFM dysfunction and pelvic pain (see **Building Block 18-1**). Therapists are encouraged to seek additional information on sexual abuse survivors (see the "Recommended Reading" section) (**Evidence and Research 18-6**).

DISPLAY 18-2

Symptoms of Sexual Abuse

- Low self-esteem, feelings of loss of control
- Poor body awareness, often not trusting their own physical or emotional feelings
- Difficulty with anger and violence
- Difficulty with sexuality and intimacy; may avoid sex completely or compulsively seek sex
- Denies and forgets instructions or appointments
- Self-mutilating or addictive behaviors
- Controlling of environment, treatment, or your time
- Multiple personalities
- Dissociation (i.e., avoidance of eye contact, distant look), an unconscious defense mechanism to separate the mind from the body and protect the mind from impending trauma; may occur during the treatment sessions

DISPLAY 18-3

Guidelines for Therapy with Known or Suspected Sexual Abuse Survivors57

- Give the patient control over as much as you can in the environment and in therapy.
- Offer names of community support services and psychologists skilled in the treatment of sexual abuse survivors.
- Do not touch the patient without permission, and avoid hugging or other nonessential physical contact.
- Never allow the patient to disassociate.
- Be honest with the patient about your ability and knowledge (or lack of) in this area.

BUILDING BLOCK 18-1

Another therapist is working in the gym with a 15-year-old male with Osgood Schlatter. You notice this patient moves away when the therapist touches his thigh and appears uncomfortable when the therapist is standing close to him. Your colleague has expressed frustration with this patient's lack of coordination and body awareness making accurate exercises very difficult in the clinic and at home. In addition, the patient is very particular about the time of his appointment, which plinth he wants to work on, how the Thera-Band is arranged, and always cleans the mat before he sits on it. Discuss how you might share your concerns of possible sexual abuse history in this patient with your colleague and what steps might be taken to make his therapy more tolerable for him and more effective.

EVIDENCE and RESEARCH 18-6

An estimated one of three girls has been abused before the age of 14. One in six boys will be sexually abused before the age of 18. Only one of five cases is reported. Some studies show that there is a higher incidence of gynecologic problems among sexual abuse survivors.[50,51] 40% to 50% of women with chronic pelvic pain (CPP) have a history of abuse.[52–55]

EXAMINATION/EVALUATION

All patients could benefit from screening for PFM dysfunction, especially patients with lumbo-pelvic-hip pain (**Evidence and Research 18-7**).

EVIDENCE and RESEARCH 18-7

Bi et al.[56] investigated the effect of PFM training on outcomes in patients with chronic LBP. The authors reported that the addition of PFM training to routine LBP treatment resulted in significantly lower scores for pain severity and the Oswestry Disability Index when compared with the control group.

Understanding the risk factors for PFM dysfunction helps the therapist identify patients who may benefit from in-depth questioning. Screening tools are provided to identify PFM impairments and dysfunctions. Therapists are cautioned that questionnaires can be misleading[56] and full urologic workup is indicated if conservative treatment is not successful. This section also outlines the information that is gathered by specialized therapists from internal vaginal examinations and from patient self-evaluations. Other examination tools used by the specialized therapists include external observation, EMG and pressure biofeedback, and real-time ultrasound imaging.

Risk Factors

Risk factors are related to the causes of various dysfunctions (see **Display 18-4** and **Case Study 18-1**). Patients with medical histories that include many risk factors may be screened using a more detailed questionnaire (**Evidence and Research 18-8**).

DISPLAY 18-4

Risk Factors for Underactive and Overactive PFM

Underactive PFM[59–62]

- Vaginal childbirth, pregnancy.
- Increased body mass index, increased waistline.
- Chronic or prolonged coughing, as with pulmonary diseases, smoking.
- Arthritis, functional impairments, hip fracture, falls.
- Long-term incorrect lifting or straining with a Valsalva maneuver (i.e., increased intra-abdominal pressure with bearing down), including incorrect straining with exercise.
- Chronic constipation.
- Menopause and estrogen use.
- Neurologic dysfunctions that may affect peripheral nerves of the pelvis and many CNS diseases including dementia.
- Medical comorbidities such as diabetes mellitus (DM), peripheral vascular disease, congestive heart failure, thyroid problems.
- Decreased awareness of PFMs with disuse atrophy.
- Pelvic surgery, previous hysterectomy.
- Age—although UI increased with age, it is not a significant factor after adjustment for confounding conditions. UI does occur in young women, especially athletes.[63–65]

DISPLAY 18-4

Risk Factors for Underactive and Overactive PFM (*continued*)

Overactive PFM

- Back and pelvic pain with joint dysfunction, especially if related to a direct fall on the buttock or pubic bone[66]
- Muscle imbalance of the hip muscles, abdomen or pelvis, or lumbar spine, including shortened muscles or connective tissue in the trunk and pelvis[66]
- Habitual PFM holding (e.g., excessive emotional stress, or fighting the urge to urinate)[67]
- Abdominal adhesions and adhered scars in the pelvic region[68]
- Deep episiotomy or perineal tearing with childbirth
- Pelvic surgery[69]
- Pelvic conditions, such as endometriosis, irritable bowel syndrome, or interstitial cystitis[70,71]
- History of or current fissures or fistulas
- Connective tissue disease such as fibromyalgia
- History of or current sexually transmitted disease or recurrent perineal infections, including yeast infections
- Dermatologic conditions such as lichen sclerosis and lichen planus

CASE STUDY 18-1

Mary Smith is a 50-year-old mother of two with LBP. She works in a busy office and does not exercise often. List Ms. Smith's risk factors for underactive and overactive PFMs.

EVIDENCE and RESEARCH 18-8

Nygaard et al.[58] conducted a retrospective study of 96 women with UI who received supervised PFM training. Premenopausal and postmenopausal patients reported significant improvement in symptoms of UI.

Screening Questionnaires

A brief screening questionnaire should be given to all patients. Two types, brief or detailed, can be used to determine whether patients have dysfunctions of the pelvic floor. Questions should be clear and direct. A broad question such as "Are you incontinent?" usually results in a false-negative response.

Brief Screening Questionnaire

Evaluation of all patients, especially those with the risk factors listed in Display 18-4, should include three questions:

- Do you ever leak urine or feces?
- Do you ever wear a pad because of leaking urine?
- Do you have pain during intercourse?

Detailed Screening Questionnaire

Therapists must understand the dysfunctions of the PFM, their diagnostic classifications, and the types of incontinence to fully understand the interpretation of the results of this screening tool. A detailed screening questionnaire should be given if the patient responds affirmatively to the questions of the brief screening questionnaire. The longer version should be administered to a patient with pelvic, trunk, or back pain who is recovering slower than expected (see **Display 18-5**). If the patient has symptoms of overactive PFM (i.e., positive response to questions 13 through 19), proceed with full evaluation of the sacroiliac, hip girdle, and pelvic fascia (see **Case Study 18-2**).

Interpretation of Detailed PFM Questionnaire

Positive response to:

- Questions 1 to 14: indicates underactive PFM that may be treated using PFE
- Questions 1 to 3: indicates stress incontinence
- Questions 4 to 8: indicates urge incontinence
- Questions 13 and 14: indicates pelvic organ prolapse
- Questions 13 to 19: indicates overactive PFM, incoordination, or urinary retention
- Questions 15 to 17: indicates obstruction and may need physician evaluation to rule out mechanical obstruction

DISPLAY 18-5

Detailed PFM Questionnaire

The patient should respond with *never, sometimes,* or *often* to the following questions:

1. Do you leak urine when you cough, laugh, or sneeze?
2. Do you lose urine when you lift heavy objects such as a basket of wet clothes or furniture?
3. Do you lose urine when you run, jump, or exercise?
4. Do you ever have such an uncomfortable, strong need to urinate that you leak if you do not reach the toilet? Do you sometimes leak with this strong urge?
5. Do you develop an urgent need to urinate when you hear running water?
6. Do you develop an urgent need to urinate when you are nervous, under stress, or in a hurry?
7. When you are coming home, can you usually make it to the door but then lose urine just as you put the key in the lock?
8. Do you have an urge to urinate when your hands are in cold water?
9. Do you find it necessary to wear a pad at any time because of leakage?
10. Does your bladder awaken you from sleep? How many times each night?
11. How often do you leak urine or feces?
12. How often do you inadvertently leak gas?
13. Do you ever feel as though you are "sitting on a ball" or that there is something "in the way" when you are sitting?
14. Do you ever feel as though something is "falling out" of your perineal area?
15. Do you find it hard to begin urination?
16. Do you have a slow urinary stream?
17. Do you strain to pass urine?
18. Do you have pain during vaginal penetration, including intercourse, insertion of a tampon, or vaginal examination?
19. Do you have pelvic pain with sitting, wearing jeans, or bike riding?

CASE STUDY 18-2

You have asked Ms. Smith the PFM screening questions. She does report urine leakage with sneezing but does not wear pads. She denies pain with intercourse. Create a list of follow-up questions to ask Ms. Smith to determine more about her condition.

Results of the Internal Examination

A complete PFM evaluation is necessary to prescribe an appropriate exercise. It includes an extensive history, symptom documentation, identification of associated factors, and internal vaginal or rectal examinations. Surface EMG or pressure biofeedback evaluation may also be added. The specialized therapist obtains the following information from the internal examination of the PFMs[31]:

- *Muscle performance* is assessed in the form of power and endurance.
- *Power* is defined as the ability to contract (manual muscle grade of 0 through 5). This grade provides information on how much lift (i.e., supportive function) and closure (i.e., sphincteric function) the PFMs have. The muscle bulk of the PFMs can be palpated to help determine possible duration of rehabilitation and rehabilitation potential. Patients with a small, thin PFM require a longer rehabilitation time and generally have less rehabilitation potential than those with good PFM bulk.
- *Endurance* is defined as the ability to hold a slow-twitch muscle contraction and repeat the contraction. Clinicians also determine how many fast-twitch muscle contractions can be done. The quality of the contractions is also evaluated.
- *Resting tone between contractions* is assessed, looking specifically for altered tone impairments.
- *Coordination* of the PFMs and the relationship with associated muscles are assessed. Muscle dominance patterns or inappropriate contractions of the gluteal muscles, adductor group, and abdominal muscles are assessed.
- *Other impairments*, such as pelvic floor trigger points, decreased sensation, and scars or myofascial adhesions, may limit strengthening.

DISPLAY 18-6
Contraindications or Precautions to Internal Evaluation of the PFM

- Pregnancy
- Within 6 weeks of vaginal or cesarean delivery
- Within 6 weeks after pelvic surgery
- Atrophic vaginitis, a condition of fragile skin seen in cases of estrogen deficiency
- Active pelvic infection
- Severe pelvic or vaginal pain, especially pain during penetration or intercourse
- Children and presexual adolescents
- Lack of informed consent
- Lack of therapist's training (The therapist should obtain specialized training in performing internal evaluations of the PFM. Training can be obtained in postgraduate courses or through individual instruction from a midwife, physician, nurse, or trained physical therapist.)

Internal examination of the PFMs is the gold standard for determining if the patient is performing a PFM contraction correctly.[72,73] However, internal examinations cannot or should not be performed in some cases (see **Display 18-6**). During this time, the specialized therapists would choose one of the alternative examination techniques.

Patient Self-Assessment Tests

When an internal evaluation cannot be performed, self-assessment tests can help patients and the therapist identify some of the impairments of the PFMs. Therapists can use the results of self-assessment tests to prescribe PFEs with some accuracy.

A possible evaluation tool used when the therapist cannot perform an internal evaluation is the digital vaginal self-examination (i.e., finger in the vagina test). Begin with patient education, as outlined later in the active PFEs. This section also includes information about verbal cues for the proper contraction of PFMs. After a brief introduction to the PFMs and the exercise, the patient should be instructed in the digital vaginal self-examination test (see **Patient-Related Instruction 18-1**). This method is

Patient-Related Instruction 18-1

Testing Your PFM by Performing the Digital Vaginal Self-Examination

The following test can help you determine your current ability and monitor your recovery. Perform this test before beginning your PFM exercise program and then periodically throughout the training period, approximately every 2 to 4 weeks. Fluctuations in muscle ability occur in response to fatigue, medications, hormones, and other factors. The PFMs are more likely to be weak at the end of the day, when you are sick, and just before menstruation.[27] For an accurate comparison, repeat the test at the same time of the day and the same time of the monthly menstrual cycle as the original test. Any exercise program takes time and dedication. As with other muscles, the PFMs may take 4 to 6 months to strengthen. After you have performed the test, report the following information to your therapist: how many seconds you can hold the contraction, how many of these long-hold contractions you can do, and how many quick contractions you can do.

Digital Vaginal Self-Examination (Finger in Vagina or Rectum)

Place your finger into the vagina or rectum up to the level of the second knuckle. Palpate the muscle on either side of the vagina or rectum while you contract the PFM, pulling the muscles up and in. You should feel the muscles contract around your finger and pull your finger up and in. If you feel tissues pushing out of your body or bulging, ask your health care professional to evaluate the area.

often accepted by female patients and can be taught to male patients (i.e., finger in the rectum test) in the same manner if they are having trouble learning the correct contraction with other methods. Men can also be taught to palpate the perineal body (just behind the testicles). They should notice a tightening of the tissue if the PFM is contracting correctly. Many factors influence continence and PFM function. Some practitioners use the stop urine test to determine PFM function. Current literature does not support the value of this test.[74]

The finger in the vagina test cannot evaluate all aspects of muscle function but can give some indication of the muscles' abilities and provide guidance in prescribing exercises. Patient progress should be judged by reexamination of the PFM function; however, if this is not possible, it may be judged by decreasing symptoms. Patients can perform the test at home and report to the therapist, or the test can be done in the clinic if sufficient privacy is available (i.e., closed-door treatment room with a plinth or recliner is suggested). In the clinic, the therapist can briefly step out of the room while the patient performs the test or can remain in the treatment room with the patient adequately draped. The patient should provide the following information:

- Duration (in seconds) of PFM endurance contraction
- Number of repetitions of PFM endurance contractions
- Number of repetitions of quick muscle contractions

A second self-assessment test, the jumping jack test, is a test of advanced strength (see **Patient-Related Instruction 18-2**). It is usually not given to sedentary, incontinent patients. It is helpful for athletes and other active individuals who know how to do the PFE well. Patients may use this test to judge continued progress after active therapy has ended (see **Building Block 18-2**).

Patient-Related Instruction 18-2

Jumping Jack Test

This test is used only to evaluate PFM ability under physical stress. To begin, empty your bladder, and then perform five jumping jacks. If no urine leaks out, wait ½ hour, and do five more jumping jacks. If no leakage occurs, wait 1 hour, and repeat the five jumping jacks. The test proceeds until leakage occurs. Make a note of how long after urination and how many jumping jacks you could do before urine leakage occurs. It is important to continue drinking as usual during the test. There are no normative values for this test, but some therapists feel a patient should be able to do 5 to 10 jumping jacks 2 to 3 hours after urination without leaking.

Circle the number of jumping jack at which urine leakage occurs

Immediately—1 2 3 4 5
½ hour—1 2 3 4 5
1 hour—1 2 3 4 5
1½ hours—1 2 3 4 5
2 hours—1 2 3 4 5
2½ hours—1 2 3 4 5
3 hours—1 2 3 4 5
3½ hours—1 2 3 4 5
4 hours—1 2 3 4 5

BUILDING BLOCK 18-2

Your patient is a 24-year-old female 2 month postsurgical repair of an anterior cruciate ligament. She has been progressing nicely in her recovery and is now returning to jumping practice in preparation for return to volleyball. During one of her therapy sessions, she suddenly stops and excuses herself to the bathroom. Upon her return, she is not as aggressive with her jumping and appears self-conscious. During one of her exercises, you notice a small wetness in the perineal area. Describe how you might approach this patient's apparent urinary leakage during therapy. Describe how to perform the patient self-assessment tests.

Ultrasound Imaging for PFM Dysfunction

Over the past 10 years, the interest and availability of ultrasound imaging in PT have increased. Imaging of the PFM gives the general physical therapist a valid tool to objectively measure the PFM without internal palpation.[75] This modality can also be used to provide biofeedback to the patient and enhance PFM contraction learning. The ultrasound probe is placed transverse or sagittal in the suprapubic region with the sound waves directed caudal into the pelvis (**Evidence and Research 18-9**).

EVIDENCE and RESEARCH 18-9

Ultrasound imaging has been shown to be an effective assessment tool for PFM volume, anatomy, and movement.[76,77]

Sample patient goals

- The patient will have decreased number of nighttime voids from ___ no. to___ no.; allowing improved sleep and decreased fall risk.
- The patient will be able to participate in _____ (sport, housework, and work) with ___% decrease in urinary leakage.
- The patient verbalizes understanding of independent home exercise program to increase PFM function.
- The patient achieves increased time between voids to ___ no. hours for work and social activities.
- Activities of daily living (ADLs) are not limited by urgency UI or frequency (see **Case Study 18-3**).

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON PHYSIOLOGIC IMPAIRMENTS

This section outlines the physiologic impairments and possible treatments of the PFMs and related structures. Several types of impaired PFM functions are possible:

- Impaired muscle performance of the PFMs, abdominal muscles, and hip muscles
- Pain and altered tone of the PFMs, hip muscles, and trunk muscles

CASE STUDY 18-3

Ms. Smith states that she does not exercise partly because of fear of leaking and has had to leave the movie theater during a movie to urinate. You have both decided it is important to address this dysfunction. You explained the self-assessment tests last week, and the patient has performed them as you requested and is reporting the results.

Results of jumping jack test—1½ hours first jumping jack

The number of repetitions and amount of hold time per contraction—5-second hold 10 times

The number of quick contractions—20

List three goals specific to UI for this patient.

- Mobility impairments causing PFM dysfunction as a result of adhesions, scar tissue, and connective tissue disorders
- Posture impairments
- Coordination impairments of the PFMs, PFMs during ADLs, PFMs with the abdominal muscles, and abdominal muscles alone

Impaired Muscle Performance

Pelvic Floor Muscles

Impaired muscle performance (impairment in strength, power, or endurance) is the most commonly treated impairment of the PFMs and is usually the primary impairment in the underactive PFM diagnostic classification. PFM performance may be impaired by the following:

- Trauma during vaginal delivery
- CNS or PNS neurologic dysfunction
- Surgical procedures
- Decreased awareness of PFMs
- Disuse
- Prolonged increased intra-abdominal pressure
- Pelvic congestion or swelling
- Back or pelvic pain

The PFMs are 70% slow-twitch muscle fibers with the critical role of providing support to pelvic organs against gravity in all upright positions. PFMs are postural muscles and must be able to maintain some baseline tone for long periods. Weak, easily fatigued, saggy muscles do not support the pelvic organs. Poor endurance of the PFMs is a common finding in many women without symptoms of PFM dysfunction. Most women probably have endurance impairment of the PFMs long before functional impairments of leaking urine or prolapse occur. Teaching PFEs to *all* adults may help to prevent PFM dysfunctions in the future.[4] This is especially true with prenatal and postpartum women and women after menopause or gynecologic surgery.

The treatment for impaired muscle performance is active PFEs.[78–81] These strengthening exercises are explained later in the "Therapeutic Exercise Intervention for Common Diagnoses" section.

Abdominal Muscles

Impaired abdominal muscle performance often results in a pendulous abdomen and can contribute to PFM dysfunction, especially incontinence. Restoring abdominal wall length and strength and avoiding Valsalva maneuvers (bearing down) during exercises and ADLs are the goals of PFM dysfunction treatment. Valsalva maneuvers can contribute to incontinence and may increase the chance of pelvic organ prolapse.[82] Treatment of impaired abdominal muscle performance is described in detail in Chapter 17.

Hip Muscles

Hip impairments (see Chapter 19) are often underlying causes of overactive PFM. The piriformis, obturator internus, and adductors are the most likely muscles involved because of their proximity to the PFMs. Any muscle impairment affecting the sacroiliac joint may also contribute to overactive PFM (see Chapter 17).

Active PFEs

PFEs, known as Kegel exercises by many patients, specifically address impaired muscle performance of the PFMs. Proper contraction and relaxation of the PFMs are necessary for normal function and are the focus of treatment for most PFM impairments. A correct technique is essential and should ideally be confirmed with vaginal or rectal palpation. If this is not possible, use patient self-assessment described above or rehabilitative imaging ultrasound. Teaching PFE without internal palpation or biofeedback is difficult for the therapist and the patient. However, this section gives the therapist a comprehensive plan for teaching an effective and individualized PFE program:

- Patient education
- Verbal cues for proper PFM contraction
- Home exercise programs
- Methods for putting the exercise program together

Dosage

The therapist uses the results from the patient's self-evaluation test (i.e., digital vaginal self-examination test) to prescribe an individualized exercise program for PFM strengthening. The therapist should remember the basic principles of overload (i.e., the muscle must be challenged to its fullest capacity to improve strength) and specificity (i.e., patients should exercise the muscle correctly in isolation). Patients can be taught these ideas and can learn to progress in their own programs.[83] PFEs must be individualized for the patient to reach his or her full rehabilitation potential. Many well-intentioned publications give "cookbook" exercise programs that are too hard for the average incontinent patient (e.g., hold for 10 seconds and repeat 10 to 15 times). Patients try to follow these instructions, realize that their symptoms are not changing, and ultimately abandon the exercises. These same patients have achieved good results with careful instructions and individualized programs.

Duration How many seconds should the patient hold the endurance muscle contraction? If the evaluation reveals that the patient can hold the contraction for 3 seconds (not uncommon for weak muscles), the therapist asks the patient to hold the PFM contraction (i.e., Kegel contraction) for 3 to 4 seconds before resting and repeating the exercise. Sustained PFM contractions are progressed to a maximum of 8 to 12 seconds.[84,81]

Rest How long should the patient rest between endurance muscle contractions? Increased resting tone (i.e., overactive PFM) and weak muscles require longer rest times. Twice as much rest time as hold time is advised for a weak muscle (e.g., 3-second hold, 6-second rest, and repeat). Rest time is decreased as strength increases (e.g., 10-second hold, 10-second rest, and repeat). A quality PFM contraction requires complete relaxation at the end of each exercise.[83] Incomplete relaxation does not train a muscle in its full range of motion and may result in excessive tension and pain. Complete relaxation between contractions produces a more functional muscle.

Endurance Contraction Repetitions How many endurance contractions should the patient do in one set before fatigue? For the patient previously described, the therapist would determine how many 3-second contractions the patient can complete. The average patient with endurance impairment is able to perform only 5 to 10 repetitions before fatiguing. The exercise program must be individualized for maximum benefit.

Quick Contraction Repetitions How many quick contractions should the patient do in one set? A complete PFE program includes quick muscle contractions. The therapist prescribes the number of quick contractions based on how many can be done at the initial evaluation. Quick contractions involve quick, maximal recruitment of the PFMs, followed by quick relaxation. These contractions are usually held for <2 seconds. Quick contraction of the PFM is necessary to avoid leaking during quick movements such as sneezing, jumping, and running.

Sets How many sets should the patient do in 1 day? Patients with weak PFMs should do a set of contractions (as determined previously) several times during the day. The sets should be spaced throughout the day and performed up to three to four times per day, with a total of 30 to 60 pelvic floor contractions per day[73] (**Evidence and Research 18-10**).

EVIDENCE and RESEARCH 18-10

A meta-analysis of PFE and symptom reduction shows that as little as 24 contractions per day can be beneficial.[84]

Activity

Posture Gravity pulls down on the pelvic floor in upright positions. Patients with very weak PFMs should therefore do their exercises in the horizontal position (i.e., gravity neutral). Patients with moderately strong PFMs can perform exercises in the sitting position (i.e., against gravity) and advance to the standing position as they feel stronger. Results of the manual muscle test (MMT) using an internal examination of the PFMs provide the basis for prescribing exercise positions accurately. All patients should eventually progress to doing PFEs while standing, because it is necessary for the muscles to function well in this position (i.e., most incontinence occurs while standing). Some publications recommend that women practice PFEs while driving or waiting in line. However, initially, patients should learn these exercises in a quiet place so they can concentrate and perform the exercises correctly. After the exercises are learned well, patients can do them while waiting in line or watching TV.

Accessory Muscle Use Contraction of the abdominal, adductor, and gluteal muscles can result in an overflow to the PFMs,[85] facilitating strengthening of weak PFMs. Simply stated, overflow is the intentional contraction of associated muscles to increase recruitment of very weak muscles. This technique is usually reserved for patients with an MMT result of 1/5 or 0/5 or in patients who are unable to learn the isolated technique, such as those with cognitive deficits. Conversely, if the patient has an MMT result of 3/5 or higher, the therapist discourages the use of accessory muscles. Eventually, all patients should learn to contract the PFMs without accessory muscles. However, an abdominal contraction with bearing down is never desirable and will result in poor results (**Evidence and Research 18-11**).

EVIDENCE and RESEARCH 18-11

Several studies[86,87] have shown the close synergy of the abdominal muscles (particularly the transversus) and the PFM (see Chapter 17). Therefore, it is neither necessary nor desirable to keep the abdominal muscles completely silent during a PFM contraction.

A pilot study of 27 women with SUI investigated outcomes of a 6-week protocol of pelvic floor muscle training (PFMT) compared to resisted hip rotation (RHR) exercises. The PFMT group was instructed to perform isolated PFM contractions, while the RHR group was instructed to perform seated hip external rotation and internal rotation exercises. Both groups demonstrated significant improvement in all outcome measures. The authors concluded that PFMT and RHR are both effective interventions for the treatment of SUI.[88]

Patient Education Before teaching patients how to do the PFEs, they should be educated about the location and function of the PFMs, and the importance of normal PFM function.

There are many commercially available charts, posters, and handouts that give a two-dimensional view of the location of the PFMs. However, many patients find three-dimensional models more helpful. Pelvic models that have the PFMs and obturator internus muscles in place help in explaining the proximity of the PFMs to the muscles of the buttocks and hips. Alternatively, the therapist can use a standard pelvic bone model and place her hand from the coccyx to the pubic bone to signify the muscles. The patient should understand that the PFMs are internal (approximately 2 inches into the vagina) and are in close proximity to the hip muscles. However, it is neither necessary nor desirable to contract the hip muscles while exercising the PFM, unless the therapist is using overflow principles.

An explanation of Dr. Kegel's three functions of the PFMs (the three Ss) is usually sufficient for the patient[6]:

- *Supportive*: They hold the pelvic organs up.
- *Sphincteric*: They stop urine, feces, and gas from escaping until the person reaches the toilet.
- *Sexual*: They help women grip the penis and increase sexual feelings. They help men form and maintain an erection.

The therapist should teach the differences in function between quick and endurance contractions. The analogy of sprinters and marathoners helps to explain the quick and endurance properties of the muscle. Sprinters depend on the quick muscle fibers, which are mainly responsible for the sphincteric function. The quick fibers contract quickly before a sneeze or cough. Marathon runners depend on the endurance muscle fibers, which provide the supportive function and hold up the organs. A combination of quick and endurance fibers assists in sexual function.

The following points are examples of the importance of normal muscle function. The information can be individualized for each patient:

- A well-exercised muscle has a good blood supply and may recover better from trauma such as childbirth or surgery.
- It is easier to learn these exercises before changes occur from surgery, pregnancy, childbirth, or aging. All women should have a basic knowledge of the PFMs and how they should be exercised. PFEs should be a part of a woman's basic self-care, such as brushing her teeth and showering.
- Incontinence is a symptom not a disease. It is not an inevitable sequel of pregnancy, surgery, or aging.
- Exercising these muscles before and after bladder suspension surgery may enhance the operative results.[89] Some patients still have symptoms after bladder surgery or become incontinent several years later. Strengthening the PFMs may reduce the likelihood of recurring symptoms.

The normal PFM function is helpful in the treatment of low back and pelvic pain.[90] Weakness or tension in this muscle group may result in stress to adjacent hip muscles and perpetuate activity limitations. Hip, buttock, and leg pain may not resolve unless this muscle group is functioning normally (**Evidence and Research 18-12**).

EVIDENCE and RESEARCH 18-12

PFEs started during pregnancy result in less incontinence and pain after delivery.[91,92] 87% of patients can significantly reduce or eliminate incontinence with PFEs.[73] About 49% of patients verbally instructed in PFEs are doing them incorrectly.[93] Approximately 25% are pushing down (bearing down) on the pelvic floor.[93] Precontraction of PFM before moderate cough results in 98% decrease in UI.[83]

Home exercises are an essential aspect of PFM strengthening. Before patients begin to perform these exercises on their own at home, they must have a complete understanding of their muscles and how to exercise them, avoiding a Valsalva maneuver. The therapist must describe the exercises correctly and encourage patients to use the home exercises described in the next section. **Display 18-7** provides verbal cues that can be used to instruct a patient how to perform a PFM contraction. The therapist should be aware of a patient's comprehension of the following exercises. Many patients nod and agree just to end the discussion of an embarrassing subject. The therapist should address this form of exercise with the same professionalism and completeness as she does for any other exercise. This approach can place the patient at ease, and it emphasizes the importance of the exercises (**Evidence and Research 18-13**).

DISPLAY 18-7
Verbal Cues Used to Teach Pelvic Floor Contractions

- Best female instruction—Tighten the muscles that you would use to stop gas from escaping at an embarrassing time.[96]
- Best male instruction—"shorten the penis" or "stop the flow of urine."[94]

Other instructions

- Tighten and lift the muscles around your vagina, and pull them up and inward, as if to stop urine flow.
- Pull your muscles up and in, as if you had the urge to urinate and could not stop to use the toilet.
- Gently push out, as if to pass gas, and then quickly pull the muscles back up and in.

EVIDENCE and RESEARCH 18-13

Stafford et al.[94] investigated the activation of PFMs in 15 healthy men with various verbal cues utilizing transperineal ultrasound imaging which was validated with fine wire EMG recording. The investigators concluded that the instructions to "shorten the penis" resulted in the greatest striated urethral sphincter activity and "tighten around the anus" resulted in the greatest anal sphincter activity. Instructions to "elevate the bladder" resulted in the greatest increase in intra-abdominal pressure. It was suggested not to use the cue "elevate the bladder" when instructing men to perform PFE.

Henderson et al.[95] conducted a cross-sectional study of 779 women to determine how many women could correctly perform a PFM contraction with the instruction "squeeze the muscles in the vagina and hold like you are holding urine," if this ability differed between women with or without pelvic floor dysfunction and if women could learn correct contraction with basic instruction. 120 women could not perform a correct PFM contraction; however, 78% were able to learn with the instruction to "use your vaginal muscles instead of your bottom muscles." Women with pelvic organ prolapse were less likely to learn than women with neither pelvic organ prolapse nor SUI.

Follow-up of the home exercise program is important. To improve compliance, it may be helpful for patients to keep a diary of the exercise routine and list how many times per day incontinence occurs. At subsequent sessions, ask patients the following information:

- How many, how long, and in what position they are doing the exercises
- If they feel the contraction
- If the muscles are getting stronger
- If the symptoms are decreasing

These home exercises are used in conjunction with the self-assessment test described in the evaluation section of this chapter (see **Self-Management 18-1**). After going over the self-assessment test and home awareness exercises with the patient, this information may be copied and given to the patient to take home with her. The patient should perform the tests and awareness exercises at home and then report to the therapist for documentation of results and development of an individualized PFE program.

SELF-MANAGEMENT 18-1
Home Awareness Exercises

These exercises are used to help you understand what you should be doing during the Kegel or PME. Try the exercises at home, and report the results to your physical therapist. Remember that this is an internal muscle, and you should try not to contract the leg or buttock muscles. During these exercises try to identify

1. If you are doing the exercises correctly
2. How long you can hold the contraction (in seconds) up to 10 seconds
3. How many repetitions you can perform holding the contraction for the previous length of time
4. How many quick contractions you can perform

Index Finger on Perineal Body

Place your index finger on the perineal body (i.e., the skin between the vagina or penis and the rectum) or lightly over the anus. This can be done over your underpants in some cases. Contract the PFMs, and feel the perineal tissue moving away from your finger, up and into the pelvic cavity. If the PFM is very weak, you may not feel much movement. However, you should never feel the anus or perineal tissue moving toward your finger or bulging. If you feel tissues moving toward your finger, stop exercising, and ask your physician, midwife, physical therapist, or other health professionals to instruct you in the proper PFM contraction.

Finger into Vagina or Rectum

Place your index finger into the vagina or rectum up to the level of the second knuckle. Palpate the muscle on either side of the vagina or rectum while you contract the PFMs, pulling them in and up. You should feel the muscles contract around your finger and pull your finger up and in. If you feel tissues pushing out of your body or bulging, ask your health care professional to examine the area.

Visual Exercise

Women Lie on your back with your knees bent and your head resting on several pillows. Hold a mirror so that you can see your perineal body and rectum. Contract the PFMs up and in, and watch the perineal tissues moving up into the body. It may be difficult to see the movement if the muscles are very weak. Seek further professional instruction if any tissue comes toward the mirror or bulges outward.

Men Stand in front of a long mirror, and watch the penis as you contract the PFM up and in. The penis should move slightly upward during the contraction.

Sexercise (for Women)

Contract the PFMs around the penis during intercourse.

Putting It All Together—The Exercise Program

The exercises described in Self-Management 18-1 are designed to help the patient identify and effectively contract the PFMs. However, it is important to create an exercise program that challenges the PFMs of each patient.

For example, if a patient's self-assessment test (e.g., digital self-examination) shows that the PFM contraction was held for 5 seconds and repeated 5 times and that 10 quick contractions were performed, her evaluation results would be as follows:

- Duration of endurance contraction hold: 5 seconds
- Repetitions of endurance contractions: 5 times
- Repetitions of quick contractions: 10 times

With this information, the therapist could prescribe the following exercise prescription (see **Display 18-8**).

Self-assessment and modification of the exercise program continue periodically throughout rehabilitation. Remember to ask the patient how often and how many PFM exercises she can do (see **Case Study 18-4**). Ask if her symptoms are improving (i.e., decreasing incontinence).

Pain

Pelvic Floor Muscles

Increased PFM tension with or without muscle shortening occurs in response to many situations outlined in the "Overactive PFM" section of this chapter. Pain and altered tone impairments are usually the primary impairments of overactive PFM[97] and may be caused by the following:

- Lumbopelvic or hip impairments
- Tonic holding patterns of the PFMs
- Abdominal adhesions
- Adhered scars in the trunk and perineum
- Fissures and fistulas

Coccyx pain is rarely a result of sacrococcygeal joint mobility impairment, but it usually is caused by referred pain from tension and trigger points in the surrounding muscles. The PFMs, obturator internus, gluteus maximus, and piriformis can refer pain to the coccyx (**Fig. 18-8**).

DISPLAY 18-8
Sample Exercise Prescription

- Duration of endurance muscle contractions: 5 seconds
- Rest between endurance muscle contractions: 10 seconds (*double rest for patients with weak PFMs*)
- Repetitions of endurance muscle contractions: 5 times (*complete relaxation between contractions*)
- Repetitions of quick muscle contractions: 10 times (*to train the fast-twitch muscle fibers*)
- Sets per day: 3 to 4 (*exercise weak muscles in short sessions, frequently*)
- Position: *gravity eliminated—lying down on back or side*
- Accessory muscle use: *not at this time*
- Functional training: "*squeeze before you sneeze*" (*contract PFM before and during coughing, sneezing, lifting, straining*)

CASE STUDY 18-4

Develop a PFE program for Ms. Smith using the self-assessment information provided earlier.

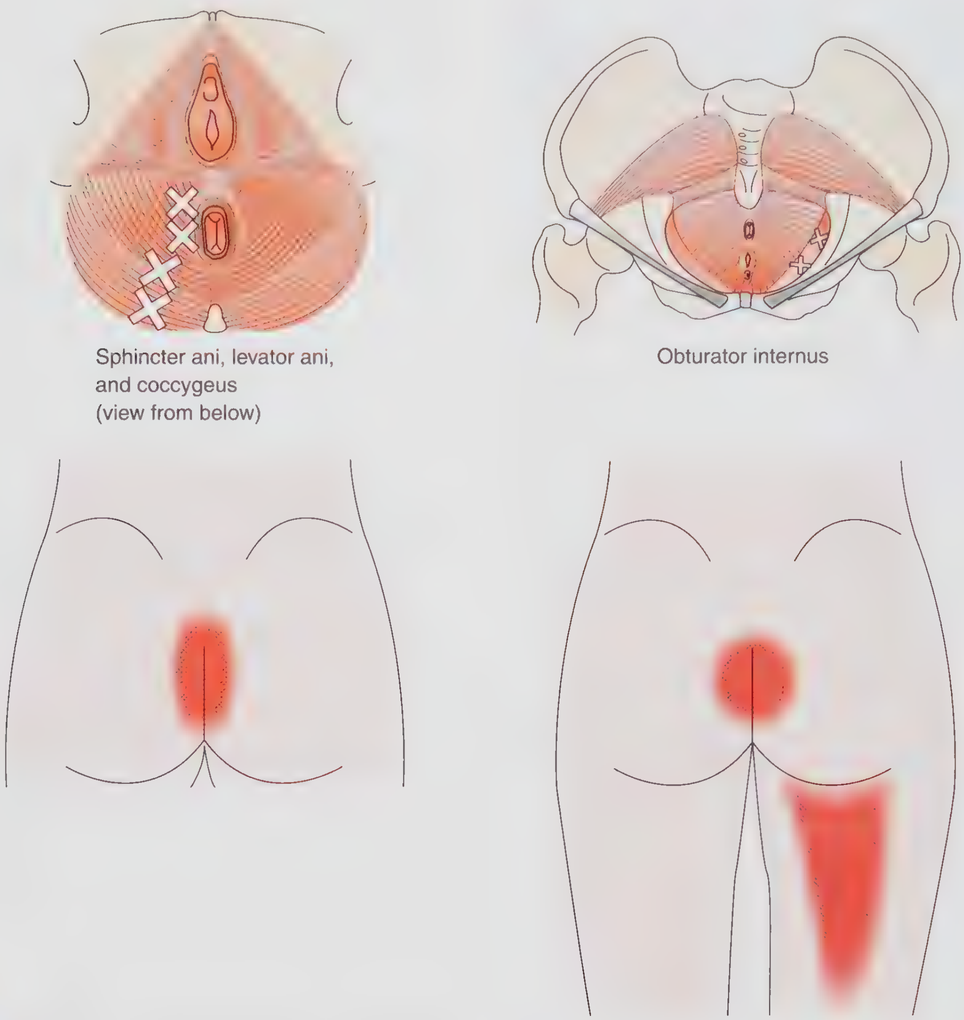

FIGURE 18-8 Trigger points (x) and their referral pain patterns (*shaded areas*).

Treatment of increased PFM tension includes manual soft tissue manipulation of the PFM vaginally, rectally, or externally around the ischial tuberosities and coccyx. Surface EMG biofeedback and PFEs may also help restore the normal tone of the PFMs. In some cases, the PFMs become "frozen" and cannot relax or contract effectively (see **Patient-Related Instruction 18-3**).[68] Modalities such as electrical stimulation, ultrasound, hot, and cold may be used on the perineum to treat the spasm. The therapist should learn the logistics of applying the modality onto the perineum.[98] Modality parameters and other treatment considerations are the same as those used for increased muscle tension in other areas of the body.

Patient-Related Instruction 18-3

Importance of Relaxing the PFMs

PFMs must be completely relaxed for normal function. For example, if you hold a brick in your hand all day and at the end of the day are asked to throw the brick 10 feet, you would probably not be able to throw it, because your arm muscles would be cramped and tired. Tonic holding of the PFMs often results in a crampy pain in the groin, rectum, or tail bone area. One goal of recovery is to be able to contract and relax the PFMs well.

Hip Muscles

Any muscle imbalance at the hip and trunk may contribute to overactive PFM through sacroiliac joint impairments.[90] It is often difficult to pinpoint the origin of pain in the lower pelvic region. Increased muscle tension and trigger points are common causes of pain in the perineum, groin, and coccyx areas. Travell and Simon[13] described referred pain patterns originating from trigger points in the adductors, PFMs, obturator internus, and piriformis (**Figs.** 18-8 and **18-9**). Spasm and trigger points in these muscles may be primary or secondary impairments and should be treated in all patients with PFM dysfunction. The treatment for increased hip muscle tension includes soft tissue manipulation, modalities (i.e., ultrasound, electrical stimulation, hot or cold packs), therapeutic exercises for stretching and strengthening, and patient education about body mechanics and postures.

Trunk Muscles

Iliopsoas and abdominal trigger points and tension may be the primary muscular impairment in pelvic pain conditions. Increased iliopsoas tension may irritate the pelvic organs that overlie them and vice versa, making iliopsoas altered tone impairments an important condition to treat in cases of visceral dysfunction. Treatment of these muscles is essential to full recovery.[99]

Joint Mobility and Range of Motion (Including Muscle Length) Impairments

An increase in PFM resting tone is often related to sacroiliac, sacrococcygeal, pubic symphysis, and lumbar joint mobility impairments. These impairments may be primary or secondary and include hypomobility or hypermobility (see Chapter 7). Mobility restriction of scar tissue and connective tissue in the perineum and groin can also affect PFM's function greatly.

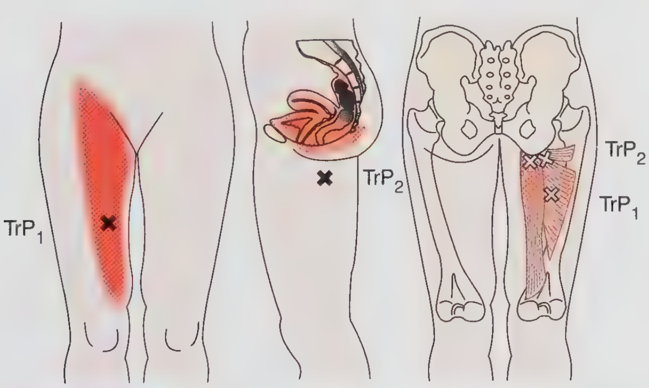

FIGURE 18-9 Trigger points (TrP) of the hip adductors (x) and their referral pain patterns (*shaded areas*).

Joint Integrity and Mobility Impairments of the Lumbopelvic Region Resulting in PFM Dysfunction

Hypomobility or hypermobility of the sacroiliac joint, pubic symphysis, or sacrococcygeal joint may cause the secondary impairment of PFM altered tone.[90,100] Pain from lumbopelvic–hip joint integrity or mobility may lead to a tonic holding pattern of the PFMs similar to that seen in the cervical muscles after an acceleration/deceleration injury (i.e., whiplash). The hypogastric plexus (T10 through L2) provides sympathetic innervation to the pelvic and perineal areas. Normal joint mobility in the T10 through L2 region may normalize sympathetic nerve output to the perineum and decrease pelvic pain symptoms. This hypothesis is based on clinical findings and has not been researched in experimental trials (see **Case Study 18-5**). Sacroiliac mobility impairments may also cause pain-induced PFM weakness. Any malalignment of the pelvis can alter the origin and insertion alignment of the PFMs and impair function by causing altered muscle tone or weakness. Significant joint integrity and mobility impairments of the lumbo-pelvic-hip complex should be treated with joint mobilization, positioning, soft tissue mobilizations, therapeutic exercise, and other modalities to achieve full recovery in PFM dysfunction.

Lumbopelvic Joint Mobility Impairments Resulting from PFM Dysfunction

A unilateral increase in PFM resting tone may contribute to and perpetuate pelvic joint mobility impairments. In some cases, altered PFM tone that is untreated may be the reason for continued mobility impairments. This is seen commonly in the sacroiliac joint and less frequently in the sacrococcygeal joint. Because of PFM attachment onto the sacrum, unilateral PFM tone impairments can result in torque of the sacrum similar to the torque created by a unilateral piriformis tonic holding pattern. Unilateral PFM altered resting tone can occur as a result of trauma, such as adductor strain with insertion injury, birth injury, or a fall on the pubic rami. PFM tone impairments can be caused by sacroiliac joint mobility impairment and then become the reason for continued joint dysfunction. Whether it is the primary or secondary impairment, normalizing PFM resting tone is necessary to restore and maintain normal sacroiliac joint mobility in these cases.

Lumbopelvic Joint Mobility Impairments Resulting from Adhesions

Visceral adhesions may cause sacroiliac joint mobility impairments, especially if unilateral adhesions from the organ to the sacrum are severe. Therapists with additional training use visceral mobilization techniques to manipulate organs and abdominal fascial tissue. These techniques are used to stretch adhesions and restore normal movement of lumbopelvic joints and pelvic organs.

CASE STUDY 18-5

During the pelvic examination, you identify signs of sacroiliac dysfunction. Explain to Ms. Smith how her urinary leakage may be related to her LBP.

For example, in endometriosis, endometrial tissue implants in the abdominopelvic cavity outside the uterus. As with the tissue inside the uterus, the explanted tissue responds to hormones during the menstrual cycle causing irritation, inflammation, and eventually scars and adhesions. Adhesions from endometriosis can be extensive throughout the abdomen and are often treated with laparoscopic laser surgery. Adhesions can pull on the ilium, coccyx, or sacrum and constrict bowels or fallopian tubes, altering joint and organ function. Bowel adhesion to the pelvic side wall is found in 14 out of 15 patients with chronic pelvic pain.[85] Soft tissue mobilizations of abdominal adhesions and organs can enhance organ function and may be the necessary link in maintaining normal mobility in the pelvic joints.

Scar Mobility Restrictions

Episiotomy is a common obstetric procedure that involves making a cut in the perineal body immediately before vaginal delivery, usually to ease delivery (**Fig. 18-10**). Vaginal tissue may tear as an extension of an episiotomy or in lieu of an episiotomy at the time of delivery. Episiotomies and tears may result in adhesions and pain wherever the scar tissue occurs—at the perineal body, tissue inside the vagina, and even toward or into the rectum. Adhesion pain usually occurs in the immediate postpartum stage and abates in most women after 4 to 6 weeks. However, this pain persists in some women and can be so severe that intercourse is impossible and every bowel movement hurts. Sitting may be impossible, or sitting tolerance may be limited. An increase in PFM resting tone and adhesions are the most common impairments in these patients.[101] Treatment includes soft tissue manipulation and friction massage of scars externally and internally. Modalities, such as ultrasound, hot packs, and cold packs, also are used. PFEs and biofeedback are important in restoring the normal contraction and relaxation of muscles (see **Building Block 18-3**).

BUILDING BLOCK 18-3

A 40-year-old female with thoracic pain recently underwent a tummy tuck. She has limited trunk extension and weakness in the upper back. What measurements would be important to collect in the abdominal region? List three abdominal treatments that may decrease her thoracic pain.

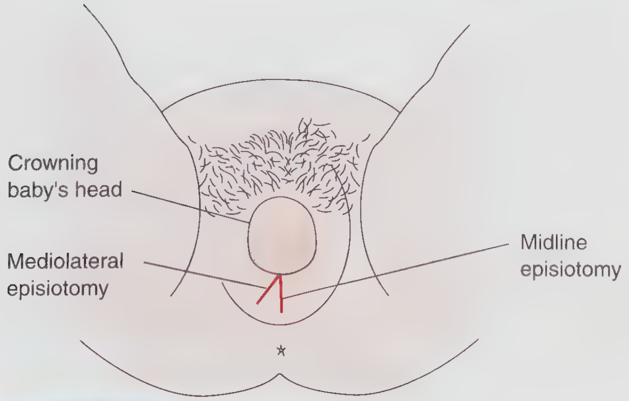

FIGURE 18-10 Possible sites of episiotomy.

Connective Tissue Mobility Restrictions

Muscle strains often result in irritation to connective tissues and shortening of fascia and tendons. Groin injuries commonly traumatize the adductor muscle group. This is a very large muscle group that inserts onto the pubic ramus and ischial tuberosity. Physical therapists often treat the distal adductor muscle and fascia, whereas restrictions in connective tissue mobility and increased resting tone of the proximal adductor muscles are often left untreated. Tissue at the insertion of the adductor muscles to the pubic arch should be evaluated and treated in patients with persistent groin pain. A similar condition may occur in the hamstring muscles. The hamstring tendon sends a slip of connective tissue to the sacrotuberous ligament, which eventually fuses with the posterior sacroiliac ligaments. Impaired mobility of connective tissue at the proximal hamstring muscle may be related to persistent sacroiliac joint dysfunction. These conditions may occur with increased resting tone of the PFMs. Treatment of connective tissue mobility impairment includes soft tissue mobilization, therapeutic exercise, and modalities (i.e., ultrasound, electrical stimulation, and hot packs).

Posture Impairment

Poor posture and body mechanics are commonly associated with joint mobility impairments. Education about proper posture and body mechanics is included in the treatment of all patients with joint dysfunction of the lumbopelvic area. Sitting posture demands special attention in patients with overactive PFM (see **Patient-Related Instruction 18-4**).

Coordination Impairment

Coordination impairment is related to inappropriate patterns of timing and recruitment of the PFMs and abdominal muscles. This impairment includes incoordination of the PFM contraction, incoordination of the abdominal contraction, incoordination of the PFMs during ADLs, and incoordination of the PFMs with the abdominals.

Pelvic Floor Muscles

Coordination impairment of the PFMs is the inability of all the PFMs to contract and relax at the appropriate times. Manual evaluation of the PFMs and biofeedback training may reveal the patient's inability to create and hold a synchronous contraction. This problem is usually related to decreased awareness of the PFMs. In nonneurologic conditions, the patient can usually learn the correct sequencing and timing of contraction through some form of biofeedback (e.g., surface EMG; pressure; contracting around a finger, penis, or similar object).

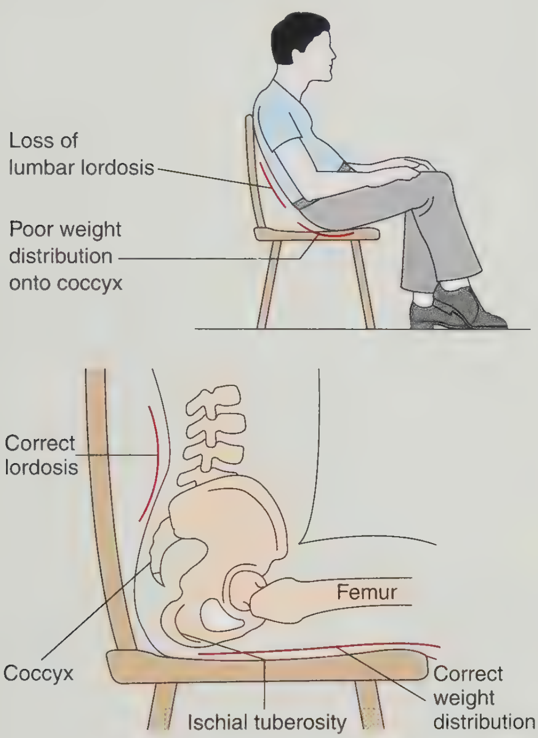
Pelvic Floor Muscles During ADLs

Coordination impairment of the PFMs during ADLs is observed in stress incontinence, with urine leaking during lifting, coughing, and sneezing. In some cases, leaking results from impaired performance of the PFMs. However, some patients have fairly good PFM strength but do not contract the PFMs at the proper time during the activity. All patients must learn to contract the PFMs before and during increased intra-abdominal pressure (e.g., cough, lift, sneeze) (see **Patient-Related Instruction 18-5**).

Patient-Related Instruction 18-4

Proper Sitting Posture

- Proper sitting posture is essential for relief of perineal and tail bone pain.
- Weight should be shifted forward on the two "sit bones" and thighs.
- There should be no pressure on the tail bone.
- Push your buttocks back in the chair so there is no space between your very low back and the chair.
- Use a small towel roll at your waist to maintain the inward curve if needed.
- A firmer chair can support your posture better and decrease pressure on the tail bone.
- Poor sitting posture places weight on the coccyx.



Proper sitting posture places weight on the ischial tuberosities and posterior thigh.

Patient-Related Instruction 18-5

Squeeze Before You Sneeze

Practice contracting the PFMs immediately before sneezing, coughing, laughing, lifting, or straining. This is similar to training yourself to bring your hand to your mouth before you sneeze. By voluntarily contracting the PFMs before increases in abdominal pressure, you will eventually create a habit, and the PFMs will contract automatically.[83]

In addition, it is necessary to relax the PFM during activities such as micturition and defecation. Inability to relax during these activities may result in obstructed voiding and defecation in which the bowel and bladder are unable to empty completely (see **Building Block 18-4**). Inability to relax during intercourse may result in painful penetration (also known as dyspareunia) (**Evidence and Research 18-14**).

BUILDING BLOCK 18-4

A 34-year-old tennis player is having SUI during the serving maneuver of her game. What might be the pathophysiology of this condition? What could you suggest she do to decrease her leakage?

EVIDENCE and RESEARCH 18-14

One study showed that training patients to contract their PFMs prior to performance of ADLs that increase intra-abdominal pressure can decrease urine leakage up to 70%.[83,102]

Pelvic Floor Muscles with Abdominal Muscles

The therapist should understand proper contraction of the PFMs with the abdominal muscles to correctly instruct the patient. An exercise to experience this can help the student to understand the relationship of the PFMs and abdominal muscles. Start by sitting up in a chair and pouching the abdominal muscles outward. Keep the abdomen pouched out and contract the PFMs, notice the amount of effort needed and the force generated by the PFMs. Next, sit up in the chair and pull the abdominals inward, supporting the abdominal contents and the back. While holding the abdominal contraction gently and contracting the PFMs, notice the effort needed and the force generated by the PFMs (**Evidence and Research 18-15**).

EVIDENCE and RESEARCH 18-15

Needle EMG studies show that the abdominal muscles participate in a synergy with the PFMs.[86,87]

Most persons feel a stronger PFM contraction when the abdominals are pulled inward properly. This is especially evident in the presence of PFM weakness. The PFMs cannot contract effectively when the abdominals pouch out, while bearing down, or during a Valsalva maneuver. In PFM training, it is especially important not to bear down and bulge the abdominals outward with the PFM contraction.

Bearing down is associated with PFM relaxation during bowel movement. PFM contraction during defecation is an example of PFM coordination impairment. This results in difficulty passing feces and often causes constipation and pain, which may be diagnosed as obstructed defecation. The patient must learn how to relax the PFMs at the proper time in association with the proper abdominal contraction for defecation (**Table 18-3**).

Abdominal Muscles

Coordination impairment of the abdominal muscles results in an inability to pull the muscles inward. These impairments must be treated before considering PFM timing with the abdominals. See Chapter 17 for specific training techniques.

TABLE 18-3

Coordination of the PFM

ACTIVITY	NORMAL PFM ACTION	NORMAL ABDOMINAL ACTION	DYSFUNCTIONAL PFM ACTION	RESULT OF DYSFUNCTIONAL ACTION
Lifting	Contraction	Inward contraction by obliques	Relaxation or weak contraction	Leaking urine
Bowel movement	Relaxation	Bulging contraction by rectus abdominis with Valsalva maneuver	Contraction	Difficulty passing feces, constipation, pain

CLINICAL CLASSIFICATIONS OF PELVIC FLOOR MUSCLE DYSFUNCTION

PFM dysfunctions have two clinical classifications, which are used internationally by specialized physical therapists, nurses, and physicians.[7] Two additional classifications are presented for a complete view of pelvic floor rehabilitation. Clinical classifications are intended to guide the therapist in treatment planning. However, the type and severity of physiologic impairments within the dysfunction vary, and treatments must be individualized. Each classification has a brief description of the syndrome and a discussion of the cause, common impairments, and activity limitations. There are many possible causes for these dysfunctions, which often result from a combination of pathologic conditions and comorbidities. In many cases, the primary cause is unknown. Therapists should have some understanding of the causes and comorbidities of the dysfunction they are treating. It is necessary to identify the correct impairment for effective treatment.

Much of the information on PFM dysfunctions is based on the clinical observations of pelvic floor physical therapists around the country. All four clinical classifications are presented to provide a complete view of the dysfunctions treated by physical therapists. The medical diagnoses associated with supportive and overactive PFMs are discussed later in this chapter (see **Fig. 18-11**).

There are two internationally accepted clinical classifications:

1. Underactive PFM
2. Overactive PFM

Other classifications are:

1. Incoordination dysfunction
2. Visceral dysfunction

Underactive PFM

Underactive PFMs results from the loss of strength and integrity of contractile tissues; this dysfunction is weakness and sagging of the PFMs. Common medical diagnoses often associated with underactive PFMs are stress incontinence, mixed incontinence, and pelvic organ prolapse (see **Patient-Related Instruction 18-6**). The supportive role of the PFMs in continence is discussed earlier in this chapter.

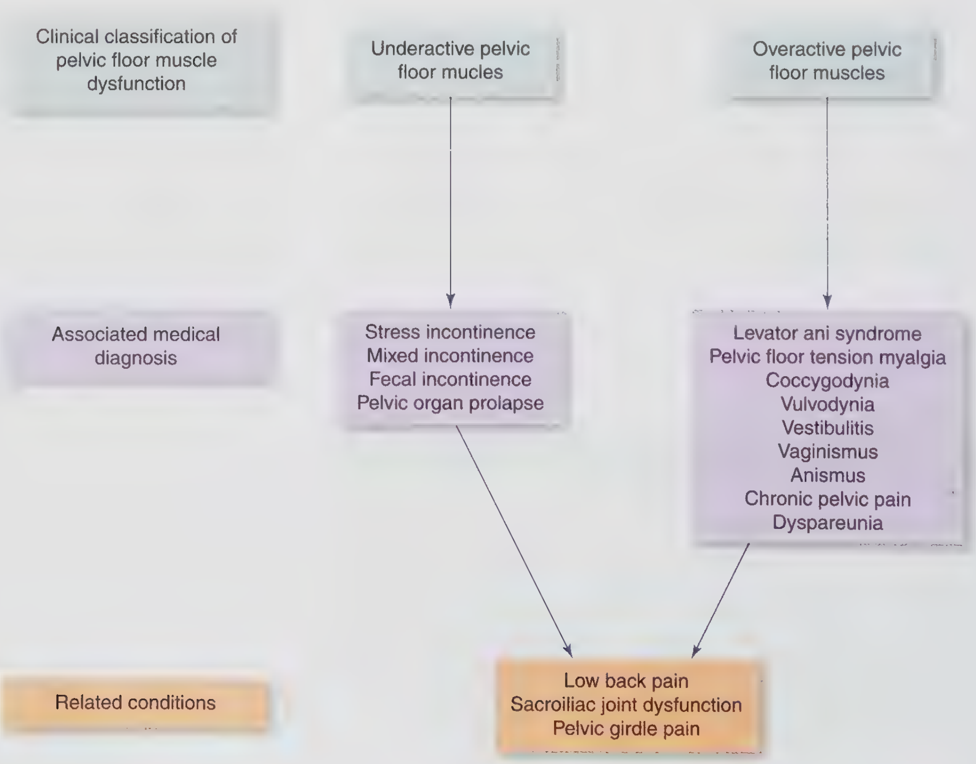


FIGURE 18-11 Classification of different types of pelvic floor dysfunction.

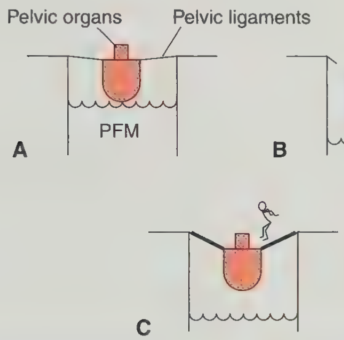
Patient-Related Instruction 18-6

Boat at the Dock–Role of PFMs in Organ Prolapse

- Imagine there is a boat tied to a dock **(Fig. A)**. The pelvic organs (i.e., bladder, uterus, and rectum) are the boat. The ropes holding the boat to the dock are the ligaments that support the organs from above. The water is the PFM.
- If the water level drops **(Fig. B)** (i.e., loss of support or weakness of the PFMs), the boat (organs) hangs on the ropes (ligaments). Eventually, the ropes stretch out and break, resulting in the boat (organs) falling down (i.e., prolapse).
- If you pull the boat back up by replacing the ropes (i.e., organ suspension surgery) without raising the water level (i.e., PFMs strengthening) **(Fig. C)**, the boat will continue to hang on the ropes and eventually falls down again (i.e., recurrent prolapse). Falling happens quicker if you jump on the boat (i.e., increase pressure in the abdomen from cough, sneeze, lift, or improper exercise).
- Long-lasting results are more likely if you raise the water level (i.e., PFM strengthening) and stop jumping on the boat (i.e., reduce unnecessary increases in abdominal pressure). In this case, the ropes (ligaments) may or may not need to be replaced (i.e., ligament and pelvic organ surgery).



Etiology and Comorbidities

Severe birth injury may result in anatomic impairments of the PFMs and nerves in the area. Altered muscle length or tension may occur with stretch during delivery. Stretching of connective tissue or muscle beyond its elastic capacity renders the tissue permanently long. The increased length of connective tissue means that the muscle must generate more force to accomplish the same function. Functional weakness and impaired muscle performance result. Hypertrophy of the remaining muscles often produces the desired effect of improved support of the PFMs.

Muscle atrophy can result from central and PNS dysfunction, including nerve damage from pelvic surgery. Temporary neurologic dysfunction, such as mild stretch to the pudendal nerve during delivery, often responds well to PFE. In conditions of mild or incomplete nerve damage, the remaining PFMs often become hypertrophied and produce good functional outcomes. Pelvic surgery may result in complex anatomic changes that affect PFM function.[103] (**Evidence and Research 18-16**)

EVIDENCE and RESEARCH 18-16

One study reported 15% to 20% of patients undergoing radical pelvic surgery had permanent voiding dysfunctions.[104]

Prolonged increased intra-abdominal pressure may result in stretching of the PFMs or their tendons and may contribute to pelvic organ prolapse. Repeated, incorrect lifting or straining with Valsalva maneuvers and chronic or prolonged coughing or vomiting perpetuate incontinence and prolapse symptoms and slows recovery of PFM strength. These chronic increases in intra-abdominal pressure may initiate PFM impairment. Pregnancy and abdominal obesity increase intra-abdominal pressure. Obesity correlates with increased incontinence.[104–106]

Hormones released during pregnancy loosen the connective tissue of PFM tendons, which causes the muscles to sag. Because pregnancy is a temporary condition, most physicians and therapists are not concerned about symptoms of underactive PFMs during pregnancy. However, 9 months of prolonged intra-abdominal pressure, especially with improper lifting at work, during exercise and ADLs, or with lifting another child, and prolonged, hormone-induced lengthening may result in significant postpartum supportive PFM dysfunction, even with a cesarean delivery.[107]

Many young children are taught not to touch or look at the perineum. In some cases, this early training results in adults with decreased awareness of the PFMs. Decreased awareness does not necessarily result in PFM weakness, but disuse atrophy may occur when decreased awareness is combined with other risk factors, such as menopause and bed rest. The PFMs are used less when a Foley catheter is in place and while patients are on prolonged bed rest. Decreased awareness of PFM contraction often exists concurrently with other impairments and makes rehabilitation more challenging. Many patients with severely decreased awareness can benefit from biofeedback instruction to identify the correct muscle contraction.

Common Impairments

The most common physiologic impairments of underactive PFM are:

- Impaired PFM performance
- PFM weakness
- Increased PFM length
- Increased connective tissue length
- Muscle atrophy
- Endurance impairment of the PFMs
- Impaired abdominal muscle performance
- Abdominal muscle weakness
- Increased length of the abdominals

The less common physiologic impairments associated with underactive PFM should also be treated for full recovery. Coordination impairment of the PFMs during ADLs often exists to some degree in underactive PFMs; coordination impairments of the abdominal muscles also occur with underactive PFMs. When the PFMs are fairly strong and incoordination is significant, the patient is given the diagnosis of incoordination dysfunction. Pain impairments of the PFMs may be a concurrent problem that may lead to pain-induced weakness. In this case, the origin of pain must be treated to reach maximum muscle strength. Joint mobility impairment of the lumbo-pelvic-hip region may also affect the PFMs. A summary of impairments and suggested interventions for underactive PFM is provided in **Display 18-9**.

DISPLAY 18-9
Summary of Impairments and Suggested Interventions for Underactive PFMs

- Impaired performance and endurance of the PFM: weakness, increased length, atrophy
- PFE with facilitation, overflow, biofeedback
- Neuromuscular electrical stimulation
- Coordination impairment of the PFM: decreased awareness of how to contract correctly
- PFE with biofeedback and during ADLs
- Coordination and impaired performance of the abdominals
- Therapeutic exercise for the abdominals
- Proper contraction of abdominals with function
- Pain in PFM and mobility of pelvic joints
- Soft tissue mobilization, scar mobilization
- Joint mobilization, muscle energy techniques
- Modalities such as heat, cold, ultrasound, and electrical stimulation

Activity Limitations

Patients may exhibit symptoms of stress incontinence, mixed incontinence, and organ prolapse. Loss of urine with coughing, sneezing, laughing, lifting, or exercising often requires the use of absorbent products (i.e., incontinence pads or diapers). Some patients limit or modify activities for fear of leaking urine.[108] Patients may avoid shopping trips, overnight vacations, outdoor activities, and sports because of incontinence. Urinary frequency is urination more than seven times in a 24-hour period, and urination sometimes occurs as often as every 30 to 40 minutes. Frequency in conjunction with urinary urgency may require modification of ADLs, because patients usually do not venture far from the toilet. Lack of PFM support may be painful and result in decreased ability to ambulate or exercise.

Overactive PFM

Overactive PFM is a complex category related to pain and increased resting tone of the PFMs. Common medical diagnoses associated with overactive PFM include:

- Levator ani syndrome
- Pelvic floor tension myalgia
- Coccygodynia
- Vulvodynia
- Vestibulitis
- Vaginismus
- Animus
- Chronic pelvic pain
- Dyspareunia

Overactive PFM may result from pelvic joint dysfunctions, hip muscle imbalance, and abdominopelvic adhesions and scars affecting PFM function.

Etiology and Comorbidities

The cause of overactive PFMs is often more difficult to identify than the cause of other dysfunctions. Lumbopelvic joint mobility impairments or pathology is one of the most common findings in patients with overactive PFMs. Injuries, such as a fall onto the coccyx or pubic ramus, are common for these patients. Lumbopelvic joint dysfunction may result from PFM dysfunction or may directly or indirectly cause an increase in PFM resting tone. Tonic holding patterns may result from the proximity of muscles to traumatized pelvic joints.

Hip joint integrity and mobility, pain, and muscle performance impairments contribute to overactive PFM through its effect on the pelvic joints. Altered tone of the associated muscles, particularly the obturator internus and piriformis, can directly irritate the PFMs, causing a tonic holding pattern.

Abdominal or perineal adhesions and scars can cause overactive PFMs. Pelvic organs must slide freely during physiologic functions such as peristalsis, bowel movement, or vaginal penetration during intercourse. Abdominal adhesions can restrict pelvic organ movement and cause pain and altered tone of PFMs during bowel movements or intercourse. Severe adhesions of the uterosacral ligaments may restrict sacroiliac joint mobility. Adhesions may be a result of pelvic or abdominal surgery or an inflammatory condition of the abdomen, such as endometriosis. Perineal scars (often found in third- or fourth-degree episiotomies) can cause adhesions to the rectum and vaginal walls. These scars can be so painful that patients dread every bowel movement. Other painful conditions such as interstitial cystitis, endometriosis, fissures, and fistulas may also cause holding patterns in response to pain. Holding patterns of the PFMs may occur as a response to excessive generalized stress or reflect an emotional connection to the perineum.[109] Excessive holding of the PFMs because of pain or stress often leads to trigger points, ischemic changes, and tissue shortening.

Connective tissue diseases such as fibromyalgia are associated with overactive PFMs, particularly vulvodynia. Pelvic pain, as discussed earlier, may be a problem for sexual abuse survivors. The exact connection is unknown, but emotional holding of the PFMs and physical trauma to the perineum may play a part in the eventual development of overactive PFMs.

Common Impairments

There are many possible primary physiologic impairments in overactive PFMs. Careful evaluation is necessary to determine the most significant impairments in each patient. The most common impairments of overactive PFM are:

- Altered tone of the PFMs
- Trigger points of the PFMs
- Altered tone and trigger points of associated muscles of the hip, buttock, and trunk
- Impaired muscle performance and coordination impairments of the hip, leading to muscle imbalance around the hip
- Joint mobility impairments of lumbopelvic joints, particularly the sacroiliac, pubic symphysis, and lower lumbar facet joints
- Mobility impairments of scar and connective tissue
- Posture impairment, contributing to pelvic joint dysfunction

Pain impairment because of hypersensitivity of the perineal skin is common in vulvodynia, and Witzeman et al.[110] showed that PFM pain is correlated with dyspareunia in women with provoked vestibulodynia. A summary of impairments and suggested interventions is provided in **Display 18-10**.

DISPLAY 18-10

Summary of Impairments and Suggested Interventions for Overactive PFM

- Altered tone of the PFM: increased resting tone and trigger points
  - Biofeedback for training the PFMs to relax
  - Rhythmic contract and relax of the PFMs (quick PFE)
  - Soft tissue mobilization, vaginally or rectally
  - Electrical stimulation on the sacrum, vaginally or rectally
  - Relaxation training, autonomic nervous system balancing
  - Vaginal or rectal dilators
  - Ultrasound at the insertion of the PFM at the coccyx
  - Heat or cold over the perineum
- Altered tone of the associated muscles of the hip, buttock, and trunk
  - Soft tissue mobilization
  - Therapeutic exercises for stretching
  - Modalities such as ultrasound, electrical stimulation, heat, and cold
- Muscle impairments and coordination impairments of the associated muscles of the hip, buttocks, and trunk: muscle imbalances around the trunk and hip joint
  - Therapeutic exercises for strengthening and stretching
  - Coordination training of muscles around a joint (i.e., around the hip) or between several areas (hip and abdominals)
- Mobility impairment of scar and connective tissue of the perineum, inner thighs, buttocks, and abdominals
  - Soft tissue mobilization, scar mobilization
  - Visceral mobilization
  - Modalities such as ultrasound, heat, and microcurrent
- Mobility impairments (e.g., hypermobility, hypomobility) of pelvic joints: sacroiliac, pubic, lumbar, hip, and sacrococcygeal
  - Joint mobilization, muscle energy techniques, positional release, craniosacral therapy
  - Posture and body mechanics education
  - Therapeutic exercises for muscle imbalances
  - Modalities such as ultrasound, heat, cold, electrical stimulation, and TENS
- Faulty posture leading to undue stress on the pelvic structures
  - Instruction in proper sitting and standing posture and body mechanics
  - Use of cushions, lumbar rolls, and modified chairs
- Pain in the perineum with hypersensitivity of the skin and mucosa
  - Modalities such as cold, heat, ultrasound, and electrical stimulation
  - Education on avoiding perineal irritants, and therapeutic pain education

PFE, pelvic floor exercise; PFM, pelvic floor muscle; TENS, transcutaneous electrical nerve stimulation.

Activity Limitations

Overactive PFMs have activity limitations similar to other pelvic pain syndromes, such as low back and pelvic girdle pain. The ability to work (e.g., lift, sit, push, drive, and clean house), recreate, ambulate, sleep, and perform ADLs may be limited. Activity limitations unique to overactive PFM may result in a decreased ability or inability to sit because of severe perineal pain. Some patients cannot wear jeans or ride a bike. Routine Pap smears can be painful or impossible. The affected woman often has a decreased ability or an inability to have sexual intercourse or sexual contact of any kind.

Many women and men are embarrassed to talk to their doctors, family, and friends about pelvic, perineal, or genital pain. It is difficult to explain the reasons for activity limitations if you are unable to tell someone the location or the nature of the pain. This creates emotional stress. Patient with chronic pelvic pain often suffer in silence for many years before they find a medical professional who is able to treat them effectively.

Incoordination Dysfunction

Incoordination dysfunction can be divided into neurologic and nonneurologic syndromes. Detrusor sphincter dyssynergia is a type of incoordination resulting from a neurologic lesion in the spinal cord between the brain stem and T10. The PFMs and smooth muscle internal sphincter contract during a bladder contraction so that urine is unable to be expelled. This condition should be monitored by a physician. Symptoms of neurologic incoordination are similar to the obstructed voiding symptoms listed in the screening evaluation questionnaire. The therapist should refer the patient to the physician if neurologic incoordination or obstructed voiding is suspected.

Incoordination dysfunction may be a minor dysfunction with underactive or overactive PFMs, or it may occur as the primary dysfunction. Nonneurologic incoordination dysfunction is characterized by absent or inappropriate patterns of timing and recruitment of the PFMs. Common medical diagnoses associated with incoordination dysfunction include stress incontinence, constipation with obstructed defecation, and pelvic pain.

Etiology and Comorbidities of Nonneurologic Incoordination Dysfunctions

The cause of pure nonneurologic incoordination dysfunction is often related to decreased awareness of the PFMs and abdominals. Muscle atrophy is not significant in this dysfunction. Decreased awareness may reflect an emotional condition or a social conditioning. Pain in the pelvic or abdominal area may disrupt recruitment patterns. Surgical intervention may result in inhibition of the muscles—the muscles forget what to do, when to do it, and how it should be done. Some patients have never been aware of the PFMs and have developed poor recruitment patterns.

Common Impairments of Nonneurologic Incoordination Dysfunctions

PFM weakness may be a minor impairment. Most of these patients are found to have good PFM strength on the MMT. Coordination impairment is the primary physiologic impairment. Coordination impairment of the PFMs is discussed previously in the "Coordination Impairment" section.

Activity Limitations of Nonneurologic Dysfunctions

The most common activity limitation of incoordination dysfunction is stress incontinence with urine leaking during increased intra-abdominal pressure, such as during coughing, sneezing, or lifting. Patients also may have obstructed defecation with constipation and rectal pain (see **Building Block 18-5**).

BUILDING BLOCK 18-5

You have been working with a 20-year-old female with LBP and poor trunk stability for 3 weeks. Her symptoms are somewhat better but she continues to have pain. You suspect she would benefit from PFM training. How can you measure her PFM ability? How would you explain to her why it is important to do these exercises?

Visceral Dysfunction

Visceral dysfunction is a pseudo-PFM dysfunction. It is a disease or abnormality of the abdominopelvic visceral tissues that leads to pain and musculoskeletal impairments. Detrusor instability, often found in patients with urge incontinence, is the most widely seen visceral dysfunction directly related to the PFMs. It is characterized by irritated detrusor contractions and is often related to PFM impairments. Urge incontinence responds well to underactive PFM treatments. The causes, impairments, and treatment of urge incontinence are discussed later in Therapeutic Exercise Intervention for Common Diagnoses.

Etiology and Comorbidities

Visceral dysfunction encompasses several medical diagnoses:

- Urge incontinence
- Endometriosis
- Pelvic inflammatory disease
- Dysmenorrhea
- Surgical scars
- Irritable bowel syndrome
- Interstitial cystitis/bladder pain syndrome

These conditions may result in impairments whose primary origin is abdominopelvic pain or adhesions caused by organ disease. Knowledge of the causes and medical management of these diseases are necessary to treat the resulting impairments. A multidisciplinary approach is optimal when dealing with visceral dysfunction. Treatment of comorbid musculoskeletal impairments often results in decreased pain and increased function.

Common Impairments

Weakness of the abdominal muscles, especially the oblique and transversus layers, may occur in response to pain in the abdomen, causing a pendulous abdomen with poor visceral and lumbar support. Secondary lumbopelvic joint mobility impairment and posture impairments may result. Altered tone or impaired muscle performance (e.g., weakness) of the PFMs may also occur as a result of pain in the lower pelvic organs. Chronic pelvic pain postures often occur with long-standing abdominopelvic pain.[111] This can result in the following:

- Posture impairment
- Mobility impairments of pelvic and lumbar joints
- Altered tone, pain, and trigger points in trunk and lower extremity muscles
- Impaired performance of the hip muscles with length and tension changes

Abdominal adhesions and scar mobility restrictions may result in decreased mobility or motility of abdominal and pelvic organs and pelvic joints. When organ mobility is restricted, cramping, pain, and altered organ function may result. For example, abdominal adhesions may form around parts of the bowel, constricting the bowel lumen and making passage of feces painful.

Mobility impairments play a major role in visceral dysfunctions. Visceral mobilization techniques are used by physical therapists to restore normal mobility of organs.

Activity Limitations

Activity limitations vary greatly in cases of visceral dysfunction. In the case of dysmenorrhea (i.e., painful menstruation), patients may have 2 to 3 days each month of intense abdominal pain that confines them to bed. Other conditions result in constant abdominopelvic pain and cause activity limitations such as those of patients with trunk or back pain, who have a decreased ability to work, sit, walk, lift, have intercourse, play sports, exercise, or perform ADLs. Activity limitations may be directly related to organ dysfunction. For example, interstitial cystitis causes the person to urinate as often as every 15 minutes. Irritable bowel syndrome may result in alternating diarrhea and constipation, with many patients experiencing abdominal pain and bloating. These functions are unpredictable and often force patients to remain near the toilet for fear of severe cramping or incontinence of feces.

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON DIAGNOSES

This section describes the most common medical diagnoses for the pelvic floor region and suggests PT interventions. The diagnostic classifications mentioned in the previous section group impairments of body functions into common syndromes. The medical community uses a different classification system, and physical therapists should be aware of the medical classifications, testing, and medical treatment of these conditions to enhance their ability to provide effective PT intervention.

The associated medical diagnoses discussed here are commonly associated with underactive and overactive PFMs. Medical diagnoses associated with underactive PFM usually fall into two categories—incontinence and pelvic organ prolapse. Both can be extremely complex conditions with many associated impairments and comorbidities. Some conditions associated with underactive PFMs are impairments of body structures and cannot be changed with PT intervention.

The most common medical diagnoses associated with overactive PFMs include chronic pelvic pain, levator ani syndrome, coccygodynia, vulvodynia, vaginismus, anismus, and dyspareunia. The most common impairments of body functions for each diagnosis are discussed with the diagnosis in the following section. Any impairment may be significant, and failure to address all significant impairments may limit the patient's progress. Any and all combinations of impairments listed for overactive PFM can be associated with these diagnoses. Each patient should be evaluated thoroughly, impairments identified, and treatment plans developed based on the severity and significance of each impairment.

Incontinence

Incontinence is defined as the complaint of any involuntary leakage of urine, feces, or gas.[112] Careful evaluation of these patients often reveals PFM weakness and treatable comorbidities (**Evidence and Research 18-17**).

EVIDENCE and RESEARCH 18-17

More than 13,000,000 persons in the United States have UI. This figure includes approximately 50% of nursing home patients. Several large studies have found overall UI prevalence of 13% to 25%.[4,65] Approximately 80% of these incontinent patients can be significantly helped with noninvasive behavioral techniques used by physical therapists, occupational therapists, and registered nurses.[73]

Incontinence can be a limiting condition that may occur during sports activities and cause embarrassment.[113] Some women even stop exercising because of incontinence. This disruption in exercise ability may have a significant effect on PT for other areas of the body. The therapist may encounter poor compliance with exercises that cause incontinence. The instructions included in this chapter may be enough to correct or minimize symptoms so that the patient can return to active exercises (**Evidence and Research 18-18** and **18-19**).

EVIDENCE and RESEARCH 18-18

Nygaard et al.[108] conducted a questionnaire study of women who exercised. The authors found that 47% had incontinence during exercise. Twenty percent of those women modified their exercise routines solely because of incontinence.

EVIDENCE and RESEARCH 18-19

Women with urge UI and nocturia are three times more likely to fall.[114,115]

Incontinence also may limit elderly persons' activity levels. In some cases, incontinence causes embarrassment and may result in seclusion from social activities, family functions, and work.[116] PFM strengthening can help these patients return to an active lifestyle without fear of embarrassing leakage.[117] Incontinence also may result in secondary conditions such as skin breakdown, which can be a serious medical consequence for the elderly patient. All PT patients should be questioned about leakage, and, if appropriate, instructions should be given to help remedy the situation.

Understanding the most common types of incontinence assists therapists in developing treatment plans. Physicians broadly categorize bladder dysfunctions as the failure to store urine and the failure to empty urine. Stress, urge, and mixed incontinence are examples of a failure to store urine. Overflow incontinence is the failure to empty urine. The full screening questionnaire provided earlier helps to identify the type of incontinence. Stress and mixed incontinence are the two types directly related to underactive PFMs (see **Table 18-4**). The pathophysiology of incontinence is complex. Recent research into this complexity is beyond the scope of this chapter. A simplified explanation of incontinence is provided here and should give the beginning practitioner a good basis for general clinical assessments.

Stress Incontinence

Stress incontinence is defined as involuntary leaking of urine on effort or exertion such as during coughing, laughing, sneezing, and lifting.[112] Continence is maintained when the pressure in the urethra is higher than the pressure in the bladder. Strong PFMs help to increase the pressure in the urethra.[118] The perineal membrane and the sphincter urethrae muscles play a large role in the closure of the urethra (see Fig. 18-4).

TABLE 18-4

Types of Incontinences, Symptoms, Diagnosis Classification, and Possible Treatments

TYPES OF INCONTINENCES	SYMPTOMS	DIAGNOSIS CLASSIFICATION	POSSIBLE TREATMENT
Stress incontinence	Small urine leak with cough, sneeze, exercise	Underactive PFM, PFM weakness	PFEs, biofeedback, vaginal cones, electrical stimulation
Urge incontinence	Moderate or large urine leaks with strong urge to urinate	Visceral dysfunction, may have PFM weakness also	Bladder training, PFEs if needed, biofeedback, electrical stimulation
Mixed incontinence	Symptoms of stress and urge incontinence	Underactive PFM, PFM weakness, visceral dysfunction	Bladder training, PFE biofeedback vaginal cones, electrical stimulation
Overflow incontinence	Small amounts of urine leaking constantly with cough and sneeze, straining to start urination, feeling of incomplete emptying	Possible incoordination dysfunction (PFM contraction during urination), visceral dysfunction (atonic bladder), overactive PFM (PFM spasm or pain)	Medical evaluation may be needed, advanced PFM rehabilitation with biofeedback, electrical stimulation, MFR, PFE, bladder training
Functional incontinence	Long or difficult trip to the toilet with leaking on the way	Mobility impairment of decreased ambulation ability, poor transfer ability, decreased finger coordination	Gait training, strengthening exercises for lower and upper extremities, environmental modifications

MFR, myofascial release; PFEs, pelvic floor exercises; PFM, pelvic floor muscle.

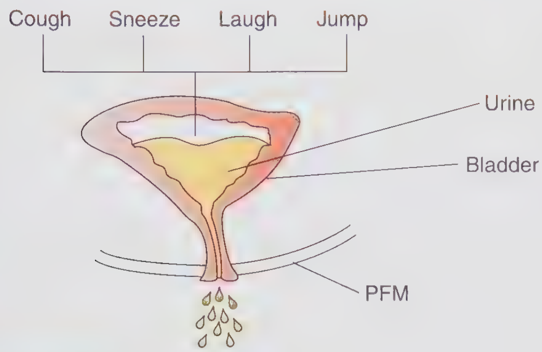


FIGURE 18-12 Stress incontinence.

In stress incontinence, the patient coughs, and pressure in the abdominal cavity is increased, pressing down on the bladder. If urethral pressure is low (usually because the PFMs are not strong enough), the urethra is forced open slightly, and a small amount of urine leaks out (**Fig. 18-12**). The causes of stress incontinence are similar to the causes of underactive PFM. Impairments of body functions include impaired PFM performance, shortened endurance, and coordination impairments. The treatment for pure stress incontinence includes PFM exercises, functional PFM training, biofeedback, and electrical stimulation[79,80] (**Evidence and Research 18-20**).

EVIDENCE and RESEARCH 18-20

A randomized controlled trial of 130 subjects with stress and mixed UI was conducted to determine if symptoms of UI can be reduced by PFEs and if symptoms can be eliminated by strengthening the PFMs to a MMT grade of 5. At the end of a 12-week PFE program, the exercise group reported a statistically significant improvement in UI symptoms and demonstrated improved PFM strength compared to the control group.[119]

McLean et al.[120] reported that following a 12-week PFM training program, women with SUI demonstrated hypertrophy of the urethral sphincter, decreased bladder neck mobility with a cough, and a significant improvement in UI.

Pereira et al.[121] conducted a randomized controlled trial to investigate the effect of vaginal weights for PFM training versus PFM training without vaginal weights in 45 postmenopausal women with SUI. Both groups received treatment for 6 weeks and reported significant improvement in UI and quality of life at 3 month and 12 month follow-up. There was no significant between-group difference.

A 3-month period of PFM training has been shown to improve the quality of life in patients with SUI.[122]

Urge Incontinence

Urge incontinence is defined as leaking urine associated with a strong urge to urinate.[112] The normal urge to urinate is a result of activation of stretch receptors in the detrusor muscle. During this urge, the detrusor remains stable and does not contract. In some patients, a very strong urge to urinate is associated with inappropriate detrusor contractions. Unstable detrusor contractions are contractions of the bladder muscle at incorrect times (e.g., when not positioned over the toilet to void). Strong, unstable detrusor contractions, as seen in overactive bladder or detrusor overactivity, increase bladder pressure and may result in incontinence. The volume of urine leaked is usually larger than that with stress incontinence and may include the entire contents of the bladder. In some cases, urge incontinence may occur without unstable detrusor contractions (i.e., sensory urgency).

The underlying cause of urge incontinence is often unclear and may include PNS or CNS nerve damage. It is suspected that poor bladder habits (especially going to the bathroom too frequently) and bladder irritants (such as caffeine, nicotine, and alcohol) contribute to the condition. PFM weakness with impaired muscle performance and endurance impairment is often found in patients with urge incontinence. Coordination impairment of the PFMs during detrusor contraction may also be present. In this situation, the PFMs do not contract in response to the urge to urinate, and a small increase in bladder pressure may cause urine leakage. Primary treatment for urge incontinence can include bladder retraining, avoiding bladder irritants, PFE, low-frequency electrical stimulation, and medications.

Mixed Incontinence

Mixed incontinence is a combination of stress and urge incontinence symptoms and is thought to be a progression of incontinence symptoms over time. These patients report leaking urine with increases in intra-abdominal pressure and with a strong urge to urinate. The causes of mixed incontinence are similar to the causes of underactive PFMs; the PFMs are usually weak. Treatment of this condition is similar to the treatment for stress and urge incontinence: bladder training, avoiding bladder irritants, PFM exercises, electrical stimulation, and, in some cases, medications.

Overflow Incontinence

Overflow incontinence results from a failure to empty the bladder fully. Obstruction of the urethra by tumor, scar tissue around the urethra, an enlarged prostate, overactive PFM, or other mechanical blockage may prevent the bladder from emptying. Decreased contractility of the bladder from a neurologic deficit, such as peripheral nerve injury associated with radical pelvic surgery, cauda equina injury, or diabetes, also may contribute to overflow incontinence.

In overflow incontinence, the bladder does not empty fully, and high volumes of urine are maintained in the bladder. When the bladder pressure is higher than the urethral pressure, small amounts of urine "spill out." This small but constant leaking may or may not be related to increased intra-abdominal pressure and is characteristic of overflow incontinence. PT impairments may include pain and altered tone of the PFMs. Mobility impairment may be caused by adhered scars. Many cases involve neurologic incoordination of the PFMs or primary visceral dysfunction and require medical intervention. A full medical evaluation is essential. Therapists should refer the patient to the doctor if overflow incontinence is suspected. PT treatment by pelvic floor specialists may include biofeedback, electrical stimulation, myofascial release, PFEs, and bladder training (see **Building Block 18-6**).

BUILDING BLOCK 18-6

Your new patient is a 75-year-old male with Parkinson's disease and difficulty walking. He is currently using a walker in the house and has poor balance. During an intake interview with your new patient, he admits that he has some urine leakage and gets up three to four times during the night. Discuss why nocturnal urination is of concern in this patient. List four ideas to address this concern.

Functional Incontinence

Functional incontinence is defined as the loss of urine due to gait and locomotion impairment. Incontinence is a secondary condition in pure functional incontinence; the primary impairment is a gait and locomotion impairment—an inability to get to the toilet quickly enough. It is not unusual for an elderly or disabled patient to require 5 to 10 minutes to rise from a chair, ambulate with a walker to the toilet, maneuver in front of the toilet, lower his or her clothes, and sit down. Elderly patients often have less ability to store urine because of PFM weakness and less ability to defer the urge to urinate than younger persons. The mobility-impaired patient may leak urine on the long journey to the toilet. Patients may also have PFM dysfunction or impairments of body structures. However, treatment of gait and locomotion impairments and adjustments to the environment can improve function, and physical therapists are well suited to help these patients. Some ideas for helping these patients are detailed in **Display 18-11** (**Evidence and Research 18-21**).

DISPLAY 18-11
Helping Patients with Functional Incontinence

- Improve the speed of sit-to-stand transfers by raising the height of the chair, providing a chair with arms, improving shoulder depression and elbow extension strength, and improving lower extremity strength in the quadriceps and gluteals.
- Improve the speed of ambulation to the bathroom by providing appropriate assistive devices, clearing obstacles from the pathway to the toilet, bringing the patient's chair closer to the toilet (e.g., move the sitting room to the side of the house nearest the toilet) or bringing the toilet closer to the patient (e.g., place a commode or urinal near the bed or sitting room), and improving balance and coordination, strength, and endurance of the lower extremities.
- Improve the speed of ambulation in the bathroom by clearing obstacles (especially rugs) and providing grab bars for ambulation without assistive devices if the bathroom is too small for the device to fit easily.
- Improve speed of lowering clothes by providing patient with Velcro-open pants, suggesting that women wear skirts and dresses, and improving finger coordination and dexterity to manage buttons and zipper more quickly.
- Improve stand-to-sit transfer onto the toilet by providing a raised toilet seat and handrails and by improving lower extremity function.
- Consider impairments of mental function in a patient's ability to recognize the bathroom. It may be helpful to place a picture of a toilet on or near the door or to leave the door open. In severe cases, even when patients are brought to the toilet, they may still not understand what to do.
- Absorbent garments (i.e., diapers and pads) are available for men and women in a variety of sizes. Helping patients and caregivers to choose appropriate garments may allow increased participation in work, social, and recreational activities. Always make sure that the physician has been informed of the patient's incontinence and that conservative treatments have been tried.

EVIDENCE and RESEARCH 18-21

A study of 50 elderly (age 60 to 74) women with SUI was conducted to investigate the effect of PFEs on incontinence and self-esteem. The results demonstrated a statistically significant difference in average self-esteem scores in the treatment group versus the control group.[123]

Pelvic Organ Prolapse

Pelvic organ prolapse is the second largest category of medical diagnosis associated with underactive PFMs. The cause of prolapse may be complex and is often associated with underactive PFM and prolonged increases in intra-abdominal pressure. A simple explanation of prolapse and PFM function is presented in the Patient-Related Instruction 18-6. The most common types of organ prolapses (**Fig. 18-13**) are cystocele (i.e., protrusion of the bladder into the anterior vaginal vault), uterine prolapse (i.e., displacement of the uterus into the vaginal canal), and rectocele (i.e., protrusion of the rectum into the posterior vaginal vault).

Common symptoms include a sensation of organs "falling out," feelings of pain or pressure in the perineum[112] that may limit functional activities in standing, feeling that there is something bulging in the vagina, sensations of sitting on a ball, difficulty defecating (i.e., rectocele), difficulty urinating (i.e., cystocele), or painful intercourse (i.e., uterine prolapse). All patients should learn how to protect the PFMs from undue stress. However, it is essential that patients with pelvic organ prolapse learn how to avoid increased intra-abdominal pressure. PT treatment involves educating patients on decreasing intra-abdominal pressure (see **Patient-Related Instruction 18-7**) and PFM exercises (**Evidence and Research 18-22**).

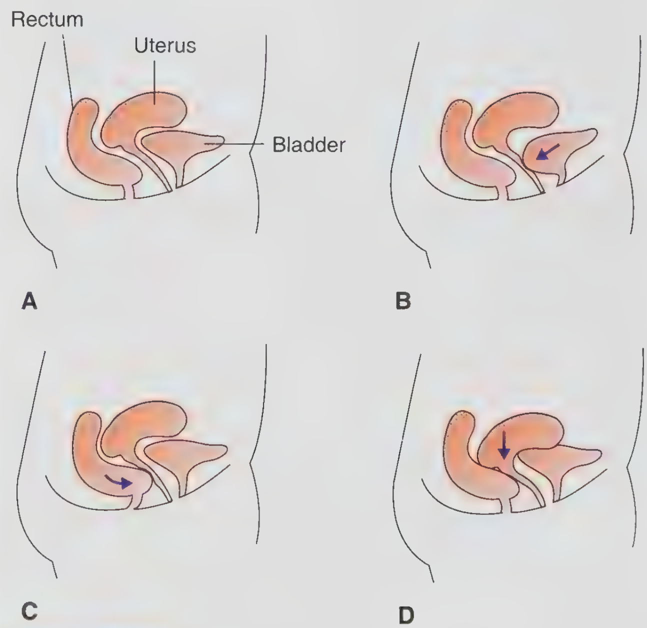

FIGURE 18-13 Common types of organ prolapses. **(A)** Normal organ positions. **(B)** Cystocele. **(C)** Rectocele. **(D)** Uterine prolapse.

Patient-Related Instruction 18-7

Decreasing Intra-abdominal Pressure

- Avoid constipation, and do not strain with defecation (i.e., bowel movement). Drink lots of fluids to help avoid constipation and soften stools. Consult with a dietitian or physician about dietary changes and medications to avoid constipation.
- If you have difficulty getting out of the chair, scoot to the edge of the chair, lean forward, and push up with the arms. Avoid bearing down and breath holding. Instead, contract the abdominals inwardly, breathe out, and contract the PFMs while you stand up.
- Lift properly with inward contraction of abdominals and outward breath on effort. Avoid bulging the abdominals outward and bearing down.
- Exercise correctly using an inward abdominal contraction. Avoid bearing down and pouching the abdominal muscles outward. Unnecessary increases in intra-abdominal pressure may occur while lifting weights that are too heavy and with abdominal exercises that are too advanced. Curl-ups or sit-ups commonly cause the abdominals to bulge. Avoid curl-ups if you have organ prolapse. Patients with PFM weakness should advance to weight lifting, advanced abdominal exercises, and jogging slowly and carefully.
- If you are a postpartum woman, it is especially important to restore adequate PFM strength before returning to high-impact aerobics, jogging, and advanced weight lifting. The jumping jack test (see Patient-Related Instruction 18-2) can be used to determine the ability of the PFM to withstand stress. It is important to continue active rehabilitation of the PFM during your return to vigorous exercise. If incontinence persists or worsens, you may have to delay the return to vigorous exercises until more strength of the PFM is gained.
- It is important to seek medical treatment for chronic coughing or vomiting and to contract the PFM before and during coughing or vomiting. You can counterbrace the PFMs by contracting during coughing and vomiting. Support the perineal tissue with gentle upward pressure of the hand over the perineum during coughing and vomiting spells.

EVIDENCE and RESEARCH 18-22

A multicenter, randomized controlled trial of 447 patients with symptomatic pelvic organ prolapse of stage I, II, or III investigated outcomes of individualized PFM training versus no muscle training with a "prolapse lifestyle advice leaflet." At 12-month follow-up, patients in the intervention group reported a greater improvement in prolapse symptoms on the POP-SS (pelvic organ prolapse symptom score) compared to the control group; this difference was statistically significant and reached the minimally important change for the POP-SS. 80% of patients in the intervention group were still performing muscle training exercises at 12 months.[124]

Ninety women participating in group exercise were assessed for PFM contraction utilizing transabdominal ultrasound to determine the ability to perform a correct PFM contraction and bladder-base movement during an abdominal curl exercise. 25% of the subjects did not demonstrate a correct PFM contraction and all subjects demonstrated depression of the bladder-base with an abdominal curl exercise. The authors concluded that "exercising women may be at risk of PFM dysfunction when performing abdominal curl activities."[125]

A randomized controlled trial evaluated the effect of PFEs on sexual function in women with pelvic organ prolapse. Fifty women received 6 months of PFEs and lifestyle advice, while the control group (59 women) received lifestyle advice only. 39% of the women in the PFE group versus 5% in the control group reported improved sexual function. "Women reporting improvement in sexual function demonstrated the greatest increase in PFM strength and endurance."[126]

Kashyap et al.[127] conducted a study to compare the effect of individual PFM training instruction versus a self-instruction manual for PFM training in women with pelvic organ prolapse. While both groups demonstrated improvement in the Pelvic Organ Prolapse Symptom Scale, visual analog scale, and Pelvic Floor Impact Questionnaire, the group that received individual training reported significantly greater improvement compared to the self-instruction group.

Chronic Pelvic Pain

Chronic pelvic pain is the most common diagnosis associated with overactive PFM. It is analogous to the diagnosis of LBP—it does not give specific information about what type of impairment may be present. The most common impairments are altered tone and performance impairments of the associated muscles of the trunk and hips, poor posture, and mobility impairments of the pelvic and lumbar joints. Therapists should remember the role of the PFMs in sacroiliac dysfunctions. All patients with chronic pelvic pain should be screened for PFM dysfunction, evaluated, and treated if needed (see **Building Block 18-7**).

BUILDING BLOCK 18-7

Your new patient is a 45-year-old female with primary complaint of left buttocks and posterior leg pain. List five risk factors for overactive PFMs that might be present in this patient. What finding would lead you to consider a PFM dysfunction and how would you address it?

Levator Ani Syndrome

Levator ani syndrome is another diagnosis that may be used universally for patients with vaginal or rectal pain. Patients report pain in the coccyx, sacrum, or thigh. Levator ani syndrome refers to increased resting tone and trigger points in the pelvic diaphragm layer of the PFMs. Patients often report pain with defecation and increased pain with sitting. Some patients say they feel like they are "sitting on a ball" (this can also be a symptom of organ prolapse).

Pelvic floor tension myalgia is pain in the PFMs, which is usually associated with increased resting tone or chronic tension. This diagnosis is similar to levator ani syndrome, and many practitioners use the two names interchangeably.

Coccygodynia

Coccygodynia indicates pain at the coccyx bone. Pain at the coccyx is usually not related to the sacrococcygeal joint. More often, it is related to trigger points of the PFMs, obturator internus, gluteus maximus, or piriformis. Patients often have

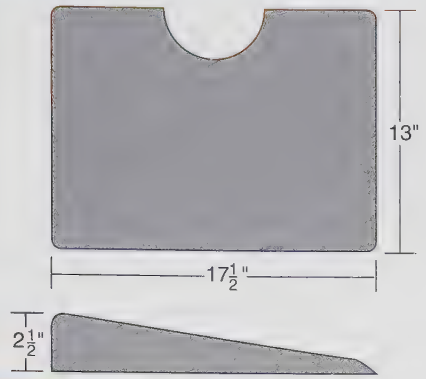

FIGURE 18-14 Coccygodynia seat cushion.

sacroiliac joint mobility impairments and less frequently have sacrococcygeal joint mobility impairments. Coccygodynia is a common sequel of falls directly on the buttocks. Patients report pain with sit-to-stand transfers, possibly because of gluteal muscle contraction or sacroiliac dysfunction. Coccygodynia patients have pain that limits sitting.

The most common impairments associated with levator ani, tension myalgia, and coccygodynia include altered tone of the PFMs and associated muscles; mobility impairments of scars, connective tissues, and pelvic joints; and faulty posture, especially in sitting. All patients with this diagnosis must learn to sit with their weight balanced on the ischial tuberosities and not on the tail bone (see Patient-Related Instruction 18-4). Some patients need to use a special cushion to relieve pressure on the coccyx. The most effective cushion is a seat wedge approximately 2.5 inches tall with a small cutout in the posterior aspect (**Fig. 18-14**). A typical donut-shaped cushion places direct pressure on the coccyx and is therefore not recommended.

Vulvodynia

Vulvodynia is a broad diagnosis of pain in the external genitalia, perineum, and vestibule. It can be a severe, often idiopathic condition that may or may not be associated with PFM dysfunctions. It is categorized as localized (involving only one area) or generalized (symptoms in many areas of the perineum). It is also categorized as provoked (only occurring with palpation or penetration) or unprovoked (pain is present at all times even without contact).[128] Patients report stabbing pain in the vagina and less commonly the rectum. Many patients are completely unable to have vaginal penetration of any kind (e.g., intercourse, speculum evaluation, tampon insertion). Symptoms are increased with sitting and by wearing tight pants.

The causes of vulvodynia are complex and can include overactive PFMs, environmental irritants or reactions, alteration in the vaginal mucosal properties and nerve inputs in the area, or a complication of pelvic surgery. Infection by bacterial and viral organisms (i.e., yeast infections are common) commonly precede the onset of vulvodynia but their relationship to the condition is not understood.[129] Vulvodynia is a difficult condition to treat. A multidisciplinary approach is best. All impairments should be considered, especially mobility impairments of the pelvic and lumbar joints, mobility impairments of scars, and altered tone of the PFMs and associated muscles. These patients need special instructions in avoiding perineal irritants (see **Patient-Related Instruction 18-8**) and may benefit from pain-reducing modalities such as transcutaneous electrical nerve stimulation at the sacral nerve roots.

Patient-Related Instruction 18-8

Avoiding Perineal Irritants

Avoid unnecessary irritation to the vaginal tissue to encourage healing of the area. The vaginal tissue is like the tissue in your mouth. It needs to stay moist and should not be vigorously cleaned with harsh soaps. Here are some suggestions to decrease the irritation of the vaginal tissue:

Clothing

- Avoid tight clothes, especially jeans and pantyhose. It is also helpful to avoid bike riding, because pressure and rubbing on the perineum can increase irritations.
- Wear 100% cotton white underpants that are washed separately in hot water with a mild detergent; avoid bleach and fabric softeners.

Hygiene

- Use white, unscented toilet tissue and pat dry after urination. Some women spray the vaginal area with a fine mist of plain water then pat dry.
- Wash the outside of the vaginal area gently with mild soap (i.e., natural glycerin-based soaps without deodorants or fragrances). Do not douche unless it is suggested by your doctor.
- Avoid dripping shampoo or other soaps on the vaginal area while in the shower.
- Soak in the tub with clear water—no bubble bath, bath beads, or other fragrance additives. Do not wash yourself in the tub; wash in the shower.

Menstruation

- Avoid tampons if possible.
- Avoid pads with fragrances. Consider trying cotton washable menstrual pads.
- Do not douche, unless suggested by your doctor.

Medications

- Speak to your doctor before using any prescription or over-the-counter cream on the perineum. Many creams can be irritating and make the situation worse.
- Do not self-medicate for yeast infections.
- Some contraceptive creams or jellies and lubricants can irritate. Speak to your doctor about an appropriate contraceptive method. Pure olive oil can be used as a vaginal lubricant without irritation by many women.

Vaginismus

Vaginismus is defined as increased tension of the muscle around the vagina, the superficial muscle layer, or pelvic diaphragm layer. Patients report symptoms similar to those of vulvodynia, although to a lesser degree. Dyspareunia (i.e., painful intercourse) is the common symptom of vaginismus. Muscle tension may be a secondary impairment in response to a medical condition, such as atrophic vaginismus or fistula (i.e., a small opening in the skin similar to a small cut at the corner of the mouth). Primary dyspareunia may occur with vaginismus as a result of fear of penetration.

Nonrelaxing Puborectalis Syndrome

Nonrelaxing puborectalis syndrome or anismus is increased tone of the anal sphincters. It is similar to vaginismus in that it may be a secondary impairment caused by trauma, fissure, fistula, or hemorrhoids at the anal opening. Patients report severe pain with defecation, which often leads to constipation because patients delay defecation. Other PFMs may or may have increased tension.

Dyspareunia

Dyspareunia is the symptom of painful penetration and can be associated with all of the diagnoses previously described. It can be divided into two categories: pain at initial penetration or pain with deep penetration. Pain with initial penetration may be caused by superficial muscle spasm (i.e., vaginismus), skin irritation (i.e., vulvodynia), or adhered, painful episiotomy. Deep penetration dyspareunia may be related to altered tone of the PFMs (e.g., levator ani syndrome, tension myalgia) or organ prolapse with visceral adhesions. The most common impairments found in vaginismus, anismus, and dyspareunia are altered tone of the PFMs and associated muscles and mobility impairment of scars and connective tissue.

ADJUNCTIVE INTERVENTIONS

Many patient-related instructions have been included throughout this chapter. Education is essential for this patient population. When was the last time someone talked with you about how to urinate? Take time and make sure your patients understand anatomy and good bladder health, because they are often too embarrassed to admit that they do not know.

PT for the PFMs applies the same principles of treatment used for other weak and painful muscles. Therapeutic exercise principles are the same, and modalities are used for the same reasons. This section lists the modalities used in underactive and overactive PFMs. Several techniques are explored in more detail to enhance the therapist's ability to treat PFM impairments.

The skilled practitioner can employ various modalities and techniques to enhance the effect of active PFE for the treatment of underactive PFMs, including the diagnosis of incontinence. Modalities and techniques are chosen based on the patient's degree of muscle weakness. For a MMT grade of 0 to 2, the practitioner can include the following modalities or techniques:

- Facilitation with muscle tapping of the PFMs inside the vagina
- Overflow exercises of the buttocks, adductors, and lower abdominals
- Biofeedback with a pressure or a surface EMG device
- Electrical stimulation
- Bladder training
- Coordination of PFMs during ADLs

For MMT grade of 3 to 5, the practitioner can include weighted cones inserted into the vagina and PFEs in more stressful activities, such as weight lifting. These patients continue to benefit from bladder training and biofeedback but should be weaned away from facilitation, overflow, and electrical stimulation.

Many other interventions are used in conjunction with exercises for the treatment of overactive PFMs (see Display 18-10). Interventions used for altered muscle tone in other areas of the body can be used with the PFMs as well. Later sections describe perineal scar mobilization and a method for externally palpating the PFMs.

Biofeedback

It is necessary to give all patients some form of feedback, whether it is with the finger in the vagina, a mirror, or biofeedback machines during PFEs. Some practitioners use biofeedback machine evaluation and treatment with all PFM dysfunction patients. Surface EMG and pressure biofeedback are two methods of machine biofeedback. This type of biofeedback is especially helpful if the patient has decreased sensation or decreased motivation.

Pressure biofeedback involves an air chamber connected to a manometer, which records pressure changes. The air chamber is inserted into the vagina, and the patient contracts the PFMs around it. The PFM contraction creates an increase in pressure in the vagina that is recorded and displayed for the patient and therapist. Some pressure devices collect specific data on pressure changes; others are used only for immediate feedback to the patient. Therapists must be careful to instruct PFE correctly, because bearing down increases pressure and may be misinterpreted as proper PFM contractions.

Surface EMG can provide even more information about the muscle contraction, patterns of recruitment, and resting tone. It is a powerful tool in treating PFM dysfunction.[130] An internal vaginal or rectal probe or surface electrodes are used to pick up the electrical muscle activity of the PFMs and display it for the patient. Stand-alone surface EMG units provide feedback in the form of a bar graph or line of lights. This gives information about one part of the contraction at a time. These units are helpful for home training. Computer-assisted surface EMG units can show the electrical muscle activity of the entire PFM contraction or several contractions in a row on one screen (**Fig. 18-15**). This allows the therapist to compare recruitment at different times in the contraction. Surface EMG is the ideal method of feedback in down training (i.e., relaxation training) for patients with overactive PFMs. Biofeedback therapy for patients with stress, urge, or mixed incontinence is given an A rating by the Agency for Health Care Policy and Research guidelines on the management of UI.[73] This means that properly designed research studies support the effectiveness of biofeedback for the treatment of these patients.

Basic Bladder Training

Bladder training is scheduled voiding to regain normal voiding patterns. It is used in cases of urgency, frequency, urge incontinence, or mixed incontinence. Have the patient record the time of day he or she urinates in the toilet, the time of urine leakage (i.e., incontinence), and why urine leaked (e.g., cough, sneeze, lift). It is also helpful for the patient to record the amount and type of fluid intake. Information should be collected for 3 to 6 days. This type of record is called a bladder diary (see **Fig. 18-16**). Bladder diaries can be simple or complex. The purpose of the simple bladder diary is to determine the features shown in **Table 18-5**.

Column # Directions

1 Urination in toilet: check, measure, or count # of seconds.
2 Make a check if a urine leak occurs, note small or large.
3 Note the reason for the accident (jump, sneeze, lift, water, urge).
4 Note type and amount of fluid intake.

Fill in the day and date at the top of each column.

TABLE 18-5

Features Determined from a Bladder Diary

MEASURE	PURPOSE
Average voiding interval	Determine bladder schedule
Frequency of voids in 24 h	Bladder habits and outcome data
Nocturnal voiding frequency	Bladder habits and outcome data
Number of incontinence episodes in 24 h	Outcome data
Cause of accidents	Stress or urge symptoms
Total fluid intake	Counsel on normal fluid intake
Number of bladder irritants per day	Counsel on decreasing bladder irritants

Abrams P, Cardozo L, Fall M, et al. The standardization of terminology of lower urinary tract function: report from the standardization sub-committee of the International Continence Society. Am J Obstet Gynecol 2002;21:167–178.

The cause of the accidents helps identify the type of incontinence. Total fluid intake and the number of bladder irritants can be used to counsel patients on appropriate fluid intake. Bladder irritants must be limited for successful treatment of urge incontinence. However, limiting overall fluid intake does not decrease incontinence.[104] Patients should be encouraged to drink six to eight cups of fluid per day.

The average voiding interval (i.e., average time between urinations) is the most important piece of information gained from the bladder diary for bladder retraining. Ask the patient to urinate in the toilet at the average voiding interval you determined from the bladder diary, whether they need to urinate or not. For example, if the average voiding interval was 1 hour, ask the patient to void in the toilet every 60 minutes—no sooner and no later. The bladder eventually becomes accustomed to the schedule, and urgency decreases. Most patients can increase the voiding interval by ½ hour every week. Do not increase the voiding interval if incontinence or urgency is worse or unchanged. Patients do not follow the bladder training schedule at night. Nocturnal voiding gradually improves as the daytime voiding interval increases. The goal is a voiding interval of 2 to 5 hours during the day, with seven or fewer voids per day.

Urge deferment is taught to allow patients to maintain the voiding interval. If the urge arrives before the prescribed voiding interval, patients are encouraged to use the techniques in **Patient-Related Instruction 18-9**. Patients need to practice several different techniques to find the most effective technique for them. After the urge has passed, patients should try to wait until the correct time to urinate (**Evidence and Research 18-23**).

EVIDENCE and RESEARCH 18-23

Patients unable to complete a bladder diary have been shown to have less success with behavioral therapy for UI.[79]

Patient-Related Instruction 18-9

Urge Deferment

- Sit down; pressure on the perineum helps calm the bladder.
- Relax and breathe; nervousness and anxiety contribute to urgency.
- Small PFM contractions help to reflexively relax the bladder.
- Raise up on the toes; contracting the plantar flexors can quieten the bladder.
- Keep the mind busy; attend to a task involving a lot of attention. Tell yourself you cannot stop to go to the bathroom, count backward, or pretend you are in the car and there is no bathroom available.
- Practice mind over matter; the mind has great influence over the bladder. For example, you are on a 2- or 3-hour car ride, and you feel the urge to urinate. If you say to your bladder, "Not now; calm down; I'll go later," the urge goes away. The bladder may become conditioned to produce the sensation of urgency and bladder contractions with certain activities (e.g., before leaving home, before a speech, walking past the bathroom, arriving home, while unlocking the door). It is important to break these habits and establish control over the bladder. (Rather than the bladder controlling your actions.)

Scar Mobilization

Adhesion of perineal scars can cause pain with intercourse (i.e., dyspareunia), pain with bowel movement, and weakness or increased resting tone of the PFMs. The goal of scar mobilization is to lengthen connective tissue and scar adhesions, allowing fascial layers to slide easily over one another. Complete vaginal scar management includes internal myofascial release of scars, mobilization of scars by patients or their partners, ultrasound, PFE, and heat if needed. One method for teaching mobilization of scar tissue is described in **Patient-Related Instruction 18-10**.

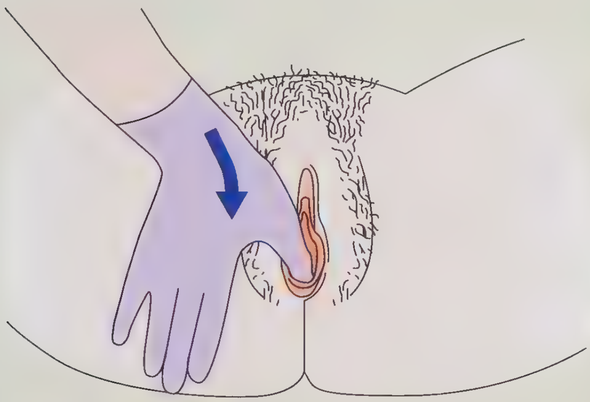
The therapist can describe the technique using the patient's web space between the thumb and the first finger as the posterior vagina (**Fig. 18-17**). This allows the therapist to give the patient the experience of the amount of pressure that is appropriate and to show how to perform the oscillations. Oscillations are similar to friction massage in that the goal is to slide the skin over the second layer of fascia, thereby breaking adhesions and restoring mobility.

Tolerance to scar mobilization varies with the severity of adhesions. Most women find that pain with deep myofascial release of scars decreases as the adhesions loosen. Dyspareunia usually decreases as scars loosen. Some women find it difficult to effectively massage their own vaginal scars. It may be difficult to reach the vagina, or it may be difficult to cause self-inflicted pain. In this case, partners can be trained in a similar manner to assist with treatment. Scar mobilization before intercourse can help decrease dyspareunia. Scar mobilization should not be performed in the presence of open wounds, rash, or infection. Postpartum women should wait at least 6 to 8 weeks after delivery and should check with the physician if questions arise.

Patient-Related Instruction 18-10

Self-Mobilization of Scar Tissue

- Wash your hands thoroughly before beginning
- Choose one of the following positions:
  - Lying on the bed with pillows to prop the head up
  - Sidelying on the bed
  - In the tub
- Use your index finger to reach around from the back while sidelying, or use your thumb to reach the vagina from the front.
- Apply firm, downward pressure on the scar, usually located on the posterior vaginal wall. This probably feels uncomfortable but should not be extremely painful. Constantly holding pressure results in softening of tissue, similar to the feeling of your thumb sinking into a stick of butter.
- Maintain downward pressure for 1 to 3 minutes; then begin gentle oscillations in all directions. Do not allow your finger or thumb to slide over the skin; take the skin with you as your thumb oscillates. Continue these oscillations for several more minutes.
- Move on to another area of the scar, or finish the session.
- Use a hot towel on the perineum or soak in a hot tub to help dissipate any residual soreness.



Episiotomy scar massage.

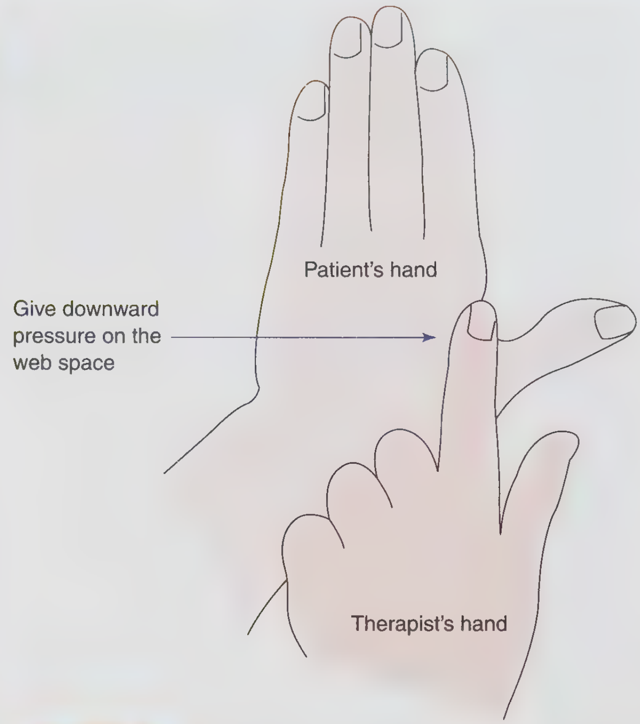


FIGURE 18-17 Describing self-mobilization of a vaginal scar using the patient web space.

Externally Palpating the Pelvic Floor Muscles

It is possible to palpate the PFMs externally at the insertion to the coccyx and along the length of the muscle at the medial ischial tuberosity. The benefits of this palpation are limited, but it is helpful in palpating and treating trigger points in some parts of the levator ani and obturator internus muscles. This method does not give access to all areas of the PFMs. This palpation requires skilled instruction and practice to perfect. Patient position, therapist preparation, therapist position, hand positions, and technique are described in **Display 18-12**.

DISPLAY 18-12

Externally Palpating the PFMs

- Patient position: Place the patient in sidelying with the top leg in approximately 60 to 80 degrees of hip flexion and the knee comfortably bent. Put two or three pillows under the top leg to provide stability in neutral abduction or adduction, and allow the patient to relax the leg fully. Total patient relaxation is necessary for deep PFM palpation.
- Therapist's position: The therapist is positioned behind the patient and finds the tip of the ischial tuberosity on the uppermost ilium.
- Therapist's preparation: This palpation may be done through underpants but is more effective if the fingers are on bare skin. The therapist should wear a vinyl glove on the palpating hand because it will be close to the anus and perineum.
- Hand position: The most effective hand position is supination, with all four fingers adducted in full finger extension. Keep the hand parallel to the table, and place the fingertips on the skin between the ischial tuberosity and the anus (just medial to the ischial tuberosity).
- Technique: Apply gentle inward pressure, directing your fingertips toward the anterior-superior iliac spine of the top ilium. Closeness to the ischial tuberosity results in the skin pulling taught and restricting deep palpation. In this case, reposition the

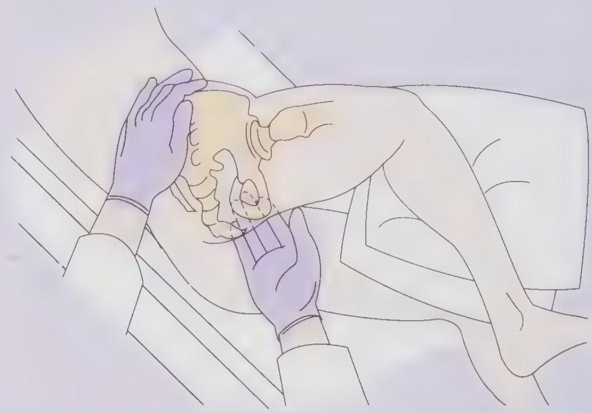
(continued)

DISPLAY 18-12

Externally Palpating the PFMs (*continued*)

fingers more medially toward the rectum, taking up some skin slack (see figure below). The levator ani muscles are rather deep, being the third layer in the pelvic floor. Depth from the skin varies greatly and can be more than 1.5 inches. When a firm resistance is felt, ask the patient to contract the PFMs. You should feel a firm PFM contraction pushing your fingers outward.

- With the PFMs at rest, assess for pain, muscle tone, and connective tissue restriction in the usual manner. Angling the fingers anteriorly and posteriorly can give information about different areas of the levator ani muscle group. The obturator internus is a little more difficult to palpate. A review of anatomy is necessary to orient yourself to the location of the muscle in the sidelying position. Keep the palpating hand in the position described previously, and gently change the angle of the hand so that the wrist and elbow drops and the fingers move upward into the tissue above. The obturator internus is located in this area. The muscle should feel somewhat soft. Have the patient contract the muscle to ensure correct location. External rotation can be tested by asking the patient to lift the top knee upward toward the ceiling while keeping the foot on the supporting surface. The therapist resists this motion with a hand on top of the knee. A small isometric contraction should result in palpable muscle tension. The palpation depth is important. Shallow palpation results in palpation of the medial ischial tuberosity. In this case, continue straight, inward pressure until the tissue releases to a deeper level, and then angle the wrist down and the fingers upward. Myofascial release of the muscle or connective tissue can be carried out in this position if impairments are identified.



External palpation of PFMs. (Adapted from Hoppenfeld S. Physical Examination of the Spine and Extremities. New York, NY: Appleton-Century-Crofts. 1976.)

KEY POINTS

- The PFMs include four skeletal muscle layers: anal sphincter (continence), superficial genital muscles (sexual functioning), perineal membrane (continence), and pelvic diaphragm (continence, pelvic support).
- The pelvic diaphragm includes the levator ani which is made up of the coccygeus, pubococcygeus, puborectalis, and iliococcygeus and is the largest muscle group in the pelvic floor. These muscles are skeletal muscles under voluntary control and have 70% slow-twitch and 30% fast-twitch muscle fibers. They span from the pubic bone to the tail bone and between the ischial tuberosities. The PFM is close to many hip muscles (i.e., obturator internus and piriformis), but it is neither necessary nor desirable to move the legs while contracting the PFMs.
- The three functions of the PFM are supportive (i.e., prevents pelvic organs from prolapsing), sphincteric (i.e., prevents involuntary loss of urine, feces, and gas from the urethra and rectum), and sexual (i.e., increases sexual appreciation and maintains erection).
- All patients should be screened for PFM dysfunction with these simple questions. Do you ever leak urine or feces? Do you ever wear a pad because of leaking urine? Do you have pain during intercourse? If indicated, a more comprehensive questionnaire can be given to attempt to identify the type of incontinence and other limiting factors.
- Patients can be given self-assessment tests and taught self-awareness exercises: jumping jack test, digital self-examination (finger in the vagina), index finger on the perineal body, visual exercise, sexercise, and squeezing around an object. These home exercises help to develop the exercise program and ensure the patient is contracting the PFM correctly.
- Through home self-assessment, the patient reports the number of seconds a PFM contraction can be held, repetitions of endurance contractions, and repetitions of quick contractions.
- Impairments that affect PFM function include performance impairments of the PFMs, abdominals, and hip muscles; pain and altered tone of the PFMs, hip muscles, and trunk muscles; lumbopelvic joint mobility impairments; posture impairments; and coordination impairments of the PFMs and the abdominal muscles.
- PFM dysfunctions have two clinical classifications that are used by pelvic physical therapists internationally: underactive PFM (i.e., loss of support usually as a result of impaired PFM performance) and overactive PFM (i.e., pain and altered tone impairment in the PFMs). Two additional classifications include incoordination dysfunction (i.e., coordination impairment with poor timing and recruitment of PFMs) and visceral dysfunction (i.e., dysfunctions of the pelvic viscera with possible PFM involvement). PFM dysfunctions can result in significant activity limitations and affect the quality of life.
- Incontinence is the most common result of underactive PFM. The most common types of incontinence are stress incontinence (i.e., loss of urine and increased intra-abdominal pressure with a cough, sneeze, laugh, or lift), urge incontinence (i.e., very strong urge to urinate, usually associated with a bladder contraction, which results in leaking urine), mixed incontinence (i.e., combined stress and urge incontinence), overflow incontinence (i.e., obstruction at the urethra or a flaccid bladder that allows

high volumes of urine to collect in the bladder and spill over), and functional incontinence (i.e., leaking of urine because of an inability to ambulate to toilet quickly).

- Pelvic organ prolapse is another common diagnosis resulting from PFM weakness. Forms include cystocele (i.e., bladder prolapse into the vagina), uterine prolapse (i.e., uterine displacement into the vagina), and rectocele (i.e., rectal prolapse into the vagina).
- The PFMs contribute greatly to the stability of the trunk, and impairments of the PFMs are present in many orthopedic dysfunctions including LBP and chronic pelvic pain. Treatment of PFM dysfunction will greatly enhance outcomes of orthopedic treatment in this area.
- With the results of screening questionnaires, the physical therapist should be able to develop an exercise program, including the duration of endurance contraction, rest between endurance contractions, repetitions of endurance contractions, repetitions of quick contractions, number of sets per day, exercise position, need for overflow facilitation from accessory muscle, and other treatments that may be helpful.
- All physical therapists should be aware of the PFMs and be prepared to give generalized strengthening instructions.
- Teaching PFEs involves educating the patient on the location and function of the PFMs and the importance of normal PFM function, providing accurate verbal clues, and teaching home assessment and awareness exercises. The most effective verbal cue for females seems to be "Pull your sphincter muscles up and in as if you do not want gas to come out." Many patients become discouraged and abandon PFEs. Therapists must continue to monitor the patient's progress and to actively encourage participation in the PFE program.

CRITICAL THINKING QUESTIONS

1. Imagine you have urge UI and are being sent to PT for shoulder pain. For some reason the therapist always puts you on the plinth farthest from the bathroom near the kitchen where someone always seems to be washing dishes during your therapy time. Your therapist is a very attractive younger person of the opposite sex and you are embarrassed to share your dilemma. Describe how you would feel about your situation. Describe the impact on your life (i.e., work, family, social interactions, emotions). List some things you might change because of your condition.
2. You are treating a 30-year-old man who fell off a ladder onto his right buttock. After 3 weeks of quality treatment, he has experienced significant decrease in low back and sacroiliac pain, but he can only sit for 1½ hours and experiences pain with sit-to-stand transfers and when going up stairs. He finally admits that his tail bone hurts and that it feels as though he is "sitting on a ball." Your evaluation shows no dysfunction in the lumbar spine and persistent hypomobility of the right sacroiliac. Which muscles should you assess for dysfunction, and how would you treat them? Think about how you would explain to the patient that his pain may be related to the PFMs.

LAB ACTIVITIES

1. Work in groups of two. One person pretends to be the patient. Pick a scenario from the list below or make up your own. Possible patient scenarios—add details as needed
   A 24-year-old female 4 months after vaginal delivery of her third child with buttocks pain and stress incontinence
   A 61-year-old male with urgency and LBP
   A 55-year-old male a fall on the tail bone during roller-skating. Now with coccyx pain
   An 81-year-old female with DM, rheumatoid arthritis, chronic obstructive pulmonary disease, mild dementia, and limited ambulation
   An 18-year-old gymnast with LBP, dysmenorrhea, and occasional urine leakage
   A 44-year-old female with endometriosis and abdominal pain
   A 70-year-old male status post prostatectomy with mixed incontinence symptoms, LBP, and abdominal weakness
   A. Practice administering the screening and long questionnaires.
   B. Practice explaining the location and function of the PFMs and the importance of PFEs using words, posters, and models. Write down layman's terms used to describe the area.
   C. Practice explaining the appropriate self-assessment test and home awareness exercises to the patient.
2. Bladder diary interpretation—two examples given (see additional files)
3. Develop a PFE program—two examples given (see additional files)
4. Perform the self-assessment test and self-awareness exercises at home, and develop an appropriate exercise program for yourself. Exercise programs should include the following:
   a. Results of jumping jack test
   b. The number of repetitions and amount of hold time per contraction
   c. The amount of rest that should be taken between contractions
   d. The number of quick contractions per set
   e. The number of sets per day
   f. Suggested position of exercises (i.e., lying down or upright)
   g. Other methods of strengthening that should be considered
5. Practice palpating the PFMs externally at the ischial tuberosity. Evaluate for pain, trigger points, spasm, and connective tissue tension. Make sure you are on the correct muscle by having the patient contract that muscle.
6. Sit up tall in the chair, and push your abdominal muscles outward. Keep the abdomen distended, and contract the PFMs. Notice the amount of effort needed and the force generated by the PFMs. Next, sit up in the chair, and pull the abdominals inward, supporting the abdominal contents and the back. Hold the abdominal contraction gently and contract the PFMs. Notice the effort needed and the force generated by the PFMs. Next, try to contract the PFMs and bear down, pouching out the abdominals. Try to contract the PFMs and then pull the abdominals inward correctly.

CHAPTER

19

The Hip

CARRIE M. HALL

The primary roles of the hip joint are to support the weight of the head, arms, and trunk (HAT) during erect standing postures and dynamic weight-bearing activities such as walking, running, and stair-climbing and to provide a pathway for transmission of forces between the lower extremities and pelvis. The structure and function of the hip affect the function of the entire lower kinetic chain and the upper quadrants through its articulation with the pelvis proximally and the femur distally.

Neither structure nor function of the hip joint can be examined without considering the weight-bearing function of the joint and the interdependence with the other joints of the lower extremity and lumbopelvic (LP) region. These issues are examined in this chapter. Anatomy and kinesiology review can be found on thePoint.lww.com/BrodyHall4e. Common anatomic impairments and the evidence-based components of examination and evaluation of the hip joint also are described. Therapeutic exercise interventions are suggested for the treatment of physiologic impairments and selected diagnoses of the hip joint.

IMPAIRMENTS OF BODY STRUCTURES

Six impairments of body structures (or anatomic impairments) of the hip joint are worthy of consideration because of the impact they have on hip function: femoral torsion, angle of inclination, lateral center edge angle, leg length discrepancy (LLD), pincer morphology, and cam morphology. Each impairment of body structure, independently or in combination with other impairments (body structure or function), warrants careful consideration about the impact on hip joint function and the function of joints proximal or distal to the hip.

Angles of Inclination and Torsion

Femoral Angle of Inclination

Angles of inclination and torsion are normal anatomic relationships of the femur. However, the degree of inclination or torsion can become abnormal when the values are greater or less than normal. Abnormal angulations of the femur are considered impairments of body structures. These anatomic impairments of the femur can significantly alter hip joint mechanics, which can alter the mechanics of adjacent segments proximally and distally in the kinetic chain. Understanding the impact of these structural impairments assists the practitioner in developing an individualized intervention.

In early infancy, the angle of inclination is about 150 degrees because of the abducted position of the femur in utero. The angle decreases with age to the normal adult value of 125 degrees.[1,2] The angle is somewhat smaller in females and somewhat larger in males.[2] A pathologic increase in the angle is called coxa valga (**Fig. 19-1A**), and a pathologic decrease is called coxa vara (Fig. 19-1B).[2] Research has shown a much higher incidence of coxa valga (48%) versus coxa vara (4%).[3]

The position of the greater trochanter influences the mechanical stress of the hip joint, the extent of contraction of the gluteus medius (GM) and minimus muscles, and the mechanical stress of the femoral neck.[4] A normal neck-shaft angle appears to achieve a maximum lever arm of the abductor muscles and the best compromise between articular pressure and bending stress on the femoral neck. Coxa vara can result in shortening of the lever arm of the abductor muscles, resulting in lower articular pressure,[5] whereas a valgus hip results in a greater hip abductor moment arm and higher articular pressure.[6]

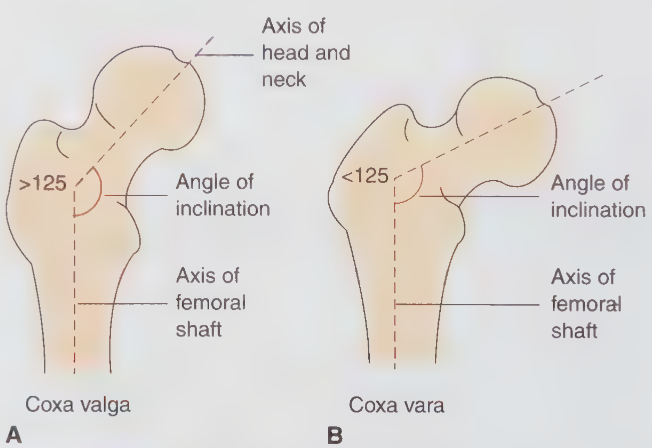

FIGURE 19-1 Abnormal angles of inclination. **(A)** A pathologic increase in the angle of inclination is called coxa valga. **(B)** A pathologic decrease in the angle of inclination is called coxa vara.

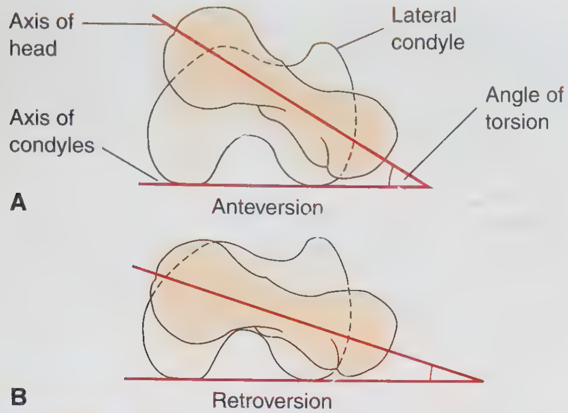

FIGURE 19-2 **(A)** A pathologic increase in the angle of torsion is called anteversion. **(B)** A pathologic decrease in the angle of torsion is called retroversion. (From Norkin CC, Levangie PK. Joint Structure and Function: A Comprehensive Analysis. 2nd Ed. Philadelphia, PA: FA Davis, 1992.)

Angle of Torsion

The newborn infant has a maximum angle of femoral torsion of approximately 40 degrees. This decreases to approximately 16 degrees by the age of 16 years.[7] The angle is normally about 12 to 15 degrees in the adult, but it may range from 8 to 30 degrees and, as with the angle of inclination, varies between sexes and among persons.[1,8] A pathologic increase in the angle of torsion is called anteversion (**Fig. 19-2A**), and a decrease is called retroversion (Fig. 19-2B). Anteversion and retroversion can be screened for during a clinical examination (see "Examination and Evaluation").

Because the hip joint can only tolerate a limited amount of torsion (12 to 15 degrees) without jeopardizing its congruence, a pathologic increase (>15 degrees) or decrease (<12 degrees) in the angle of torsion is manifested distally at the femoral condyles. In the standing position, the femoral condyles of an individual with femoral anteversion are oriented medially, and in femoral retroversion, they are oriented laterally when the femoral head is in a position of maximum congruence. The individual with femoral anteversion functioning with the femoral condyles facing laterally risks losing congruence of the femoral head in the acetabulum. Similarly, the individual with femoral retroversion functioning with the femoral condyles facing medially also risks losing congruence of the femoral head in the acetabulum. As these impairments are anatomic and cannot be directly treated therapeutically, the practitioner must be aware of these impairments of body structures when guiding femoral alignment during exercise and function.

Center Edge Angle or Angle of Wiberg

A line connecting the lateral rim of the acetabulum and the center of the femoral head forms an angle with the vertical known as the center edge angle, also called the angle of Wiberg (**Fig. 19-3**). The center edge angle for the average adult is 22 to 42 degrees.[8] Although this is a normal angle, variations in the angle can lead to altered stability of the femoral head, in which case it would be considered an anatomic impairment.

A smaller center edge angle (i.e., more vertical orientation) of the acetabulum may result in decreased congruency of the head of the femur and the acetabulum, placing the head of the femur at increased risk of superior dislocation of the head of the femur. Children are at greater risk for this type of dislocation than adults, because the center edge angle normally increases with age.[9] It may be for this reason that congenital dislocation is more common at the hip than at any other joint in the body.[10]

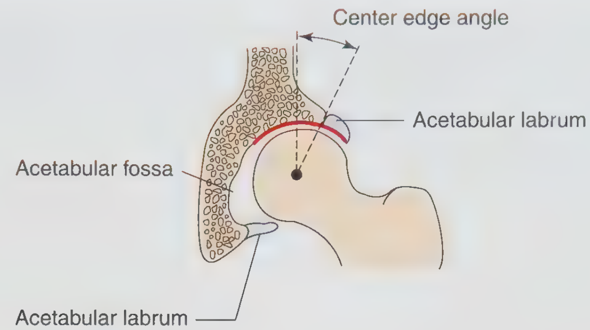

FIGURE 19-3 The center edge angle or angle of Wiberg.

Leg Length Discrepancy

Limb length discrepancy (LLD) is discussed in this chapter primarily, because the femur and pelvis constitute large contributions to both structural LLD (SLLD) and functional LLD (FLLD). However, the spine, knee, ankle, and foot are also involved in total LLD. The impact of LLD on kinetics and kinematics of the lower limb can be significant and must be well understood to develop a comprehensive plan of care (see **Evidence and Research 19-1**).

EVIDENCE and RESEARCH 19-1

Limb Length Discrepancy

LLD has been associated with hip pain, knee pain, low back pain (LBP), and with lower extremity stress fractures.[11–14] Studies have shown increased hip joint forces of up to 12% in the relatively short and long limbs with LLDs of 3.5 to 6.5 cm.[15] In general, an LLD of more than 2.0 cm results in asymmetry in contact time, first and second force peaks, and loading and unloading rates of the vertical ground reaction force in gait.[16] The most common mechanism for compensation of minor LLD is the induction of pelvic tilting in the coronal plane. In normal individuals, pelvic obliquity of 6.1 degrees can totally accommodate for a LLD of 2.2 cm.[16] With LLD >2 cm, the coronal plane mechanism is necessarily augmented by changes in the sagittal plane, which occur at the ankle and knee in standing. At initial contact, the knee responds with flexion of the long limb, whereas at terminal stance, the long leg ankle demonstrates increased dorsiflexion and the short leg ankle produces early heel rise and greater degrees of plantar flexion during stance.[17] The combination of these changes has the effect of shortening the functional length of the long limb in both the stance and swing phases while lengthening the shorter limb during the stance phase. Because of the changes in forces incurred at the hip and gait asymmetries, it appears that more than 2 cm of LLD can significantly affect kinetics and kinematics throughout the kinetic chain and therefore should be addressed. LLD of < 2 cm affect pelvic alignment and may need to be addressed depending on the associated impairments and pathology.

TABLE 19-1

Definitions of Structural and Functional Leg Length Discrepancies

TERM	TYPE OF IMPAIRMENT	DEFINITION	MEASUREMENT TECHNIQUE
Structural	Body structure or anatomic	Actual osseous length difference between the hemipelvis, femur, and tibia	Standing anteroposterior X-ray film or ultrasound imaging[16]
Functional	Body function or physiologic	Position of osseous structures as they relate to each other and to the environment during weight-bearing function	Actual difference between two pairs of identical reference points (e.g., greater trochanter and medial malleolus)

When measured from one common bilateral point of reference proximally to another common bilateral point of reference distally, there is a unilateral difference in the total length of one leg compared with the other. LLD is commonly thought of as resulting from a structural fault in the anatomic length of the long bones, hemipelvis, or asymmetric structural development of the spine (i.e., scoliosis), in which case it would be considered an impairment of body structures, or structural LLD (SSDD). However, LLD often is the result of the functional relationships of the spine, pelvis, long bones, and bones of the feet about all three axes of motion. For example, an individual standing in a neutral subtalar position, measured bilaterally from the tip of the medial malleolus to the horizontal plane (i.e., flat surface), should have equal measurements of both limbs. If the individual is allowed to pronate one foot, the medial malleolus of the pronated foot moves closer to the ground. The difference in height may be as much as ¼ to ¾ of an inch. This would be considered an impairment of body function as opposed to body structure, resulting in a functional LLD (FLLD). SLLD and FLLD are common clinical terms used to describe the two types of LLDs.[18,19] **Table 19-1** summarizes definitions of the clinical terms used to describe LLD. Evaluation and treatment of LLD is addressed in later sections.

Cam and Pincer Morphology

A condition commonly referred to as femoroacetabular impingement (FAI) can result from abnormalities in the shape of the femoral head and neck and acetabulum. Cam (**Fig. 19-4B**) refers to the morphology on the femur; pincer (Fig. 19-4C) refers to morphology on the acetabular side of the hip joint.[20,21] Either of these abnormalities or a combination of the two (Fig. 19-4D) can result in decreased space between the femoral head/neck and the acetabulum and theoretically subsequent impingement. This impingement theoretically occurs with the combined movement of hip flexion, adduction, and internal rotation.[22] However, the underlying cause of the morphologic changes is under considerable debate. It is possible that overload of the joint can cause changes to the bone and cartilage because of the abnormal arthrokinematic motions during activities of daily livings (ADLs) and sport (see **Evidence and Research 19-2**).

Delineating morphology from etiology of symptoms is paramount. Morphology, relative to the hip, is the form and structure of the bones of the hip, whereas FAI is considered the mechanical abutment of the femoral head against the acetabulum.[20] A misconception is that the presence of cam or pincer morphology automatically implies FAI and hence the underlying cause of symptoms and eventual pathology. There has been an 18-fold increase in the surgical procedures related to treatment of FAI between 1999 and 2009, varying by geographic region in the United States.[27,28] Furthermore, the FAI surgery rate has increased by over 600% among newly trained surgeons from 2006 to 2010[29] (see **Evidence and Research 19-3**).

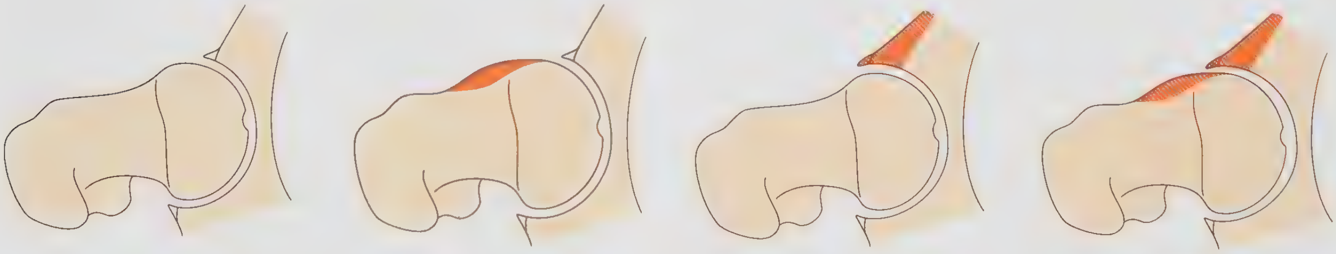

FIGURE 19-4 **(A)** Normal femoral head, neck, and acetabular labral anatomy. **(B)** Femoral sided impingement got its name, "cam," from the Dutch word meaning "cog" describing the femoral head and neck relationship as aspherical or not perfectly round. During motions such as hyperflexion and MR of the hip, the cam lesion is able to fully engage within the joint. This results in cartilage loss over the femoral head and corresponding acetabulum, as well as labral tears. Cam lesions predominately affect the cartilage within the hip joint, resulting in a characteristic peeling of the cartilage off the bone. Cartilage wear is the definition of arthritis; therefore, this type of impingement is considered a prearthritic condition. **(C)** The second category of FAI is the "pincer" type lesion, referring to the "over coverage" of the acetabulum in respect to the femoral head. Pincer comes from the French word meaning "to pinch." The "extra" bone of the acetabulum repetitively hits upon the femoral neck resulting in the pinching of the labrum in between. **(D)** Cam lesions often coexist with pincer lesions. cam lesions are believed to lead to articular cartilage injury first, whereas pincer lesions are believed to crush and tear the labrum first.

EVIDENCE and RESEARCH 19-2

Stress Across the Epiphysis as a Possible Etiology of Cam Morphology

In a 1926 classic article on epiphyseal displacement, this theory, named the static theory, was suggested as a possible etiology for cam morphology.[5] The static theory infers that growing bone is less able to stand strain than is adult bone and that in many adolescents, there is a disproportion between the superincumbent weight and the strength of the femoral neck, potentially resulting in displacement of the epiphysis, alterations of the neck, and laying down of bone to meet the altered mechanics of the hip. No other epiphysis is subjected to such cross strain. A recent retrospective study supporting this theory reviewed 72 hips in 37 male basketball players with a mean age of 17.6 years (range, 9 to 25 years) and 76 asymptomatic hips of 38 age-matched volunteers who had not participated in sporting activities at a high level.[23] Eleven (15%) of the 72 hips in the athletes were painful and had positive anterior impingement tests on physical examination. MR of the hip averaged 30.1 degrees (range, 15 to 45 degrees) in the control group compared with only 18.9 degrees (range, 0 to 45 degrees) in the athletes. The maximum value of the alpha angle throughout the anterosuperior head segment was larger in the athletes (average, 60.5 ± 9 degrees), compared with the control group (47.4 ± 4 degrees). The athletes had a 10-fold increased likelihood of having an alpha angle greater than 55 degrees at least at one measurement position. This study supports the theory that vigorous exercise may trigger cam deformity, as high skeletal stresses have been associated with a pathologic skeletal growth pattern and morphologic alterations in gymnasts and baseball players.[24,25] It is speculated that the cumulative effect of high stresses and perhaps more or less subtle differences in the direction of loading on the proximal femur during growth may modulate growth toward an abnormal shape. This notion was suggested by Murray and Duncan,[26] who observed the greatest prevalence (24%) of femoral head tilt deformities in adolescents who started a compulsory sports regimen during boarding school before the age of 14 years. The upstream question becomes, should we be looking at the hours spent in vigorous activity in pre-physeal closure children to prevent development of cam morphology?

EVIDENCE and RESEARCH 19-3

What Is the Level of Evidence for FAI Surgery?

The current evidence to answer this question is limited to case series (Level IV) studies. Although these case series demonstrate promising outcomes post FAI surgery, the outcomes are short term,[30–32] dependent on status of chondral damage,[33] and are notably less favorable in patients over the age of 40 years.[34] Currently, no systematic reviews or randomized controlled trials (RCTs) on the efficacy of FAI surgery compared to nonsurgical or sham treatments exist.[35] Recently, several trials on efficacy of FAI surgery have been registered at http://www.clinicaltrials.gov.offcampus.lib.washington.edu. These trials seek to determine whether the innovation of FAI surgery will stand the test of evidence-based principles. A good lesson to learn from previous findings is that case series for other surgeries (e.g., meniscus tear, shoulder impingement) are often favorable, but subsequent RCTs show no additional benefit over nonsurgical or sham therapy.[36–43] Furthermore, reported postsurgical complication rates are quite variable.[44,45] They range from the development of adhesions to deep vein thrombosis and chronic regional pain syndrome.[46] Complication rates also appear to be higher than previously reported.[29,47,48] Owing to variability and inconsistency in the current literature, reliable reporting of these complications has, therefore, been suggested as one of the principal requirements for future studies.[44] There is uncertainty as to how symptomatic FAI is best treated,[49] and the principal two management options are physical therapy with activity modification or surgery. Both modalities have been shown to improve symptoms in the short term.[50–55] However, no published studies compare efficacy with each other or with sham procedures. It is not known whether treatment provides sustained symptomatic benefit in the long term, or whether it delays or prevents development of osteoarthritis (OA). Future research is needed to answer these questions.

Similar to the proposal of "shoulder impingement syndrome" as a generic term for patients with shoulder pain,[56] the term "FAI syndrome" is suggested to more accurately encapsulate the nebulous nature of this condition.[56] As with the shoulder, it has become evident that "impingement syndrome" is not likely an isolated condition that can be easily diagnosed with clinical or imaging tests or most successfully treated surgically. Rather, it is likely a complex of conditions involving a combination of intrinsic and extrinsic factors. A mechanical impingement phenomenon as an etiologic mechanism of hip pain may be distinct from the broad diagnostic label of "impingement syndrome." Acknowledging the concepts of mechanical impingement and movement-related impairments may better suit the diagnostic and interventional continuum as they support the existence of potentially modifiable impairments within the conservative treatment paradigm. The diagnosis of FAI is no more informative than the diagnosis of "hip pain." Although both terms are ambiguous, the latter is less likely to presume an anatomic tissue pathology that may be difficult to isolate either with a clinical examination or with diagnostic imaging and may prevent potentially inappropriate surgical interventions.

From a physical therapy perspective, postural habits and movement patterns as potential mechanisms for the development of hip pain need to be further investigated. Researchers need to investigate homogenous patient groups with accurately defined specific pathologies, or with classification based on specific movement deviations. Diagnostic labels based on the movement system may allow more effective subgrouping of patients to guide treatment strategies.

EXAMINATION AND EVALUATION

Examination and evaluation of the hip can focus primarily on the hip in the case of specific hip pathology (e.g., rheumatoid arthritis, OA, avascular necrosis of the femoral head, labral pathology, FAI, or hip dysplasia). However, regardless of diagnosis, evaluation of the knee, ankle–foot, and LP regions may provide useful information (e.g., rigid, supinated foot contributing to reduced shock absorption to the arthritic hip) and identify impairments that are contributing factors to the patient's hip condition. Similarly, the hip is commonly included in the examination and evaluation of other regions to assess impairments of body structures or function of the hip that may be contributing to dysfunction in the affected region (e.g., a stiff hip contributing to lumbar hypermobility).

The descriptive examination and evaluation information presented in this section is not intended to be comprehensive or reflect any specific philosophical approach; it simply serves as a general review of pertinent tests performed in most hip examinations.

History

In addition to the general data generated from a patient/client history as defined in Chapter 2, the following information is important to obtain from a patient with impairment, activity limitation, participation restriction, or disability involving the hip joint:

- History of congenital hip dysfunction (e.g., congenital hip dysplasia treated with or bracing or surgery)
- Childhood hip conditions (e.g., slipped capital epiphysis, severe anteversion treated with bracing, FAI)
- Previous hip joint injury (torn labrum, stress fracture, femoral neck fracture)
- Family history of OA or rheumatoid arthritis.

These conditions along with age and gender received an evidence grade of Level I in a recently published clinical practice guideline.[57] Although the hip can become injured as a result of trauma, the clinician is more likely to encounter hip dysfunction as a result of cumulative microtrauma. In the latter case, it is important for the practitioner to gain an understanding of the ADLs, recreational, and occupational activities with which the patient is involved on a repetitive basis and identify which activities seem to provoke symptoms. Of particular interest is *a history of intense sport before skeletal maturity*. Much of this information can be obtained through patient-reported outcome measures (PROs). They are an important component of outcomes assessment, because they represent the patient's health status as assessed by the patient, without interpretation of the healthcare provider.[58] To be useful, PROs must be reliable, valid, responsive, and representative of the patient population of interest. It is beyond the scope of this text to present disease-specific PROs conclusively; the literature supports various PROs for specific conditions.[59,60]

Lumbar Spine Clearing Examination

The prevalence of LP conditions in the general population, combined with the fact that pathology in the LP region can manifest in referred pain patterns into the hip (e.g., posterior buttock and greater trochanteric region) and cause neurologically mediated weakness of hip joint musculature (particularly the gluteal musculature), supports routine lumbar screening during any hip examination. A typical lumbar clearing examination is outlined in Chapter 17. Although this scan may seem extensive, excluding or diagnosing lumbar or sacroiliac joint (SIJ) involvement is critical to accurate diagnosis of lower quadrant symptoms. Positive test results for the lumbar clearing examination can indicate a need for a more thorough lumbar or SIJ examination. It is not unusual to have symptoms from both the lumbar and hip region, complicating the examination and treatment of patients with lower quarter (LQ) dysfunction.

Other Clearing Tests

The practitioner should examine and evaluate associated regions. Although the hip may be the source of symptoms, it is common for multiple regions to be involved, particularly in patients with long-standing impairments, activity limitations, and participation restrictions. A thorough examination of all involved regions permits the clinician to develop an integrated and comprehensive plan of care. For example, impairments of the pelvic floor may affect function of the hip. Screening for pelvic floor dysfunction can alert the practitioner to any associated pelvic floor conditions (see Chapter 18).

Visceral involvement or serious disease or disorders should be excluded. Pain in the hip and pelvic region can also result from visceral sources (see Appendix 1). A thorough history and physical examination and evaluation can alert the practitioner to visceral involvement or serious disease or pathology.

The hip must be excluded as the source of symptoms experienced in other regions. Because the hip is largely innervated at the L3–L4 level, hip pathology occasionally causes pain to be referred to the knee.[61,62] This is well documented in children, in whom any examination for knee pain must include a hip examination,[63] but this must not be forgotten as a source of knee pain in the adult. A patient of any age complaining of knee pain without apparent knee pathology or impairments should have the hip examined as a potential source of pain.

Gait and Balance

Gait evaluation is an essential component of the examination of a person with a hip dysfunction. Analysis of gait should include observation of the hip along with the rest of the kinetic chain about all three planes of motion during each critical event in gait. Of particular importance are the relationship of pelvic and hip motion (i.e., amount of lateral pelvic tilt and hip adduction [see **Fig. 19-5**]) and the relationship of hip and lower extremity motion (i.e., hip medial rotation, tibial medial rotation, and foot pronation). Because the hip functions interdependently with other regions in the body, the relationship of distal and proximal segments to the hip must also be evaluated.

Video analysis can assist in this complex examination procedure, because the video can be taken from any angle and can be viewed in slow motion to allow precise observation of the components of gait. Hypotheses can be generated about the

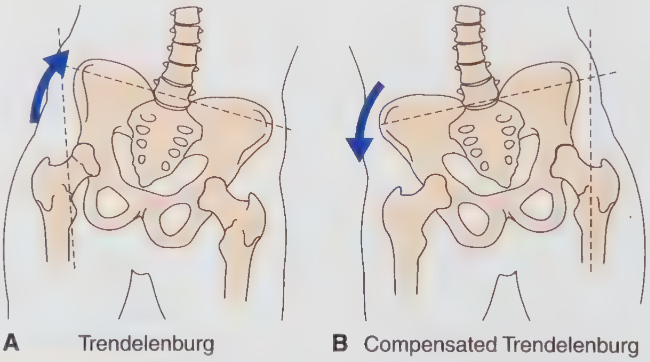

FIGURE 19-5 Trendelenburg sign. **(A)** Positive Trendelenburg sign with lateral pelvic tilt and hip adduction. **(B)** Compensated Trendelenburg sign with lateral pelvic tilt and hip abduction.

cause of any observed gait deviation that can be confirmed or negated as a result of the additional data collected.

Balance tests are often included in hip examinations because of the high incidence of falls resulting in hip injury and fracture. Balance testing should identify intrinsic (i.e., related to the individual) and extrinsic (i.e., associated with environmental factors) factors related to the risk of falling.

Low-tech balance assessments can identify risk factors for falls.[64] Strong correlations have been found among performance-based measures and fall risk, as well as between performance-based measures and self-report measures. Five variables are significantly related to fall risk[64]:

1. Berg Balance Scale score[65]
2. Dynamic Gait Index score[66]
3. Balance Self-Perceptions Test score[67]
4. History of imbalance
5. Type of assistive device used for ambulation.

High-tech, computerized, force-platform balance devices commonly measure the ability to maintain the center of pressure within the base of support against progressive perturbations. This information is highly objective and is often used to track progress in developing postural balance.

Joint Mobility and Integrity

Arthrokinematic motions are relatively limited at the hip joint in comparison with osteokinematic motions. Arthrokinematic tests of the hip should include lateral/medial translation, distraction and compression, and anteroposterior/posteroanterior glides.[68] The quantity of motion, the end-feel, and the presence/location of pain should be noted. Tests for joint integrity should assess for joint stability and pain provocation. Lee has developed arthrokinetic tests for joint stability at the hip and the reader is to refer elsewhere for details.[68]

Muscle Performance

Impairments in muscle performance can result from numerous sources, and tests of muscle performance combined with results of other tests should attempt to determine the presence and cause of reduced muscle performance. The following discussion highlights specific types of muscle performance testing procedures used to diagnose the presence and source of impairment of muscle performance.

Manual Muscle Testing

Manual muscle testing (MMT) of muscles surrounding the hip joint can provide information regarding muscle performance capability of each muscle or fiber direction of a single muscle (e.g., anterior vs. posterior GM).[69,70] Comprehensive MMT of the hip musculature can also determine the relationship of muscle performance capability of synergist and antagonist musculature around the hip (e.g., posterior GM vs. tensor fascia lata [TFL] as hip abductors). Essential muscles to test include the following:

1. Gluteus medius
2. Gluteus minimus
3. Iliopsoas
4. Deep hip lateral rotators
5. Gluteus maximus
6. Hamstrings
7. Quadriceps
8. TFL.

Positional strength testing can determine the length–tension properties of the relevant muscle (see Chapter 5). It is often of interest to the examiner to determine length-associated changes in muscles within a synergy. Management of a muscle functioning poorly resulting from length-associated changes is different from a weak muscle resulting from strain or disuse.[71] For example, length-associated changes are often present between posterior GM (abductor, extensor, and lateral rotator) and TFL (abductor, flexor, and medial rotator).[72] Typically, TFL is short and/or stiff relative to the posterior GM that allows it to produce more force in the short range and bias the position of the femur in medial rotation (MR) during function. To improve the synergy between abductors, it would appear appropriate to design rehabilitation programs using therapeutic exercises that promote activity of the posterior GM (in the short range) while minimizing recruitment of the TFL.[73–75]

Selective tissue tension tests can assist the practitioner in the differential diagnosis of a contractile versus noncontractile lesion.[76] If a selective tissue tension test is positive (through careful MMT positioning), interpretation of the resisted test can indicate severity of the tissue lesion from Grade I to Grade III and help guide prognosis and intervention.[77]

In addition, it is important to screen for a *neurologic cause* of reduced force production, particularly in reference to the fatigability of the muscle being tested. Hip musculature is innervated by the lumbar and sacral plexus; consequently, low back dysfunction often results in neurologic weakness around the hip. Numerous peripheral nerves can be involved in nerve entrapment syndromes around the hip, which can result in motor changes (see **Table 19-2** for an overview of these syndromes), This topic will be discussed in more detail in a subsequent section of this chapter.

Pain and Inflammation

Examination for pain and inflammation is done concurrently with other tests to determine the source. Inflammation is difficult to examine in the hip joint, because it is deep within the pelvis and cannot be readily palpated. Positive findings for a capsular pattern[76] (defined in **Display 19-1**) of hip mobility and end-feel assessment (i.e., pain before limitation of motion is reached) indicate former or active inflammation in the hip joint capsule.

Examination of the pain level should be incorporated into the subjective and objective portion of the examination. The patient should answer questions regarding pain level by using a visual, numeric, or verbal analog scale over a 24-hour cycle in relation to specific activities and in general.[78] During the physical examination, the patient should be questioned about the onset, location, and intensity of pain with respect to each test performed.

The specific source of symptoms may not be diagnosed without additional tests that are beyond the scope of physical therapy practice (i.e., radiologic, electrodiagnostic, and laboratory studies). However, the mechanical contribution to the development or fortitude of the symptoms can be diagnosed

TABLE 19-2

Regional Approach to Nerve Entrapment Syndromes

REGION	SUBREGION	NERVE
Anterior	Inguinal	Ilioinguinal nerve Genitofemoral nerve Iliohypogastric nerve T11/T12/L1 nerve root

DISPLAY 19-1

Established Capsular Pattern[76]

1. 50 to 55 degrees of limitation of femoral abduction
2. 0 degrees of femoral MR from neutral
3. 90 degrees of limitation of femoral flexion
4. 10 to 30 degrees of limitation of femoral extension
5. Femoral lateral rotation (LR) and adduction are fully maintained

through careful examination and evaluation of the impairments that contribute to increased biomechanical stress to the hip joint.

Posture and Movement

Specific LP and lower quadrant alignment should be examined in all three planes. Hypotheses can be developed regarding the contribution of faulty alignments at the ankle, foot, knee, and LP regions to the alignment of the hip. The practitioner can also create hypothesis regarding muscles that are too long, or too short, based on joint position, verified by specific muscle length testing. Initial screening for LLD and lower extremity asymmetries should be performed by evaluating the following:

1. Iliac crest heights
2. Spine, pelvic, femur, tibia, and foot alignments
3. Bony landmarks of the pelvis, knee, and ankle.

Unique to the pelvis is taking into consideration anatomic variations of the acetabulum (i.e., anteversion, retroversion, acetabular depth) combined with the femur (i.e., anteversion, retroversion, coxa vara, coxa valga, cam morphology). This information can assist the practitioner in determining underlying mechanical contributions to pain as it relates to femoroacetabular congruence. Undercoverage or overcoverage can contribute to impingement or hypermobility/instability (see **Table 19-3**).

In addition, the specific alignment about all three planes of motion, of the spine, pelvis, hip, tibia, and ankle/foot complex, should be noted during simple ADLs, such as squatting, ascending and descending stairs and sit-to-stand transfers. Hypothesis regarding the interrelationships of the lower limb segments can be generated (i.e., foot pronation, genu valgum, hip adduction, and lateral pelvic tilt on the short side).

Range of Motion and Muscle Length

Range of motion (ROM) testing of the hip joint includes several assessments. *Quick tests* are functional movements that are used to ascertain the patient's willingness and ability to move and the requisite extent of the examination to follow. Such tests for the hip include flexing the hip and knee while putting the foot on a standard step height, forward bending, squatting, and sitting with one leg crossed over the other.

TABLE 19-3

Summary of Acetabular and Femoral Orientation Relating to Femoral Head Coverage

Femur MR		x
Femur adduction	x	
Femur abduction		x

Active and Passive Open Chain Osteokinematic ROM

It is important to determine osteokinematic mobility of the hip joint along the continuum of hypermobility to hypomobility about all three axes of motion by carefully stabilizing the spine and pelvis during passive ROM examination techniques. Often, reduced ROM is the only finding documented when excessive mobility is not only common, it is equally as problematic with respect to joint function. Controlling excessive mobility from excessive lengthening of articular, periarticular, and myofascial sources (i.e., acetabular dysplasia in the presence of overstretched anterior capsuloligamentous structures and excessive psoas length) is vital to reducing symptoms and improving function in subgroups of hip patients. Qualitative assessment of active and passive ROM combined with clinical reasoning can supply specific diagnostic information: (Note: Caution must be taken with ROM measures to ensure a neutral start position of both the femur and acetabular sides. In addition, if measuring rotation across the hip, knee joint laxity may hide hip hypomobility by moving excessively in frontal or transverse planes.)

- A firm overpressure applied to a motion is used to exclude or diagnose joint pathology. Overpressure can also be used to determine the hip end-feel and therefore the structures providing the barrier to further motion.
- Assessment of the sequence of pain and limitation can grade the irritability of the condition and guide the intensity of treatment.[76]
- The pattern of restriction can indicate the presence of a capsular pattern (see Display 19-1). This can be an indication of joint inflammation.[76]
- The combined results of passive and active movement testing can implicate a contractile or inert structure.[76] For example, the findings of passive movement painful in one direction and active movement painful in another implicate a contractile structure.

If ROM is limited in one direction, and excessive in another (e.g., hip MR is excessive while LR is limited), the femur may not be centered in the acetabulum and thus bias the ROM findings. To restore a centric position of the femur to determine the true ROM limitations of the joint, this author proposes the use of a simple pelvic repositioning technique to alter femoroacetabular alignment and determine the effect on ROM (see **Fig. 19-6**). Isometric contraction of adductors and medial rotators theoretically creates a directional change to the acetabulum toward more anteversion and isometric contraction of the posterior GM and lateral rotators toward more retroversion. Theoretically, this has an impact on three-dimensional acetabular position relative to the femoral head. It can be beneficial to use this technique as an exercise, combined with a more comprehensive program with posture and movement training to improve femoroacetabular congruence during function, similar to altering scapular mechanics to improve scapulohumeral congruence during function.

Muscle Length

Tests of muscular extensibility are also important in assessing ROM of the hip. Common extensibility tests include determining the length of several muscles:

- Medial and lateral hamstrings (hamstring length should be examined as a group and individually)

FIGURE 19-6 Pelvic sensitization: isometric contraction of left adductor into firm ball and right abductor into table leg, wall, door. Use this pattern in the presence of a left anterior-inferior innominate and right posterior-superior innominate. Check for hip ROM pre- and post-sensitization. If ROM improves, good prognosis for exercise to modulate symptoms related to FAI or hypermobility.

- Hip flexors (hip flexor length should be assessed individually for the iliopsoas, rectus femoris, and TFL)
- Hip adductors/abductors (particularly TFL)
- Hip rotators

The examiner should assess for a lack of extensibility and for excessive extensibility. A hypothesis should be developed regarding the impact that extensibility impairments will have on the function of the hip and related regions.

Work (Job/School/Play), Community, and Leisure Integration or Reintegration (Including Instrumental Activities of Daily Living)

Although measures of physiologic impairments are important for diagnosis, prognosis, and treatment planning, functional ability and quality of life are better indicators of outcome.[79] The Harris Hip Function Scale is an outcome measure that is specific to degenerative conditions of the hip.[80] This scale combines a patient's report of pain and his or her capacity for ambulation and self-care. These tasks account for 91% of the score, and deformity and hip ROM account for 9% of the score. The advantages of this scale are that it is heavily weighted toward function, is easy to administer, and is familiar to most clinicians. The Harris Hip Function Scale has been used as the gold standard in a number of studies and has been shown to be reliable with an intraclass correlation coefficient of 0.82 to 0.91. Other measures include the Hip Osteoarthritis Outcomes Score (HOOS) and the Lower Extremity Functional Scale (LEFS).[81] The Copenhagen Hip and Groin Outcome Score (HAGOS) is a validated outcome tool used for assessing hip pain in young to middle-aged, physically active patients with long-standing hip and/or groin pain.[82]

Special Tests

Numerous special tests are used to confirm or negate symptoms or suspected diagnoses of the hip. For the commonly used special tests discussed in this section, specific information regarding the technique of application can be found in the related references.

Trendelenburg Test

In unilateral stance, the weight of the head, arms, and trunk (HAT) act at a fixed distance from the hip, producing an adduction torque. The abductors, acting a fixed distance from the hip, must generate a force to produce an abduction torque sufficient to counterbalance the torque produced by the HAT (see **Fig. 19-7A**). The Trendelenburg test is used to evaluate the functional force or torque capability of the hip abductor muscle group. During gait, the patient may exhibit a positive Trendelenburg sign (see Fig. 19-7B) or compensated Trendelenburg sign (see Fig. 19-7C).[72] Other gait deviations of the hip indicate hip abductor torque impairment, such as excessive hip medial rotation, pelvic counter-rotation, or excessive lateral pelvic shift. These other gait deviations are also indicators of reduced hip abductor muscle performance and are particularly related to positional weakness of the GM.

Limb Length Discrepancy

Limb length discrepancy (LLD) is a relatively common problem with an estimated prevalence rate of 40%[83] to 70%[84] of the population. LLD can be subdivided into two etiologic groups: an SLLD defined as those associated with a shortening of bony structures, and an FLLD defined as those that are a result of altered mechanics of the lower extremities.[85] Definitions of FLLD versus SLLD are described earlier in this chapter. In addition, persons with LLD can be classified into two categories: those who have had LLD since childhood, and those who developed LLD later in life. In terms of functional outcomes such as gait, persons who have developed an LLD later in life are more debilitated by LLD of the same magnitude when compared to persons who have had LLD since childhood.[86]

The etiology of SLLD may be congenital or acquired. Of the congenital causes, the most common include congenital dislocation of the hip and congenital hemiatrophy or hemihypertrophy with skeletal involvement. Acquired causes can be a result of infections, paralysis, tumors, surgical procedures such as prosthetic hip replacement, and mechanical such as slipped capital femoral epiphysis.

If the examiner suspects that one of a patient's legs may be shorter than the other, specific tests are indicated to determine whether an SLLD or an FLLD exists. Radiographs or other imaging techniques should be used when accuracy is critical. Ultrasound measurement of LLD offers a reliable, noninvasive, and easily performed method.[87] This technique is superior to clinical measuring methods and radiologic examinations.[88] In general, although imaging techniques are considered to be the most accurate method for determining LLD, they are costly, time consuming, and, in the case of radiographs and computed tomography (CT), the patient is exposed to radiation. As a result, alternative clinical methods have been developed. Two methods have emerged over the years: (a) an "indirect method" performed in standing using lift blocks under the short leg and visually examining the level pelvis, termed the "iliac crest palpation and book correction" method (ICPBC)[84,89] and (b) a "direct method" done in supine measuring the distance of fixed bony landmarks with a measuring tape. Two commonly used tape measure methods include measuring the distance between (a) the anterior superior iliac spine (ASIS) and the lateral malleolus[84] and (b) the ASIS and the medial malleolus.[90] There is still disagreement regarding the validity and reliability of both the clinical methods. Both measures, between the ASIS and the lateral malleolus and the ICPBC method, appear to have acceptable validity and reliability when used as a screening tool.[89,91]

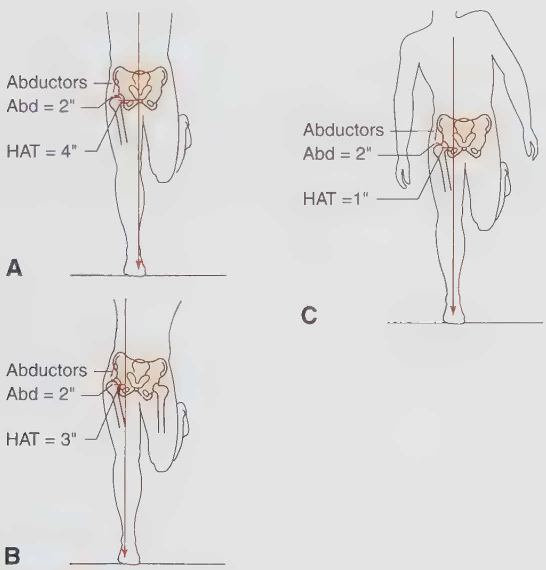

FIGURE 19-7 **(A)** R unilateral stance. **(B)** The pelvis drops on the opposite side of the stance limb when the abductor force cannot counterbalance the torque produced by HAT. This is called a positive Trendelenburg sign and is used as a compensation for hip abductor weakness. **(C)** When the trunk is laterally flexed toward a stance limb, the moment arm of the HAT is substantially reduced, whereas that of the abductors remains unchanged. The result is a substantially diminished torque from the HAT and a corresponding decreased hip abductor force to counterbalance the HAT torque. This is called a compensated Trendelenburg sign. Patients will use this gait pattern to reduce the joint reaction force and thus alleviate pain.

Angle of Torsion

There are several methods for measuring the angle of torsion, including radiography, CT, magnetic resonance imaging (MRI), and ultrasound sonography. However, only one clinical method, the trochanteric prominence angle test (TPAT, also known as the Craig's test), has been described to measure angle of torsion by determining the angle formed by the vertical line and the tibial crest, when the greater trochanter is most prominent laterally[92–96] (**Fig. 19-8**). The developers of this test demonstrated that this measurement correlates well with intraoperative measurements, and it is considered to be more accurate than radiographic techniques.[96] Yet, a more recent study concluded that clinical application of the TPAT is limited by both the variable anatomy of the proximal femur and examiner difficulties related to the soft tissues surrounding the hip joint.[93] However, this method may be acceptable if the goal of the test is to screen for abnormality. If accuracy is desired, two- or three-dimensional CT imaging is thought to be the most precise method for determining femoral anteversion.[97]

Differences in hip rotation ROM can also indicate abnormal femoral torsion. To predict an abnormally high anteversion angle (above mean +2 standard deviations [SD]), the difference between medial and lateral rotation (measured in hip extension) must

FIGURE 19-8 TPAT test. The TPAT presumes that when the subject is prone, with the hip in extension, and the most prominent portion of the greater trochanter is rotated into maximum lateral position, the femoral neck will be parallel to the floor. The angle of rotation of the shank segment relative to vertical at this point reflects the overall angle of torsion.

be 45 degrees or more, whereas an abnormally low anteversion angle (lower than mean −2 SD) could be predicted when LR is at least 50 degrees higher than medial rotation[98] (**Evidence and Research 19-4**).

EVIDENCE and RESEARCH 19-4

Trochanteric Prominence Angle Test (TPAT) or Craig's Test

Previous investigations have reported a wide range of reliability coefficients (0.45 to 0.97) and measurement errors (1.1 to 8.4 degrees) of the TPAT.[96,99–101] The application of TPAT may be limited by obesity, scarring about the proximal femur, and ligamentous laxity in the knee joint.[93,96] In particular, several reports indicate that using the tibia as a lever in 90-degree knee joint flexion increases the medial knee joint space (KJS) because of laxity of the knee joint.[102–104] Thus, any potential increase in KJS could affect the angle between the vertical line and the tibial crest during the TPAT.

Anterior Impingement/FABER

In the FAI literature, the anterior impingement test (flexion and MR in 90 degrees of hip flexion) is positive in 88% to 99% of patients while the FABER test (flexion, abduction, LR in 90 degrees of hip flexion) is positive in 69% to 97% of patients who have subsequently surgically confirmed FAI.[105,106] A review of additional common special tests for the hip can be found in the research.[107–109]

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON PHYSIOLOGIC IMPAIRMENTS

After examination and evaluation of the hip and all related regions, the clinician should have a thorough understanding of the activity limitations affecting the patient and their participation restrictions. The diagnosis and prognosis are formulated, and an intervention is planned.

The decision to treat any impairment lies in its relationship to the activity limitation and participation restriction. Prioritization of impairments is critical to effective and efficient intervention. Exercise intervention should be kept as functional as possible. However, if the impairment is significant, specific exercise may be necessary to improve the mobility, level of performance, and motor control until it can be incorporated into a functional activity. Specific exercise and functional activity examples are provided in the discussion of exercise intervention for common impairments of body functions affecting the hip.

Pain

Pain is undoubtedly the most common reason persons seek physical therapy for hip-related dysfunction. In one study, 14.3% of adults 60 years and older reported significant hip pain on most days over the previous 6 weeks.[110] Although athletic injuries to the adolescent hip have been reported in the literature over the past 25 years,[111,112] this anatomic area in this patient population receives increased attention because of the advent of hip arthroscopy and the development of more advanced imaging of this joint through MR arthrography.[113–116] Unique attributes of the adolescent hip places it at risk for injury and pain leading to functional limitations and participation restrictions at a young age when activity levels should be high (see **Evidence and Research 19-5**).

EVIDENCE and RESEARCH 19-5

The Adolescent Hip

About 30 million children in the United States participate in organized sports programs, with over one-third of school-age children sustaining an injury that requires evaluation and treatment by the medical community.[117] There are physical and physiologic differences between the adolescent athlete and adult athlete that may cause the former to be more prone to sports injury. Adolescent athletes may have a temporary decline in coordination and musculoskeletal imbalance, as limb mass increases at a faster rate compared with limb length.[118] In addition, as muscle tendon growth lags behind bony growth, there is a lack of flexibility, which may predispose to injury. This increase in functional demand on the muscles can cause increased stress on the tendons, musculotendinous junctions, and apophyses. Adolescents have open growth plates, and increased stress to the growth plate can lead to damage to this area and possibly early physeal closure. Growing cartilage is more susceptible to stress and may predispose the adolescent to an overuse injury. All of these factors place the adolescent athlete at risk for injury during sporting activity.[119]

The most important aspect of therapeutic exercise intervention for hip pain is the differential diagnosis of the etiology as well as the mechanical cause of the pain. Traumatic and overuse soft tissue injuries include muscular, bursal, tendinous, or ligamentous inflammation, contusions, strains, and sprains. Skeletal injuries can involve the physis or apophysis in children, and skeletal disorders include fractures, subluxations, dislocations, stress injuries, infections, bony changes (i.e., cam and pincer morphology), and avulsions. Patients with nontraumatic hip pain from systemic conditions such as rheumatoid arthritis, juvenile arthritis, ankylosing spondylitis, tumors, and metabolic

DISPLAY 19-2

Guidelines for Pain Relief Involving the Hip Joint

- *Activity modification*: Initially, the clinician should encourage patients to maintain muscle performance and ROM of the hip while avoiding risk activities, such as running, carrying heavy loads (especially contralateral to the painful hip[122]), or prolonged standing.
- *Physical agents or electrotherapeutic modalities*: The use of cryotherapy, moist heat, or electrotherapeutic modalities may help modulate pain or decrease inflammation. Because of the anatomic position of the hip, these modalities may have limited effectiveness in treating intra-articular inflammation or sources of pain.
- *Manual therapy*: Appropriate use of joint and soft tissue mobilization can improve physiologic impairments related to pain and inflammation, such as joint mobility and tissue extensibility. Joint mobilization can also be used to modulate pain (see Chapter 7).[123]
- *Therapeutic exercise intervention*: Gentle active ROM exercises in the pain-free range can be used to modulate pain, similar to the Grade III joint mobilizations described by Maitland.[123]
- *Assistive devices*: When a person has a limp caused by pain, use of an assistive device in the contralateral hand is necessary to reduce the load on the hip. A cane in the contralateral hand of a patient can reduce the joint reaction force by as much as 30%.[124,125] Patients often are reluctant to use an assistive device for fear of "giving in to the condition." Patient-related instruction must include an explanation that temporary use of an assistive device will reduce the load at the hip and allow the pain and inflammation to resolve. Exercise to improve mobility and force- or torque-generating capability of the appropriate musculature is required to discontinue use of the assistive device without risk of recurrence of symptoms.
- *Weight loss*: Overweight persons must work diligently on weight loss through proper nutritional counseling and aerobic activity tolerated by a painful hip, including non–weight-bearing activity such as aquatic activities or cycling. It is possible that cumulative exposure to excessive body mass may increase the risk of developing hip OA[126,127] and the worsening of the disease.[128,129]
- *Biomechanical support*: Carefully prescribed foot orthotics can improve skeletal alignment and potentially influence contact forces at the hip.[130]

bone disease should be suspected when the severity or course of the injury is atypical. Persistent hip pain can originate from intra-articular disorders such as avascular necrosis, OA, loose bodies, labral tears, or pyarthrosis. Hip pain also may be secondary to a lumbar spine disorder. Nerve entrapment syndromes involving the ilioinguinal, genitofemoral, obturator, and lateral femoral cutaneous nerve of the thigh may present as hip pain or paresthesias (to be discussed in more detail under **Nerve Entrapment Syndromes**).

Pain from the hip joint can be referred anteriorly to the groin, laterally in the region of the greater trochanter spreading down the lateral thigh, or may radiate down the anterior and medial thigh to the knee. Occasionally, referred knee pain can occur with little or no pain in the hip, particularly in the pediatric population.

Pain posterior to the hip or in the buttock is frequently associated with lumbar spine pathology, but it can also arise from the hip. Pain from the spine commonly radiates down the posterior thigh, occasionally to below the knee, but hip pain rarely radiates below the knee. Acute synovitis or arthritis can produce pain in the entire hemipelvis. Pain related to iliotibial band (ITB) fasciitis/fasciosis can be experienced in the lateral thigh and can be mistaken for lumbar radiculopathy.[120,121] Because this condition occurs commonly in the elderly, spinal stenosis can be incorrectly implicated as the source of the lateral thigh pain.

Whether or not the source of the pain is diagnosed, the underlying biomechanical cause should be attempted to be established. Treatment must work toward alleviating impairments related to the cause of tissue changes resulting in nociception and the experience of pain, leading to loss of function and participation in meaningful activities. Treatment focused on the underlying cause(s) of tissue inflammation, sprain, strain, or degeneration often relieves symptoms without specific treatment of the source. Several examples of treatment focused on underlying contributing components of the movement system are presented throughout this chapter. Interventions for pain relief can follow the general guidelines illustrated in **Display 19-2**. Treatment of the underlying contributing factors of pain is a more complicated decision-making process and takes into consideration impairments in the subsystems of the movement system (see **Building Block 19-1**).

BUILDING BLOCK 19-1

Consider a 71-year-old female post open reduction internal fixation (ORIF) of the left femur secondary to a fall. She currently is walking with a walker with toe touch weight bearing. The patient can now progress to ambulating weight bearing as tolerated (WBAT), but she has 8/10 pain in the lateral hip and thigh when she places increased weight on her left limb. She presents with significant Trendelenburg pattern upon left weight bearing and fear of falling. Examination reveals 3/5 strength in hip flexion and extension, and 3−/5 of her hip extension and lateral rotation. What subsystems are contributing to her experience of pain? How would you address each subsystem in a therapeutic exercise intervention?

Muscle Performance

The section on kinetics describes the powerful forces required from the musculature surrounding the hip joint for accomplishing ADLs. The force-generating capability of any muscle around the hip joint may be compromised for one of the following reasons:

- Neurologic pathology (e.g., peripheral nerve, nerve root, neuromuscular disease)
- Muscle strain

- Altered length–tension relationships (resulting from either anatomic or physiologic impairments)
- General weakness from disuse, resulting from muscle imbalance, general deconditioning, or reduced muscle torque production for a specific performance level (e.g., high-level athlete in training)
- Pain and inflammation

Endurance impairments at the hip must be thought of in light of the tremendous force-generating requirements of the gluteal musculature during functional activities. Endurance is required to meet the repetitious demands of walking, jogging, running, sprinting, and so on. Proper synergy among all muscles involved in the gait cycle keeps the intensity of muscle action at an aerobic level. When one muscle in a synergy group reduces its function, it imposes greater demands on other muscles, potentially rendering them anaerobic and therefore far less efficient.[131] In addition, loss of muscle function can result in compensatory strategies, such as reliance on the ITB for stability or a compensatory Trendelenburg pattern to reduce the need for muscle force to keep the center of mass within the base of support. Dosage parameters depend on the performance level desired by the individual (e.g., walking 50 feet without pain, running a marathon in the best time possible), with an emphasis on high repetitions instead of maximal force production.

Neurologic Pathology

To develop the appropriate plan of care, it must be determined whether the source of the neurologically induced weakness is a lower or upper motor neuron lesion.

If the clinician has determined that the cause is lower motor neuron in origin, it must then be determined whether the pathology is at the level of the nerve root or in a peripheral nerve. A dysfunction at the level of the lumbar spine can induce nerve root pathology that can manifest as weakness of the muscles innervated by the affected segmental levels.[132] The clinician must thoroughly screen the LP region to confirm or negate the hypothesis of spinal influence on the reduced force-generating capability of muscles surrounding the pelvic girdle.

Numerous peripheral nerves surround the hip. The section on **Nerve Entrapment Syndromes** will discuss the potential peripheral nerve injuries affecting the hip region.

After a thorough examination and evaluation process, the neurologically induced hip joint weakness must be treated. Whether the source of the neurologic involvement is from the nerve root or peripheral nerve, the origin of the problem must be treated appropriately for the affected muscle torque production to improve.

Despite alleviation of neurologic factors, weakness contributing to activity limitation may still exist. The level of weakness depends on the degree and duration of neurologic involvement. **Display 19-3** provides a clinical example to illustrate this point.

Muscle Strain

Force-generating capability may be compromised by an injury to the muscle in the form of muscle strain.

Acute hamstring injuries are one of the most common injuries resulting in loss of time for athletes at all levels of competition.[133–137] Those involved in sports that require high sprinting speeds, such as track, football, and rugby, are especially prone to injury.[138] Previous literature has indicated that nearly one in three hamstring injuries will recur and that many of these would happen within the first 2 weeks on return to sport.[139,140] This high rate of recurrence may be due to a combination of ineffective rehabilitation and inadequate return to sport criteria.

Two specific injury mechanisms have been defined that seem to influence the injury location and rehabilitation requirement: high-speed running and excessive stretching. During high-speed running, the terminal swing phase has been identified as the time of hamstring injury occurrence, most often involving biceps femoris long head.[141,142] During this phase of the running cycle, the hamstring muscles are active while lengthening (eccentric contraction) to absorb energy to slow the advancing limb in preparation for foot contact. At initial contact and loading response, the biceps femoris is thought to decelerate MR that occurs with foot pronation.[131,143–145] These injuries typically

DISPLAY 19-3

Case Example of Neurologic Factors Contributing to Weakness at the Hip

Case Presentation

A 13-year-old gymnast has had a 5-month complaint of posterolateral hip pain. At the time of her initial evaluation, she was diagnosed with a GM strain. Appropriate treatment of her GM strain did not improve her condition after 3 months. At that time, her physician performed a thorough lumbar screen. Radiologic reports indicated a Grade II L5–S1 spondylolisthesis with slight L5 nerve root compression occurring with end range lumbar extension. As a result of the additional diagnosis of spondylolisthesis, she was treated with lumbosacral bracing and exercise to correct impairments related to the spine instability. During the next 3 months, her hip pain began to resolve, although only after a dual program was developed for treatment of the spondylolisthesis and GM strain.

Explanation of Outcome

The L5 nerve root innervates the gluteal musculature. Irritation of the nerve root at the unstable spinal level could interrupt the motor function of the L5 nerve root, resulting in neurologically induced weakness of the GM.[48] Without full afferent input into the GM, it may be vulnerable to strain, especially at the level of this patient's activity. Effective healing could not occur until afferent input into the GM was fully restored, which could not occur until the stability of L5–S1 segmental level was sufficient for her activity level. After the L5–S1 level became more stable and normal afferent input was restored to the affected musculature, a gradual conditioning program for the GM muscle was necessary to restore muscle performance to the functional level desired by this patient.

Sample Exercise Program

An example of a progressive strengthening program for the GM is illustrated in Self-Management 19-4. This progression begins in prone for the muscle with a 3/5 or lower MMT grade[28] and progresses to sidelying with increasing lever arms to increase the load on the muscle. As muscle performance improves, transition to functional positions and movements can be introduced. Self-Management 19-2 can be progressed to a leap, with the focus on controlling frontal and transverse plane forces at the hip on landing.

involve the intramuscular tendon, or aponeurosis, and the surrounding tissues.[146]

The second defined injury mechanism involves an overstretch, which more commonly injures the proximal free tendon of the semimembranosus.[146–148] These injuries are common to dancing and kicking activities, in which a combined hip flexion with knee extension movement occurs. Current evidence indicates that athletes with injuries involving the proximal free tendon take longer to recover.[148]

Sahrmann proposes hamstring overuse as another etiology for hamstring strain.[149] The hamstrings participate in force couples around the LP-hip complex, contributing to posterior pelvic rotation, hip extension, and, indirectly, hip medial and lateral rotation. Because of the multiple roles of the hamstrings, it is quite possible to sustain an overuse injury. **Display 19-4** describes possible mechanisms of hamstring overuse.

The goals of rehabilitation for hamstring injuries are to return the individual to prior level of function. With an athlete, the goal is to return to prior level of performance and participation with minimal risk for reinjury. As such, impairments experienced as a direct result of the injury (e.g., pain, swelling, weakness, reduced ROM) must be addressed throughout the rehabilitation process. In addition to treating the muscle injury, underlying mechanical imbalances may be corrected to reduce the risk of recurrent injuries. Previous research has identified risk factors for initial hamstring injury. Of these, modifiable risk factors include hamstring weakness, fatigue, reduced flexibility,[133,150,151] imbalances in hamstring eccentric and quadriceps concentric strength,[152–154] decreased quadriceps flexibility,[155] and strength and coordination deficits of the pelvis and trunk musculature.[156] It can be speculated that addressing these issues after hamstring injury would also likely decrease reinjury risk.

Treatment of a hamstring strain should follow the guidelines for tissue healing outlined in Chapter 11. After remodeling and repair, the hamstring muscle displays (1) decreased peak torque production,[157] (2) peak force at shorter lengths, which may predispose the muscle to further injury when functioning at a lengthened position, (3) altered firing patterns,[158] and (4) decreased eccentric strength.[159,160] Eccentric exercise can shift the peak force production to longer muscle lengths[161] (see **Fig. 19-9**). This shift in force production may help to restore optimal musculotendon length for tension production to reduce risk of injury. However, for the hamstrings to fully recover, treatment must be focused on the underlying *cause*

DISPLAY 19-4

Mechanisms of Hamstring Overuse

- Subtle imbalances in force or torque production and endurance between the hamstrings and gluteus maximus may lead to excess demand on the hamstrings to decelerate hip flexion during late mid-swing and hip MR at initial contact.
- Significant forefoot varus (see Chapter 21), combined with length–tension alterations and reduced force or torque production of the deep hip lateral rotators, may lead to overuse of the biceps femoris. Without optimal foot mechanics and hip lateral rotator function, the biceps femoris load is exaggerated because of the increased role it must play in decelerating femoral and tibial MR at initial contact through the midstance phase of gait.
- Underuse of the oblique abdominal muscles may lead to overuse of the hamstrings because of the increased role they must play to exert a posterior rotational force on the LP region.

SELF-MANAGEMENT 19-1
Stomach-Lying Hip Extension

Purpose: To strengthen the gluteal muscles, train to move your hip independent of your pelvis and spine and stretch the muscles on the front of your hip.

Start Position: Lie on your stomach on a firm surface and place ____ pillows under your torso.

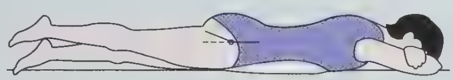
Movement Technique:

- Preset your spine and pelvic position by activating your abdominal wall and gently squeezing your gluteal (seat) muscle. Try to keep your hamstring muscles relaxed.
- Use your abdominal muscles to control the position of the pelvis. Think of keeping your pubic bone rotated upward toward your ribs.
- Use your gluteal muscles to barely lift your thigh off the floor.
- Return your thigh to the floor and repeat the lift with the other leg.

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________



of the strain and predisposing risk factors. If the cause of the strain is overuse, the load must be reduced on the hamstrings during meaningful functional activities. Improving the muscle performance and neuromuscular control of the *underused synergists* and correcting for any biomechanical factors (e.g., foot progression relative to knee in sagittal plane) constitute a recommended course of action.

Two commonly underused synergists involved in the cause of hamstring overuse strain are the gluteus maximus and deep hip lateral rotators. Examples of therapeutic intervention for progressive strengthening of the gluteus maximus and deep hip lateral rotators are shown in **Self-Management 19-1** and **Figure 19-10.** These exercises illustrated are considered specific, nonfunctional exercises. There are two reasons to prescribe this type of exercise instead of more functionally relevant exercise. First, the force-generating capability of the muscle is inadequate to allow it to fully participate in a functional task. Second (and possibly more importantly), the kinesthetic awareness of the muscle may be such that the patient's ability to selectively recruit it during a functional task may be insufficient.

After force-generating capability and kinesthetic awareness of the proximal posterior hip musculature are improved sufficiently, graded functional activities can be initiated. **Self-Managements 19-2** and **19-3** illustrate functional progressions of specific exercises that use the gluteus maximus, hamstrings, quadriceps, and deep hip lateral rotators in sagittal plane kinetic chain activities. Other functional exercises shown to activate this musculature to at least 40% of maximum voluntary contraction (MVC) include single-limb squat and the lunge (forward, sideways)[162]

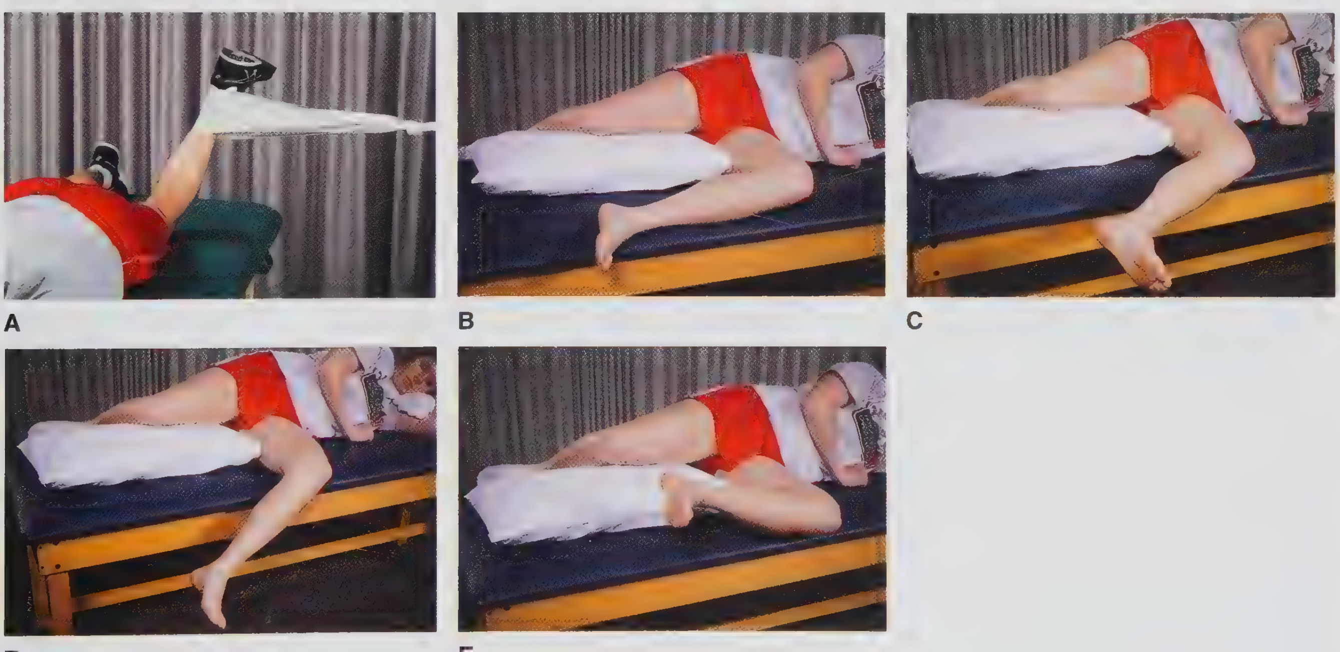


FIGURE 19-10 **(A)** Prone hip LR with elastic. The patient is instructed to stabilize the pelvis in the sagittal and transverse planes with abdominal wall recruitment while rotating the hip from MR to midline or slight lateral rotation. The slow release back to MR emphasizes eccentric control of the lateral rotators. The hip-extended position favors all hip lateral rotators, including lateral hamstrings and gluteus maximus. **(B)** The sidelying position at 90 degrees of hip flexion provides better isolation of the deep hip lateral rotators from the gluteals and hamstrings. **(C)** This illustration shows an isometric contraction by slightly extending the knee so that the hip rotators are holding the tibia against gravity. Be careful of adductor recruitment by ensuring the pelvis is perpendicular to the ground. **(D)** This diagram shows an eccentric contraction. **(E)** This diagram shows a concentric contraction. All types of contractions can be trained for various purposes as they relate to function of the deep hip lateral rotators.

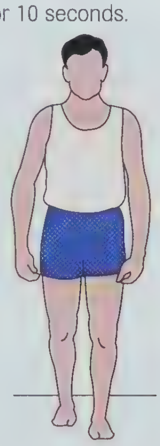
SELF-MANAGEMENT 19-2
Walk Stance Progression

Purpose: To teach the correct pattern to move your body over your hip, teach a good strategy to balance on one leg, and strengthen your hip and other lower extremity muscles to support your lower extremities in good alignment for activities you perform in standing.

Level I

Start Position:
- Stand in a staggered stance position with your involved leg in front of your uninvolved leg.
- Check the position of your feet, knees, hips, and pelvis.
- Feet should be facing straight ahead with arches in neutral.
- Knees should be facing straight ahead without turning in or out excessively (if you have anteverted or retroverted hips, the knee position may be modified).
- Hips and pelvis should be facing forward and level.

Movement Technique:
- Slowly bend your front hip and knee while leaning slightly toward your front leg.
- Pivot at your hips and lean your trunk forward so that it is parallel to the line of your lower leg. Do not round or arch your back.
- Do not bend your knee further than the length of your foot. Hold this position for 10 seconds.
- Activate your abdominal wall. (Note: activate your abdominal wall in preparation for all the levels of this exercise.)
- Turn on your deep hip lateral rotators by keeping your knee centered over your feet (do not let your knee turn inward).
- If your arch drops excessively, hold the arch of your foot up while you keep your big toe down. If your arch remains high and rigid, allow it to roll inward slightly. Your physical therapist will clarify the movement of your foot based on your foot type.



Dosage:

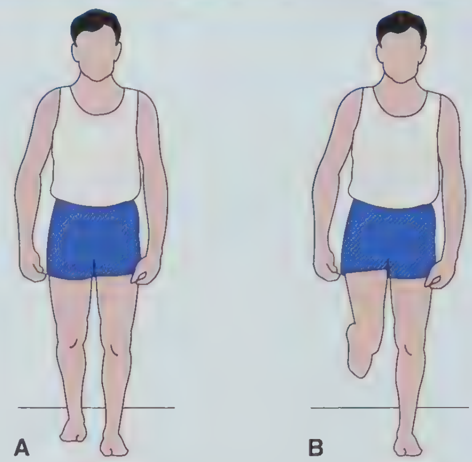
Sets/Repetitions: ______________________

Frequency: ______________________

Level II: Single-Limb Stance

Start Position:
- The start position for this exercise is the end position of Level I.

Movement Technique
- Progress from the walk stance position by lifting your back heel upward as you straighten your front knee and hip (**Fig. A**).



- Be sure your feet, knees, hips, pelvis, and spine are in good alignment.
- Hold this position for 3 seconds.
- Slowly bring your back thigh forward by bending the hip and knee (as if to take a step forward) (**Fig. B**).
- Balance for up to 30 seconds.

Dosage:

Sets/Repetitions: ______________________

Duration: ______________________

Frequency: ______________________

Level III: Split Squat

Start Position:
- Position yourself in a staggered stance with your involved leg forward.
- Lean toward your front limb as in Level I.
- Keeping your spine, pelvis, hips, knees, and ankles steady, slowly lower yourself until you see or feel your pelvis tilting or rotating out of the start position.

SELF-MANAGEMENT 19-2
Walk Stance Progression *(continued)*

- The movement should be occurring at your hip and knee. Your front knee should only bend as far as the length of your foot. (Note: a good rule of thumb is to keep your lower leg bone parallel to your torso throughout the entire maneuver.)
- Most of your weight should be over your front limb; if you feel your back limb straining, shift your weight onto your front limb.
- Slowly rise upward while keeping your weight shifted forward.
- Repeat up and down while remaining in a forward position over your front foot.

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________

Level IV: Lunge

Start Position: Stand with both feet on the floor and weight equally distributed between both limbs.
Take a step forward and watch your pelvis, hip, knee, ankle, and foot position as in Level I. Do not let your back arch.

This is a ballistic exercise. Be extra careful about your position.

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________

SELF-MANAGEMENT 19-3
Step-Up, Step-Down

Purpose: To strengthen your spine, hip, knee, ankle, and foot muscles and to improve your balance in single-limb stance.

Step-Up (Fig. A)

Start Position: Stand facing a step.

Movement Technique: Lift your leg onto the step, keeping your thigh in midline and your pelvis level. Do not hike your pelvis while lifting your leg onto the step. This movement should take place only at the hip and knee.
After your foot is on the step, check its position. The arch should be up with the big toe down.
Lean toward the step, being sure that your knee is in line with your foot (Note: this may vary if you have anteverted or retroverted hips) and your pelvis is level.
Looking at your body from the side, a good rule of thumb is to flex your knee no further past the length of your foot and to keep your lower leg bone parallel to your torso throughout the entire step-up and step-down maneuver.
Step up while keeping your pelvis level, knee over toes, and arch up. Be sure to lean into your hip, but do not let your pelvis tilt.

Variation: You can stand to the side of a step and step up sideways. This variation places more stress on your outside hip muscles. Be sure to keep your pelvis level.
Variation: You can step off the back of the step. Do not step down fully, but merely touch your toe on the floor and step back up again so as not to fully unload the weight of your body through the stance leg. This makes the stepping leg work harder. This variation places more stress on your quadriceps.

Dosage:

Sets/Repetitions: ______________________

Resistance (step height): ______________________

Frequency: ______________________

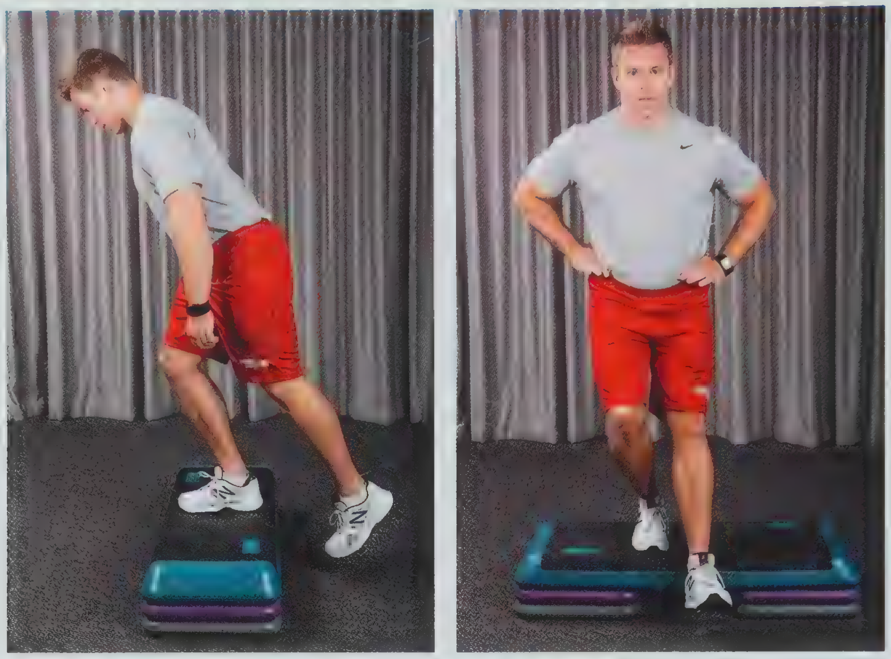
Step-Down (Fig. B)

Start Position: Stand on a step that is higher than you can control during a step-down movement.

Movement:
- Flex the foot of the leg you are stepping down with.
- Bend the hip and knee of the foot remaining on the step as you lower your flexed foot toward the floor.

(*continued*)

SELF-MANAGEMENT 19-3
Step-Up, Step-Down (*continued*)



A B

- Lean forward so as to bend at your hip. Do not let your knee bend further than the length of your foot.
- Do not completely step down, but stop just short of the floor and hold this position for up to 10 seconds.
- Be sure that your pelvis is level, your knee over your toes (Note: this may vary if you have anteverted or retroverted hips), and you arch up as you lower your leg. Do not deviate from this position.
- Variation: You may need to use an external device to assist you in your balance.
  - ___ Hold a ski pole, dowel rod, or upside down broom in each hand.
- ___ Hold a ski pole, dowel rod, or upside down broom in the opposite hand from which you are balancing.
  - ___ Hold a weight in the hand of the hip on which you are balancing.
- Variation: After you can balance well during the lowering phase, you can further challenge your balance by using arm movements. When you have lowered yourself as far as you can control, raise the arm on the same side or opposite side of the leg on which you are balancing.
  - ___ Raise it up and down to the side.
  - ___ Raise it up and down to the front.
  - ___ Raise it toward and away from the midline of your body.

Dosage:

Sets/Repetitions: ____________________

Assistance (amount of weight in hand): ____________________

Resistance (step height): ____________________

(see **Fig. 19-11**). The clinician must be concerned with the recruitment of the underused synergists during each exercise. Subtle changes in lower quarter kinematics can affect muscle recruitment strategies.[163] For example, keeping the trunk more vertical during a step activity can diminish the use of gluteus maximus relative to the quadriceps (**Fig. 19-12A**), whereas inclination of the trunk toward a more horizontal position can increase the use of gluteus maximus relative to the quadriceps[164] (see Fig. 19-12B). **Display 19-5** describes the role of various muscles during these exercises.

Overstretch can also be a contributing factor to muscle strain. For example, the GM muscle is susceptible to strain resulting

FIGURE 19-11 **(A)** Single-limb squat: ensure the patient/client maintains a sagittal plane alignment during the squat and that tibia and torso remain parallel as the squat progresses in depth. Watch for sagittal, transverse, and frontal plane alignment from thorax to foot. Lunge: similar to the squat, ensure optimal alignment in all planes during **(B)** front and **(C)** side lunges. Cue forward lean in the lunge.

from length-associated changes, which can occur in an individual with an apparent LLD and resulting iliac crest height asymmetry.[149] On the side of the high iliac crest, the hip is adducted, and the GM is in a chronically lengthened position. As a result, this muscle is at risk of strain. Treatment of this type of strain must involve exercises that resolve the contributing factors to the LLD in conjunction with treatment to improve the length–tension properties, muscle performance, and neuromuscular control of the GM. In the early stages of recovery, taping (**Fig. 19-13**) can unload the muscle and support it at an appropriate length, providing a positive environment for healing. Severe strains may require use of a cane in the contralateral hand to unload the muscle

A B

FIGURE 19-12 **(A)** Side view of step-up exercise with vertical trunk orientation, decreased hip flexion, and center of mass posterior to the axis of rotation of the hip and knee. Step-up from this start position promotes use of a hamstring and soleus strategy to pull the hip and knee into extension to raise the center of mass upward. Relative to the quadriceps and gluteus maximus recruitment, this position favors use of the quadriceps primarily because of the lack of hip flexion. **(B)** Side view of step-up exercise with good spine, hip, knee, and ankle–foot relationships. Note the forward inclination of the trunk. A good rule of thumb is to teach the exerciser to keep the trunk parallel to the tibia during the entire phase of vertical to lowering and the return motion. This will best ensure proper balance between the gluteus maximus, hamstrings, and quadriceps during closed chain activities.

DISPLAY 19-5

Role of Lower Extremity Muscles During Closed Chain Exercises

- The gluteus maximus muscle decelerates hip flexion in the lowering phase of the split squat, lunge, and step-down and accelerates hip extension during the rising phase of the split squat, lunge, and step-up.
- The quadriceps muscle decelerates knee flexion during the lowering phase of the split squat, lunge, and the step-down and accelerates knee extension during the rising phase.
- The deep hip lateral rotators are recruited to control hip MR during all phases of each exercise.
- The posterior tibialis and peroneus longus muscles control foot pronation during the stance phase of each exercise, which assists in controlling tibial and femur MR up the kinetic chain.

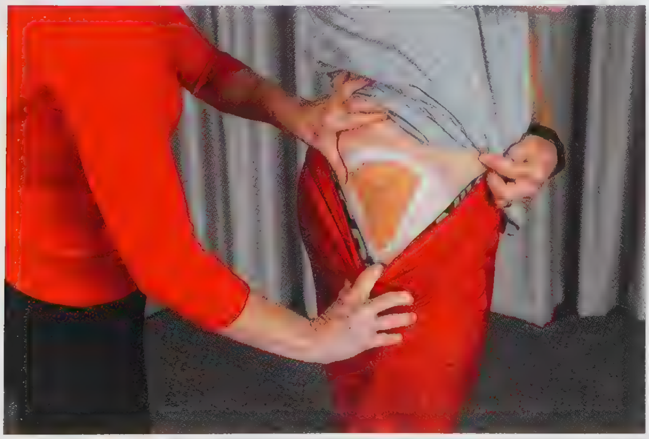

FIGURE 19-13 Taping to support a strained GM. This tape is best applied with the hip and is biased in abduction and LRto prevent strain to the GM.

enough to induce healing. Exercises to progressively strengthen the GM are depicted in **Self-Management 19-4**, and also in Self-Management 19-2. Other exercises shown to activate the GM include the lateral band walk (**Fig. 19-14**), single-limb squat (Fig. 19-11A), single-limb dead lift (Fig. 19-9A), hop (forward, sideways), and lunge (forward and sideways), though these are high-level progressions and require 4 to 4+/5 GM strength.[162] When prescribing closed chain exercises, caution must be taken in ensuring proper kinematics. Of particular concern are pelvic, femur, tibia, ankle–foot alignment and movement patterns to prevent further stretch to the GM (i.e., lateral pelvic tilt, femur adduction, femur MR).

Disuse and Deconditioning

Disuse and deconditioning of the hip joint musculature, particularly of the abductor muscles, is quite common. Disuse or deconditioning can result from injury or pathology affecting the hip and surrounding structures or from acquired movement patterns that promote disuse. For example, weakness in the gluteal musculature in hip joint OA is a common finding, but research has not determined whether it is the cause or the result of hip joint pathology.[165] Atrophy and pain both contribute to the decrease in muscle strength in hip OA.[166] Because hip muscles participate in gait, sit to stand, squatting, and ascending/descending stairs, weakness of hip muscles can affect the performance of basic ADLs.

In addition, hip weakness and decreased ROM has been associated with low back and various lower extremity pathologies. A moderate relationship currently exists between hip dysfunction and low back pathology,[167] whereas a much stronger relationship has been identified between hip dysfunction and knee pathology.[168] Hip abduction and lateral rotation weakness has been associated with patellofemoral pain syndrome (PFPS). Ireland[169] revealed that females with PFPS demonstrated 26%

SELF-MANAGEMENT 19-4
Gluteus Medius Strength Progression

Purpose: To strengthen the hip muscles that keep your hip and pelvis in good alignment when you walk (highest level of this exercise [Level V] helps to stretch the band on the outside of the thigh).

Level I: Prone Hip Lift

Start Position:
- Lie on your stomach on a firm surface. Place ___ pillows under your torso as indicated in the illustration.
- Your legs should be in line with your hips and rotated *slightly* outward.

Movement Technique:
- First you must activate your inner core plus abdominal muscles to stabilize your pelvis. Contract your abdominal muscles so that your pubic bone moves toward your ribs.
- Squeeze your buttock muscle.
- *Slightly* lift your leg and move it sideways through as much range as your hip allows. The indication that your hip has moved through its full available range is that your pelvis begins to tilt sideways and your spine sidebends. Do not move your hip any further after you feel your pelvis or spine move. Hold this position for 10 seconds.
- Return your hip to a start position.

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________

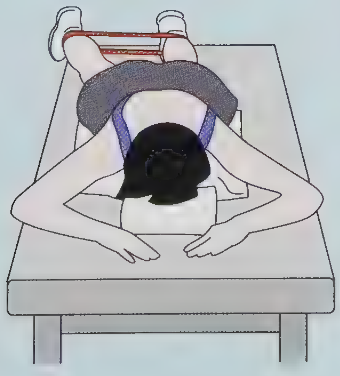
Level II: Prone Hip Lift with Elastic

Perform as in Level I, but attach a ___ piece of elastic around your ankles.

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________



Level II: Prone hip abduction with elastic

Level III: Sidelying Hip Rotation

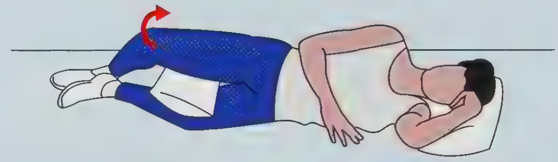
Start Position:
- Lie on your uninvolved side, with your hips in full extension and knees bent to 90 degrees, Place ___ pillows between your knees.
- Be sure you are on your side, with your head and neck in line with your spine and your spine in neutral, not rotated forward or backward. Your physical therapist may instruct you to position yourself against a wall to assist you in proper alignment.

Movement Technique:
- Slightly lift your lateral trunk off the floor by activating your lateral trunk muscles. Maintain this position while you perform the limb motion. Do not allow your pelvis to roll backward, or your waist drop during the limb motion.
- Slowly roll your hip backward (like opening a clamshell). This movement is very small. Your PT will assist you in feeling how subtle this movement is. Hold this position for 10 seconds.
- Slowly return to the start position.

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________



Level III: Sidelying hip lateral rotation

Level IV: Sidelying Knee Extension

Start Position:
- As in Level III.

Movement Technique:
- Slightly lift your lateral trunk off the floor by activating your lateral trunk muscles. Maintain this position while you perform the limb motion. Do not allow your pelvis to roll backward, or your waist drop during the limb motion.
- Turn out your hip without letting your pelvis or spine tilt backward or forward by activating your inner core and abdominal muscles.
- Extend your knee fully. Hold this position for 10 seconds.
- Keeping your hip turned outward, slowly return your thigh to the start position.
- You can progress this position by using ankle weights.

(continued)

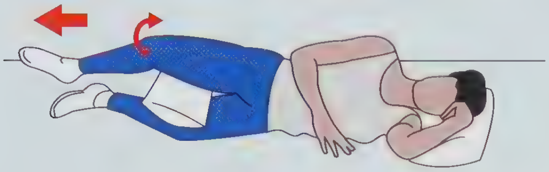
SELF-MANAGEMENT 19-4
Gluteus Medius Strength Progression (*continued*)

Dosage:

Resistance: ______________________

Sets/Repetitions: ______________________

Frequency: ______________________



Level IV: Sidelying leg extension

- Relax your leg onto the pillow before you begin the next repetition.
- *Variation*: You can also perform this level from a fully hip-extended position. It is helpful to lie against a wall, positioning your pelvis such that your pelvis is against the wall and both "cheeks" are touching the wall. In addition, your therapist may ask you to position a small towel behind your upper buttock to ensure your hip is in extension when it slides up the wall. Slide your heel up the wall through a full hip ROM. Do not compensate by tilting your pelvis or sidebending your spine. Hold this position for 10 seconds.
- Keeping your hip turned outward, slowly lower your leg to the start position.

Dosage:

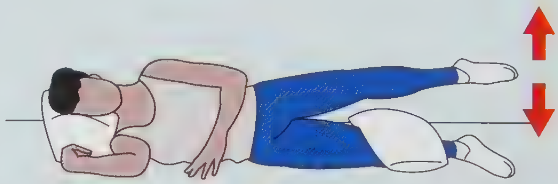
Sets/Repetitions: ______________________

Frequency: ______________________

Level V: Sidelying Concentric/Eccentric Contractions

Start Position:
- You can now begin to work on concentric (shortening) and eccentric (lengthening) contractions.
- As in Level IV, move to fully extended position.

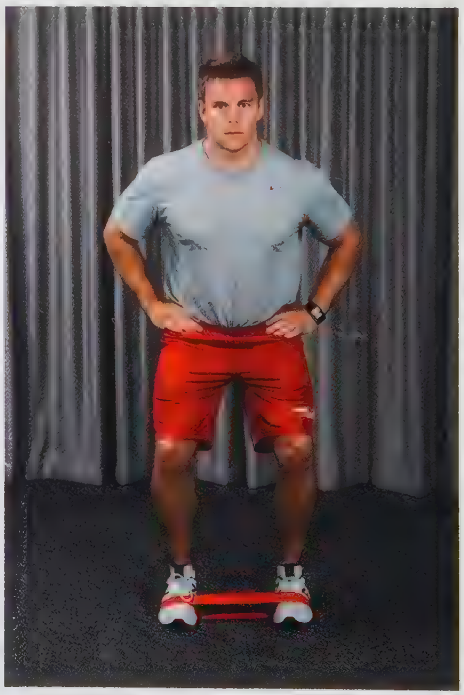
Movement Technique:
- Slightly lift your lateral trunk off the floor by activating your lateral trunk muscles. Maintain this position while you perform the limb motion. Do not allow your pelvis to roll backward, or your waist drop during the limb motion.
- Slowly lift your leg about 10 degrees above neutral, hold top position for 10 seconds.



Level V: Sidelying concentric/eccentric contraction

FIGURE 19-14 Lateral band walk. Traditional placement is at the knee **(A)**. Distal band placement offers a significantly higher activation level of gluteal muscles **(B)**. (From Cambridge ED, Sidorkewicz N, ideda DM, et al. Progressive hip rehabilitation: the effect of resistance band placement on gluteal activation during two common exercises. Clin Biomech 2012;27:719–724.)

A



B

less hip abductor and 36% less hip LRstrength than controls. Others have identified similar trends[170–173] while Powers[174] has theorized that hip abductor and lateral rotator weakness can lead to knee valgus, hip adduction, and hip internal rotation, a position that can place undue stress on lower extremity joints. Ferber[175] found that correcting the hip strength deficits improves lower extremity pain in runners.

Because the hip plays such a critical role in ADLs, instrumental ADLs, and recreational activity, minimizing disuse and deconditioning is imperative. According to Ayotte[73] and Escamilla,[176] moderate electromyographic (EMG) activation (21% to 40% maximum voluntary isometric contraction (MVIC) is best used to facilitate endurance and neuromuscular reeducation, and high activation (41% to 60+% MVIC) to promote strength gains. However, clinicians can also use lower level activation exercises to facilitate neuromuscular activation[73] and progress patients with marked weakness to more demanding tasks (**Evidence and Research 19-6**).

EVIDENCE and RESEARCH 19-6

Gluteal Activation During Common Therapeutic Exercises

Reiman et al.[177] conducted a literature search for experimental studies, RCTs, systematic reviews, narrative reviews, and meta-analyses using the Medline (1966 to 2005/2010), CINAHL (1982 to 2005/2010), and Sports Discus (1975 to 2005/2010) databases. Six studies for the gluteus maximus (GMax)[73,162,178–181] and four studies for the GM (GMed)[73,162,179,182] met the inclusion criteria. To make meaningful comparisons of EMG activation levels between studies, the authors categorized activation into four levels (low-level muscle activation at 0% to 20% MVIC; moderate-level activation at 21% to 40% MVIC; high-level activation at 41% to 60%, and very high-level activation at greater than 60%).[176] Nine exercises met the criteria for inclusion in the category of high-level activation and one for very high level for gluteus maximus and nine exercises met the criteria for inclusion in the category of high-level activation and two for very high-level activation for GM (see **Display 19-6**).

It is reasonable to consider that acquired posture and movement habits can contribute to altered length–tension properties and disuse of the hip musculature. For example, a slightly high iliac crest, as commonly occurs in a handedness pattern on the dominant side, contributes to lengthening of the ipsilateral GM,[69,149] which affects its force-generating capability during function.[183] The muscle tends to function at its relatively lengthened state during gait (with the hip adducted).[184] Eventually, this movement pattern may become more exaggerated, contributing to excessive hip adduction during the stance phase of gait and further reliance on stability from passive tension of the ITB.[185] As the hip increases its use of the ITB for passive stability, GM participation may decrease. Subsequently, the GM is subject to further deconditioning. This imbalance has been demonstrated in distance runners with iliotibial band syndrome (ITBS).[185] Long-distance runners with ITBS have weaker hip abduction strength in the affected leg compared with their

DISPLAY 19-6

High-Level Gluteus Maximus Activation[177]

- Sideways lunge (41% ± 20% MVIC)
- Lateral step-up (41% MVIC; 90% CI)
- Transverse lunge (49% ± 20% MVIC)
- Quadruped with contralateral arm/leg lift (56% ± 22% MVIC)
- Unilateral mini-squat (57% ± 44% MVIC)
- Retro step-up (59% ± 35% MVIC)
- Wall squat (59% MVIC; 90% CI)
- Single-limb squat (59% ± 27% MVIC)
- Single-limb dead lift (59% ± 28% MVIC)

Very High-Level Gluteus Maximus Activation

- Forward step-up (74% ± 43% MVIC)

High-Level Gluteus Medius Activation

- Lateral step-up (41% MVIC; 90% CI)
- Quadruped with contralateral arm and leg lift (42% ± 17% MVIC)
- Forward step-up (44% ± 17% MVIC)
- Unilateral bridge (47% ± 24% MVIC)
- Transverse lunge (48% ± 21% MVIC)
- Wall squat (52% ± 22% MVIC)
- Sidelying hip abduction (56% MVIC; 90% CI)
- Pelvic drop (57% ± 32% MVIC)
- Single-limb dead lift (58% ± 22% MVIC)

Very High-Level Gluteus Medius Activation

- Single-limb squat (64% ± 24% MVIC)
- Side-bridge to neutral spine position (74% ± 30% MVIC)

unaffected leg. After 6 weeks of training with special attention directed to specifically strengthen the GM, hip abductor torque increased from 34% to 51%, and 22 of 24 athletes were pain-free and able to return to running.

The iliopsoas is active in the initial swing phase and terminal stance phase of gait, and presumably in ascending stairs.[186] Its activity is probably related to LRand hip flexion, which accompanies the initial swing phase of gait. Faulty patterns of hip flexion can indicate underuse of the iliopsoas and overuse of another synergist. The following examples describe faulty hip flexion patterns:

- Hip hike during the swing phase of gait or stair-climbing suggests recruitment of lateral trunk musculature to hike the hip instead of using the iliopsoas to flex the hip (**Fig. 19-15**).
- Hip flexion with MR (**Fig. 19-16**) suggests use of TFL as the predominant hip flexor instead of the iliopsoas.

Sahrmann states that repetitive alteration in the optimal path of instant center of rotation of the hip during flexion and the resulting compensatory hip and LP movement patterns predispose the hip and LP region to further impairments and pathologic conditions.[149] Specific exercises to improve the force-generating capability of the iliopsoas (see **Self-Management 19-5**) and gradual movement reeducation

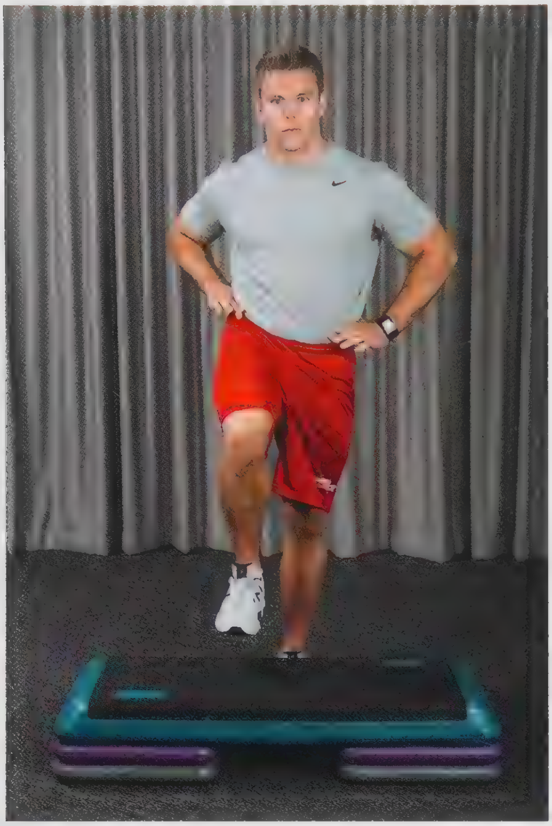


FIGURE 19-15 Use of a hip-hike strategy versus independent hip flexion on the left to ascend the stairs.

FIGURE 19-16 Medial femoral rotation versus neutral hip rotation of the left femur accompanying hip flexion during stair-climbing.

SELF-MANAGEMENT 19-5
Iliopsoas Strengthening

Purpose: To strengthen the muscle deep in the front of your pelvis that lifts your leg and controls the forward rotation of your hip joint.

Start Position: Sit with your feet flat on a firm surface, back straight, pelvis erect, and arms resting at your sides.

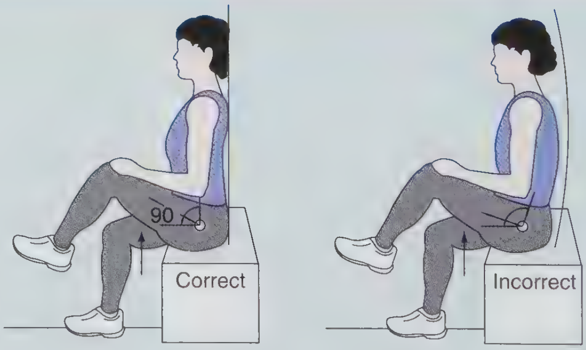
Movement Technique:

Level I—Passive lift, hold, lower

- Use your hands to lift your knee toward your chest as far as possible without letting your lower back round or "slump" backward.
- Hold this position for the prescribed number of seconds.
- Lower your leg to the start position.

Level II—Resisted hip flexion

- Perform as in Level I, but push against your knee in a down and slightly outward direction for the prescribed number of seconds.
- Lower your leg to the start position.



Level II: Resisted hip flexion

Dosage:

Sets/Repetitions: ______________________

Duration: ______________________

Frequency: ______________________

in hip flexion patterns during function (i.e., swing phase of gait and stair-climbing) are indicated to improve iliopsoas muscle performance and participation in the hip flexion force couple.

Reduced participation of the gluteus maximus profoundly affects gait and the ability to ascend stairs.[131] During gait, gluteus maximus activity is related to deceleration of hip flexion at terminal swing and isometric extensor support of the flexed hip at initial contact and during the loading response phases of gait.[131] Squatting, step-ups, step-downs, and sit-to-stand exercises are functional methods for improving the gluteus maximus force-generating capability and its recruitment during functional movement patterns, provided the proper kinematics are promoted (see Display 19-5 and **Fig. 19-17**).

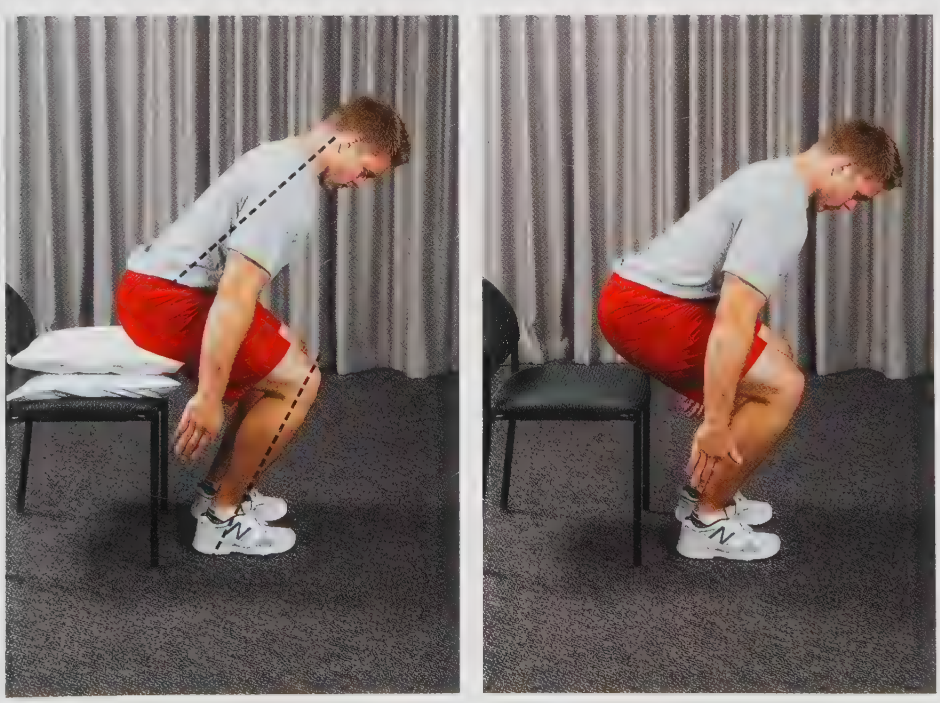
Hip lateral rotators are active from the initial contact to midstance of gait, presumably to decelerate the medial femoral rotation occurring as a result of foot pronation. Signs of excessive hip MR during weight acceptance and the single-limb support phases of gait need to be examined to determine the contributing impairments (e.g., hip anteversion, knee valgus, foot pronation, hip medial rotation). Use of orthotic support as the exclusive remedy for hip MR should be avoided. There is evidence that the kinematic effects of orthotic intervention are small and not systematic.[187] Instead, specific exercise (Fig. 19-10) and functional retraining of the hip lateral rotator control should be emphasized (**Fig. 19-18**; see Self-Management 19-2). Even in the presence of foot and ankle-related impairments and orthotic intervention, isolated hip lateral rotator muscle strengthening is indicated to assist in pronation control (see **Building Block 19-2**).

BUILDING BLOCK 19-2

Consider a 57-year-old female with a positive Trendelenburg sign on the left side and bilateral weakness in the hip abductors and lateral rotators. She shows some mild OA bilaterally but does not want to have surgery. She presents with slow gait speed, poor control of the core musculature, and bilateral pronation. Develop three exercises that would be appropriate for this patient to maximize her function.

ROM, Muscle Length, Joint Mobility, and Integrity Impairments

ROM and joint mobility impairments of the hip can span the continuum of hypomobility to hypermobility. The extreme clinical manifestation of hypomobility is the arthritic hip with a capsular pattern of limitation. The extreme clinical manifestation of hypermobility is congenital dysplasia of the hip, creating chronic instability in the hip joint. Between these extreme conditions, more subtle mobility impairments can affect the function of the hip. Joint stability refers to the resistance that musculoskeletal tissues provide at a joint and is the product of contributions from all the subsystems of the movement system. Joint hypo/hypermobility may result from



A B

FIGURE 19-17 Chair squats. Note the forward inclination of the trunk and parallel lines of the trunk and tibia. **(A)** Chair squats can be made easier with the use of pillows. **(B)** Gradually taking away the pillows can make the exercise more difficult by increasing the depth of the squat. Cue the patient to "hover" just above the seat before completely sitting down into the chair.

A B

FIGURE 19-18 Single-limb balance challenges hip rotators in a more functional position by adding torsional destabilizing stress through resisted movement of the upper extremities into horizontal abduction **(A)** and adduction **(B)**.

an impairment in one or more component of these subsystems and lead to limited or excessive joint translation and subsequent joint overload.[188–193]

Hypermobility

The etiology of hypermobility can be either arthrokinematic or osteokinematic. "Arthrokinematic hypermobility" is defined as linear translation that is excessive, whereas "osteokinematic hypermobility" is angular translation that is considered excessive. "Joint instability" refers to insufficient stabilizing structures and mobility that exceeds the physiologic limits along a continuum. Unfortunately, the term "instability" is used interchangeably with hypermobility in the literature, which causes much confusion. Hip joint instability was previously thought to be rare and usually associated with trauma,[194–196] or developmental bony abnormalities such as acetabular dysplasia. Although the hip joint is considered to be stable because of its bony architecture and strong capsuloligamentous restraints, evidence suggests that deficits in the acetabular labrum and iliofemoral ligaments may lead to increased femoral head translation[197–199] and possibly to early degenerative hip pathology[200] (**Evidence and Research 19-7**).

Capsuloligamentous laxity may be generalized or focal. Generalized laxity is associated with connective tissue disorders, whereas focal laxity results from an acute injury or from repetitive weight-bearing rotational forces overloading specific parts of the capsuloligamentous system. Sporting activities involving repeated axial loading and rotation, such as gymnastics, football, tennis, ballet, martial arts, and golf, may influence the development of focal laxity. Active stability

EVIDENCE and RESEARCH 19-7

Surgical Intervention for Hip Dysplasia

For some patients with acetabular dysplasia, the Bernese periacetabular osteotomy (PAO) can be an effective surgical treatment that reorients the dysplastic acetabulum to stabilize the hip and to improve coverage of the femoral head.[3,201–208] One systematic literature review included 13 studies containing 626 hips with a minimum 2-year follow-up (average 5 years). Overall, 79% of patients experienced a good or excellent clinical result with a low rate of conversion to total hip arthroplasty (THA) (7.3%).[202] This review demonstrated that the clinical benefit of the procedure is optimal in younger patients with no or mild preoperative OA. It is less predictable, and failure rates are higher, when preoperative OA is graded moderate or advanced. The procedure also is associated with decreased postoperative hip ROM. Finally, at short- to midterm follow-up, reduction in pain and enhanced hip function were noted in all studies, yet patients with early failures and/or poor clinical results also were observed. The complication rate is noteworthy with these procedures, as 6% to 37% of patients experienced a major complication. Increased surgeon experience may reduce the complication rate in the future.[209] These studies have not shown long-term survivorship of the reconstruction and have not proven the prevention or delay of secondary OA. Given the lower level of evidence provided by the available studies and the concurrent evolution of surgical techniques, many factors regarding PAO remain unknown. Future studies need to determine optimal selection criteria for surgery, risk factors for clinical failure, optimal deformity correction parameters, the incidence and characteristics of associated complications, and the role of adjunctive surgical procedures.

of the hip joint from tension in hip muscles may augment passive stability in the normal and structurally abnormal hip.[192] Despite this likely important role, little is known about what muscle or muscle synergies are involved or if hip pathology has an influence on hip muscle function. Currently, it is unclear which muscle synergies have the potential to stabilize the femoral head within the acetabulum. This is largely due to the inherent difficulties with measuring joint stability and muscle forces in vivo. It is hypothesized that there is a "cuff" of the hip involving deep hip rotators, iliopsoas, and gluteus minimus[210] (**Display 19-7**; **Figs.** 19-10, **19-19**, **19-20**; Self-Management 19-5). The trail limb on split squat or lunge drills also target the iliopsoas in the hip extension phase (see Self-Management 19-2).

The ability for a muscle to hold the femur centered in the acetabulum is based on the muscle's fiber orientation and size (see **Evidence and Research 19-8**).

DISPLAY 19-7

Rotator Cuff of the Hip

- Deep hip rotators posteriorly
- Iliopsoas anteriorly
- Gluteus minimus laterally

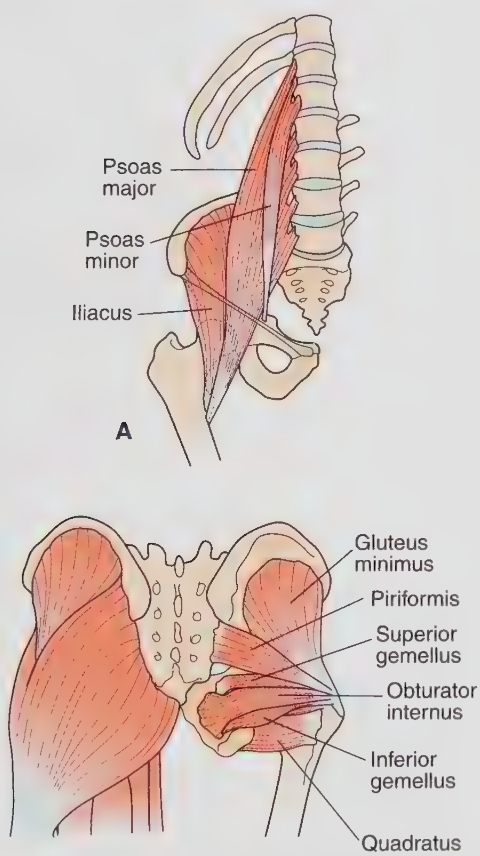


FIGURE 19-19 "Cuff" of the hip. **(A)** Iliacus and psoas. **(B)** Gluteus minimus and deep hip lateral rotators.

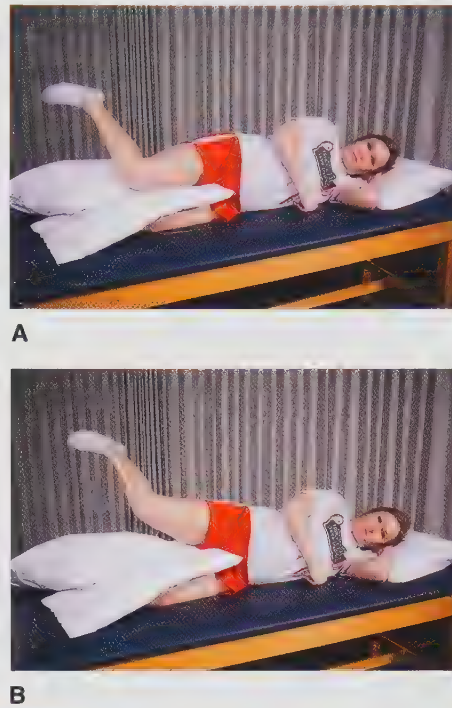

FIGURE 19-20 Gluteus minimus strengthening is also important when stabilizing against adduction moments. **(A)** The patient is positioned in sidelying with hip extended, knees bent to 90 degrees, and one to two pillows between the knees to keep the femur in neutral with respect to the frontal plane. The patient is instructed to turn the knee inward and lift the foot upward (engaging the medial rotators). **(B)** The next step to better isolate the gluteus minimus is to slightly abduct the femur while it remains in extension and medial rotation. To make this exercise more difficult, cuff weights can be added to the ankle.

EVIDENCE and RESEARCH 19-8

Evidence for Cuff of the Hip

Gray[211] defined the **short hip rotators** as "adjustable ligaments" for all hip positions. Cat anatomic and histochemical work supported this notion with evidence of design features considered ideal for hip control: short mean fiber lengths; small fiber pennation angles; small physiologic cross-sectional area; and a high proportion of slow twitch fibers.[212] Human data of short fiber length[213] have been interpreted to imply function in hip joint stabilization rather than torque generation.[214] Hodges et al. demonstrated a viable and valid technique to record obturator internus EMG and provides the first direct evidence of activation in simple functions.[215] Data from this study can be interpreted to suggest that a role as an "adjustable ligament" according to its muscle fiber anatomy would be limited to situations in which torques are applied in specific directions as an abductor, extender, or lateral rotator, rather than a generalized role.

Gluteus minimus, the deepest part of the abductor synergy, is an abductor, rotator, and flexor of the hip.[216] However, its primary function is considered to be as a stabilizer of the hip and pelvis.[216–218] Gluteus minimus fibers run parallel to the neck of the femur,[217] and it has attachments to the superior aspect of the capsule,[219] supporting the contention that gluteus minimus is an important stabilizer of the femoral head in the acetabulum.

(continued)

EVIDENCE and RESEARCH 19-8 (continued)

Gluteus minimus may therefore be important in stabilizing the hip by being able to modulate joint capsule stiffness. A fine wire EMG study has provided support for the role of the gluteus minimus as a stabilizer by demonstrating that the anterior portion of gluteus minimus is active in both prone hip extension and late stance phase, acting presumably to provide anterior support to the joint, rather than as a hip extensor for which it has no moment arm.[220]

A fine wire EMG study by Andersson et al.[221] investigating 11 subjects supports the role of the **iliacus** as a stabilizer of the hip, particularly in the late stance phase of gait. Lewis et al.[222] surmised that the iliacus and **psoas** muscles may play a role similar to that of the rotator cuff muscles at the shoulder by being able to influence joint stability not only by insertion but also by tension in musculotendinous units as they pass over the anterior aspect of the hip joint.

Sahrmann[149] describes a syndrome in the hip (femoral anterior glide syndrome) in which abnormal anterior translation of the hip accompanies hip flexion and excessive anterior translation occurs with hip extension. Correlating impairments may include stiffness in the posterior capsule combined with impaired force couple function of hip flexor torque producers (dominant rectus femoris, TFL) and stabilizers (insufficient iliopsoas and deep hip rotators).[222] Another syndrome (femoral adduction with medial rotation) is described in which excessive hip adduction and MR occur in combination, without the presence of excessive linear translation of the hip joint.[149] Femoral adduction syndrome can become exaggerated to the point that lateral glide mobility becomes excessive, thus involving both osteokinematic and arthrokinematic hypermobility (femoral lateral glide syndrome).[149] A person with femoral adduction or lateral glide syndrome may have a broad pelvis, an apparent LLD (the high side being symptomatic), femur medial rotation, genu valgum, and foot pronation as predisposing risk factors. These alignment faults contribute to chronic stretch of the abductor and lateral rotator muscle groups and lateral capsuloligamentous structures allowing excessive adduction, medial rotation, and lateral glide to occur during ADLs and sports. Patterns of sustained postures and repetitive movements can predispose an individual to a variety of syndromes because of soft tissue extensibility changes in the myofascia or periarticular tissues leading to hypermobility in osteokinematic or arthrokinematic patterns.

Careful examination should distinguish between osteokinematic and arthrokinematic hypermobility; the diagnosis of the latter is more difficult to resolve than the former. The primary objective of any therapeutic exercise intervention for the treatment of hypermobility, regardless of etiology, is to promote joint stability and prevent continued stress on the overstretched or torn tissues (myofascia or periarticular) via posture and movement pattern changes to improve length–tension properties (passive subsystem). Strength dosage can improve muscle performance (active subsystem), and precision practice can improve motor control (neural subsystem) of all muscles involved. For example, if a patient has hypermobility in the frontal plane, correction of postural habits such as sitting with his or her legs crossed, or standing with the affected leg in adduction, is indicated. Protecting the lateral structures from excessive stretch in the sidelying position with pillows between the legs would be recommended. Hip adductor stretching may be indicated to reduce the adductor tension on the hip joint (see **Fig. 19-21**).

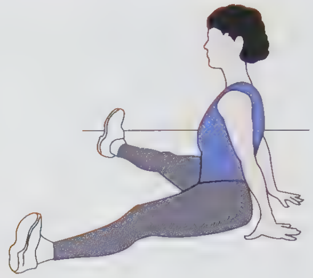

FIGURE 19-21 A method of stretching hip adductors. The patient is instructed in maintaining a neutral pelvis (sitting with the back against the wall can help prevent posterior pelvic tilt) and increasing the range of hip abduction versus trunk forward bend (as is commonly depicted in adductor stretches).

Hip muscle strengthening exercises, particularly hip abductor strengthening, are the most commonly prescribed intervention by physiotherapists in patients with hip pain, but current evidence suggests that joint stability may be enhanced via retraining of deep hip stabilizers in a direction-specific manner. Although current trends advocate the use of functional rehabilitation exercises, there is some evidence to suggest that this alone is inadequate for the effective retraining of normal feed-forward postural activity.[223] Much akin to the current rationale of strengthening the local muscles at the lumbar spine and pelvis, cervical spine, and shoulder joint prior to addressing the more superficial global muscles, it could be argued that effective therapeutic exercise programs for the pathologic hip should initially target local stabilizing muscles using low-load tonic exercises. Specific exercises for retraining the local muscles of the hip are commonly started in positions of low postural load such as prone, supine, or sidelying. The patient can be taught to monitor their motor performance by careful palpation. In the case of a patient presenting with concurrent aberrant LP motor control, cocontraction of the deep hip stabilizers and LP stabilizers can be taught. Clinically, such an approach appears to be effective; however, there is currently no evidence to support its use as it has not been evaluated.

Strengthening both GM (Self-Management 19-4) and gluteus minimus (Fig. 19-20) can be valuable to improve stability against adductor moments. Dosage for strengthening hip abductor and lateral rotators should prioritize muscle hypertrophic changes to enhance joint stiffness.

Whenever excessive MR ROM is measured, care must be taken to screen for anteversion. A common associated finding with hip anteversion is weakness of the hip lateral rotators (i.e., deep hip rotators, gluteus maximus, posterior fibers of GM). In the presence of excessive MR ROM, with or without anteversion, exercise to improve muscle performance of the lateral rotators is indicated. Lateral rotator strengthening exercises, to be most effective, should be coupled with education about altering postural habits (e.g., reduce the incidence of standing

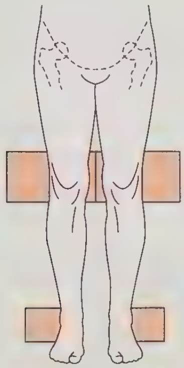
Patient-Related Instruction 19-1

Standing Knees over Toes

Your neutral hip position may vary depending on the structure of your hips. Your physical therapist will instruct you as to your neutral position if you have a structural variation in your hips.

From the Front

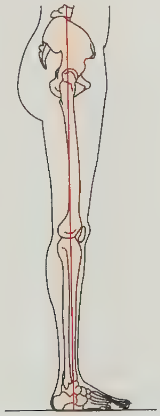
- Your weight should be distributed equally between both feet.
- Your pelvis should be level from side to side.
- The left side of your pelvis should be in line with the right side of your pelvis (i.e., one side of your pelvis should not be in front of the other side).
- Your knees should be in line with your feet; if you bend your knees, your knees would be directed over the midline of your feet.
- Your feet should be hip-width apart and *slightly* turned outward.
- The arch of your foot should be *slightly* elevated, with your big toe down.



Ideal alignment

From the Side

- Your pelvis should be in neutral, with the front pelvis bones in the same plane as your pubic bone.
- Your knees should not be bent or locked.
- Your ankle should fall below your knee, with your lower leg at a 90-degree angle with respect to your foot.



with the femur in excessive medial rotation) and movement training to improve recruitment of lateral rotators during closed chain function (see **Patient-Related Instructions 19-1** and **19-2** for examples of posture and gait education and training). Caution must be taken when strengthening hip lateral rotators in the presence of anteversion so as not to push the individual into too much lateral rotation, which will induce arthrokinematic hypermobility (see the following section for further explanation).

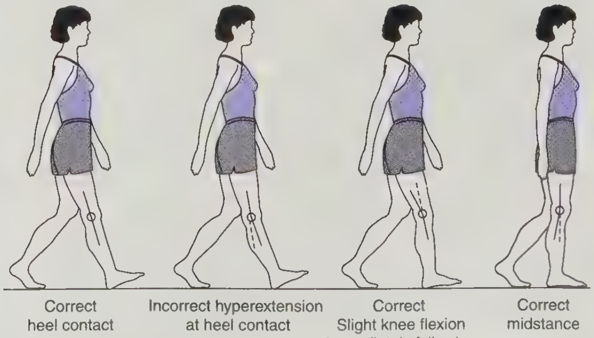
Individuals with hip anteversion can present with two unique hypermobility problems related to attempts to compensate for

Patient-Related Instruction 19-2

Walking with Knees over Toes

When you walk

- Your knee should be fully extended at the instant of heel strike, then immediately bend slightly to absorb shock. Do not let your knee lock back as you bring your weight over your foot. This hyperextension reduces your shock absorption and places undesirable stress on the ligaments and joint surfaces on your knees.
- Though your hip should turn inward slightly at heel strike, think of activating your deep hip lateral rotators to slow down this rotation and prevent your knee from turning in excessively as your body weight moves over your foot.
- Though your arch must drop a slight amount (pronation) at the time of heel strike in order to absorb shock, think of using your foot muscles to prevent your arch from dropping too low or too quickly as your body weight moves over your foot.
- Keep your abdominal muscles activated to prevent your pelvis from tilting forward. This is particularly important as your body weight moves in front of your foot and your hip must extend. If you do not activate your abdominal muscles, your pelvis may tilt or rotate instead of your hip extending.
- Be sure to roll through your foot to a full toe-off phase of gait. If someone were behind you, he or she could see the backs of your toes if you achieve full toe-off phase. This re-supinates your foot and prepares you for the next step.



the anatomic impairment. Persons with hip anteversion may engage in activities that promote extreme hip lateral rotation, such as ballet or soccer. The anteverted hip is forced to function in extreme LR for accurate performance of the activity. The head of the femur can be forced to translate excessively anteriorly and laterally to achieve the laterally rotated femur position,[224] often resulting in anterior groin pain. Hip joint hypermobility subsequently develops in an anterior and lateral direction.[224] Mounting evidence suggests a link between increased anteversion angles and OA.[225–230] It is possible that the anterolateral hypermobility seen in patients with anteversion may be a predisposing factor in the development of OA. To prevent or alleviate this impairment, the patient should be educated about his or her unique lower extremity biomechanics and LR ROM limitations. The therapist may need to counsel the individual to seek a recreational activity that does not require significant LR ROM.

Another common movement impairment that develops in the individual with anteverted hips is to achieve LR ROM by laterally rotating the tibia on the femur (see **Fig. 19-22**).[81] This is to be distinguished from tibial torsion, an anatomic impairment of the tibia bone twisting in an internal or external direction.[231] The person with this compensatory alignment should also be educated about his or her unique lower extremity biomechanics and hip LR ROM limitations to prevent rotational hypermobility problems at the tibiofemoral joint and potential knee joint pathology[225,232,233] (see **Building Block 19-3**).

Once isolated contraction of the deep hip stabilizer and abductor muscles is successfully achieved, progression can be made to the rehabilitation of secondary stabilizers and prime movers of the hip, particularly the gluteus maximus, initially using non–weight-bearing exercises and progressing to weight-bearing exercises once motor control and strength allow. Preactivation of the deep external rotators, iliopsoas, and gluteus minimus may make closed chain functional exercises more effective. Deficits in flexibility and proprioception should also be addressed at this stage with appropriate muscle lengthening and balance exercises. Once adequate hip muscle strength and endurance is achieved, functional and sports-specific exercises can then be implemented.

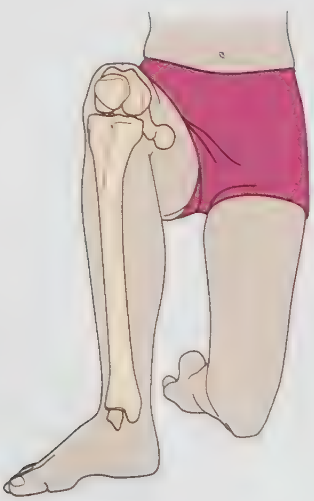


FIGURE 19-22 Excessive tibiofemoral rotation.

BUILDING BLOCK 19-3

Consider the 15-year-old female with generalized hypermobility. The patient is enrolled in ballet and tap dance classes. She complains of anterior and lateral hip pain that gets worse after dance. She presents with weakness of the GM and gluteus minimus, deep hip lateral rotators, poor transverse plane control with a squat, and no evidence of retro/anteversion. Develop three specific exercise interventions (include at least one closed chain exercise)and one taping technique for this patient to decrease her pain and increase her stability.

Hypomobility

Hypomobility impairments, particularly in the direction of flexion and medial rotation, can be found across all age populations. Subtle losses in flexion and MR may indicate early arthritic changes[76] or hypomobility caused by chronic lack of use, as a result of altered movement patterns. A fully established capsular pattern (see Display 19-1) can be a hallmark finding for the arthritic hip.[76] Recent advances in understanding cam morphology associated with FAI (see Fig. 19-4B) link loss of hip IR and adduction with morphologic changes to the head and neck of the femur as well as femoral and acetabular version angles[234] (see **Evidence and Research 19-9**).

EVIDENCE and RESEARCH 19-9

Passive ROM According to the Degree of Femoral Torsion or Acetabular Version

Decreased MR and adduction ROM, as found in FAI, is not solely dependent on the size or even the occurrence of cam morphology but should be interpreted by taking into account the overall hip anatomy, specifically femoral version and acetabular coverage. In a study by Audenaert et al.,[234] MR ROM at a neutral hip position was greatest (mean, 44.2 degrees) in hips with femoral anteversion and concomitant acetabular anteversion; conversely, it was least (20.1 degrees; $P < .001$) in hips with femoral retroversion and concomitant acetabular retroversion. Trends observed for LR ROM were consistently the opposite of those described for MR ROM. Hip flexion ROM was greatest (mean, 113.5 degrees) in hips with femoral anteversion and acetabular anteversion and least (103.8 degrees; $P = .011$) in hips with femoral anteversion and acetabular retroversion. Size of the cam lesion and ROM significantly differed between groups ($P < .05$). The range of MR on impingement testing was found to average 27.9 degrees in the healthy control group compared with 21.1 degrees in the asymptomatic control group with radiographic features specific to FAI ($P < .001$) and 12.3 degrees in the patient group ($P < .001$). Cam size, acetabular coverage, and femoral version appeared to be predictive variables for the range of MR. Seventy-five percent of variance between patients could be attributed to the combined effect of these three variables ($R = 0.86$).

Structural Impairments Contributing to Hypomobility

Mechanistically, hip MR is thought to introduce a mechanical conflict between the anterolateral femoral head–neck junction and the acetabulum, whereas LR results in posterior impingement that occurs extra-articularly between the greater trochanter and the ischium[235] and intra-articularly between the femoral head–neck junction and the posteroinferior aspect of the acetabulum.[236] In support of this view, Ross et al. demonstrated that a 10 degrees increase in anterior pelvic tilt (acetabular retroversion) caused mechanical conflict between the femur and acetabulum, reducing MR ROM.[237] PTs must consider the ramification of pelvic position on hip ROM limitations as well as structural impairments that might limit motion. In these instances, ROM exercises or mobilization would be contraindicated. However, every attempt should be made to improve 3D pelvic positioning, both at the total pelvic level and at the intrapelvic alignment levels (i.e., anterior pelvic tilt, lateral pelvic tilt, total pelvic rotation, intrapelvic torsion) (see Fig. 19-6).

Hypomobility Secondary to Degenerative Changes

Pain need not be an essential component of early arthritic changes and hypomobility findings. For example, OA (confirmed radiologically) leading to considerable restriction of range in the capsular pattern may not cause pain, even when the capsule is stretched quite hard.[76] This is a typical finding in middle-age men with a capsular pattern of restriction at the hip. Commonly, they have no complaints of hip pain or related activity limitation, but they may complain of LBP because of increased movement imposed on the back as a result of decreased hip mobility.

Emphasis has been placed on hip flexion and MR hypomobility impairments, but loss of hip extension ROM is another common finding, particularly in patients with end-stage hip arthritis. With myofascial or periarticular stiffness across the anterior hip, the pelvis may rest in a relative anterior tilt in relaxed standing. This posture may contribute to a relative increase in anterior pelvic tilt and lumbar extension to achieve an upright position (see **Fig. 19-23A**). On return from the forward bend, the patient leads with lumbar extension versus hip extension (Fig. 19-23B), the pelvis does not achieve a neutral position, and the anterior pelvic tilt imposes excessive lumbar extension to achieve an upright position (Fig. 19-23C).

A common finding associated with loss of hip extension ROM is positional weakness in the external oblique muscles, lower rectus abdominis, and transversus abdominis because of the chronically anterior tilted pelvis. Treatment of this impairment requires careful stretching of the affected hip flexor muscles concurrent with positional strengthening of the appropriate abdominal muscle groups (see Chapter 18).

Specific muscle length tests reveal which hip flexor muscles are contributing to the lack of hip extension ROM. Often, the diarthrodial hip flexors (i.e., rectus femoris and TFL/ITB, and sartorius) are stiff or short. Traditional stretches for the diarthrodial hip flexors do not follow the basic guidelines for optimal stretching because proximal stability is often not maintained (**Fig. 19-24**). Alternative stretches are recommended for optimal results. **Self-Management 19-6** illustrates an isolated passive diarthrodial hip flexor stretch. For maximal efficiency with this stretch, it is critical to maintain the stability of the pelvis and spine while maintaining the femur and tibia in a neutral position during knee flexion. To isolate the stretch to the TFL, slight LR and adduction of the femur at end range is suggested. Compensatory tibia LR may occur as the ITB is stretched. The patient must be cautioned to maintain tibiofemoral alignment by medially rotating the tibia during the stretch.

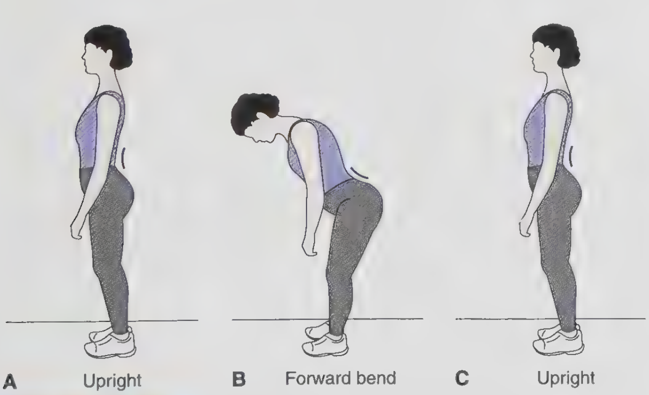

FIGURE 19-23 **(A)** Anterior pelvic tilt and lumbar lordosis. **(B)** On the return from forward bend the patient leads with lumbar extension versus pelvic extension. **(C)** If the pelvis stops rotating posterior before it reaches a neutral position, excessive lumbar extension is imposed on the spine to achieve an upright posture.

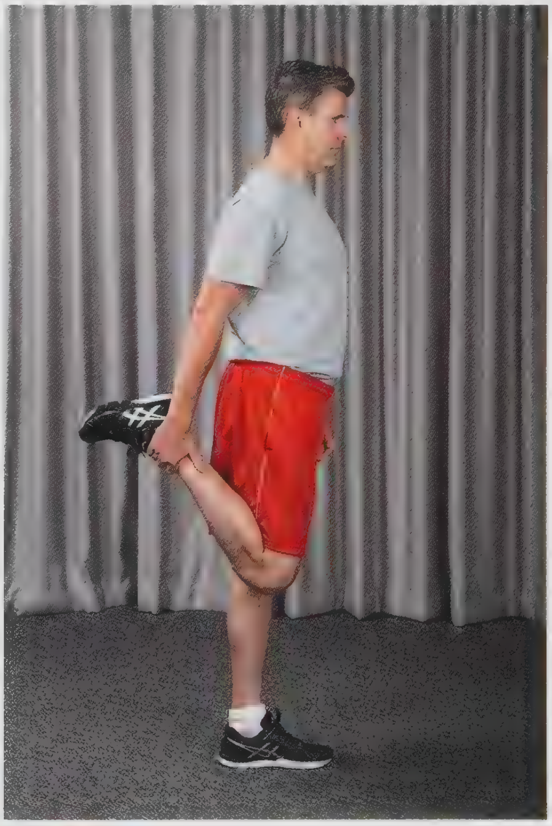

FIGURE 19-24 Traditional standing hip flexor stretches do not effectively stabilize the spine and pelvis. Note the anterior pelvic tilt and hip flexion in this individual attempting to perform this commonly used hip flexor stretch.

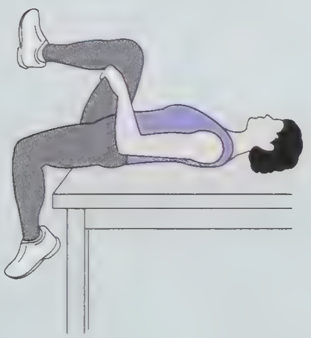
SELF-MANAGEMENT 19-6
Hip Flexor Stretch

Purpose: To stretch the front thigh muscles.

Start Position:
- Sit on the edge of a table so that your thigh is halfway off.
- Lie back while bringing both knees toward your chest.
- Pull your knees toward your chest until your low back just touches the tabletop surface.

Movement Technique:
- While grasping behind your knee, lower your other leg toward the floor, keeping your knee bent to 90 degrees. Your low back should maintain contact with the surface.
- Keep your thigh in the midline; do not let it drift out to the side.
- Do not let your thigh rotate inward.
- Variation: Let your thigh drop out to the side instead. Turn your lower leg inward. Gently pull your thigh toward midline until you feel slight tension in your iliotibial band.
- Hold for 15 to 30 seconds.



Dosage:

Sets/Repetitions: Repeat up to four times each limb

Frequency: ____________________

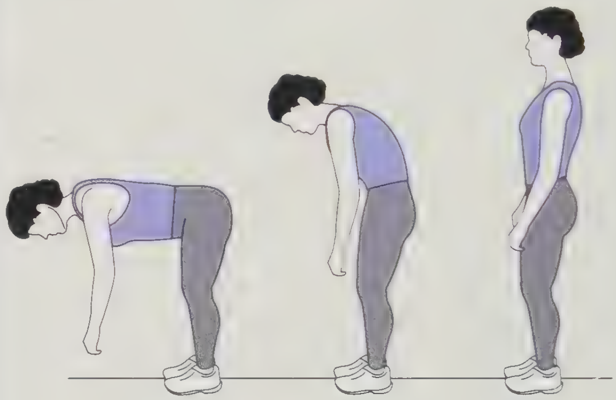
Self-Management 17-5 in Chapter 17 illustrates an active diarthrodial hip flexor stretch. This stretch uses active movement of knee flexion in an extended hip position to place repeated stretch on the diarthrodial hip flexors while contracting the abdominal muscles to stabilize the pelvis. As the abdominal muscles are recruited to stabilize the pelvis in this stretch, simultaneous elongation of the diarthrodial hip flexors and abdominal strengthening in the shortened range occur.

To ensure that gains in hip extension mobility are used in a functional context, the clinician must confirm that proper movement patterns are being used during functional activities. Optimal performance of functional movement patterns requires hip extension mobility and abdominal control to prevent anterior pelvic rotation and to achieve full hip joint extension.

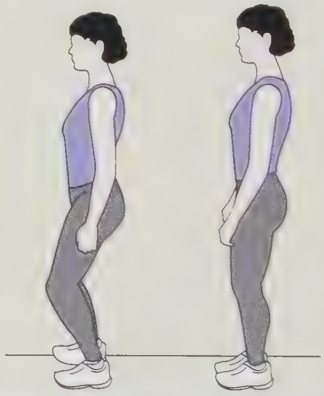
Patient-Related Instruction 19-3

Return from Forward Bending with a Neutral Pelvis

When You Come Up from Bending Forward
- Lead with your hips by activating your seat muscles.
- Do not arch your back. Avoid this by activating your inner core and gently pulling your belly button toward your spine.
- Complete the motion by bringing your pelvis back to neutral before finishing the spine movement.
- At the bottom of the motion, be sure your spine, buttock, and thigh muscles are fully relaxed before you reverse the motion.



When You Rise Upward from a Squatting Motion
- Be sure to complete the motion by fully extending your hips until your pelvis reaches neutral. Finish the motion with spine extension.
- Activate your inner core and abdominal muscles as you rise to ensure your pelvis remains in neutral. Your back extensors finish the motion.



Achieving control over hip extension and pelvic position during functional activities such as the late stance phase of gait (see Patient-Related Instruction 19-2), sit to stand, hip extension phase of squatting, and the return from forward bending (see **Patient-Related Instruction 19-3**) is necessary to ensure the specific ROM improvements are carried into ADLs.

Hypomobility Secondary to Altered Lumbopelvic Rhythm

Hip joint hypomobility may result from altered LP movement patterns because of a combination of anthropometric (e.g., high center of mass), occupational, and environmental (e.g., sports, recreation, hobbies) factors. It is hypothesized that, ultimately, as hip mobility decreases, lumbar and intrapelvic mobility increases. This finding has been demonstrated in measuring LP rhythm during forward bending,[238–242] particularly in the early phase of forward bending. The investigators of these studies found a significant relationship between a relative loss of hip flexion mobility and relative increased lumbar flexion mobility. Knowledge of this relationship is critical for the clinician prescribing exercise and retraining movement patterns. Functional activities such as bending forward to brush one's teeth, making the bed, and reaching into the refrigerator involve moderate amounts of hip and lumbar flexion. Hip stiffness resulting from reduced extensibility in capsule, ligament, or myofascial structures may impose excessive motion on the lumbar spine during forward-bending activities, which may ultimately lead to pathologic changes in the lumbar spine. Exercises to increase hip flexion mobility and lumbar stability, combined with retraining LP rhythm during forward-bending activities, are important to mitigate impairments associated with the cause of LBP in this particular patient subset. A useful exercise to retrain hip and lumbar movement is illustrated in **Self-Management 19-7**.

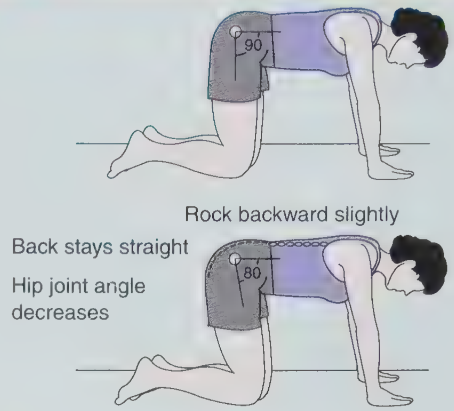
Hamstring Length as a Source of Hip Hypomobility

The hamstrings have been implicated as a potential source of hip stiffness.[242] A common stretch for the hamstrings is illustrated in **Figure 19-25**. A selective medial or lateral hamstring stretch can be induced by rotating the hip in the medial direction to stretch the lateral hamstrings and lateral direction to stretch the medial hamstrings. Because the hamstrings are a diarthrodial muscle, knee extension must be maintained while the hip flexes to ensure optimal stretch stimulus. After the hamstrings have been stretched passively, an active exercise should be performed to ensure the new length is used during function. One exercise that uses hamstring length during an active movement pattern is illustrated in **Self-Management 19-8**.

Sequelae to Hip Hypomobility

Other regions in the kinetic chain that may become stressed because of a relative loss of mobility in the hip joint are the lumbar spine and the knee. During squatting movements, loss of hip flexion ROM may impose increased motion on the lumbar spine in the direction of flexion (**Fig. 19-26A**) and/or the knee joint via excessive knee flexion (Fig. 19-26B). Loss of hip joint mobility is a common finding in persons complaining of overuse-related knee conditions such as patellofemoral dysfunction and patellar tendinopathy. Improved hip joint ROM and muscle performance of the gluteus maximus coupled with improved squatting movement patterns can reduce the stress on the knee joint. Progressive squatting exercises with optimal kinematics at the hip and knee are recommended to decrease excessive forces at the low back and knee (see **Self-Management 19-9**).

SELF-MANAGEMENT 19-7
Hand-Knee Rocking



Purpose: To improve the ROM of your hips, stretch the posterior hip muscles, and train independent movement between your hips, pelvis, and spine.

Start Position:
- Position yourself on your hands and knees so that your hips are directly over your knees and hands are directly under your shoulders.
- Knees and ankles should be hip-width apart with feet pointing straight back.
- Your spine should be flat with a slight curve downward in your low back and your pelvis tilted so that your hip joint is at a 90-degree angle.

Movement Technique:
- Rock backward at the hip joint only. Stop at any sensation of movement in your back.
- Variation: Your physical therapist may ask you to gently squeeze a ball or towel roll between your heels to activate your deep hip lateral rotators. This will help to stabilize your hip in the socket and prevent excessive flexion at the hip joint.

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________

Balance

Approximately 25% to 35% of persons older than 65 years experience one or more falls each year.[243–245] Falls are a leading cause of morbidity and mortality of persons older than 65 years,[246,247] and many of the falls result in hip fractures.[248] Hip fracture is an international public health problem. Worldwide, approximately 1.5 million hip fractures occur per year, with roughly 340,000 in the United States in individuals older than 65 years.[249] In 2050, there will be an estimated 3.9 million fractures worldwide, with more than 700,000 in the United

SELF-MANAGEMENT 19-9

Progressive Squat *(continued)*

A B C

States.[249] The hip fracture rate in the United States is about twice as high for women as for men,[250,251] and residents of nursing homes have been reported to have a 3 to 11 times greater risk than non–nursing home residents of hip fracture in the United States,[252] Netherlands,[253] France,[254] and Finland.[255] Hip fracture has a high impact on patients' health and medical costs. A high risk for hip fracture is predicted by low bone density, calcium, and vitamin D levels,[256] prior fragility fractures, and a high risk of falling.[257–259] Benzodiazepine treatment is also known to increase the risk of hip fracture in older populations by 50%.[260] Improved postural stability during functional activities is complex and multifaceted involving not only balance but also other internal factors such as strength, proprioception, integrity of the neuromuscular system, **pain**, vision, and in some instances fear of falling[261,262] (**Evidence and Research 19-10**).

T'ai chi has been valuable in promoting posture stability and balance control in the well elderly.[264–267] The T'ai chi progression (i.e., bipedal weight shifting to uniped positions) focuses less on centering the center of mass within the base of support and more on learning corrective strategies for instability. The advanced forms serve the purposes of destabilizing the individual in a controlled fashion, engaging new movement strategies and facilitating the confidence level of the participant.

Force-platform biofeedback systems can also be used to train posture stability and balance control. However, the focus of force-platform biofeedback systems is different than that of T'ai chi balance training. The former is typically concerned

EVIDENCE and RESEARCH 19-10

Exercise Intervention for Balance

A 2011 Cochrane Review presented the best evidence for effectiveness of exercise interventions designed to improve balance in older people living in the community or in institutional care.[263]

The general direction of findings presented a positive effect of exercise on balance immediately post intervention, but typically not maintained on cessation of the intervention. A cautious interpretation of the available evidence is necessary, particularly given the extent of the missing data for primary outcomes. From the data available, this systematic review provides some evidence that some exercise types compared with usual activity are moderately effective, at least immediately post intervention, in improving clinical balance outcomes in older people. These data show that exercise programs involving gait, balance, coordination and functional exercises, strengthening exercise appear to improve at least some "indirect" quantifiable measures of balance such as the Timed Up and Go test, single-leg stance, walking speed and a global subjective measure of balance, the Berg Balance Score. Although the duration and frequency of these exercise programs vary, in general, the effective programs ran three times a week for 3 months and involved standing, challenging balance exercises. Where studies provided data following cessation of exercise, there was no evidence of differences between exercise and control groups, probably indicating that the positive effects on balance are only evident while the patient is engaged in programs.

with learning to enhance center of mass or center of pressure movement within the limits of stability, and the latter is concerned with learning controlled motions as those limits are passed. Furthermore, the force-platform–based systems utilize visual feedback to the patient, which may not be as effective as other types of intrinsic feedback, such as proprioception.[268] Controlled clinical studies have not demonstrated a reduction in falls or delays in fall occurrences among older persons using force-platform biofeedback systems.[269] This may be because the ability to control the center of pressure during quiet standing or with the added provision of random but moderate perturbations, used during typical machine-based postural training, may not translate well into functional situations.

The ability to effectively treat patients with balance disorders can be enhanced by a clearer understanding of the problems underlying balance. Treatment of impaired balance must focus on the intrinsic and extrinsic factors related to the balance disorder. This requires extensive examination and evaluation of muscle performance, ROM, joint mobility, vestibular function, balance reactions, and environmental factors. Clinicians trained in balance-related rehabilitation have shown that compliance with a multidimensional, individualized exercise program that addresses the impairments and activity limitations associated with balance deficits can improve balance and mobility function and reduce the likelihood of falls.[67]

Display 19-8 lists general guidelines that can assist the practitioner in developing balance training activities for the hip, and **Display 19-9** describes a sample progression of balance tasks (see **Building Block 19-4**).

DISPLAY 19-8
Guidelines for Balance Training Activities

- In treating balance impairments with training programs, including T'ai chi, progressive drills, and computerized balance devices, the specific demands of compensatory stepping or grasping reactions that are found to cause difficulty (e.g., lateral weight transfer, rapid foot or arm movement, crossover steps) should be addressed. These skills can be addressed through unpredictable exercise conditions, such as the use of dense foam or having an outside perturbation such as a partner pushing or pulling the patient off balance. Cautious progression toward uniped motions is indicated, especially because this position is experienced by most older persons before falling.
- When training balance control, stepping and grasping reactions are not just strategies of last resort. These strategies can be initiated very early, well before the center of mass is near the stability limits of the base of support.[269] One goal of balance training may be to reduce the incidence of stepping and grasping strategies as posture stability and balance are increasingly challenged. Display 19-9 provides examples of progressive uniped balance tasks. The goal of the exercise would be to balance on one limb, with the progressive self-induced perturbations (e.g., arm movements), without using a grasping or stepping strategy to prevent a fall.
- For anteroposterior perturbations, the fixed-support ankle strategy (i.e., ankle muscular response to arrest the motion of the center of mass) may provide an early defense against destabilization, followed by a stepping or grasping strategy.[269] When using an anteroposterior destabilizing force (e.g., uniped with sagittal arm movements), we expect the ankles to provide the stabilizing force to maintain postural stability.
- A fixed-support hip strategy (i.e., hip muscular response to arrest the motion of the center of mass) may be limited to a special task condition that precludes the option of stepping or grasping.[269] Use of a fixed-support hip strategy would be inappropriate under normal conditions.
- Lateral destabilization complicates the control of compensatory stepping because of anatomic or physiologic restrictions on the lateral lower extremity movement and the associated prolonged uniped balance demand. Aging appears to be associated with increased difficulty in controlling lateral postural stability, which may be of specific relevance to the problem of lateral falls associated with hip fractures.[270] Exercises designed to provide frontal plane destabilizing forces (e.g., uniped with frontal plane arm movements) would especially be indicated in the aging population. Side-stepping strategies for recovery to prevent a fall are important skills for this population to learn.
- Assistive devices can aid the individual in balance control before developing functional balance control through a comprehensive training program. Use of a cane in the nondominant hand has reduced the rate of falls by up to fourfold.[271] Cutaneous information from fingertip contact, through a cane, and from a stable surface is more powerful than vision in stabilizing sway in stance.[271]

DISPLAY 19-9
Examples of Progressive Balance Tasks

- Balance on one leg on a firm surface is progressed to an unstable surface such as dense foam.
- Balance on one leg while rotating the head on a firm surface is progressed to dense foam.
- Balance on one leg with frontal, sagittal, or transverse plane arm movements on a firm surface is progressed to dense foam.
- Perform the previous balance task, but follow the arm movements with the eyes and head.
- Balance on one leg and move the trunk and upper body into contralateral flexion and rotation (i.e., reach for inside of ipsilateral ankle and foot) and ipsilateral extension and rotation (i.e., reach for object superior, lateral, and posterior to the head), and follow the arm movements with the eyes and head.
- Perform the previous three exercises while holding a weighted ball.

BUILDING BLOCK 19-4

An 81-year-old male is referred to you with a diagnosis of "poor balance" and orders to "evaluate and treat." The patient ambulates very slowly, with short step length, flexed, rigid posture, and no assistive device. The patient can only stand on one leg for 1 to 2 seconds and presents with increased sway even during quiet standing. The patient also presents with decreased flexibility of the hip flexors and adductors. Develop three interventions to improve this patient's safety and maximize his function.

Posture and Movement Impairment

Posture and movement training of the hip is used to optimize kinetics and kinematics at the hip joint as well as to positively affect the kinetics and kinematics of other joints in the kinetic chain. Similarly, posture and movement training of other joints in the kinetic chain can influence the kinetics and kinematics of the hip. Intervention focusing on posture and movement is pivotal to all therapeutic exercise interventions. Exercise should be taught with careful attention to details of posture and movement. All patients should be provided with instruction in avoiding posture and movement habits that contribute to the cause of symptoms and in developing alternative habits that will reduce or eliminate symptoms.

With respect to hip alignment, it is important to understand that pelvic tilt is not the only factor contributing to hip joint angle in the sagittal plane. Knee joint angle can also affect hip joint angle. For example, when the knees are flexed, the hips are flexed, even if the pelvic tilt is near neutral, and when the knees are hyperextended, the hips will be extended, even if the pelvic tilt is slightly anterior (**Fig. 19-27**). Be sure to correct for pelvic tilt *and* knee joint angle when treating posture impairments at the hip. This holds true for transverse and frontal plane posture impairments as well.

Movement impairments at the hip, as with posture impairments, can be affected by impairments at other segments. The cause of any given hip movement impairment must be diagnosed from the data collected during the examination of the patient. For example, limited hip flexion during a step-up activity may result from a loss of hip flexion ROM, reduced joint mobility, weakness in the hip flexors, or poor trunk stabilization. Only a thorough examination can reveal the cause of the movement impairment. Once the underlying cause(s) are established, an appropriate intervention can be developed to manage the associated impairments.

To affect a posture or movement change, mobility, length–tension properties, and muscle performance must be at functional levels, and kinesthetic awareness about joint position, joint motion, or a specific muscle recruitment pattern must be developed.

The initial focus of any intervention should be on improving impairments of body functions to a functional level. After these impairments have achieved a functional level of capacity, gradual transition from specific exercises, addressing physiologic impairments to greater emphasis on posture and movement patterns used during functional exercise, and activities should occur until the primary emphasis is on functional retraining. Examples of exercises to improve posture and movement of the hip joint are presented throughout this chapter.

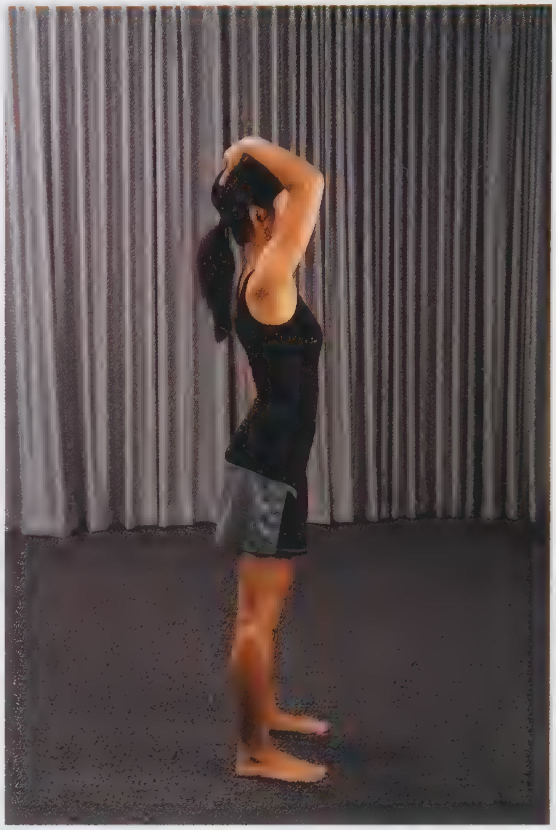


FIGURE 19-27 Note the anterior pelvic tilt. When the knees are hyperextended, the hips will be extended, even if the pelvic tilt is anterior.

Limb Length Discrepancy

Although limb length discrepancy (LLD) is not considered a postural impairment isolated to the hip, it is discussed here because of its functional implication at the hip as the transmitter of forces from the ground and lower extremities to the trunk and upper extremities. FLLD is the most difficult form to diagnose and treat. Nearly any movement of an osseous segment out of its normal plane of reference in relation to other bones can create a shorter or longer distance between proximal and distal reference points. Altered osseous positions can occur about any axis of motion and in any segment. Minor alterations in position in any one segment, when added to minor alterations in position of other segments, can lead to a substantial LLD.

To further complicate matters, FLLD can coexist with SLLD—sometimes exaggerating the LLD and sometimes compensating for the LLD. For example, a structurally longer limb may compensate for its length with lateral pelvic tilt, knee flexion, or foot pronation. After the type of LLD and the segments involved are accurately diagnosed as functional, structural, or combined LLD, appropriate intervention must be determined.

Treatment of LLD ranges from posture and movement training to shoe inserts to various surgical techniques including limb lengthening and shortening and epiphysiodesis. After it has been determined that the LLD is not completely amenable to posture and movement training, other nonsurgical or surgical interventions are indicated. There is disagreement regarding the correct treatment in regard to magnitude of LLD (**Evidence and Research 19-11**).

EVIDENCE and RESEARCH 19-11

Limb Length Discrepancy

Reid and Smith[272] suggest dividing LLD into three categories: mild (0 to 30 mm), moderate (30 to 60 mm), and severe (>60 mm), in which mild cases should go either untreated or treated nonsurgically, moderate cases should be dealt with on a case-by-case basis and some should be dealt with surgically, and severe cases should be corrected surgically. Moseley suggests a similar breakdown: 0 to 20 mm requiring no treatment, 20 to 60 mm requiring a shoe lift, epiphysiodesis, or shortening, 60 to 200 mm requiring lengthening that may or may not be combined with other procedures, and >200 mm prosthetic fitting.[273]

Structural Leg Length Discrepancy The most common treatment for mild SLLD is the use of shoe lifts, which consists of a heel lift, shoe insert, or building up the sole of the shoe on the shorter leg. In general, up to 20 mm of correction can be made with an insert, whereas further corrections should be done on the sole of the shoe.[274–275] If an equinus anatomic impairment exists, a heel lift is more appropriate than a full-sole lift. The amount of lift prescribed depends on the limb length difference and the patient's physiologic tolerance to change. Individuals with long-standing, significant structural discrepancies generally do not tolerate significant, rapid change because of the osseous and soft tissue adaptations that have developed over time. Minimal height adjustments at infrequent intervals should be made until the maximal necessary change has occurred.

Functional Limb Length Discrepancy Treatment of FLLD should consider the physiologic impairments at each involved segment and the interactions between levels. For example, a functionally short limb caused by femoral and tibial MR and by foot pronation could have associated impairments of the following:

- Lengthened or weak posterior GM and deep hip lateral rotators
- Lengthened or weak foot supinators
- Forefoot or rearfoot varus

Appropriate exercises combined with posture and movement training are necessary to alleviate the related impairments. Biomechanical support can be supplemented if necessary.

Patients with FLLD related to lower extremity kinetic chain pronation (i.e., femur MR, genu valgum, and foot pronation) may benefit from temporary or permanent foot orthotics to assist in controlling pronation throughout the kinetic chain. However, caution must be used in prescribing orthotics to remedy physiologic impairments up the kinetic chain. Exercises to alleviate impairments of body functions contributing to pronation should be attempted first. If performance demands exceed the ability to control pronation, use of orthotics may be a useful adjunct.

Cautious use of sole or heel lifts to compensate for an FLLD is recommended. The faulty strategy of displacing the center of mass over the base of support used by a patient with an FLLD does not necessarily alter with a lift. The more common scenario is for the individual to continue with the same faulty strategy, thereby enhancing the FLLD. For example, during the initial contact phase of gait, the short limb may be functionally short as a result of positioning the hip in adduction with minimal displacement of the center of mass over the base of support. After adding a lift, a similar gait strategy may continue to be used, causing further exaggeration of the LLD. Often, training the patient to properly position the hip and accurately displace the center of mass over the base of support alleviates the LLD without the need for orthotic correction (see Self-Management 19-2, Levels I and II).

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON DIAGNOSES

Although it is beyond the scope of this text to present a comprehensive description and intervention plan for all diagnoses affecting the hip joint, a few selected diagnostic categories are presented. A brief overview of the etiology, examination/evaluation findings, and proposed intervention, with emphasis on therapeutic exercise, is presented for each diagnosis.

Osteoarthritis

OA is the most common form of arthritis, affecting ~27 million adults in the United States.[276] Among US adults 30 years of age or older, symptomatic disease in the hip occurs in approximately 3%.[274] OA increases with age, and sex-specific differences are evident.[277–280] Other risk factors for hip OA include developmental disorders (Legg–Calvé–Perthes disease, congenital hip dislocation, slipped capital femoral epiphysis), genetics, previous injury, sports exposure, and leg length disparity.[57] Because OA is a disease whose prevalence increases with age, it will become even more prevalent in the future as the bulging cohort of baby boomers grows older.

OA is a complex disease whose etiology bridges biomechanics and biochemistry. Evidence is growing for the role of systemic factors (such as genetics, dietary intake, estrogen use, and bone density) and of local biomechanical factors (muscle weakness, obesity, and joint laxity). These risk factors are particularly important in weight-bearing joints, and modifying them may present opportunities for prevention of OA-related pain and disability. The reader is referred to Chapter 12 for an in-depth discussion of the etiology of OA (**Evidence and Research 19-12**).

EVIDENCE and RESEARCH 19-12

Hip Osteoarthritis

OA is a common and disabling disease. Because of improved treatment of chronic diseases and lower mortality from infectious diseases, the US population is aging, and older Americans are living with disabling conditions, including hip OA. The projected number of older adults with arthritis or other chronic musculoskeletal joint symptoms is expected to nearly double, from 21.4 million in 2005 to 41.1 million by 2030.[281] The burden of hip OA is increasing due to the aging population and the obesity crisis; as a result, the need for THA is expected to grow 174%, to 572,000 primary THAs per year by 2030 in the United States.[281] Genetic factors play a role in both the incidence and, very likely, the outcome of OA. It has been proposed that generalized OA (involvement of at least three joints) may be a distinct disease in which systemic (genetic) predisposition (nodal OA, associated with Heberden's or Bouchard's nodes) is more important than local environmental (e.g., mechanical) factors. It is possible that bilateral THA and younger age at surgery is also associated with genetic traits. However, it is complicated by coexisting local morphologic characteristics resulting from biomechanical stress. For example, mild acetabular dysplasia, nonspherical femoral head shape, neck-shaft angle may lead to abutment of the femoral head–neck junction against the anterior rim of the acetabulum during flexion of the hip, leading initially to labrochondral damage and ultimately to early degeneration of the joint.[282] Additional theories are proposed for developmental risk factors such as stress across the growth plate during late childhood and early adolescence predispose patients to develop morphology that may contribute to early OA.[283] If this is the case, closer attention should be paid to the stresses across the hips of children and adolescents during development, particularly with those individuals at risk of a genetic predisposition.

Diagnosis

Proper diagnosis of a patient with hip OA requires a careful history, physical examination, and review of appropriate radiographic and laboratory studies. The presence of radiographic changes (e.g., joint space narrowing, moderate malalignment, osteophytes at the marginal aspects of the joint) should correlate with positive examination findings at the hip joint to arrive at a diagnosis of hip OA. A positive radiographic finding alone does not indicate that the hip OA is the source of symptoms, because many other musculoskeletal and nonmusculoskeletal sources can mimic hip joint pain. Hip OA is a common sequelae of aging and is not always symptomatic. Many people with pathologic and radiographic evidence of OA have no symptoms.[284]

Gradual, progressive, chronic pain can be associated with hip OA. Intra-articular pain is usually described as deep, aching pain and can be experienced in the groin, around the greater trochanter, medial knee, and posterior buttock. Long periods of rest may result in joint stiffness. The stiffness of OA is not as severe as that of rheumatoid arthritis. Mild activity usually dissipates the stiffness. A clinical prediction rule for the diagnosis of hip OA is described in **Display 19-10.**

DISPLAY 19-10

Clinical Prediction Rule for Diagnosing Hip Osteoarthritis

If at least four of five variables were present, the positive likelihood ratio was equal to 24.3 (95% CI 4.4 to 142.1), increasing the probability of hip OA to 91%.

Variables

- Self-reported squatting as an aggravating factor
- Active hip flexion causing lateral hip pain
- Scour test with adduction causing lateral hip or groin pain
- Active hip extension causing pain
- Passive MR of less than or equal to 25 degrees

Sutlive TG, Lopez HP, Schnitker DE, et al. Development of a clinical prediction rule for diagnosing hip osteoarthritis in individuals with unilateral hip pain. J Orthop Sports Phys Ther 2008;38(9):542–550.

Treatment

Major advances in management of OA to reduce pain and disability are yielding an impressive array of available treatments ranging from acupuncture to chondrocyte transplantation, new oral anti-inflammatory medications, and patient-related instruction. Evidence for the efficacy of commonly used oral therapies, alternative therapies, biomechanical interventions, such as exercise, and behavioral interventions directed toward enhancing self-efficacy and self-management is mounting (see **Display 19-11**). In the vast majority of cases, surgical treatment of OA is considered only after failure of nonsurgical treatments.[125] Recently, biologic approaches to the surgical treatment of OA have been explored.[275,306] Over the last decades, more than 50 modalities of nonpharmacologic, pharmacologic, and surgical interventions for hip and knee OA have been described in the medical literature and integrated into international, monodisciplinary, and interdisciplinary clinical guidelines[307–309] (see **Table 19-4**)

The following sections will review concepts related to therapeutic exercise intervention for the treatment of impairments related to hip OA. These concepts are introduced to assist in the prevention of surgical intervention. However, if surgery is necessary, many of these concepts can be implemented in postsurgical care as well. Many impairments preceding THA

DISPLAY 19-11

Nonoperative Treatment of OA

- Systemic and topical treatments (i.e., nonopioid analgesics, nonsteroidal anti-inflammatory drugs [NSAIDs], opioid analgesics, chondroitin and glucosamine, and topical analgesics)[285–292]
- Acupuncture[293,294]
- Intra-articular injection of corticosteroids[295,296]
- Intra-articular injection of hyaluronic acid[297]
- Assistive devices[124,298]
- Patient education[299–301]
- Exercise[302–304]
- Manual therapy[305]

TABLE 19-4

Management of Osteoarthritis (OA)

General

1. Optimal management of OA requires a combination of nonpharmacologic and pharmacologic modalities

Nonpharmacologic Modalities of Treatment

2. All patients with hip and knee OA should be given information access and education about the objectives of treatment and the importance of changes in lifestyle, exercise, pacing of activities, weight reduction, and other measures to unload the damaged joint(s). The initial focus should be on self-help and patient-driven treatments rather than on passive therapies delivered by health professionals. Subsequently emphasis should be placed on encouraging adherence to the regimen of nonpharmacologic therapy.
3. The clinical status of patients with hip or knee OA can be improved if patients are contacted regularly by phone.
4. Patients with symptomatic hip and knee OA may benefit from referral to a physical therapist for evaluation and instruction in appropriate exercises to reduce pain and improve functional capacity. This evaluation may result in provision of assistive devices such as canes and walkers, as appropriate.
5. Patients with hip and knee OA should be encouraged to undertake, and continue to undertake, regular aerobic, muscle strengthening and ROM exercises. For patients with symptomatic hip OA, exercises in water can be effective.
6. Patients with hip and knee OA, who are overweight, should be encouraged to lose weight and maintain their weight at a lower level.
7. Walking aids can reduce pain in patients with hip and knee OA. Patients should be given instruction in the optimal use of a cane or crutch in the contralateral hand. Frames or wheeled walkers are often preferable for those with bilateral disease.
8. In patients with knee OA and mild/moderate varus or valgus instability, a knee brace can reduce pain, improve stability, and diminish the risk of falling.
9. Every patient with hip or knee OA should receive advice concerning appropriate footwear. In patients with knee OA, insoles can reduce pain and improve ambulation. Lateral wedged insoles can be of symptomatic benefit for some patients with medial tibiofemoral compartment OA.
10. Some thermal modalities may be effective for relieving symptoms in hip and knee OA.
11. Transcutaneous electrical nerve stimulation (TENS) can help with short-term pain control in some patients with hip or knee OA.
12. Acupuncture may be of symptomatic benefit in patients with knee OA.

Pharmacologic Modalities of Treatment

13. Acetaminophen (paracetamol) (up to 4 g/d) can be an effective initial oral analgesic for treatment of mild to moderate pain in patients with knee or hip OA. In the absence of an adequate response, or in the presence of severe pain and/or inflammation, alternative pharmacologic therapy should be considered based on relative efficacy and safety, as well as concomitant medications and comorbidities.
14. In patients with symptomatic hip or knee OA, NSAIDs should be used at the lowest effective dose but their long-term use should be avoided if possible. In patients with increased gastrointestinal risk, either a COX-2 selective agent or a nonselective NSAID with co-prescription of a proton pump inhibitor or misoprostol for gastroprotection may be considered, but NSAIDs, including both nonselective and COX-2 selective agents, should be used with caution in patients with cardiovascular (CV) risk factors.
15. Topical NSAIDs and capsaicin can be effective as adjunctives and alternatives to oral analgesic/anti-inflammatory agents in knee OA.
16. Intra-articular (IA) injections with corticosteroids can be used in the treatment of hip or knee OA, and should be considered particularly when patients have moderate to severe pain not responding satisfactorily to oral analgesic/anti-inflammatory agents and in patients with symptomatic knee OA with effusions or other physical signs of local inflammation.
17. Injections of IA hyaluronate may be useful in patients with knee or hip OA. They are characterized by delayed onset, but prolonged duration, of symptomatic benefit when compared to IA injections of corticosteroids.
18. Treatment with glucosamine and/or chondroitin sulfate may provide symptomatic benefit in patients with knee OA. If no response is apparent within 6 months, treatment should be discontinued.

(continued)

TABLE 19-4 (continued)

Management of Osteoarthritis (OA)

19. In patients with symptomatic knee OA, glucosamine sulfate and chondroitin sulfate may have structure-modifying effects while diacerein may have structure-modifying effects in patients with symptomatic OA of the hip.

20. The use of weak opioids and narcotic analgesics can be considered for the treatment of refractory pain in patients with hip or knee OA, where other pharmacologic agents have been ineffective, or are contraindicated. Stronger opioids should only be used for the management of severe pain in exceptional circumstances. Nonpharmacologic therapies should be continued in such patients and surgical treatments should be considered.

Surgical Intervention

21. Patients with hip or knee OA who are not obtaining adequate pain relief and functional improvement from a combination of nonpharmacologic and pharmacologic treatment should be considered for joint replacement surgery. Despite best practice in conservative therapy, if significant symptoms persist and functional limitations are associated with reduced health-related quality of life, replacement arthroplasties can be effective and cost-effective interventions for patients.

22. Osteotomy and joint preserving surgical procedures should be considered in young adults with symptomatic hip OA, especially in the presence of dysplasia.

do not disappear as a result of the surgery and often need to be dealt with postoperatively.

Pain and Inflammation Management of pain and inflammation for hip OA can follow the general guidelines discussed in a previous section (see Display 19-2). Activity modification may be one of the most significant aspects of treatment for pain and inflammation. The changes may include modification of basic and instrumental ADLs. The patient should be instructed in joint protection techniques during prolonged postures (i.e., standing with equal weight bearing on both feet, or, if necessary, using an assistive device) and common movement patterns (i.e., carrying heavy loads in the hand on the involved side or in both hands equally).[122,124] The patient canmoderate vigorous weight-bearing activities (e.g., walking vs. running or doubles vs. singles tennis) and add non–weight-bearing activities (e.g., biking, swimming, water aerobics) to provide ample exercise stimulus required to lower or maintain BMI.

Specific to hip OA, treatment addressing the mechanical nociceptive trigger should focus on altering the biomechanics of the hip. The degeneration in OA is caused by a breakdown of chondrocytes, which are an essential element of articular cartilage. This breakdown may be initiated by biomechanical stress. A primary goal of the intervention should be to alter biomechanical forces acting on the joint. Restoring joint ROM, tissue extensibility, and motor control in flexion, extension, MR, and abduction and restoring dynamic muscle performance of GM, minimus, maximus, deep hip lateral rotators, and iliopsoas enables the joint to function with improved femoroacetabular congruence and more diffuse load-bearing surfaces. Focus on reducing maladaptive movement patterns can lessen the biomechanical stress to the focal area of degenerative joint disease and result in decreased pain.

Range of Motion and Joint Mobility Exercises aimed at ROM and joint mobility may include passive (**Figs. 19-28** and **19-29**) and active stretching (Self-Management 197), and mobilization in the affected directions (see Chapter 7). When performing passive stretching, care must be taken to stabilize the pelvis, SIJ, and lumbar region and guide the hip in the acetabulum to prevent impingement. Active exercises should be employed whenever possible. Active exercises improve ROM and joint mobility with the added bonus of recruitment of the muscles necessary to move the joint in the desired direction during function. Examples of active exercises to improve hip mobility in persons with hip OA are shown in Self-Management 19-7 and Self-Management 19-9. Another useful technique to teach the patient with OA in the hip is self-traction (**Fig. 19-30**).

Muscle Performance The patient can be instructed in specific exercises to improve muscle performance (see Self-Managements 19-1, 19-4, and 19-5). Whenever possible, functional exercises should be employed. For example, chair squats or standing on the involved hip in neutral hip joint alignment and lifting the uninvolved hip onto a step can stimulate hip abductor recruitment on the weight-bearing side. However, weight-bearing exercises on a hip with OA may exacerbate symptoms, particularly if the alignment is faulty or muscle recruitment is maladaptive. Adjunctive use of a cane, walking stick, ski pole, or dowel rod in the contralateral hand during weight-bearing exercise can reduce the amount of work necessary for the ipsilateral hip abductors. This approach reduces the joint reaction force and joint pain and increases tolerance to weight-bearing exercise (**Evidence and Research 19-13**).

Another method to reduce the joint reaction force enough to allow weight-bearing exercise is to hold a weight in the hand on the involved side.[122–124] Biomechanically, holding a weight on the involved side will move the center of mass laterally, toward the affected hip, thereby decreasing the length of the lever arm and decreasing the force generation needed by the hip abductors. The amount of weight can be graded to use the least amount necessary to reduce pain and allow optimal alignment during the step-up activity.

Regardless of the method used to unload the hip, the appropriate strategy for unilateral balance must be reinforced. A healthy joint is dependent on the neuromuscular system to provide movement, joint stability, shock absorption, and proprioception. The results of Sims and Richardson's study[313] (**Evidence and Research 19-14**) suggest that at least part of the muscle dysfunction associated with hip OA may be a loss of precision rather than strength. Rehabilitation programs for patients in whom pain and disability are not severe should therefore include an emphasis

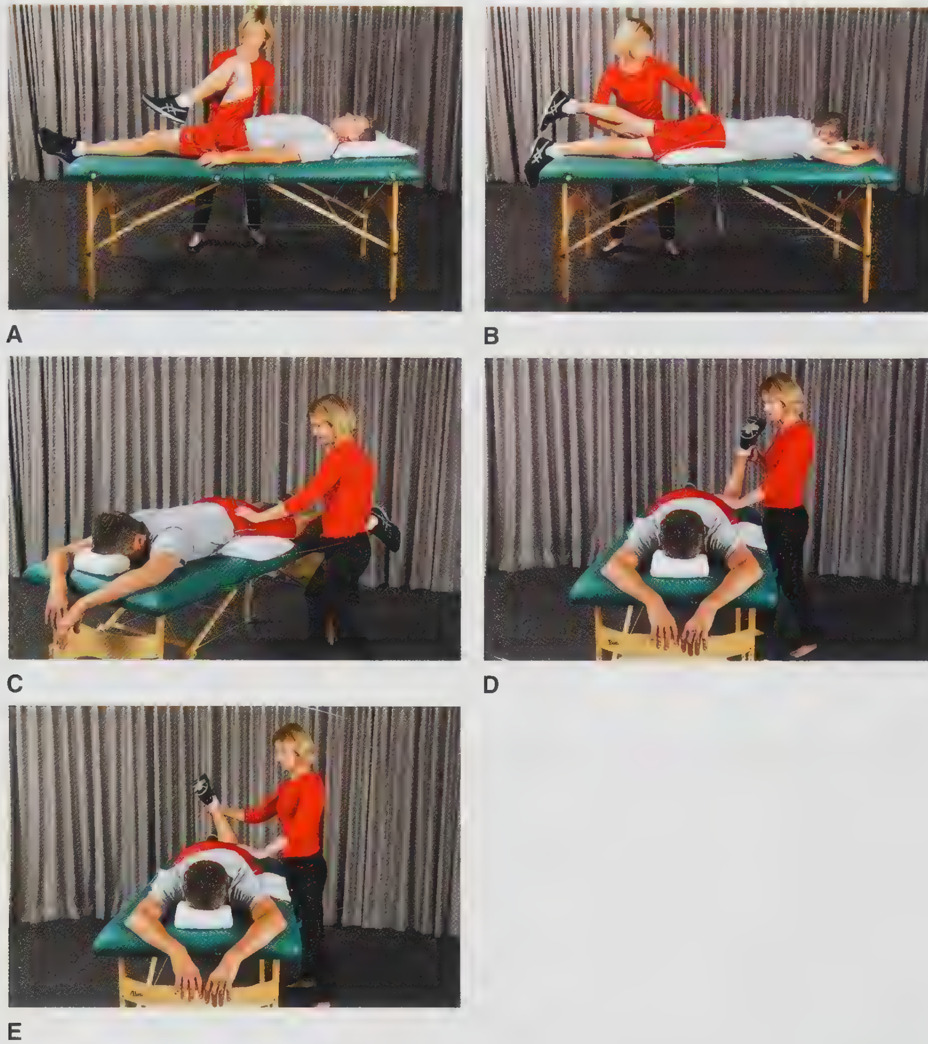

FIGURE 19-28 Passive ROM to the hip in **(A)** flexion, **(B)** extension, **(C)** abduction, **(D)** medial rotation, and **(E)** lateral rotation. Note the stabilization of the pelvis to make certain that movement occurs at the hip in isolation. In the case of hip flexion, a simultaneous posterior-inferior glide of the head of the femur can reduce anterior hip impingement that occurs with a stiff posterior joint.

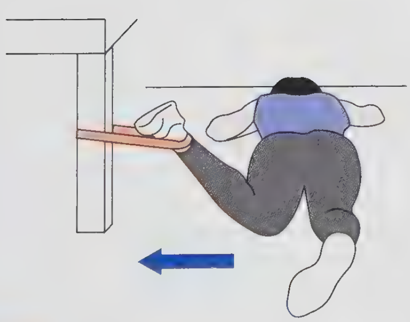

FIGURE 19-29 Prone hip MR stretch with elastic. The patient is instructed to stabilize the pelvis in sagittal and transverse planes via inner core contraction. It is important to keep the femur in contact with the floor to ensure a precise rotational stretch. If the hip flexors are short, use of a pillow under the hips can allow the knee to flex 90 degrees with minimal compensatory hip flexion. This exercise is contraindicated in the presence of knee pathology.

FIGURE 19-30 Self-traction of the hip. The involved limb is given traction by the use of a belt or other stiff material around the ankle which is secured in a door jam, whereas the contralateral limb pushes off a surface as shown. This technique can provide a decompression stress to the joint and stretch the joint capsule.

EVIDENCE and RESEARCH 19-13

Use of a Cane

By using a cane, subjects decreased vertical and shear ground reaction forces on the affected limb. The peak landing and push off vertical ground reaction forces were reduced by 7% and 9%, respectively, with the use of a cane.[310] Those decreases were expected because the cane transmitted load during the stance phase of the affected limb, thereby reducing the load on the limb.[311] The cane also significantly reduced the braking shear (anterior) and propulsive shear (posterior) ground reaction forces for the affected limb, possibly by transmitting some of those forces as well. The lateral shear was 15% smaller for both limbs during the cane trials. The cane may have decreased the lateral oscillation of the center of mass, which could have reduced the lateral shear force. Ely and Smidt[311] reported that for patients with a limp because of a hip disability, 15% body weight applied to a cane in the contralateral hand reduced the maximal vertical reaction forces from 100% to 89% body weight. Although speed remained the same for gait with or without a cane, cane-assisted gait had a longer stride length and decreased cadence. Long[165] and Kleissen[312] have reported a 25% decrease in GM EMG amplitude during cane trials.

Evidence and Research 19-14

Control Versus Strength in Hip OA

A link has been reported between abnormal muscular activity and hip OA. In all cases a dysfunction has been found in the TFL or GM, which work together to maintain the level of the pelvis in single-leg stance.[217,314] The GM also provides joint stability[217] and is active when postural stability is challenged in the mediolateral direction.[315,316] One gait study found continuous activity in the TFL and inhibition of the GM of some subjects with hip OA.[315] In contrast, another found continuous activity in the GM of subjects with severe hip OA.[316] One study found that the group with hip OA had greater GM activation than the healthy older adults.[313] The magnitude of activation of the TFL did not differ between groups or sides. The findings of increased GM activation and lack of change in TFL were contrary to traditional beliefs that their activation would reduce and increase, respectively. One possible explanation is that the increased level of GM EMG activation may reflect a failure of the central nervous system to grade the degree of muscular force required in the performance of the stepping task in subjects with hip OA. An increased level of hip abductor activity is of clinical relevance because it has the potential to cause large compressive forces on the hip. Research has shown substantial acetabular loading before heel strike, and peak acetabular pressures in midstance before peak ground reaction force, suggesting the influence of muscle contraction on the internal joint forces.[317] The challenge to the practitioner will be to balance the ideal activation of the GM and TFL during gait to optimize joint loading. This may require more focus on control over limb and pelvic position to minimize internal joint forces during muscle contractions required for the gait sequence.

on the fine control of pelvic position during single-leg stance. This would require improving the ability of the GM to activate appropriately rather than general strengthening. Appropriate rehabilitation is crucial both as a preventive measure and as a critical part of pre- and postoperative care of hip OA. The GM and TFL are synergist hip abductors. It is common for the TFL to dominate the stance recruitment pattern, particularly if the hip is in flexion or medial rotation. If a patient has decreased mobility in hip extension, the hip will rest in an anterior pelvic tilt, making it more difficult to recruit the GM, resulting in increased firing of the TFL. As such, mobility might need to be addressed prior to instruction in neuromuscular reeducation. Education regarding the neutral position of the hip and GM recruitment is critical to the optimal outcome of this exercise. This may require additional activity from the abdominal and hip extensor muscles to control anterior pelvic tilt.

Step-up activities stimulate hip extensor recruitment of the stance limb[165] and facilitate hip flexion mobility, particularly if emphasis is placed on hip flexion during the step-up (Fig. 19-12B), and step-down activities stimulate GM recruitment.[165] Care must be taken during stepping activities to prevent Trendelenburg patterns and to reinforce proper length–tension properties of the GM (i.e., hip should not adduct more than 5 to 8 degrees, and femoral MR should be kept to a minimum). All stepping activities can be graded by altering the step height or adding weight. A handheld load of 15% of body weight held ipsilateral to the hip produces an external torque in the same rotary direction as that required by the right hip abductor muscles[318] (see **Fig. 19-31**).

Joint angles and moments showed a relatively low but significant dependency on the inclination (height) of the step.[319] This can be related to the varying amount of potential energy that has to be produced (during ascent) or absorbed (during descent) by the muscles. Using this evidence, it would stand to reason that a small step height (4 inches) and carrying a weight in the involved side hand reduces the force-generating requirements of the hip extensors and abductors. Conversely, larger step heights (8 to 12 inches) and carrying a weight in the contralateral hand increase the force-generating requirements.

Dosage parameters regarding repetition for these exercises depend on whether the goal is to improve force/torque or endurance capabilities. Higher repetitions with a decreased load focus on endurance, and lower repetitions with a higher load focus on force production.

Balance Injury to a joint and musculotendinous structures, as in hip OA, probably results in altered somatosensory information that can adversely affect motor control.[320] Progressive balance training can have a positive effect on function of the arthritic hip. Self-Management 19-2, Levels I and II, can be useful in training an individual to balance on one limb with correct form. After the patient is able to stand on one limb with appropriate muscle recruitment and joint loading strategies with reduced pain, balance activities can be added to the program. Progression should be taken slowly to prevent an inflammatory reaction in the hip, which would be counterproductive to improved function.

Posture and Movement Patient-related instructions regarding improved weight-bearing habits are critical to the long-term effectiveness of therapeutic exercise. The person with hip OA must be cautioned to avoid prolonged positioning of the involved limb in the capsular pattern (i.e., hip flexion and lateral rotation). Instruction in use of the deep trunk and pelvic muscles (i.e., diaphragm, abdominal wall, deep erector spinae, pelvic diaphragm) should not be overlooked because of its effect on improving LP and thereby, acetabular position. Small ROM wall squats can be useful to provide a stretch to the anterior myofascial structures simultaneous with abdominal wall strengthening (see Fig. 13-4). During function, use of assistive devices such as canes, crutches,

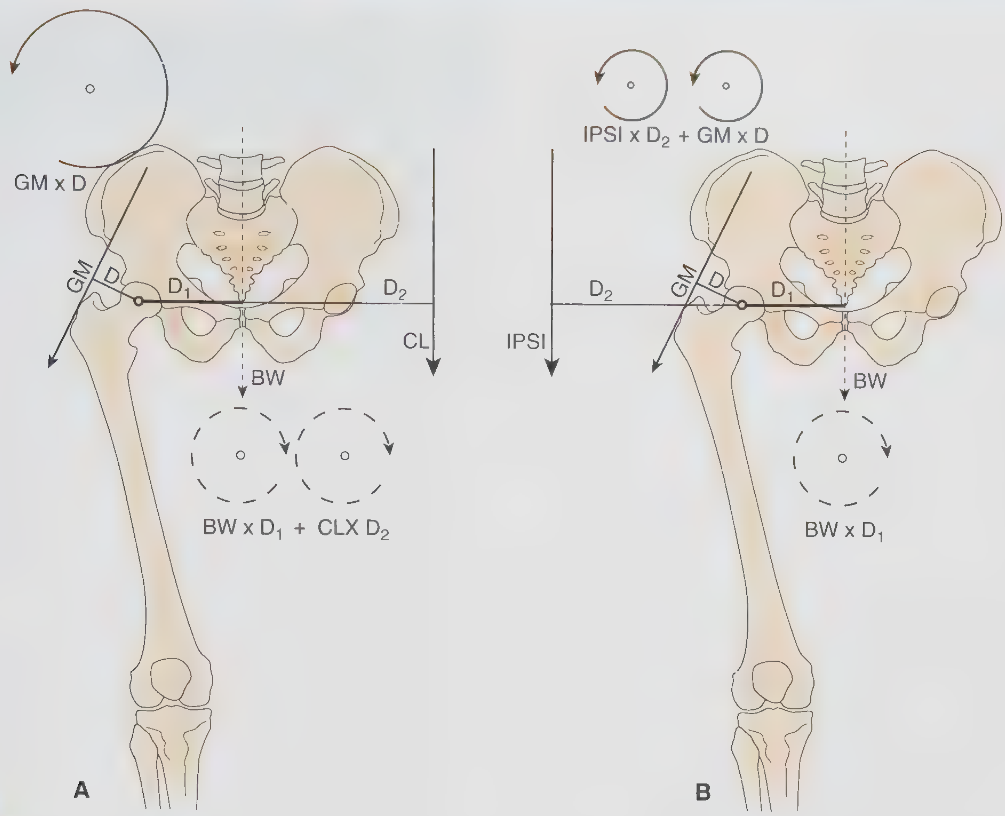

FIGURE 19-31 Diagram representing the moments that contribute to static rotatory equilibrium about the right stance hip when a load is carried (assuming negligible frontal plane accelerations about the stance hip). **(A)** Contralateral carry: The gluteus medius (GM) muscle force times its moment arm (D) must produce an internal moment (counterclockwise moment; solid arrows) large enough to neutralize the combined external moments (clockwise moments; broken arrows) of BW times its moment arm (D1) plus the contralateral load (CL) times its moment arm (D2). **(B)** Ipsilateral carry: The ipsilateral load (IPSI), by passing lateral to the stance hip and thus acting through its moment arm (D2), produces a counterclockwise moment (solid arrows) that is additive to that produced by the gluteus medius (GM) muscle. Fewer demands are therefore placed on the gluteus medius (GM) muscle to neutralize the clockwise moment produced by BW times D1. (Reprinted and modified from Neumann DA, Cook TM. Effect of load and carry position on the electromyographic activity of the gluteus medius muscle during walking. Phys Ther 1985;65:305–331, with permission of the American Physical Therapy Association.)

or walkers can be quite effective in reducing joint stress during ambulation, and consequently decrease antalgic gait patterns. Problem-solving to develop improved posture and movement patterns to allow continued participation in social and occupational activities is time well spent with a patient.

Adjunctive Interventions Because the hip is a weight-bearing joint, it is important that the individual maintains optimal body weight through proper nutrition and aerobic activity. Moderate weight-bearing or non–weight-bearing aerobic activities are recommended for persons with hip OA.[292]

Use of a stationary bike with the seat relatively high can serve as a means of maintaining aerobic activity with minimal weight-bearing stress on the joint. Aquatic exercise programs have been shown to be effective for the treatment of OA of the knee and hip, with 75% of subjects reporting improvement in pain and function after a 6-week bout of aquatic PT.[321,322] Swimming, non–weight-bearing exercise with inflatable supports, or weight-bearing exercises in a pool (see Chapter 16) minimize stress on the hip joint.

Manual therapy has been used to improve hip ROM and decrease OA pain, especially in patients without signs of severe OA. Manual therapy, consisting of stretching, manual traction, and long axis manipulation, was found to be superior to exercise in some studies. The combination of manual therapy and exercise yielded improvement in six of seven patients with hip OA.[305]

Iliotibial Band–Related Diagnoses

The extensive deep fascia that covers the gluteal region and the thigh like a sleeve is called the fascia lata. It is attached proximally to the external lip of the iliac crest, the sacrum and coccyx, the sacrotuberous ligament, the ischial tuberosity, the ischiopubic rami, and the inguinal ligament. Distally, it is attached to the patella, the tibial condyles, and the head of the fibula. The dense portion of the fascia lata situated laterally is designated the ITB. The TFL and three-fourths of the gluteus maximus insert into the ITB so that its distal attachment serves as a conjoint tendon of these muscles.[120] The TFL can be functionally differentiated into anteromedial (**Fig. 19-32A**) and posterolateral fibers (Fig. 19-32B and C). The anteromedial fibers have a greater mechanical advantage for hip flexion (Fig. 19-32A), and the posterolateral fibers have a greater mechanical advantage for hip abduction (Fig. 19-32B) and MR (Fig. 19-32C).[323]

During normal walking, the anteromedial fibers generally are quiet, whereas the posterolateral fibers are active near initial contact.[323] With sequentially increased locomotor velocity, anteromedial fiber activity increases near preswing and initial swing, presumably to decelerate the extending hip and accelerate flexion of the thigh, and posterolateral activity increases at initial contact, presumably to decelerate the adduction moment.[323] The anteromedial fibers are active during the hip flexion phase of

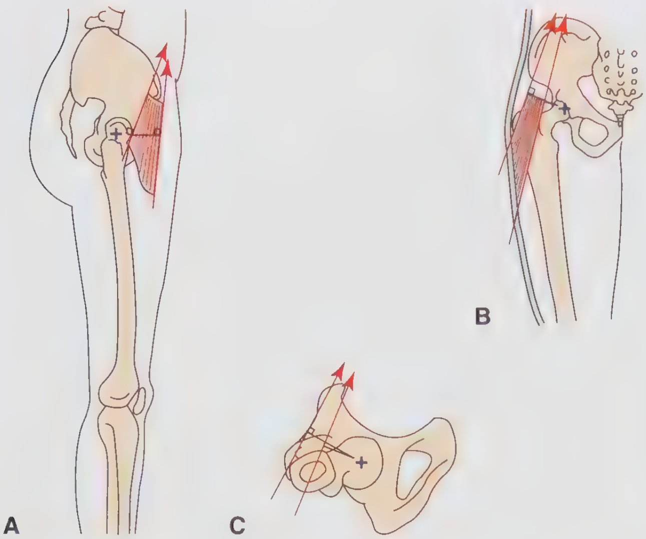

FIGURE 19-32 **(A)** The anteromedial fibers of the TFL have a greater mechanical advantage for hip flexion. **(B)** The posterolateral fibers of the TFL have a greater mechanical advantage for hip abduction and **(C)** medial rotation. (From Pare EB, Stern JT, Schwartz JM. Functional differentiation within the tensor fascia latae. J Bone Joint Surg Am 1981;63A:1457.)

the step-up, and the posterolateral fibers are active during the loading phase of the step-up. The ITB is traditionally considered to function as a "strut" during walking, stabilizing the hip in the frontal plane.[184] However, the high compliance of the ITB,[324–326] the fact that it crosses both the hip and knee, and the presence of in-series muscles suggest that the ITB may play other roles. If the ITB stretches substantially while transmitting muscle forces, storing elastic energy, then it may decrease the metabolic cost of locomotion (see **Evidence and Research 19-15**).

EVIDENCE and RESEARCH 19-15

ITB and Energy Storage

Enga et al.[327] created a model that characterizes the geometry and active and passive muscle force and fiber length properties of the ITB, TFL, and GMax to test the hypothesis that forces generated by TFL and GMax stretch the ITB during running, storing elastic energy. Analysis of the model revealed that the ITB has the capacity to store 7 J per stride during running at 5 m per second. The posterior ITB stores substantially more energy than the anterior ITB because it transmits larger muscle forces. To provide additional context, they reported that the hip extensors do 40 J of work per stride during stance, while the hip flexors do 6 J of work during swing. Recovery of 2 J from glut max/ITB during slow running could account for 5% of the work done by hip extensors in stance, while recovery of 0.3 J from TFL/ITB could contribute 5% of the work done by hip flexors in swing. Furthermore, the human ITB is stretched substantially just before swing, when the TFL is active and the hip is extending. Subsequent recoil of the ITB may help accelerate the swing limb. Although the energetic cost of running is primarily determined by muscle forces that support the body during stance,[328] the cost of accelerating the swing limb may be as much as 27% of the total metabolic cost.[329,330] The assistance of energy recovery from the ITB can significantly assist in running economy. These data provide evidence to consider when prescribing stretching or foam roller work on the ITB in the running population. The ITB appears critical in the stretch-shortening cycle and economy of running.

DISPLAY 19-12

ITB-Related Diagnoses

- *ITB fasciitis*: Inflammation of the ITB resulting from overuse of ITB for stability.
- *Trochanteric bursitis*: In trochanter bursitis, the bursa becomes inflamed because of the pressure exerted by a short ITB moving back and forth over the greater trochanter during movement.
- *ITB friction syndrome (also known as ITB syndrome)*: In ITB friction syndrome, pain and tenderness are localized to the lateral femoral condyle because of a short ITB exerting pressure over the lateral femoral condyle.
- *Patellofemoral dysfunction*: Shortness of the ITB can contribute to patellofemoral dysfunction because of its insertion into the lateral retinaculum of the patellofemoral joint and its tendency to dominate over the quadriceps for knee stability (see Chapter 20).
- *TFL strain*: TFL strain can occur from overuse of a short TFL/ITB or a stretched TFL/ITB complex. The former is more common, but there are instances of strain of the stretched TFL/ITB. The TFL/ITB on the side of the adducted hip (usually the high iliac crest), if there are no associated hip MR or hip flexion alignment or movement faults, is subject to continuous tension and therefore strain.
- *Faulty movement patterns at the hip and tibiofemoral joints*: Faulty movement patterns of the hip and tibiofemoral joints related to the TFL/ITB are critical to understanding the effect of muscle imbalance on the function of these joints. Sahrmann provides more information on this subject.[54]

Because of the vast functional roles of the TFL/ITB complex, it is prone to overuse injuries (see **Display 19-12**).[149] The following sections provide etiologic and treatment information for the most common ITB-related diagnoses.

Iliotibial Band Fasciitis/Fasciosis

A condition, sometimes mistakenly diagnosed as sciatica, is that of pain associated with inflammation or degeneration of the fascial band from overuse of the TFL, commonly called ITB fasciitis,[149] though pain may be due to degenerative changes to the ITB and edema from associated tissues.[120] Pain may be limited to the area covered by the fascia along the lateral surface of the thigh or may extend upward over the buttocks and involve the gluteal fascia. Painful symptoms may extend below the knee, with associated symptoms of paresthesia in the region of the lateral calf.

A review of the anatomy of the lateral aspect of the knee demonstrates the relationship of the peroneal nerve to the muscles and fascia in this area. Peroneal nerve irritation can result from pressure from rigid bands of fascia in a short ITB or from the effect of traction from taut bands of fascia in an overstretched ITB. Peroneal nerve irritation can manifest as symptoms in the lateral calf.[69]

Symptoms are similar to plantar fasciitis; often worse in the morning and improve with minimal weight bearing, but they then worsen with continued weight-bearing. Tests to differentiate ITB fasciitis from sciatica are summarized in **Display 19-13**. Presumably, this condition results from overuse of the TFL/ITB.

DISPLAY 19-13

Key Tests for Differential Diagnosis of Iliotibial Band Fasciitis from Sciatica

Key Tests

- Palpation over the length of the fascia lata may elicit tenderness, especially over the greater trochanter or near the point of insertion lateral to the patella.
- Hip flexion, abduction, and MR (TFL manual muscle test) may test painful.
- The Ober test (test for ITB length) reveals shortness of the TFL/ITB, and further stretch may elicit pain. Paresthesias along the peroneal nerve distribution may worsen with ankle inversion and dorsiflexion.
- Lumbar spine clearing test results are negative for reproduction of the patient's symptoms.

Associated Findings

- Hip rotation ROM may reveal excessive MR relative to LRROM.
- Positional weakness of the synergistic muscles of the GM, gluteus maximus, iliopsoas, and quadriceps.
- Hip anteversion.
- Excessive medial rotation, positive Trendelenburg sign, or limited hip extension in gait.

Concurrent with any overuse syndrome is underuse of the related synergists about any axis of motion in which the affected muscle functions. The more deconditioned the underused synergists become, the greater the force-producing requirements become for the TFL/ITB complex, until finally the force-producing requirements exceed the muscle and fascial capability, and inflammation (fasciitis)[149] or degenerative changes (fasciosis)[121] result. **Display 19-14** summarizes the synergist relationships that may become imbalanced, leading to TFL/ITB overuse.

Iliotibial Band Friction Syndrome

Although iliotibial band friction syndrome (also known as ITBS) manifests at the knee, it is presented here because therapeutic exercise intervention is focused at the imbalances in flexibility and muscle performance at the hip. ITB syndrome is an overuse syndrome first described by Olson and Armour.[331] The ITB lies anterior to the lateral femoral condyle with the knee in extension and moves posterior to the lateral epicondylar prominence with knee flexion. Biomechanical research of ITB syndrome has demonstrated that friction occurs near foot strike, predominantly in the foot contact phase, between the posterior edge of the ITB and the underlying lateral femoral epicondyle.[332] The posterior fibers of the ITB are more problematic in this syndrome than the anterior fibers. This is supported by the surgically known fact that the posterior fibers of the ITB are tighter against the lateral epicondyle than the anterior fibers.[333] Repetitive knee flexion and extension causes the posterior edge of the ITB to rub across the lateral epicondyle, which, theoretically, gives rise to an inflammatory reaction in the tissue deep to the ITB.

The ITB syndrome is quite common in long-distance runners, cited as the second most common injury, with a sex discrepancy prevalence of 38% male and 62% female.[334] ITB syndrome in runners results from a complex of training errors, muscle imbalances in performance and flexibility, inappropriate surface and terrain, lower extremity alignment, and inappropriate footwear.

The clinical symptoms of ITB syndrome include lateral knee pain and occasional snapping on the lateral side of the knee as the knee moves from extension into flexion and then returns to extension. The area is tender over the lateral femoral condyle and pain can be provoked be exerting pressure over the lateral epicondyle during active knee flexion, particularly at 30-degree flexion.[335] It is not uncommon for this syndrome to be misdiagnosed as another condition that causes lateral knee pain such as lateral meniscal tear, lateral collateral ligament sprain, or popliteal tendinitis.[333,334] Coronal MRI can be useful to determine a differential diagnosis.[333]

DISPLAY 19-14

Potential Synergist Relationships with TFL/ITB Overuse

- The anteromedial TFL can dominate the hip flexion force couple, contributing to underuse of the iliopsoas.
- The posterolateral TFL can dominate the hip abduction and MR force couples, contributing to underuse of the GM, upper fibers of the gluteus maximus, and gluteus minimus.
- Because the ITB can provide stability to the knee, overuse of the ITB may contribute to underuse of the quadriceps.
- The hip tends to function in MR patterns, thereby contributing to underuse of the hip lateral rotator force couple, including the deep hip rotators, posterior fibers of the GM, and lower fibers of the gluteus maximus.

Other ITB-Related Syndromes

Similar causes exist for the remaining ITB diagnoses, although with slightly different symptoms. Although some of these diagnoses manifest at the knee, treatment must focus on the cause of the condition, which is TFL/ITB overuse at the hip.

Treatment

Therapeutic exercise intervention for each of the ITB-related diagnoses should take into consideration the biomechanical factors causing the syndrome and the related anatomic and physiologic impairments.

Pain and Inflammation In the acute phase, treatment should be directed toward alleviating the pain and inflammation with medication (i.e., NSAIDs), physical agents (i.e., cryotherapy), and unloading (e.g., use of a cane, taping, proper positioning at night with pillows between knees if sidelying).[149,335] As acute symptoms subside, succeeding treatments should be directed toward resolving the impairments and activity limitations associated with the condition.

Range of Motion ROM impairments are most often associated with a stiff or short TFL/ITB complex.[336] Stretching the TFL/ITB complex may be indicated but can pose a challenge to the clinician and patient. Furthermore, the practitioner must consider the metabolic utility of an appropriately stiff ITB as discussed in Evidence and Research 19-15.

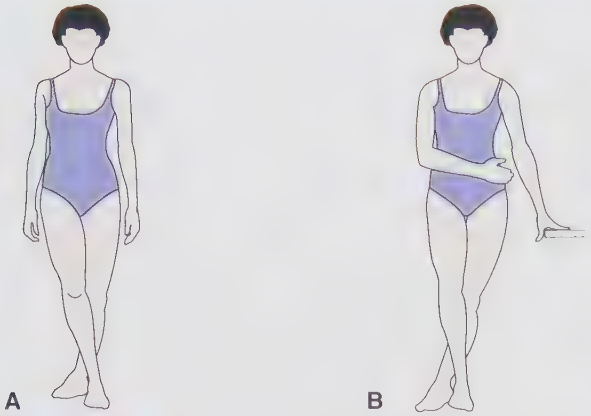

FIGURE 19-33 Commonly prescribed TFL/ITB stretch that does not stretch the TFL/ITB in all directions opposite its actions. **(A)** Crossing the legs commonly places the hip joint in medial rotation. **(B)** Swaying laterally, with the hip medially rotated, stretches the GM and lateral capsule more than the TFL/ITB.

If it is determined that the ITB is too stiff, to appropriately elongate the ITB, its multiple actions must be considered. For an optimal stretch, the TFL/ITB must be elongated simultaneously in all directions opposite its actions. It is critical that the stretching be specifically directed to the area in need of stretch, and some commonly prescribed TFL/ITB stretches do not meet these criteria (**Fig. 19-33**).

An assisted stretch emphasizing the posterolateral fibers is shown in **Figure 19-34**. This stretch ensures the most precise positioning for the best outcome. The obvious disadvantage of this stretch is that rarely can an individual self-stretch in this position. Over time, he or she may be able to master the control required after a series of hip abduction exercises with the emphasis on eccentric control of the GM (see Self-Management 19-4). This exercise also emphasizes improving the force-generating capability and kinesthetic awareness of the GM—a critical, underused synergist. A self-stretch exercise for the TFL/ITB is shown in **Figure 19-35**. This stretch is directed more toward the anterolateral fibers and is considered an active stretch because of the activation of the abdominal muscle group and gluteus maximus to rotate the pelvis posteriorly.

FIGURE 19-34 Assisted Ober stretch position. The hip must be in concurrent hip extension, lateral rotation, and adduction without lateral pelvic tilt. This is difficult to perform without assistance.

FIGURE 19-35 ITB stretch to the extended hip. In the half-kneel stretch position, the patient is asked to maximally drop the contralateral pelvis to adduct the ipsilateral hip. The patient also is asked to extend the hip by means of posterior pelvic tilt (using the gluteus maximus and abdominal muscles). A slight hip LR can be added to stretch the posterolateral fibers. This technique is best used for hip conditions as weight bearing on the knee can be uncomfortable in patients with knee conditions.

Two important issues to be mindful of with respect to stretching any structure:

1. Be cautious of overstretch. Know the goal is to restore normal ROM, not excessive. Recall the ITB is critical to energy storage and overstretch will compromise this function (Evidence and Research 19-15).
2. Stretching should not be used in isolation with the hope that the stretch will permanently improve the length. The clinician must seek the related impairments and activity limitations that perpetuate the shortness. For example, short posterolateral fibers of the TFL/ITB do not remain stretched if the person stands and moves with the hip in excessive medial rotation. Improvements in muscle performance of the underused synergists coupled with education regarding postural habits and neuromuscular training of new movement patterns are essential to restoring length to the ITB on a more permanent basis.

Muscle Performance Correction of muscle performance deficits of the hip abductor muscles has been shown to be correlated with recovery from ITB syndrome.[186] Progressive strengthening of both concentric and eccentric roles of additional underused synergists such as the iliopsoas, gluteus maximus, and quadriceps can further assist in reducing the physiologic and biomechanical requirements of the TFL/ITB. After functional muscle performance is achieved, attention to biomechanical elements to ensure recruitment of these synergists/antagonists during function is essential to full recovery.

The initial exercise prescription depends on the positional strength of these muscles. For example, the iliopsoas may require active assistance exercise initially, progressing to active holding, resistive holding, and finally functional exercises (see Self-Management 19-5 and the swing phase of Self-Management 19-3). The emphasis initially is on end range isometrics, followed by eccentric, and finally concentric, contractions to ensure the improvement of the positional strength of the iliopsoas at end range. The goal with this approach is to improve the length–tension relationships of the relatively lengthened, weaker synergist to the TFL/ITB in hip flexion. An example of a functional movement recruiting the iliopsoas may include repeated swing phase of a step-up with avoidance of hip MR or hip hike accompanying the hip flexion pattern. Additionally, eccentric control is introduced with functional movements focusing on the trail limb during lunges controlling extension forces.

Adjunctive Intervention For a strained TFL/ITB due to continuous tension, use of taping as illustrated by Kendall et al.[69] (**Fig. 19-36A**) can unload the strained structure. Because the femur must not function in excessive medial rotation, taping the hip in a slight amount of LRmay be indicated. An alternative taping technique is illustrated in Figure 19-36B. Applying firm pressure over the TFL while applying tape over this area may unload the TFL and therefore encourage more GM participation during functional activities (see **Building Block 19-5**).

BUILDING BLOCK 19-5

Consider a 19-year-old female track runner who presents with pain 6/10 on the lateral aspect of the right hip, worse with running. The patient presents with weakness of the GM and deep hip lateral rotators. You analyze her running mechanics and notice pronation at initial contact with subsequent excessive femoral adduction and MRwith knee valgus during loading response. Develop a prioritized treatment plan for this patient to return to running with less pain.

Nerve Entrapment Syndromes

Although nerve entrapment syndromes represent a relatively small group of conditions causing hip, groin, or buttock pain, an understanding of the etiology of these syndromes can facilitate a precise diagnosis and promote efficient management of the condition. **Display 19-15** lists the possible nerve entrapment syndromes that can be a source of hip, groin, or buttock pain.

The anatomic possibilities for nerve entrapment syndromes in this region arise from the lumbosacral plexus and its branches (**Fig. 19-37**). Unless nerve entrapment syndromes produce "hard" neurologic signs of motor weakness, sensory loss, or change in tendon reflexes, specific diagnosis may be difficult. This is particularly true of nerve entrapments around the pelvis

FIGURE 19-36 Taping techniques to unload the ITB. **(A)** Unloading the TFL/ITB with lateral longitudinal taping using a technique developed by Florence Kendall. **(B)** Unloading the TFL/ITB with anterior to posterior strips positioned proximally over the TFL and placed every 2 to 3 in distally. The patellofemoral joint may need to be taped medially to prevent lateral displacement from the stretch placed on the ITB distally.

DISPLAY 19-15

Specific Nerve Entrapment Syndromes as a Cause of Pain in the Hip, Groin, and Buttock

- Iliohypogastric nerve

- Femoral nerve
- Pudendal nerve.

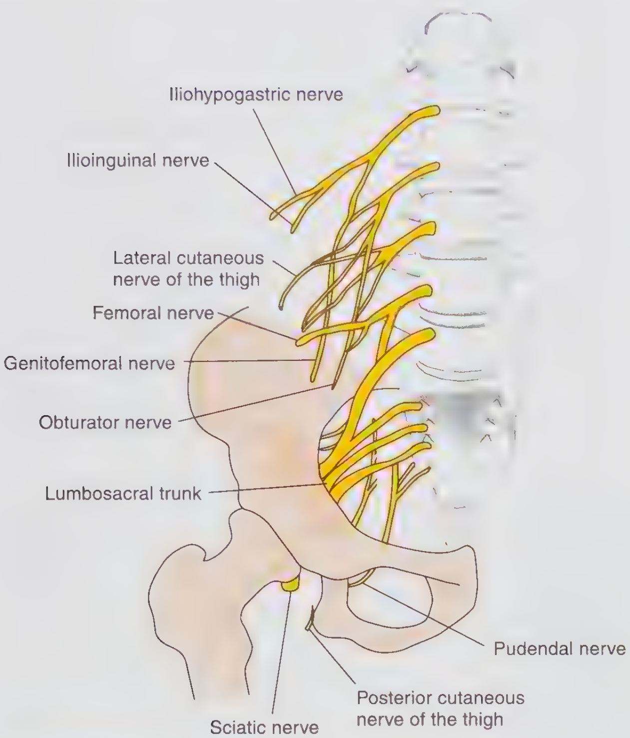

FIGURE 19-37 Anatomy of the lumbosacral plexus.

where the cutaneous sensory dermatomes overlap considerably and many of the nerves have no motor innervation that can be easily tested, resulting in nonspecific and poorly localized pain or paresthesia complaints. A thorough knowledge of the anatomy of the region is necessary to diagnose nerve entrapment syndromes at the hip. Table 19-2 assists the reader with differential diagnosis by providing a regional approach to the diagnosis of nerve entrapment syndromes.

For the purposes of this text, the discussion of entrapment syndromes will be focused on symptoms in the region of the buttock and posterior thigh. The piriformis syndrome has been described as a form of sciatic nerve entrapment causing buttock and posterior thigh pain and the piriformis muscle has been implicated as a potential source of sciatica symptoms.[337] The original description of this condition dates from 1928 when Yeoman[338] stated that insufficient attention had been paid to the piriformis muscle as a potential cause of sciatica.

Although there may be numerous cases in which sciatic pain is associated with a short piriformis, Kendall[69] and Sahrmann[149] describe a variation of this syndrome in which the piriformis is lengthened.

The length of the piriformis must be carefully assessed before planning an intervention for this syndrome. For example, in a faulty standing position with the femur in adduction and MR and the pelvis in anterior pelvic tilt, the piriformis muscle is placed on stretch. The piriformis muscle is pulled taut, potentially entrapping the sciatic nerve. Pressure on the sciatic nerve may result from tension from the adjacent taut piriformis muscle. If the nerve pierces through the piriformis, an injurious tension may be imposed on the sciatic nerve along with the stretched muscle. Because the piriformis is actively used during gait, abnormal gait patterns can impose stress on the piriformis and related sciatic nerve. With an overstretched piriformis, repetitive movements of the hip in MR and adduction and movements of the pelvis in anterior pelvic tilt can impose friction on the nerve, resulting in inflammation of the neural tissue. Strain of the piriformis can ensue because of the muscle functioning in a chronically stretched position.

Diagnosis

Differential diagnosis of buttock and posterior thigh pain can be quite complex. One should consider the potential causes of symptoms including piriformis (lengthened, shortened, strained, or hypertrophied), obturator internus/gemelli complex, lumbosacral radiculopathy, or referred pain. Given the anatomic relationship of the piriformis to the various nerves in the deep gluteal region, it is possible that the buttock pain represents entrapment of the gluteal nerves. Pain caused by piriformis strain can also be felt deep in the buttock. Posterior thigh pain can be caused by the posterior cutaneous nerve of the thigh, which would explain the absence of distal sciatic neurologic signs in some cases. It is possible that the obturator internus/gemelli complex is an alternative cause of neural compression. For this reason, "deep gluteal syndrome" may be a more appropriate term for symptoms isolated to the buttock.[339] Symptoms of sciatica related to a stretched, short, or hypertrophied piriformis can be experienced from the posterior buttock extending inferiorly as far as the toes. Symptoms of pain or tingling may appear in the cutaneous areas below the knee supplied by branches of the peroneal or posterior tibial nerve before symptoms of numbness or signs of weakness become apparent.

Key tests used in making a differential diagnosis that includes a stretched piriformis, a shortened piriformis, lumbar radiculopathy, or referred pain are summarized in **Table 19-5**.

Treatment

For the purposes of this text, this discussion will be isolated to the piriformis syndrome. Therapeutic exercise intervention is based on the physiologic and morphologic status of the piriformis. Careful differential diagnosis of whether the muscle is strained, lengthened, shortened, or hypertrophied is necessary to develop the appropriate therapeutic exercise intervention. For example, a short piriformis must be stretched, whereas this would aggravate a lengthened piriformis syndrome. Periodic ROM measures combined with positional strength testing and dynamic functional testing can indicate the status of recovery of the strain and length–tension properties. The following sections

TABLE 19-5

Differential Diagnosis of Stretched Piriformis Syndrome

Key Tests
Standing alignment
Selective tissue tension tests
Range of motion
Palpation
Positional strength
Functional tests
Lumbar clearing examination
Signs
Lordosis and anterior pelvic tilt
Hip flexion and medial rotation
High iliac crest on involved side
<90 degrees of hip flexion, with adduction and MR reproduces symptoms
Passive or active LR and abduction reduces symptoms
Resisted knee flexion is negative
Excessive hip MR relative to LR within the involved side
Excessive MR of the involved side relative to the uninvolved side
Tenderness elicited in region of the sciatic notch
Weakness in hip lateral rotators and posterior gluteus medius
Tendency to function in hip MR, hip adduction, and anterior pelvic tilt during functional activities
Repetitive movements in MR and/or adduction, with the pelvis in anterior tilt, reproduce symptoms
Lateral rotation, abduction, and neutral pelvic alignment relieves symptoms
Symptoms diminish or disappear when not bearing weight

provide guidelines for the therapeutic exercise intervention for all forms of the piriformis syndrome.

Pain Patients should be instructed in positions that relieve nerve pain and which positions to avoid to prevent further nerve irritation. Regardless of the length of the piriformis, relief may be achieved by placing the involved leg in LR and abduction in lying and standing positions. Sitting with the hips in LR (i.e., legs crossed at the ankles), avoiding extreme hip flexion, or sitting on a firm surface to support the femoral head in the acetabulum can alleviate symptoms while sitting. Sitting in bucket seats forces the hips into medial rotation. So, if your pelvis is too wide for the seat, add a pillow or foam to level the seat to reduce the force into medial rotation.

Posture and Movement Permanent changes with respect to postural habits are encouraged to help alter the length–tension properties of the muscle. The patient should be instructed to position the limb to take the muscle off stretch (i.e., hip adduction, medial rotation, or extreme flexion). Limb position should be monitored during ADLs such as transitioning from sit to stand, squatting, and during the stance phase of gait. Cues to maintain neutral transverse and frontal plane alignment can reduce repetitive stretch to the piriformis.

Muscle Performance In the case of a strained or lengthened piriformis, gradual progressive strengthening is indicated. Often the muscle is quite weak initially due to the strain or shifted length–tension properties. Caution must be used with dosage

FIGURE 19-38 Prone foot pushes strengthen the piriformis isometrically in the short range. The patient positions the hip in abduction and lateral rotation. The patient pushes the heels together with a submaximal contraction. Submaximal contraction is desired over maximal to reduce the amount of accessory muscle recruitment (i.e., lateral hamstrings and adductors). Duration and repetitions are determined based upon the goal of the exercise (i.e., strength vs. endurance).

parameters so as not to exceed the muscle's physiologic capabilities. Exercise in the short range is indicated for the lengthened piriformis. Strengthening exercises should be avoided for the short or hypertrophied piriformis. Exercises that can target hip lateral rotator strength and length–tension properties include prone foot pushes (**Fig. 19-38**), prone hip extension with pelvic stabilization (Self-Management 19-1), sidelying hip abduction with emphasis on LR (Self-Management 19-4), and hip lateral rotator strengthening in the short range (Fig. 19-10).

Strengthening the abdominal muscles (see Chapter 18) in the short range may be necessary to address an associated anterior pelvic tilt in the strained or lengthened piriformis syndrome. Strengthening the ipsilateral GM (Self-Management 19-4) may be necessary to reduce adduction patterns that will add further stress to a strained or lengthened piriformis.

After the muscle performance of the piriformis has improved to maintain the femur in neutral while bearing weight, exercises can be progressed to standing. In the lengthened or strained piriformis, the focus is to train the femur to function in less MR and adduction and the pelvis in less anterior tilt, without promoting excessive hip flexion. In the short or hypertrophied piriformis syndrome, the focus is to train the femur to function in less LR and abduction and encourage the hip to function in more flexion (see Self-Managements 19-2, 19-3, and 19-8; and Fig. 19-12).

Range of Motion Stretching the piriformis is contraindicated for the strained or lengthened piriformis. However, stretching the opposing medial rotators may be necessary if the stiffness or shortness contributes to the hip functioning in medial rotation, imposing undue tension on the lengthened piriformis. Stretching the medial rotators (e.g., posterolateral fibers of the TFL, gluteus minimus, anterior GM) can be difficult to perform unassisted. Assisted stretching with the patient in a prone position into lateral rotation, with careful stabilization of the pelvis and the tibia, ensures optimal stretch to the medial rotators (see Fig. 19-27E). The pelvis must be stabilized actively or passively to prevent anterior pelvic tilt and lumbar extension while stretching the TFL/ITB complex.

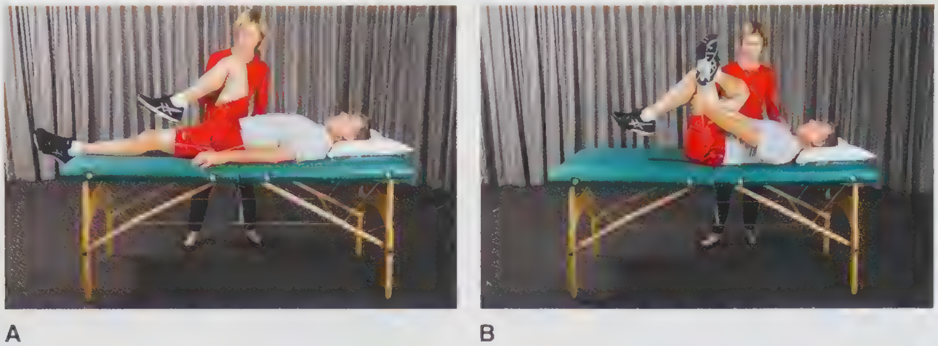

FIGURE 19-39 Piriformis stretch. **(A)** Passive stretch for the piriformis muscle. With the patient lying supine, the lower extremity is grasped at the flexed knee. The lateral aspect of the iliac crest and the ASIS are stabilized by the cranial hand while the caudal hand flexes the femur to 60 degrees and guides the femur into adduction. Self-stretch of the piriformis and other deep hip rotators. **(B)** After 60-degree hip flexion, the piriformis medially rotates the femur. To stretch the right deep hip lateral rotators, the patient lies supine and the right femur is flexed and laterally rotated such that the right ankle rests on the posterior aspect of the distal left thigh. From this position, the left hip is flexed until tension is perceived in the right buttock.

Stretching the piriformis is indicated in the short or hypertrophied piriformis syndrome. Passive stretches for the piriformis are shown in **Figure 19-39**. Caution must be taken to ensure stabilization of the sacrum when stretching by moving the femur.

Stretching the low back muscles (see Self-Management 19-7 may be necessary to reduce forces contributing to anterior pelvic tilt. This same stretch can be used to stretch the piriformis. Caution must be heeded when stretching the low back muscles in the lengthened piriformis syndrome so as not to place further tension on the sciatic nerve. While moving into hip flexion, the emphasis should be on achieving a flat low back and not on hip flexion.

Stretching the ipsilateral hip adductors (Fig. 19-21) or abductors (Figs. 19-31 and 19-32) may be necessary to improve frontal plane alignment of the hip depending on the initial length of the piriformis.

Adjunctive Interventions Support to a strained piriformis is indicated for rapid recovery. The lengthened piriformis should also be supported to relieve tension and allow for length–tension changes to occur. The combination of taping, posture, and exercise providing this support can be determined on a case-by-case basis, but it must be addressed in some fashion and for a period sufficient to allow recovery.

Taping techniques to support the limb in more neutral positions and provide feedback to avoid MR and adduction are indicated for the stretched or strained piriformis. McConnell[340] has developed a taping technique for the buttock that can support a strained piriformis and assist in unloading neural tissues. Taping behind the knee can serve as "biofeedback" to prevent excessive MR tendencies during standing exercises and function (**Fig. 19-40B**; see **Building Block 19-6**).

FIGURE 19-40 Excessive MR of the femur in standing as shown by **(A)** tape on the hamstring tendons. **(B)** Corrective taping posterior to the knee. To encourage hip LR and tibia MR, the tape is applied from the lateral femur distally to the medial tibia and from the medial tibia proximally toward the lateral femur. *Note*: Because this taping procedure does not anchor the tape to any bony prominence, its ability to prevent unwanted tibiofemoral movement is questionable. At best, it can provide temporary feedback to the patient until the tape has sufficiently stretched.

BUILDING BLOCK 19-6

Consider a patient presenting with left-sided gluteal pain that radiates down the posterior aspect of the left leg. The patient demonstrates decreased tolerance to sitting, weakness in the deep hip lateral rotators, increased MR ROM of the left hip, and increased adduction and MR patterns with sit to stand/stand to sit, step-ups/downs, and during the loading phase of gait. Develop a treatment plan for this patient to address her pain.

KEY POINTS

- The structure of the hip joint is designed for stability and to withstand high kinetic forces.
- The angles of inclination and torsion are critical to ideal functioning of the hip joint.
- The ligaments of the hip provide significant stability to the hip, particularly in hip extension, adduction, and medial rotation.
- The tension of the ligaments corresponds to positions of stability and instability of the hip.
- Hip osteokinematic ROM is closely linked to the LP region. Limitation in hip mobility may manifest in compensatory LP mobility and at the knee, ankle, and foot, although to a lesser degree.
- Hip arthrokinematic motions follow convex moving on concave rules with rolling and translation (minimal as it may be) moving opposite in direction to the distal end of the femur.
- It is important to understand the function of the muscles that cross the hip and the relationships they have with the LP region and the knee joint.
- In vivo loads acting at the hip joint have demonstrated the average patient loads the hip joint with 238% body weight (BW) when walking at about 4 km per hour, while climbing upstairs increases joint contact force to 251% BW going downstairs to 260% BW.
- A thorough hip examination is necessary to understand the anatomic and physiologic impairments in the hip and those in related regions that affect the patient's activity limitations and disability.
- Impairments in muscle performance, gait and balance, posture and movement, ROM, and joint mobility commonly occur together in hip-related conditions. Treatment must focus on the impairments most related to the presenting activity limitations and participation restrictions. The initial focus should be on restoring functional capacity of each relevant impairment and gradual progression toward functional activity.
- FAI is of unknown etiology, but there is a strong case that mechanical stress in the developing hip can contribute to cam morphology.
- 3D orientation of the acetabulum and femur can have an impact on mechanical hip pain and impingement.
- PTs can contribute to both prevention and nonsurgical management of FAI through properly prescribed therapeutic exercise.
- The primary focus of treatment of hip OA is to improve joint loading by increasing the contact area for loading. Restoring proper joint mobility and soft tissue extensibility are prerequisite to building force or torque related to optimal joint loading. Improving posture and movement patterns are critical to transition improved physiologic impairments into function. Balance skills are the final element to restoring more optimal movement patterns and joint loading.
- Numerous ITB-related syndromes exist. The focus of treatment is to improve the force or torque and functional recruitment of the underused synergists in meaningful functional movement patterns.
- The stretched piriformis syndrome can mimic lumbar radiculopathy. Correct differential diagnosis from lumbar radiculopathy, short piriformis syndrome, and hamstrings strain is mandatory for a successful outcome. Treatment focuses on improving the movement patterns and associated physiologic impairments that contribute to femur MR and adduction and on anterior pelvic tilt, all of which can contribute to stress on the piriformis and the sciatic nerve.

LAB ACTIVITIES

1. How would you progress a patient with OA in standing exercises to improve weight acceptance and single-limb support phases of gait? Would you use any assistive devices?
2. With respect to Critical Thinking Question 3, what isometric contractions can normalize orientation of each of a retroverted or anteverted acetabulum?
3. With respect to Critical Thinking Question 4, develop a program of exercises that improve the mobility and associated force or torque impairment for each scenario. Teach this program to your partner. Assume that all manual muscle test grades are 3+/5. Progress specific nonfunctional exercises to functional exercises.
4. With respect to Critical Thinking Question 6, how would you begin to improve the force or torque production of a GM underused synergist with a positional strength grade of 3−/5. How would you progress this exercise as the positional strength improved? Teach your partner these exercises. Can you feel the TFL trying to dominate the exercise movement pattern? What is the associated pattern of movement with TFL dominance? Progress this exercise to standing functional exercises. How does the foot alignment contribute to the hip position in closed chain positions and movements?
5. Your partner has been diagnosed with ITBS. List synergists that may be underused and therefore contribute to this diagnosis. Develop an exercise to improve muscle performance for each underused synergist. Consider each underused synergist has a 3+/5 muscle test grade.
6. Practice the balance progression described in Display 19-8. What type of balance strategy are you using? Develop balance drills that stress the frontal plane and crossover stepping strategies.
7. With respect to Critical Thinking Question 7, progress hip lateral rotator exercises from specific, nonfunctional exercises to functional exercises. How would you stress the lateral rotators in a single-limb balance drill (be creative)?
8. Refer to Case Study No. #9 in Unit 7. Develop a complete therapeutic exercise intervention plan using the intervention model developed in Chapter 2.
9. Refer to Case Study No. #10 in Unit 7. Develop a complete therapeutic exercise intervention plan using the intervention model developed in Chapter 2.

CRITICAL THINKING QUESTIONS

1. To which type of knee alignment does coxa vara and coxa valga contribute?
2. What direction are the femoral condyles oriented in femoral anteversion versus retroversion? If a patient with femoral anteversion participates in ballet, what type of mobility problem could he or she develop? If a patient with femoral anteversion participates in soccer, what type of mobility could he or she develop? What are your recommendations for the alignment of the anteverted femur during sport activities?
3. What 3D orientation is the acetabulum in acetabular retroversion? Anteversion? Does retroversion provide increased or decreased femoral head coverage? How would this contribute to positional FAI?
4. What would be the compensatory lumbar motions and what phases of the gait cycle would be involved if right hip mobility were restricted in (a) flexion, (b) extension, or (c) medial rotation?
5. If the hip were restricted in flexion, what are the postural patterns at the pelvis and lumbar spine contributing to this hip flexion restriction? What movement patterns would you retrain to improve hip flexion mobility? What muscle force or torque impairments at the LP region would you be concerned about that could help perpetuate the hip flexion restriction? Answer these same questions with respect to restrictions in hip extension and medial rotation. What is this pattern of restriction (i.e., restricted hip flexion, medial rotation, extension) called?
6. Describe the Trendelenburg pattern of gait. Can you describe other hip joint movement patterns that could indicate hip abductor weakness?
7. In TFL/ITB overuse diagnoses, why is the hip the focus of treatment? What are the common underused synergists that contribute to TFL/ITB overuse?
8. How would you differentially diagnose a stretched piriformis syndrome from a short piriformis syndrome, lumbar radiculopathy, or strained hamstrings?

CHAPTER 20

The Knee

JILL THEIN-NISSENBAUM • LORI THEIN BRODY

The knee is one of the most frequently injured joints in the body. The vast quadriceps muscle spans the anterior thigh and crosses the tibiofemoral joint, producing knee extension when contracted. The role of the patella is to enhance quadriceps performance across the longest lever arm of the body. Impairments at the knee joint can produce significant activity limitations and performance restrictions. The closed chain demands of daily activities such as walking, standing, and rising from a chair require smooth, coordinated action of the lower extremity neuromuscular system.[1,2] When considering impairments around the knee joint, the impact of these impairments on the related joints in the kinetic chain also must be addressed.

REVIEW OF ANATOMY AND KINESIOLOGY

A thorough understanding of the anatomy and kinesiology of the knee joint is necessary to comprehend the impact of impairments on function of the kinetic chain. The unique kinematic relationships of lower extremity joints depend on local anatomic structures. A brief review of key aspects follows, with further information available on the website.

Anatomy

The osteology of the knee joint consists of the convex medial and lateral femoral condyles articulating with the concave proximal tibial plateau.[3] The medial femoral condyle extends further distally and is wider than the lateral condyle, contributing to the quadriceps angle (Q-angle) and knee valgus posture commonly observed.[3,4] The triangular shaped patella, with its concave undersurface, articulates with the convex femoral condyles (**Fig. 20-1**).

Key aspects of the knee osteology include:

- Condylar asymmetry that contributes to the screw home mechanism (femoral internal rotation coupled with tibial external rotation during terminal extension)[3]
- Lateral tibial plateau that is small, more circular, and concave compared with the oval-shaped, flatter medial tibial plateau
- The undersurface of the patella that is covered with articular cartilage up to 5 mm thick, and has two concave facets and an additional "odd" facet[3,5]

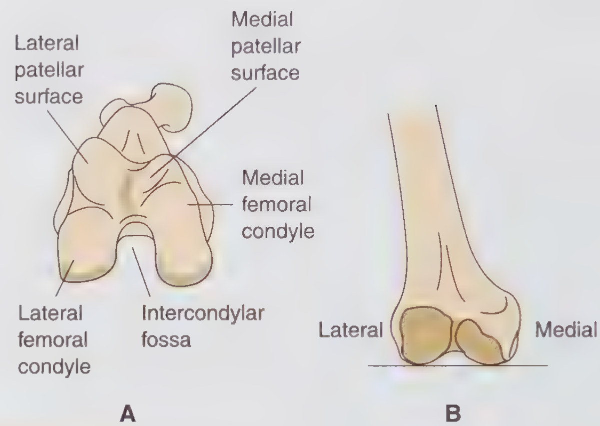

FIGURE 20-1 **(A)** View of the femoral surface from the inferior articulating surface. Note the more anterior prominence of the lateral femoral condyle. **(B)** The medial femoral condyle is longer than the lateral, and the lateral femoral condyle lies more directly in line with the shaft of the femur as compared to the medial. (Adapted from Norkin CC, Levangie PK. Joint Structure and Function: A Comprehensive Analysis. 2nd Ed. Philadelphia, PA: FA Davis, 1992:340.)

The tibiofemoral joint is housed in a fibrous capsule; the internal surface of the capsule is lined with a synovial membrane.[3] The capsule is supported by several ligaments including the medial (MCL) and lateral collateral ligaments (LCL), the oblique popliteal ligament and the arcuate complex. The primary anterior-posterior stability is provided by the anterior (ACL) and posterior (PCL) cruciate ligaments.[4] The patella is stabilized by the quadriceps muscles and the multiple fascial layers surrounding and enveloping this sesamoid bone[3,6] (**Fig. 20-2**). The medial and lateral menisci are crescent-shaped fibrocartilaginous structures interposed between the tibia and femur, adding congruity to seemingly incompatible surfaces. The medial meniscus is semilunar, attaches to the coronary ligament peripherally, and occupies ~60% of the articular cartilage contact area of the medial compartment.[7] In contrast, the lateral meniscus is almost uniformly circular, is more mobile than the medial meniscus, and occupies ~80% of the articular cartilage contact area of the lateral compartment[7] (see **Table 20-1**).

The complex interaction among joints, including the pelvis, hips, distally through the ankle mortis and foot make discussion of myology at the knee more complicated. For the purposes of

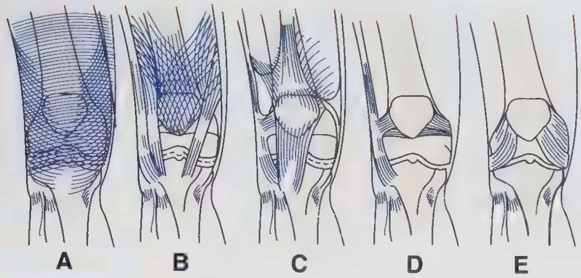

FIGURE 20-2 The multiple soft tissue layers affect the patellofemoral joint: **(A)** the superficial arciform layers with transverse fibers over patella and patellar tendon; **(B)** the intermediate oblique layer with chevron-oriented fibers from the rectus femoris, VL, and VM; **(C)** the deep longitudinal layers, which are extremely adherent to the anterior surface of the patella; **(D)** the deep transverse layer blending with fibers of the ITB; and **(E)** the deep capsular layer composed of the medial and lateral patellomeniscal ligaments. (Adapted from Dye SF. Patellofemoral anatomy. In: Fox JM, Del Pizzo W, eds. The Patellofemoral Joint. New York, NY: McGraw-Hill, 1993:5.)

TABLE 20-1

Arthrology Key Concepts at the Knee

- Posteriorly, the capsule is reinforced by the oblique popliteal ligament
- Medially, the capsule reinforced by three layers of the medial collateral ligament (superficial, middle, and deep layers)
- Laterally, the capsule extends to tibial margin and fibular head, and is reinforced by lateral collateral ligament
- Anteriorly, the capsule blends with expansion of vastus lateralis and vastus medialis muscles to attach to patella and patellar tendon
- Anterior expansion continues medially and laterally to the collateral ligaments and tibial condyles
  - This expansion is known as medial and lateral patellar retinacula or extensor retinaculum
  - Multiple layers implicated in patellofemoral pathology (Fig. 20-2)
- The capsule is reinforced by the patellar tendon
- Synovial plicae are embryonic remnants of synovial septa remaining into adulthood that may cause symptoms

anatomy, only the muscles crossing the knee joint proper will be discussed. Reviews of muscles at adjacent joints can be found in their respective chapters (Chapters 19 and 21). The primary anterior muscles are the quadriceps femoris, consisting of the rectus femoris, vastus lateralis (VL), vastus intermedius, and vastus medialis (VM). These muscles serve as the primary knee extensors. The posteriorly located hamstring muscles are comprised of the biceps femoris, semimembranosus, and semitendinosus, and serve as the primary knee flexors, besides assisting in hip extension and rotation. In addition, the popliteus, which flexes and internally rotates the tibia on the femur, plays a key role in unlocking the knee joint from the screw home position. As such, the popliteus is often termed the "key to the knee".[3] Medially, the gracilis, adductor magnus, and adductor brevis function to adduct the hip but also serve to stabilize the medial aspect of the knee joint. The lateral musculature (gluteus maximus, tensor fasciae latae, and iliotibial tract) functions primarily at the hip but can be symptomatic at the knee as well.[8]

Kinematics

Although the knee joint is classified as a simple hinge joint, the kinematics of this joint are the result of the complex interplay of bony and soft tissue anatomy. Key aspects of tibiofemoral kinematics are as follows, and further information can be found on the website:

- The tibiofemoral has two degrees of freedom, including flexion and extension in the sagittal plane and internal and external rotation in the transverse plane (provided the knee is slightly flexed).[3]
- Varus and valgus motion occur in the frontal plane.
- Shearing or translation can occur in both the anterior and posterior direction and medial and lateral direction.
- The joint experiences both distraction and compression.
- Normal range of motion (ROM) is from 0 degrees (full extension) to 140 degrees of flexion.[8]
- Flexion is limited by the cruciate ligaments and posterior horns of the menisci.[7]
- Extension is limited by the cruciate ligaments, posterior capsule, and anterior horns of the menisci.[3]
- The screw home mechanism, also called conjunct rotation, is driven by the shape of the femoral condyles, the passive tension of the ACL, and the lateral pull of the quadriceps muscle.[3]
- Varus or valgus stress is likely to damage respective collateral ligaments and, if significant, the cruciate ligaments.
- The instant center of rotation changes throughout the ROM. Alterations in the instant center of rotation following injury can produce areas of increased loading on articular cartilage[9] (see **Fig. 20-3**).

Understanding the kinematics of the patellofemoral joint helps guide intervention choices for problems such as patellofemoral pain (PFP), discussed in detail later in the chapter. At full extension, in the screw home position, there is no contact between the patella and the femur. As the knee starts to flex, the inferior patellar pole first contacts the femur at approximately 20 degrees of flexion. As flexion proceeds to 90 degrees, the contact area on the patella moves proximally, toward the central portion of the patella. The "odd" facet does not come into contact with the medial femoral condyle until the knee is flexed 135 degrees. Even with maximal contact of the femur and the patella, which occurs somewhere between 60 and 90 degrees, only approximately one-third of the patellar undersurface is in contact with the femur[3] (see **Fig. 20-4**).

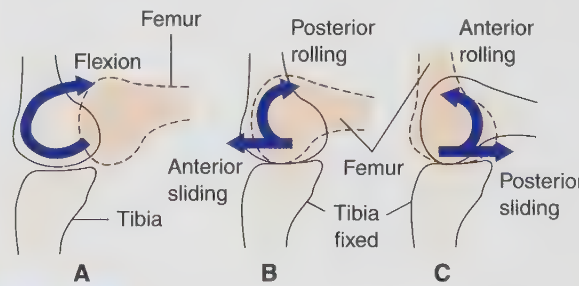

FIGURE 20-3 **(A)** Pure rolling of the femur on the tibia. The femur would roll off the tibia if no gliding occurred. **(B)** Posterior rolling and anterior gliding occur with flexion, while **(C)** anterior rolling and posterior gliding occur with extension. (Adapted from Norkin CC, Levangie PK. Joint Structure and Function: A Comprehensive Analysis. 2nd Ed. Philadelphia, PA: FA Davis, 1992:355.)

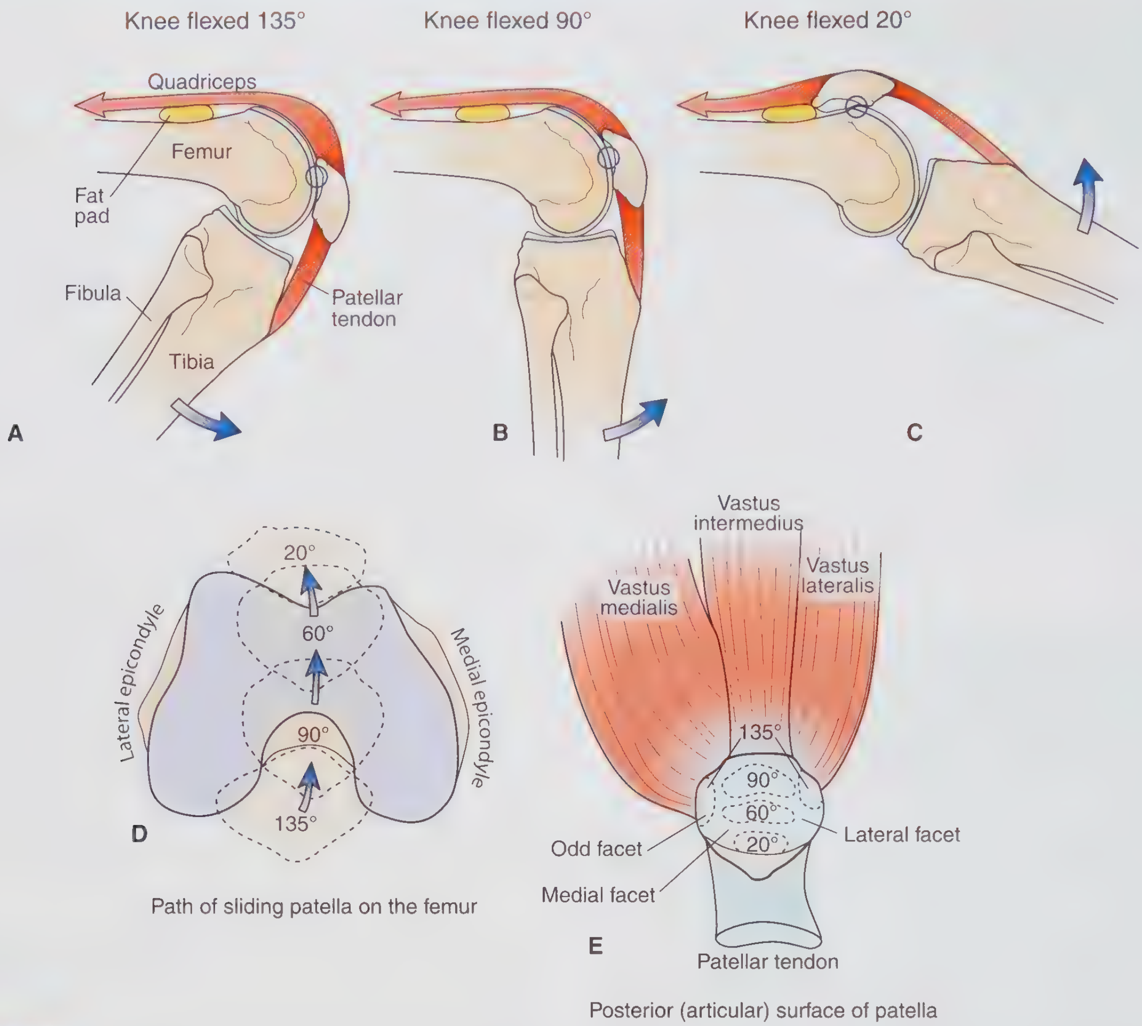

FIGURE 20-4 The kinematics at the patellofemoral joint during active tibial-on-femoral extension. The circle depicted in **(A)** to **(C)** indicates the point of maximal contact between the patella and the femur. As the knee extends, the contact point on the patella migrates from its superior pole to its inferior pole. Note the suprapatellar fat pad deep to the quadriceps. **(D)** and **(E)** show the path and contact areas of the patella on the intercondylar groove of the femur. The values 135, 90, 60, and 20 degrees indicate the flexed position of the knee. (From Neumann DA. Kinesiology of the Musculoskeletal System. 2nd Ed. St. Louis, MO: Elsevier, 2010; used with permission.)

In ideal static alignment, the patella is situated slightly laterally because of the screw home mechanism that lateralizes the tibial tubercle. As the knee flexes and the tibia derotates, the patella is drawn into the trochlear groove. The patella remains in the trochlear groove from approximately 20 to 90 degrees of flexion. With continued flexion, the patella moves laterally and completes a lateral C-shaped curve. This motion is passive when the knee is flexing. However, the tracking changes during active knee extension, and the patella moves superiorly along the line of the femur if the vastus medialis obliquus (VMO) and the VL are in balance.

Kinematics of Gait

Range of motion from 0 to 60 degrees at the knee is necessary for normal gait. However, this presumes normal mobility at the pelvis, hip, ankle, and foot. Any limitations at adjacent joints may require additional motion at the knee. When the foot makes initial contact with the ground, the knee is fully extended. The knee then flexes to 15 degrees during the loading response of gait. After this initial flexion, the knee begins to extend until it reaches full extension at midstance. As the body weight passes over the limb, the knee passively flexes to 40 degrees. As the knee moves into the initial swing phase, the knee further flexes to 60 degrees to assist the foot clearing the floor. The knee then continues to extend through the midswing and terminal swing phases, achieving full extension before initial contact (**Table 20-2**).

Kinetics

Tibiofemoral Joint

Ground reaction forces and muscle activation combine to create significant forces about the knee joint. Malalignment in any plane can result in considerable focal increases in force. Motions occurring in the sagittal plane result primarily in activation of the knee flexors and extensors. During different phases of the

TABLE 20-2

Kinetics and Kinematics of the Gait Cycle at the Knee

PHASE OF THE GAIT CYCLE	ROM (DEGREES)	MOMENT	MUSCLE ACTIVITY	MUSCLE CONTRACTION TYPE
Initial contact	0	Flexion	Quadriceps	Isometric
			Hamstrings	At hip, isometric
Loading response	Flexes 0–15	Flexion	Quadriceps	Eccentric
Midstance	Extends to 5 flexion	Flexion moving toward extension	Quadriceps	Concentric
Terminal stance	Extends to 0	Extension	Minimal	
Preswing	Flexes to 40	Flexion	Minimal	
Initial swing	Flexes from 40 to 60		Hamstrings	Concentric
Midswing	Extends from 60 to 30		Mostly passive with some hamstrings	Eccentric
Terminal swing	Extends from 30 to 0		Hamstrings	Eccentric
			Quadriceps	Concentric

gait cycle, the quadriceps and hamstrings contract in response to the moments created with walking. The muscles contract concentrically, eccentrically, or isometrically during the gait cycle. This information is summarized in Table 20-2.[3]

Ground reaction forces, muscular forces, and the normal lower extremity alignment combine to produce important loads in the frontal plane. During the stance phase, the varus moment at the tibiofemoral joint produces a relative compression in the medial compartment and distraction in the lateral compartment of the knee. This puts greater loads on the medial articular structures (e.g., articular cartilage, meniscus) and on the lateral stabilizing structures (e.g., LCL, joint capsule). Force plate analysis demonstrates that ground reaction vertical force rarely exceeds 115% to 120% of body weight during normal ambulation. However, during jogging and running, ground reaction forces approach three times the body weight.[9]

Patellofemoral Joint

In addition to ground reaction forces, joint reaction forces are created at the patellofemoral joint by tension in the quadriceps and the patellar tendon. As the knee flexes in a weight-bearing position, greater quadriceps torque is required, and joint reaction force increases. For example, the quadriceps torque during level walking is one-half of the body weight, stair-climbing is three to four times the body weight, and squatting is seven to eight times the body weight. These compressive forces can be minimized by a properly aligned patella, which disperses the force over a large surface area. Patellar subchondral bone with a strong, well-organized trabecular arrangement also minimizes joint reaction forces. Pathology, such as degeneration of patellar or femoral chondral surfaces, further reduces the ability of the patellofemoral joint to respond to load.

The balance between the VMO and VL appears to be important for maintaining normal patellar tracking, although the precise recommendations are unclear. Results of surface electromyography (EMG) have suggested an approximately 1:1 ratio of VMO to VL input in normal individuals and <1:1 in those with PFP.[10,11] This issue will be discussed further in the "Patellofemoral Pain Syndrome" section. In addition, small amounts of swelling (as little as 20 mL fluid) may inhibit the VMO.[12]

IMPAIRMENTS OF BODY STRUCTURES

The primary anatomic impairments at the knee occur in the frontal plane. Alignments of the hip, knee, and ankle combine to form an integrated kinetic chain, which must be considered in its entirety. The position of the hip affects the position of the knee, and the position of the knee dictates foot position. The anatomic impairments at the knee must be evaluated in light of the posture of the lumbopelvic, hip, ankle, and foot joints.

Genu Valgum

The femur descends obliquely from the hip in a distal and medial direction. This medial angulation with a vertical tibia results in a valgus angle at the knee, or genu valgum (**Fig. 20-5A**). This medial angle is 5 to 10 degrees. Any angle greater than this is considered to be excessive genu valgum. This valgus position places greater load on the lateral compartment of the knee and creates a tensile and unloading force at the medial compartment. Over time, development of degenerative joint disease in the lateral compartment produces physiologic lengthening of the MCL as the lateral compartment collapses and the medial compartment is unloaded. Increased knee valgum increases the lateral pull of the quadriceps, placing excessive loads on the patellofemoral joint and increasing the risk of patellar dislocation. Genu valgus is associated with coxa varum at the hip and excessive pronation at the subtalar joint.[3]

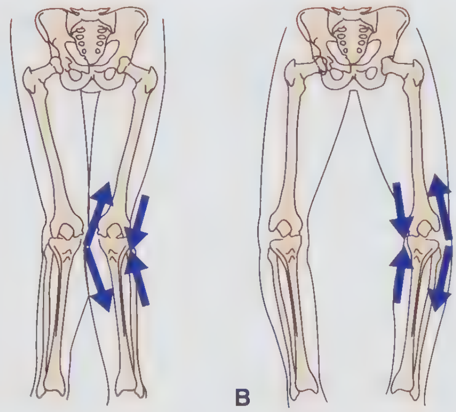

FIGURE 20-5 **(A)** Decreased tibiofemoral angle associated with coxa vara results in genu valgum. **(B)** Increased tibiofemoral angle associated with coxa valga results in genu varum. (Adapted from Norkin CC, Levangie PK. Joint Structure and Function: A Comprehensive Analysis. 2nd Ed. Philadelphia, PA: FA Davis, 1992:344.)

Genu Varum

When the angulation of the femur and tibia is vertical (0 degrees) or laterally oriented, the condition is referred to as genu varum (Fig. 20-5B). Genu varum increases the loads in the medial compartment of the knee and relatively unloads the lateral compartment. Genu varum is associated with coxa valgum, and because the heel contact occurs in a calcaneal varus position, excessive pronation occurs to orient the calcaneus vertically.

EXAMINATION AND EVALUATION

As with all the joints of the lower extremity, a comprehensive knee examination includes the adjacent joints and the lumbopelvic region. The choice of specific tests and measures for the examination depend on the situation. The following sections discuss key aspects of knee joint examination.

Patient/Client History

The most important data to be gathered first are subjective information, which subsequently guides the objective examination and provides the clinician with important information about activity limitations and participation restriction. Key questions focus on which symptoms are most disabling for the patient. Patients may report pain, instability, mobility loss, weakness, or catching as their chief complaint. From this information, the clinician selects tests and measures to match the patient's symptoms and designs a treatment program to address impairments directly related to the activity limitations and participation restrictions described by the patient. The examination must clarify the source of symptoms through thorough questioning and appropriate test and measure choices. For example, a history of a deceleration injury along with complaints of the knee giving way would lead the clinician to tests such as a Lachman's test or a pivot shift test to assess the integrity of the ACL. Refer to Chapter 2 for detailed subjective interviewing information including *History* (Display 2-1) and *Systems Review*.

Tests and Measures

The objective examination should begin with observation of posture and position of the lower extremity. Clearing tests for the lumbopelvic and hip regions should be performed. Any of these areas may refer pain to the thigh, knee, or calf; as such, the clinician needs to be certain the source of symptoms is not an adjacent joint. See Magee's *Orthopedic Physical Assessment*[13] for a more complete description of examination techniques.

THERAPEUTIC EXERCISE INTERVENTION FOR BODY FUNCTION IMPAIRMENTS

After a thorough examination and determination of the diagnosis and prognosis, the treatment plan is implemented. Any impairments identified must be correlated with an activity limitation or participation restriction, with this aspect of the patient's care treated concurrently. However, some impairments must be improved before their associated activity limitation or participation restriction can be addressed.

Mobility Impairment

The first step in treating decreased mobility of the knee is determining the cause. Decreased mobility can be caused by connective tissue (i.e., musculotendinous, capsular) shortening. Mobility can also be diminished by iatrogenic or pathologic abnormalities such as an incorrectly placed ligament graft, a hypertrophic fat pad, or disuse. Examining the pattern of limitation and the patient's location of pain can clarify the cause of mobility impairment. Hypomobility at the knee joint results in compensation at adjacent joints. For example, squatting down with limited knee motion requires additional motion at the hip, ankle, and low back, which puts these joints at risk of injury from the excessive demands placed on them. Thus, adjacent joints must be examined simultaneously.

Mobilization Techniques

Capsular restriction is common after total knee arthroplasties, surgical intervention, or immobilization. Capsular limitations can occur at the tibiofemoral joint, patellofemoral joint, or both, and the source of the limitation must be ascertained. Full knee extension requires superior glide of the patella and anterior glide of the tibia on the femur. Knee flexion requires inferior glide of the patella along with posterior glide of the tibia on the femur. Capsular restrictions are treated with the respective glides and joint distraction techniques. Distraction mobilizations are often helpful for increasing general knee ROM. To increase knee flexion ROM, the therapist can apply distraction to the tibiofemoral joint with the knee flexed while concurrently performing a posterior glide of the tibia on the femur, gently moving the knee into further flexion (**Fig. 20-6**). Manual therapy to increase knee extension can be performed with the patient in prone, with the tibia off the end of the table. The therapist can apply long-axis distraction and combine this with an anterior glide of the tibia. Additionally, if the therapist wants to focus on enhancing the screw home mechanism, the therapist can perform the anterior glide by biasing the medial side of the tibia, creating external

FIGURE 20-6 Joint distraction and posterior glide of the tibia on the femur can be performed simultaneously to increase knee joint flexion mobility.

rotation of the tibia on the femur (**Fig. 20-7**). In addition, a cable weight system works well for applying traction to increase knee extension ROM, and the patient can perform this intervention independently. Using a figure-of-eight strapping technique around the foot and ankle, attach the strap to the cable of a weight stack. A small bolster or towel roll should be placed under the ankle. The patient moves away from the weight stack enough to lift it, applying longitudinal traction to the leg. Additional weight can be placed on top of the knee to push it into further extension (**Fig. 20-8**). If the patient is irritable, treatment can begin in the loose packed or resting position of the knee, which is 25 degrees of flexion.[13] As the joint becomes less irritable, the knee can be positioned closer to full extension.

Self-stretching exercises can be performed to increase knee flexion ROM. A gravity-assisted supine wall slide will facilitate knee flexion. Starting with the buttocks approximately 18 inches from the wall, place the feet up on the wall. Slowly slide the affected knee down until a stretch is felt. The position can be modified by bringing the buttocks closer or further from the wall (**Fig. 20-9**). In addition, the knee can be easily stretched while sitting in a chair at work or school. Slide the foot of the involved knee as far back as possible, then slide forward in the chair, keeping the foot planted, further flexing the knee. Self stretching is also effective in prone, using a strap or, if at least 90 degrees of flexion is available, a weight can be used. If a strap is used, the patient can be instructed in the proprioceptive neuromuscular facilitation technique of hold-relax. The patient pulls the knee into flexion via a strap until a stretch

FIGURE 20-7 Knee distraction combines with an anterior glide of the tibia on the femur with an external rotation bias to encourage the screw home mechanism.

FIGURE 20-8 Knee extension with longitudinal distraction applied by a stack weight.

is felt in the quadriceps. The patient then tries to extend the knee against the resistance of the strap by firing the quadriceps. This mild, isometric contraction is held for 5 seconds, followed by a relaxation of the quadriceps with a concurrent pull of the strap into more knee flexion.[14] This stretching strategy may be

A

B

FIGURE 20-9 Wall slide for knee flexion ROM. **(A)** Starting position. **(B)** Slide the foot down the wall until a gentle stretch is felt.

beneficial when the patient demonstrates muscle guarding and it is necessary to inhibit the muscle.

Self stretching to increase knee extension proves to be more challenging. Prone hangs, where the patient lies prone with the knee at the edge of the table and the leg hanging off the end, may be beneficial. An ankle weight can be added to increase the force into extension. A similar activity can be performed in supine with a small bolster under the ankle, letting gravity and/or additional weight on the distal femur press the knee into extension.

Quadriceps setting is an excellent exercise to increase and maintain superior patellar glide (see **Self-Management 20-1**). However, if adhesions in the suprapatellar pouch limit the excursion of patellar glide, these exercises may increase patellar pain. Patellar mobilization in the direction of limitation can be performed by the therapist or by the patient in a home program (see **Self-Management 20-2**).

SELF-MANAGEMENT 20-1
Quadriceps Setting Exercise

Purpose: To strengthen quadriceps muscle, mobilize patella superiorly, stretch tight tissues behind the knee, and reeducate the quadriceps how to work

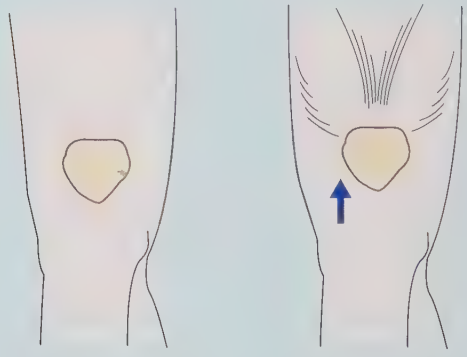
Position: Sitting with the legs straight out, toes pointed up to the ceiling; a small towel may be placed behind the knee

Movement Technique: Level 1: Tighten the quadriceps muscle on top of your thigh. You should see your kneecap move up toward your hip. Your knee may push down toward the floor, and your foot may come up off the floor. You should be unable to manually move your kneecap when doing a quadriceps set correctly. If you are having difficulty, try doing a quadriceps set on the other leg at the same time. Be sure your hip muscles stay relaxed.

Level 2: Perform the same quadriceps set in a standing position.

Dosage:

Repetitions: ______________________ times



SELF-MANAGEMENT 20-2
Patellar Mobilization Performed by the Patient

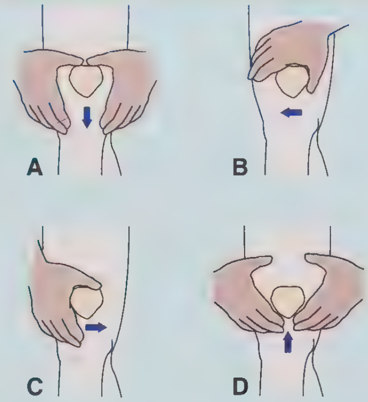
Purpose: To increase the mobility of the kneecap in all directions

Position: Sitting with the legs straight out, toes pointed up to the ceiling

Movement Technique: Using your fingers or the heel of your hand, push your kneecap (**Fig. A**) down toward your foot, (**Fig. B**) toward the outside, (**Fig. C**) toward the inside, and (**Fig. D**) up toward your hip. Hold each position for a count of five. These movements should not be painful; do not push the patella down as you move the patella.

Dosage:

Repetitions: ________________________ times



Stretching Techniques

Muscles that cross the knee joint may be identified as having decreased length. Limitations caused by muscle shortening usually are treated with stretching exercises. The quadriceps and hamstring muscles may be lengthened in several positions, but care must be taken to ensure proper positioning of the spine, pelvis, and hip. Incorrect positioning can increase the stress in these areas and decrease the effectiveness of the stretch. The quadriceps may be stretched across the knee only or, with the addition of rectus femoris stretching, across the hip (**Fig. 20-10**). The pelvis must be prevented from tilting anteriorly, increasing lumbar extension during this stretch (see **Self-Management 20-3**). Stretching the quadriceps at the knee may also be performed in prone with an abdominal support to prevent excessive lumbar extension.

The hamstrings are easily stretched in a sitting position with the knee extended and the lumbar spine held in neutral. Avoid posteriorly tilting the pelvis or flexing the lumbar spine. This exercise can be performed throughout the day at a variety of

FIGURE 20-10 Quadriceps stretching while standing. **(A)** Across the knee only. **(B)** Across the hip and knee.

SELF-MANAGEMENT 20-3

Quadriceps Stretching While Avoiding Lumbar Extension

Purpose: To increase flexibility of the quadriceps muscles

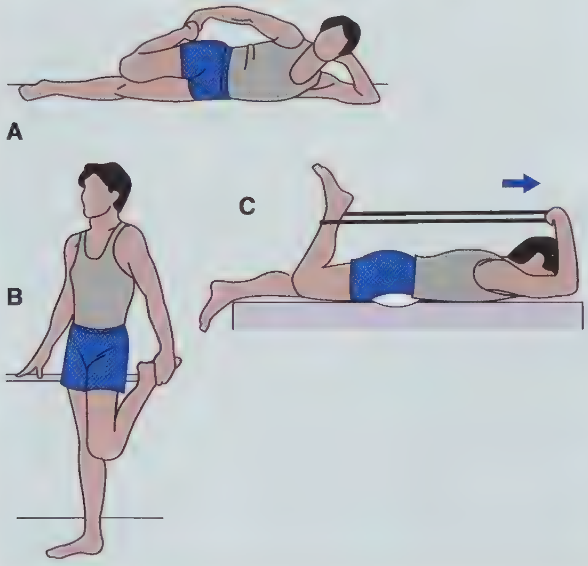
Position: This exercise can be performed in several positions. Pick a position that is comfortable or convenient for you, but avoid arching your back when stretching; tighten your abdominal muscles to keep your back steady.

1. In a sidelying position, with abdominal muscles tightened (**Fig. A**)
2. In a standing position, with some support, abdominal muscles tightened, and knees close together (**Fig. B**)
3. On your stomach, with a small pillow or towel under your hips and abdominal muscles tightened (**Fig. C**)

Movement Technique: Grasp your ankle or a strap attached to your ankle, pull it toward your buttocks until you feel a gentle stretch in the front of your thigh. Hold each stretch for 15 to 30 seconds.

Dosage:

Repetitions: ______________________ times



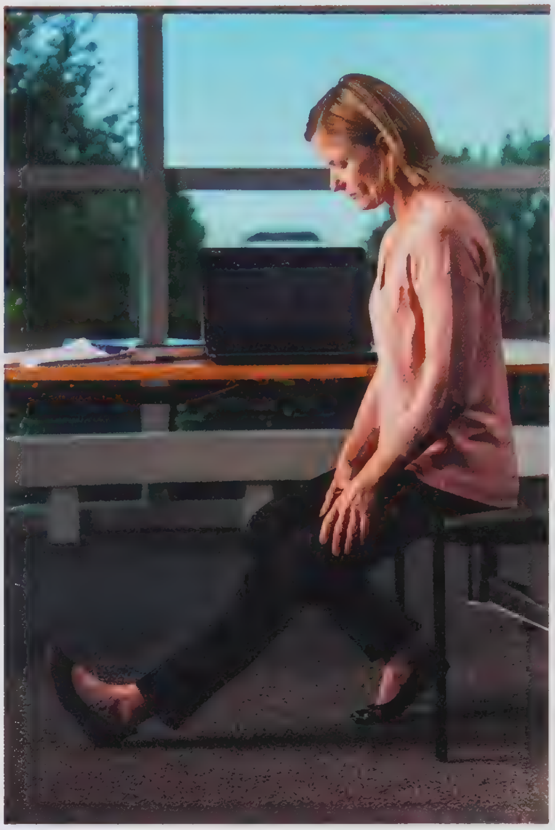


FIGURE 20-11 Hamstring stretch while seated at a workstation. Avoid lumbar flexion or a posterior pelvic tilt.

FIGURE 20-12 Lateral hip and leg stretch. Close observation prevents trunk rotation substitution for hip adduction.

workstations (**Fig. 20-11**). The medial hamstrings may be emphasized by laterally rotating the leg, and the lateral hamstrings may be emphasized by medially rotating the leg. Horizontally adducting the hip with internal rotation of the hip enhances stretching of the iliotibial band (ITB) and its associated lateral structures (**Fig. 20-12**).

In addition to the major muscle groups acting at the knee, the closed chain nature of the lower extremity necessitates assessment at adjacent joints. For example, shortening of the medial rotators of the hip or the gastroc-soleus can contribute to PFP at the knee. These tissues must be examined and treated as necessary. The reader is referred to Chapters 19 and 21 for discussions of hip and ankle flexibility.

Stability of Joint Functions

Issues with lack of stability at the joint level can result in instability. At the knee joint, stability is related to patellar instability and tibiofemoral instability. Instability is associated with clinical signs such as knee recurvatum and subtalar joint pronation. This combination may predispose individuals to PFP at the knee.

Treatment of instability at the knee joint requires postural education and retraining. This education is focused at all lower extremity joints and the lumbopelvic area. Good posture requires an integrated approach throughout the entire kinetic chain. Any further training must be superimposed on correct postural mechanics. After this posture is achieved, closed chain activities emphasizing cocontraction of lower extremity musculature enhance postural stability (**Fig. 20-13**). High-repetition, low-resistance activity is used to enhance stability (**Display 20-1**).

A B

FIGURE 20-13 Lower extremity strengthening exercise using tubing and with a focus on posture and utilization of all lower extremity musculature, including frontal plane muscles. This is a closed chain exercise on the weight-bearing side, and an open chain exercise on the non–weight-bearing side. It requires considerable balance and postural control. **(A)** Start position. **(B)** End position.

DISPLAY 20-1

Impaired Muscle Performance Associated with Neurologic Condition

Patient Case Study No. 1: The patient is a 54-year-old woman diagnosed with post anoxic Parkinsonism 10 years earlier. She has managed well until the past year when she experienced a progressive increase in her symptoms. She notes a decrease in her walking ability as well as lower extremity weakness. The patient reports three falls in the last 6 months, each time landing on her knees. This resulted in her changing her assistive device from a wide-based quad cane to a walker. However, her falls resulted in constant knee pain which compounds her gait dysfunction. Her pain is rated at 5 on a 0 to 10 scale, located in her knees and low back.

PMH: A medication error during hospitalization produced an anoxic brain injury 12 years earlier. One year after the injury, the patient began developing symptoms of Parkinsonism. The patient also has a history of chronic low back pain. The patient has a history of meniscectomy in the left knee.

Obs: The patient has resting tremor B with low amplitude; no rigidity in upper extremity (UE) with cogwheeling in right arm; finger tapping movements markedly bradykinetic; gait markedly impaired with the following characteristics: difficulty initiating gait; small shuffling steps; marked bradykinesia during attempts to turn; significant and prolonged freezing; the patient displays 1+ effusion in the left knee.

Examination

MMT: Strength testing limited by parkinsonism; quadriceps and hip flexor muscle strength grossly 4/5; hip abductor and hip extensor 4/5

ROM: Decreased mobility in hip rotation; decreased trunk ROM in all directions 25% to 30%. Knee flexion ROM from 5 to 110 degrees because of decreased use.

Flexibility: Decreased flexibility in hamstring muscles, quadriceps, and hip flexor muscles

Activity Limitations:

1. Unable to walk more than ¼ mi; requires use of walker
2. Unable to do most household chores
3. Unable to walk a full flight of stairs
4. Unable to squat ¼ normal distance
5. Unable to stand for more than 20 minutes

Participation Restrictions:

1. Unable to work outside the home or participate in usual volunteer activities.
2. Limited socialization secondary to inability to walk any distance or to stand for more than 20 minutes

Muscle Performance Impairments

Impaired muscle performance about the knee includes decreases in strength, power, and endurance of major muscle groups such as the quadriceps and hamstrings. The quadriceps are essential for controlling the motion and joint reaction forces across the knee joint, and as such, are critical for maintaining the long-term health of the joint surfaces. The muscles controlling the knee joint require, at a minimum, both strength and endurance. For many activities, power is a critical component as well. Strength is necessary to many functional activities such as rising from a chair or ascending stairs. Endurance is necessary for walking any distance, such as grocery shopping. Common non–weight-bearing exercises for increasing quadriceps and hamstring strength can be found in **Table 20-3**. These exercises isolate or bias the muscle of interest (quadriceps or hamstrings).

TABLE 20-3

Quadriceps and Hamstring Strengthening in Non–Weight-Bearing Positions

EXERCISE	GOAL	POSITION	PATIENT CUES	KEY POINTS
Quadriceps setting	1. Quadriceps strength 2. Dynamic knee control 3. Patellar mobility 4. Muscle reeducation	Any position with knee extended	"Tighten the quadriceps, push knee down, push from front of thigh, lock kneecap"	Ensure that quadriceps are firing and that the patient is not substituting with hip extension. Patella should be locked down and unable to be moved by therapist; cue patient that activation should be comfortable and does not need to be maximal
Straight-leg raise	1. Quadriceps and hip flexor strength 2. Dynamic knee control 3. Muscle reeducation 4. Core muscle strengthening	Supine with knee extended, bend opposite knee and put the foot flat on the floor to stabilize the spine	"Breathe, tighten quadriceps, lift leg to 60 degree angle, lower slowly, relax quadriceps, exhale"; if performed in standing, cue patient to "tighten knee then lift leg as in a soldier march"	Make sure patient has full control of knee via quadriceps set and maintains extension while lifting the leg (i.e., avoid a quadriceps lag); if patient is unable to perform in supine, decrease lever arm length relative to gravity; i.e., perform in standing
Short arc quad	1. Quadriceps strengthening 2. Muscle reeducation 3. Eccentrics for tendinopathies	1. Supine or long sitting with knee flexed over a bolster or short sitting with block for knee flexion 2. Standing	"Tighten quadriceps, lift foot until knee is extended, lower slowly" or "pretend you are trying to gently kick a ball"	1. If for eccentrics only, have patient lift leg to full extension with contralateral leg, then quadriceps set and lower involved leg slowly; work only in pain-free range, which may be any portion of the knee extension range of motion 2. The shorter lever arm in standing often makes this an easier exercise
Multi-angle isometrics	1. Quadriceps strengthening 2. Muscle reeducation	Short sitting with knee flexed	"Push and hold for 6 seconds, then relax." Repeat approximately every 15 degrees or in positions as dictated by injury or surgery	Can use manual resistance from another person, isometric against opposite leg, isometric against resistive bands, or with an ankle weight, using the contralateral limb to move the involved knee to the appropriate angle and hold
Knee extension: isotonic concentric and/or eccentric contractions	1. Quadriceps strengthening 2. Muscle reeducation	Short sitting	"Straighten out your knee, hold and lower slowly"	Verbal cues will change depending upon type of muscle contraction
Hamstring isometrics	1. Hamstring strengthening 2. Muscle reeducation	Short sitting, long sitting, or supine	"Tighten and hold your hamstrings as if you were trying to pull your heel back toward your buttocks"	Can be done at any angle or at multiple angles, as with multiple angle isometrics for the quadriceps
Hamstring curls	1. Hamstring strengthening 2. Muscle reeducation	Nearly any position depending upon how resistance is applied: standing, sitting, prone, supine, etc.	"Bend your knee pulling your heel toward your buttocks"	Ankle weights: best lever against gravity is in standing; in prone exercise will become gravity assisted after 90 degrees of flexion, making it an eccentric quadriceps exercise Resistive bands: any position Isokinetics: any position

Many persons also need power for performing work or recreational activities that require generating a great deal of strength in a short period of time (as in jumping activities or lifting very heavy objects). Chapter 5 describes a variety of strength, endurance, and power training activities. Plyometric exercises are commonly used to build power in the muscles surrounding the knee joint. It is critical that the individual is ready for such vigorous, impactful activities, or an overuse injury may occur. Also be sure that activities of this level are necessary and indicated for the patient. Not all patients are candidates for plyometric exercises. Common weight-bearing exercises for the lower extremity can be found in **Table 20-4**. These exercises encourage cocontraction of synergistic muscles.

Neurologic Causes

Neurologic disorders can produce impairments in muscle performance in muscles surrounding and supporting the knee joint. The most common cause is a lumbar spine injury or disease. In addition to directly affecting the quadriceps or hamstring musculature, lumbar spine pathology affecting proximal or distal musculature affects gait and other movement patterns. Altered movement patterns affect knee joint mechanics and ultimately the joint itself. Any complaints of knee joint impairments should prompt examinations of the spine and proximal and distal joints.

Other neurologic disorders, such as multiple sclerosis or Parkinson disease, profoundly affect the ability to produce torque about the knee. Each of these situations must be evaluated within the context of the disease process. Because many muscles and movement patterns are affected, a more global examination is necessary to determine the treatment strategy.

Some authorities have suggested there is a neurologic component to PFP. Studies of different quadriceps activation patterns in response to a patellar tendon tap have suggested timing differences in those with and without PFP.[15–17]

The key consideration when designing interventions for those with neurologically mediated impaired muscle performance is ensuring use of the desired muscle. Neurologic weakness produces alterations in firing patterns to accomplish movement in the most efficient manner possible. Synergists may accommodate for weakness, or biomechanical modifications may enhance the activity of other muscles as compensation for the weakness. For example, a forward lean during stair ascent allows the hip extensors to compensate for weak quadriceps (**Fig. 20-14**). Close monitoring of exercise quality is necessary to ensure training of the desired muscle (see **Building Block 20-1**).

BUILDING BLOCK 20-1

Consider the patient in Display 20-1, Case Study No. 1.

1. Given the history and examination findings, what are the likely compensations this patient is making in order to maintain her functional abilities?
2. How might your treatment program reflect these compensations? What exercises or components might be emphasized?
3. Write possible short- and long-term goals for this patient.

TABLE 20-4

Common Weight-Bearing Exercises for the Lower Extremity

EXERCISE	POSITION	PATIENT CUES	KEY POINTS
Wall sits/slides	Feet away from wall so that tibia remains vertical at lowest point of sit	"Squeeze your buttocks together and tighten your quadriceps. Slowly slide down the wall"	Core tight and stabilized; hips, knees, feet in alignment, avoiding valgus at knees. A resistive band can be placed around the distal femur with cues to the patient to keep the legs in alignment. This will increase gluteus medius activation.
Weight-bearing terminal knee extension (TKE)	Standing facing therapist or stationary object with tubing attached; tubing around posterior aspect of knee	"Keeping your foot fixed on the floor, extend your knee against the resistance of the tubing"	Tighten quadriceps with gluteals as a secondary agonist; avoid trunk flexion
Squat	Feet shoulder width apart, hips, knees, and feet in line; may modify depending upon patient situation	"Sit back like sitting on a chair; keep trunk upright, slight curve in low back; hips and knees in line"	Avoid forward lean; can be performed, full (to 90 degree flexion), partial, or mini; can be advanced by adding resistive tubing under the feet, weights in hands, or weight bar across shoulders
Split squat (stationary lunge)	Feet in stride with pelvis level	"Squat down keeping trunk vertical and avoid leaning forward"	Keep tibia in front vertical; tighten pelvis and keep neutral spine
Lunge	Normal stance with one foot stepping out	"Step forward and squat down"	Can be performed stepping forward, backward, or to side
Step-ups	Facing step	"Tighten quadriceps and hip muscles, then step up and return to the start position"	Can be performed stepping forward, backward, or to side; keep good alignment of hip, knee, and foot

FIGURE 20-14 **(A)** Ascending stairs using proper mechanics. **(B)** Ascending stairs with the hip extensor muscle substituting for a weak quadriceps muscle.

Muscular Strain and Contusions

The ability to produce torque at the knee can be affected by muscular strain injuries. The quadriceps and hamstring muscle groups are the most commonly injured, often the result of sudden decelerative forces. The quadriceps decelerates the flexing knee during the loading response of the gait cycle, and the hamstrings decelerate the forward swinging shank during the terminal swing phase. In sprinters, the hamstring works eccentrically to rapidly decelerate the tibia during the swing phase, and is at risk of injury during that phase. These eccentric muscle contractions may produce macrotraumatic or microtraumatic injury.

In addition, the quadriceps may be injured as the result of a contusion. A blow from an object such as a ball or hockey puck can produce a deep muscle contusion. With both a muscle strain and a contusion, the initial bleeding that occurs within the muscle must be controlled through relative rest, gentle stretching, and icing. The acute phase is followed by progressive mobility and strengthening. When returning the patient to function, the affected muscle should be retrained to fit the expected activity. For example, the runner with a hamstring strain injury as a result of the swing phase of gait should be trained in an open chain, decelerative function (**Fig. 20-15**). For those returning to sports, plyometric exercises

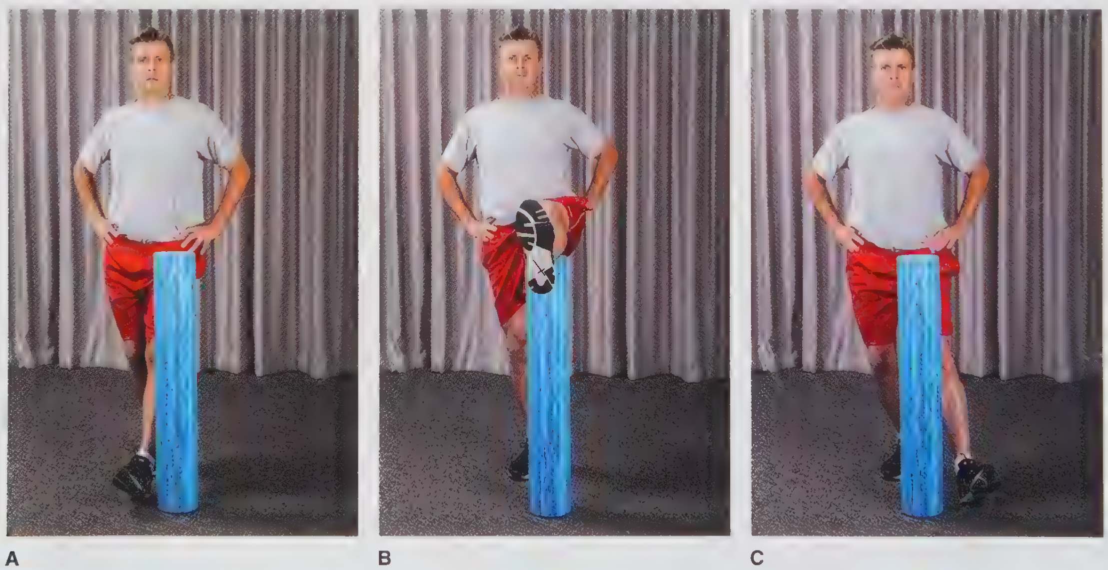

FIGURE 20-15 Open chain hamstring muscle training performing rapid concentric and eccentric hamstring contractions. **(A)** The patient starts with their involved leg on one side of the barrier (in this case, a foam roller), and rapidly lifts the leg up to the top of the barrier. **(B)** The hamstrings must act eccentrically to decelerate the leg as it reaches the top of the barrier. **(C)** The patient rapidly lowers the leg on the other side of the barrier, remaining as close as possible to the barrier. This is a concentric contraction of the hamstrings. The foot is lightly tapped on the ground, and the movement is rapidly performed back to the starting position. The movement is repeated rapidly without a pause.

are an excellent choice for retraining the lower extremity muscles. In addition, proper instruction and utilization of core muscles is a key component of lower extremity muscle rehabilitation (**Evidence and Research 20-1**).

EVIDENCE and RESEARCH 20-1

Hamstring strains are a common sports-related injury; the risk of reinjury is as high as 35%. Research has shown that athletes who completed a core stabilization and progressive agility program had a significantly lower reinjury rate than those who completed a traditional program.[18] Of the athletes who completed the agility rehabilitation program, 13% suffered a recurrent hamstring injury during the year following completion of the rehabilitation program, whereas 70% of athletes completing a traditional rehabilitation program suffered a recurrent injury. More recently, the effectiveness of two rehabilitation protocols for acute hamstring injury in Swedish elite sprinters and jumpers was compared. One protocol consisted of traditional stretching and strengthening; the other program consisted of multiplanar concentric and eccentric muscle lengthening exercises. Similar to the previous study, the authors found the athletes in the multiplanar group returned to sport sooner and suffered less reinjuries than the traditional rehabilitation group.[19]

Disuse and Deconditioning

Disuse of the knee musculature occurs primarily in the quadriceps and may occur as a result of an injury at the knee or from any other joint in the kinetic chain, including the low back. An injury at an associated joint can prevent participation in usual activities, leading to disuse of musculature throughout the kinetic chain. Disuse of the quadriceps affects the loading and midstance phases of the gait cycle, during which the quadriceps decelerate the flexing knee, followed by a change of direction and acceleration into knee extension. This quadriceps action decreases load on the joint surfaces and is critical in maintaining the health of the knee joint (**Display 20-2**).

The quadriceps muscles work to decelerate the body when descending stairs and, along with the hip musculature, to ascend stairs and arise from a sitting position. Disuse can lead to profound changes in how activities of daily living (ADLs) are performed. Failure to perform these activities efficiently and continuously places additional loads on adjacent joints. Treatment should focus on the primary cause of the disuse as well as strengthening activities for the quadriceps muscle (see **Building Block 20-2**).

BUILDING BLOCK 20-2

Consider the patient in Display 20-2, Case Study No. 2 to answer the following questions:

1. Do you think the patient's activity limitations and participation restrictions are related to underlying impairments? If so, how might you evaluate this theory?
2. If you are unable to determine the underlying cause of his functional loss, or if you believe it to be a combination of multiple factors, please suggest three exercises that might address the multifactorial nature of the problem.
3. Write some possible short- and long-term goals for this patient.

DISPLAY 20-2

Impaired Muscle Performance Due to Disuse and Deconditioning

Patient Case Study No. 2: The patient is a 78-year-old male who complains of increased leg tiredness with walking and inability to walk as far as he could previously; having difficulty getting in and out of chairs and ascending stairs; knees "feel weak." The patient has moderate to severe osteoarthritis in both knees.

PMH: Chronic asthma; stable ventricular tachycardia with right bundle branch block since 1988; renal cancer status post radical nephrectomy in 2001; left flank gunshot wound 62 years ago with continuous problems with abdominal hernias; bilateral hand tremor, left greater than right, getting worse per patient report.

Obs: The patient has bilateral Trendelenburg pattern, truncal obesity and B LE atrophy; walks with short steps, DOE after walking into treatment room from waiting area

6 Minute Walk Test: at rest: HR 49, O2 sat 96%; distance walked 885 feet without assistive device with 1 rest period; post-walk vitals: HR 116, recovers in 3 minutes; O2 sat 96%

BERG Balance Scale: 47/56 total score. Indicates a low risk of falls with standing tasks without upper extremity support. With no history of falls in the last 6 months, indicates 22% probability of future falls. Dynamic Gait Index: 21/24 total score, without an assistive device, indicates a low risk of falls with walking

MMT: normal throughout except: hip abd 4/5 B; hip ext 4-/5 B; knee extension 4/5 B

ROM: normal throughout with the exception of decreased hip external rotation

Functional Strength: requires extensive UE use for transfers in and out of chair

Activity Limitations

1. Patient unable to walk more than 400 feet without stopping to rest.
2. Unable to walk more than one flight of stairs.
3. Inability to walk on uneven ground.
4. Able to squat only ¼ of normal depth.

Participation Restrictions

1. Patient unable to maintain household and yard due to LE weakness and fatigue.
2. Unable to participate in his usual walking group, a primary social outlet for him.

THERAPEUTIC EXERCISE INTERVENTION FOR COMMON DIAGNOSES

Ligament Injuries

Anterior Cruciate Ligament

The ACL is one of the most commonly injured ligaments in the knee. The short- and long-term morbidity associated with an ACL injury with or without reconstructive surgery has made this injury the nemesis of many athletes. Fortunately, ACL injuries have become better understood and better managed, resulting in significant decreases in morbidity. The ACL tear usually occurs as the result of rapid deceleration, hyperextension, or rotational injury and does not involve contact with another individual. Injury to the ACL is frequently associated with injuries to the MCL, the medial meniscus, and the lateral meniscus. In the adolescent, the ACL may avulse from the tibial spine rather than tear in the midsubstance, and it should be surgically repaired with bone-to-bone fixation.

Although functioning independently, the ACL and PCL guide the instant center of rotation of the knee, thereby controlling joint arthrokinematics. Any alteration in normal kinematics can produce focal areas of increased articular cartilage and soft tissue loading. Sequelae such as degenerative joint disease and tendinitis must be considered when determining prognosis and treatment approach (**Evidence and Research 20-2**). Injury to the ACL can result in significant activity limitations and potential participation restrictions because of its role as the primary restraint against anterior tibial translation. Patients with ACL-deficient knees were found to have altered joint arthrokinematics in the transverse plane during walking.[20] The authors suggest that repeated rotational instability may play a role in the development of meniscus tears or osteoarthritis (OA). Rupture of the ACL results in substantially increased anterior translation of the tibia on the femur, with the maximum occurring between 15 and 45 degrees of flexion. The posterior horn of the medial meniscus provides secondary restraint against anterior tibial translation and is at risk of injury after an ACL rupture. The ACL provides stability against tibial medial and lateral rotation against varus and valgus stresses.

Because of its role in controlling the instant center of rotation, some individuals experience episodes of instability after ACL injury and subsequently fail conservative management. They may have surgery using the central one-third of the patellar tendon, the hamstring or quadriceps tendon, or an allograft.[22] Regardless of graft selection, those involved in high-demand sports may have more difficulty returning to activities without symptoms. Severe articular cartilage injury to the medial and patellofemoral compartments, as well as the presence of a lateral meniscal tear are predictive of poorer outcomes.[23] In addition, functional testing at 6 months, specifically, the single-legged hop tests, can predict the likelihood of successful outcome at 1 year after ACL reconstruction. Patients with minimal side-to-side differences on the crossover hop test at 6 months will have good knee function at 1 year if they continue with their current training regimen. Preoperative single-legged hop tests are not able to predict postoperative outcomes.[24] However, in the individual with a tear of the ACL who is managed conservatively, continued vigorous activity with an unstable knee can lead to meniscal tears, especially at the posterior horn of the medial meniscus.

Significant impairments, activity limitations, and participation restrictions occur after ACL tears, and are outlined in **Table 20-5**.

Persons may become disabled because these limitations prevent return to work, leisure activities, or basic or instrumental ADLs. This may be the beginning of a downward spiral of decreased physical activity, increased weight gain and obesity, and systemic disease, such as diabetes.

Rehabilitation issues of concern when treating the individual after ACL injury include the impairments, activity limitations, and participation restrictions identified during the evaluation. In addition, any concomitant injuries and the impairments caused by them must be identified. Associated injury to the MCL, meniscus, or articular cartilage impacts the rehabilitation program. The arthrokinematic changes and potential for secondary injury guide rehabilitation. Resistive open chain quadriceps exercises between 15 and 45 degrees are often avoided because of the increased anterior tibial translation found with this type of exercise.[25] This translation is minimized in a closed chain exercise, a good choice after ACL injury or reconstruction. Because of the difficulty in returning to deceleration and cutting maneuvers, the rehabilitation program should include these types of movements in addition to multiplanar resistive, balance, and coordination activities. Exercises may include resisted lateral movements, resisted rotational movements, and activities on unstable surfaces. Individuals returning to high-demand athletics frequently participate in a plyometric program as well (see **Building Block 20-3**).

EVIDENCE and RESEARCH 20-2

The development of knee osteoarthritis (OA) after anterior cruciate ligament (ACL) injury has been reported in the literature. A recent meta-analysis reported on the progression of OA after ACL injury, with a mean follow-up of 10 years. The authors found that 20.3% of ACL-injured knees had moderate or severe radiologic changes compared with 4.9% uninjured ACL-intact contralateral knees. Interestingly, after sustaining an ACL injury, irrespective of whether the patients were treated operatively or nonoperatively, the relative risk (RR) of developing minimal OA was 3.89, while the RR of developing moderate to severe OA was 3.84. ACL tears treated nonoperatively had a higher RR of 4.98 of developing any OA compared with those treated with reconstructive surgery, who had a RR of 3.62. The authors concluded that ACL injury predisposes knees to OA. As a clinician counseling patients who have injured their ACL, this information should be considered when educating patients. Regardless of whether the patient is managed conservatively or surgically, the patient must understand their role in the long-term management of their knee. The patient should be encouraged to maintain a healthy weight, and continue strength training, flexibility exercises, and cardiovascular exercise throughout their lifetime to promote the long-term health of their knee.[21]

TABLE 20-5

Common Impairments, Activity Limitations, and Participation Restrictions Following Knee Ligament Injuries

LIGAMENT INJURY	EXAMINATION FINDINGS	ACTIVITY LIMITATIONS	PARTICIPATION RESTRICTIONS	REHABILITATION ISSUES
ACL tear: acute	Effusion + Lachman test + Arthrometer testing Pain, instability, LOM, limited WB	Need for assistive device ADL, IADLs limited Difficulty with stairs	Inability to participate in work, sports, leisure activities requiring any physical exertion, full WB or lifting or carrying objects	Concomitant injuries (MCL, meniscus, etc.) Avoid open chain quadriceps exercises from 15 to 45 degrees due to increased anterior tibial translation. Restore full motion, prepare for surgery if planned
ACL tear: chronic (symptomatic)	Chronic low-grade effusion + Lachman's, pivot shift tests Instability + Arthrometer testing	Inability to participate in usual activities due to instability	Inability to participate in usual activities due to instability	Protection of secondary stabilizers such as medial meniscus Joint protection perspective
PCL tear	+ Posterior drawer, posterior sag tests Effusion, LOM, limited WB	Need for assistive device ADL, IADLs limited Difficulty with stairs Difficulty walking down ramps/inclines	Inability to participate in work, sports, leisure activities requiring any physical exertion, full WB, or lifting or carrying objects	Protection of structures in medial and anterior compartments History of osteoarthritis, varus alignment, patellofemoral pain, and arthrofibrosis
MCL tear	Loss of full extension, flexion + Valgus stress test at 30 degrees Tender over MCL History of valgus stress Local swelling but no joint effusion	Difficulty with frontal and transverse plane movements Difficulty walking on uneven surfaces	Inability to participate in work, sports, leisure activities requiring walking on uneven surfaces, frontal plane movements, etc.	Structural properties of ligament may lag behind clinical testing ability
LCL tear	History of varus, hyperextension stress Loss of full extension + Varus stress test at 30 degrees Tender over LCL Local swelling but no joint effusion	Minimal limitations unless combined with posterior-lateral corner injury Difficulty with frontal plane movements and may have difficulty with walking if increased varus is noted with ambulation	Limitations in high-demand physical activities, especially those involving quick direction changes	Prolonged course of ligament remodeling, as the weight-bearing phases of ambulation constantly tense the LCL

ACL, anterior cruciate ligament; WB, weight bearing; ADL, activities of daily living; IADL, instrumental activities of daily living; MCL, medial collateral ligament; PCL, posterior cruciate ligament; LOM, loss of motion.

BUILDING BLOCK 20-3

Consider a 22-year-old male recreational basketball player who tore his ACL 2.5 weeks ago and will be undergoing surgical ACL reconstruction in a few weeks if he continues to experience instability. He also has a first-degree MCL injury.

1. Describe three exercises you might use to strengthen his quadriceps in preparation for surgery. Include rationale for your choices.
2. What criteria might be used for initiating frontal or transverse plane activities? Provide examples of low-level frontal and/or transverse plane activities.

Because of the high incidence of ACL injuries in athletes, particularly female athletes, clinicians have been searching for factors predisposing females to these injuries, and for interventions to prevent their occurrence.[26–31] A number of factors have been considered, including joint laxity, postural factors (i.e., genu recurvatum, excessive foot pronation), notch width, neuromuscular coordination, hormone levels, training and conditioning, and position. Sorting out the contributions of these factors has been a challenge, particularly because there is overlap among many of the factors. Factors such as increased knee laxity, increased dynamic knee valgus, and high abduction loads during landing from a jump seem to be predictive of future ACL injuries.[32]

However, a large body of evidence is accumulating supporting the success of neuromuscular training (NMT) programs on the biomechanics of jumping, neuromuscular performance and on the subsequent incidence of ACL injuries.[27,33–38] These studies have found that NMT can improve neuromuscular performance by improving the biomechanics of landing from a jump and by decreasing knee adduction moments and peak landing forces.[39] More importantly, NMT programs have significantly reduced the incidence of ACL injuries[26,28,29,31–34,36,37,39,40] (**Evidence and Research 20-3**).The NMT programs should include education on the proper mechanics of landing, jumping, acceleration, deceleration, and changing direction (see **Patient-Related Instruction 20-1**). It is difficult to determine which component resulted in the decreased incidence of injury: the education, strength increases, neuromuscular coordination improvement, or changes in biomechanics/posture. However, the combination of these factors in the NMT program has been effective in decreasing ACL injuries in female athletes (see **Display 20-3**).[26,28,29,31–34,36,37,39,40]

EVIDENCE and RESEARCH 20-3

In a meta-analysis by Sugimoto et al,[41] the authors found a greater knee injury reduction in female athletes who participated in neuromuscular training (NMT) as compared to females who did not participate in NMT. In fact, the NMT reduced the risk of sustaining an ACL tear by 46%. In a subsequent meta-analysis, the authors determined the potential dosage effects of NMT for ACL injury reduction in female athletes. The authors found that NMT of long duration (>20 minutes) was more effective than short-duration (<20 minutes) NMT. NMT performed two times per week or greater indicated greater ACL injury reduction compared to NMT performed one time per week. The authors concluded that the higher NMT volume, the greater prophylactic effectiveness of the NMT program and increased benefit in ACL injury reduction among female athletes.[42]

For individuals involved in sports requiring deceleration, cutting, jumping, and pivoting, ACL reconstruction may be necessary to allow return to the previous competitive level. A new ligament is comprised of either the middle third of the patellar tendon or quadriceps tendon or a looped hamstring tendon. An allograft may also be used. The ligament is placed within the knee arthroscopically and is fixated in bony tunnels. A sample protocol for rehabilitation following ACL reconstruction can be found in **Table 20-6**. A similar program can be followed for nonoperative treatment of ACL injuries, keeping in mind any complications of continued instability.

Patient-Related Instruction 20-1

Proper Landing, Cutting, and Direction Change Techniques for Prevention of ACL Injuries

- Land softly on both feet with weight distributed equally over both lower extremities
- Land on the forefoot and roll to the rearfoot
- Keep knees over toes, avoiding letting the knees roll in
- Activate and tighten hip and thigh muscles while landing to decelerate the landing
- Take several small steps to slow down and change direction, rather than a plant and twist

DISPLAY 20-3

Neuromuscular Training for Injury Prevention

- Warm-up: any large muscle group activity
  - Jogging
  - Bicycling
  - Calisthenics
- Flexibility: stretching hip and leg muscle groups via static and dynamic stretching
  - Quadriceps and hamstring muscles
  - Hip flexors, extensors, rotators, abductors, adductors
  - Calf musculature
  - Low back
- Dynamic balance: teaching proper landing techniques
  - Land on ball of foot
  - Hop with knees bent
  - Land with knees in flexion
  - Knees under hips avoiding hip internal rotation and knee adduction
- Dynamic balance: impact activities
  - Front-back and side-to-side hopping
  - Hop and stick the landing
  - Cone hopping: with and without turns
  - Agility drills including direction changes
  - Vertical box hops: single and multiple, with and without turns

Posterior Cruciate Ligament

PCL injuries represent an estimated 1% to 30% of all knee ligament injuries.[43] Most injuries occur as the result of a trauma such as a motor vehicle accident, with fewer PCL injuries occurring in sports.[43] The mechanism producing a PCL injury is most often a blow to the anterior aspect of the tibia, forcing it posteriorly. Less commonly, the PCL is injured as a result of hyperflexion, hyperextension, or a varus or valgus injury. In the case of hyperextension, the ACL is usually injured first. In the varus or valgus injury, the respective collateral ligament is injured, and in some cases, the ACL is injured before the PCL injury.

The PCL is the primary restraint to posterior translation of the tibia on the femur, providing approximately 95% of the resistance against posterotibial translation.[44] A tear of the PCL results in significant increases in posterior tibial translation, with the greatest occurring between 70 and 90 degrees.[43,44] The PCL also resists varus or valgus translation and is a secondary restraint to lateral tibial rotation.[43,44] Along with the ACL, the PCL helps control the instant center of rotation at the knee and joint arthrokinematics. The alteration in joint arthrokinematics after PCL rupture can result in significant problems. Articular cartilage contact pressures in the medial and anterior compartments are increased after PCL rupture, with peak medial pressures at 60 degrees and peak anterior compartment pressures at 90 degrees of flexion.[43] The individual with a PCL rupture generally complains of pain related to these changes, as well as PFP, rather than frank instability.

TABLE 20-6

Rehabilitation Following an ACL Reconstruction

	PHASE 1	PHASE 2	PHASE 3	PHASE 4
Goals	1. Full active knee extension comparable to contralateral knee and flexion to 125 degrees 2. No swelling 3. Knee control weight-bearing and non–weight-bearing 4. Normalize gait	1. Restore posture and control with basic movements 2. Increased lower extremity and core strength 3. Increased static and dynamic balance 4. ROM equal to contralateral leg	1. Performance of multi-plane strengthening and functional exercises 2. Effective eccentric control for impact loading 3. Functional dynamic mobility	1. Single-leg control during impact 2. Effective posture and eccentric control with direction change 3. Efficient performance of skill activities
ROM and mobility	Knee extension with bolster under ankle Prone hang Supine wall slides Heel slides Seated knee flexion Patellar mobilization	Continue phase 1 until goal is achieved Stationary bike with seat lowered for gentle stretch Prone knee flexion Stretching for other lower extremity muscle groups	Continue previous exercises as needed Add dynamic warm-up and dynamic mobility activities (i.e., skipping all directions, carioca, shuffles, etc.)	Continue dynamic warm-up
Muscle performance and proprioception	Quadricep and hamstring sets Standing leg lifts Weight shifts Double leg minisquats Toe raises Core strength (abdominals, crunches, etc.)	Squats Step backs down off a step Stationary lunge Single-leg balance with arm and weight shift perturbation Core strength (advanced crunches and bridges)	Squat with knee lift Squat and reach Retro step-up Lunge walk (forward, back, side, diagonal) Takeoff and landing drills Advanced balance exercises Core strength (continue to advance)	Landing control: Jump rotations Fast feet and lunge Multi-plane leap and land Stop and go Hopping Cutting and pivoting drills Lunge with resistance Advanced core activities
Gait and cardiovascular	Diagonal weight shifts Backward stepping Step over 4 in obstacle	High knee walking all directions Hurdler walk with hip circles Diagonal stride and hold forward and back	Progress to appropriate cardiovascular activity	Progress to sport or activity-specific cardiovascular training

ACL, anterior cruciate ligament; ROM, range of motion.

The natural history of the PCL-deficient knee is difficult to assess because of the heterogeneity of most populations studied. Many patients remain asymptomatic and are able to return to their preinjury activity levels, but others develop osteoarthritic changes in the medial and anterior compartments.[43] The clinician must consider the possibility of these changes and modify the rehabilitation program appropriately. Some persons with multiple ligament or soft tissue injuries undergo reconstruction of the PCL using static restraints such as the central one-third of the patellar tendon, Achilles tendon, or allograft.[45]

The extent of impairments, activity limitations, and participation restrictions after PCL rupture depends on associated injuries (see Table 20-5). When patients are seen for chronic activity limitations because of PCL deficiency, the subjective complaints usually are related to medial and anterior compartment pain, PFP and difficulty ambulating down a decline or stairs. The literature suggests that the compensatory muscle activity seen with ambulation in the PCL-deficient knee includes increased quadriceps and gastrocnemius activation, with decreased hamstring activity, which results in decreased posterior movement of the tibia on the femur.[43]

The issues affecting the rehabilitation approach are related to the potential medial and anterior compartment changes. Any additional ligament injuries that could further alter arthrokinematics or medial meniscal damage that could modify articular cartilage pressures have the potential to exacerbate compartmental changes. Comorbidities such as underlying osteoarthritic changes, a varus alignment, or history of PFP negatively alter the prognosis. These issues guide the framework from which the rehabilitation program is designed. As in treating the ACL-deficient knee, open chain resistive exercise (knee flexion in this case) can increase posterior tibial translation. As such, closed chain activities are an important therapeutic exercise mode. A sample program following PCL reconstruction can be found on the website.

Medial Collateral Ligament

The MCL consists of the tibial collateral ligament and the middle one-third of the medial capsule (deep portion), which is subdivided into a thin anterior third, a strong middle third, and a moderately strong posterior third.[46] The incidence of MCL injuries is significantly higher than that of LCL injuries, and the MCL has been reported to be the most frequently injured ligament of the knee.[46] Damage to the MCL occurs less frequently at the femoral insertion compared with the tibial insertion because of differences in the insertion site structures. The MCL is usually torn as a result of a valgus stress caused by force to the lateral side of the knee or by forced abduction of the tibia, as occurs when catching the inside edge of a ski. Associated injuries may include the ACL and medial meniscus. In the adolescent, injury to the femoral or tibial growth plate often precedes injury to the MCL and should be considered in the differential diagnosis.

The MCL is the primary restraint against valgus loads, and it resists tibial medial rotation. In the ACL-deficient knee, however, the superficial MCL also plays a role in controlling anterior tibial translation. Injury to the superficial MCL significantly increases anterior tibial translation at 90 degrees of flexion.[47] But, unlike the cruciate ligaments, the MCL has the capacity for repair without surgical intervention. Most MCL injuries heal well without any long-term damage to the knee, despite some residual valgus laxity. For this reason, most MCL injuries are usually treated conservatively.[46,47] In the individual with a combined MCL and ACL injury, a short period of recovery usually is allowed, followed by reconstruction of the ACL. Injuries to the MCL in the presence of ACL ruptures do not heal as well as isolated MCL sprains and may require additional time to heal.[46] Certain situations exist which warrant surgical intervention of the MCL. If the superficial MCL is torn from the tibial insertion and it is displaced outside the pes anserinus tendons, the ligament is unable to reattach to its insertion on the tibia, and surgical stabilization is indicated. Surgical reattachment of bony avulsions has an excellent prognosis.[47]

The impairments, activity limitations, and participation restrictions seen after acute MCL sprains are similar to those of cruciate ligament sprains (see Table 20-5). The prognosis after isolated MCL sprain is generally good because of the ligament's ability to heal well. Some individuals may experience difficulties with lateral and rotational movements or with activities on uneven surfaces. Persons returning to physical work or higher level recreational activities are most at risk of limitations in these areas. Although the clinical examination may be benign after 6 to 8 weeks of rehabilitation, the lengthy ligament remodeling process may limit the MCL's tolerance for high-demand loading.

The most significant rehabilitation issues in the isolated MCL injury are the fact that the remodeling process lags behind the clinical examination findings. In addition, the implementation of frontal and transverse plane rehabilitation techniques is critical. Traditional clinical examination procedures are not sensitive enough to determine readiness to return to high-demand activities. Frequently, the individual has full ROM, symmetric strength, minimal or no valgus laxity, no effusion, and no tenderness to palpation a few weeks after injury with proper rehabilitation. However, the MCL is not stressed much in ordinary daily activities or even in sagittal plane activities such as straight-ahead running. The ligament must be loaded and trained just like muscle tissue to ensure adequate remodeling for high-demand activities. Loading in the frontal and transverse planes must occur to strengthen the ligament and its bony attachments and to ensure a safe return to physical activities (**Figs. 20-16** and **20-17**). A sample program for rehabilitation following a grade II MCL injury can be found on the website (see **Building Block 20-4**).

FIGURE 20-16 Side stepping in the pool is an early lateral movement activity.

FIGURE 20-17 More challenging frontal plane activity includes weight shifting on rocker boards while using a medicine ball to increase the movement of the center of mass.

BUILDING BLOCK 20-4

Consider a 35-year-old patient with a second-degree MCL injury who desires to return to recreational ice hockey.

1. Describe three frontal plane and three transverse plane exercises that you would use once the patient tolerated exercise in this plane (early phase).
2. Progress these same exercises to an advanced level to prepare this patient to return to activity.

Lateral Collateral Ligament

Injuries to the LCL are much less common than injuries to the MCL, and like MCL injuries, they heal well and without significant long-term disability. The LCL is the primary restraint to varus stress, and because of its location posterior to the axis of rotation, it also resists hyperextension, especially in the presence of a varus stress.[48] LCL injuries usually result from hyperextension varus forces, with or without contact with another individual. Complete tears occur in the ligament midsubstance or at the fibular insertion. Associated injuries may occur to the posterolateral structures, including the joint capsule, arcuate ligament, biceps femoris or popliteus tendons, or cruciate ligaments.[48] In the adolescent, injury to the growth plate usually precedes ligament injury and should be considered in the differential diagnosis.

The natural history of the LCL injury rarely includes long-term disability because of its healing potential. Surgical repair of the isolated LCL is rarely performed. The most common indication for surgical treatment of the LCL is when the injury is seen concurrently with injury to the posterolateral corner of the knee. Patients with grade 3 laxity, defined as greater than 10 mm of varus laxity or greater than a 10 degree increase in external rotation at 30 degrees of knee flexion, should be treated operatively.[49] In addition, like the MCL, a bony avulsion of the LCL attachment should be managed surgically.

The activity limitations and participation restrictions seen after a LCL injury are fewer than those seen with an MCL injury. Most individuals are minimally limited after this injury, except in the case of a third-degree tear or concomitant ligament or capsular injury (see Table 20-5). In addition, patients who ambulate with a varus thrust, which would create a tensile load to the ligament, may have their rehabilitation decelerated initially.[50]

Rehabilitation issues are similar to those for MCL injuries. The prolonged course of ligament remodeling must be considered, along with the importance of retraining the individual and loading the ligament in the frontal, sagittal, and transverse planes.

Treatment of Ligament Injuries

Interventions should be aimed at achieving specific goals related to impairments, activity limitations, and participation restrictions. Impairments should be addressed if they are associated with an activity limitation or participation restriction or if continued impairment could lead to participation restriction in the future. Pain and effusion can be managed in the short term with physical agents, mechanical and electrotherapeutic modalities, and gentle therapeutic exercise. Cold packs, ice massage, compression therapies, and electrical stimulation are commonly used to minimize pain and effusion. Therapeutic exercise such as active and passive ROM activities within a comfortable range can provide lubrication to joint surfaces and can assist in resorption of excessive joint fluid. The patient should receive instruction in the application of these procedures at home and receive additional guidance regarding activity modification to minimize pain and effusion.

Traditional physiologic stretching and osteokinematic active and passive ROM activities facilitate restoration of preinjury joint motion. Occasionally, joint mobilization techniques may be necessary, although ligamentous injury, when managed conservatively, generally results in too much mobility rather than too little. However, lengthy immobilization or muscle inhibition of the quadriceps may result in a loss of knee extension ROM. Neuromuscular reeducation exercises such as quadriceps setting, hamstring setting, and other muscle activation techniques can restore the ability to fire muscles, which is a prerequisite for normalization of movement patterns. The home program should include exercises to facilitate ROM increases and neuromuscular reeducation exercises to advance gains made in the clinic (**Fig. 20-18**) (see **Self-Management 20-4**).

FIGURE 20-18 Active assistive ROM for knee flexion using a towel. As knee flexion increases, the hamstrings will become shortened generating less force. At this point, the patient can use the towel to pull further into knee flexion.

SELF-MANAGEMENT 20-4
Performing Flexion and Extension Mobility Exercises During the Day

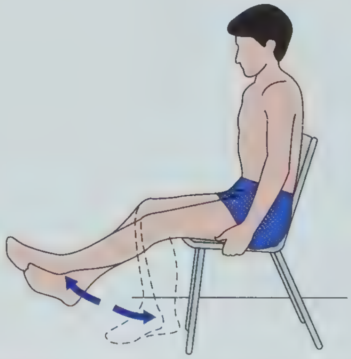
Purpose: To increase mobility in the knee

Position: Sitting or in another position of comfort

Movement Technique: Actively extend the leg as far as possible and then bend it back as far as possible. You may use your other leg to help lift it the last little bit or to push it back a little farther. If lifting your leg is a challenge, you can place your foot on a towel on a floor with a smooth surface and slide your foot along the floor to increase knee flexion and extension.

Dosage:

Repetitions: ______________________ times



The pool is an excellent environment for performing mobility, normalizing gait, and initiating balance and gentle strengthening exercises. The water's buoyancy minimizes weight-bearing while the hydrostatic pressure controls effusion. Walking, physiologic stretching, leg kicks, toe raises, single-leg balance, and squats can be easily accomplished in the pool (**Fig. 20-19**). If the patient recently had surgery, cover the surgical incision with a bioclusive dressing and obtain medical clearance from the operating physician.

As the patient progresses out of the acute phase, more vigorous exercises may be initiated. Continuation of ambulation training and progression to ambulation without an assistive device are primary considerations for the return to normal activities. Land-based, closed chain exercises such as wall slides, minisquats, step-ups, stair stepping, and leg presses can facilitate functional activities such as stair-climbing, rising from a chair, and getting in and out of a car (**Fig. 20-20**). Balance and coordination exercises such as step-ups, wobble board, single-leg pulleys, and toe raises without support can retrain balance reactions. Any motion loss, impaired muscle performance, pain, or effusion that is related to activity limitations should be addressed concurrently. Traditional progressive resistive exercises can be incorporated, keeping in mind the arthrokinematic issues. Weight machines, free weights, isokinetic devices, pulleys, and body weight are means to accomplish increases in the ability to produce torque (see **Building Block 20-5**). The clinician must be aware of the loads placed on the knee ligaments with various exercises and use caution to avoid overstressing a healing ligament. For example, resistive hip adduction using a resistive band around the ankle places a significant load on the MCL, which may be fine in the late stages but too much in the early stages (**Fig. 20-21**). At home, the use of body weight as resistance in the form of wall slides, squats, lunges, and step-ups is convenient and cost effective (see **Patient-Related Instruction 20-2**).

FIGURE 20-19 Single-leg minisquats in the pool are performed to increase mobility and strength.

FIGURE 20-20 Single-leg wall slides.

BUILDING BLOCK 20-5

The patient is a 36-year-old female UPS driver with a second-degree L knee MCL injury that occurred 3 weeks ago when she caught her foot on the step of her truck while getting out to do a delivery. She has recovered full ROM and has functional quadriceps strength for light activities. She is returning to work next week doing deliveries of packages <20 lb. Truck requires ability to use a clutch.

1. Design three exercises to help her with the functional demands of her job.
2. In trying to get the exercise dose correct, consider that the exercises may have been too easy or too hard. For each exercise, besides increasing or decreasing the repetitions, describe a way to make the exercise easier and a way to make it harder.

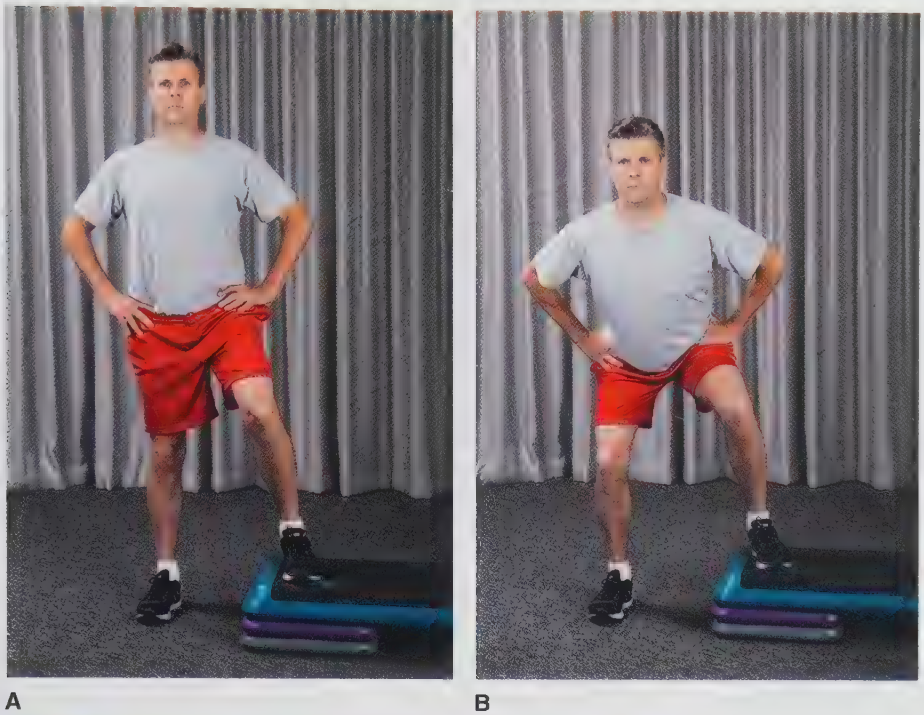


FIGURE 20-21 A transition between double-leg and single-leg strengthening is a modified squat with one leg on a step. The patient will have some weight in the leg on the step, but most of the weight is in the leg on the ground. The higher the step, the more weight that is shifted to the leg on the ground. **(A)** Start position. **(B)** End position.

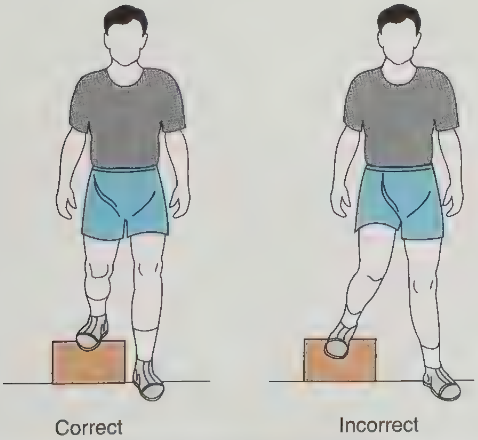
Patient-Related Instruction 20-2

Performing Weight-Bearing Exercises

When performing exercises in weight-bearing, the following important points should be reviewed:

1. Place only the amount of weight on your leg as prescribed by your clinician. This may be only part of your body weight.
2. Be sure that your knee is at the correct angle, as directed by your clinician.
3. Avoid locking or hyperextending your knee (bending it backward).
4. Keep your knee in line with your toes and your hips. Avoid letting your knees "roll in" (i.e., being "knock-kneed").
5. Squeeze your buttock muscles together, and use the muscles in the front of your thigh, as directed by your clinician.
6. Hold each exercise for the amount of time specified by your clinician. Be sure to breathe in and out slowly while performing each exercise.



The final phase of rehabilitation helps return the patient to their premorbid level of function in ADLs, work, or recreation. Because the activity level and functional goals are different for each patient, the rehabilitation program must be tailored to individual needs. For the individual returning to sedentary work and recreational walking, discharge to an independent program may be considered after motion, strength, endurance, balance, and impairments and activity limitations have been normalized. The patient should demonstrate a thorough understanding of the home management of impairments, including inflammation, pain, ROM, and strength. For individuals returning to a higher level of physical functioning, such as physical labor or sports activities, reconditioning to that level is necessary. This may require advanced work-related activities such as lifting, pushing, pulling, and carrying objects over uneven surfaces. A functional capacity evaluation may be performed to determine restrictions or precautions affecting a return to work.

Running, cutting, jumping, and sports skill activities can help ensure a safe return to sporting activities (**Fig. 20-22**). A running program or sport-specific drills may be used to test readiness to return to play. Completion of an appropriate functional progression can ensure a safe return to sports. Although this program does not need to be under the direct supervision of the physical therapist, it should be constructed with and guided by the clinician in conjunction with the patient. Any deficits in movement patterns should have been corrected by the clinician in the earlier therapy stages and should not be an issue at the functional progression stage.

Fractures

Knee fractures can involve the patella, distal femur, or proximal tibia. These fractures generally occur as a result of trauma such as a fall or motor vehicle accident but can also result from osteoporosis.

FIGURE 20-22 **(A)** Lateral crossover running in the late stage of rehabilitation. **(B)** Slide board lateral movements.

The rehabilitation issues associated with knee fractures include the cumulative effects of the original trauma, surgical procedures, and immobilization. A trauma significant enough to fracture a bone also causes substantial soft tissue damage, which is frequently overlooked. Damage to articular cartilage and fractures extending through the articular cartilage to the joint surface (intraarticular fractures) have the potential to affect the long-term health of the joint, and these issues should be considered in the rehabilitation program.

Patellar Fractures

Patellar fractures account for approximately 1% of all skeletal injuries and occur most frequently in persons between the ages of 40 and 50 years.[51] A direct blow to the anterior knee, as seen with a fall or a motor vehicle accident, typically results in a comminuted fracture.[52] Fortunately, the majority of these fractures are nondisplaced, but bear in mind that significant damage to the articular cartilage can occur. More commonly, patellar fractures occur indirectly via a forceful contraction of the extensor mechanism, which ultimately exceeds the strength of the bone.[52] Indirect fractures typically result in a transverse fracture or an avulsion of the inferior pole of the patella. The degree of knee flexion, the patient's age, the overall health of the bone, and the velocity of injury can affect the type and location of the patellar fracture.[52]

The goal of patellar fracture management is to restore the extensor mechanism and optimize articular cartilage congruency at the patellofemoral joint. Conservative treatment, consisting of immobilization and rehabilitation, may be indicated. However, surgical intervention, such as open reduction with internal fixation (ORIF) utilizing Kirschner wires (K-wires) or a partial patellectomy may be warranted to maximize articular cartilage congruency and to restore the extensor mechanism. Because of the morbidity associated with immobilization, ORIF is often the treatment of choice for medically sound candidates. Because of the superficial nature of the patella, the hardware is frequently removed after healing is ensured. Occasionally, a small fragment or fragments are removed rather than fixated (i.e., partial patellectomy). A total patellectomy is only indicated in extremely rare cases, as complete removal of the patella results in a 50% reduction in quadriceps strength.[52] The prognosis after patellar fracture is good if PFP, muscular atrophy, and loss of motion (LOM) are addressed. These impairments occur regardless of treatment method. With conservative management, the clinician must also be aware of the effects of immobilization on the soft tissues.

Distal Femur Fractures

Distal femur fractures are rare and severe. In the younger population, they are the result of a high energy trauma, whereas in the elderly, they can result from a low-energy movement, such as a twisting injury.[53] Associated fractures are common and include the patella, tibial plateau, foot, ankle, and hip. Distal femur fractures can be classified as pure supracondylar, supracondylar and intercondylar, or monocondylar, each with subclassifications. Fractures through the growth plate occur in children and adolescents and are challenging to treat, with complications that require a secondary surgery 40% to 60% of the time.[54] Poor outcomes have been associated with Salter–Harris classification III and IV in 29% to 32% of cases.[54]

Distal femur fractures can be managed conservatively or surgically. Nondisplaced, minimally displaced, stable, or impacted fractures or fractures in individuals who are not surgical candidates may be treated with immobilization. Because of the morbidity associated with lengthy immobilization, and because over 50% of fractures are intraarticular, surgical ORIF is often the treatment of choice.[53] Reduction of distal femur fractures requires restoration of the anatomic alignment and mechanical axes in the sagittal, frontal, and transverse planes. The specific surgical procedure and fixation choice depend on factors such as the type and location of fracture, quality of bone, associated injuries, and the patient's age and lifestyle. Complications after ORIF include deep vein thrombosis, infection, and delayed union or nonunion.[53]

Tibial Plateau Fractures

Tibial plateau fractures occur almost exclusively as the result of trauma such as motor vehicle accidents, pedestrians hit by cars, accidental falls, or twists or direct blows to the knee. Fractures are typically produced by a combination of valgus stress and axial compression while the knee is flexed and result in lateral plateau, medial plateau, or bicondylar fractures.[55] Although numerous classification systems for tibial plateau fractures exist (Schatzker, AO, Duparc), the general classification is based upon morphology[56]:

1. Split fracture, in which the margin of the tibial plateau is separated from the rest of the plateau
2. Compression fracture, in which the subchondral bone is crushed but the margins are spared
3. Combination split-compression fracture

Compression fractures are the most difficult to diagnose, because the depressed fragments are often missed on standard radiographs. As such, a CT scan is commonly performed on patients with a tibial plateau fracture.[56] Compression fractures are also the most difficult to treat, because adequate reduction requires the elevation and stabilization of depressed fragments. Compression fractures are seen most commonly after falls from heights and in elderly individuals with osteoporosis.

Treatment of tibial plateau fractures depends on the location and type of fracture. Compression fractures with depressed fragments require surgical elevation and stabilization of the fragments. These fragments are supported with bone grafts. Split fractures are stabilized with screws, wires, or plates. Conservative management with or without traction and immobilization is an option that must be considered in light of the deleterious effects of immobilization. Postoperative or post immobilization rehabilitation depends on the numerous factors outlined previously.

Treatment of Fractures

Treatment programs for individuals with fractures at the knee may begin once the fracture site is stable, either through surgical methods or via immobilization. Persons with fractures surgically fixated generally begin mobility and strengthening exercises soon after the operation (see **Self-Managements 20-5** and **20-6**). Active and passive ROM for flexion and extension and functional mobility exercises for the entire kinetic chain are initiated early. Quadriceps setting and hamstring setting exercises are started early to retrain these muscle groups. When permitted, closed chain weight-bearing exercises should be initiated, even if only partially weight-bearing (see **Patient-Related Instruction 20-3**). This will be determined by the physician based upon the fracture site and healing, as well as by the patient's ability to control the knee. Before beginning any weight-bearing exercise, the patient should demonstrate a good quadriceps set and the ability to dynamically control the knee. These activities can enhance articular cartilage nutrition throughout the kinetic chain and provide a stimulus for muscle activation. An exercise bicycle with little or no resistance can enhance nutrition and muscle activity in the area while improving mobility.

Pool exercise is excellent for the individual with a knee fracture. Weight-bearing may be limited while muscle activation and mobility exercises are performed with assistance from buoyancy. Passive motion assisted by buoyancy or active motion can improve ROM about the knee (**Fig. 20-23**). Gait can be normalized with or without railing assistance.

SELF-MANAGEMENT 20-5
Prone Hang for Knee Extension

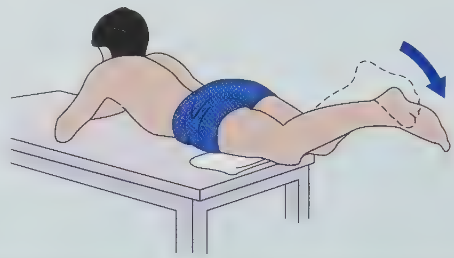
Purpose: To increase mobility in knee extension and stretch tight tissues behind the knee

Position: On your stomach, with your knee just over the edge of the table; a towel under your thigh may be more comfortable.

Movement Technique: Let your knee straighten by hanging over the table's edge. Your clinician may want you to put weight on your ankle or to use your other leg to increase the stretch. Hold for 1 to 2 minutes.

Dosage:

Repetitions: ____________________ times



SELF-MANAGEMENT 20-6
Straight-Leg Raises

Purpose: To increase the strength of the quadriceps and hip flexor muscles and to improve control of the knee

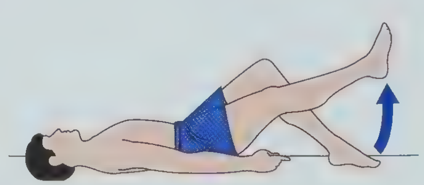
Position: Lying on your back, with your opposite knee bent and foot flat on the floor; stomach muscles are tightened.

Movement Technique: This is a four-step process.

1. Perform a quadriceps set, tightening the quadriceps muscles.
2. Slowly raise the leg until it is even with the opposite thigh.
3. Slowly lower the leg back to the floor.
4. Relax the quadriceps set. Be sure to relax the quadriceps muscle between each repetition.

Dosage:

Repetitions: ____________________ times



Patient-Related Instruction 20-3

Walking with Crutches

When walking with crutches and some of your weight on the involved lower extremity, several guidelines should be followed:

1. Make sure your weight is on your hands, not under your arms. Your arms should be slightly bent when your crutches fit properly.
2. When walking, place your crutches out first, followed by your involved leg and then your uninvolved leg.
3. Place your involved heel down first, let your knee bend slightly, and allow your foot to roll toward your toes as you begin to bring your uninvolved leg forward.
4. As you bring your uninvolved foot through, bend your involved knee, and pick it up behind you. Straighten the involved knee as you bring it past your crutches to place it on the floor in front of you. Your knee should be straight just before your heel contacts the ground.
5. When using a single crutch, be sure to use it on the side *opposite* your injured knee.

Check with your clinician to ensure that your gait with crutches is correct.

FIGURE 20-23 Buoyancy-assisted knee flexion using a buoyant strap. The return motion (to extension) is buoyancy resisted, eliciting a concentric quadriceps muscle contraction.

Meniscal Injuries

Although the menisci were once thought to be useless remains of leg muscles, their importance is now well understood.[57] The meniscus absorb shock during weight-bearing activities, assist in joint lubrication, and restrain anteroposterior tibial translation in ACL-deficient knees.[57] Because of its many roles, the importance of the meniscus to the long-term health of the knee has resulted in efforts to preserve the meniscus following injury. The menisci are composed primarily of type I collagen and are more fibrous than articular cartilage. The herringbone arrangement on the surface allows for shear forces that occur with normal joint arthrokinematics; the deeper major fiber orientation is circumferential. The menisci receive their blood supply from the medial and lateral superior and inferior geniculate arteries and have variable vascularity. The vascular supply penetrates 10% to 30% of the width of the medial meniscus and 10% to 25% of the width of the lateral meniscus. The peripheral one-third is often called the red zone, the middle one-third is the red-white zone, and the central one-third is the white (avascular) zone. The meniscus receives its nutrition by diffusion, and it has a low metabolic rate and a low reparative response. Repair of the meniscus considers this low reparative response and often uses the peripheral blood supply to assist the healing process.[57]

The menisci have many functions, underscoring the importance of maintaining their structure. In addition to enhancing joint congruity and stability, the menisci also function to transmit load across the knee joint, with approximately 40% to 50% of the compressive load transmitted through the meniscus in full extension and 85% at 90 degrees of flexion.[58] Partial meniscectomy with a 10% decrease in contact area increases peak local stresses by 65%, whereas total meniscectomy decreases the contact area by 75% and increases peak local stresses by 235%.[59] Total meniscectomy is no longer routinely performed because of the Fairbanks changes seen postoperatively. These changes include marginal femoral osteophyte ridging, flattening of the medial femoral condyle, and narrowing of the joint space.[60] In addition, the menisci work as shock absorbers, although the subchondral bone is the main static shock absorber at the knee. Some of the most important functions of the menisci are joint lubrication and articular cartilage nutrition. The biphasic properties of the meniscus assist in providing a lubricant film across the joint surface with cyclical loading and unloading of the knee.[61]

The meniscus is most often injured traumatically, although degenerative tears are also common. Traumatic tears typically require more energy and usually occur in the younger, active population or in individuals who sustain trauma via a fall or motor vehicle accident. In contrast, degenerative tears occur with advancing age, are often complex tears, and can be sustained through low-energy movements. For example, a degenerative tear can be precipitated by a stress as simple as turning to walk a different direction.

Treatment

Degenerative tears associated with articular cartilage lesions often require surgery to remove loose fragments and to stimulate a healing response in the articular cartilage. Acute traumatic tears may heal without intervention if the tear is in the periphery, where a blood supply exists, and if the tear is longitudinal. Some tears may not heal but remain asymptomatic.[62] Tears producing mechanical symptoms such as catching, locking, and effusion are treated by partial meniscectomy or by meniscal repair. The treatment of choice depends on the type and location of the tear, on the associated injuries, and the overall health of the knee joint. For example, a meniscal repair in the posterior horn of the medial meniscus in an ACL-deficient knee does not heal well. However, if the ACL is reconstructed simultaneously, the meniscal repair has an opportunity to heal if provided a blood supply. In contrast, complex degenerative tears are nearly impossible to repair and probably will fail in the presence of articular cartilage degeneration.

The management of patients after a partial meniscectomy must consider the changes in load distribution and increases in peak local stresses associated with this procedure. The knee has been distributing and dispersing loads during activities based on the patient's anatomy for many years. Suddenly, the load distribution is changed, and other structures must shoulder the burden of the load previously supported by the intact meniscus. The joint's ability to adapt to this change in loading pattern depends on numerous factors, including lower extremity alignment, quadriceps function, comorbidities, and the response to the stresses placed on it (i.e., Wolff's law). The body must have time to adapt to the changing loading pattern, and although some individuals adapt quickly, others may develop symptoms of overload such as inflammation, effusion, or pain. Any activity that produces significant shear forces with compressive loading (e.g., squatting, steps) may overwhelm the load-bearing capabilities in some knees. Individuals with suboptimal alignment, degenerative joint disease, poor quadriceps function or neuromuscular control, or limited ROM will most likely experience difficulty.

Issues associated with meniscal repair are related to the normal meniscal motion during knee flexion and extension, the shear forces across the repair, and the location and type of tear repaired. The meniscus moves posteriorly up to 12 mm during knee extension to flexion, with most motion occurring between 0 and 15 degrees and beyond 45 degrees.[63] Although motion up to 80 to 90 degrees is permitted in the early phase actively and passively, weight-bearing activities through a large range should be avoided. Early partial weight-bearing or weight-bearing as tolerated is often permitted depending on the tear size, type, and location. The knee goes through 60 degrees of motion during normal gait. Repairs in the white zone, repairs with additional vascular access, or repairs of complex or radial tears are protected longer, and progression is dictated by the procedure. A sample program for intervention following meniscal repair can be found in **Table 20-7**.

TABLE 20-7

Rehabilitation Guidelines Following Meniscal Repair

	PHASE 1	PHASE 2	PHASE 3
Goals	1. Post-op knee protection 2. Restore extension ROM 3. Eliminate effusion 4. Restore leg control	1. Single-leg stance control 2. Normalize gait 3. Good control and no pain with functional movements, including step-up/down, squat, partial lunge at <60 degrees of flexion	1. Good control and no pain with sport and work-specific movements, including impact
ROM exercises	Knee extension on bolster Prone hangs Supine wall slides to 90 degrees Heel slides to 90 degrees	Stretching for patient-specific imbalances	Stretching for patient-specific imbalances
Strength exercise	Quad sets Straight-leg raise Standing 4-way leg lifts with brace Calf raises with brace	Nonimpact balance and proprioceptive drills Gait drills (stepping over hurdles, etc.) Hip and core strengthening Quadriceps strengthening: closed chain 0–60 degrees flexion	Strength and control drills related to sport or work movements Sport/work-specific balance and proprioceptive drills Hip and core strengthening Movement control exercises beginning with low velocity, single plane progressive to higher velocity, multiplanar movements Impact control exercises beginning 2 feet to 2 feet and progressing to single foot
Cardiovascular exercise	Upper body circuit training or UBE	Nonimpact endurance training: Stationary bike	Sport and work-specific energy demands

(continued)

TABLE 20-7

Rehabilitation Guidelines Following Meniscal Repair (*continued*)

	PHASE 1	PHASE 2	PHASE 3
Precautions	1. Gradually wean from 2 to 1 to 0 crutches as long as the knee is in the locked brace and there is no increase in pain or swelling 2. Keep brace locked for all weight-bearing activities for 2–4 w 3. No flexion past 90 degrees	No forced flexion past 60 degrees Avoid post-activity swelling No impact activities	Post-activity soreness should resolve in 24 h Avoid post-activity swelling Avoid posterior knee pain with flexion
Progression criteria	1. Pain-free gait with locked brace without crutches 2. No effusion 3. Active knee flexion to 90 degrees	1. Normal gait on all surfaces 2. Able to carry out functional movements without pain or unloading affected leg 3. Demonstrates good control 4. Single-leg balance >15 s	Return to work/sport when patient achieves dynamic neuromuscular control with multi-plane activities without pain or swelling

ROM, range of motion; UBE, upper body ergometer.

DEGENERATIVE ARTHRITIS PROBLEMS

Articular Cartilage Lesions

Articular cartilage is a unique tissue that has remarkable properties, including an ability to be deformed and regain its original shape, exceptional durability, and an unparalleled low-friction surface.[64] These are just a few of the properties that make articular cartilage so difficult to reproduce. Despite the prevalence of artificial joint replacements, the average life of an artificial joint is much shorter than that of native articular cartilage. This comparison highlights the unique characteristics of this material, which functions optimally in the presence of adequate ROM, joint stability, and an equitable load distribution.[65]

Articular cartilage is composed primarily of water, type II collagen, and proteoglycans.[66] Water is approximately 65% to 80% of the weight of articular cartilage and is responsible for its biphasic properties.[66] The majority of water in articular cartilage is located in the interstitial intrafibrillar space and is held in place by negatively charged proteoglycans. This fluid phase provides articular cartilage with its ability to deform and dissipate load.[66] The water content decreases with age, resulting in increased stiffness and deformation of cartilage and also decreasing its biphasic material properties. This decrease contributes to the changes seen in the normal aging process. Every joint has its own pattern or "footprint" on the surface, reflecting the specific shear forces the joint has incurred over time. Articular cartilage in adults receives its nutrition by diffusion; the cartilage in children receives some nutrition from the underlying subchondral bone.[66]

Articular cartilage responds to loads in a time-dependent manner like any other viscoelastic material; it creeps under a constant applied load and relaxes under a constant deformation. When an external load is applied to the cartilage surface, an instantaneous deformation occurs, and approximately 70% of the water within the cartilage may be moved, until the compressive stress within the articular cartilage matches the applied stress, and equilibrium is reached. Stress and relaxation also occur, depending on the length of time the cartilage is loaded. Cartilage also increases the congruity of the surfaces, distributing loads over a greater surface area. The ability to withstand compressive loads (based on these properties) varies from joint to joint and within the same articular surface.[7]

From a mechanical perspective, the requirements for a healthy joint include three factors: (1) freedom of motion, (2) stability, and (3) an equitable load distribution.[65] These necessities form the basis for some of the treatments for articular cartilage lesions. Adequate lower extremity strength to absorb loads during the loading response of the gait cycle, and normal movement patterns help minimize excessive loads on the articular cartilage. Partial thickness articular cartilage lesions in adults do not heal, but they may not get any worse in a joint with good mobility, stability, and an equitable load distribution. However, in an ACL-deficient knee or a knee with a significant varus alignment, the lesion may progress from partial to full thickness. When a lesion continues to degrade to subchondral bone, a bleed will occur, and the healing process commences. This is the rationale for the microfracture technique, one of the marrow stimulation techniques. The microfracture technique uses an awl to place multiple small holes in the lesion to create a bleed to stimulate a healing response. However, the replacement tissue is fibrocartilage, which is a lesser-quality tissue than the original articular cartilage. This fibrin clot may be adequate for the individual, especially if adequate motion, joint stability, and equitable load distribution are present.

The rehabilitation program must consider the fundamental requirements for a healthy joint when determining the appropriate mode and progression of therapeutic exercise. Activities that minimize shearing forces while increasing stability and mobility provide the foundation for the therapeutic exercise program (see **Patient-Related Instruction 20-4** and **Building Block 20-6**). Additionally, the therapist must consider the importance of adjacent joints on knee function. Interventions directed toward the hip such as strengthening and mobilization have been shown to improve symptoms at the knee.[67–69]

Patient-Related Instruction 20-4

Tips to Maintain the Long-Term Health of Your Knee

The following tips can help you maintain the long-term health of your knee:

1. Maintain the mobility of your knee. With your clinician's help, choose a few simple exercises to be done daily to maintain your ability to fully bend and straighten your knee.
2. Keep the muscles around your knee strong, especially the muscles in the front of your thigh and your hip muscles. With your clinician's help, choose a few simple exercises to be done daily to maintain the strength of your leg.
3. Maintain a healthy body weight.
4. Wear good supportive shoes that provide some shock absorption.
5. If necessary, use a supportive device (e.g., cane, crutch) when walking long distances.

BUILDING BLOCK 20-6

Consider the 78-year-old patient with knee osteoarthritis in Display 20-2, Case Study No. 2. You have determined that the patient's sense of weakness in the knees is due to a combination of weak hip extensor muscles and weak quadriceps muscles. For each muscle group, describe three exercises that would isolate and focus strengthening on that group.

Surgical Procedures

A variety of surgical procedures are used to improve function in patients with articular cartilage lesions. They can be classified as marrow stimulation techniques, resurfacing procedures, realignment procedures, and arthroplasty. Marrow stimulation techniques, such as abrasion arthroplasty, drilling and microfracture, create a bleed at the joint surface in an attempt to initiate a healing response. These procedures result in the articular cartilage defect being filled in with fibrocartilage, which mechanically does not withstand the test of time. It may provide some temporary relief until the fibrocartilage fails. Resurfacing procedures include techniques such as osteoarticular transplants and autologous chondrocytes implantation. Discussion of these procedures can be found in Chapter 11.

Unicompartmental Osteoarthritis: High Tibial Osteotomy and Unicompartmental Joint Arthroplasty

Osteoarthritis can affect any or all of the three compartments (medial, lateral, patellofemoral) of the knee joint. About one-third of patients have OA predominantly in only one compartment, called unicompartmental OA.[70] Although the most common unicompartmental OA is patellofemoral, approximately one-third of patients suffer from medial-sided OA, whereas isolated lateral compartment OA of the knee is seen in only 3% of the patients.[70] The goal of treatment of unicompartmental OA is to reduce pain, restore function, and improve quality of life. Surgical options to treat unicompartmental OA include high tibial osteotomy (HTO) and unicompartmental knee arthroplasty (UKA), whereas a total knee arthroplasty (TKA) is commonly reserved for patients with OA in multiple compartments.

The HTO may be performed when medial compartment OA is due to varus alignment; a supracondylar (femoral) osteotomy can be used to treat unicompartmental OA due to a valgus alignment.[71,72] Malalignment causes excessive loading of one compartment of the joint, resulting in subchondral sclerosis, loss of cartilage space, and osteophyte formation, all of which are indicative of OA. The ideal candidate for an HTO is less than 60 years old and active, with symptomatic mild-to-moderate varus knee (5 to 15 degrees) with mild medial compartment involvement, good knee ROM, and a stable knee.[70] The surgical technique requires a wedge cut in the proximal tibia with a concurrent fibular osteotomy performed as well.[73] Complications include infection, nonunion, patella baja, infrapatellar scarring, peroneal nerve palsy, and lateral ligament laxity. The 10-year survivorship rate of HTOs has recently increased from 50% to 80%.[74]

Rehabilitation after tibial osteotomy is guided by the requirements for a healthy joint and the sudden change in loading patterns across the compartments. The change in weight-bearing distribution may overload a previously underloaded compartment. The bony and soft tissues need adequate time to remodel and adapt to the change. How well the tissues adapt varies significantly from individual to individual, accounting for the variation in intervention choices, treatment frequency, and treatment duration. Restoration of normal ROM is essential to ensure distribution of loads over as large a range as possible. Normalization of movement patterns to minimize impact loads and excessive compartmental loading can prolong the life of the osteotomy. Quadriceps strengthening for shock absorption during the loading response of the gait cycle can minimize loads on the articular cartilage and subchondral bone.

A second option for patients with unicompartmental OA is a unicompartmental joint replacement (UKA).[75] Although the UKA was introduced in the 1970s, it did not gain wide acceptance due to poor early results, high failure rates, and high technical demands. Recently however, with improved prostheses, surgical techniques, and postoperative outcomes, the UKA has become a viable option for patients with unicompartmental OA.[74] UKA is the partial surface replacement of the knee joint; advantages include the ability to replace a single component of the joint while preserving bone stock, resulting in a faster recovery time and minimal invasiveness compared to TKA.[74] The ideal candidate for a UKA is a patient between 45 and 65 years of age with a low-to-moderate-demand knee and minimal pain at rest. In addition, the patient must not be obese, must have ROM from

0 to 90 degrees with minimal axial malalignment.[74] The surgical procedure involves resurfacing of the distal femur and proximal tibia in the affected compartment, and can be performed with robotic assistance.[76] Outcomes following UKA have improved dramatically. The 15-year survivorship rate has been reported to be as high as 95.7% with a 25-year survival rate of 72%.[74] Patient satisfaction mirrors these excellent survivorship results, particularly in activities requiring complete knee ROM, such as going down stairs and kneeling.[74]

Rehabilitation following a UKA involves ROM exercises, strengthening exercises for the lower extremity and balance exercises, similar to the plan of care for the patient after a HTO. The difference, however, is the knee of the patient who has undergone a UKA has not had any malalignment issues addressed; as such, the load incurred by each compartment remains unchanged. However, the arthritic compartment has been resurfaced with prosthetic components, abolishing the arthritis-related pain. As such, exercise progression is based on symptom tolerance. Outcomes after UKA are good. Approximately 97% of patients return to low to moderate sporting activities after a UKA; 88% of the patients after UKA felt that surgery had increased or maintained their sporting ability.[77]

Total Knee Arthroplasty

Individuals with significant bicompartmental (medial and lateral) or tricompartmental (medial, lateral, and patellofemoral) OA and associated impairments, activity limitations, and participation restriction are candidates for TKA. These individuals may have undergone previous osteotomies or unicompartmental arthroplasties that subsequently deteriorated and may present with impairments such as pain, joint instability, or LOM. Pain is one of the chief indications for TKA; stability, bone integrity, and age are additional considerations.[78] Patients generally seek medical attention when the pain becomes disabling, affecting their ability to participate in community, work, leisure, or basic ADLs. The materials and techniques used in TKA procedures have advanced significantly, thereby increasing the patient pool, minimizing complications, and decreasing participation restriction.

The prostheses used are classified in many ways, including the degree of constraint (i.e., unconstrained, partially constrained, or fully constrained), and the type of fixation (i.e., cemented, cementless, or hybrid). The prosthesis choice depends on the status of the bone and any soft tissue deformities (e.g., ligament laxity, absence of PCL). Most prostheses are tricompartmental and partially constrained with hybrid fixation. Hybrid fixation usually includes a cemented tibial component and cementless femoral component.[79] Information regarding the type of prostheses and fixation utilized should be obtained prior to initiating treatment.

Each design has its strengths and weaknesses and should be matched to the specific needs of the patient. Cemented fixation allows for earlier weight-bearing than biologic ingrowth, but loosening at the bone–cement interface may be problematic. The uncemented femoral component decreases operative time, reduces polyethylene wear from cement debris, and avoids an adverse reaction to the materials, but is more costly and requires a more precise fit. The tibial component is the most problematic in both cemented and uncemented designs, with difficulty achieving fixation resulting in micromotion and failure. Specific design features are incorporated to assist in balancing soft tissues in three planes to avoid instability problems.

Complications of TKA include component loosening, infection, peroneal nerve palsy, patellar instability, fracture, instability and osteolysis. Bone ingrowth is negatively affected by nonsteroidal anti-inflammatory medication.[80] Other complications include polyethylene wear reactions, resulting in pain, effusion and LOM developing about 5 years after surgery. Most complications are on the medial side, and the component may sink into the tibia on the medial side.

Several factors affect the rehabilitation approach after TKA. The type of prosthesis provides an indication of the underlying stability, bone quality, and ultimately the prognosis. Fixation choice also affects rehabilitation, with non-cemented components protected longer to allow biologic ingrowth. Patellar instability is a problem in 5% to 30% of TKAs, and the clinician should be alert to signs of patellar subluxation or dislocation.[81] Most prosthetic designs assume that no ACL exists and that the PCL is variably intact. The medial and lateral ligaments and joint capsule provide most of the stability. In addition, the status of the patient's overall lower extremity can affect rehabilitation. Individuals with OA at the knee may have concurrent changes in other lower extremity joints. Limitations in ROM at the hip and ankle can affect the function and prognosis at the knee. Barring any complications at other lower extremity joints, it is reasonable to acquire 120 degrees of knee flexion postoperatively. Patients with <120 degrees of flexion after TKA use compensatory movements of the hip, trunk, and ankle during daily activities. See **Table 20-8** for a sample rehabilitation program following TKA.

TABLE 20-8

Rehabilitation Following TKA

	PHASE 1: INPATIENT	PHASE 2: EARLY OUTPATIENT	PHASE 3: MID- TO LATE OUTPATIENT
Goals	Pain control Independent in bed mobility Independent in transfers Safe stair ambulation Safe use of assistive device ROM 5–90 degrees	Pain and swelling control Independent in mobility, transfers, stairs, and ambulation ROM 0–100 degrees Strength 3/5 to 4/5	Return to previous activities Gait 300 ft without assistive device ROM 0–120 degrees Effective home exercise maintenance program

TABLE 20-8

Rehabilitation Following TKA (*continued*)

	PHASE 1: INPATIENT	PHASE 2: EARLY OUTPATIENT	PHASE 3: MID- TO LATE OUTPATIENT
Mobility	Tibiofemoral joint: AROM, AAROM, PROM into flexion and extension Joint mobilization: patellar mobilization, tibiofemoral distraction and mobilization Continuous passive motion Heel slides	Patellar mobilization AROM of all LE joints Stretching of major muscle groups Tibiofemoral mobilization	Mobilization as needed Contract-relax, other stretching activities as needed
Muscle performance	Quadriceps, hamstring, gluteal setting Active knee extension Straight-leg raises TKE Hip abduction	Resisted knee extension Leg raises in all directions Minisquats Toe raises Hamstring curls Leg press Isokinetics Lunges	Progressive resistive exercises Lower extremity and core strengthening exercises Activity-specific strengthening
Functional activities	Transfers Bed mobility Assistive device use; ambulation with walker or crutches Stair negotiation	Gait training with or without assistive device Up and down from chair Stair negotiation Balance activities	Work or activity-related activities, including addressing balance impairments ADL, IADL activities
Cardiorespiratory	N/A	Stationary bicycle as tolerated Water walking	Per patient preference
Other	Ankle pumps for circulation Ice, compression for pain and swelling	Ice, compression as necessary to control swelling Community mobility	
Progression criteria	Independent in bed mobility Independent in transfers Ability to ambulate 150 ft with standby assistance Ability to negotiate stairs safely	ROM 0–115 degrees Strength 4/5 or 75% of contralateral side Full weight-bearing although may still use assistive device Ambulation 300 ft Stairs using alternate pattern

Interventions for Degenerative Arthritis Problems

Interventions used by physical therapists should address the impairments, activity limitations, and participation restrictions identified during the initial and subsequent evaluations. Impairments should be treated if they are associated with an activity limitation or participation restriction or if continued impairment could lead to participation restriction in the future. For example, limited ROM after abrasion arthroplasty may not be immediately disabling, but it could lead to future activity limitations or participation restriction by overloading focal areas of articular cartilage or by damaging other joints because of compensatory movements. Individuals with articular cartilage damage cannot expect to be cured of their problem, but they must learn to manage their symptoms and maintain the long-term health of their joint. Individuals with joint surface damage must demonstrate an understanding of the independent management of impairments, including inflammation, pain, and mobility and strength loss.

After surgery, physical therapy interventions are generally aimed at the acute impairments of pain, effusion, and LOM and neuromuscular control. Physical agents, mechanical and electrotherapeutic modalities, and gentle mobility exercises can minimize pain and facilitate resorption of an effusion. Therapeutic exercise in the form of active and passive motion, physiologic stretching, and joint mobilization can facilitate normal osteokinematics and arthrokinematics. After the surgical incisions are healed or with the use of a bioclusive dressing, many of these impairments can be treated in the pool. The hydrostatic pressure of water minimizes effusion, and water's buoyancy can be utilized to limit weight-bearing to a comfortable level. If progressive loading of the joint surface is the goal, gradually decreasing the water's depth can slowly increase the joint load.[82–84] Isometric exercises for the quadriceps, hamstrings, and gluteal muscles help reeducate these muscles while facilitating circulation.

In the subacute phase, rehabilitation continues to focus on residual impairments, activity limitations, and participation restrictions identified during reexamination. Ambulation training and progressive weight-bearing advance according to the specific injury and therapeutic procedure. The rehabilitation should continue to focus on restoring full mobility, normalizing gait, and reestablishing full function to the individual. Mobility activities should emphasize activities that enhance articular cartilage nutrition, such as gentle active and passive ROM or cyclic compressive loading and unloading. Combining these two modes should be approached with caution to avoid overloading developing or remodeling fibrocartilage or articular cartilage. Closed kinetic chain exercises with significant weight-bearing through a ROM should be incorporated judiciously with close monitoring of increased pain or effusion. Strengthening exercises must respect the changes in loading patterns after some surgical procedures. Eccentric strengthening of the quadriceps and gluteals facilitates shock absorption during the loading response phase of gait, stair and incline descent, and lowering into a chair. Strengthening can be initiated in an open kinetic chain and progressed to a closed kinetic chain as the joint tolerates. Similar exercises must be performed on a daily basis as part of the home exercise program to continue the advances made in the clinic.

The final rehabilitation phase emphasizes return to the previous activity level or a higher level, depending on the goals of the patient and the integrity of the joint. For the individual undergoing a tibial osteotomy, the expectation is to return to a higher level of function because of a decrease in pain and restoration of joint congruency. Each person should be provided with a functional retraining program tailored to the activities to which he or she will be returning. Moreover, the importance of continuing an exercise program incorporating activities to maintain the long-term health of the joint must be emphasized. Demonstration of the ability to home manage an exacerbation of symptoms is fundamental to safe and cost-effective long-term management of articular cartilage lesions. Patient education to manage lifestyle factors such as walking distances, floor surfaces, time spent in static standing, maintenance of appropriate body weight, shoe wear, and use of assistive devices is also a critical intervention.

TENDINOPATHIES

Tendinopathies about the knee occur most frequently in the patellar tendon but can also be found in the hamstring tendons, the quadriceps tendon and pes anserine tendon. In addition, ITB friction syndrome can be considered a type of tendinopathy. Although tendinopathies can result from an acute injury, they usually are caused by microtrauma or overuse. Repetitive loading without adequate recovery time prevents normal adaptations within the tendon to occur. Although single loads do not exceed the strength of the tendon, cumulative loads exceed the reparative capabilities. Intrinsic factors contributing to tendinopathies include malalignment, limb length discrepancies, and muscular imbalance or insufficiency. Aging tissue has a lower reparative capability, diminishing its ability to recover from overuse. Extrinsic factors include training errors, surfaces, environmental conditions, and footwear.[85]

Patellar Tendinopathy

Patellar tendinopathy typically occurs at the insertion of the tendon into the distal pole of the patella. It is distinct from Sinding-Larsen–Johanssen disease, which is apophysitis of the distal patellar pole, and from Osgood–Schlatter disease, which is apophysitis at the tibial tubercle. Both of these syndromes occur in adolescents before closure of the growth plates. Patellar tendinopathy has also been called *jumper's knee* because of its high prevalence in jumping and impact sports. The eccentric nature of jumping places tremendous loads on the patellar tendon, often resulting in overuse. The patellar tendon attaches one of the strongest muscle groups in the body, the quadriceps femoris, to its insertion using the patella to increase the lever arm of the muscle. The loads generated by the quadriceps mechanism are transmitted through the tendon to its bony attachments. Areas of increased stress such as transitional zones are susceptible to overuse. In the adult with closed epiphyses, the transition zone on the undersurface of the patella's distal pole is the most vulnerable area.

Tendinopathies of the patellar tendon can take various forms. Tendinopathies tend to demonstrate a normal macroscopic appearance, but microscopic abnormalities at the bone–tendon junction most always exist.[86] Necrosis and fragmented tissues with mucoid degeneration usually involve the deep central fibers at the tendinous insertion and can be palpated at the undersurface of the patella's distal pole.[87]

Individuals with patellar tendinopathies present with various degrees of impairments, activity limitations, and participation restrictions. The person often reports a history of pain and stiffness in the anterior knee that improves as the knee is warmed. The knee then gets sore as the activity continues, and gets stiff and sore after completion of the activity. Point tenderness is experienced on the undersurface of the distal pole of the patella and is best palpated by tipping the inferior border anteriorly to allow access to the undersurface. This is best achieved by pushing the superior patellar pole posteriorly with the knee over a bolster, in approximately 30 degrees of flexion. Activity limitations may include abnormal walking or running gait, pain with jumping, landing from a jump, pain with kneeling, or pain when ascending and descending stairs. Participation restrictions can include an inability to participate in community, work, or leisure activities, depending on the individual's lifestyle and activity limitations.

Treatment

Rehabilitation for the individual with patellar tendinopathies focuses on the patellar tendon's role in decelerating knee flexion in gait, jumping, descending stairs, and many other functional activities. The role of tendon length and ability to perform deceleration during activities forms the foundation for the rehabilitation program. Stretching exercises to ensure adequate tendon length are combined with eccentric quadriceps strengthening of progressively increasing velocity up to the speeds used in daily activities. Before an individual can perform an eccentric muscle contraction, she must be able to preset isometric tension in the muscle. The rehabilitation program may begin with isometric contractions before progressing to isotonic and eventually eccentric contractions (**Evidence and Research 20-4**). Eccentric contractions can be performed in

EVIDENCE and RESEARCH 20-4

Patellar tendinopathy can be very debilitating. Cook et al[93] found that more than one-third of athletes presenting for treatment for patellar tendinopathy were unable to return to sports within 6 months; 53% of athletes with patellar tendinopathy were forced to retire from sports.[94] Most recently. a clinical commentary by Malliaras et al suggested a four-step approach to the management of patellar tendinopathy.

1. **Isometric Loading:** Five repetitions of 45-second isometric mid-range quadriceps exercise at 70% of maximal voluntary contraction have been shown to reduce patellar tendon pain for 45 minutes post exercise.
2. **Isotonic Loading:** Pain must remain 3 or less out of 10 on a pain numeric rating scale. Isotonic load is important to restore muscle bulk and strength through functional ranges of motion.
3. **Energy Storage Loading:** Initiating this stage is based on the following strength and pain criteria: (1) good strength (e.g., ability to perform four sets of eight repetitions of single-leg press with around 150% bodyweight for most jumping athletes); (2) good load tolerance with initial energy storage exercises defined as minimal pain (3 or less out of 10 on a pain numeric rating scale) while performing the exercises, and return to baseline pain (if there was an initial increase) during load tests such as the single-leg decline squat within 24 hours. This phase focuses on eccentric loading of the tendon, Variables that are trained include the rate, volume and intensity of eccentric loading. (This is what is thought of as the traditional eccentric exercise approach to patients with tendinopathy.)
4. **Return to Sport:** Progression back to sports specific training can be commenced when the individual has progressed through energy storage progressions that replicate the demands of their sport in regard to the volume and intensity of relevant energy storage functions. At that time, stage 3 exercises are replaced by a graded return to training and eventually competition.[95]

an open or a closed chain, recognizing that substitution may occur during a closed chain exercise. However, body weight used during a closed chain exercise may provide enough assistance to the injured tendon to allow for adequate strength training. A vigorous eccentric program is recommended prior to any surgical intervention.[88] Eccentric squats performed on a decline board (a board declined approximately 25 degrees) have been shown to be effective in treating patients with patellar tendinopathy.[89] In most research, patients performed exercises with external resistance on a decline board for 3 sets of 15 repetitions twice daily for up to 12 weeks. It has been suggested that the eccentric exercise results in decreased neovascularization at the tendon and resultant decreases in pain and improvements in function.[90,91] To create an optimal healing environment, adjuncts to the therapeutic exercise program are used and typically include forms of cryotherapy. The outcome for conservative management of patellar tendinopathy shows that only 55% of athletes achieve an excellent or good outcome 12 months post injury.[92]

Iliotibial Band Syndrome

Iliotibial band syndrome (ITBS) is the most common cause of lateral knee pain in individuals who regularly jog, bicycle, or walk for exercise.[96–98] Postural problems such as anterior pelvic tilt, knee hyperextension or hyperpronation, combined with poor mechanics, such as decreased gluteus medius or quadriceps activity, can be predisposing factors. Biomechanical analysis of patients with ITBS showed greater hip adduction and knee internal rotation moments compared to patients without symptoms.[96–98] Increased hip adduction and femoral internal rotation causes increased ITB strain at the lateral femoral condyle. It has been suggested that the *rate* of strain is more important than the *magnitude* of the strain, particularly in runners.[99] While ITBS has traditionally been considered to be the result of friction over a bursa as the band passes anterior and posteriorly over the lateral femoral condyle, biomechanical and anatomic studies suggest that few people actually have a bursa in this area.[100,101] Moreover, it has been suggested that the band does not actually move across the epicondyle, but that the appearance of movement is the result of tensioning of the anterior and posterior bands of the ITB.[100]

The individual presenting with ITBS often complains of a sharp, stabbing pain at the lateral femoral epicondyle that begins with the onset of activity and worsens as the activity progresses. Palpable tenderness over the lateral femoral epicondyle can confirm the diagnosis. Predisposing factors such as poor postural habit of standing in genu recurvatum and whole-limb pronation or muscle imbalance should be identified during the examination. Hamstring, gluteal, quadriceps, iliopsoas, and ITB flexibility and strength should be assessed. Any impairments or activity limitations identified during the examination should form the basis for the rehabilitation program. In many cases, a combination of predisposing factors, activity choices, a rapid increase in activity and impairments converge to produce ITBS.

Treatment

Rehabilitation focuses on the identification and treatment of predisposing factors, impairments, and activity limitations. Patient education regarding these factors and conscientious participation in self-managing this problem contribute to a successful outcome. Postural education and identification of the underlying impairments (e.g., hip rotator weakness, core weakness, lack of flexibility in the lower extremity) provide the foundation for appropriate stretching or strengthening exercises. Stretching for the hip and knee musculature with emphasis on good posture is the mainstay of treatment. These stretches may be performed on land or in the pool (see Figs. 20-10 through 20-12). Ice may be used to treat pain and inflammation associated with this problem. Self-mobilization or massage is commonly used to decrease the pain associated with ITB symptoms. Foam rollers or other firm materials can be rolled along the ITB to self-massage this tissue.

Patellofemoral Pain Syndrome

The typical patient with patellofemoral pain syndrome (PFPS) is a young female who complains of pain in the anterior aspect of the knee.[102,103] The pain is aggravated by closed chain knee extension activities such as ascending or descending stairs, squatting, rising from a chair, or jumping. A wide variety of interventions for PFPS have gained widespread acceptance in the clinical community, including general and specific hip and knee strengthening using both open and closed kinetic chain exercises, providing surface EMG biofeedback, stretching, acupuncture, low-level laser therapy, patellar mobilization, corrective foot orthoses, patellar taping, and external patellar bracing.[104,105] Unfortunately, experimental evidence to support the use of many of these approaches, either combined or in isolation, is lacking, and conventional clinical practice often flies in the face of what little evidence does exist. An understanding of what is known about the efficacy of various interventions, and, where the research lags behind clinical practice, a thorough understanding of the etiology of the condition should guide the intelligent choice of management strategies for the patient with PFPS.

Cause: Etiology

The causes of PFPS can be due to a macrotrauma, such as a patellar subluxation or dislocation, or from microtrauma, caused by overuse with patellar malalignment. Frank dislocation resulting from a blow to the knee is simple to determine through history. Recurrent subluxation is suggested when the patient reports that her knee gives way with a sharp pain, usually with slight knee flexion combined with tibial external rotation in weight-bearing. Rates of patellofemoral dislocations are highest during adolescence.[106] Patients with acute traumatic patellar instability will experience chronic instability or PFP. Age at initial dislocation, anatomic abnormalities, including trochlear dysplasia, and activity level may predispose a patient to a poor outcome.[107] Patella alta also increases the risk of patellar instability. Other causes of the knee "giving way" should be ruled out. Other sources of instability include ligamentous tears, meniscal pathology, and quadriceps inhibition.[12]

Microtrauma due to overuse can be a cause of PFP; not all patients with PFP demonstrate lateral subluxation or tracking.[108] This suggests other reasons must exist, and one should look for an increase in usage patterns associated with the onset of the anterior knee pain. Again, the patient's history will provide the clues, with repetitive work or recreational activities that stress the knee being key factors. The patient may report an increase in running distance, a change in running surface, an increase in workload demands, or a change in shoe wear.

It is generally accepted that PFPS results from a cascade of events. Poor alignment of the patella in the trochlear groove, typically with the patella seated laterally, results in poor distribution of the patellofemoral joint reaction forces (PFJRF) on the posterior aspect of the patella.[109] The PFJRF is the amount of pressure on the joint surfaces of the patellofemoral joint, and is a function of the flexion angle of the knee and the amount of tension developed by the quadriceps muscle. As the knee flexes and the quadriceps become more active, the PFJRFs increase. Under normal circumstances, the pressure is distributed to both the medial and lateral facets, and with near end-range flexion, to the odd facet. When the patella tracks poorly, the PFJRFs will be concentrated into a smaller contact area, resulting in increased shear on the articular surfaces, leading to tissue breakdown, pain, and impaired function.[109,110] There is some evidence that runners who develop PFP have increased impact forces during heel strike and push off as compared to runners without PFP.[111] In addition, foot posture was not found to be different between individuals with PFPS and controls.[112] The possible causes of patellar malalignment seen with microtrauma are generally separated into two basic categories. The first includes problems with the static structures such as the shape of the osseous surfaces or length of the fascia. The second category of patellar malalignment etiology includes issues related to the dynamic structures about the knee. As the discussion that follows suggests, there is a lack of consensus in the research literature with regard to the etiology of PFPS, although the search continues. In the meantime, clinical experience and outcome studies demonstrate the effectiveness of conservative treatment for this disorder, although the relative effectiveness of any individual intervention has yet to be shown.

The Role of Static Structures

The Q-angle is formed by a line drawn from the anterior superior iliac spine (ASIS) to the middle of the patella, and from the middle of the patella to the tibial tuberosity. In theory, a greater Q-angle would be associated with increased lateral forces on the patella and therefore associated with lateral patellar tracking. The Q-angle can be measured in supine, standing (either single or double leg), and either statically or dynamically. Because of this large variability, the association between Q-angle and PFP remains in question.[2,113,114] This underscores the need for the whole lower kinetic chain to be evaluated in the patient with PFPS.

The depth of the trochlear groove may play a role in PFP.[115] In a study by Powers et al, subjects with a shallower trochlear groove had a laterally tilted patella in terminal extension (30 to 0 degrees) and a laterally displaced patella in the last 9 degrees of extension.[116] Although a defect in the trochlear groove is not amenable to physical therapy intervention, understanding all the contributing factors to the patient's PFPS will guide the clinician to establish realistic goals for the patient.

It has been theorized that controlling overpronation at the foot would help alleviate PFPS by positively affecting the Q-angle. Foot pronation causes tibial internal rotation, which, when carried into late midstance and terminal stance when the knee is extended, will cause hip internal rotation as well. This shifts the patella medially relative to the ASIS and theoretically increases the lateral forces on the patella. However, the utilization of foot orthoses, either custom or off-the-shelf, in the management of PFPS remains controversial.[117–124] Clearly more work needs to be done to determine the effectiveness of foot orthoses in the management of PFPS.

The Role of Dynamic Structures

Historically, there had been discussion about the role of the VMO, and the VL muscles' function in the development of PFPS. The thought was that an imbalance in the amount of pull or the timing of the contraction of these muscles could either cause or allow the patella to track laterally in the trochlear groove, resulting in a concentrated force on the retropatellar surface. And although this theory has been tested repeatedly via numerous studies, it appears there is no difference between symptomatic and asymptomatic subjects in either amount of VMO:VL EMG activity or the timing of the onset of the two heads of the quadriceps.[113,125] Another early theory suggested that joint effusion could cause pain and inhibit quadriceps function in the knee.[12] In addition, other theories supported a difference in reflex response times or neural adaptations as contributing factors to PFPS. However, most of these studies were refuted or found to have flaws within their methods.[11,111,114,126,127] However, research has consistently shown that improving quadriceps strength and endurance is an integral part of any rehabilitation program for PFPS.[126,128]

More recently, the increased forces on the lateral undersurface of the patella have been attributed to increased femoral internal rotation, which brings the lateral femoral condyle into contact with the lateral retropatellar surface.[129] The increased femoral internal rotation may be osseous, due to femoral anteversion, or may be dynamic, due to gluteus medius weakness.[69,125,126,130] Increasing evidence has demonstrated the benefits of incorporating hip strengthening to the multifaceted plan of care of the patient with PFPS.[69,125,126,130] Hip strengthening, either in isolation or combined with quadriceps strengthening, for the management of PFPS, has been proven to be successful.[120] In addition, hip strengthening exercises in addition to quadriceps exercises appear to be more beneficial than quadriceps strengthening alone for the management of PFPS[126] (**Evidence and Research 20-5**).

EVIDENCE and RESEARCH 20-5

Strengthening of the hip abductors, specifically the gluteus medius, has been shown to be effective in reducing pain and increasing function in patients with PFPS, particularly in women. When prescribing gluteus medius strengthening exercises, it is imperative that the clinician know which exercises provide the greatest amount of electromyographical (EMG) activity. Studies have found the following %MVC of the gluteus medius with each listed exercise[131,132]:

Exercise	% Maximal Voluntary Contraction (MVC)
Side plank, DL down	103
Sind plank, DL up	89
Single limb squat	82
Sidelying hip abduction	81
Clamshell	76
Single limb squat	64
Lateral band walk	61
Single limb deadlift	58

In addition to dynamic muscular imbalances at the hip, foot or ankle dysfunction can cause a change in the angle of pull of these muscles and lead to altered patellar tracking as well. As such, management of impairments at the foot and ankle must be addressed as well.

Differential Diagnoses

It is important to differentiate PFP from other disorders of the knee. Generally, PFPS will manifest in the anterior aspect of the knee as a diffuse ache, with the pain aggravated with activity such as ascending or descending stairs. Other pathologies, however, will also cause anterior knee pain; therefore, general questions about the location of the pain may not be helpful in establishing the correct diagnosis. In addition, disorders can coexist, further complicating the picture. Other causes of anterior knee pain include irritation of the infrapatellar fat pad, patellar tendinopathy, Osgood–Schlatter disease, Sinding-Larsen–Johansson disease, or pes anserine bursitis.

Patients with PFP may complain of the knee locking or giving way. A patient may report that their knee “locks,” which actually may be a catch or click in the patellofemoral joint, versus true knee locking, as seen with meniscal pathology or a cruciate injury. “Giving way,” as described by the patient, may be quadriceps inhibition, commonly seen in patients with PFPS with low-grade swelling.[12] Regardless, these types of complaints warrant further investigation during the physical examination.

Examination

History taking should narrow the differential diagnosis for the clinician. Specifically, questions should determine if the mechanism of injury is due to a macrotrauma, repeated microtrauma, or if congenital structural problems play a role. Questions regarding aggravating and alleviating factors may help differentiate between anterior knee pain, patellar subluxation, and patellar dislocation.[107–109] Particular attention should be paid to determining what activities reproduce the patient’s pain, as these motions can be used to monitor the patient’s progress and the efficacy of an applied intervention.

Examination should include an assessment of the patient’s static alignment. Impairments in static structures, such as femoral anteversion and foot pronation, can be identified. Dynamic assessment might reveal impaired motor control or performance. For example, the patient may have asymmetry or excessive lateral weight shift when assuming a single limb stance posture. This may signal weakness of the hip abductors or lack of hip control. This will result in a relative hip adduction on the stance limb (Trendelenburg stance), which will bias the knee toward an increase in Q-angle, resulting in an increase in the lateral forces acting on the patella and lateral patellar tracking. In addition, over time, the hip adductors may become shortened.

Postural deviations, such as standing with most of the weight on one limb, and habitual usage can result in changes in the normal length--tension relationships of the muscles. It is important to perform a careful assessment of muscle function in the entire lower extremity. A useful assessment of function that incorporates the entire lower extremity is the step-down task. When properly performing this task, the knee should remain aligned over the second toe. The hip should remain in the same alignment as during double limb stance, with allowance made for slight weight shift over the weight-bearing leg as the non–weight-bearing leg is lifted. Excessive lateral shift or a drop of the non–weight-bearing pelvis suggests hip weakness, particularly in the abductors and extensors. In addition, if the knee moves medially over the foot during the step-down, weakness of the hip abductors, extensors, and hip external rotators should be suspected. If increased foot pronation occurs, poor muscular control of the posterior tibialis and gastrocnemius/soleus complex may be the cause. This movement pattern will result in relative hip adduction and increase the lateral pull on the patella. When this pattern of movement is observed, assessment of muscle strength (manual muscle testing at minimum) in these muscles is mandatory. The results of the strength tests will guide the choice of exercises.

Intervention

An appropriate management plan for PFPS should be based on the evaluation of all the collected data, which is distilled into a diagnosis. Issues related to impairments of body structures are not appropriate for physical therapy intervention. However, habitual movement patterns can be corrected with movement reeducation. ROM impairments and motor deficits can be addressed through strengthening, stretching, and manual interventions. Once pain has been reduced, rehabilitation of the extensor mechanism and control of proper lower extremity alignment are the foundation of managing PFPS.

Historically, much has been made about the imbalance between the VL and the VMO as a causative factor in PFPS. It was once thought that the VMO was primarily responsible for stabilizing the patella medially, and that poor VMO function would result in lateral tracking of the patella and cause PFPS.[110] However, despite multiple investigations, there does not seem to be a consensus about whether there is reduced VMO activity in patients with PFPS.[2,111–114,125,126,130,133–135] What has been supported in the literature is the use of general quadriceps strengthening to improve the overall function of the quadriceps, as discussed below.[115]

Evidence for PFPS Interventions It is important to address the symptoms experienced during knee extension, particularly closed chain. Pain will cause muscle inhibition and therefore will interfere with daily activity, such as walking, and will limit any attempt at muscle strengthening. Interventions that minimize pain should be implemented. These include icing, electrical stimulation, and soft tissue massage as indicated. Additionally, an intervention that appears to be of benefit to reduce anterior knee pain during closed chain activities is taping. Several studies have shown that patellar taping or the use of Kinesio Tape can decrease knee pain.[116,124,129,136] While the exact mechanism of the pain relief is unknown, it appears that taping alters neither the amplitude nor the timing of the vasti muscles.[120,123] However, the tape may distribute the PFJRF more evenly across the posterior surface of the patella, increasing contact area. And although the precise mechanism of decreased pain is not well understood, functional measures improve after the application of tape[113,120] (**Evidence and Research 20-6**).

EVIDENCE and RESEARCH 20-6

The effectiveness of taping, bracing, and Kinesio Tape for the treatment of PFPS has been examined. Patient with PFPS were taped three different ways: will a medial pull, with a lateral pull, and neutral (no pull). Each patient performed four single step-downs with each taping method, as well as with no tape, and reported their pain. The authors found that all taping methods significantly decreased pain when compared to the untaped condition. The authors concluded that patellar taping produced an immediate decrease in pain in patients with PFPS, irrespective of how taping was applied. As such, the tape may decrease pain by simply increasing contact area of the patella within the trochlear groove. It is unlikely that taping works by altering patellar position.[124]

In lieu of taping, patellofemoral braces may also be effective in reducing pain and increasing patellofemoral contact area.[117–119,122] While there is no evidence that supports the use of knee orthoses in all patients, it may be that a trial use of an orthosis will benefit certain patients.

Once pain has subsided, improving the static and dynamic alignment of the entire lower extremity can be addressed. The presence of structural deformities may be addressed using compensatory measures, such as over-the-counter foot orthoses. Although foot orthoses have been shown to be better than flat inserts in the short term, they do not improve outcomes when added to typical physical therapy interventions.[121]

Other than structural deformities, the main impairments associated with poor alignment are limitations in ROM, muscle flexibility, and motor function. Patients with PFPS demonstrate significantly less flexibility of the gastrocnemius, soleus, quadriceps, and hamstrings compared to healthy control subjects.[137] ROM limitations can be generally categorized as either being due to joint mobility restrictions or to soft tissue shortness. Appropriate joint mobilization techniques should be used to improve hip, tibiofemoral, patellofemoral, tibiofibular (both inferior and superior), talocrural, intercarpal, and metatarsophalangeal joint motion, as indicated by examination findings (see Chapter 7). Soft tissue restrictions can be addressed using soft tissue mobilization techniques that address specific areas of hypomobility, through longitudinal stretching either done manually by the therapist or done by the patient independently, or both. Contract-relax techniques work well in improving the overall length of the muscle. With regard to PFPS, key areas that need to be addressed include improving hip adduction (indicated by a positive Ober test), hip extension (Thomas test), external hip rotation, knee flexion with the hip extended (Thomas test), and ankle dorsiflexion (see **Table 20-9**). There is evidence that a 3-week program of quadriceps stretching improves flexibility, pain, and knee function.[138] Poor ankle dorsiflexion can lead to compensatory pronation at the subtalar joint, which causes internal rotation of the tibia. As noted earlier, this may adversely affect patellar alignment. Posterior glides of the talus on the tibia will increase ankle dorsiflexion at the talocrural joint, while stretching of the gastrocnemius will also increase dorsiflexion. ITB tightness affects patellofemoral and tibiofemoral kinematics; stretching the ITB has been advocated as part of an overall intervention program, with positive outcomes reported.[127,139] Based on the structure, tissue makeup and tensile properties of the ITB, it is unlikely that a stretching or soft tissue mobilization program will significantly lengthen it. It is more probable that length is gained in the proximal attachments of the ITB, likely the tensor fasciae latae. In addition, soft tissue mobilization might gate pain, which may improve knee function.

A simple active combined hamstring and gastrocnemius stretching exercise that can be performed in sitting is appropriate and convenient for most patients. In a sitting position, the patient should support the low back with a firm hand support to maintain the lumbar lordosis. The patient then slowly extends the lower leg while maintaining this lumbar lordosis. At the end of the comfortable ROM, the patient should dorsiflex the foot intermittently at 3-second intervals. Prolonged holding of this position might irritate the sciatic nerve, as nerves, when stretched, can become hypoxic. This exercise can be performed frequently throughout the day (see **Self-Management 20-7**).

TABLE 20-9

Stretching Exercises to Address Hip Soft Tissue Mobility Impairments

IMPAIRMENT–LACK OF:	PATIENT POSITION	KEY POINTS
Hip extension	Half-kneel Supine, leg off table Sidelying Prone	■ Bias the pelvis into a posterior pelvic tilt to maximize the length of the hip flexors
Hip flexion (with a focus on 2–joint hip extensors)	Supine straight-leg raise Knee extension with hip maintained in flexion	■ Bias the pelvis into an anterior pelvic tilt to maximize the length of the hamstrings
Hip adduction	Half-kneel	■ Maximize stretch to tensor fasciae latae, minimize lateral trunk stretch
Hip external rotation	Half-kneel on a chair	■ Stabilize pelvis
Knee flexion with hip extended	Half-kneel Sidelying with the knee flexed Prone with the knee flexed	■ Bias the pelvis into a posterior pelvic tilt to maximize the length of the rectus femoris
Ankle dorsiflexion	Standing	■ Bias the foot into supination to isolate ankle dorsiflexion ■ Address both gastrocnemius and soleus

SELF-MANAGEMENT 20-7
Hamstring and Gastrocnemius Stretching While Maintaining a Lumbar Neutral Position

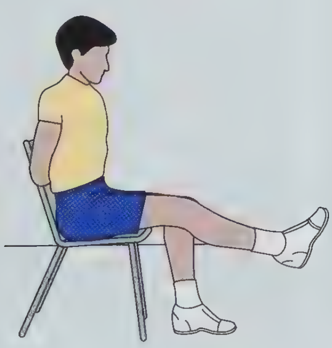
Purpose: To increase the flexibility of the hamstring and calf muscles

Position: In a sitting position, place one hand behind your back to maintain the proper position of your lower back.

Movement Technique: Maintaining this position, slowly straighten the knee until you feel a gentle stretch behind your thigh. While holding this position, pull your toes up, flexing your ankle until you feel a gentle stretch behind your calf. Hold for 3 seconds.

Dosage:

Repetitions: ______________________ times



Once pain has been addressed, the cornerstone of management of PFPS is improving strength and neuromuscular control of the lower extremity.[11,140–142]

All resistance exercises should be performed in a pain-free ROM. It may be that only isometric exercise is tolerated in a highly irritated condition. If this is the case, multi-angle isometrics should be employed. There is no reason to emphasize terminal knee extension over exercise in greater amounts of flexion. Avoidance of patellofemoral joint compression forces can be counterproductive, considering that cartilage nutrition is dependent in large part on weight-bearing. The guiding principle should be dispersing the PFJRF by increasing the patellofemoral contact area by improving patellar tracking. As the patient progresses to closed chain exercises, examples of controlling the ROM include altering the depth of squat, height of the step (step-ups) or height of the chair (stand to sit exercise).

A review of the available literature showed strong evidence that both open and closed kinetic chain exercises lead to equal long-term good functional outcomes, even at a 5-year follow-up.[128] However, considering interventions should be directed at improving activity limitations and participation restrictions, given the principle of specificity of exercise, closed chain exercises may be a better choice for most patients.

Performing all exercises with proper lower extremity and trunk alignment is essential to addressing dynamic malalignment issues. For example, step-up and step-down exercises are important, as stairs are a problem for most individuals with PFP. In performing this exercise, the patient should maintain the knee aligned over the second toe. Exercise difficulty should be adjusted to allow motion through the total target ROM while maintaining good alignment. This may affect the choice of open versus closed chain exercise. For example, many individuals with PFPS have poor eccentric control during stair descent. When asked to control the step-down motion, many are unable to do so because of pain or inadequate muscle control. In this case, the step-down exercise from a standard step height is too demanding of the patient and is contraindicated because the patient cannot maintain optimal alignment. Starting with a small step, perhaps 4 inches, may be appropriate. In addition, open chain strengthening may prove beneficial at this point, as specific muscles can be targeted for strengthening and the appropriate amount of resistance applied. In addition, taking into consideration the functional task required, emphasizing eccentric exercises in open chain would begin the training necessary for control of lowering the body weight during the step-down task. For example, sidelying hip abduction with weight applied to the knee or ankle will selectively strengthen the gluteus medius. Eccentric contractions can be accomplished by assisting in the concentric lifting of the leg. One way to accomplish this is to simply have the patient flex the knee while raising the leg (shortening the lever arm and therefore decreasing the resistance to the abductors), and extending the knee prior to lowering the leg, thereby increasing the resistance during the eccentric phase of the movement. Alternatively, it may be that closed chain exercises can be performed using equipment that can minimize body weight, such as a leg press or inclined squat machine. These machines and others like them allow the amount of resistance to be adjusted to proper levels, as opposed to full weight-bearing exercises that demand control of body weight. Once strength has improved and pain has subsided, a progression toward closed chain exercises is indicated.

The speed of the movement is an important exercise variable to consider. As the patient's control of the movement improves at slower speeds, the speed of movement should be increased to approximate normal function. Good alignment and form are still paramount goals regardless of the speed of movement. The individual should move slowly enough to be able to stop at any point during the motion to correct malalignment. Close observation can detect poor alignment of the hip, knee, and ankle or substitution at the hip (**Fig. 20-24**). The use of mirrors and video recordings of movements can be beneficial. A mirror provides immediate feedback to the patient and encourages the patient to self-correct.[143] In addition, the use of a mirror has been shown to positively affect transfer of skill to other tasks, even at 1 and 3 months post training[143] (**Evidence and Research 20-7**). Utilization of video recordings, such as those created with an iPad, can provide the patient with feedback. Oftentimes, fast movements can be played back for the patient at a slower speed to increase motor learning and help the patient identify faulty movement patterns.[105]

EVIDENCE and RESEARCH 20-7

Observational learning, as with video feedback, is an effective way to enhance motor skill learning. Imitation of body movements that are observed activates mirror neurons. The mirror neurons map the observed movements onto a motor program. Interestingly, mirror neurons fire when an action is performed as well as when a similar action is observed (as in watching video of oneself performing the skill).[105] In a study by Onate et al,[144] both verbal and self-video feedback were tested during a jump-landing task.

The group that received both verbal and self-video feedback significantly reduced peak vertical ground reaction forces compared to the group that was instructed to self-analyze jumps using internal feedback and a control group, who received no feedback.[144]

When a faulty movement pattern is identified, bracing or taping may offer increased neuromuscular control during activities.[145] Lastly, when observing closed chain exercises, remember the foot position can influence the lower extremity alignment. Ideally, the foot should be in a position close to neutral for all standing activities. To obtain a relatively neutral position of the foot, the tibialis posterior should lift the subtalar joint while the peroneus longus stabilizes the first ray. Pressing down (plantar flexing) through the first metatarsal head is often

A

B

FIGURE 20-24 **(A)** Patient performing a squat exercise. **(B)** Progressing to a lifting exercise.

a beneficial cue to facilitate correct alignment and appropriate muscle recruitment. Recruitment of the foot intrinsic muscles to maintain a stable arch should be encouraged.

Postoperative Rehabilitation

The three most commonly performed surgical procedures for the patellofemoral joint include:

- Arthroscopic debridement of patellar or femoral chondral degeneration
- Lateral retinacular release for severely restricted lateral structures
- Realignment procedures for those with more complicated biomechanics

Surgery for PFPS is utilized very judiciously, as surgical outcomes are no better than conservative management, even at a 5-year follow-up.[143] Rehabilitation after any of these procedures should follow the program as previously outlined. With arthroscopic debridement, the program should progress without problems unless significant pain or swelling exists. If more progressive chondral damage has occurred, more caution should be placed on gradual and careful reintroduction of activity and exercise to allow the accommodation of the chondral surfaces. With lateral retinacular releases, care should be taken to ensure the lateral retinaculum does not adhere to surrounding soft tissues. Aggressive releases must be progressed much more slowly than conservative releases, because postoperative pain and large amounts of edema are common. Realignment procedures require careful patient selection and are typically only considered after conservative management has failed. The Maquet procedure, which is an older procedure, involved advancing the tibial tuberosity anteriorly 2 to 2.5 cm via a bony wedge. The rationale of this procedure was to reduce patellofemoral pressure.[146] However, the complication rate was fairly high, and rehabilitation was lengthy. As such, the procedure has fallen out of favor and is rarely performed. More recently, the medial patellofemoral ligament (MPFL) has been identified as the primary medial restraint to a laterally subluxing patella. In patients with a history of recurrent patellar instability, the MPFL can be stretched or completely torn, rendering it nonfunctional. Surgery to reconstruct the MPFL has become increasingly popular.[147] The goal of this procedure is to recreate the MPFL, thereby resisting lateral dislocation and restoring stability. Many surgical techniques as well as grafts are used to accomplish this. Graft options include semitendinosus, patellar or quadriceps tendon, and allografts. Systematic reviews show favorable outcomes while failure rates continue to decrease.[147] Management of the patient after a MPFL reconstruction includes a focus on ROM, patellar and tibiofemoral mobility, neuromuscular reeducation, and lower extremity strengthening. Close attention should be paid to the quality of quadriceps contraction and patellar tracking.

Prognosis

The prognosis for PFPS is generally good.[105] Strengthening exercises, in addition to stretching of the hamstrings, quadriceps, hip flexors, and gastrocnemius, combined with activity modification have proved to be effective in managing PFPS.[115] Regarding strengthening exercises, closed chain exercises are more closely associated with ADLs than open kinetic chain exercises. Although both open and closed chain exercises were effective in decreasing patient's pain, there is a tendency for better results with the use of closed chain exercises.[128] Most recently, studies have supported the addition of hip strengthening exercises, combined with quadriceps strengthening exercises, to decrease PFPS.[134,145,148–150] Lastly, although the addition of off-the-shelf foot orthoses and patellar taping may be of benefit, at the cornerstone of every well-designed intervention program is therapeutic exercise, including stretching and strengthening.

KEY POINTS

- The relationships among the lumbopelvic, hip, knee, ankle, and foot necessitate a thorough examination and an integrated approach to treatment. This includes hip and core muscle strengthening for distal problems.
- Impairments of body structures, including femoral anteversion, coxa valgum and varum, genu valgum and varum, a shallow trochlear groove, and foot pronation can predispose the patellofemoral joint to poor tracking, resulting in excessive loads.
- Impairments of body functions such as mobility or muscle performance loss at the hip, ankle, or foot can be manifested as symptoms in the anterior knee.
- Because of these compensations and the relationships among joints, therapeutic exercises may be performed incorrectly, allowing substitution to occur.
- Examination of the patellofemoral joint must include muscle length and joint mobility at the hip, knee, and ankle, as well as static and dynamic assessment of the patella.
- Examination of key functional movements such as ascending or descending stairs or a step-down task will reveal lower kinetic chain mechanics.
- Improvements in impaired joint and soft tissue mobility, muscle performance and motor control, and general quadriceps strengthening result in positive outcomes with PFPS.
- Currently, no evidence exists to support specific recruitment of the VMO separate from the rest of the quadriceps.
- The major impairments of body structures at the knee are genu valgum and genu varum. These postures predispose the lateral and medial compartments, respectively, to excessive loads.
- Impairments of body functions such as mobility loss at the knee can be compensated by motion at other joints. For example, increased ankle, hip, or lumbar motion can compensate for decreased knee flexion.
- Palpation, education, and biofeedback are techniques to ensure proper muscle firing patterns without substitution during rehabilitative exercises.
- Loss of the meniscus can lead to degenerative joint disease. Treatment after meniscectomy should focus on preservation of articular cartilage and joint protection techniques.
- The major function of the quadriceps muscle in the long-term health of the knee is its ability to absorb shock eccentrically in the loading phase of the gait cycle. A focus on eccentric, closed chain quadriceps exercise in the first 0 to 15 degrees of flexion is essential to maintain the health of articular cartilage.
- Patellar tendinopathy results from the tendon's inability to withstand eccentric forces during impact activities. The rehabilitation program must eventually progress to eccentric impact activities if the patient is to return to this type of activity.

case, the step-down exercise from a standard step height is too demanding of the patient and is contraindicated because the patient cannot maintain optimal alignment. Starting with a small step, perhaps 4 inches, may be appropriate. In addition, open chain strengthening may prove beneficial at this point, as specific muscles can be targeted for strengthening and the appropriate amount of resistance applied. In addition, taking into consideration the functional task required, emphasizing eccentric exercises in open chain would begin the training necessary for control of lowering the body weight during the step-down task. For example, sidelying hip abduction with weight applied to the knee or ankle will selectively strengthen the gluteus medius. Eccentric contractions can be accomplished by assisting in the concentric lifting of the leg. One way to accomplish this is to simply have the patient flex the knee while raising the leg (shortening the lever arm and therefore decreasing the resistance to the abductors), and extending the knee prior to lowering the leg, thereby increasing the resistance during the eccentric phase of the movement. Alternatively, it may be that closed chain exercises can be performed using equipment that can minimize body weight, such as a leg press or inclined squat machine. These machines and others like them allow the amount of resistance to be adjusted to proper levels, as opposed to full weight-bearing exercises that demand control of body weight. Once strength has improved and pain has subsided, a progression toward closed chain exercises is indicated.

The speed of the movement is an important exercise variable to consider. As the patient's control of the movement improves at slower speeds, the speed of movement should be increased to approximate normal function. Good alignment and form are still paramount goals regardless of the speed of movement. The individual should move slowly enough to be able to stop at any point during the motion to correct malalignment. Close observation can detect poor alignment of the hip, knee, and ankle or substitution at the hip (**Fig. 20-24**). The use of mirrors and video recordings of movements can be beneficial. A mirror provides immediate feedback to the patient and encourages the patient to self-correct.[143] In addition, the use of a mirror has been shown to positively affect transfer of skill to other tasks, even at 1 and 3 months post training[143] (**Evidence and Research 20-7**). Utilization of video recordings, such as those created with an iPad, can provide the patient with feedback. Oftentimes, fast movements can be played back for the patient at a slower speed to increase motor learning and help the patient identify faulty movement patterns.[105]

EVIDENCE and RESEARCH 20-7

Observational learning, as with video feedback, is an effective way to enhance motor skill learning. Imitation of body movements that are observed activates mirror neurons. The mirror neurons map the observed movements onto a motor program. Interestingly, mirror neurons fire when an action is performed as well as when a similar action is observed (as in watching video of oneself performing the skill).[105] In a study by Onate et al,[144] both verbal and self-video feedback were tested during a jump-landing task.

The group that received both verbal and self-video feedback significantly reduced peak vertical ground reaction forces compared to the group that was instructed to self-analyze jumps using internal feedback and a control group, who received no feedback.[144]

When a faulty movement pattern is identified, bracing or taping may offer increased neuromuscular control during activities.[145] Lastly, when observing closed chain exercises, remember the foot position can influence the lower extremity alignment. Ideally, the foot should be in a position close to neutral for all standing activities. To obtain a relatively neutral position of the foot, the tibialis posterior should lift the subtalar joint while the peroneus longus stabilizes the first ray. Pressing down (plantar flexing) through the first metatarsal head is often

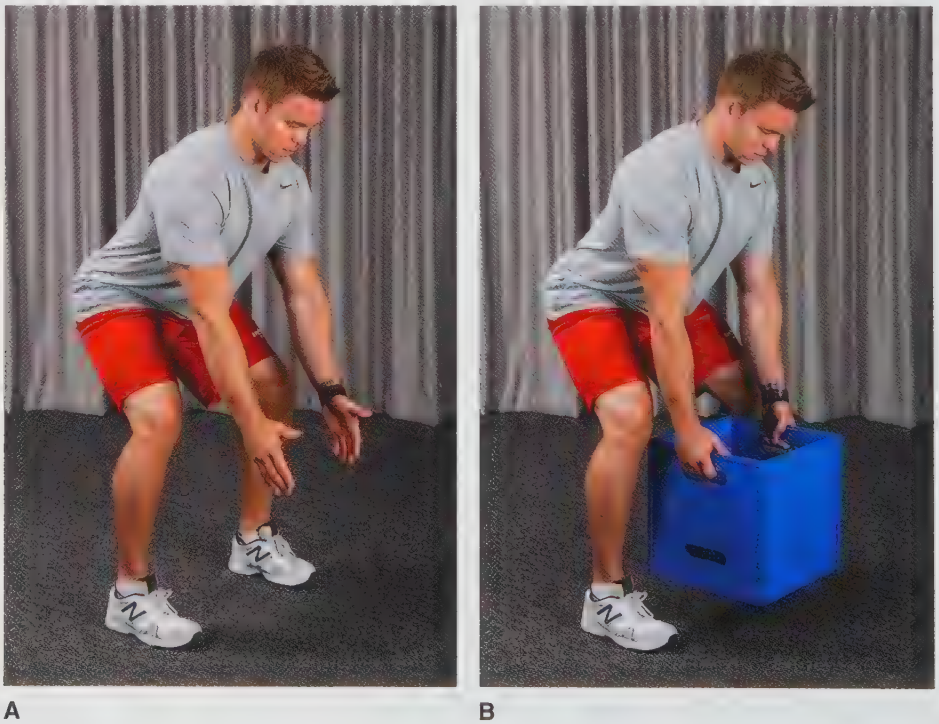


FIGURE 20-24 **(A)** Patient performing a squat exercise. **(B)** Progressing to a lifting exercise.

a beneficial cue to facilitate correct alignment and appropriate muscle recruitment. Recruitment of the foot intrinsic muscles to maintain a stable arch should be encouraged.

Postoperative Rehabilitation

The three most commonly performed surgical procedures for the patellofemoral joint include:

- Arthroscopic debridement of patellar or femoral chondral degeneration
- Lateral retinacular release for severely restricted lateral structures
- Realignment procedures for those with more complicated biomechanics

Surgery for PFPS is utilized very judiciously, as surgical outcomes are no better than conservative management, even at a 5-year follow-up.[143] Rehabilitation after any of these procedures should follow the program as previously outlined. With arthroscopic debridement, the program should progress without problems unless significant pain or swelling exists. If more progressive chondral damage has occurred, more caution should be placed on gradual and careful reintroduction of activity and exercise to allow the accommodation of the chondral surfaces. With lateral retinacular releases, care should be taken to ensure the lateral retinaculum does not adhere to surrounding soft tissues. Aggressive releases must be progressed much more slowly than conservative releases, because postoperative pain and large amounts of edema are common. Realignment procedures require careful patient selection and are typically only considered after conservative management has failed. The Maquet procedure, which is an older procedure, involved advancing the tibial tuberosity anteriorly 2 to 2.5 cm via a bony wedge. The rationale of this procedure was to reduce patellofemoral pressure.[146] However, the complication rate was fairly high, and rehabilitation was lengthy. As such, the procedure has fallen out of favor and is rarely performed. More recently, the medial patellofemoral ligament (MPFL) has been identified as the primary medial restraint to a laterally subluxing patella. In patients with a history of recurrent patellar instability, the MPFL can be stretched or completely torn, rendering it nonfunctional. Surgery to reconstruct the MPFL has become increasingly popular.[147] The goal of this procedure is to recreate the MPFL, thereby resisting lateral dislocation and restoring stability. Many surgical techniques as well as grafts are used to accomplish this. Graft options include semitendinosus, patellar or quadriceps tendon, and allografts. Systematic reviews show favorable outcomes while failure rates continue to decrease.[147] Management of the patient after a MPFL reconstruction includes a focus on ROM, patellar and tibiofemoral mobility, neuromuscular reeducation, and lower extremity strengthening. Close attention should be paid to the quality of quadriceps contraction and patellar tracking.

Prognosis

The prognosis for PFPS is generally good.[105] Strengthening exercises, in addition to stretching of the hamstrings, quadriceps, hip flexors, and gastrocnemius, combined with activity modification have proved to be effective in managing PFPS.[115] Regarding strengthening exercises, closed chain exercises are more closely associated with ADLs than open kinetic chain exercises. Although both open and closed chain exercises were effective in decreasing patient's pain, there is a tendency for better results with the use of closed chain exercises.[128] Most recently, studies have supported the addition of hip strengthening exercises, combined with quadriceps strengthening exercises, to decrease PFPS.[134,145,148–150] Lastly, although the addition of off-the-shelf foot orthoses and patellar taping may be of benefit, at the cornerstone of every well-designed intervention program is therapeutic exercise, including stretching and strengthening.

KEY POINTS

- The relationships among the lumbopelvic, hip, knee, ankle, and foot necessitate a thorough examination and an integrated approach to treatment. This includes hip and core muscle strengthening for distal problems.
- Impairments of body structures, including femoral anteversion, coxa valgum and varum, genu valgum and varum, a shallow trochlear groove, and foot pronation can predispose the patellofemoral joint to poor tracking, resulting in excessive loads.
- Impairments of body functions such as mobility or muscle performance loss at the hip, ankle, or foot can be manifested as symptoms in the anterior knee.
- Because of these compensations and the relationships among joints, therapeutic exercises may be performed incorrectly, allowing substitution to occur.
- Examination of the patellofemoral joint must include muscle length and joint mobility at the hip, knee, and ankle, as well as static and dynamic assessment of the patella.
- Examination of key functional movements such as ascending or descending stairs or a step-down task will reveal lower kinetic chain mechanics.
- Improvements in impaired joint and soft tissue mobility, muscle performance and motor control, and general quadriceps strengthening result in positive outcomes with PFPS.
- Currently, no evidence exists to support specific recruitment of the VMO separate from the rest of the quadriceps.
- The major impairments of body structures at the knee are genu valgum and genu varum. These postures predispose the lateral and medial compartments, respectively, to excessive loads.
- Impairments of body functions such as mobility loss at the knee can be compensated by motion at other joints. For example, increased ankle, hip, or lumbar motion can compensate for decreased knee flexion.
- Palpation, education, and biofeedback are techniques to ensure proper muscle firing patterns without substitution during rehabilitative exercises.
- Loss of the meniscus can lead to degenerative joint disease. Treatment after meniscectomy should focus on preservation of articular cartilage and joint protection techniques.
- The major function of the quadriceps muscle in the long-term health of the knee is its ability to absorb shock eccentrically in the loading phase of the gait cycle. A focus on eccentric, closed chain quadriceps exercise in the first 0 to 15 degrees of flexion is essential to maintain the health of articular cartilage.
- Patellar tendinopathy results from the tendon's inability to withstand eccentric forces during impact activities. The rehabilitation program must eventually progress to eccentric impact activities if the patient is to return to this type of activity.

LAB ACTIVITIES

1. Demonstrate the likely gait pattern if your quadriceps strength was 3/5.
2. Demonstrate three strengthening exercises to treat quadriceps strength impairment, given a strength grade of 3/5.
3. Demonstrate two exercises to treat the activity limitations seen in the gait pattern.
4. Is an assistive device necessary? If so, what would you choose for this patient if she had no other impairments? Fit and instruct the patient in use of the device.
5. Demonstrate the likely gait pattern if the patient's quadriceps strength was 2/5.
6. Demonstrate three strengthening exercises to treat the quadriceps strength impairment, given a strength grade of 2/5.
7. Refer to Case Study No. 2 in Unit 7. Instruct your patient in the first phase of the exercise program. Have your patient demonstrate all exercises.
8. Create five exercises for a patient with subacute patellar tendinitis.
9. Determine your patient's 10 repetition maximum for a straight-leg raise with the weight.
   a. At the ankle
   b. Above the knee
10. Teach your patient how to check quadriceps firing during the following activities:
    a. Isometric quadriceps contraction while
       i. Sitting with the knee at 90 degrees
       ii. Sitting with the knee at 70 degrees
       iii. Sitting with the knee at 45 degrees
       iv. Sitting with the knee at 30 degrees
       v. Sitting with the knee at 0 degrees
    b. Wall slide
    c. Sit to stand
    d. Lunge
    e. Gait

CRITICAL THINKING QUESTIONS

1. Read Case Study No. 6 in Unit 7.
   a. List the patient's impairments and activity limitations.
   b. Describe the relationship between this patient's impairments and activity limitations.
   c. Describe the relationship between this patient's impairments, activity limitations, and any participation restriction.
   d. Identify and prioritize short- and long-term goals.
   e. Choose a specific goal, and describe five different exercises used to achieve that goal. Include posture, mode, and movement.
   f. This patient is returning to work as a delivery truck driver. Describe three functional exercises that can prepare him for this activity.
   g. Presume that this same patient is returning to work as a basketball referee. Describe three functional exercises that can prepare him for this activity.
2. Read Case Study No. 3 in Unit 7.
   a. Describe three exercises to address her difficulty with stairs. Include posture, mode, movement, and precautions.
   b. Given her history, describe three exercises to increase the endurance of her quadriceps muscles. Include posture, mode, movement, and precautions.
   c. Describe three exercises to increase the endurance of her calf muscles. Include posture, mode, movement, and precautions.
   d. The patient no longer feels any muscle fatigue when performing the exercises outlined in questions b and c. Describe how you would progress each of these exercises. Include dosage parameters.

CHAPTER

21 The Ankle and Foot

JILL MCVEY • CARRIE M. HALL

The ankle and foot interact with the knee, hip, and trunk to produce smooth, coordinated movement throughout the entire limb. Understanding these relationships is key to developing a successful therapeutic exercise program for the ankle and foot. Anatomic impairments (e.g., femoral anteversion, genu valgum, forefoot equinus), physiologic impairments (e.g., joint hypermobility, diminished muscle performance, loss of balance), or trauma at one joint can lead to dysfunction at other joints in the kinetic chain. Appropriately addressing this interplay throughout the kinetic chain typically results in improved lower extremity function. Specific examination techniques and exercise interventions are essential for long-term resolution of impairments, activity limitations, and participation restrictions.

COMMON FOOT TYPES

The following suboptimal foot types are described as structural and are therefore considered anatomic impairments.

Subtalar Varus

Subtalar varus is defined as an inverted twist within the body of the calcaneus.[1] While the foot is held in the subtalar neutral position, the bisection of the posterior calcaneus is inverted relative to the bisection of the distal tibia and fibula (**Fig. 21-1**). Subtalar varus may result in excessive pronation during loading response and midstance phases of gait. The subtalar joint may resupinate in midstance; however, if the excessive pronation is significant, the subtalar joint may not reach the ideally neutral to slightly supinated position before heel rise. This may result in decreased midtarsal joint stability and increased forefoot shearing during terminal stance, potentially straining supportive soft tissues.

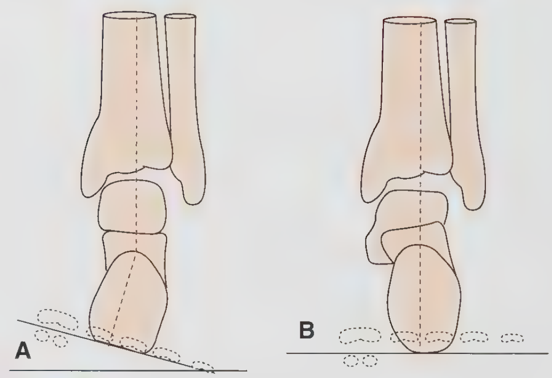

FIGURE 21-1 Posterior view of right foot subtalar varus. **(A)** Uncompensated subtalar varus. **(B)** Compensation for this impairment is usually excessive pronation. (From Gould JA. Orthopaedic and Sports Physical Therapy. 2nd Ed. St. Louis, MO: C.V. Mosby, 1990.)

Forefoot Varus

Forefoot varus is an inversion deviation of the forefoot relative to the bisection of the posterior calcaneus (**Fig. 21-2**).[2] A forefoot varus posture may result in excessive pronation during midstance. As with subtalar varus, prolonged pronation enables excessive forefoot mobility during push off, increasing lower extremity medial rotation when lateral rotation should occur. This rotational fault can contribute to symptoms anywhere up the kinetic chain.

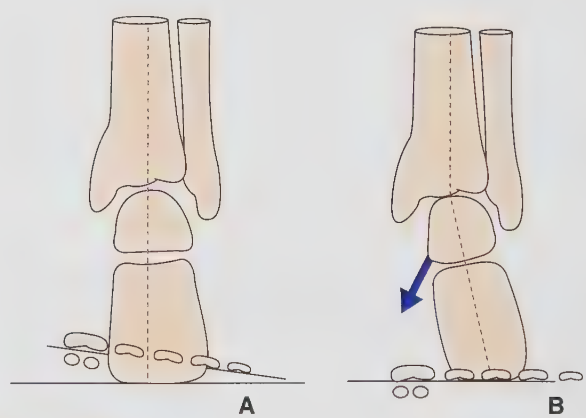

FIGURE 21-2 Posterior view of right foot forefoot varus. **(A)** Uncompensated forefoot varus. **(B)** Compensation for this impairment is usually excessive pronation. (From Gould JA. Orthopaedic and Sports Physical Therapy. 2nd Ed. St. Louis, MO: C.V. Mosby, 1990.)

Forefoot Valgus

Forefoot valgus is an eversion deviation of the forefoot relative to the bisection of the posterior calcaneus (**Fig. 21-3**).[2] This may result in early and excessive supination in midstance phase. This produces foot rigidity and may compromise terrain adaptation

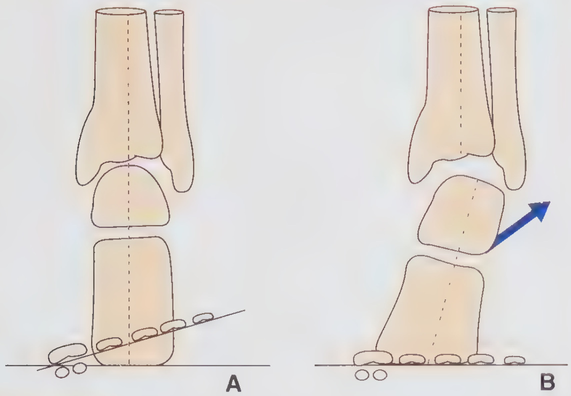

FIGURE 21-3 Posterior view of right foot forefoot valgus. **(A)** Uncompensated forefoot valgus. **(B)** Compensation for this impairment is usually excessive supination. (From Gould JA. Orthopaedic and Sports Physical Therapy. 2nd Ed. St. Louis, MO: C.V. Mosby, 1990.)

and shock absorption. This may also cause a lateral weight shift, creating greater forces at the fifth metatarsal and potential lateral instability. At terminal stance, the subtalar joint is likely to pronate to shift body weight from the lateral stance foot to the contralateral limb. The altered loading and subsequent instability increases the vertical ground reaction forces and may increase the risk of developing plantar pathology.[3]

Ankle Equinus

Ankle equinus is a structural abnormality of the talocrural joint whereby the 10 degrees of talocrural dorsiflexion necessary for gait is absent.[3] If ankle equinus is compensated, the forward progression of the tibia during stance phase forces significantly increases subtalar and midtarsal pronation; this may lead to a variety of lower limb pathologies including Achilles tendinosis, plantar fasciitis, and digital neuritis.[3,4] If uncompensated, the patient may manifest a "bouncy" or apropulsive gait secondary to early heel rise, which excessively increases pressure on the forefoot.[4] During the examination, the clinician must determine if the patient presents with a true osseous deformity versus limited talocrural dorsiflexion due to short or stiff extrinsic musculature or a stiff talocrural joint (see **Building Block 21-1**).

BUILDING BLOCK 21-1

Name one possible deviation in body structures and functions you would expect to see in an individual with:

1. Forefoot varus
2. Ankle equinus

EXAMINATION AND EVALUATION

Examination and evaluation of the foot and ankle must consider the findings related to the foot and ankle and their relationships to more proximal segments. While the tests described in this section are primarily for the ankle and foot and should be considered in any foot and ankle examination, examination of the knee and hip is also essential.

Patient/Client History

The patient's history guides the overall examination and provides the clinician with important information about activity limitations and participation restrictions. In addition to standard history and subjective examination questions, the clinician should inquire about usual footwear and daily activities, as these extrinsic factors can affect (or cause) symptoms.[5] The clinician uses this information to choose tests according to the patient's symptoms and designs a treatment program to address the impairments, activity limitations, and participation restrictions described by the patient.

Balance

Balance is important to assess when a patient presents with foot and ankle dysfunction. See Chapter 8 for details.

Joint Integrity and Mobility

Several special tests are recommended to assess the integrity of foot and ankle structures. Magee[6] provides a complete listing and description of special tests, including varus and valgus stress testing of the ankle and the anterior drawer test.

Muscle Performance

All ankle and foot muscle function should be tested. Any proximal muscles that may affect the foot and ankle should be tested as well, as their weakness can compound distal mechanical faults. Muscular performance of the trunk, hip, knee, foot, and ankle should be tested in a logical order and based on patient history information and the clinician's impression.

Pain

Assessing the patient's pain is performed as part of their subjective examination and further clarified during the objective examination. Palpable tenderness, warmth, and swelling are objective indications of inflammation. The subjective and objective information are then correlated to guide the remaining examination and treatment planning.

Posture

Observation of posture and position of the lower extremity, including the lumbopelvic and hip regions, is an important aspect of the examination.[6–8] A detailed discussion of foot and ankle alignment is available in the online supplement to this text.

Range of Motion and Muscle Length

Range of motion (ROM) and muscle length examination for this region should include both the foot and the ankle as well as the knee, hip, and spine. The following tests of ROM and muscle length should be performed:

- Hip and knee ROM and muscle length
- Femoral anteversion/retroversion
- Calcaneal inversion and eversion ROM
- Midtarsal joint supination and pronation ROM
- First ray position and mobility

- Hallux dorsiflexion ROM
- First to fifth ray mobility
- Ankle dorsiflexion and plantar flexion ROM with the knee flexed and extended

Assessing ankle dorsiflexion with the knee flexed and extended will help determine whether any observed flexibility impairments are due to stiffness/shortening of the gastrocnemius, soleus, or both. As it attaches on the femur, a short or stiff gastrocnemius will limit ankle dorsiflexion with the knee extended whereas a short or stiff soleus will impair ankle dorsiflexion regardless of knee angle.

Impairments of Body Structures

Observed alignment faults may result from either an impairment of body structure or function. Whereas an impairment of body function can be altered with appropriate interventions, such as joint mobilization or muscle strengthening, an anatomic impairment cannot because it is a fixed structural abnormality. However, it can be accommodated with orthotic therapy and movement reeducation to prevent the development of associated impairment of body function. Please refer to the "foot types" section at the beginning of this chapter for information on recognizing structural impairments.

Other Examination Procedures

A variety of additional examination procedures may be used depending on the specific patient situation. For example, patients with diabetes should have sensory testing and assessment of pulses. Anthropometric measurements such as circumferential measures are important in patients with swelling of the foot or ankle. Other measures include:

- Footwear and orthotic assessment to evaluate fit and wear.
- Assessment of foot callous patterns for evidence of shearing and load transfer.
- Observational gait analysis to determine foot and ankle kinematics.

THERAPEUTIC EXERCISE INTERVENTION FOR COMMON IMPAIRMENTS OF BODY FUNCTIONS

Abnormal alignment and movement patterns (see Chapter 9) can excessively stress and strain soft tissue and bony structures, leading to cumulative microtrauma and musculoskeletal pain. If left untreated, this can result in musculoskeletal system pathology that limits participation in meaningful activities. Impairments of body structures (anatomic impairments) throughout the lower extremity can lead to suboptimal alignment and movement patterns of the foot and ankle. Conversely, anatomic impairments of the foot and ankle can impair alignment and movement patterns at the knee, hip, pelvis, and spine.

Therapeutic exercise is an invaluable clinical tool for treatment of body function impairments of the ankle and foot. This section provides examples of therapeutic exercise for the treatment of impairments in balance, muscle performance, pain, posture and movement, ROM, muscle length, joint mobility, and integrity.

The clinician may need to appropriately modify based on individual signs and symptoms. Exercise recommendations for specific diagnoses of the ankle and foot are addressed in a later section.

Balance Impairment

Only a well-conditioned and neurologically trained ankle can function in a variety of directions as the center of gravity fluctuates, sometimes through extremes of motion, as the patient simultaneously performs actions with other extremities. The clinician should take care to vary the speed and intensity of training as appropriate to enable maximal functional carryover and to prevent reinjury. The array of training surfaces and conditions is vast, allowing ample opportunity to offer fresh challenges throughout a patient's rehabilitation.[9]

An average person recovering from an ankle or foot injury/condition should be able to balance on one leg for 30 seconds with eyes closed and mild external perturbation (i.e., with a balance board, foam, a balance machine, or another person providing an external force). This prepares the patient to regain balance through improved neurologic input to the ankle and foot musculature.

The Specific Adaptations to Imposed Demands (SAID) principle states that given stressors on the human body, whether biomechanical or neurological, the involved tissues will specifically adapt to the stressor.[10] While standing on a pillow is helpful to develop increased balance time and neurologic control, the intervention needs to be eventually tailored to enable return to specific functional activity performance. An elderly patient who sustains an injury from slipping on gravel may not prevent future falls unless the surface they practice balance on is similar to gravel. Another patient may need to return to high-level gymnastics; in this case, sport-specific drills implemented on a low balance beam are appropriate. Plyometric exercises in the form of progressive height jump-down activities prepare the ankle/foot to balance during high-impact activities.

Restoration of balance and coordination requires position sense, or proprioception. With an ankle sprain or muscle strain, peripheral proprioceptive nerve fibers are often injured. Just as muscles can become deconditioned after a period of disuse, so too can proprioception. The proprioceptors should be retrained in a controlled, progressive manner starting as soon as possible. Use of a balance board can provide predictable and progressive stress. The following exercise progression can be used at home without special equipment:

- Balancing on one leg with eyes open; progress to eyes closed standing in a door fame with hands close to the door jam for safety.
- Controlled weight shifts to the limits of stability while standing on one leg with eyes open; progress to eyes closed.
- Swinging the uninvolved lower extremity first in flexion and extension and then in abduction and adduction (see **Self-Management 21-1**). The faster and greater excursion of the swing, the more the static stance is challenged.
- Hopping from one foot to the other with practice of stabilization in one-legged stance.

Elastic bands can be used for the advanced patient. The band is tied in a circle and looped around a table leg or similar secure structure. Standing facing the table leg, the patient places their

SELF-MANAGEMENT 21-1
Balance Activities

Purpose: Increased balance on a single leg.

Position: Standing on one leg, near a counter or in a doorway to provide a surface to stabilize if necessary. Keep a slight bend in the knee.

Movement Technique: Level 1: Practice standing on a single leg with your eyes open for 30-second periods, practicing with and without a mirror.

Level 2: Eyes open, no mirror, standing on unstable surface.

Level 3: Eyes closed.

Level 4: Eyes closed, standing on unstable surface.

Dosage:

Repetitions: ______________________

Frequency: ______________________

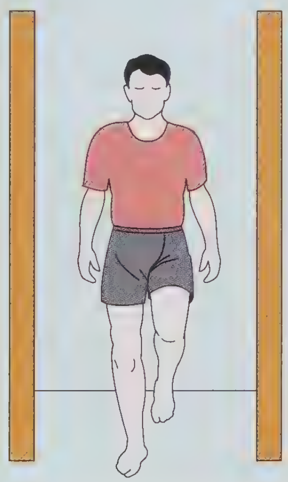

FIGURE 21-4 Resisted hip adduction retrains balance and proprioception on the weight-bearing limb. A chair or other stable surface must be available to ensure patient safety.

uninvolved ankle inside the circled elastic band. While balancing on the involved foot, the patient extends their hip against the elastic band. The patient performs extension–flexion oscillations before returning to double-limb support. The patient then turns 90 degrees and performs adduction–abduction oscillations into the band (**Fig. 21-4**). The rotating continues until the patient returns to the initial starting position. The exercise can be progressed by:

- Increasing oscillation repetitions or speed
- Moving the uninvolved limb through noncardinal planes
- Upgrading the tension of the elastic band
- Adding foam or a balance board with single-limb support.

The importance of removing the visual system during balance training cannot be overemphasized. Individuals with a history of multiple ankle sprains present with impaired postural control as a result of repeated trauma to articular and ligamentous joint receptors. These individuals must rely heavily on visual cues to maintain equilibrium during dynamic activities.[11] Forcing the somatosensory system to reorganize is only possible when it is trained independent of the visual system (see **Building Block 21-2**).

BUILDING BLOCK 21-2

How might balance programs differ for the following individuals:

1. A 21-year-old college basketball player recovering from a mild ankle sprain
2. A 75-year-old woman with osteopenia recovering from a fall

Muscle Performance

Resisted exercise is used to restore muscle performance because of muscle strain, neurologic deficit, or disuse. Although open chain exercise is useful to improve physiologic strength parameters and patient awareness of muscle function (i.e., muscle reeducation), it is critical to progress the exercise to functional weight-bearing activities as soon as tolerated. In many cases, closed chain activity can be broken into simple steps to serve as a starting point for exercise prescription.

Intrinsic Muscles

The intrinsic muscles of the foot contribute to the support of the medial longitudinal arch, and work with the plantar fascia, plantar ligaments, and extrinsic musculature to control the stresses on the foot during gait.[12]

Intrinsic muscle strengthening can be performed in a sitting position. The patient makes an arch with the tarsal and metatarsals by pressing the first metatarsophalangeal joint (MTP) into the floor while rolling the arch upward. The heel and first MTP must remain in contract with the ground. Repeat this process holding for 6 seconds (see **Fig. 21-5**). Using the toes to pick up marbles and other small objects exercises the intrinsic musculature, but also recruits the long toe flexors and other extrinsic musculature, which may not be a desirable cocontraction to facilitate. Additionally, these are low-intensity exercises and may require high repetitions to achieve a training effect. Maintenance of the longitudinal and transverse arches during closed chain exercises such as small knee bends, the walk stance position, stair-stepping, and gait use the intrinsic musculature in a functional manner (see **Self-Management 21-2**). The clinician observes patient performance carefully to prevent unwanted hammer or claw toe positions during functional training drills (see **Building Block 21-3**).

FIGURE 21-5 Intrinsic muscle strengthening of the foot.

SELF-MANAGEMENT 21-2
Squatting with Longitudinal Arch Control

Purpose: Increased strength of foot intrinsics and motor control of the lower extremity.

Position: Standing, bare feet, with the arch of your foot actively lifted up, without clawing of toes (**Fig. A**).

Movement Technique: While maintaining control of the arch of your foot, squat until your thighs are parallel to the ground, then return to the starting position (**Fig. B**).

BUILDING BLOCK 21-3

How might you instruct foot intrinsic strengthening so as to maximize appropriate form?

Extrinsic Muscles

The ankle musculature is vulnerable to neurologic weakness at the peripheral or nerve root level (see "Functional Nerve Disorders" later in this chapter). Careful examination and evaluation will diagnose the underlying etiology of the weakness. Optimal strengthening effects cannot be realized until neurologic sources of weakness are resolved.

Once it is determined that the musculature could benefit from progressive strengthening, open chain strengthening exercises for extrinsic musculature can be performed with elastic bands, tubing, or manual resistance. Muscles must be recruited in isolation before they can be strengthened in functional exercises to avoid substitution patterns. Care must be taken not to overload weak muscle groups, which may cause unwanted substitution patterns, abnormal joint shearing, and pain.

Strengthening the gastrocnemius and soleus can be performed in a long-sitting position with a towel roll under the talocrural joint providing heel clearance from the floor. Adding inversion will better isolate the tibialis posterior, whereas adding eversion will better isolate the peroneals. Strengthening of the tibialis anterior and toe extensors (**Fig. 21-6**) can be completed with an elastic band looped around a table leg or similar secure structure. The patient dorsiflexes against the resistance of the band, inverting slightly to isolate the tibialis anterior if desired. If this position may also be used to train pronation and supination (**Fig. 21-7**), the clinician should ensure the motion originates at the subtalar joint and not at the tibiofemoral or hip joint.

Resisted talocrural plantar flexion can be performed in a long-sitting position with the elastic band wrapped around the plantar surface of the forefoot. While holding the opposite end of the band, the patient plantar flexes against the resistance of the band (**Fig. 21-8**). A towel roll or small pillow placed under the leg proximal to the talocrural joint provides heel clearance from the floor. Resisted talocrural dorsiflexion (Fig. 21-6) and foot/ankle pronation and supination (Fig. 21-7) can be completed with an elastic band looped around a table leg or similar secure structure. The patient performs the intended movement against the resistance of the band. During these pronation and supination activities, the clinician should ensure the motion originates at the subtalar joint and not at the tibiofemoral or hip joint. A pulley and weight stack system can also be used for resistance.[9] For all extrinsic muscle strengthening activities, slow eccentric lengthening should be emphasized because of the deceleration function of these structures during gait. In the active population, it is common to see athletes perform a high volume of repetitions with various grades of exercise tubing, yet the musculature does not significantly fatigue.[9] For these individuals, manual resistance applied for 3 to 5 seconds (progressing to 6 to 10 seconds) for 10 to 12 repetitions may be a more appropriate challenge.

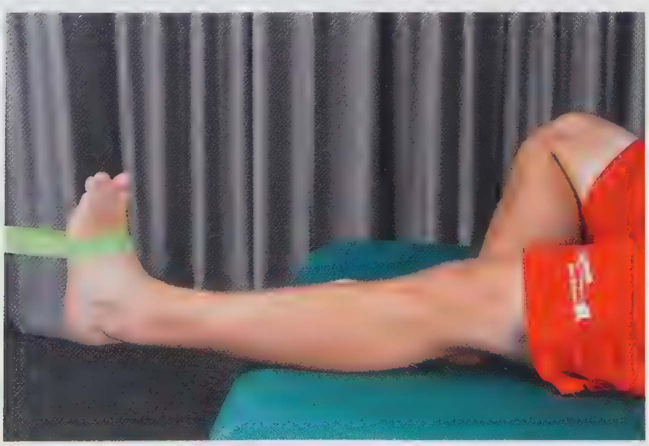

FIGURE 21-6 Talocrural dorsiflexion with a resistive band. A patient may require a high volume of repetitions to drive strength changes given the tibialis anterior's role during gait.

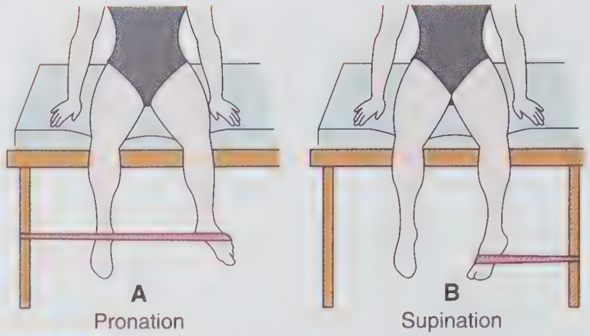

FIGURE 21-7 Resisted supination and pronation with the knee flexed. Flexing the knee minimizes hip rotation substitution. **(A)** Resisted pronation. **(B)** Resisted supination.

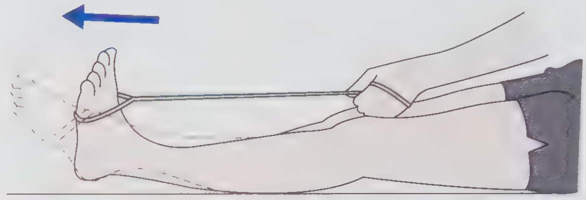

FIGURE 21-8 Resisted plantar flexion with a resistive band should emphasize plantar flexor-controlled eccentric dorsiflexion.

Closed chain, weight-bearing exercises are a natural progression toward functional activity recovery. Talocrural joint plantar flexors can be strengthened by performing double-leg toe stands off the end of a stair step with body weight equally distributed, with the emphasis on eccentrically controlling descent to end-range talocrural dorsiflexion without excessive pronation (**Fig. 21-9**). This is followed by concentric contraction to a neutral or slightly plantar-flexed position without excessive supination. The exercise is progressed by shifting weight toward the involved extremity and eventually performing a single-heel rise.

Dynamic ankle strengthening and stabilization can be performed in a sitting position with the knee at 90 degrees with the foot in contact with a small physioball (**Fig. 21-10**). This can be progressed to closed chain activities such as step-ups or lunges on a Both Sides Up (BOSU) device (**Fig. 21-11**). The latter exercises improve dynamic joint stabilization in a potentially safer context than with a wobble or balance board due to the wide and flat base of support of the BOSU device.[13]

Foot and ankle supinators can be strengthened by performing double-leg arch lifts. In a standing position, the patient is instructed to lift both arches, thereby rocking outward to the lateral portion of the feet. The clinician should ensure the patient's first MTP joint remains in contact with the floor in order to optimize the peroneus longus' action of stabilizing the first ray. Slow, controlled lowering to a neutral position is emphasized. Exercise intensity is increased by progressing body

FIGURE 21-9 A standing toe raise will strengthen a number of muscles throughout the foot and ankle as medial, lateral, and intrinsic muscles stabilize the foot and ankle while the gastrocnemius and soleus muscles plantar flex the ankle.

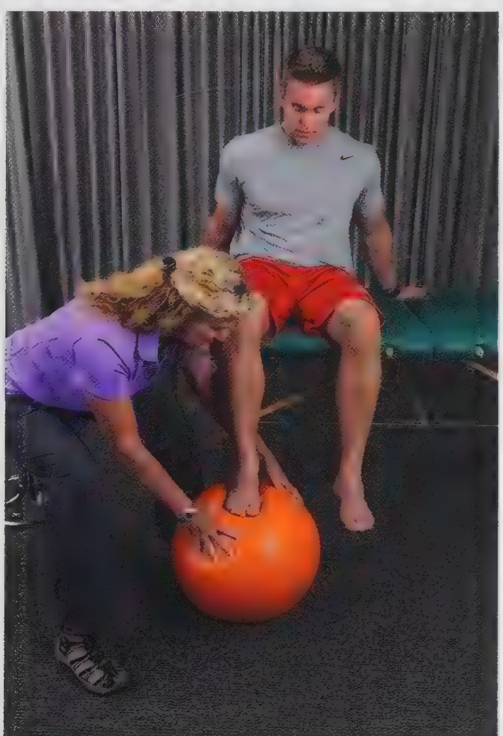

FIGURE 21-10 The therapist provides perturbations to the physioball while the patient maintains a neutral position of the knee and foot. To increase difficulty, start with predicted patterns and move to unpredicted patterns or close the eyes for an additional challenge with perturbations.

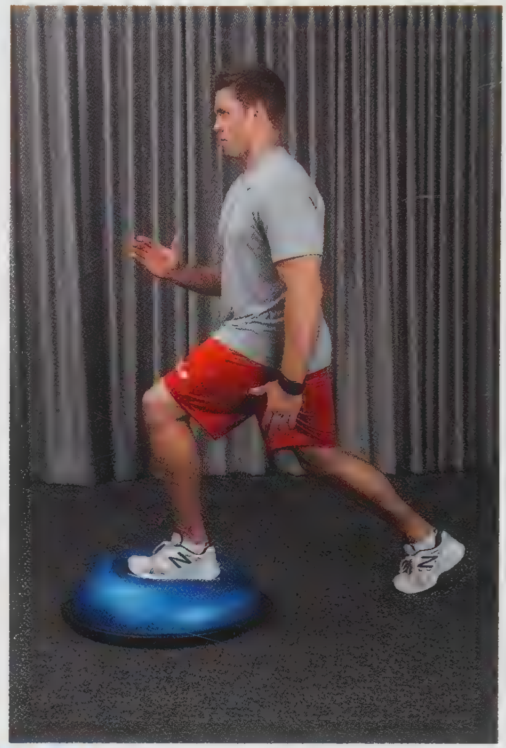

FIGURE 21-11 BOSU ball lunge. This device provides stability challenges to the ankle in a safe context when the flat side faces the floor.

weight toward the involved extremity and varying the stability of the standing surface.

Pain

Prescription of appropriate exercise intensity is key when addressing pain. The severity, irritability, and nature of the patient's pain must be assessed and considered when developing and progressing exercise. For example, exercise for the involved joint should be initiated in the pain-free range during the acute stage, just up to the painful range in the subacute stage, and slightly into the painful range in the chronic stage. Active-assisted exercise may be required if the patient demonstrates poor active control. Exercise for the involved limb's hip and knee may be indicated to prevent disuse weakness, improve proximal control, and decrease pain. In many situations, stationary biking is tolerated well and can maintain or improve cardiovascular and musculoskeletal health. Soft-tissue mobilization, taping and wrapping, thermotherapy, electrical stimulation, and a variety of other therapeutic modalities may be beneficial in conjunction with exercise for the control of pain and swelling.

Treating pain requires the clinician to determine its biomechanical cause. This chapter provides the reader with the theoretical framework and sample exercise options to diagnose and treat the underlying cause of pain.

Posture and Movement Impairment

Posture and movement impairments are often treated simultaneously with the foot and ankle. Ideal alignment and movement should be emphasized with all interventions, regardless of which impairments are addressed.

The most common faulty movement patterns affecting the ankle and foot complex are excessive pronation and supination and should not be reinforced in prescribed exercise (see **Patient-Related Instruction 21-1**). The impairments responsible for excessive pronation (e.g., short gastrocnemius, stiff talocrural joint, forefoot varus, weak posterior tibialis) or supination (e.g., hypomobile first ray, hypomobile supinated talus post immobilization, ankle equinus) must be treated specifically and addressed during functional activity performance.

Numerous repetitions of exercise derived from gait components (e.g., walk stance, single-limb stance, step-through) should be employed frequently throughout the day to shape neuromuscular function and change a habitual faulty movement pattern (**Fig. 21-12**).

Functional exercise can begin early in the rehabilitation process with consideration of the nature of the injury. The aim of a functional exercise progression is to control a variety of motions into and out of a static position at varying speeds, to further reinforce ideal posture and movement habits. The program should also be consistent with the patient's activity level and functional goals. Trunk and lower extremity alignment, strength, mobility, and movement patterns must be assessed and treated during a functional exercise program.

Ambulating on a painful foot without an assistive device results in compensations and abnormal gait biomechanics, cumulatively stressing the lower extremities and trunk. These compensations can become habits that are difficult to alter.[14] Since gait is a primary functional goal, the patient is encouraged to use a four-point gait pattern with walker or two axillary crutches in conjunction with controlled partial weight bearing and a near-normal gait pattern (i.e., heel-to-toe pattern). External support is valuable when performing static and dynamic weight-shifting drills in preparation for full weight bearing. Static weight-shifting drills consist of progressively shifting weight toward the involved foot. A bathroom scale under each foot, indicating the relative proportion of weight bearing, can be used for objectivity, control, and motivation. Dynamic weight-shifting drills may include the patient's involved foot on the floor and the uninvolved extremity stepping forward and backward. This drill can increase weight-bearing tolerance, promote heel to toe weight transfer, and facilitate controlled talocrural dorsiflexion.

Patient-Related Instruction 21-1

Ideal Alignment During Walking

You should attain ideal alignment during walking. The most difficult phase to control is during the weight-bearing phase of the step. Place the heel, ball of the foot, and toes down on the floor as three distinct areas. The heel should hit slightly on the outside border without turning the entire foot out. The weight line should progress from the outside of the foot toward the big toe. Attempt to maintain the knee over the toes, with the foot progressing straight ahead and the long arch of the foot held upward. If these alignments are maintained throughout the weight-bearing period, the foot should feel stable for push off.

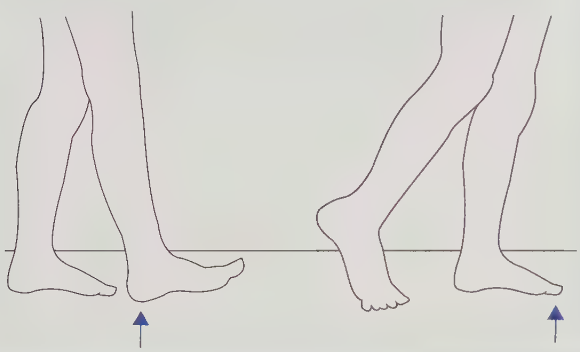

FIGURE 21-12 Walk-stance progression. Keeping the pelvis in neutral and minimizing rotation at the knee, the patient shifts their weight toward the front leg **(A)** and then flexes the back hip to 90 degrees **(B)**. The patient may balance here for as long as able before returning their flexed leg back to the start position.

Medial-lateral weight shifting can be facilitated through a circular weight-shifting drill. The patient uses an assistive device for balance and stands with weight equally distributed between their feet. The patient shifts their weight in a slow circular pattern beginning at the fifth metatarsal head. The patient then progresses posteriorly to the lateral heel, medially to the medial heel, and anteriorly to the first metatarsal head. The drill can be performed clockwise and counterclockwise and may be easier for the patient to perform with both lower extremities simultaneously. As weight-bearing tolerance improves, the drill can be progressed by increasing body weight toward a single-leg stance.

Functional exercises such as retrowalking, side-stepping, cross-over stepping, and resisted walking are also beneficial for upgrading the patient's level of function. These drills are progressed by distance, speed, and resistance through elastic tubing or a pulley and weight-stack system. Exercise must be progressed to higher levels of function (e.g., stair stepping, running, jumping, cutting, sidestep over cones, slideboard, clock step) that are appropriate for each patient's goals (see **Self-Management 21-3**). Jumping down may be a critical functional demand for athletes and persons returning to moderate- and high-intensity occupations. This task can be initiated bilaterally on a 2- to 4-in box.

Ideal alignment and movement patterns must be reinforced with each repetition of any drill. Orthotic prescription or counseling about proper footwear may be necessary to promote ideal function (see **Patient-Related Instruction 21-2**). If the patient requires a shoe to control excessive pronation, they may benefit from learning how to stress test potential footwear (**Display 21-1**).[15] However, exercise in bare feet may be appropriate during low- to mid-level activities to ensure foot muscle function enables ideal alignment and movement patterns instead of the orthotic or footwear. An exception is a severe anatomic impairment (e.g., significant forefoot varus), for which the use of a custom orthotic during all exercise is recommended.

ROM, Muscle Length, Joint Integrity, and Mobility

Pronation and supination involve all cardinal planes of movement: pronation incorporates dorsiflexion, abduction, and eversion, while supination incorporates plantarflexion, adduction, and inversion. The talocrural, subtalar, and midtarsal joints have triplane axes and therefore demonstrate triplane motion, meaning that they move in a coordinated fashion through three planes at once, to varying degrees. For example, the subtalar joint everts more than it abducts and dorsiflexes when pronating.

Passive and active-assisted ROM exercise for treatment of hypomobility should include consideration of triplane movement. When assessing accessory joint mobility or initiating joint mobilization techniques, the clinician should guide the joint through its major planes of movement (e.g., assessing subtalar joint eversion and abduction) to accurately determine the available motion.

Open chain active stretching can be progressed to closed chain passive stretching and eventually to utilization of the new mobility during functional movements. Any exercise should promote mobility of the hypomobile segment/plane while stabilizing the relatively more mobile regions in order to resolve the mobility impairment.

SELF-MANAGEMENT 21-3
Clock Step

Purpose: Improve dynamic stability, control, coordination, and proprioception of the lower extremity.

Position: Standing on involved lower extremity in the center of a circle with markers at each hour (i.e., like a clock).

Movement Technique: Single-leg squat with involved lower extremity while reaching out in a clock hour-type pattern with opposite lower extremity. Toe touch with the outstretched lower extremity. Do this in clockwise and counterclockwise directions.

Dosage:

Repetitions: ____________ times ____________ seconds

Frequency: ________________________________

First Ray Hypermobility

First ray hypermobility is defined as dorsal translation of the first metatarsal and medial cuneiform with a soft endpoint. The structures responsible for first ray stability are plantar ligaments, extrinsic muscles inserting onto the first ray, and the plantar aponeurosis. Any changes in these structures can lead to abnormal function and progressive deformity of the first ray. If deformity develops in the first ray, functional stability is often compromised.[16] For example, during the stance phase of gait, vertical ground reaction forces will excessively dorsiflex the first ray, transferring the load to the other metatarsals.[17] This may lead to acquired pes planus, metatarsalgia, and metatarsal stress fractures.

Patient-Related Instruction 21-2

Purchasing Footwear

Know your foot type. Your shoe size and width give a two-dimensional picture of your foot, but your foot is a three-dimensional object. Your foot's arch height affects the fit of your shoe. You can gauge your foot's arch height with a "wet test." Wet the soles of your feet, and then stand on a dry surface, such as a piece of cardboard, to leave an imprint of your foot. The imprint shows whether you have a flat (pronated), normal, or high-arched (supinated) foot. Match the bottoms of the shoes you are considering with your foot type.

Specific guidelines should be followed in addressing hypermobility impairments:

- In the acute phase, the hypermobile segment is protected from excessive motion by taping, bracing, casting, or use of more stable footwear.
- Adjacent hypomobile segments are mobilized with manual therapy or mobility exercise to prevent excessive motion from transferring to the hypermobile segment.
- Dynamic stabilization exercise should be initiated at the hypermobile segment while promoting controlled mobility at adjacent segments.

At the foot and ankle, dynamic stabilization exercise can include proprioceptive training (see the "Balance Impairment" section) and functional retraining (see the "Posture and Movement Impairment" section).

DISPLAY 21-1

Shoe Stress Tests

Individuals who demonstrate excessive pronation will benefit from motion-controlling footwear.

A

(A) Longitudinal stress. The toe break should occur where the patient's naturally does.

B

(B) Torsional stress. The shoe should "give" only minimally when twisted along the longitudinal axis.

C

(C) Heel counter pinch. There should be minimal to no "give."

Talocrural Joint

Talocrural joint dorsiflexion is a common limitation after injury or immobilization of the foot and ankle, resulting from a short or stiff gastrocnemius or soleus muscle, talocrural joint hypomobility, or both. Limited talocrural dorsiflexion can provoke anterior ankle discomfort during dorsiflexion. The clinician must rely on a careful examination to determine the source.

Gastrocnemius and soleus stretching are depicted in **Figure 21-13**. Carefully observe the patient during this activity to prevent excessive foot pronation to isolate dorsiflexion to the talocrural joint. If the patient is using the long-sitting position, the clinician must ensure proper patient positioning by preventing posterior pelvic tilt and lumbar flexion due to stiff or short hamstrings. A cushion under the pelvis reduces tension in the hamstrings and improves the patient's position (Fig. 21-13B). Talocrural joint dorsiflexion ROM can also be performed in a long-sitting position, but a pillow is placed under the knee to minimize the gastrocnemius and hamstring stretch. The soleus is stretched in this position if the talocrural joint has adequate dorsiflexion mobility (Fig. 21-13C).

The supine position is an alternative to the long-sitting position and can accommodate short hamstrings, maintaining more optimal lumbopelvic-hip alignment. It has the added benefit of stretching the hamstrings without overstretching the lumbar spine (**Evidence and Research 21-1**)

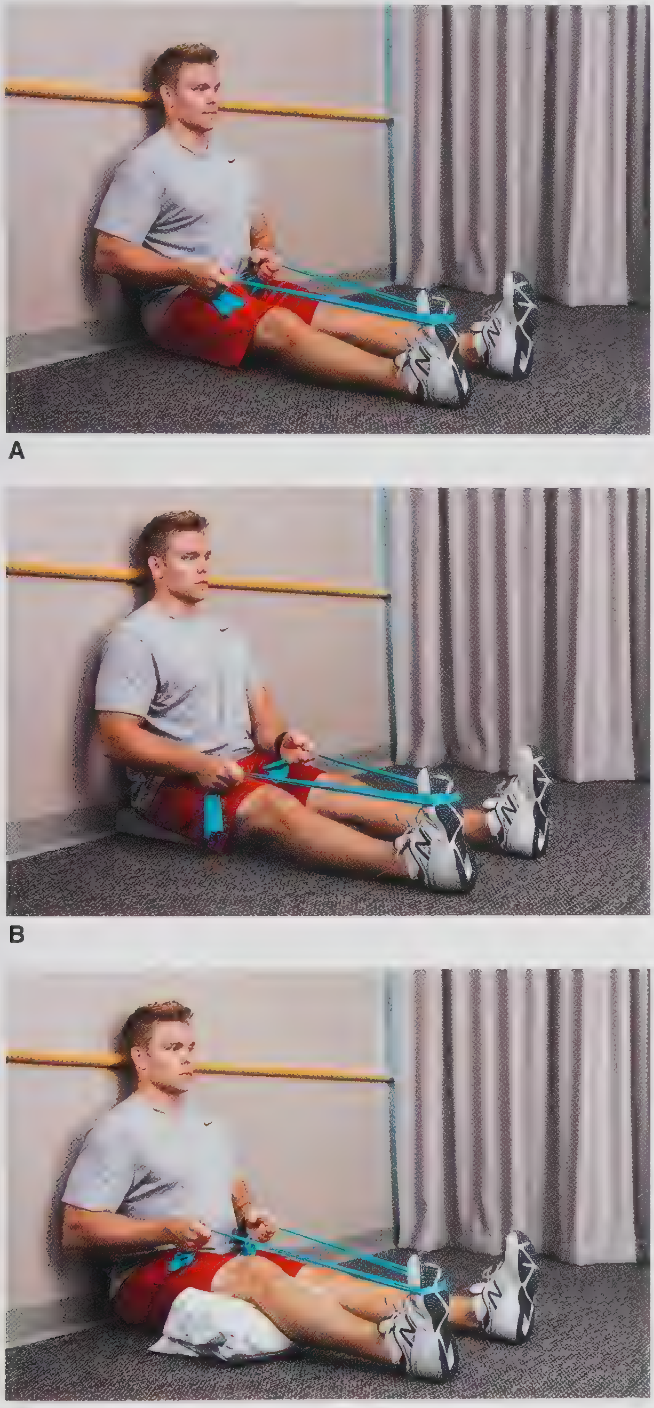

FIGURE 21-13 Increasing dorsiflexion mobility of the ankle. **(A)** Long-sitting gastrocnemius muscle stretch using a band or towel. **(B)** A cushion under the pelvis relieves some hamstring tension, allowing proper lumbopelvic posture. **(C)** Talocrural joint and soleus muscle stretching is emphasized by placing a pillow under the knees.

EVIDENCE and RESEARCH 21-1

Calf Stretching

Multiple studies find that a basic static stretching protocol is effective in not only increasing passive ankle dorsiflexion ROM[18,19] (acute effects, unilateral PF SS), but also reducing peak muscle force production and pre-activation, reducing jump height, and increasing postural sway[18-20] (PF stretch training, unilateral PF SS, acute effects). These effects resolved in approximately 10 minutes, indicating that static stretching may have an immediate effect on central nervous system inhibition[18,19] (unilateral PF SS, acute effects of unilateral PFs).

Despite the multiple effects of stretching on neuromuscular function, static stretching has no effect on injury prevention, and is not recommended in the absence of or in place of a proper warm-up[21] (update on ankle sprains).

Manual therapy techniques can be used to treat talocrural joint hypomobility. The patient can supplement in-clinic manual interventions with self-mobilization of the talus as part of their home program. The patient places the involved foot on a step and loops a stiff band or tubing around the anterior aspect of the ankle, securing the end under their other foot. The patient performs a set of lunges, with the band providing a posterior glide force on the anterior talus. The height of the step and stiffness of the band can be adjusted to improve patient comfort and increase the specificity of the mobilization. Alternately, the patient can loop the band around the back of the ankle on the tibia and place the other end of the loop around a table leg in front of them. The patient assumes a squat (either double or singe leg) position. As the patient performs a squat, the band will pull the tibia anteriorly, which must occur with normal arthrokinematics.

Lower extremity biomechanics must be considered when progressing dorsiflexion ROM exercises to a weight-bearing position. If the subtalar joint is pronated in stance, talocrural joint or gastrocnemius stretching will increase the pronation forces in the rearfoot, midfoot, and/or forefoot. Stretching should be completed with the following watch points (**Fig. 21-14**):

- The patient stands at arm's length plus approximately 6 in away from the wall.
- The subtalar joint is actively stabilized in neutral or slight supination.
- The involved foot is positioned with its lateral border perpendicular or slightly toe-in to the wall to minimize subtalar pronation forces.

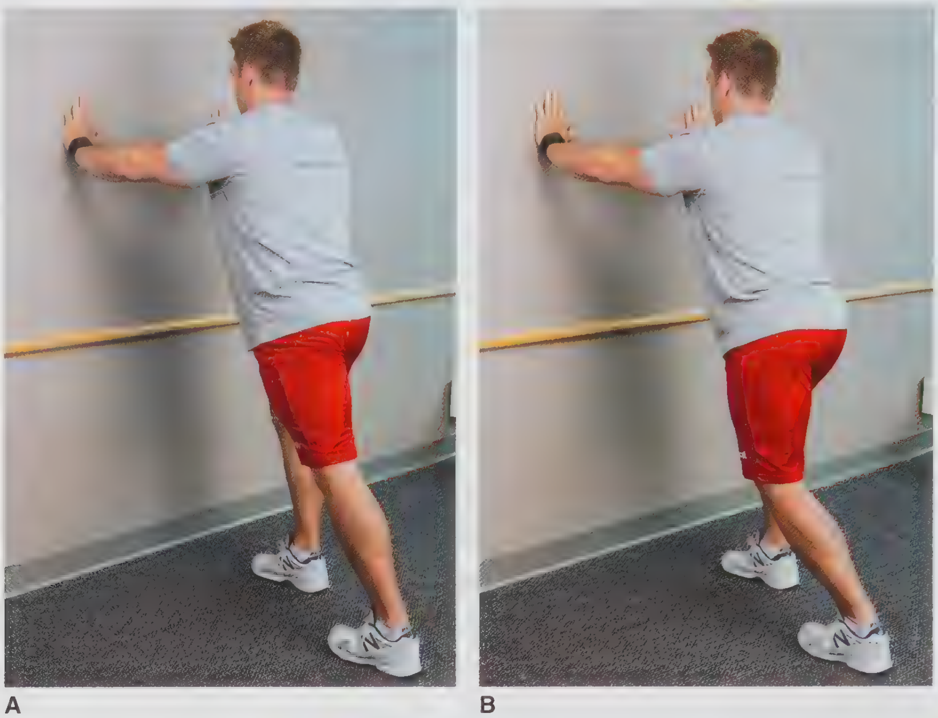

FIGURE 21-14 **(A)** The gastrocnemius muscle can be stretched by leaning against a wall. Be sure to instruct the patient to keep the foot in the sagittal plane. Any turn-out of the foot will contribute to pronatory forces. **(B)** The soleus muscle can be stretched with the knee slightly flexed. Again, instruct the patient to keep the foot in the sagittal plane.

- A small hand towel folded under the medial longitudinal arch may help support the subtalar and midtarsal joints.
- Keep knee extended to stretch the gastrocnemius; bend knee slightly to isolate the soleus.

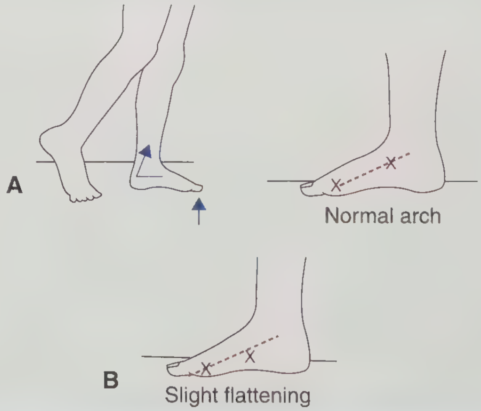
Active exercises should be incorporated into a patient's functional activities throughout the day. For example, small knee bends in standing with the arch stabilized may reinforce functional mobility of talocrural dorsiflexion instead of subtalar or midfoot pronation. Progressing small knee bends to a walk stance position reinforces gastrocnemius lengthening as the knee is in extension. The walk stance position can also be used to mobilize the hallux in order to ensure appropriate extension at terminal stance. Therapeutic exercise progression must incorporate functional retraining of newly gained mobility during swing phase and during late midstance of gait, when maximal dorsiflexion is required. As previously stated, the patient must maintain a subtalar neutral position and avoid a toe-out position with all activities (see **Patient-Related Instruction 21-3**).

Step-down training can facilitate controlled eccentric lengthening of the calf muscle group and of the knee and hip extensors. A patient stands on a 2- or 4-inch box and is instructed to maintain heel contact of the involved side while lowering the uninvolved heel to the floor (**Fig. 21-15**). This exercise may be progressed by increasing the step height, speed, and/or direction of movement of the uninvolved limb.

Patient-Related Instruction 21-3

Ankle Mobility and Walking Patterns

To restore the most ideal walking pattern, you must have adequate ankle mobility. You will be asked to perform a specific exercise or series of exercises frequently throughout the day to improve your ankle mobility. The pictures show what your walking pattern should look like. Halfway through the step, you need the most ankle mobility. Be sure that your foot remains pointed forward and does not toe-out (**Fig. A**). Be sure that you do not allow your arch to flatten (**Fig. B**).



Subtalar Joint

Subtalar joint supination mobility can be addressed with the patient sitting with the involved distal leg placed on the opposite knee. Full active supination is performed, followed by the patient using their hands to progressively pull the calcaneus and foot into greater supination (**Fig. 21-16A**). If combined with dorsiflexion, this exercise also stretches the peroneal musculature. Subtalar joint pronation mobility can be completed in a similar position by the patient actively pronating and applying graded overpressure (Fig. 21-16B). If combined with dorsiflexion, this exercise also stretches the tibialis posterior muscle. Therapeutic exercise progressions should involve functional retraining of the new pronation and supination mobility during the appropriate phase of the gait cycle.

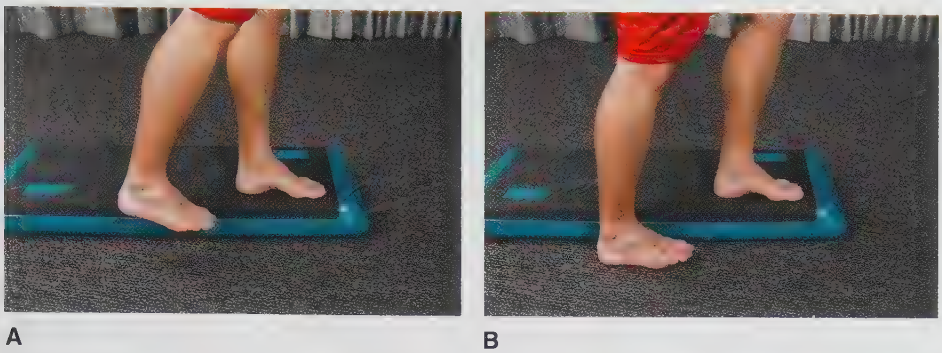


FIGURE 21-15 The medial longitudinal arch is actively lifted and stabilized **(A)** and is sustained as the opposite foot is lowered to the floor **(B)**.

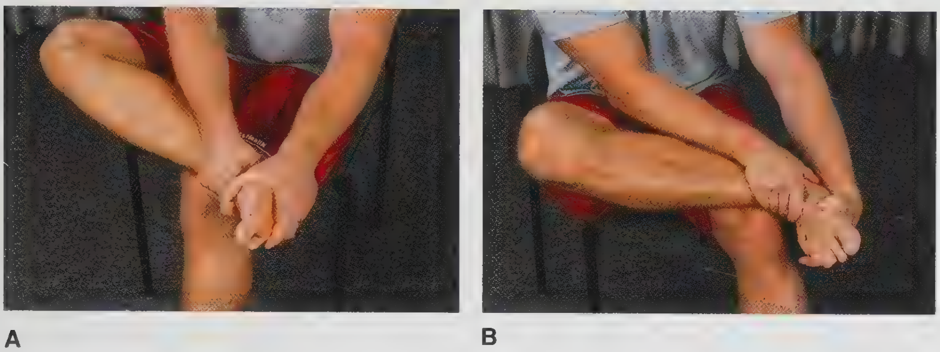

FIGURE 21-16 Passive stretching for triplane motion of the foot. **(A)** Subtalar joint supination. **(B)** Subtalar joint pronation.

Swelling

Swelling is often the result of impaired joint or soft tissue integrity. As the ankle is the most dependent weight-bearing joint in the body, swelling can become a chronic problem. Early intervention is critical to efficiently treat this impairment. Low-level dynamic exercise and compression in conjunction with frequent elevation can be effective for control of swelling. Emphasis is placed on high-repetition, low-intensity dynamic exercise for adjacent noninjured joints. For example, a patient with swelling at the rearfoot and pain with subtalar joint supination may be instructed how to perform elevated active toe flexion and extension as well as midrange talocrural joint plantar flexion and dorsiflexion (see **Self-Management 21-4**). High-repetition exercise can be prescribed as multiple repetitions at one sitting, but it is probably more effective if prescribed as moderate repetitions completed frequently throughout the day (e.g., every 2 hours).

SELF-MANAGEMENT 21-4
Toe and Ankle Active ROM

Purpose: Increased mobility in the foot and ankle after an injury

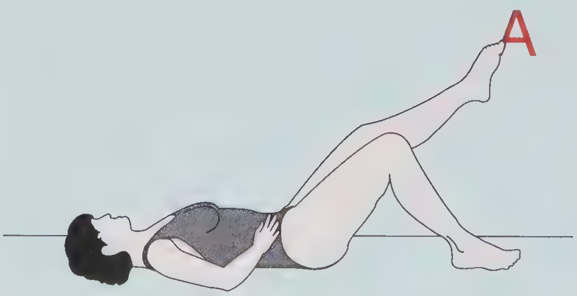
Position: Lying on your back with your foot elevated above chest level

Movement Technique: Repeatedly flex and extend your toes. Move your ankle up and down or write the alphabet with your ankle

Dosage:

Repetitions: ____________________

Frequency: ____________________



THERAPEUTIC EXERCISE INTERVENTION FOR COMMON ANKLE AND FOOT DIAGNOSES

Although therapeutic exercise prescription should be based on the impairments, activity limitations, and participation restrictions of each patient, certain impairments are commonly associated with specific diagnoses. Though this section is not exhaustive, it addresses the most common conditions encountered. The problems fall into the broad categories of connective tissue disorders (ligament sprains and ankle instability), fractures, functional nerve disorders, localized inflammation (e.g., heel pain/plantar fasciitis, posterior tibialis tendinitis/tendinopathy, medial tibial stress syndrome (MTSS), and Achilles tendinosis), and postsurgical rehabilitation (Achilles tendon repair and total ankle arthroplasty [TAA]).

Ligament Sprains

Ligament sprains are the most common sports-related injuries to the foot and ankle.[22–25] Between 70% and 80% of the sprains involve the anterior talofibular ligament (ATFL), calcaneal fibular ligament (CFL), or posterior talofibular ligament (PTFL).[8,26–28] Ligaments of the midfoot, including the dorsal calcaneal cuboid and the bifurcate ligament, may also be involved. The mechanism of injury is usually an inversion and plantar flexion twist. Isolated injuries of the ATFL constitute 65% of ankle sprains, and a combination injury involving the ATFL and CFL comprise 20% of the cases. Isolated injury of the CFL or PTFL is rare.

Ligament sprains are generally classified as one of three grades:

- Grade I: minor tearing with no functional loss of ankle stability.
- Grade II: partial tearing of the ligament with moderate instability.
- Grade III: complete rupture with significant functional instability.

Grade III sprains are further classified by degrees of injury. First-degree lateral sprains suggest complete rupture of the ATFL. A second-degree sprain is a complete rupture of the ATFL and CFL. A third-degree sprain suggests a dislocation in which the ATFL, CFL, and PTFL are ruptured.[29]

The patient can usually recall the mechanism of injury and note a specific site of pain and tenderness. Local edema is often observable. Ecchymosis may occur, indicating injury to blood vessels in the area. Stability testing of the affected ligaments may produce guarding, pain, and excessive mobility.

Syndesmosis sprains involve a disruption of the distal tibiofemoral ligaments and can occur in up to 24% of ankle injuries. This results in a diastasis, or widening, of the mortise at the talocrural joint. The mechanism of injury is external rotation on a fixed foot or extreme dorsiflexion. These mechanisms force the talus into the mortise formed by the tibia and fibula, widening this space and disrupting the distal tibiofibular ligaments; this can worsen and lead to degenerative joint changes. Clinically, reports of pain out of proportion to the injury has the highest sensitivity for diagnostic accuracy, but weight-bearing radiographs may be necessary to assess the integrity of the tibiofibular joint with a suspected syndesmosis sprain. If missed on initial evaluation, the patient may subsequently complain of posterior ankle pain, particularly when trying to push off of the involved ankle, or anterior pain when the foot and ankle are loaded.

Healing of a ligament sprain, as with soft-tissue injuries, follows a process of inflammation, repair, and remodeling. These events are sequential but each phase overlaps another, and the duration of the phases can vary individually. Optimal healing occurs with the introduction of phase-appropriate exercise and functional activity. Controlled stress promotes healing and results in a stronger repair, but excessive loading can interrupt healing and prolong the inflammatory process. The time needed for healing depends on the grade of injury, and clinical decisions should be based on signs, symptoms, and functional assessments.[29]

The initial treatment goals should focus on controlling the pain and swelling associated with inflammation. Early weight bearing,[30] ankle stability, and movement coordination impairments[4] is encouraged. Grade II sprains may require the use of axillary crutches for additional protection during ambulation (**Evidence and Researches 21-2** and **21-3**).

EVIDENCE and RESEARCH 21-2

Cryotherapy

Traditional treatment recommendations for grade I and II lateral ankle sprains during the first 1 to 4 days include rest, ice, compression, and elevation (RICE).[31,32] Cryotherapy may enable early rehabilitation due to pain control, but at present most of the rationale for using RICE or individual components is based largely on low-quality clinical trials and laboratory studies with uninjured participants or animal models.[33] Icing may actually delay tissue healing due to its effect on local vasculature.[34]

Insufficient evidence is available to determine the relative effectiveness of cryotherapy for acute ankle sprains in adults.[32,35] While superficial heating appears to positively affect muscle pain and stiffness in the acute phase of healing, no high power evidence exists for heat either.[31] Treatment decisions must be therefore made on an individual basis, carefully weighing the relative benefits and risks of each option, and based on expert opinions and national guidelines.[35]

EVIDENCE and RESEARCH 21-3

External Ankle Supports

External support in the form of wrapping, taping, or bracing promotes proprioceptive sense recovery and reduces the risk of repetitive injuries.[36] Support selection should be based on injury severity, phase of healing, and pain.[37] The most effective supports are semirigid and protect against reinjury but that allow dorsiflexion and plantarflexion.[36,38,39]

Early passive manual interventions are utilized to promote lymphatic drainage, improve anterior-to posterior talus arthrokinematics, and enable pain-free foot mobility. Mobilization at the beginning of the talocrural joint's physiologic range (i.e., grade I/II, ceasing the force before the onset of tissue resistance) is an effective treatment for improving pain-free ROM and gait variables such as step length symmetry and stride speed.[40] These gains may occur though the physiologic modulation of pain and mechanical alteration of tissues.

Midrange active dorsiflexion and plantar flexion ROM exercises are also initiated early, with care not to elongate the injured ligament. Achilles tendon stretching should commence within 48 to 72 hours of injury regardless of weight-bearing capacity, given its tendency to contract after trauma.[9] .

Progress exercise as pain and swelling are controlled and weight-bearing tolerance increases. Open chain inversion ROM is progressed as tolerated, but dorsiflexion ROM and calf flexibility can be performed more aggressively. Weight-shifting drills performed with full or partial weight bearing and with an external support help to maintain muscle tone and promote balance reactions (see **Self-Managements 21-5** and **21-6**). Proprioception boards are helpful, but exercise must be controlled to prevent interruption of tissue repair. Toe raises-off

SELF-MANAGEMENT 21-5
Dynamic Weight Shifting

Purpose: Promotes return to weight bearing and proper heel-toe weight transfer during walking

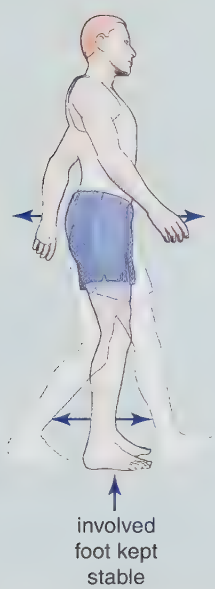
Position: Standing in a stride position

Movement Technique:
1. Step forward with ___ (uninvolved) leg, keeping ___ (involved) leg stable on the ground
2. Step back again with ___ (uninvolved) leg, keeping (involved) stable on the ground

Dosage:

Repetitions: ______________________________

Frequency: ______________________________



SELF-MANAGEMENT 21-6
Medial/Lateral Weight Shifting

Purpose: Improve control and coordination of standing balance, and prepare for dynamic activities

Position: Standing, using a supportive surface or assistive device if necessary

Level 1: Standing on two legs

Level 2: Standing on one leg

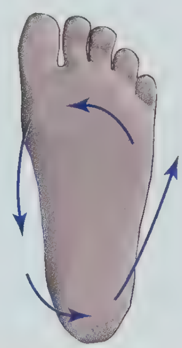
Level 3: Remove support/assistive device

Movement Technique: Shift weight in a slow, circular pattern around the perimeter of the foot. Do this in clockwise and counterclockwise directions

Dosage:

Repetitions: ____________ times ____________ seconds

Frequency: ______________________________



of a step maintains strength and flexibility of the calf. Trunk, hip, and knee exercises are helpful in preventing the effects of inactivity as well as promoting proximal control. The hip musculature is vital in maintaining ankle control, influencing foot placement and equilibrium during dynamic activities.[41] The gluteus medius in particular is active through the loading response and midstance phases of gait and can control excessive ankle inversion force moments. Early strengthening of the hip abductor musculature, especially the gluteus medius, may promote improved exercise performance and help prevent recurrent ankle sprains (see **Building Block 21-4**).

BUILDING BLOCK 21-4

A patient comes to physical therapy with a grade II ankle sprain. Initially he has non–weight-bearing orders, progressing over 4 weeks to full weight bearing. How might you progress this patient?

The collagen remodeling process is underway 3 to 6 weeks after an injury. Restoration of proprioception and muscle performance are key treatment goals to prevent recurrent hypermobility impairments. Reinjury may occur during this phase because many patients have overconfidence of their ankle's function, so return to a high level of activity should be controlled. Running at slow speeds in straight lines must precede fast speeds and cutting. Slow running in a large figure-eight pattern can be progressed to faster speeds in a smaller figure-eight pattern. Other exercises include double-leg, progressing to single-leg hopping, resisted walking or running using a pulley weight or tubing, and agility exercises. Obstacle courses and agility ladders require minimal resources and can be progressed by speed, direction of movement, and negotiation of the obstacles.[42] Functional strengthening should challenge the entire lower limb to address muscular power as well as promote appropriate body mechanics; exercises may include squats, pushing or pulling weighted objects, stair or ladder climbing.[43] External support should be used during high-level activity for 6 to 8 weeks after injury; both taping and bracing are effective in stabilizing the foot and ankle during higher level activity.[44–48]

Immediate treatment of grade III sprains is debated. Some studies suggest that, in the short term, surgical treatments do not show any advantage over functional treatment for grade III sprains.[49] More recent research recommends initially immobilizing the ankle in a below-knee cast for approximately 10 days to control swelling and protect injured tissues.

The rehabilitation approach for grade III sprains, whether treated with surgical repair or immobilization, is similar to that for grade I and II sprains. A clinician should expect greater deficits in ROM, flexibility, balance, and muscle strength throughout the lower extremity. External supports are important until full strength and proprioception have been obtained.

Recurrent sprain or functional loss is usually related to insufficient recovery of proprioception and strength, with hypomobility related to abnormal scarring or hypermobility resulting from insufficient ligamentous healing. A patient with ankle dysfunction related to hypomobility usually demonstrates limitation and pain with inversion and plantar flexion stress testing. Cross-friction massage, joint mobilization, and mobility exercises are usually beneficial. Postural control may also be compromised with an overreliance on hip balance strategies in individuals with hypermobility.[11,50]

Syndesmosis sprains are treated more conservatively than lateral ankle sprains, with an average return to play time twice that of a grade III inversion injury. Talocrural dorsiflexion involves widening of the mortise, and if this movement is unchecked due to syndesmosis injury, early or excessive weight bearing could lead to excessive strain on the injured ligaments. As such, syndesmosis sprains are treated initially with cast immobilization for 4 to 6 weeks. An unstable and widened mortise is often treated with surgical fixation.

Rehabilitation is similar to that for medial or lateral ankle sprains (**Building Block 21-5**), though some authors recommend initially limiting external rotation and end range dorsiflexion to protect healing tissues. At present, there is little research to guide rehabilitation of syndesmosis sprains.

BUILDING BLOCK 21-5

A 30-year-old female comes to physical therapy 2 months after sustaining a grade II left ankle inversion sprain. Most of her symptoms have resolved without rehabilitation but she reports increased left foot and medial knee pain that increases when she runs more than half a mile. This patient's goal is to complete a half marathon in 6 months. Past medical history is significant for multiple left ankle sprains. She has not sought physical therapy until today.

In standing, she presents with an increased left rearfoot valgus angle, apparent left pes planus, and increased medial rotation of the left femur. Left dorsiflexion is stiff and limited but nonpainful. She ambulates and runs with her left lower extremity in lateral rotation and with excessive bilateral lateral trunk flexion. Single limb stance is limited to <10 seconds on each limb with eyes open. Her squat is limited to ½ a range and she demonstrates increased L hip medial rotation and adduction with the activity. Ankle ligamentous stress testing is positive for increased nonpainful gapping of her anterior talofibular and calcaneofibular ligaments.

1. What proximal impairments in body structures and function might you expect to see?
2. Given that this patient presents with multiple problems, what interventions might be most pertinent to address first?

Chronic Ankle Instability

Even with appropriate intervention and rehabilitation, a significant number of individuals may present with mechanical ankle laxity and report instability up to a year after their sprain.[51] An even greater number will sustain multiple sprains. Clinicians should be aware of characteristics that define chronic ankle instability, which include but are not limited to increased laxity, impaired dorsiflexion ROM, deficient leg and hip strength, diminished postural control, and impaired movement strategies (**Evidence and Research 21-4**).

EVIDENCE and RESEARCH 21-4

Proprioceptive Training for Chronic Ankle Instability

The available evidence recommends at least 6 weeks of balance and coordination training to reduce the risk of reinjury in cases of chronic ankle instability.[52,53] However, the literature also indicates that the risk of recurrent ankle injury between those with and without proprioceptive training is not statistically different.[54] Additionally, balance training on unstable surfaces does not affect ligamentous proprioceptive fibers, and should not be used solely for proprioceptive training.[55]

Ongoing use of bracing during activity appears to reduce the risk of reinjury, though the mechanism is thought to be mechanical restraint rather than proprioceptive influence.[56] Further research is needed to determine the best interventions to effectively reeducate ligamentous proprioception.

Recurrent sprains resulting from hypermobility that do not respond to conservative management may require long-term use of external supports or surgical repair.

Ankle Fractures

The talocrural region sustains the highest incidence of fractures in the lower extremity. Excessive talar external rotation, abduction, or adduction within the malleoli can result in shearing or avulsion fractures of the malleoli. Ligament sprains are frequently associated with malleolar fractures. Talocrural joint fractures are commonly classified by the position of the foot (pronated or supinated) and by the direction of force exerted on the malleoli by the talus. Symptoms are similar to those of ankle sprains, although more severe in nature. **Table 21-1** contains a description of common talocrural fractures using the Lauge-Hansen classification system.[57–59]

Treatment

The key element in the acute treatment of talocrural joint fractures is the restoration of tibiotalar anatomic alignment. Fractures can be treated with closed reduction or with open reduction and internal fixation (ORIF). Fibular fractures without loss of tibiotalar alignment are usually treated with closed reduction. Fractures of both malleoli or one malleolus with a ligament rupture usually result in malalignment and therefore require ORIF. Patients are usually immobilized in a plaster cast for 6 to 10 weeks after ORIF. The clinician should note that muscle profoundly atrophies during even short periods

TABLE 21-1

Lauge-Hansen Fracture Classification

FRACTURE MECHANISM	AFFECTED STRUCTURES
Supination Adduction: extreme lateral loading of foot)	Potential distal fibula avulsion, lateral collateral sprain, shearing fracture of distal medial malleolus with sufficient force.
Supination External Rotation: external rotation of the talus on a supinated foot	ATFL sprain, fracture of distal fibula. More extreme external rotation will lead to injury of the deltoid ligament and/or avulsion fracture of medial malleolus.
Pronated Abduction: excessive talus abduction on a pronated foot	Sprain/rupture of anterior/posterior tibiofibular ligaments with possible diastasis injury. Shear fracture of lateral malleolus at the joint line.
Pronated External Rotation: external rotation of the talus on a pronated foot	Avulsion fracture of medial malleolus, tearing of anterior talofibular ligament and fibular shaft fracture. Possible tibiofibular diastasis injury.

of immobilization with no known method of prevention.[60] At present there is insufficient high-quality evidence regarding functional outcomes, adverse effects, and cost-effectiveness to draw any conclusions regarding surgical or conservative treatment. Considering the severity of the injury and duration of immobilization is key when designing appropriate interventions.

The initial phase of rehabilitation should include instruction in elevation and active exercise of the noninjured joints. Edema massage, surgical scar mobilization, and modalities for edema reduction are beneficial. Talocrural accessory joint motion must be assessed and joint mobilization techniques initiated as indicated. Active ROM begins in midrange with low intensity and high repetition activity. Controlled, partial–weight-bearing ambulation with an assistive device (i.e., walker or axillary crutches) is often the preferred mode of mobility. Conversely, unprotected ambulation may increase pain and swelling at the foot and ankle and result in undue strain at the lumbopelvic region and opposite lower extremity. Early stationary biking provides a gentle exercise for both lower extremities. Patients are instructed to pedal with the heel and progress to pedaling with the forefoot.

As the cardinal signs of inflammation resolve, treatment emphasis should focus on aggressive ROM interventions, strengthening, and functional exercise. Involved knee and lumbopelvic-hip biomechanics should be assessed and treated. The key structural deficit seen in ankle fractures is usually lack of talocrural joint dorsiflexion. Common gait compensations for limited dorsiflexion include the following:

- Abduction and external rotation of the lower extremity
- Genu recurvatum
- Excessive subtalar joint pronation

Early use of heel lifts can help eliminate these compensations (see "Heel and Full Sole Lifts" section). As function normalizes, exercise is generally better tolerated, and progress accelerates. The goal is to remove the heel lifts as soon as ROM is improved to enable normal gait patterns. If trauma was extreme and the structural impairment is deemed permanent, heel lifts can be fabricated externally on the shoe for long-term use.

Excessive subtalar joint pronation as a compensation for limited talocrural joint dorsiflexion can lead to midfoot hypermobility and dysfunction. Foot orthotics may be indicated for the current condition and future foot health. Heel lifts in conjunction with foot orthotics are an adjunct to functional strengthening and proprioceptive training. These supportive devices should be considered early in the rehabilitation process and may be needed for long-term function; periodic reassessment of the patient's dynamic foot control and function is warranted throughout the rehabilitation process to ensure that any external supports are still indicated.

As the median age of the population increases, so does the incidence of ankle fractures among elderly adults.[61] The mechanism of injury is usually low-energy, such as a fall or stumble. It is very important for these individuals to recover function as fast as possible, since bone mineral density, proprioception, and muscle strength are already reduced because of the higher age and decreased activity.

Functional Nerve Disorders

Assessment of impairments associated with nerve dysfunction affecting muscles of the lower leg, ankle, and foot should always begin with screening of proximal entrapment sites. Paresis or paralysis of muscles innervated by the posterior tibial or common peroneal nerves can be the result of lumbar spine impairment. After the spine is excluded as the source of the nerve disorder, distal entrapment sites are ruled out.

Many nerve disorders are considered to be functional, which means that the nerve is compressed during functional activity. Nerves can be compressed by bony impingements, compartment syndromes, or as a result of joint hypermobility or instability. Occasionally, a nerve can be compressed in multiple locations. It is important to understand the anatomy and innervation patterns to diagnose and treat nerve disorders appropriately (see Review of Neurology in the online supplement to this text). Nerve compression or entrapment may resolve with shoe changes, orthotics, or alteration of impairments in alignment, mobility, and movement patterns through the application of therapeutic exercise. The following sections describe selected sites for injury, compression, or entrapment of the posterior tibial and common peroneal nerves and branches.

Tibial Nerve

The tibial nerve is injured less frequently than the common peroneal nerve because of its deep and protected position within the popliteal fossa. If a lesion or entrapment occurs in the popliteal fossa, all of the calf muscles and plantar muscles of the foot are affected. A complete lesion in the popliteal fossa results in a shuffling gait and difficulty raising the heel during propulsion because of ankle plantar flexion loss. The unopposed action of the muscles innervated by the common peroneal nerve can lead to a reduced concavity of the longitudinal arch of the foot (acquired pes planus) and clawing of the toes. Sensory loss occurs on the sole of the foot and the plantar surfaces of the toes. Painful disorders, such as causalgia (a form of complex regional pain syndrome), are common with incomplete or irritative lesions.

If entrapment is suspected, the muscles surrounding the popliteal fossa must be assessed for length. If the popliteus, plantaris, and gastrocnemius are short, the tibial nerve may be compressed. Appropriate stretching and changes in alignment and movement patterns that perpetuate muscle shortening may alleviate the pressure and reduce nerve compression.

A more common disorder affecting the tibial nerve is tarsal tunnel syndrome. The tarsal tunnel is a fibro-osseous tunnel formed by the flexor retinaculum, the medial wall of the calcaneus, the posterior portion of the talus, the distal tibia, and the medial malleolus. The tibial nerve travels through this tunnel and may be compressed behind the medial malleolus, under the retinacular ligament, or via a space-occupying lesion. Compression leads to an insidious onset of sensory impairment of the medial and lateral side of the sole of the foot and toes, progressing to muscle atrophy and weakness and of toe flexion, abduction, and adduction.[62,63] Other signs and symptoms include burning, tingling, numbness, pain in the medial portion of the ankle and or the plantar aspect of the foot, local tenderness posterior to the medial malleolus, and a positive Tinel sign. End range ankle dorsiflexion and eversion may reproduce symptoms.[64] These signs and symptoms should be present but often the complete constellation is not found.[65,66]

A hypermobile subtalar joint will stretch the posterior tibial nerve due to the prominence of the posteromedial talus. Intervention for compression or entrapment in this region should include treating the impairments associated with subtalar pronation. This may involve stretching a short gastrocnemius, strengthening a weak posterior tibialis, educating the patient regarding altered postural habits, and instruction in proper foot biomechanics during gait and other functional activities. In conjunction with exercise, the use of appropriate footwear with or without bracing or orthotics to control excessive pronation may be necessary for complete resolution of symptoms related to nerve compression. Patients who do not respond to physical therapy interventions may undergo surgical decompression of the tarsal tunnel with mobility activities initiated within the first 2 weeks postoperatively.[64]

Peroneal Nerve

The common peroneal nerve is the most commonly injured nerve in the lower limb, primarily because of its superficial position as it winds around the neck of the fibula. Injury causes paresis or paralysis of all the muscles supplied by the deep and superficial peroneal nerves. The result is a loss of dorsiflexion and eversion of the foot and extension of the toes, producing foot drop and a steppage gait. Recurrent ankle sprains may also result from peroneal weakness. An accompanying loss of sensation occurs in the anterior lower leg, dorsum of the foot, and adjacent sides of all toes. A thorough knowledge of anatomy, innervation patterns, and function of the affected muscles during gait is necessary to develop an appropriate exercise program during the stages of nerve recovery. Care must be taken to prevent fatigue of a muscle recovering from a nerve injury. External support (i.e., dorsiflexion assist splint) is usually necessary during the early phases of recovery, when the muscles are weakest.

The deep peroneal nerve may become entrapped distally under the extensor retinaculum, a condition known as anterior tarsal tunnel syndrome. Trauma often plays a role. Recurrent ankle sprains place the deep peroneal nerve on maximal stretch as the foot supinates. Tight-fitting shoes or ski boots have also been implicated. Compression of the deep peroneal nerve usually results in pain radiating into the first web space. The extensor digitorum brevis may be weak or atrophied.[67] Active maximal foot eversion and dorsiflexion with maximal metatarsophalangeal joint dorsiflexion is a helpful clinical test for increasing the sensitivity of the physical examination.[65]

When treating patients with anterior tarsal tunnel syndrome, ensure that nerve compression is not caused by poorly fitting footwear. If the ankle is hypermobile or unstable, associated impairments should be treated with appropriate therapeutic exercise, footwear, bracing, taping, or orthotics to reduce excessive strain on the deep peroneal nerve. Exercise may include peroneal strengthening combined with drills to train ankle proprioceptors and help prevent recurrent ankle sprains.

Plantar Fasciitis

The plantar fascia provides stability to the foot by supporting the longitudinal arch during the propulsion phase of gait by means of the windlass mechanism.[16,68–71] "Windlass" refers to the tightening of a cable or rope. In this model, the plantar fascia simulates a cable running between the calcaneus and the metatarsal heads. Hallux dorsiflexion (extension) during terminal stance of gait winds the plantar fascia around the metatarsal heads, shortening the distance of the "cable" and elevating the medial longitudinal arch.[72]

Plantar fasciitis may be more correctly termed fasciosis because of the chronicity of the condition and histological evidence of tissue degeneration rather than inflammation. Intrinsic risk factors for painful plantar fascia include reduced plantar flexion and intrinsic foot strength, reduced ankle dorsiflexion ROM, torsional malalignment of the lower extremity, age, obesity or sudden weight gain, and foot structure.

Plantar fasciitis is typically considered a chronic overload condition with excessive pronation as the most common cause. Excessive subtalar pronation, pes planus, and/or medially shifted weight-bearing forces impose strain on the plantar fascia where it arises from the medial calcaneal tuberosity on the anteromedial aspect of the heel. A common symptom is sharp pain at the medial aspect of the heel. Patients with plantar fasciitis may report increased heel pain with the first few steps in the morning or after prolonged rest periods, which improves with further ambulation.[73] The clinician may differentiate this pain from a stress fracture or nerve entrapment, as the latter conditions will continue to provoke pain with increased walking.[74] Dorsiflexion of the toes almost always exacerbates the patient's symptoms because of the windlass mechanism loads the fascial fibers.

Other plantar structures may be painful besides the plantar fascia and should be considered for differential diagnosis, including:

- Abductor hallucis, flexor digitorum brevis, or abductor digiti minimi muscles
- The long plantar ligament
- The nearby calcaneal bursae
- Compression or diabetic neuropathy.[73,75]

Treatment

Management of plantar fasciitis must be multifactorial, as no single intervention is effective for all patients. Broadly, treatment is classified into three categories: decreasing pain, reducing tensile tissue strain, and restoring muscle strength and controlled mobility to the involved limb.[75,76]

The primary goal of treatment of plantar fasciitis in the acute stage is pain control. Passive therapeutic interventions include the use of nonsteroidal anti-inflammatory medications,[77] steroid injection, iontophoresis,[78,79] phonophoresis, ultrasound, deep tissue massage, cryotherapy, and hydrotherapy.

Activity modification may provide symptomatic relief through active rest. For the running athlete, mileage reduction, alternate activities, footwear evaluation, work reduction, and shortened workouts should be considered. Low-resistance cycling and aquatic running are effective alternatives to running on land.

Mechanical methods of reducing strain on the plantar fascia include:

- Taping
- Footwear modification
- Night splints
- Foot orthoses

Circumferential or low-dye taping of the foot is usually beneficial as an initial intervention to unload the plantar fascia and reduce pain (see **Displays 21-2** and **21-3**). Shoe modification may include a medial heel wedge to limit pronation or changing lacing to provide control of midfoot.[76] Changing to shoes with a firm heel counter to control rearfoot motion may be beneficial.

Night splints can apply low loads over a long duration in order to prevent plantar flexion and stretch tissues during sleep. Using a night splint decreases recovery time when compared to standing gastrocnemius–soleus complex stretching.[80] Individuals with chronic (>6 months duration) plantar fascia pain may derive greater benefit from custom-fabricated versus prefabricated night splints.[73]

Abnormal intrinsic rearfoot and forefoot alignment must be assessed for potential orthotic therapy. Proper orthotic prescription with appropriate forefoot and rearfoot posting can support the plantar fascia without direct pressure on the soft tissue underneath the longitudinal arch. The research literature supports the use of economic prefabricated or over-the-counter orthoses over expensive custom orthotics.[81] A temporary custom orthosis may also effectively unload the plantar fascia to promote more optimal soft tissue remodeling and resolve symptoms. Care must be taken to assess the need for orthotics as a long-term solution to the problem.

In the subacute phase, progressive cross-friction massage and stretching of the plantar fascia helps prevent abnormal scar formation and is theorized to help promote a more normal

DISPLAY 21-2
Preparing the Foot for Adhesive Strapping

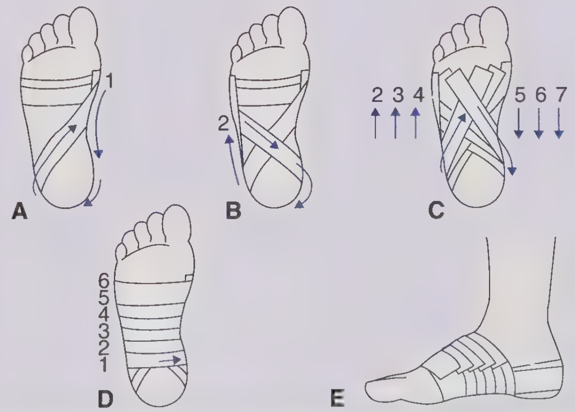
1. The foot must be clean and dry. Soap and water or alcohol wipes are used to remove perspiration and skin oils, which decrease the tape adherence to the skin.
2. Hair should be shaved to avoid irritation to hair follicles and the pain associated with pulling hair out during tape removal.
3. Skin should be sprayed with a skin preparation or "toughener" that improves tape adherence.
4. Thin foam prewrap used before taping helps protect the skin, but when maximal support is necessary, the tape should be applied directly to the skin. Prewrap has been used successfully when patients are limited to a medium or low activity level.

DISPLAY 21-3
Longitudinal Arch Strapping Technique

Tape: 1-in athletic tape

Taping Position: Patient is supine on the treatment table, with their foot over the edge, ankle dorsiflexed to neutral.

Taping Technique: Place two anchor strips circumferentially just proximal to the metatarsal heads (apply lightly). Begin the first diagonal strip of tape on the medial side of the foot, just proximal to the head of the first metatarsal. Angle the tape posteriorly around the heel, then crossing the plantar surface, and return medially near the origin of this strip (**Fig. A**). Place the second diagonal strip of tape on the lateral side of the foot, just proximal to the head of the fifth metatarsal. Tape under the foot, around the heel, and up the lateral side toward the origin of this strip (**Fig. B**). Continue alternating strips in the same pattern until the "fan" is filled in (**Fig. C**). Tie down the entire procedure by placing plantar strips over the previous strips by starting on the dorsolateral aspect of the foot; continue under the arch, and finish on the dorsomedial aspect of the foot. Leave a gap on the top of the foot; bridge this by placing short strips of tape across the gap (**Fig. D**) and (**Fig. E**). Each strip of tape should overlap the previous strip by approximately ¼-inch.



resting length. Mobilization of the plantar fascia has statistically the best long-term results (see **Self-Management 21-7**). If this stretch increases heel pain, the exercise may be modified to passive toe dorsiflexion in the non–weight-bearing position up to the painful range.[73]

Long-term resolution of symptoms of plantar fasciitis can only be achieved by addressing the physiologic and/or anatomic impairments directly affecting the biomechanics of the plantar fascia. If pronation is straining the plantar fascia, and a stiff talocrural joint and/or short gastrocnemius–soleus complex are contributing to the pronation, mobilization to the talocrural joint or stretching of the gastrocnemius–soleus complex is indicated. The clinician should note, however, that simply stretching the gastrocnemius has not been demonstrated to significantly decrease plantar pain.[82] In conjunction with mobilization and stretching, strengthening the tibialis anterior and extensor digitorum is critical to maintain and utilize dorsiflexion range during functional activities. If intrinsic muscle weakness is contributing to loss of longitudinal and transverse arch support, strengthening can be initiated to promote dynamic stability against excessive pronation. In addition, lower extremity alignment, muscle flexibility, muscle performance, and movement patterns must be assessed for extrinsic pronatory factors. Functional exercise and proprioceptive training should be initiated to reduce pronatory forces and improve talocrural dorsiflexion. The patient might practice step ups onto a 12 inches box with their involved limb, and practice controlling pronation through the foot as the ankle moves through its available dorsiflexion ROM. This could be progressed by increasing the speed or angle of step up, or increasing the hold time in single limb balance on the box.

SELF-MANAGEMENT 21-7
Plantar Fascia Step Mobilization

Purpose: Restore normal resting length of plantar fascia.

Position: Standing with the toes extended against the vertical part of a step and the heel on the floor.

Movement Technique: Slowly bend the knee above the toes you are stretching back. Keep your arch from rolling in.

Posterior Tibial Tendon Dysfunction

The tibialis posterior tendon is the primary dynamic stabilizer of the medial longitudinal arch.[83] During open chain mechanics, the tibialis posterior inverts and plantar flexes the foot, whereas during closed chain mechanics, it decelerates subtalar joint pronation in the loading response phase and supinates the subtalar joint in the midstance and terminal stance phases.[84] Its contraction serves to elevate the medial longitudinal arch, which "locks" (supinates) the midfoot and assists the foot converting to a rigid lever for propulsion. This action allows the gastrocnemius muscle to act with much greater efficiency during gait.[83]

The mechanism of posterior tibial tendon dysfunction is usually excessive subtalar joint pronation and results in acquired flatfoot deformity. However, the tendon can be strained because of poor physical condition, training errors, or by excessive physical activity. This dysfunction is most common in females who are obese, in their fifth and sixth decade of life, and lead sedentary lifestyles.[85] The least common mechanism of injury is an eversion ankle sprain. Symptoms are commonly located at the distal one-third of the medial tibia or inferior and posterior to the medial malleolus resulting from a zone of hypovascularity that correlates with the region of tendon pathology.[85] Typical symptoms include tenderness to palpation along the tendon, pain and/or weakness with resisted inversion and plantar flexion, and pain with closed chain pronation. Walking can become painful if accompanied by excessive pronation. Running, cutting, or jumping may also be impaired because of the posterior tibialis' role during the deceleration phase of these activities. The patient may note feeling increasingly unstable at the ankle, indicating altered proprioception, strength, and coordination.[85]

Treatment

As with plantar fasciitis, a primary goal of treatment in the acute phase is to control pain with appropriate medications and therapeutic modalities. Arch or navicular strapping is beneficial to control end-range pronation, thereby decreasing the strain on the tibialis posterior. Low-intensity, high-repetition, open chain plantar flexion and inversion exercises in a pain-free range should be initiated early in the rehabilitation process to control pain and promote tissue remodeling. In the subacute phase, resistance may be introduced to open chain strengthening, and closed chain strengthening exercises should commence as tolerated. For example, the patient can practice progressive weight transfer on the affected foot while actively stabilizing the medial longitudinal arch, preventing excessive pronation. This may be progressed to single leg balance. The strength of proximal musculature (hip abductors and hip extensors) is critical to absorb ground reaction forces in the early stance phase of gait; they should be assessed and reeducated as indicated to minimize distal pronatory forces in weight bearing. Given the tibialis posterior's role during gait, eccentric and concentric strengthening may yield positive results, though this has yet to be substantiated in the literature.[86] Assess intrinsic and extrinsic pronatory factors and use orthotic therapy and functional exercise as indicated for long-term resolution of symptoms.[87]

Short leg casting with non-weight bearing for 4 to 6 weeks may be necessary for patients with evidence of a partial tear, signified by delayed heel varus with toe raises and weakness.[85] Posterior tibial tendon dysfunction is resistant to conservative treatment and often involves surgery because of the progressive nature of the disorder.[85,88] However, at present there is no method to determine which patients will respond most favorably to conservative intervention and which will ultimately require surgery.

Medial Tibial Stress Syndrome

Although MTSS is one of the most common lower leg injuries sustained in sports, its mechanism remains unknown.[89] It likely involves a stress reaction by the crural fascia or bone along the posteromedial portion of the tibia most commonly associated with the insertion of the soleus.[90] Some authors have suggested that MTSS is a consequence of repetitive stress that fatigues the soleus and overloads the bone-remodeling capabilities of the tibia,[91] but histological studies are needed to confirm this theory. Proposed risk factors include increased pronation, forefoot varus, a positive navicular drop test, high body mass index, hard or inclined running surfaces, and inappropriate footwear. Training errors account for 60% of patients in the research literature. MTSS is one of the most common overuse injuries in the athletic population, especially females.

Patients may report a dull ache along the middle or distal posteromedial tibia which occurs with exercise.[3,90,91] Initially, the pain may occur at the beginning and end of activity; with continued training, the pain increases in severity and duration.[3,91] Positive physical findings include tenderness to palpation of the middle to distal tibia and pain with heel raises, resisted dorsiflexion, plantarflexion, and/or inversion.[91] Dorsiflexion ROM is not a significant contributor to symptoms. While stiff plantar flexors are a feature of this condition, this should be considered a consequence rather than a cause.

Prevention of MTSS is difficult as the causal factors remain unknown. Methods which show promise in the literature include use of shock-absorbent and pronation-control insoles and graduated running programs. Nonspecific strengthening exercises, stretching, sports compression stockings, low-energy laser treatment, and leg braces have not been shown to have an effect.[89] Some research suggests a relationship between dynamic thorax and hip stability and altered limb movements that are associated with MTSS development. Interventions to improve strength and coordination of the entire kinetic chain may yield more successful outcomes. Therapeutic exercise should focus on improving the strength and endurance of the soleus and other weak ankle invertors to resolve any imbalance with the evertors, as well as strengthening weak proximal musculature. Footwear or training alterations may also be necessary. For example, individuals who exercise daily should commit to at least 1 day per week to a form of cross-training that unloads the tibia and allows bone remodeling to occur, such as a pool workout.

Achilles Tendinosis

Despite its large cross-sectional area, the Achilles tendon is particularly susceptible to degeneration and injury approximately 2 to 6 cm above its insertion into the calcaneus due to a poor blood supply.[92] The blood supply decreases with age, increasing the risk of rupture.[93]

Degenerative pathology of the Achilles tendon is one of the more common tendon injuries of the lower extremity.[94–100] It is especially prevalent among persons participating in running and jumping sports, given the high ground reaction forces involved. The tendon functions eccentrically to control the heel as it lowers to the ground upon landing, as well as during the late midstance phase of gait to slow the advancing tibia. Strain is particularly high when walking or running uphill, when the tendon must slow the tibia eccentrically while propelling the body uphill concentrically, with the ankle in extreme dorsiflexion. Intrinsic factors contributing to injury include BMI, gastrocnemius–soleus and hamstring stiffness or shortening,[91] and forefoot varus.[101] Extrinsic factors include training errors, type and fit of footwear, and running surface.

Pain is elicited with loading and/or direct palpation to the tendon and crepitus may occur with active ankle motion.[91] Symptoms may increase with passive talocrural dorsiflexion as a result of Achilles tendon stretch; dorsiflexion ROM may also be diminished. There may be visible edema along the length of the Achilles, as well as tendon thickening secondary to increased collagen deposition.

Treatment of Achilles tendinosis should follow the guidelines in Chapter 11. Stretching of the gastrocnemius–soleus complex is essential to increase the length over which the tendon loads can be dispersed. Stretching is recommended only after talocrural joint mobility is restored; otherwise, excessive tension will be placed on the Achilles if talocrural motion is absent. Stretching should be performed with the knee straight to isolate the gastrocnemius, and with the knee bent to isolate the soleus, while maintaining a neutral foot position (see Fig. 21-14).

Strengthening exercises are an important intervention but should only be introduced following resolution of an acute pain episode or symptom flare to avoid exacerbating the patient's condition. If a patient is unable to tolerate weight-bearing activities, an aquatic-based intervention may be appropriate until symptoms decrease; this allows the patient to maintain cardiovascular health while exercising the Achilles in a safe environment.[102] See Chapter 16 for further details. The strengthening program is eventually progressed to eccentric activities such as controlled lowering from a plantar-flexed to dorsiflexed position. Use of a decline board may assist these exercises[101] (**Evidence and Research 21-5**).

EVIDENCE and RESEARCH 21-5

Eccentric Loading Programs for Achilles Tendinosis

Eccentric calf strengthening in patients with painful chronic Achilles tendinosis has previously resulted in significantly better outcomes when compared to concentric strengthening, though only 45% of patients respond favorably to this intervention.[95,103–105] Eccentric exercises may also decrease tendon thickening, possibly indicating a resolution of abnormal collagen deposition described earlier.[106] However, to date, there are no studies which have documented an improvement in tendon structure following a course of eccentric loading exercises.[107]

The speed and load should also be gradually increased to appropriately and progressively challenge this muscle group (see **Self-Management 21-8**), as forces of 2.5 times the body weight act on the tendon during normal gait.[101] Given the size of and functional demands on the Achilles tendon, the patient may likely experience a more favorable outcome with a mix of plyometrics and heavy load training if a goal is to improve tendon cross sectional area. Most Achilles loading recommendations specify the patient perform exercise repetitions to pain provocation, and the physical therapist can provide education to help appropriately manage patient expectations and promote program adherence.

SELF-MANAGEMENT 21-8
Hop-Down Drills

Purpose: Increased balance and coordination during dynamic movement, impact loading, and controlled lengthening of the Achilles

Position: Standing on a small step of about 4 in.

Movement Technique: Level 1: Hop down onto both feet, controlling the landing.

Level 2: Hop down, landing on a single leg.

Postoperative Management

Achilles Tendon Rupture

The typical patient sustaining an Achilles tendon rupture is a middle-aged male active in recreational or competitive athletic activities. Signs of chronic degeneration are observed in most ruptured tendons, although the majority of ruptures occur without any preexisting complaints.[108] At the time of rupture, the patient complains of feeling as if she or he had been kicked in the back of the leg, despite the fact that most ruptures are the result of noncontact injuries. A defect may be palpable and the Thompson test result is positive.

Achilles tendon ruptures may be treated conservatively with immobilization in a cast or cast boot for up to 12 weeks. The effects of immobilization and the extent of the damage to the Achilles tendon must be considered when planning interventions; prolonged immobilization will have deleterious effects on gastrocnemius–soleus length, strength, and size. ROM activities to restore the length of the gastrocnemius–soleus complex and the mobility of the talocrural joint are necessary.

Although Achilles tendon rupture is a relatively common injury, discussion continues regarding whether surgical or nonsurgical treatment is the best management.[109] Recent studies have suggested improved outcomes and superior strength in operatively treated patients, with a decreased rate of re-rupture compared to a nonoperatively managed cohort.

Early, active rehabilitation is associated with better outcomes after surgical repair. Rehabilitation activities should commence with non–weight-bearing plantar flexion and progress to closed chain and eccentric activities as similarly outlined for Achilles tendinosis. The ability to perform a single full range heel rise is correlated with a more rapid return to preinjury physical activity levels, whereas fear of movement is correlated with a worse outcome. Physical therapy is critical to improve muscle performance and reduce fear associated with activity so that the patient can achieve a positive outcome.

Total Ankle Arthroplasty

TAA is a relatively new procedure which still requires significant evidence regarding the best surgical technique, prosthesis, and rehabilitation strategy. The surgery was initially developed to provide an alternative to ankle fusion with the inherent advantage of preserving joint motion. However, early efforts failed to appropriately reproduce the triplanar motion of the talocrural joint and lead to excessive complications.[110] Newer generation prostheses have improved outcomes, though the median survival rate of the component parts is 90% at 10 years—much lower than for total hip or knee arthroplasty.[111,112] Surgical complications include prosthesis loosening, infection, bony nonunion or fracture, and persistent pain and stiffness.[110]

Despite these limitations, the popularity of TAA continues to grow. Individuals indicated for the procedure include those with a history of painful rheumatoid or osteoarthritis that limits ROM and functional mobility. In general, most patients who undergo TAA have a good outcome, with the main postsurgical difficulty of limited dorsiflexion[110] (**Evidence and Research 21-6**).

EVIDENCE and RESEARCH 21-6

Total Ankle Arthroplasty Versus Arthrodesis

While the stimulus for its development was in part dissatisfaction with ankle arthrodesis, the TAA procedure remains challenging due to the unique morphology of the ankle.[113,114] In the research literature, clinical outcomes of both procedures were very satisfactory after 5 years postoperatively,[115] though the complication rate for TAA is higher[116] and the revision rate is roughly twice than of arthrodesis.[116] TAA has potential to normalize gait mechanics more than fusion due to its preservation of ankle dorsiflexion,[117] but research finds no significant difference in sporting/recreational activities or functional outcome in patients who underwent either procedure for treatment of end stage ankle arthritis.[116,118]

As with other forms of joint replacement, treatment in the initial postoperative phase should focus on reducing inflammation with manual therapy, cryotherapy, compression, and patient use of an assistive device. Return to full weight bearing is primarily dependent on the surgeon's recommendations and patient tolerance. Stretching of the gastrocnemius–soleus complex is recommended, but talocrural dorsiflexion may primarily be limited by the replaced talocrural joint. A heel wedge may be appropriate to enable functional mobility and appropriate gait mechanics until full dorsiflexion is achieved, but the patient should be aware that they may not fully gain this motion under current technological limitations. Rehabilitation should progress to improving strength of the proximal, as well as extrinsic and intrinsic foot and ankle, musculature. Balance and equilibrium reactions should be retrained as outlined previously in this chapter.

ADJUNCTIVE INTERVENTIONS

A therapeutic exercise program for the ankle and foot can be enhanced with the use of supportive devices. Adhesive strapping, wedges and pads, biomechanical foot orthotics, and sole or heel lifts can help control excessive compensation and promote early return to functional activity. The supportive devices are an adjunct to a thorough exercise program and, if used independently, may be less successful. In many situations, the converse is also true.

Adhesive Strapping

The use of adhesive strapping is beneficial in stabilizing end range of joint motion or improving neuromuscular control. Athletic tape or Leukotape may be utilized, depending on the degree of control desired or the anticipated duration of wear. Strapping should improve the patient's symptoms, and if symptoms increase, the strapping should be removed immediately. Approach any taping with caution if the foot is swollen. The foot must be properly prepared before adhesive strapping is applied to enhance support and decrease the risk of skin irritation. Display 21-2 provides guidelines for preparing the foot for adhesive strapping. The patient must be instructed to remove the strapping slowly by pulling the tape backward on itself. Quick jerking movements and excessive skin distraction with tape removal could pull superficial skin layers off.

Longitudinal arch strapping is valuable when excessive pronation is deemed a primary stressor. The longitudinal arch strapping technique presented in Display 21-3 is designed to decrease soft-tissue strain caused by excessive subtalar joint pronation. Many additions and variations of supportive foot strapping can be explored, such as the navicular strap detailed in **Display 21-4**.

Wedges and Pads

Medial heel wedges, longitudinal arch pads, and metatarsal pads are placed in a shoe or on a flat insole to decrease soft-tissue strain. Medial or varus heel wedges are thicker medially and

DISPLAY 21-4

Navicular Strap Technique

Tape: 1½ inches athletic or Leukotape

Taping Position: Patient is supine on the treatment table in long or short sitting.

Taping Technique: If using Leukotape, begin with Cover Roll and finish with Leukotape. Apply athletic tape directly to skin. The foot should be in a neutral or slightly relaxed position. Apply tape over the lateral plantar surface of the foot or over the most lateral aspect of the dorsal surface of the foot and draw the tape medially (**Fig. A**). Gently pull the tape over the medial longitudinal arch, directly crossing the navicular tuberosity. Continue to wind the tape over the dorsal surface of the foot, crossing approximately over the anterior talocrural joint (**Fig. B**), and finishing over the posterolateral distal leg. This process may be repeated twice per foot/ankle to improve midfoot support.

A

B

taper laterally. They are made of firm rubber and used with the philosophy of controlling excessive calcaneal eversion, decreasing the degree of subtalar joint pronation. Longitudinal and metatarsal arch pads are made of felt or foam rubber. The metatarsal pad is placed directly proximal to the symptomatic metatarsal head. Medial wedges, longitudinal arch pads, and metatarsal pads are most successful when used in conjunction with adhesive strapping. Longitudinal arch and metatarsal pads can be taped on top of foot strapping for precise positioning. The medial wedge can be secured in a shoe with the use of double-faced tape.

If symptoms are relieved and performance is improved through adhesive strapping and supportive pads and the patient has exhausted all intrinsic solutions, a biomechanical orthotic may be indicated.

Biomechanical Foot Orthotics

It is beyond the scope of this text to provide a detailed description of orthotic evaluation and prescription. This section describes the purpose of orthotic devices, the general fabrication method, the concept of posting, and therapeutic exercise prescription to augment orthotic prescription.

A biomechanical foot orthotic is a device that attempts to control dysfunction by controlling the subtalar joint near its neutral position. **Display 21-5** describes the general purposes of a foot orthosis.[119] An orthotic with posting decreases the compensation caused by the individual's structural abnormality.

A foot orthotic is composed of a shell, which conforms to the contours of the foot, and posting material, which tilts the shell according to the angulation and degree of control desired.

The shell is fabricated from an impression of the foot taken while the subtalar joint is maintained in a non–weight-bearing neutral position. The shell encompasses the heel, fits closely to the arch, and ends immediately proximal to the metatarsal heads. The shell can be made of a variety of materials, ranging from a flexible foam to a semirigid thermoplastic. Generally, the more rigid shells are indicated for the foot requiring motion control. Flexible accommodative shells are used for arthritic conditions, diabetes, and the hypomobile foot. Body weight is also a deciding factor when choosing a shell's rigidity. A heavy individual may require a more rigid shell for more adequate motion control without rapid material breakdown.

Orthotic posting is prescribed from the findings of a biomechanical evaluation of the entire lower extremity. Posting material is added to the shell's undersurface to conform to the foot and ankle angles, as specified below:

- Rearfoot posting is placed under the heel of the shell
- Forefoot posting runs under the metatarsal area to the end of the shell
- Medial or varus posting for a subtalar, forefoot, or tibial varum abnormality
- Lateral or valgus posting for a subtalar, forefoot, or tibial valgum abnormality

In combination with proximal strengthening, foot and ankle exercises such as calf stretching, arch lifts, and single-leg standing balance drills can help prepare the foot before orthotic therapy, which requires a break-in period of 1 to 6 weeks. During the break-in period, the orthotics are worn intermittently, perhaps as little as 1 to 2 hours per day, with a 1-hour progression each day. The break-in period can be accelerated based on orthotic tolerance and nature of the injury. Open chain exercises established before orthotic wear should continue. Closed chain exercise in the orthotics should be progressed as tolerated. Initially, patients can be instructed to actively supinate off of the orthotic and slowly lower onto it. Static weight-shifting drills can be progressed to exercise involving higher ground reaction forces. Athletic activity should not begin until light activity is well tolerated.

Foot orthotics must be reassessed for wear and breakdown, as periodic refurbishment or upgrading may be necessary. During orthotic reassessment, the patient's foot and function should also be reexamined. Alignment resulting from anatomic impairments does not change, but the patient's ability to control their compensation may improve. Alignment resulting from physiologic impairments may change. Day-to-day orthotic wear and wear for various activities may be adjusted. The reassessment schedule varies with each individual, ranging from 1 week to 1 year after the break-in period.

DISPLAY 21-5
Purposes of a Foot Orthosis

1. To even the distribution of weight-bearing forces
2. To reduce joint strain
3. To control foot motion at the subtalar and midtarsal joints, including magnitude, end range, and rate
4. To balance intrinsic foot deformities if necessary

Heel and Full Sole Lifts

Heel lifts can be helpful in the treatment of foot and ankle dysfunctions related to limited motion of the talocrural joint. A lack of 10 degrees of talocrural joint dorsiflexion can result in compensatory subtalar joint pronation during midstance and propulsion. A heel lift places the talocrural joint in a few degrees of plantar flexion at midstance (**Fig. 21-17**). This increases the available range of dorsiflexion and decreases the abnormal compensation.

Heel lifts can be used in the acute phase to decrease strain on the Achilles tendon, talocrural joint, and subtalar joint. Early ambulation with less pain increases independent function and enhances the effects of an exercise program. The goal is to normalize the impairment and remove the heel lifts.

FIGURE 21-17 A heel lift is used to increase the range of dorsiflexion at midstance.

If a heel lift is necessary, the following information can guide the proper amount of lift to prescribe.

- A patient with 0 degrees dorsiflexion may require a ¾- to 1-inch heel lift. Less severe limitations can be treated with smaller lifts.
- A ¼- to ⅜-inch lift can be placed inside the shoe. The lift depends on shoe style and fit.
- All or some portion of the lift can be added to the sole of the shoe by a shoe repair service.
- A lift of the same height should be added to the uninvolved extremity to avoid creating a leg length discrepancy.

Heel lifts are commonly used for correction of leg length discrepancies, but should be isolated for use in equinus contractures or temporarily to relieve foot/ankle strain. Full sole lifts are more appropriate for the treatment of leg length discrepancies, because the heel is in contact with the ground for only a short period in the gait cycle. After the loading response phase is completed and the foot enters the midstance phase, the forefoot is in contact with the ground. If the lift is only in the heel, the foot functions as if it is descending a small step after the forefoot contacts the ground. The full sole lift eliminates this problem. However, the disadvantage of the full sole lift is that it can occupy excessive room within the shoe. Typically, if a lift beyond ⅛ in is recommended, it should be added to the outside of the shoe. The prescription of a sole lift should be considered carefully, because an apparent leg length discrepancy often is functional and not structural.

Please refer to Chapter 19 for a detailed description of functional versus structural leg length discrepancy. A functional leg length discrepancy often can be treated with therapeutic exercise intervention, focusing on alignment and movement impairments throughout the kinetic chain. The use of a lift for a functional leg length discrepancy can capture and reinforce the alignment impairment rather than resolve the impairment (**Selected Intervention 21-1**).

SELECTED INTERVENTION 21-1

For the Lower Quadrant

See Case Study No. 1.

Although this patient requires comprehensive intervention as described in previous chapters, only one exercise prescribed in the final stage of recovery is described.

ACTIVITY: Lunging ball drill

PURPOSE: Improve balance, proprioception, and agility

RISK FACTORS: 10 weeks after second-degree sprain of the right calcaneofibular ligament

SUBSYSTEMS OF THE MOVEMENT SYSTEM: Neural subsystem

STAGE OF MOTOR CONTROL: Skill

POSTURE: Standing in "ready" position with knees flexed

MOVEMENT: Step forward and lunge as ball is tossed toward you

SPECIAL CONSIDERATIONS: Be sure foot lands in a good position and that it is in good alignment with respect to the knee, hip, pelvis, and spine.

DOSAGE

Special Considerations

Anatomic: Calcaneofibular ligament

Physiologic: Late-stage recovery from grade II sprain

Learning Capability: Good body awareness and coordination, should be no trouble

Repetitions/sets: To form fatigue, pain, or 20 to 30 repetitions, up to three sets

Frequency: Every other day

Sequence: Following warm-up of light activity and stretching

Speed: Functional speed

Environment: Home with a partner

Feedback: Initially in clinic with mirror and verbal feedback, tapered to no mirror in home environment

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF SPECIFIC EXERCISE: Play basketball with same form

EXPLANATION OF CHOICE OF EXERCISE: Chosen as skill-level activity to prepare patient for return to basketball. Patient will require excellent balance, proprioception, and agility to return to basketball without recurrent ankle sprain. High repetitions of this exercise for 2 to 3 weeks should prepare patient for basketball without recurrent injury.

LAB ACTIVITIES

1. Perform resisted ankle dorsiflexion, plantar flexion, inversion, and eversion using a variety of resistive bands. Perform exercises in long-sitting and short-sitting positions and while standing on one leg. What are the most likely substitutions in each position?
2. Instruct a laboratory partner in correct lower extremity standing posture.
3. Perform the following exercises, maintaining subtalar neutral position and exaggerating pronation. Observe the differences in alignment throughout the lower extremity:
   a. Wall slide
   b. Single-leg wall slide
   c. Step down
   d. Standing on a minitramp
   e. Stair stepper, forward and backward
4. Consider the patient in Case Study No. 1 in Unit 7. Design a rehabilitation program for this athlete in the early, intermediate, and late phases. Instruct your patient in the exercise program, and have your patient perform all exercises.

KEY POINTS

- Common lower extremity anatomic impairments include subtalar varus, forefoot varus, and forefoot valgus.
- The foot and ankle examination must include a subjective history and evaluation of the weight-bearing and non–weight-bearing foot. Relationships of the lower extremity joints must be evaluated.

- Common physiologic impairments at the foot are mobility loss, loss of force or torque production, impaired posture and movement, pain, and impaired balance and coordination.
- The therapeutic exercise program must consider the kinetics and kinematics of the foot during gait, as well as consider proximal musculature length and performance to ensure appropriate coordination of mechanics throughout the kinetic chain.
- Adjunctive agents may be necessary to treat structural impairment or to prevent secondary problems associated with physiologic impairments.

CRITICAL THINKING QUESTIONS

1. Consider Case Study No. 1 in Unit 7. How would the treatment program differ if the patient was
   a. A competitive runner
   b. A landscaper walking on uneven surfaces
   c. An elderly individual who is a community walker
   d. A recreational golfer
2. Consider again Case Study No. 1 in Unit 7. The patient has progressed well with your interventions and demonstrates full ankle ROM and extrinsic muscle strength. However, her balance remains faulty. How would you modify your treatment to both address her balance and help her return to basketball? How would you progress the balance program as she improves?
3. Consider Case Study No. 9 in Unit 7. Theorize about potential relationships between this patient's plantar fasciitis, her thigh pain, and other symptoms. Describe a comprehensive treatment program for this individual.
4. Consider again Case Study No. 9 in Unit 7. The patient's thigh pain has improved moderately but has plateaued. Assuming her posture and hip muscle strength is improving and she is regularly performing her home program, what other factors might you consider addressing to drive further symptom resolution?

Functional Approach to Therapeutic Exercise for the Upper Extremities

UNIT 6

CHAPTER

22

The Temporomandibular Joint

LISA M. FLEXNER • DARLENE HERTLING

The temporomandibular joints (TMJs) connect the mandible to the cranium and are the only two moving joints in the head. They work together with the cranium, jaw, cervical spine, dental arches, muscles of mastication, teeth, tongue, and associated neurovascular tissues and are known as the stomatognathic system. The TMJs and proper functioning of the stomatognathic system are critical to basic functions such as eating and talking. The TMJ is a weight-bearing joint, with joint compression occurring every time the teeth come in contact. Temporomandibular joint dysfunction (TMD) affects between 5% and 12% of the population, with some studies suggesting that the number may be as high as 26%.[1–3] It is 1.5 times more likely to occur in women than in men, and onset occurs in younger adults (18 to 44 years old) more than in children or the elderly.[2,4,5] It may also be referred to as craniomandibular dysfunction or orofacial pain.

Understanding TMD depends on thorough examination and evaluation, determination and treatment of the source of symptoms, and addressing contributing factors to the condition. The source may be myogenous and extracapsular; arthrogenous and intracapsular; or referred from other structures.[6,7] Common sources of referred pain include mandibular fractures, trigeminal neuralgia, neoplasms, otologic sources, and cardiac issues. The underlying cause for myogenous and arthrogenous problems may be postural dysfunction in the cervical and thoracic spine, such as forward head posture (FHP) affecting occlusion of the teeth, or it may be due to parafunctional activities such as grinding of the teeth or gum chewing. Treatment of TMD should address the person as a whole, taking into account the musculoskeletal relationships, the performance of functional activities, and the influence of physical and emotional stress on this system. Understanding how the TMJ relates to the patient's body structure and function is key to treatment planning, decreasing the patient's pain, and improving their quality of life.

REVIEW OF ANATOMY AND KINESIOLOGY

This section contains a brief summary of the key structures and relevant kinesiology of the TMJ.

The Temporomandibular Joint Structures

The bones most commonly associated with the TMJ are the mandible and the temporal bone of the cranium, which articulate directly to create the joint. A biconcave fibrocartilage disk sits between the convex condylar process of the mandible (the floor of the joint) and the temporal bone (the roof). From anterior to posterior, the articular surfaces of the temporal bone are the articular tubercle, articular eminence, mandibular fossa, and posterior glenoid spine; the disk will articulate with different parts of the temporal bone as the jaw opens and closes. The disk divides the joint into two cavities, which compensates functionally for the incongruity of the two opposing joint surfaces and effectively creates two articular surfaces (**Fig. 22-1**). The joint is synovial, and both bony surfaces are covered with vascularized fibrocartilage, unlike the hyaline cartilage in most synovial joints.[8] This fibrocartilage structure allows for greater force attenuation and the possibility of repair and remodeling. The disk is also fibrocartilage; it consists of three portions with varying vascularity and innervation (**Fig. 22-2**).

The ligamentous structure of the joint capsule is thin and loose, which allows for great mobility but sacrifices stability. The capsule is attached to the disk anteriorly and posteriorly, but not on the sides. This allows the disk to translate anteriorly and promotes greater mouth opening. A posterior ligament attaches

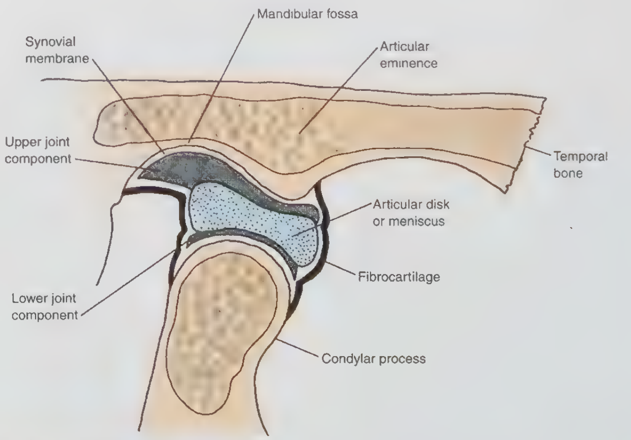

FIGURE 22-1 Articular structures of the TMJ in the closed position.

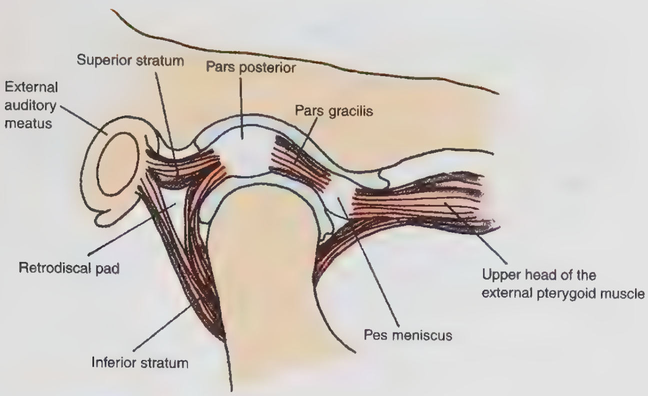

FIGURE 22-2 Sagittal section of the TMJ. The lateral pterygoid inserts into the mandibular condyle and the disk. The disk has three parts: (1) a thick anterior band (pes meniscus), (2) a thicker posterior band (pars posterior), and (3) a thin intermediate zone (pars gracilis) between the two bands.

the disk to the posterior aspect of the neck of the mandible, the bilaminar zone, and the posterior portion of the TMJ.[8–14] This ligament restricts anterior translation of the disk during mouth opening.

The innervated tissues of the TMJ are supplied by divisions of the trigeminal nerve (cranial nerve V), which also innervates the middle ear muscles. The auriculotemporal nerve is the major nerve innervating the capsular blood vessels, the retrodiskal pad, the posterolateral capsule, and the TMJ ligament of the TMJ. These tissues have an abundant supply of type IV articular pain receptors. Because branches of the auriculotemporal nerve supply the tragus, external acoustic meatus, and tympanic membrane, TMD is often associated with hearing problems, tinnitus, and vertigo. Buergers et al.[15] found that prevalence of tinnitus is eight times greater in those with TMD, and occurs ipsilaterally. The tensor tympani and tensor palati muscles may provide a musculoskeletal etiology for these auditory and vestibular issues, due to their shared innervation and proximity to the TMJ. Ren and Isberg[16] found a strong correlation between unilateral tinnitus and an ipsilateral anteriorly displaced disk in the TMJ.

Movement of the joint is guided by five key muscles on each side: the masseter (**Fig. 22-3**) and temporalis (**Fig. 22-4**) elevate the mandible; the digastric (**Fig. 22-5**) depresses the

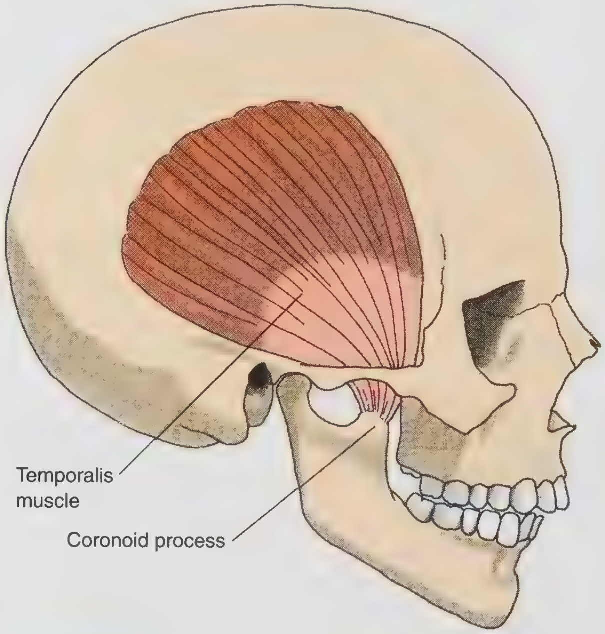

FIGURE 22-4 Temporalis muscle.

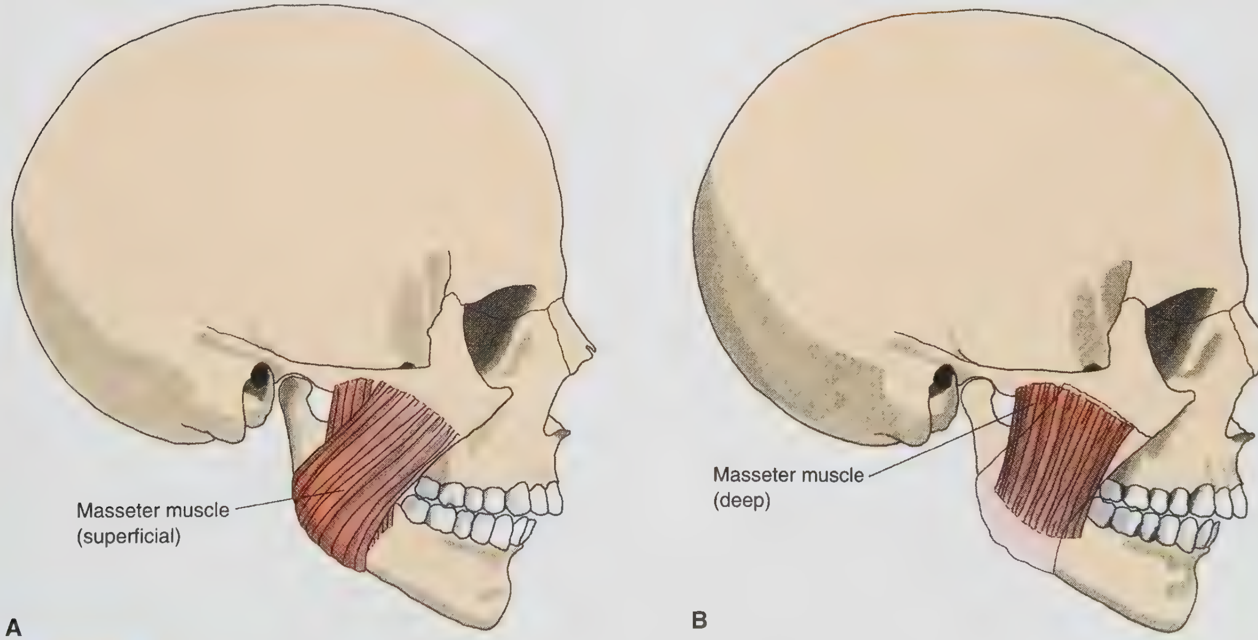

FIGURE 22-3 **(A)** Superficial and **(B)** deep layers of the masseter muscle.

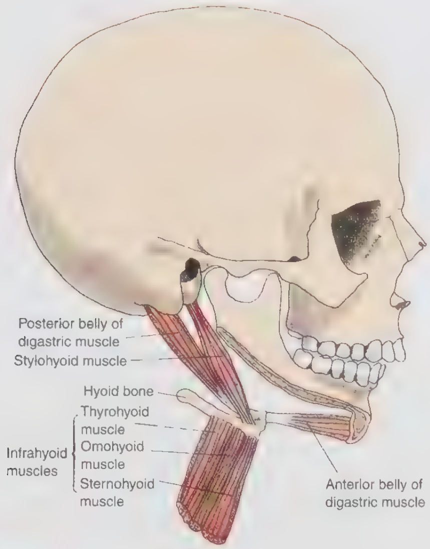

FIGURE 22-5 Hyoid bone and the digastric, stylohyoid, and infrahyoid muscles.

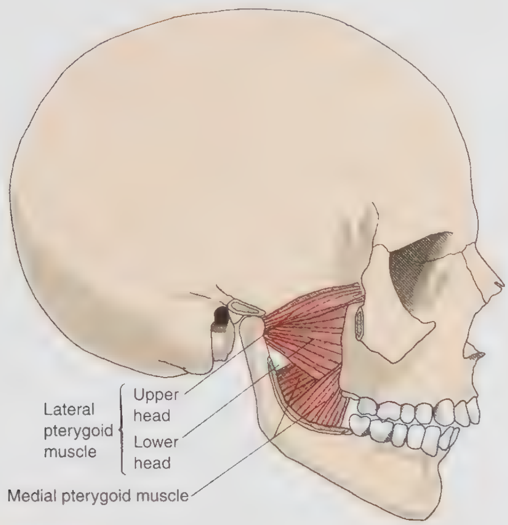

FIGURE 22-6 Medial and lateral pterygoid muscles.

mandible and elevates the hyoid, particularly in swallowing; the medial pterygoid (**Fig. 22-6**), which elevates and protrudes the mandible, and when working unilaterally will rotate the mandible to the contralateral side; and the lateral pterygoid (Fig. 22-6), which also protrudes and rotates the mandible. The lateral pterygoid also directly inserts into the articular disk and helps control the disk's movement during mouth opening and closing.

Associated Structures

Upper and lower teeth contact (occlusion vs. malocclusion) will directly affect the distribution of compressive forces acting on the TMJs. The suprahyoid and infrahyoid muscles and their interaction with the digastric and the hyoid bone can affect both speech and swallow function and head and neck posture (Fig. 22-5). When functioning appropriately, the infrahyoids

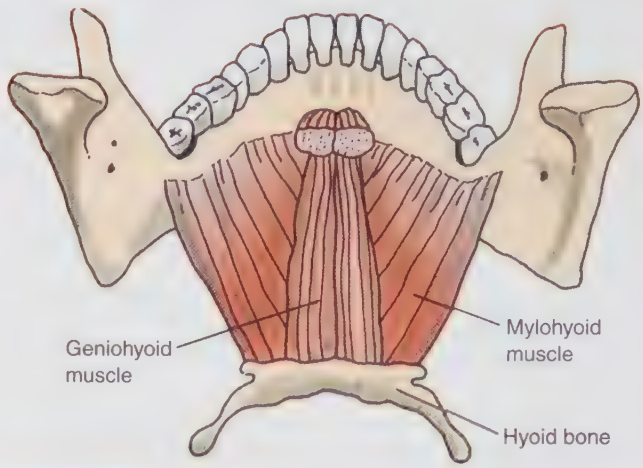

FIGURE 22-7 Mylohyoid and geniohyoid muscles viewed from above and behind the floor of the mouth.

stabilize the hyoid bone, which creates a stable base from which the suprahyoids can contract and move the mandible for chewing and talking (**Fig. 22-7**). The position of the upper cervical spine may alter mandibular position and masticatory muscle tone, affecting pain, occlusion, and TMJ function.[17]

Kinesiology

The jaw has three basic osteokinematic movements, with six degrees of freedom: depression/elevation, protrusion/retrusion, and lateral excursion to either side. These basic cardinal-plane movements can be combined to produce an infinite variety of mandibular motions. During opening and closing, the convex surface of the condylar head must move across the convex surface of the articular eminence. The biconcave disk moves forward with the condylar head on opening to increase joint surface contact between the two convexities and returns to its posterior position on closing to allow for full occlusion.

Arthrokinematically, the accessory movements of the TMJ are rotation (spin of the condylar head), anteroposterior translation, and lateral glide to either side.[11] Gliding movements occur in the upper cavity of the joint, whereas rotation or hinge movements occur in the lower cavity. Gliding and rotation are essential for opening and closing the mouth. Accessory movements most often restricted because of periarticular tissue tightness and disk displacement are lateral glide, translation, and distraction. According to Kraus,[12] of these accessory movements, loss of translation causes the most limitation of osteokinematic movement of the mandible and is more difficult to restore.

The normal range of mandibular opening is 40 to 50 mm; minimum functional opening is 40 mm for most activities. The first 25 mm of opening should take place in the lower portion of the joint, through rotation of the condylar head against the inferior surface of the disk. The additional 15 mm of movement is translation in the upper cavity, as the superior surface of the disk moves anteriorly across the articular eminence.[18] Normal lateral excursion is 10 mm (5 mm to each side), and protrusion is 4 to 6 mm, or at least the ability for the incisors to meet. If the capsule is restricted bilaterally, the patient will have significant loss of lateral movements, limited protrusion, and decreased mouth opening. In unilateral capsular patterns of restriction,

Patient-Related Instruction 22-1

TUTALC

To remind yourself of the resting position of the tongue, mouth, and jaw, use the acronym "TUTALC"

- Tongue Up—Place the front of the tongue on the hard surface just behind your upper teeth.
- Teeth Apart—Let your teeth separate slightly (less than a finger's width)
- Lips Closed—Keep your lips together and breathe through your nose

Allow the muscles in your face and neck to relax in this position. Practice throughout the day; after a week or two, you may find yourself already resting in the TUTALC position.

contralateral excursions are most limited and the mandible will deviate toward the restricted side in a C-curve motion.

The TMJ has two close-packed positions. The anterior position occurs when the disk and condyle translate forward toward the articular eminence during maximal opening; the posterior position is in maximal retrusion, when the mouth is closed, the teeth are clenched, and the condylar head is translated posteriorly, maximally compressing into the posterior elements of the joint. The rest (loose-packed) position for the TMJ is with the teeth 4 mm apart, sometimes termed "freeway space." To maintain the TMJ's resting position with minimal muscle activation, the tongue should remain in its postural resting position. The anterosuperior tip of the tongue should lie in the area against the hard palate, just posterior to the back side of the upper central incisors; this position should be discussed with and demonstrated to the patient.[19,20] The complete functional resting position for the mouth and jaw is: tongue up, teeth apart, and lips closed. The patient can be taught the acronym "TUTALC" to help remember this position (**Patient-Related Instruction 22-1**). When the tongue, teeth, and lips are in this position, the mandible is stabilized against gravity with minimal muscle activation. If not, the masseter and temporalis must contract to hold the jaw against gravity, increasing muscle tone and potentially causing clenching, which close-packs the TMJ.

Proper resting position of the tongue, in addition to helping maintain normal posturing of the mandible and axial spine, enhances normal swallowing patterns and makes daytime clenching more difficult.[21] Instructing the patient to maintain TUTALC helps to achieve the resting position of the jaw and tongue and overcome parafunctional and functional muscle hyperactivity.[22]

Cervical spine posture and muscle imbalances are frequently associated with TMJ symptoms. Functionally, the TMJ, the cervical spine, and the articulations between the teeth are intimately related (**Fig. 22-8**). Muscles attach the mandible to the cranium, the hyoid bone, and the clavicle. The cervical spine is, in essence, interposed between the proximal and the distal attachments of some of the muscles controlling the TMJ.[10] The balance between the flexors and the extensors of the head and neck affects and is affected by the muscles of mastication and the suprahyoid and infrahyoid muscles.[23] Dysfunction

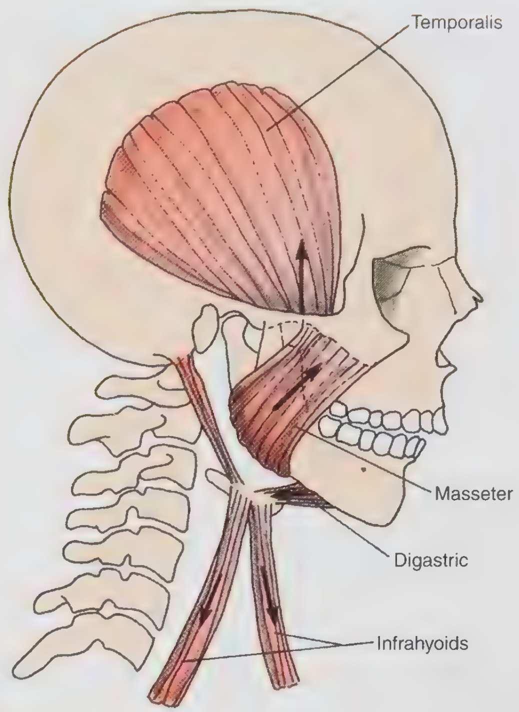

FIGURE 22-8 A lateral view of the head, neck, and mandible showing the muscular forces that flex the head. The infrahyoid muscles depress the hyoid bone; the suprahyoids depress the mandible. The muscles of mastication elevate the mandible and stabilize it against gravity.

anywhere in this system can easily disturb this balance. The neuromusculature of the cervical and masticatory regions actively influences the function of mandibular movement and cervical positioning.[24–26]

Cervical posture change affects the mandibular path of closure, the mandibular rest position, masticatory muscle activity,[22,23,27] and occlusal contact patterns. As discussed in Chapter 23, FHP increases the gravitational forces on the head. To correct for visual needs, the head typically tilts backward (posterior cranial rotation), the neck flexes over the thorax, and the mandible migrates posteriorly (**Fig. 22-9A**).[24] The posterior cervical muscles are shortened and forced to contract excessively to maintain the head in this position, while the anterior submandibular muscles are stretched, resulting in a retraction force on the mandible and an altered occlusal contact pattern. The retruded mandible may then require excessive mandibular shuttling (i.e., excursions) between opening and closing for functional activities such as chewing and eating, which may lead to hypermobility of the TMJ from overstretching of the capsule.[28]

In the presence of an FHP with no significant posterior cranial rotation (Fig. 22-9B), the suprahyoids shorten while the infrahyoids lengthen, leading to a decrease in the freeway space. The hyoid bone is repositioned superiorly, and the degree of elevation is proportional to the decrease in the cervical lordosis or the increase in the FHP.[29,30] Hyperactivity of the suprahyoids produces a depressive force on the mandible. According to Mannheimer and Rosenthal,[28] when combined with hyoid anchoring by means of the infrahyoids, the net mandibular repositioning effect is one of retraction and depression with increased contact in the molar region (see **Building Block 22-1**).

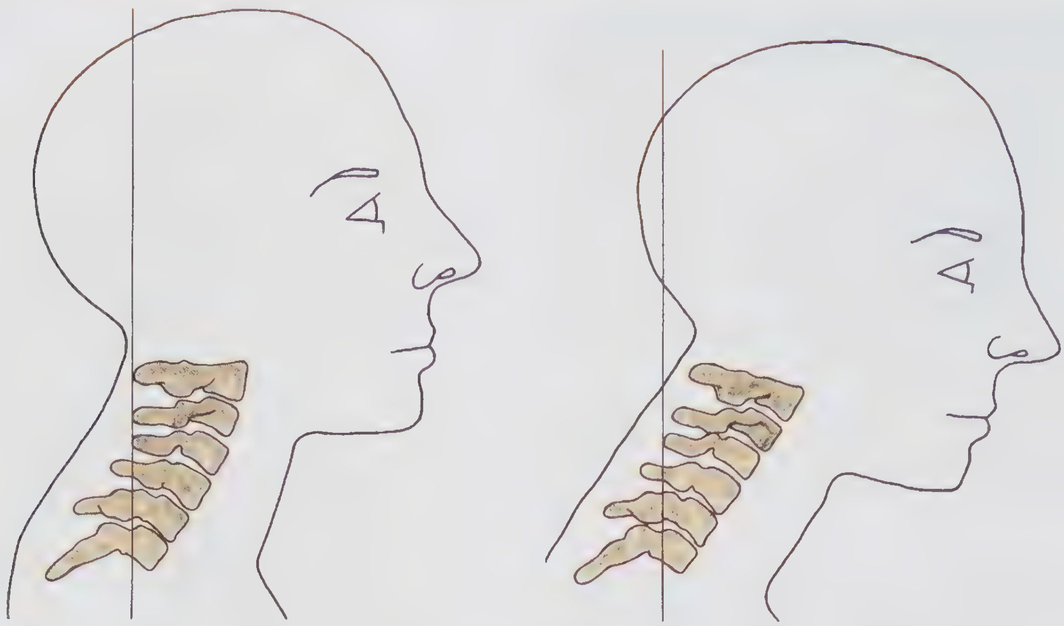

FIGURE 22-9 Types of forward head: **(A)** increased cervical lordosis with posterior cranial rotation (PCR) and **(B)** total flattening out of the cervical lordosis without PCR.

BUILDING BLOCK 22-1

How might a FHP affect tongue position and swallowing? Why is it important to address swallowing function in patients with temporomandibular joint and muscle disorders (TMD)?

Another contributing factor to TMD is mouth breathing. The dysfunctional patterns of the mouth-breathing syndrome constitute a chain reaction of body adaptation to abnormal breathing patterns. Various investigations have shown that postural relationships change to meet respiratory needs.[20,31] Breathing through the mouth facilitates FHP, a low and forward tongue position with resulting abnormal swallowing pattern, and increased activity of the accessory muscles of respiration (i.e., sternocleidomastoids, scaleni, and pectorals).[20,32,33] This pattern is perpetuated by decreased activity of the diaphragm and hypotonicity of the abdominal musculature.[20]

EXAMINATION AND EVALUATION

A thorough evaluation of the TMJ includes all components of the stomatognathic system, including the cervical spine. This assessment assists the therapist in determining the cause of the dysfunction and the influence of other factors and in designing an effective treatment plan. This section will discuss examination specific to the TMJ; for more information on evaluation of the cervical and thoracic spine, see Chapters 23 and 24 (**Case Study 22-1**).

CASE STUDY 22-1

The patient is a 21-year-old college student with complaints of a 6-week history of limited opening and right-sided jaw pain. Present symptoms include limited opening, right jaw pain, and difficulty with speaking, chewing, and brushing teeth due to pain. History includes a 3-year history of right TMJ clicking with occasional pain. The patient reports that she has pain and described it as a dull ache, which worsens with chewing, yawning, and talking. Pain is reported on the visual analog scale (VAS) at 2/10 at rest, and it will increase to 5/10 with function. Aggravating factors include talking, chewing, yawning, brushing teeth, sleeping position, and clenching. Alleviating factors include heat, rest, and ibuprofen (600 mg) for pain. 24-hour report: the patient reports increased pain upon waking in the morning and following meals. The patient reports difficulty finding a comfortable sleeping position due to pain, reporting mild sleep disturbance of 1- to 2-hours sleeplessness. The patient's medical and dental history is noncontributory, and she takes oral contraceptives in addition to the ibuprofen. Management to date included an evaluation by student health services, who recommended scheduled ibuprofen (600 mg three times a day [t.i.d.]), soft diet, warm compresses, and referral to therapy.

On opening, the patient demonstrates 25 mm of opening, with pain at end range. No clicking or crepitation is noted. Lateral excursion is 10 mm to the right and 4 mm to the left with pain at end range. Deflection to the right is noted on opening. She reported tenderness with palpation of the right TMJ at the joint line and with palpation of the masseter on the right. Joint play assessment demonstrates decreased mobility of the right TMJ in all planes. The patient demonstrates a FHP; swallowing and breathing functions are normal.

Subjective History

A comprehensive patient history helps to direct the objective evaluation. The client should provide detailed information about the onset of symptoms, incidence of joint locking, presence of joint noise, history of surgery and trauma, and medical history. Pain should be described in terms of location, intensity, frequency, time of day, and activities that reproduce it. The therapist should investigate associations with headache, tinnitus, vertigo, or hearing dysfunctions. Medical screening should be performed for issues that contribute to or refer to the TMJ, such as rheumatologic illness, fracture, neoplasia, otologic problems, and visceral referral patterns (particularly cardiac).

DISPLAY 22-1

Examples of Parafunctional Activity

Gum chewing
Bruxism/tooth clenching or grinding
Pipe smoking
Thumb sucking
Tongue thrusting
Nail/cuticle biting
Pen/pencil chewing
Mouth breathing
Resting chin on hand (e.g., to study)

Functions and Parafunctions

Oral functions such as talking, chewing, and swallowing should be thoroughly discussed and evaluated. A term found in TMJ management is "parafunction," which means using the body part for some function other than its primary functions (i.e., eating, drinking, and speaking). Gum chewing and tooth grinding (bruxism) are common; other examples are listed in **Display 22-1**. Stress has been linked to an increase in parafunctional habits.[34–36] Clients should be asked about their level of psychosocial, environmental, and postural stress, and asked if they notice an increase in clenching or other parafunctional habits when under stress. The type of job a patient has can provide information about postural parafunctions and the effect on the TMJ. For example, picture the different stresses placed on the TMJ by a student slouching to study on the couch versus a musician who must hold a violin between her chin and shoulder. Use of a functional outcome measure such as the Jaw Functional Limitation Scale (JFLS) may be helpful in evaluating these patients and tracking outcomes (**Display 22-2**).[37]

DISPLAY 22-2

Jaw Functional Limitation Scale[35]

For each of the items below, please indicate the level of limitation **during the last month**. If the activity has been completely avoided because it is too difficult, then circle "10." If you avoid an activity for reasons other than pain or difficulty, then leave the item blank.

		No Limitation										Severe Limitation
1.	Chew tough food	0	1	2	3	4	5	6	7	8	9	10
2.	Chew hard bread	0	1	2	3	4	5	6	7	8	9	10
3.	Chew chicken (for example, prepared in oven)	0	1	2	3	4	5	6	7	8	9	10
4.	Chew crackers	0	1	2	3	4	5	6	7	8	9	10
5.	Chew soft food (for example, macaroni, canned or soft fruits, cooked vegetables, fish)	0	1	2	3	4	5	6	7	8	9	10
6.	Eat soft food requiring no chewing (for example, mashed potatoes, apple sauce, pudding, pureed food)	0	1	2	3	4	5	6	7	8	9	10
7.	Open wide enough to bite from a whole apple	0	1	2	3	4	5	6	7	8	9	10
8.	Open wide enough to bite into a sandwich	0	1	2	3	4	5	6	7	8	9	10
9.	Open wide enough to talk	0	1	2	3	4	5	6	7	8	9	10
10.	Open wide enough to drink from a cup	0	1	2	3	4	5	6	7	8	9	10
11.	Swallow	0	1	2	3	4	5	6	7	8	9	10
12.	Yawn	0	1	2	3	4	5	6	7	8	9	10
13.	Talk	0	1	2	3	4	5	6	7	8	9	10
14.	Sing	0	1	2	3	4	5	6	7	8	9	10
15.	Putting on a happy face	0	1	2	3	4	5	6	7	8	9	10
16.	Putting on an angry face	0	1	2	3	4	5	6	7	8	9	10
17.	Frown	0	1	2	3	4	5	6	7	8	9	10
18.	Kiss	0	1	2	3	4	5	6	7	8	9	10
19.	Smile	0	1	2	3	4	5	6	7	8	9	10
20.	Laugh	0	1	2	3	4	5	6	7	8	9	10

Used with permission Ohrbach R, Larsson P, List T. The Jaw Functional Limitation Scale: development, reliability, and validity of 8-item and 20-item versions. J Orofac Pain 2008;22:219–230.

An abnormal tongue position, with the tongue resting behind the lower teeth, is often accompanied by tongue thrust and other parafunctional habits.[20,38,39] Tongue thrust occurs with protraction of the tongue against or between the anterior teeth, altering swallowing sequence and leading to excessive masticatory muscle activity.[12,37] Although tongue thrust is more common in children, it also occurs in adults, where it is referred to as an acquired adult tongue thrust.[12] It is theorized that tongue movement and positioning in the oral cavity are influenced by dysfunctional mobility and positioning of the cervical spine[18] (see **Building Block 22-2** and **Evidence and Research 22-1**).

BUILDING BLOCK 22-2

In Case Study 22-1, the patient demonstrates a FHP with no significant PCR. How does the presence of a FHP affect her tongue and jaw function?

EVIDENCE and RESEARCH 22-1

Ergonomics as Parafunction: TMD and Musicians

While the prevalence of TMD is around 10% in the general population, ergonomic demands may increase this rate. For instance, playing-related pain in the teeth or jaw occurs in 19% to 47% of musicians, and localized TMJ pain in 15% to 34%, depending on instrument group. Vocalists and musicians who play brass instruments, violin, and viola are most likely to report TMJ pain, due to the positions of the head, neck, and jaw required to play these instruments.[40,41]

Screening Exam for the TMJ

A local screening exam for the TMJ should include: range of motion for vertical opening, lateral excursion, and protrusion; joint function assessment for rotation and translation; joint play; and muscle tests for length, strength, and coordination/motor control. The therapist should also assess the mandible, hyoid, and TMJ and note their resting positions, palpate the soft tissue structures of the neck, and evaluate the patient's oral function, and patterns of occlusion, swallowing, and respiration, as these will have direct influence on the TMJ. Finally, regional screening including cervicothoracic movement, atlantoaxial stability, posture, and medical screening for referred pain of non-musculoskeletal origin and for systemic hypermobility will help inform the treatment plan.

THERAPEUTIC EXERCISE FOR COMMON IMPAIRMENTS OF BODY FUNCTIONS

A treatment plan cannot be determined without a thorough examination and evaluation of the diagnosis, activity limitations, and participation restrictions. Certain causes of mandibular dysfunction, particularly those stemming from disorders of the mandible or cranial bone—aplasia, dysplasia, hypoplasia, hyperplasia, fractures, and neoplasms—may not be appropriate for physical therapy interventions, while jaw pain of nonmechanical origin warrants referral for medical management.[42] Therapeutic exercise interventions should address specific impairments that directly relate to activity limitations and participation restrictions to increase overall function of the TMJ.

Mobility Impairments

Hypomobility

Etiology The primary mandibular hypomobilities seen in the clinic may be intra-articular, with the restriction due to the joint capsule or articular structures, or myogenous, occurring in the muscles extrinsic to the joint.[7] Arthrogenous temporomandibular dysfunctions that can contribute to mandibular hypomobility are ankylosis (fibrous or bony); arthropathies involving the periarticular tissue (capsule) and structural bony changes (e.g., osteophytes); disk displacement (i.e., acute disk displacement that does not reduce); and inflammation or joint effusion. Myogenous hypomobility is due to masticatory muscle disorders such as myofascial pain, muscle splinting, myositis, spasm, contracture, and neoplasia.[31] Differentiating between intra-articular and myogenous causes of hypomobility will help with appropriate treatment planning and exercise choices.

Hypomobility of either type may lead to capsular fibrosis, a result of the intermolecular cross-linking adhesions of collagen fibers. It most commonly accompanies one or some combination of three situations: resolution of an acute articular inflammatory process, such as may occur after a whiplash injury; a chronic, low-grade articular inflammatory response, often due to overloading the joint from parafunctions like bruxism; or, immobilization such as after surgery or fracture.

The hypomobile jaw may or may not be painful. If painful, the pain is felt over the side of involvement, with possible reference into areas innervated by cranial nerve V. Pain increases during functional and parafunctional movements of the mandible, with the pain pattern dependent on the source of the restriction (myogenous vs. arthrogenous). If significant capsular shortening exists, the mandibular opening is less than functional, and the patient presents with a capsular pattern of restriction.

Treatment Treatment for the hypomobile jaw typically begins with gaining tissue extensibility through soft tissue mobilization and joint mobilization. The gains are maintained with a series of passive and active stretches. Motor control into the new ranges must be developed in order to restore functional movements to the jaw. Strength and stability can then be progressed, finally moving into higher-speed motions and transfer from conscious motor control to subconscious performance during daily movements. Patient education is a significant part of the rehabilitation program throughout, including instructions on proper posture, maintaining the normal rest position of the tongue and jaw ("TUTALC"), and avoiding aggravating factors.[43]

Mobilization of the involved soft tissues can decrease muscle tone, which will facilitate stretching techniques and joint mobilization procedures, making them more tolerable and effective. Effective soft tissue mobilization by therapist and patient is a primary intervention for myogenous hypomobility. Static

FIGURE 22-10 **(A)** Interoral distraction. The clinician's thumb is positioned to apply a distraction force. **(B)** Lateral glide. The clinician's thumb is positioned on the lingual side of the teeth to apply a lateral glide force. **(C)** Intraoral translation (ventral glide). The clinician's index and third fingers are positioned to apply translation.

stretches, dynamic movements, and strengthening exercises are used to promote mobility, motor control, and strength for both myogenous and arthrogenous restrictions. Joint mobilization techniques are used to further enhance capsular extensibility in arthrogenous limitations. These may be performed initially by the therapist intra-orally or extra-orally, with the patient instructed in self-mobilization procedures for the TMJ including distraction, medial glide, and translation (**Figs. 22-10** to **22-12**).[12,21,44,45]

Most patients with hypomobility impairment require a home program of active ROM exercises, self-mobilization, and a passive stretching program with tongue depressors or a device such as the Thera Bite Jaw Motion Rehabilitation System (ATOS Medical

FIGURE 22-11 Extraoral articulation techniques are performed with the patient sidelying on the noninvolved side with the head supported on a pillow. **(A)** Extraoral medial glide. Gentle oscillatory mobilizations are performed over the lateral pole of the condyle in a medial direction with the thumbs. **(B)** Extraoral protrusion. Gentle oscillatory mobilizations are performed over the posterior aspect of the condyle in an anterior direction.

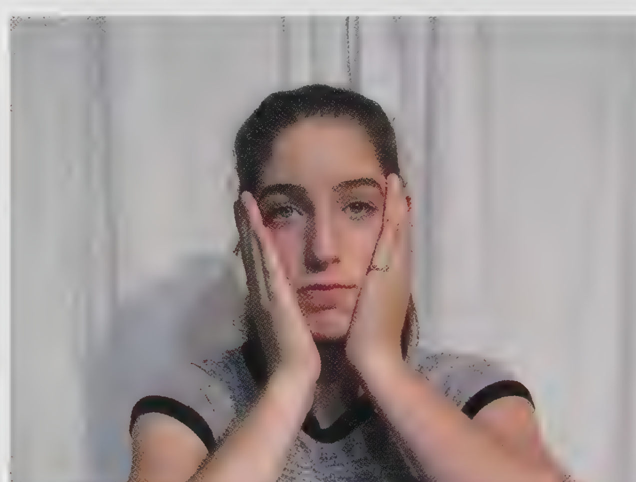

FIGURE 22-12 Self-distraction may be performed by the patient by gently squeezing the face and pulling forward and downward on the mandible. The elbows should rest on a firm surface, or the patient should hold the forearms firmly against the chest. To enhance the mobilization techniques, active participation by the patient is encouraged. The patient actively opens or closes the mouth using minimal muscle contraction, and after relaxing, additional distraction can be applied.

FIGURE 22-13 Stack tongue depressors between teeth for passive stretch.

AB, Hörby, Sweden) to maintain and facilitate tissue extensibility. Passive stretch, also known as prolonged static stretch, may be used by placing stacked tongue depressors horizontally between the upper and the lower incisors, adding layers as able to increase the mandibular opening (**Fig. 22-13**). As the range of motion increases, the patient can gradually increase the number of tongue depressors until he or she can open far enough to insert the knuckle of his or her index and middle fingers between the anterior teeth. Another simple method of self-stretch is to use the thumbs crossed over the index fingers, actively opening the jaw, and applying gentle overpressure with fingers until a stretch is felt (**Fig. 22-14** and **Self-Management 22-1**).

Post-isometric relaxation techniques (PIRs) can be very effective in managing myogenous restrictions of the TMJ. These techniques are similar to muscle energy and proprioceptive neuromuscular facilitation (PNF) exercises. PIRs use active

SELF-MANAGEMENT 22-1
Mandible Self-Stretch

Purpose:	Stretch the soft tissues of the mouth and jaw to improve mouth opening.
Start Position:	Sit comfortably in good posture. Place index fingers of both hands on lower teeth, with thumbs on upper teeth, trying to get as far back in the mouth as possible.
Movement Technique:	Actively open mouth as far as possible. While opening the mouth, press your fingers apart to add extra pressure to the stretch.
Dosage:	Hold stretch 15 to 60 seconds. Relax and repeat. Perform daily.

FIGURE 22-14 Mandibular opening self-stretch (see Self-Management 22-1).

muscle contractions at various intensities from a precisely controlled position in a specific direction against a counterforce to facilitate motion.[46] The muscle being targeted is placed in a stretch position. The patient is then cued to isometrically contract against gentle resistance at approximately 20% of MVC, then relax. During the relaxation phase, passive stretch is applied[47] (See **Patient-Related Instruction 22-2** and **Evidence and Research 22-2**).

Patient-Related Instruction 22-2

Post-Isometric Relaxation Techniques

Mouth opening (**Fig. 22-15**)	Sit at a table with one elbow on the table, and your forehead propped on that hand. Place the fingers of your other hand on your lower teeth. Open your mouth until you feel a stretch. Breathe in, open as wide as possible, as if yawning. Resist with your fingers as you try to close your jaw; don't let your jaw move (isometric contraction). Hold for a few seconds. Breathe out and relax, stretching mouth further open.
Lateral pterygoid (**Fig. 22-16**)	Lie on your back. Place your thumbs on the front of your chin. Press the chin forward into your thumbs, resisting with gentle force. Breathe in and hold for a few seconds. Breathe out and relax, letting the chin drop back toward the throat for a stretch.
Digastric (**Fig. 22-17**)	Sit at a table with one elbow on the table, and your chin propped on that hand. Wiggle the bone in your throat side to side—your therapist will teach you how. Place your thumb on the side of the bone that is more tense. Open your mouth against the resistance of your hand on your chin. Breathe in and hold for a few seconds. Breathe out and relax, while you gently press the bone in your throat to the opposite side for the stretch.

FIGURE 22-15 Post-isometric relaxation technique for mandibular opening (temporal, masseter, and medial pterygoid muscles).

FIGURE 22-16 Post-isometric relaxation technique of the lateral pterygoid.

FIGURE 22-17 Post-isometric relaxation technique for the digastric muscle.

EVIDENCE and RESEARCH 22-2

Post-Isometric Relaxation Exercises

In a study of 244 patients and across 351 muscle groups, the PIR technique produced immediate pain relief in 94%, lasting pain relief in 63%, and lasting relief of point tenderness in 23% of the sites treated. Patients who learned how to do the technique on themselves had the best long-term outcomes.[45]

Active stretch exercises into newly gained ranges of motion help maintain mandible mobility as well as facilitating motor control. The patient should be encouraged to open and close the mouth throughout the day. Active protrusion and lateral excursions (with or without tongue depressors positioned between the teeth) can be used to actively mobilize the mandible in other directions (**Fig. 22-18**).

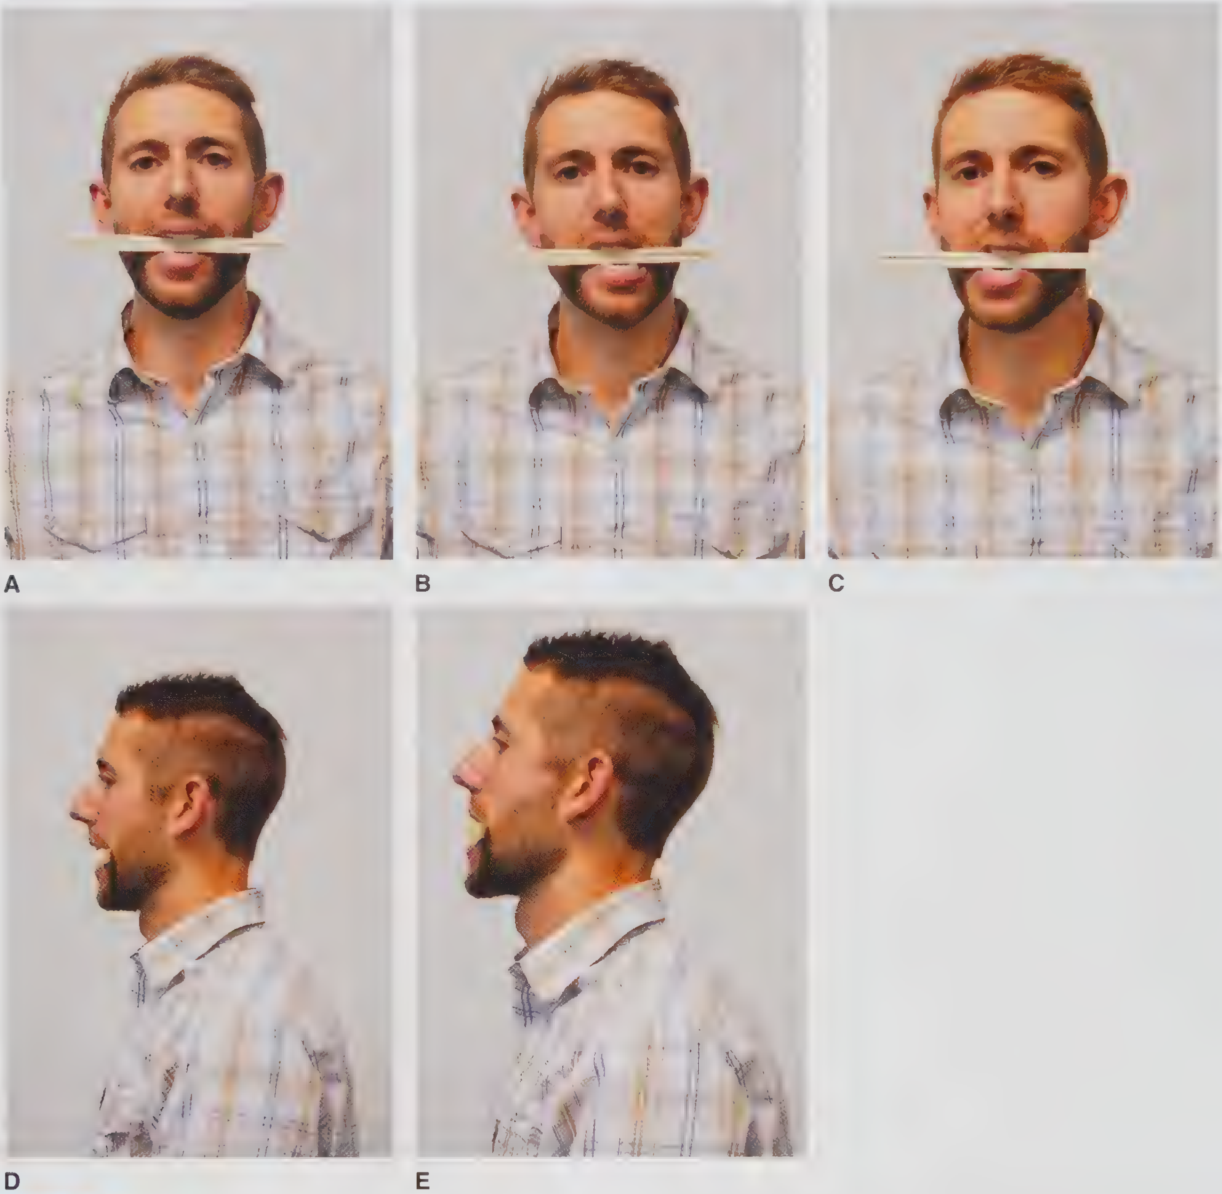

FIGURE 22-18 Active exercise to increase mandibular lateral excursions and protrusion. The patient is given enough tongue depressors to place between the teeth to allow for approximately 10 to 11 mm of opening **(A** and **D)**. The patient is then asked to protrude the mandible at this opening to improve translation **(E)**. The patient may also be instructed to protrude and glide the mandible to one side to improve translation of one side **(B** and **C)**.

Once movement has been restored, the patient needs to learn motor control and coordination into the newly available range. Functional kinetic exercises developed by Klein-Vogelbach[48,49] develop this motor control, helping the patient learn to move the TMJs freely and with precision in all directions. In normal TMJ activity, the mandible moves while the head remains stationary. If movement at the TMJ is restricted, Klein-Vogelbach suggests it may be helpful to reverse these roles and move the head over a stable jaw, transmitting the active movements to the upper cervical spine joints (i.e., atlantooccipital and atlantoaxial joints). The therapist can instruct the patient to move head-on-jaw, rather than jaw-under-head, as an exercise for motor control. Note that the therapist should screen the upper cervical spine to ensure full and safe function prior to beginning these exercises.

Begin practicing these exercises in the clinic, with the therapist stabilizing the mandible and then teaching the patient how to do so at home. While the patient sits with good vertical alignment, the therapist or the patient provides fixation of the mandible; the fingers of both hands should grasp the mandible. Exercises include opening and closing of the mouth, lateral deviations, and protrusion and retrusion (**Fig. 22-19**). These precise and unfamiliar movements of the TMJ must be performed at low intensity and slowly, because the body is learning movements that it does not need in normal motor behavior.[47] These head-on-mandible exercises are

FIGURE 22-19 Functional kinetic exercises moving the proximal lever (the head). **(A)** Opening: with the mandible stabilized, the patient extends the head (the tip of the nose moves cranially and dorsally). The joints of the upper cervical spine extend, and the mouth opens, moving through the TMJs. **(B)** Closing: the patient flexes the head (the tip of the nose moves caudally and ventrally); the joints of the upper cervical spine flex and the mouth closes. **(C** and **D)** Lateral movements: with the mandible stabilized, rotate the atlantooccipital and atlantoaxial joints of the cervical spine, allowing the upper teeth to slide laterally on the stabilized mandible. The movement causes lateral translation in the TMJ contralaterally and medial translation ipsilaterally. **(E)** Protrusion: with the mandible stabilized, retract the cervical spine, bringing the upper teeth dorsal (posterior) to the lower teeth for relative mandibular protrusion and TMJ anterior translation. **(F)** Retrusion: with the mandible stabilized, protract the cervical spine, bringing the upper teeth ventral (anterior) to the lower teeth for relative mandibular retrusion and TMJ posterior translation.

then followed up with normal mandible-under-head motions to assess progress and maintain function. Progress the Klein-Vogelbach exercises by placing the head in an inverted position (**Fig. 22-20**). The therapist should ensure the patient is safe and comfortable in this position. By changing the position of the head, opening of the mouth is performed against gravity. The suprahyoids must now contract concentrically to open the jaw, while the masseter and temporalis fire eccentrically to control speed; closing is assisted by gravity, with the suprahyoids firing eccentrically.

Hypermobility

Etiology While the cause of bilateral hypermobility is unknown, unilateral hypermobility can occur as a compensatory reaction to hypomobility of the contralateral side. Other potential predisposing factors range from joint laxity to psychiatric disorders to skeletal disorders.[50] Investigations suggest that systemic hypermobility (i.e., ligament laxity) may be closely related to TMJ hypermobility, and other investigations suggest disk displacement and osteoarthrosis.[48,51,52] Parafunctional habits in childhood such as

FIGURE 22-20 Opening the mouth against gravity, with the long axis of the body inverted.

prolonged bottle-feeding, thumb sucking, and pacifier use may contribute to hypermobility of the TMJ in the adult.[20] Many adult patients also present with a history of habitually opening their mouths excessively wide when yawning or eating.

Believed to be the most common mechanical disorder of the TMJ, hypermobility is characterized by early and excessive anterior translation of the mandible.[53] In cases of hypermobility, translation occurs within the first 11 mm of opening rather than the last 15 to 25 mm. Excessive anterior translation results in laxity of the capsule and ligaments, particularly posteriorly. The breakdown of these structures may lead to disk derangement in one or both TMJs. Ultimately, impairments such as loss of motion and arthritic changes may occur, leading to loss of function.

Treatment Patient education regarding joint function, the reason for the symptoms, and activity modification is key to successful management of hypermobility. Once the patient begins to attend to and limit provocative activities in daily life, therapeutic exercises are likely to be more effective.

Teach and Reinforce Resting Position For the therapist to teach control of the jaw muscles, the patient must first recognize the resting position of the mandible: lips closed, teeth slightly apart, and the tongue on the hard palate (Patient-Related Instruction 22-1). The patient should breathe in and out through the nose and use diaphragmatic breathing.

Temporomandibular Rotation and Translation Control The patient starts by learning to limit TMJ mechanics to condylar rotation. Initial training uses an active technique with the index finger and thumb monitoring and guiding the movement. The patient begins in the TUTALC position and uses the fingers to monitor both mandibular movement and joint motion. As the patient begins to open the mouth, they monitor for movement quality, speed, and rotation in the joint, stopping as soon as translation begins (**Self-Management 22-2**). The patient may also use a mirror to watch for normal tracking and to ensure that the tongue stays elevated and the jaw does not deviate from the midline. The exercise is progressed by decreasing tactile input (**Fig. 22-21**), lowering the tongue, and finally increasing speed.[12] Kraus found this a useful technique in reducing symptoms associated with inflammatory disorders such as synovitis and capsulitis and when inflammation coexists with hypermobility, hypomobility, or excessive parafunctional activities (see **Building Block 22-3**).[12]

SELF-MANAGEMENT 22-2
Rotation Motor Control

Purpose: To restore proper "tracking" to the TMJ, to improve rotation, to limit early translation through an active assisted technique, and to decrease or eliminate clicking, cracking, popping, or excessive movement occurring in the TMJ.

Cues: Carefully monitor the movement of the TMJ, feeling for rotation and stopping the movement if translation (forward sliding) begins.
Use a mirror for visual feedback. The tongue should stay on the roof of the mouth and the jaw should move straight down the midline without deviations.
Exercise should be performed slowly and rhythmically in pain-free range.

Start Position: Sit on a firm chair, close to the front edge, with feet on the floor hip-width apart.
Sit with good posture, including a neutral pelvis, lumbar, thoracic, and cervical spine alignment.
Use supports as needed to achieve this neutral posture. For instance, you can sit against a wall to support your back, place towels behind your head to get a neutral neck position, or sit on a folded towel for neutral pelvis and lumbar spine.

Movement Technique: Keep the tongue on the roof of the mouth.
Place one index finger on the TMJ.
Place the opposite thumb and index finger lightly on the tip of the chin. Allow the lower jaw to drop down and back, guiding the movement with your thumb and index finger on the chin. STOP when you feel the jaw begins to move forward (translation).

Dosage: Sets/Repetitions: Repeat this exercise five times
Frequency: Do five times per day.
As you are able to open more and move more smoothly, perform throughout the day, such as whenever you are in front of a mirror.

Progression: Level II: Repeat exercise with tongue still on roof of mouth, but without the finger and thumb on the chin (Fig. 22-19).

Level III: Remove tongue from roof of mouth and open the jaw with controlled motion. Allow the finger and thumb on the chin to guide and assist.

Level IV: Control jaw opening without support either from the tongue or the finger and thumb on the chin.

Level V: Add speed as you perform all the above versions of the exercise, but stay focused on opening without allowing translation.

SELF-MANAGEMENT 22-2
Rotation Motor Control (*continued*)

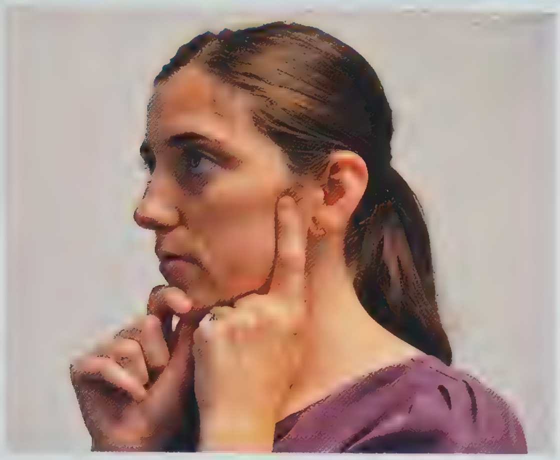

FIGURE 22-21 Neuromuscular reeducation for rotation and translation control (see Self-Management 22-2).

BUILDING BLOCK 22-3

Why is it important to teach the normal resting position of the tongue to patients with TMD? How would you teach this to a patient?

Muscle Performance Impairments

Etiology Muscle imbalances, including asymmetric weakness of the muscles controlling one TMJ with normal strength on the other side, may be due to many factors. Disuse, habit, and parafunctional activities may play a role, for instance if the patient habitually chews only on one side of the mouth. Impairments of muscle performance may also be caused by trauma or surgical procedures. Restoring muscle balance both around a single joint and symmetrically between both TMJs is important for long-term success.

Treatment Strength and stabilization exercises may be initiated concurrently with or after motor control exercises to develop TMJ rotation and translation control. These exercises are designed to strengthen the jaw muscles and balance the strength and function of the right and the left TMJs. Dynamic exercises may be used in the management of painless clicking, after a painful episode is resolved, and when the click is not caused by a displaced articular disk.[54] Strengthening exercises are also indicated after surgical interventions and for a variety of other TMJ dysfunctions and disorders.

Isometric or Static Exercises PNF techniques such as the alternating isometrics and rhythmic stabilization may be used to build isometric strength. Light pressures are applied to the jaw with the index finger and thumb on either side of the mandible. The patient maintains the TUTALC position while applying gentle pressure for 6 to 10 seconds in varying directions (see **Self-Management 22-3**). Motion in each direction is repeated

SELF-MANAGEMENT 22-3
Mandible Stabilization and Strength

Purpose:	To improve muscle strength and muscular stability of the jaw and TMJ and to help improve normal positioning of the jaw at rest and on opening.
Cues:	Use gentle resistance—a 2 on a scale of 0 to 10, where 10 is maximum resistance. Do not allow the jaw to move while applying pressure. Monitor exercise and movement in mirror if needed.
Start Position:	Sit in good posture (head, neck, and back). Let jaw and mouth drop slightly open with teeth apart.
Movement Technique:	Place index finger at desired resistance point. Apply gentle pressure (2 out of 10) in varying directions, changing the placement of your finger each time to fire different muscles. Sideways at the left or right side of the jaw (alternate) Up toward the ceiling Back/in toward the throat Diagonally toward the left or right ears (alternate)

(*continued*)

SELF-MANAGEMENT 22-3
Mandible Stabilization and Strength (*continued*)

Hold each position for 10 seconds; do not increase pressure over time.

Dosage: Sets/Repetitions: ______________

Frequency: ______________

Progression: Level II: open mouth further, approximately one knuckle width apart, and repeat the exercise (**Fig. 22-22**).

Level III: Repeat the exercise, opening mouth almost as wide as it will go (maximum mouth opening).

FIGURE 22-22 Isometric stabilization exercises. First one and then two knuckles are placed between the upper and lower teeth **(A)**. The knuckle or knuckles are removed, keeping the teeth apart. Apply gentle pressure to the lower jaw laterally **(B)**, posteriorly **(C)**, and/or superiorly **(D)** to stabilize in the desired direction (see Self-Management 22-3). Not all patients are progressed to the two-knuckle-width opening.

several times to exercise various muscles and stimulate neuromuscular awareness. Progression is by repeating the exercise at increasing interincisal distances.

PNF techniques resisting isometric opening strengthen the lateral pterygoids and suprahyoids and promote relaxation of the mandibular elevators (i.e., temporalis and masseter) through reciprocal inhibition. This technique may then improve maximum oral opening measurements.[55,56]

Isotonic or Dynamic Exercises Dynamic exercises are performed against manual resistance as the patient moves the mandible through the available range of motion. Exercises include resisted opening, closing, and lateral movements (**Figs. 22-23** to **22-25**). Open-close movements are initially limited to about 15 mm of opening (i.e., width of one knuckle) to strengthen motion during the rotation phase of opening without allowing anterior translation. The patient should be reminded not to push the jaw forward during the opening movement and to allow the jaw to open in an arc toward the throat. Lateral movements are limited to about 5 mm to train normal ROM. Resisted movements should initially be performed with slow, controlled movement, increasing speed as the patient is able while maintaining normal rotation/translation relationships and avoiding deviation from midline. ROM should be limited to pain-free, click-free movements (see **Building Block 22-4**).

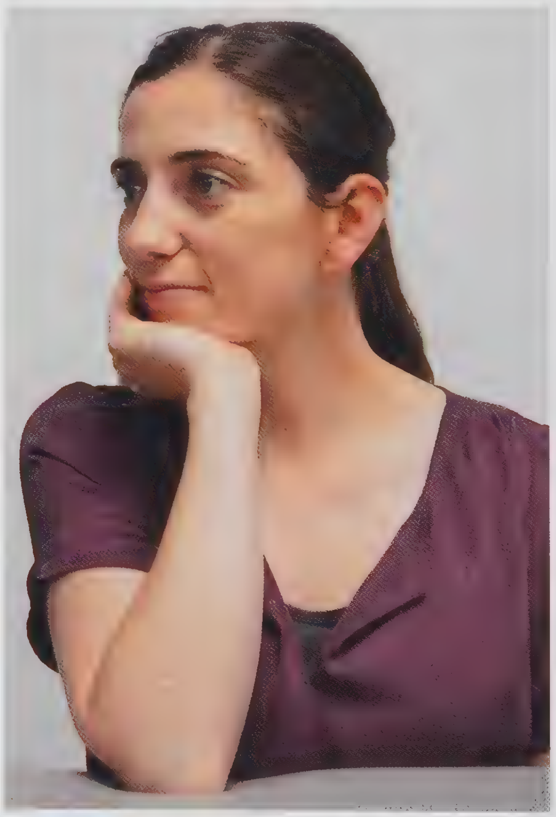

FIGURE 22-23 Dynamic strengthening exercise. Resisting against the right lateral force provided by the patient's right hand strengthens the left lateral pterygoids. Resistance is provided by placing the palm against the chin with the arm stabilized (i.e., the elbow resting against a firm surface or with the arm held firmly against the chest).

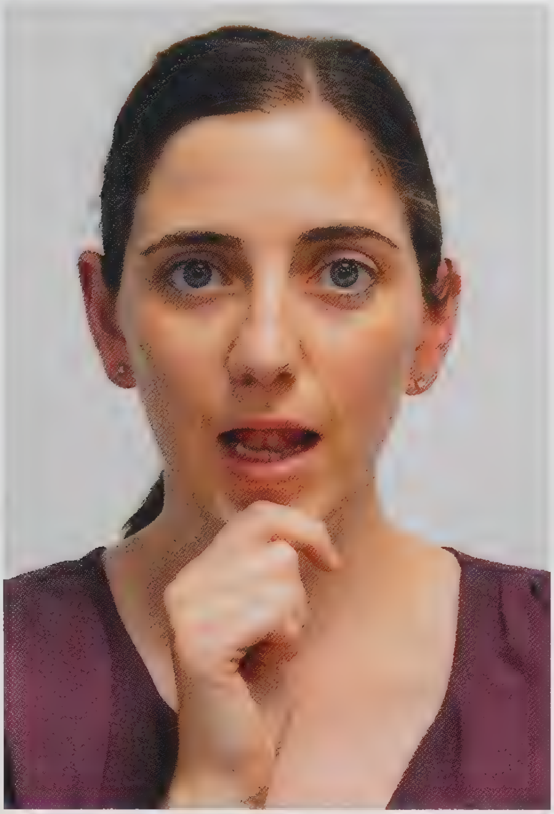

FIGURE 22-24 Resisted concentric opening at the midline is performed by the closing force provided by the therapist's or the patient's hand. Emphasis is placed on straight, midline mandibular depression and protrusion with the tongue on the hard palate. To avoid provoking pain or clicking, opening should be restricted to <20-mm interincisor separation.

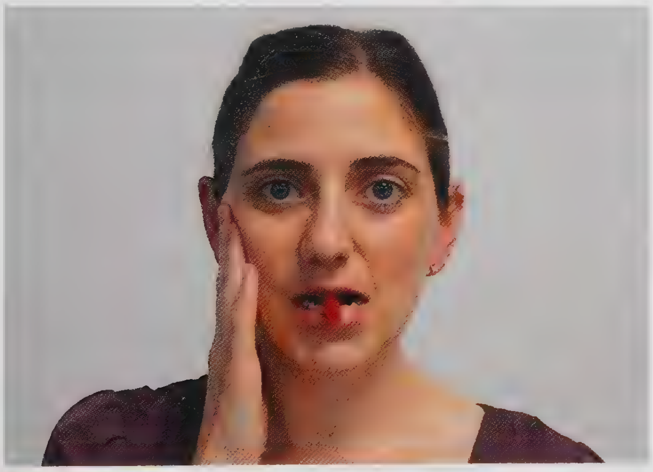

FIGURE 22-25 Lateral deviation of the mandible. Tubing is maintained with the frontal incisors at an end-to-end position. Active exercises are performed by rolling it side to side. A mirror should be used for visual feedback to ensure that no retrusion occurs.

BUILDING BLOCK 22-4

A patient demonstrates 55 mm of vertical opening with early and excessive translation noted on opening. What is the movement fault for this patient? What exercises would you teach to help correct this fault?

Posture Impairments

Etiology

FHP with resultant rounding of the shoulders can produce dysfunction of the craniocervical and temporomandibular systems. To restore balance to the system, patients must address excess tension, head and shoulder girdle alignment, jaw and tongue position, and respiratory pattern. This section will focus on postural impairment interventions specific to the TMJ. For more information and general exercise instructions to alleviate FHP, please refer to Chapter 23.

Treatment

Neuromuscular Relaxation Training Effective self-regulatory and neuromuscular relaxation training involves development of habits of attention, bringing conscious awareness to tension in the face and jaw. With regular practice, this is eventually transferred to subconscious performance during everyday activities. Various relaxation procedures that employ physical and mental exercises to increase awareness have been devised.[57–59] Any of these relaxation techniques may be integrated into biofeedback-assisted attention training.

Progressive relaxation involves a structured isometric approach that asks the patient to contract the muscle of interest, and then relax that muscle.[60,61] It may also use a reverse approach, in which the muscles are passively stretched and then relaxed.[62,63] Autogenic training employs adaptive mental imagery.[64,65] The verbal content of the standard exercises is focused on the neuromuscular system (e.g., heaviness of the limbs), the vasomotor system (e.g., warmth of the limbs, coolness of the forehead), and slowing of the cardiovascular system and respiratory mechanisms.

Yoga, meditational mantra, and diaphragmatic breathing techniques may be helpful in management of TMD.[66–69] Approaches which focus on integrated functions of the tongue, jaw, and breathing, including the use of sensory awareness techniques[65,70–73] and sensory-motor learning exercises,[74–79] may be particularly valuable for these patients.

Head, Neck, and Shoulder Postural Exercises A significant aspect of the therapy for the head, neck, and shoulder is a postural exercise program. The principles proposed by Kendall et al.[80] and Sahrmann[81,82] are beneficial for these patients (see Chapters 9, 17, 23–25). Cue the patient to avoid flattening of the cervical curve and excessive cranial flexion (**Fig. 22-26**). Therapists may also use a variety of movement reeducation approaches to attain balanced posture, alignment, structure, and function. Therapeutic approaches include a variety of methods, such as Aston Patterning,[83,84] the Alexander Technique,[68,69,85] the Feldenkrais Method,[73–77] tai chi,[86–88] and Trager Psychophysical Integration,[82] which use sensory, kinesthetic, and proprioceptive feedbacks to the body-mind system. A TMJ sensory awareness CD, part of the Intelligent Body CD/DVD series, has been developed based on the Feldenkrais Method for home use (Feldenkrais Movement Institute, Berkeley, CA).

Conscious practice must transfer to the subconscious level for long-term success. To facilitate this, it is often helpful for the patient to practice awareness exercises directed at restoration of the neutral resting position of the head, neck, tongue, jaw, and shoulder girdle throughout the day. The RTTPB system (relaxation, teeth apart, tongue on the palate, posture, and breathing) proposed

A B

FIGURE 22-26 Cervical posture. **(A)** Forward head with PCR: line between forehead and chin angled posteriorly. **(B)** Neutral position: line between forehead and chin is nearly perpendicular to the floor.

by Ellis and Makofsy[19] expands on the TUTALC concept, and is one way to help the patient remember and practice frequently. This helpful acronym addresses the common imbalance seen in the upper quadrant (see **Building Block 22-5**).

BUILDING BLOCK 22-5

Your patient has a history of asthma and allergies. How may this affect his or her jaw symptoms?

Mandibular and Tongue Postural Exercises Once the patient is familiar with the TUTALC position, additional mouth, jaw, and tongue posture exercises may be added to the program. Tongue push-ups may be used as an initial exercise to strengthen the tip of the tongue and familiarize the patient with correct placement.[37] The tongue tip is pointed and pressed against the hard palate, just behind the upper teeth, held and then released, and the exercise is repeated. Increase challenge by instructing the patient to "cluck" the tip of the tongue repeatedly against the hard palate at increasing speed.[42] The patient may also practice the sounds made by the letters T, D, L, and N, all of which raise the tip of the tongue to the hard palate. Words such as "Ted," "dad," "love," and "nut" can be practiced, working to add force to activate the tongue muscles.[37]

Swallowing and Respiratory Impairments

Etiology

A commonly overlooked problem in patients presenting with TMJ and craniocervical disorders is an altered swallowing sequence, which is associated with tongue thrust swallow and/or abnormal breathing. In abnormal breathing, such as mouth breathing, the tongue usually rests against the lower teeth, the teeth are apart, and the mouth remains open. This position is maintained during abnormal swallowing, causing the tongue to thrust forward. Persons who swallow abnormally usually bring their tongues forward to meet the glass or cup when taking a drink, and excessive lip activity may be evident. The hyoid bone may elevate on swallowing, and abnormal contraction of the suboccipital musculature may occur.[89]

Intervention

Funt and colleagues[37] have proposed a way of altering this abnormal swallowing pattern. The patient is instructed to drink from a cup or glass. While doing so, the patient bites the back teeth together, puts the tongue "to the spot" on the anterior palate directly behind the upper incisors, siphons the water in between the teeth, and swallows (**Fig. 22-27**). As water is siphoned during the initial phase of swallowing, the tip of the tongue should return

FIGURE 22-27 Swallowing exercise. As water is siphoned during the initial phase of swallowing, the tip of the tongue should return to its resting position. When successful, the patient will be able to swallow repetitively without movement of the facial muscles.

to its resting position without putting pressure on the posterior teeth. When this is accomplished, successive sips of water may be taken and swallowed without any movement of the facial muscles. Because a tongue thrust habit is usually well rooted, this exercise should be practiced several times daily. Once the patient is comfortable with using the new swallowing pattern for all eating and drinking activities and has learned proper posturing, he or she should begin to monitor all swallowing activities and become aware of the rest position of the tongue throughout the day, in order to assess transfer of the exercise to the subconscious level.

Proper diaphragmatic breathing is also important to normal TMJ function.[64,68,70,90–92] For more information on respiratory training techniques, please refer to the section on diaphragmatic breathing in the Thoracic Spine chapter.

The Rocabado 6 × 6

A well-known series of exercises proposed by Rocabado[93] attempts to address the multifactorial nature and management of mechanical jaw pain. Patients will often find these exercises during Internet searches for information, so the physical therapist at minimum should be aware of and able to discuss them. It includes exercises addressing the relationships between the structures of the stomatognathic system, tongue position, and diaphragmatic breathing practice (**Self-Management 22-4**). While not well validated in formal study, these exercises are generally accepted clinical practice and may provide a good starting point for exercise (**Evidence and Research 22-3**).

SELF-MANAGEMENT 22-4
Rocabado 6 × 6[91]

Purpose: To learn a new postural position, fight the soft tissue memory of the old position, restore the original muscle length–tension relationships, restore normal joint mobility and restore normal body balance.

Movement Technique:

1. Practice tongue rest position
   - Make a clucking sound with the tongue six times
   - Find normal resting position (TUTALC)
   - Diaphragmatically breathe through the nose while the tongue is in the resting position for six breaths
2. Control TMJ rotation on opening
   - Tongue on roof of mouth and open six times (see Self-Management 22-2)
3. Stabilize the mandible against resistance
   - Apply light resistance to opening, closing, and lateral deviation with the jaw in a resting position (see Self-Management 22-3), holding each position for 6 seconds
4. Upper cervical flexion (nodding)
   - Nod head slightly up and down (approximately 15 degrees) six times
5. Lower cervical retraction
   - Tuck your chin slightly back toward throat and hold 6 seconds.
6. Shoulder girdle retraction
   - Pull your shoulder blades back and down toward opposite hip pockets and hold 6 seconds

Dosage: Sets/Repetitions: Do each exercise in the series six times.
Frequency: Perform the series six times per day.

EVIDENCE and RESEARCH 22-3

Does the 6 × 6 Series Work?

In a randomized double-blind controlled study, Mulet et al.[94] evaluated whether the 6 × 6 exercise series proposed by Rocabado added value to a self-care based program (self-care only vs. self-care + 6 × 6). They found that jaw pain and neck pain intensity showed a statistically and clinically significant improvement within both treatment groups, and there was no difference between groups. There was no clinically or statistically significant change in head posture for either group. In this study, therefore, the addition of the 6 × 6 exercises did not change the outcomes compared to self-care alone, nor did they alter head posture during the 4-week study.

THERAPEUTIC EXERCISE FOR COMMON DIAGNOSES

In the typical physical therapy setting, the most common disorder of the TMJ is dysfunction involving the capsule and intra-articular structures. Some of the more common intra-articular diagnoses of the TMJ are reviewed in the following sections. Remember to consider the possibility of more serious pathologies and refer to an orofacial medical specialist (MD or DMD) for further investigation and management if appropriate.

With any TMJ issue, the therapist should remember to consider the cervical spine's influence, including the suprahyoid-infrahyoid length–tension relationship and its influence on tongue physiology and the resting position of the jaw.[95,96] Treatment of the cervical spine, based on the evaluation findings, may be directed at postural corrective exercises for the head and neck, releasing myofascial restrictions, restoring joint mobility, or providing segmental stabilization exercises for hypermobile segments.[97] Refer to Chapter 23 for more information (**Evidence and Research 22-4**).

EVIDENCE and RESEARCH 22-4

Effect of Head Position on TMJ Mechanics and Pain

Twenty-nine TMJ patients were evaluated for maximum mouth opening (MMO) and pressure-pain threshold (PPT) in neutral, retracted, and forward head positions. Significant differences were found in both MMO and PPT between the three positions. Mouth opening was greatest in the forward head position, and lowest in craniocervical retraction. PPT was highest for neutral position, and worst in FHP. These findings support the biomechanical relationship between the craniocervical region and the temporomandibular joint; they also support the theory that patients may be more sensitive to pain in different craniocervical postures.[17]

Capsulitis and Retrodiskitis

Etiology

Overloading of the joint from bruxism, excessively hard chewing, trauma, strain, or infection may cause an inflammatory response in the fibrous capsule, synovial membrane, and retrodiskal tissues. This condition is called capsulitis. Parafunctional habits can alter the normal pattern of masticatory behavior and lead to asymmetric muscle activity, altered muscle length, and mandibular malalignment. Overload problems are often related to emotional stress which is correlated with increased muscular tone and excessive muscular activity.[32–34]

Retrodiskitis occurs with encroachment of the condyle on the articular disk. This may directly cause inflammation or may exacerbate an existing inflammatory condition. It can occur gradually, as a result of chronic repetitive microtrauma when the condyles are displaced posteriorly because of anterior disk displacement, or by acute external trauma to the chin, forcing the condyles posteriorly into the retrodiskal tissues.

Persistent, subtle changes in joint kinematics may cause muscular imbalance between the elevators and the depressors and produce abnormal stresses sufficient to result in improper loading of the articular cartilage. This pattern can lead to potential fatigue failure and possible arthritic changes in the articular cartilage. Repeated overload leads to microtrauma and an inflammatory reaction in the capsule, the peripheral parts of the disk, and the lateral pterygoid insertion. The overfatigued lateral pterygoid's ability to control disk movement during jaw movements can be upset and result in disk derangement and damage.[30]

Signs and symptoms of capsulitis include pain at rest that intensifies during functional maximum contact of the teeth (e.g., chewing) and parafunctional movements of the mandible (e.g., bruxism). Pain occurs on the side of involvement in the area of the TMJ, with possible reference of pain into areas innervated by cranial nerve V. Impairment resulting from capsulitis ranges from minor joint restriction to total immobility.

Signs and symptoms of retrodiskitis include constant pain and palpable tenderness posterior and lateral to the joint. Pain is usually increased by clenching or by moving the mandible to the affected side, which permits the condyle to press against the inflamed tissue. With swelling, the condyle may be forced anteriorly, resulting in acute malocclusion. When an object such as a bolus of food is placed between the teeth on one side, it can cause increased compression of the contralateral TMJ, as the teeth come closer together on the nonfood side. This can increase pressure in an inflamed joint, causing more pain, so—although it may be counterintuitive—the patient should be advised to chew on the involved side.[98,99]

Treatment

The therapist's choice of treatment depends on the cause and the acuity. An acute injury caused by a single traumatic event will initially make use primarily of passive interventions to decrease pain and inflammation and maintain or improve range of motion. This program may include limited mandibular function, mild analgesics, ice, and moist heat or ultrasound. Because hemarthrosis may occur in an acutely traumatized joint, measures should be taken to prevent ankylosis, with gentle, cautious movement of the joint. In the case of direct trauma such as a blow to the chin, make sure to eliminate the possibility of fracture prior to treatment.

Retrodiskal or capsular inflammation due to chronic microtrauma warrants use of more active interventions. The goals of therapy are to reduce inflammation, decrease joint compression, and alter the parafunctional activities contributing to the perpetuation of the problem. Placement of a joint-stabilization splint may reduce bruxism and decrease pressure on the joint.[100] Surface electromyography (SEMG) is often beneficial in the treatment of diurnal parafunction.[101,102] Maintaining the mandibular rest position via the TUTALC postural cue also reduces joint pressure; with the teeth apart and the lips closed, the mandible is supported in the loose-packed position of the TMJ.

After inflammation, pain, and muscle guarding are under control, a program of stretching and muscular reeducation should be instituted. The techniques discussed in the "Hypomobility" section help to restore muscle length and increase capsular extensibility. Functional kinetic exercises and strengthening and stabilizing exercises can assist in muscular reeducation and relaxation.

Internal Derangement of the Disk

Etiology

Malocclusion (i.e., overclosure of the mouth with backward displacement of the condyle) or trauma may cause derangement of the disk. Macrotrauma or repetitive microtrauma to the disk may cause tears in the capsular attachments to the disk, particularly the thin posterior ligamentous structures. This allows the disk to migrate from its normal anatomic position, typically displacing anteriorly or anteromedially. Two general classifications of this disorder are recognized: the anteriorly displaced disk that reduces during joint translation and the anteriorly displaced disk that does not reduce during joint translation.[103] These two conditions may be independent and persist indefinitely or may be one of the stages in the continuum of a disease process that leads to degenerative joint disease.[104]

Among the various theories regarding the cause of disk derangement are excessive pressure on the joint from clenching or trauma; incoordinate contraction of the two bodies of the lateral pterygoid so that the disk snaps over the condyle rather than following the movement smoothly and coordinately when the mouth is open; deterioration of the disk and cartilaginous surfaces; and stretching of the joint ligaments by frequent subluxation.[98,105,106]

Joint sounds, particularly clicking, are considered hallmarks of disk derangement. The frequency and quality of clicking or other sounds and their association with specific functional movements and pain often help to provide important clues regarding the condition of bony and soft tissues within the joint. Clicking may occur in one or both joints, and it may or may not be associated with pain. Various types of clicking noises have been observed during sagittal opening, including an opening click, an intermediate click during the opening phase, and an end-range click at full opening.

An opening click is believed to be caused as the posteriorly and superiorly displaced condyle passes over the posterior portion of the anteriorly displaced disk. This reduces the anteriorly displaced disk, bringing the condyle back into its normal position in the concave articular surface beneath the disk (**Fig. 22-28**).[104] This

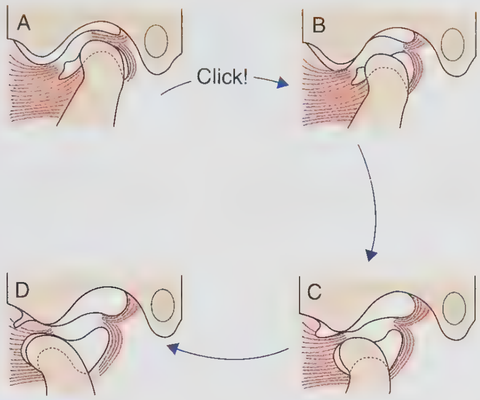

FIGURE 22-28 Mandibular depression (opening) with anteriorly displaced disk with reduction. **(A)** TMJ with the mouth closed, disk displaced anterior to the condyle. **(B)** Early in the translatory cycle, the condyle rides up on the posterior disk material, relocating the disk and causing a click. **(C, D)** Normal joint motion allows complete opening.

reduction is often accompanied by a concurrent palpable jarring of the joint. The timing of the click correlates with the severity of the derangement. A click occurring early in jaw opening indicates a small degree of anterior disk displacement; a click occurring near maximal opening suggests farther anterior displacement. Mandibular ROM is usually normal in disk displacement with reduction, and the amount of vertical opening may be greater than normal.[98]

A second, quieter click may also be detected during closing, as the condyle slips behind the posterior edge of the band of the disk, leaving the disk displaced anteriorly and medially. Clicking can worsen with time as the posterior ligamentous attachments become further stretched and damaged. In addition to clicks produced during mandibular opening, clicks may be produced by eccentric movements. These clicks may result from structural changes in the disk or incoordinate function of the parts of the joint. Inconsistent clicking during other parts of opening is probably caused by internal derangement of the disk.[107]

The sign of an anterior disk dislocation that does not reduce is the absence of joint noises combined with reproducible restrictions during mandibular movements. These restrictions are caused by the disk remaining anterior to the condyle and blocking translatory glide. This limits condylar translation in the affected joint, which restricts mouth opening. This is often referred to as a "closed lock."[108–110] A restricted maximum opening of 20 to 25 mm is the most obvious sign of an acute anterior disk displacement without reduction. Additionally, the mandible will sharply deflect to the affected side at end range, as the contralateral side continues to translate forward. Lateral excursion to the contralateral side is limited, particularly if the disk is displaced anteromedially. Over time, the closed lock may partially or even fully resolve and a more normal range may be achieved as the posterior disk attachments continue to stretch and tear.[103,111,112]

Pain due to disk derangement may be felt in the region of the TMJ on the side of involvement, with possible reference of pain into areas innervated by the trigeminal nerve (cranial nerve V). Pain increases or is altered during functional and parafunctional movements of the mandible. Most patients with chronic anterior disk displacement without reduction report a prior history of clicking and occasional locking, suggesting the disk initially reduced itself (**Evidence and Research 22-5**).

EVIDENCE and RESEARCH 22-5

Disk Morphology and Displacement

To investigate if disk morphology correlates with displacement, 218 TMJs (109 patients) were reviewed on MRI. A normal temporomandibular disk is biconcave. Imaging showed that anteriorly displaced disks that reduced were more likely to be round, hemiconvex, or biconvex, while nonreducing disks were more likely to be folded. This suggests that the type of displacement correlates with the severity of the morphologic change of the disk.[113]

Treatment

Techniques used to improve mandibular opening may be helpful in decreasing joint restrictions caused by anterior disk displacement with and without reduction. In the case of a nonreducing disk, it is important to limit intercisal opening to approximately 30 mm to protect the retrodiskal tissue from being overstretched.[87] Management of disk derangements may best be accomplished by normalization of muscle tone and function. When pain or hindrance of function is significant and therapeutic intervention and appliances are unsuccessful, consultation with an oral surgeon is indicated (see **Building Block 22-6**).

BUILDING BLOCK 22-6

What would your diagnosis and treatment plan be for the patient in the case study?

Temporomandibular Joint Clicking In a study of young adults, Au and Klineberg[52] found that clicking was a reversible condition that could be treated successfully with noninvasive isometric exercises (see Self-Management 22-1). This suggests that there may be a neuromuscular cause for many TMJ clicking problems not caused by internal derangement. In the absence of obvious malocclusion, simple exercises designed to allow controlled joint movement under load with simultaneous activity of the extensor and flexor muscles operating about the joint have been found to alleviate the annoying problem of TMJ clicking. Gerschmann[114] found that lower jaw movement protrusion/retrusion exercises done with a pencil placed between the teeth while performing chewing exercises with the pencil could decrease clicking in about 2 weeks (**Fig. 22-29**).

Anteriorly Dislocated Disk with Reduction An anteriorly dislocated disk with reduction may be treated with an anterior repositioning appliance or a nonrepositioning appliance. These are prescribed and fit by a dentist specializing in the treatment of TMD. Physical therapy modalities such as heat and ice help to decrease pain and muscle guarding, enhancing the effectiveness of the appliance. The patient and physical therapist should begin by instituting a home program to identify and decrease the incidence of parafunctional activity. The patient should be instructed in self-cueing techniques to monitor and decrease parafunctional frequency. These techniques may include: checking the position of the tongue and mandible frequently throughout the day; visual cues, such as a clock or a sticky-note

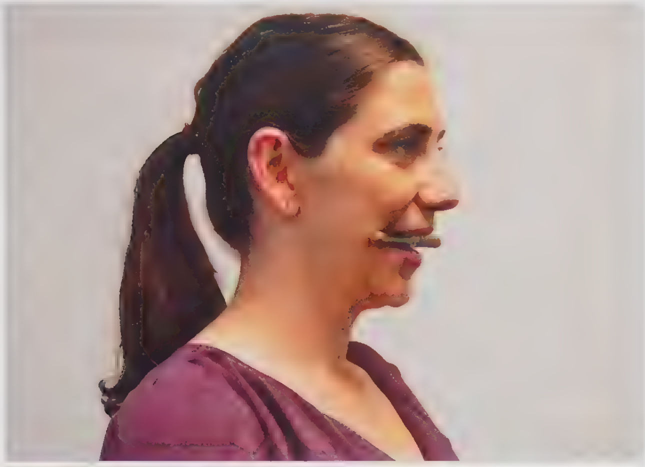

FIGURE 22-29 Chewing the pencil exercise. A soft cylindrical rod (1.5 to 2 mm) is placed horizontally at the back of the mouth. The patient is instructed to bite on the rod with a grinding movement so that the object moves forward and back with the mandible.

placed where the patient will see it; and a timer or reminder set on the patient's phone or computer. When the patient recognizes clenching or other parafunctional activity, he or she is cued to take a deep breath, exhale, and return the tongue and mandible to their resting positions. The patient may also benefit from education and exercises in facilitating relaxation of muscle tone of the jaw and cervical muscles, such as those discussed in the sections on Neuromuscular Relaxation Training.

Anteriorly Dislocated Disk Without Reduction Therapeutic modalities and soft tissue mobilization techniques, such as myofascial release and massage, can be used to treat impairments. A joint mobilization technique of distraction (i.e., caudal glide) combined with translation (i.e., protrusion) may help relocate an anteriorly displaced disk that otherwise blocks opening (Fig. 22-10A and C). If joint mobilization techniques successfully relocate the disk, proceed immediately with the treatment plan for an anterior disk dislocation that reduces.

Degenerative Joint Disease/Osteoarthritis

Etiology

Osteoarthritis of the TMJ, also called degenerative joint disease, is considered primarily a disease of middle or older age. Osteoarthritis alters the weight-bearing surfaces of the TMJ, often leading to secondary inflammation of the capsular tissue. The joint space narrows, with spur formation and marginal lipping of the joint. There is often erosion of the condylar head, articular eminence, and fossa.[30] Advanced joint disease may lead to atrophy of associated muscles. Some causes of this degenerative process include repetitive overloading and internal derangement of the disk. Moffett et al.[115] demonstrated that injury to the disk is usually followed by osteoarthritic changes on the condylar surface, which is followed by similar bony alterations on the opposing surface of the fossa. The clinical features of osteoarthritis are similar to those of other forms of joint dysfunction. Typically, pain and crepitus occur during mandibular motions; crepitus remains even once other symptoms resolve. Most persons experience some restriction of mandibular movement, although not necessarily in a capsular pattern.

Treatment

The primary therapy for DJD is directed at symptom management. Interventions may include pharmacologic management, physical therapy, and/or surgery. Conservative management includes active ROM exercises, mobilization techniques, and stretching, as discussed in the "Hypomobility" section. Graded exercises involving a few simple movements performed frequently during the day are often prescribed as a home treatment. Joint protection techniques, such as avoidance of excessive opening and parafunctional habits, and proper resting position of the tongue and mandible should be taught. Surgical intervention is reserved for patients with advanced bony changes within the joint and may include joint debridement and/or arthroplasty.

Postoperative Physical Therapy Following Surgical Intervention

Overview

Rehabilitation of the TMJ following surgical intervention can take 6 months to 1 year, and physical therapy is considered key to successful outcomes. The oral surgeon may refer the patient for a preoperative physical therapy consult, which is the therapist's opportunity to help set the patient up for postoperative success. Patient education and patient adherence are critical to successful postoperative treatment. At the preoperative visit, patients may be made aware of the surgical procedure and what to expect postoperatively. Patients should be instructed in techniques of pain control and the reduction of swelling (e.g., cryotherapy, transcutaneous electrical nerve stimulation [TENS], diaphragmatic breathing) to be used immediately after surgery. Active and passive exercises to be started after surgery can be explained and practiced at the preoperative appointment.

Postoperatively, physical therapy procedures initially consist of interventions designed to decrease inflammation, edema, reflex muscle guarding, and pain. The patient's diet is often limited to soft foods for up to 3 months, depending on the extent of surgery and possible scar growth. Again, the home exercise program is the most significant part of the patient's rehabilitation program.

Postoperative Arthroscopic Surgery

Arthroscopic surgery is indicated for diagnosis and treatment of intracapsular derangement and joint adhesions.[116] Patients are seen in physical therapy as soon as 24 to 48 hours after surgery.[117] At the postoperative appointment, the physical therapist reevaluates the patient to determine changes in pain patterns, sensation, occlusion, active motions, and evidence of intracapsular or extracapsular swelling. The therapist should make sure to discuss any postoperative protocol with the surgeon.

In most postoperative procedures, an immediate goal is to maintain the interincisal opening achieved under anesthesia by the surgeon.[87] Postoperative adhesions between the articular surfaces and the disk may occur if mobility is not maintained. Intraoral joint mobilization techniques may include distraction and lateral glides (Fig. 22-10). These techniques are designed to inhibit reformation of adhesions, decompress the TMJ, enhance synovial lubrication, promote muscle relaxation, and restore functional ROM.[12,118] Joint mobilization techniques must be performed gently and slowly within the pain-free range. They are usually done on the uninvolved TMJ as well, to prevent developing hypomobility due to disuse. Self-distraction (Fig. 22-12) may be taught to the patient if appropriate.

Studies by Osborne[119,120] and Salter[121] have shown that constant mobility after joint trauma or surgery usually lyses blood clots, forestalling organization into connective tissue. Following the surgeon's protocol as the primary guide, the therapist may choose from exercises for hypomobility, motor control, condylar rotation without translation, and mandibular stabilization. The typical postarthroscopic surgical patient is followed up for 5 to 7 weeks.[87]

If hypomobility develops as healing progresses and the problem is attributed to capsular restriction, ultrasound treatment in combination with home exercise may be more effective than home exercise program alone (**Evidence and Research 22-6**).[122] If hypomobility is attributed to fascial restriction or muscle dysfunction, refer to the techniques discussed in the sections on myogenous hypomobility and neuromuscular relaxation training.

EVIDENCE and RESEARCH 22-6

Ultrasound Enhances Home Exercise Program

While ultrasound alone is not effective in TMJ management,[123] it may enhance the efficacy of a home exercise program. In a recent study, two intervention options were investigated. The first group received home exercises with patient education and information about parafunction, while the second received intervention plus 5 days a week of ultrasound to the TMJ and masticatory muscles. Pain decreased and mouth opening improved in both cases, but the addition of ultrasound resulted in a statistically significant improvement over home exercise alone.[122]

Postarthrotomy Surgery

The most common indication for postarthrotomy surgery is a derangement of the disk that has not responded to conservative management. Arthrotomy (i.e., open joint) procedures vary, depending on the existing pathology and the technique of the maxillofacial or oral surgeon. Surgical options include disk plication and partial or total discectomy with grafts or without replacement. The degree of disk deformation and the health of the intercapsular disk attachments dictate the feasibility of the plication.

The patient is typically seen within the first 3 to 4 days postoperatively to administer appropriate anti-inflammatory modalities and to begin active or passive ROM, depending on physician protocol.[124] Most surgeons request that only active motion without resistance be used during the first 3 days after surgery, due to concern that passive mobilization may disrupt healing and cause surgical failure.[87] Once cleared by the surgeon, additional exercises may be included. These may include exercises for hypomobility, motor control, and stabilization and strength.

Physical therapy after a disk plication procedure is based on an understanding of revascularization and healing of the involved tissues. The greatest change in vascularity and healing occurs in the second and third week after surgery, and complete healing occurs in 6 weeks.[125] If a disk has been reconstructed or retrodiskal tissue repair performed, motion may be quite limited, initially allowing only condylar rotation. Splint therapy is usually an integral part of the patient's overall treatment.

ADJUNCTIVE THERAPIES

Many other interventions are available to the physical therapist for management of TMJ dysfunction. In a systematic review published in 2006, McNeely et al.[126] found some level of support for postural training, manual therapy, exercise, acupuncture and dry needling, biofeedback, and low-level laser therapy, but not for pulsed radiofrequency energy or TENS.

Therapeutic modalities such as ice or heat can help to decrease pain and muscle guarding. Soft tissue mobilization techniques may include deep pressure-point massage,[127] friction massage,[128] acupressure,[129] strain–counterstrain,[130] craniosacral therapy,[121–133] and myofascial release or manipulations.[87,134,135] Massage of the temporalis and inferior to the masseter decreases myofascial tone and may allow the therapist or patient to more easily stretch the surrounding soft tissue.[118] Ultrasound in conjunction with active motion or prolonged static stretch may be effective in increasing extensibility of the capsular tissues.[120,136]

SEMG of the muscles of mastication is used routinely by some dentists and therapists as part of the diagnosis and treatment of TMD and has been comparatively well studied. Muscle hyperactivity, spasms, and imbalance have been suggested in the literature for many years to be major features of TMJ disorders, although supporting evidence is mixed.[137–139] Records of SEMG activity before and after therapeutic intervention have been used to document changes in muscle function and have been cited as proof that the treatment was successful.[140–142] Most researchers agree that SEMG can measure a behavioral event such as bruxism or clenching.[143,144] With portable SEMG devices, relaxation of the masticatory muscles may be attained by the patient through biofeedback at home or work. A few controlled studies have shown significant reduction in diurnal masseter muscle activity by using diurnal biofeedback.[75,99] Nocturnal biofeedback exercise can produce a significant decrease in the frequency and duration of nighttime bruxism,[145–149] but the benefits of this treatment did not last long, and a return to pretreatment SEMG levels was observed as soon as biofeedback stopped.[144,145] Ultimately, though, at least one systematic review indicates that SEMG in combination with cognitive-behavioral therapy is an efficacious treatment, and SEMG alone is probably also effective.[150]

KEY POINTS

- The relationships of the head, neck, tongue, teeth, and jaw, collectively called the stomatognathic system, require a thorough evaluation and integrated treatment approach addressing both structure and function.
- Contact between the top and bottom teeth leads to weight bearing through the TMJ. Repetitive contact from parafunctional habits such as bruxism or job requirements can lead to overuse, structural changes, and pain in the joint.

LAB ACTIVITIES

1. Outline a conceptual model of musculoskeletal TMJ dysfunction and its sequelae. How might an untreated myogenous hypomobility progress over years and decades?
2. List nine generic treatment goals appropriate for treatment of a patient with musculoskeletal pain and dysfunction of the TMJ.
3. Provide an initial treatment plan with at least two exercise progressions, using the goals identified in question no. 2 for the following:
   a. Lateral pterygoid muscle spasm without capsular restriction
   b. Restricted joint play in a capsular pattern
   c. A closed-lock restriction

- Any deviation from neutral in upper cervical spine, including FHP, affects the position of the mandible, tongue, and hyoid. Long-term postural habits alter mandibular rest position, swallowing function, breathing pattern, and muscle balance.
- Proper positioning of the tongue on the roof of the mouth helps to maintain normal resting position of the mandible and promotes normal swallowing function.
- Hypomobility of the TMJ may result from various conditions involving the bones, muscles, joint capsule, retrodiskal tissue, or disk. Treatment seeks to decrease inflammation and pain and increase motion and function.
- Hypermobility of the TMJ is characterized by early and excessive translation of the mandible. Treatment seeks to increase joint proprioception and retrain motion, limiting translation through controlled motions and stabilization exercises.
- Hypermobility is usually bilateral; however, it may occur unilaterally as a result of hypomobility in the contralateral joint.
- In the case of a nonreducing disk, it is important to limit interincisal opening to approximately 30 mm to protect the retrodiskal tissue from being overstretched.
- Most studies show conservative management is the treatment of choice for TMD, but surgical intervention may be indicated if conservative methods fail. Postoperative rehabilitation can take 6 months to 1 year. Therapeutic intervention should begin as soon as possible to administer appropriate anti-inflammatory modalities and to begin active or passive ROM, following the surgeon's preferred protocol. A key postoperative exercise is teaching the patient to open the mouth with the tip of the tongue on the hard palate to facilitate joint rolling and inhibit early translation.
- Systematic reviews suggest that exercise and posture training are the physical therapist's most effective tools for managing TMD, with manual therapy also somewhat effective. Encourage patients to be actively engaged in their treatment plan and emphasize the home program as the most significant part of their rehabilitation program.

CRITICAL THINKING QUESTIONS

1. Describe:
   a. The resting position of the TMJ, considering jaw, teeth, tongue, and other associated structures.
   b. The osteokinematic and arthrokinematic motions available to the TMJ
   c. The relationship of the cervical spine and the TMJ
   d. The muscular control necessary for normal TMJ motion
2. Differentiate between:
   a. The motions available in the upper and lower joint components of the TMJ
   b. Signs, symptoms, and evaluation findings for myogenous versus arthrogenous TMD
   c. The classic signs of anterior disk displacement with reduction and an anterior disk displacement that does not reduce
3. Describe (in order) the major elements of the exercise prescription for:
   a. Hypomobility
   b. Hypermobility

CHAPTER

23

The Cervical Spine

CAROL N. KENNEDY

Therapeutic exercise interventions are crucial in the rehabilitation of any cervical spine disorder, particularly those of a recurrent or chronic nature. However, exercise programs designed for the treatment of the cervical spine cannot function in isolation. Because of the close relationship between the cervical spine, thoracic spine, shoulder girdle, and temporomandibular joint (TMJ), a complete and successful examination, evaluation and therapeutic exercise program must also address impairments in adjacent regions that contribute to activity limitations and participation restrictions. This chapter briefly reviews cervical spine anatomy and kinesiology and provides guidelines for examination and evaluation. Therapeutic exercise interventions are described for common impairments of body structure and functions and common diagnoses affecting the cervical spine.

REVIEW OF ANATOMY AND KINESIOLOGY

A detailed description of the anatomy and biomechanics of the cervical spine is beyond the scope of this chapter, and the reader is directed to other texts for this information.[1–3]

The cervical spine is composed of two functional units: the craniovertebral (CV) complex and the middle to lower cervical spine. The two units are different in structure and biomechanics, but act together to enable the large range of motion (ROM) available in the cervical spine while concurrently supporting and protecting the vital structures found in this region. One important function of the cervical spine is to place the head in space for the vital functions of sight, hearing, and feeding.

The CV complex includes the atlantooccipital (AO) and atlantoaxial (AA) joints. The biomechanics of the CV complex are governed by the articular surfaces, the complex ligamentous system, and, to a large degree, the intricate specialized muscular system.

Laxity of the CV ligamentous system results in increased motion of this complex. Signs and symptoms, such as headache, dizziness, vision complaints or altered face sensation are most likely the result of overreactivity of the articular and muscle receptors. In addition, these signs and symptoms along with more sinister complaints such as quadrilateral symptoms, ataxia dysarthria, dysphagia, or drop attacks could be related to pressure on the cervical cord or vertebral artery insufficiency.

The midcervical spine consists of the region from the C2–C3 intervertebral segment to the C7–T1 segment. Each mobile segment of the midcervical spine consists of several joints, including the paired zygapophyseal and uncovertebral (UV) joints and the interbody (disk) joint.

Panjabi[4] divided the full ROM of an intervertebral segment into two parts (**Fig. 23-1A**); the neutral zone, which is the portion of the ROM that produces little resistance from the articular structures and the elastic zone, which consists of the portion of the ROM from the end of the neutral zone up to the physiologic limit of motion. The entire cervical spine, particularly the CV region, has a large neutral zone of motion. Because of the lack of tension in the capsular or ligamentous system in this middle part of the range, there is less passive control and the muscular system must be recruited to actively control the motion in the neutral zone. If there is damage to the ligamentous system, resulting in an increased neutral zone, dynamic muscular control becomes even more important (Fig. 23-1B).

The cervical nerve roots exit from the intervertebral foramen above the vertebra, with the exception of the C8 nerve root, which exits below the 7th cervical vertebrae. The C1 nerve root exits through the osseoligamentous tunnel formed by the posterior AO membrane, which puts it at risk of impingement. As the cervical nerve roots exit the intervertebral foramen, they are surrounded by several structures, including the zygapophyseal and UV joints, cervical disk and bony pedicle.

Degenerative changes affecting any of these structures may diminish the foramen size and alter nerve function. Cervical roots 4 through 6 have strong attachments to the transverse processes. The dural sleeve at each level forms a plug that protects the nerve and cord from traction forces. Tension in

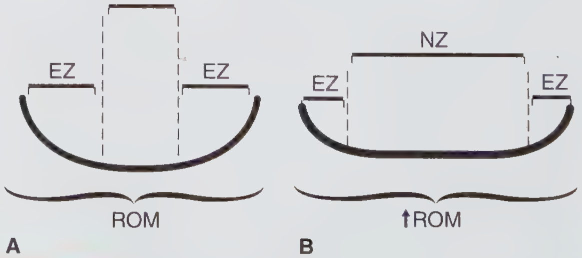

FIGURE 23-1 Neutral zone. **(A)** Normal. **(B)** Hypermobile. EZ, elastic zone; NZ, neutral zone; ROM, range of motion.

the neuromeningeal structures may produce tension on the cervical vertebrae.

Muscles

The musculature of the cervical spine is complex, and anatomy texts[2] should be consulted for descriptions of origins and insertions and their actions.

Table 23-1 lists the muscles of the CV complex and their actions. These muscles enable the specific, fine movements of the head on the neck that are required for sight, hearing, and balance. They are richly supplied with mechanoreceptors, which are integral to the muscles' strong proprioceptive function and are implicated in the production of dizziness in patients with dysfunctions of this region. The upper cervical flexors are crucial in obtaining and maintaining optimal postural balance of the head on the neck. Several long muscles, such as the sternocleidomastoid, link the head directly to the trunk.

The muscles of the midcervical spine, arranged as elsewhere in the spine, consist of slips traversing a variable number of segments. **Table 23-2** lists these muscle groups and their actions. In individuals with forward head posture (FHP), the deep anterior cervical musculature lengthens and becomes functionally weak, and conversely the posterior group tends to shorten.

As in other regions of the spine, the muscle system can be grouped into three layers: deep, intermediate, and superficial. The deep groups tend to be single segmental muscles that function as local stabilizers of the spine rather than prime movers. These muscles tend to become weak or inhibited in pathological states. The intermediate groups are multisegmental but still attach into each segment. They also stabilize the spine, particularly during movement. They often become facilitated or overactive. The superficial muscle groups have little, if any, segmental insertions and function to move and balance the head on the trunk. They generally become overactive and tight, and have a tendency toward protective spasm, resulting in inhibition of the deeper muscle groups. Despite this overactivity, the intermediate and

TABLE 23-1

Craniovertebral Region Musculature

MUSCLE	ACTION
Rectus capitis posterior minor	AO joint extension
Rectus capitis posterior major	CV complex extension and ipsilateral rotation
Superior oblique	AO joint ipsilateral side flexion and extension
Inferior oblique	AA joint ipsilateral rotation
Rectus capitis lateralis	AO joint ipsilateral side flexion
Rectus capitis anterior	AO joint flexion

CV, craniovertebral; AO, atlantooccipital; AA, atlantoaxial.

TABLE 23-2

Midcervical Musculature

	ACTION			
MUSCLE	FLEXION	EXTENSION	ROTATION	IPSILATERAL SIDE FLEXION
Longus colli	X	NA	MC–bilateral	MC–bilateral
Longus capitis	X	NA	Ipsilateral–MC	NA
Scalenes (elevates first or second rib)				
Anterior	X	NA	Contralateral–MC	X
Medius	MC	NA	NA	X
Posterior	NA	MC	Ipsilateral–MC	X
Sternocleidomastoid	X (midC)	X (CV)	Contralateral	X
Trapezius upper fibers	NA	X	Contralateral	X
Levator scapula	NA	X	Ipsilateral	X
Splenius, capitis, and cervicis	NA	X	Ipsilateral	X
Spinalis, capitis, and cervicis (inconsistent–blends with semispinalis)	NA	X	NA	NA
Semispinalis, capitis, and cervicis	NA	X	Ipsilateral	NA
Longissimus, capitis, and cervicis	NA	X	Ipsilateral	X
Iliocostalis cervicis	NA	X	NA	X
Interspinalis (most distinct in cervical spine)	NA	X	NA	NA
Multifidus	NA	X	? direction–MC	MC
Rotators (inconsistent)	NA	X	Ipsilateral	MC
Intertransversarii (most distinct in cervical spine)	NA	NA	NA	MC

MC, minimal contribution; NA, no action; X, active; ? direction: debate on direction of action superficial layers are often found to be weak when tested via manual muscle test.

Deep Cervical Flexors

The deep neck flexors (DNF) include rectus capitis anterior minor, longus capitis, and longus colli. These muscles function as deep segmental stabilizers of the cervical spine. Contraction of these muscles decreases the cervical lordosis. Longus colli has been shown to be active bilaterally as a stabilizer during talking, coughing, swallowing, and rotation/side flexion motion of the head and neck. The deep anterior segmental muscles have been shown to weaken and lose their endurance capacity in various types of cervical spine dysfunction, thus producing loss of dynamic stability.

Suprahyoid and Infrahyoid Muscle Groups

The suprahyoid and infrahyoid muscle groups are primarily involved in the functions of swallowing, speech, mastication, and the TMJ. These muscle groups are discussed in Chapter 22. This muscle group can also assist in flexion of the cervical spine. However, they are inefficient and produce excessive shear forces at the TMJ. Dysfunction of these muscle groups can have a significant effect on cervical posture as well as the TMJ; as such, they should be assessed in persons with chronic neck conditions.

Scalene Muscle Group

Of particular clinical interest is the scalene muscle group. These muscles have a tendency to become dominant neck flexors, especially the anterior scalene, and are also often overused during a poor pattern of apical respiration. Because of the angle of pull, increased muscle activity creates compressive and lateral forces on the intervertebral segment. Because of its insertion onto the first and second ribs, the increased activity can elevate these ribs. This elevation decreases the space available in the thoracic outlet, which can eventually lead to the symptoms of thoracic outlet syndrome (TOS). Adaptive shortening of this group also can impinge on the cervical nerve roots as they travel between the anterior and middle scalenes.

Sternocleidomastoid Muscle

With FHP, the sternocleidomastoid muscle (SCM) tends to shorten, increasing the compression load on the cervical spine. It is a prime mover of CV extension and head on trunk flexion, but the movement pattern it produces causes substantial amounts of anterior translation of the spine. When flexing the head forward on the trunk, it may increase cervical lordosis. A study by deSousa[3] demonstrated sternocleidomastoid activation in both cervical extension and flexion.

Cervical Extensors

The deep segmental stabilizers in the posterior aspect of the spine are the posterior suboccipitals, multifidus, and interspinalis. The middle layer of the erector spinae, specifically semispinalis cervicis and longissimus cervicis, also have segmental insertions and likely act primarily as stabilizers, as suggested by Conley et al.[5] The cervical extensors also play a role in producing and controlling rotation. These muscles have been shown to both shorten and weaken in the presence of cervical dysfunction, possibly secondary to shortening with a FHP, or reflex inhibition from underlying joint pathology and pain. The more superficial erector spinae muscles tend to extend the head on the trunk. As mentioned previously, SCM is also an upper cervical extensor and increases the cervical lordosis.

Levator Scapula and Upper Fibers of Trapezius

Several muscles create movement in both the cervical spine and shoulder girdle. The levator scapula and the upper fibers of the trapezius originate at the scapula and have broad insertions into the cervical spine. Alterations in the shoulder girdle resting position change the length of these muscles, affecting the cervical spine as well. For example, a depressed scapular resting position lengthens the upper fibers of the trapezius muscle and produces a lateral translation and compression force on the cervical spine. These continuous translational forces on the cervical spine can eventually lead to hypermobility in certain planes of movement and subsequent restriction of motion in other planes.

EXAMINATION AND EVALUATION

Examination of the cervical spine should include evaluation of the entire spine, particularly the thoracic region, as well as the TMJ, and shoulder girdle complex. These regions directly influence the posture and mobility of the cervical spine. The clinician must have the knowledge and skills necessary to perform all the appropriate tests to diagnose impairments related to activity limitations and participation restriction in the cervical spine.

History and Clearing Tests

In addition to the questions included in any musculoskeletal subjective examination, some questions specifically address the cervical region. These questions are detailed in texts such as Grieve's *Common Vertebral Joint Problems*.[6] In addition, functional questionnaires provide an excellent baseline determination and can be used to monitor the progress of treatment over time. For example, the Neck Disability Index[7] provides a reliable and valid measure of cervical spine disability.[7]

Shoulder girdle tests should be performed on the patient if indicated by the subjective history and outcomes of postural alignment tests.

Physical Examination

Standing alignment should be assessed in all three planes. The examination includes the spinal curves (i.e., CV region, midcervical region, and cervicothoracic [CT] junction), pelvic alignment, and the scapular resting position.

Sitting alignment should also be evaluated in all three planes. The examiner should observe the patient for changes that occur from standing to sitting. In addition, supine alignment also is evaluated. Various motion tests are used to assess the patient's flexibility and ability to move in certain ways. The clinician should note which examination procedures recreate the patient's symptoms as well as identify impairments that directly relate to the patient's activity limitations. The clinician should assess the following:

- Active ROM
- Combined movements
- Foraminal compression tests
- Assessment of cervical spine passive mobility
  - Passive intervertebral movements
  - Passive accessory vertebral movements
- Stability tests
- Vertebral artery tests
- Neurologic testing
  - Dermatomes (sensation)
  - Myotomes (motor activity)
  - Deep-tendon reflexes
- Assessment of neuromeningeal extensibility
  - Upper limb neurodynamic test
    - Median nerve bias
    - Radial nerve bias
    - Ulnar nerve bias
- Muscle performance
  - Ability to recruit appropriate muscles
  - Strength and endurance assessment
  - Assessment of myofascial extensibility
    - Muscle lengths

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON IMPAIRMENTS OF BODY FUNCTIONS

Any comprehensive therapeutic exercise program for the cervical spine must address the impairments that are directly related to activity limitations and participation restriction. This section describes exercise interventions for impairments of muscle performance (including endurance), mobility (i.e., hypomobility and hypermobility), and posture. Appropriate modifications may be necessary for some patients, depending on their signs and symptoms.

Impaired Muscle Performance

Etiology

Over the past two decades, many studies have investigated the motor dysfunction that is present in patients with neck pain. Regardless of the cause of the neck pain, both the flexors and extensors, deep and superficial, show deficits in strength, endurance and fatigability. In addition, these muscle groups show deficits in motor recruitment, with a tendency toward overactivity or dominance of the superficial muscles and inhibition of the deep stabilizing muscles (**Evidence and Research 23-1**). These deficits have been seen in patients with:

- Cervicogenic headache (CHA)[8]
- Mechanical neck pain[9]
- Osteoarthritis[10]
- Whiplash associated disorder (WAD)[11]

EVIDENCE and RESEARCH 23-1

Muscle Strength and Patterning Deficits

Studies of patients with CHA symptoms have found decreased maximal isometric strength and endurance of the short upper cervical flexor muscles compared with those of normal subjects.[8] A group of patients with mechanical neck pain also showed significant weakness of the neck flexor muscles compared with controls.[9] A study of patients with osteoarthritis showed more pronounced fatigue curves for anterior and posterior neck muscles than for the muscles of normal subjects.[10,12] This finding was more pronounced on the painful side of the neck.[13] Subjects with neck pain showed a decrease in EMG output of the DNF muscles during a craniocervical flexion test.[14] Patients with WAD show an inability to isolate and isometrically contract the DNFs as well as early and excessive activation of both the anterior scalene and SCM muscles.[11,15] Similar impairment of the extensors has also been found, although the effect seems to be greater on the flexors.[16,17]

Other findings include:

- Atrophy, fatty infiltration, and other histological changes in both flexor and extensor muscles (**Evidence and Research 23-2**)
- Timing delay in activation of the neck stabilizers during arm movement perturbations
- Excessive activity and delayed relaxation times of neck and shoulder girdle muscles post-activity (**Evidence and Research 23-3**)

EVIDENCE and RESEARCH 23-2

Muscle Changes

On real-time ultrasound and magnetic resonance (MR) imaging, atrophy of both multifidus and semispinalis capitus, the deep and intermediate groups, have been found in subjects with neck pain.[18-21] The atrophy was more profound on the side of the pain. Transition of muscle fiber type[22] as well as fatty infiltration of the deep anterior and posterior cervical muscles.[23-26] has been demonstrated in subjects with cervical pain, causing a loss of tonic function.

EVIDENCE and RESEARCH 23-3

Timing Delay and Relaxation Times

Falla et al.[27] found a timing delay for all cervical flexors, particularly the DNF group during arm movements, suggesting a lack of control of the neck with arm activities in patients with neck pain. During simulated keyboarding tasks, there is increased activation of upper fibers of the trapezius, SCM, and the anterior scalenes, but less activation of the cervical extensors.[28-31] This was more profound in patients with WAD as compared to patients with mechanical neck pain, with both being increased over controls. Following repetitive arm movements, relaxation times for the excessive muscle activity are prolonged in subjects with neck pain, again more noticeably in the WAD subgroup.[28,29,32-34] The superficial neck muscles also demonstrated increased relaxation times following a head lift.[32]

Changes in motor function have been shown to occur quickly after the onset of neck pain.[35] Despite complete resolution of symptoms, these motor impairments have been shown to remain and may contribute to the high recurrence rate of neck pain.

In a systematic review[36] of the conservative management of subacute and chronic mechanical neck pain, the authors found that the multimodal approach of a combination of manual therapy and exercise demonstrated strong evidence of benefit for long-term pain reduction, improved function, and positive global perceived benefit. There is also moderate to strong evidence supporting the use of strengthening, stretching, and proprioceptive exercises.[36–38] Several studies have shown improvements related to cervical exercise to be maintained over the long term of 1 to 3 years.[39–41] Patients receiving supervised and individually tailored exercise programs have been shown to achieve greater improvement than those instructed in an unsupervised home exercise program.[42,43]

Although it is clear that cervical exercise programs are an important and effective component in the management of neck pain, the most effective type of exercise has not yet been determined.[44] Various approaches of low load supported nod exercises, higher load head lift exercises and resisted exercises have all been found to be effective in terms of reducing pain and improving function, but not necessarily superior to each other.[45–49] Although higher loaded exercises do seem to be more effective in increasing overall strength,[48,50] lower load exercise has been shown to be superior for postural control and normalizing movement patterns.[51,52] The higher load programs may not be appropriate for patients with higher pain levels and irritability. Gains made with an exercise appear to be directly linked to the mode of that exercise (**Evidence and Research 23-4**). As such, it is important to include various types of exercise when designing comprehensive cervical rehabilitation programs.[53]

EVIDENCE and RESEARCH 23-4

Mode of Exercise

O'Leary et al.[53] compared three different modes of cervical exercise over a 10-week training time frame: a coordination task that used the Craniocervical Flexion Test protocol with a Pressure Biofeedback Unit to retrain motor patterning, a strength/endurance exercise group, and a mobility control group. All three groups achieved improvement in pain and disability, but each group improved predominately in the motor performance of their assigned mode of exercise, with only minimal change in the other domains.

Exercise dosage should be determined on an individual basis, depending on the characteristics of the patient's presentation; type of pathology, pain intensity, irritability, as well as the aim of the exercise; recruitment, patterning, strength, or endurance. A better response seems to occur when loads are initially very low (less than the weight of the head) and progressed slowly. An exercise is considered too difficult or is stopped when it produces pain, muscle tremors occur because of fatigue, or the exercise cannot be executed correctly. The endurance function of many of these cervical postural muscles should be emphasized by encouraging longer, sustained contractions.

Therapeutic Exercise Intervention

Deep Cervical Flexors The most common muscles to become weak with neck dysfunction are the deep, single segment cervical flexors. It is important to teach the patient to isolate these dynamic stabilizers without substituting with the more superficial muscle groups, such as the SCM and scalenes. The primary exercise to recruit these muscles is the DNF nod exercise of CV flexion, continuing segmentally into midcervical flexion. During this exercise, it is important to control the tendency to substitute with the overactive superficial flexors that would excessively translate anteriorly (see **Patient-Related Instruction 23-1**). If done initially in the upright position at the wall (**Fig. 23-2**), the exercise is gravity assisted, but the head must stay back in contact with the wall at all times to prevent any forward movement that would change the exercise into an eccentric contraction of

Patient-Related Instruction 23-1

How to Activate Your Cervical Core Muscles

What are the cervical core muscles?

The cervical core muscles work together to provide deep segmental stability of the cervical spine and maintain optimal posture of the head on the neck with dynamic extremity and trunk movements. They also enable specific, fine movements of the head on the neck. The cervical core consists of the deep cervical flexors at the front of the neck and the deep cervical extensors at the back.

How do you activate the cervical core muscles?

The cervical core muscles are the most common muscles to become weak for those who suffer from neck pain; therefore, it becomes very important to retrain them. It is important for you to learn how to isolate the cervical core muscles without substituting larger, superficial muscle groups. Cervical core recruitment must be mastered before using them with more challenging exercises.

Start in either a lying position with the head supported, or up against the wall with your head in contact with the wall. To contract the deep cervical flexors, gently nod the head so flexion occurs only at the junction between the head and the neck. Head motion should occur about an imaginary axis that runs through your ears. You can progress the movement down toward the middle of your neck, but do not lift your head up off the ground or away from the wall. Do not allow superficial muscles such as the sternocleidomastoid and scalene muscles to activate. Your therapist will instruct you in palpating for the superficial muscles.

Slowly return to the neutral position. Think about moving one vertebrae at a time. Do not allow superficial neck extensor muscles such as the erector spinae to activate by pushing your head back into the surface.

Practicing to activate the deep cervical core muscles in many different positions is important before learning to use them with dynamic activities. Usually, it is best to start to practice in either lying or upright against a wall, but you can practice cervical core activation in the following positions:

_________ Standing _________ Backlying _________ Sitting
_________ Quadruped _________ Walking

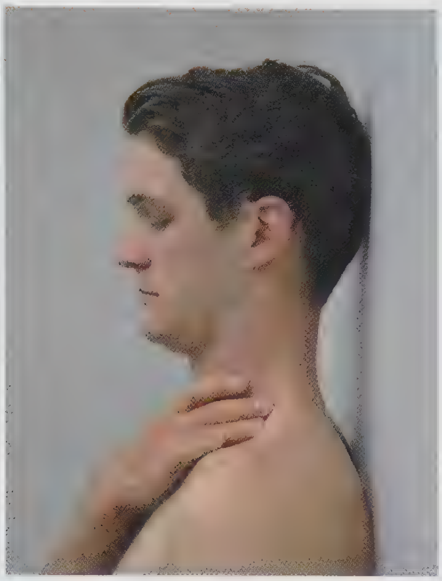

FIGURE 23-2 Standing deep neck flexor nod: for deep flexor muscle recruitment, the patient's hand palpates for unwanted superficial muscle activity as the head slides up the wall.

the cervical extensors. The retracted position also discourages the use of the SCM muscle. The patient is taught to palpate at the front of the neck for any unwanted contraction of the SCM or scalene muscles and to rest the tongue on the roof of the mouth to inhibit hyoid muscle activity.

The patient slowly nods the chin down, while sliding the back of the head up the wall. The nod is stopped at the furthest point in range that can be achieved without superficial activity, held for 10 seconds to encourage the endurance function, and is repeated 10 times. The assistance of gravity can be decreased by performing the exercise supine on an incline board, with difficulty increased by progressively tilting the board backward toward horizontal.

When this same nod exercise is performed with the patient supported in supine (**Fig. 23.3**), the DNFs work against the slight resistance of gravity theoretically making the exercise more difficult. However, this position is both well supported and non–weight bearing, so for some patients this might be more easily executed than at the wall, despite the gravity assist. The head is positioned in neutral, either resting on a pillow, or with a small folded towel placed under the occiput as needed to achieve a neutral posture. A small rolled towel can be placed under the hollow of the midcervical spine to support the normal cervical lordosis. As a low load recruitment exercise, the head nod is performed with no lifting of the head off the surface, with the patient again palpating anteriorly to ensure no superficial muscle activity. The patient is also instructed to avoid using a neck retraction strategy as compensation during this exercise. If the patient is unable to obtain much excursion of motion because of tight extensors or an extremely ingrained pattern of superficial recruitment, the exercise can be started in a more outer range of some extension, nodding toward neutral. Using eye motion to look down as the movement is initiated can also assist in correct muscle activation.

FIGURE 23-3 Supine deep neck flexor nod: deep flexor muscle recruitment, palpating for unwanted superficial muscle activity performed in lying with or without a pillow or towel roll.

The DNF nod exercise can also be performed in a prone position over an exercise ball or in the four-point kneeling (FPK) position. In this position, gravity draws the head forward into a position of upper cervical extension. The head is drawn back in line with the trunk and then the head nod motion is performed, while maintaining this position. This exercise recruits the upper cervical flexors only; gravity is assisting the lower cervical flexors in this position. If the patient maintains the retracted neutral posture of the spine while nodding, it is very difficult to substitute with SCM because this muscle protrudes the neck, and so this is a useful option for patients with very dominant SCM muscles.

Eventually, the patient should be progressed to higher load exercises to increase strength, rather than just recruitment. Auto-resistance, where the patient provides their own resistance to the exercise, can be applied to the head nod motion to increase the load. Resistance must be applied at such an angle to appropriately resist the head nod motion and not encourage a head forward translation movement (a shearing motion). Resistance under the chin rather than at the forehead can encourage the proper movement pattern. This is considered an easier progression than head lift exercises, as the auto-resistance can be graded to be substantially less than the weight of the head.

Further progression to strengthen the entire flexor group would add the weight of the head as resistance in several options of a head lift exercise in supine. An isometric neutral head lift (**Fig. 23.4**) can be performed by nodding the CV unit to neutral and then lifting the head off the surface to add the load. The neutral posture of the neck must be maintained using a balance of both deep and superficial muscles, not allowing dominant superficial muscles to cause an anterior translation. The patient no longer palpates the front of the neck, because the superficial muscles must now be active to lift the weight of the head against gravity. If there is proper balance between the deep and superficial muscles, the patient will be able to maintain the neutral CV position while holding the weight of the head.

As an alternate, a nod lift-off motion can be performed supported on a high incline (**Fig. 23-5**). The patient is instructed to nod to the point of CV neutral and then nod further to just lift the head off the supporting surface to take the weight of the head as resistance not allowing any anterior translation. The patient will progress to holding this sustained neutral position for 10 seconds, repeating 10 times and gradually working up to three sets. The exercise can be further progressed by gradually bringing the incline down toward the horizontal, as long as the patient can control the neutral posture of the neck.

FIGURE 23-4 Neutral head lift: for strengthening of the entire flexor synergy, the head is nodded to craniovertebral (CV) neutral and then lifted off the surface and held. The patient no longer palpates, because the superficial muscles have to be active to lift the weight of the head against gravity. A loss of CV neutral would indicate dominance of the superficial muscles over weak deep neck flexor muscles.

FIGURE 23-5 Incline nod lift-off: a nod lift-off motion can also be performed supported on a high incline. The patient is instructed to nod to the point of cervical spine neutral and then nod further to just lift the head off the supporting surface to take the weight of the head as resistance. The neutral posture of the neck must be maintained, not allowing dominant superficial muscles to cause anterior translation.

Another option is an isotonic exercise, such as performing a segmental flexion curl-up in supine. The head lift pattern should be segmental, starting at the head with a CV nod and continuing a curl-up into full flexion without lifting the thorax or shoulders off the surface (**Fig. 23-6**). The chin should remain tucked throughout the lift; if the chin comes forward, this is a sign of excessive anterior translation caused by relative dominance of SCM and scalenes over weaker DNFs. The ROM allowed depends on the muscle balance and the ability to continue the neck curl without anterior translation. A towel roll under the neck can be used as a fulcrum and provides feedback for the segmental motion pattern. A head nod into a flexion quadrant (e.g., flexion, side flexion, rotation to the same side) emphasizes contraction of the flexors more unilaterally and may be appropriate in cases of asymmetric weakness.

FIGURE 23-6 Segmental flexion curl-up head lift: isotonic strengthening of the full flexion synergy with bias toward the group. Starting with a craniovertebral nod, the patient continues to nod segmentally to full range of flexion, ensuring that the chin remains tucked throughout. A towel roll can be placed under the neck to act as a fulcrum to encourage the correct movement pattern.

The choice of head lift options is dependent on several variables, and there is not a fixed stepwise progression through the three options as different patients find some exercises more challenging than others. Some patients find that the isometric hold is easier to perform, while others find that moving through the range is less challenging than holding the sustained contraction. The lift on the incline is often easier as there is less gravity resistance than in supine. The segmental curl-up pattern adds another element of motor control that may be more challenging for some. As well as the type of motor function required (isometric vs. isotonic), the recruitment pattern of the deep and superficial muscles is also different, with the segmental curl-up head lift biasing toward greater contribution of the deeper muscles[54] (**Evidence and Research 23-5**). Identifying the patient's activity limitations and determining how the cervical muscles are utilized for that activity will dictate the type of muscle contraction that is the most appropriate for that particular patient.

EVIDENCE and RESEARCH 23-5

Choice of Head Nod/Lift Exercise

Cagnie et al.[54] used functional MR imaging to evaluate the recruitment patterns of longus capitus, longus colli, and SCM during three cervical flexor exercises: supported head nod, neutral CV head lift, and combined CV flexion with neck flexion (curl-up). During the head nod exercise, the longus capitus showed significantly higher recruitment than the other two muscles, with minimal activity in SCM, making this an excellent choice of exercise to isolate that DNF muscle. All three muscles were strongly activated during the neutral CV head lift action, suggesting that this higher load exercise trains the full flexor synergy more equally. There was significantly more activity in the two deep flexors compared to SCM during the combined nod and curl-up lift task showing preferential activation for the deep over the superficial flexors, although because of its larger cross-sectional area, SCM would still be considered the main contributor to lifting the head.

To increase the resistance of the exercise, an elastic band can be looped around the head. In sitting with the band secured behind the head, the patient adopts a neutral spine posture. While maintaining a neutral chin nod position, the patient leans forward at the hips, creating an isometric load to the cervical flexor muscle group (**Fig. 23-7A**). Alternatively, the patient can perform isotonic flexion against the band resistance, starting at the CV region and progressing segmentally down the cervical spine. The therapist must cue the patient to use a nodding action and to avoid anterior translation or shearing. In standing, a forward lunge can be used to increase the tension in the band and because of the additional balance challenge, there is a dynamic component to this exercise (Fig 23-7B).

Table 23-3 outlines potential exercise progressions for the cervical flexor muscle group from low load recruitment of the deep stabilizer muscles to higher load strengthening of the full flexor synergy.

Cervical Extensor Muscles Both the deep and middle layers of the cervical extensors atrophy and decrease in strength and endurance in response to neck pain. The use of electrical muscle stimulation is effective in the initial stages of retraining, especially when the patient has a high level of pain that precludes resisted exercise. With the patient lying supine with the head supported, small electrodes are placed over the extensor muscles bilaterally at the vertebral level with poor segmental recruitment. Contraction should be a sustained tonic hold, and the patient can simultaneously perform a nod to obtain cocontraction of both the flexors and extensors.

A 'muscle energy' type technique (MET) can be used to encourage a localized contraction of the weak suboccipital or multifidus muscle at the involved segment as determined on assessment (**Fig. 23-8**). The patient can then be taught to apply auto-resistance to the contraction of a specific muscle. For example, a weak superior oblique muscle can be retrained by applying auto-resistance to AO joint side flexion into extension on the same side (**Fig. 23-9**). Contraction of the multifidus at the C4–C5 level can be obtained by pressure applied to the C4 lamina, as the patient attempts side flexion to the same side into extension. Schomaker et al.[55] found that resistance applied bilaterally at the vertebral arch of C2 was more effective in preferentially recruiting deeper rather than superficial extensors, as compared to pressure at the occiput or C5. Resistance to a nod-retract motion can be applied by gently pushing the head back into hands at the back of the head, a wall in standing or a pillow in supine.

A study by Mayoux-Benhamou et al.[56] suggested that the motions of return to neutral (RTN) from the flexed posture, and retrusion, are less likely to recruit the superficial extensors. If this motion is performed segment by segment, it is likely that the segmental extensors will need to be recruited. The patient starts in the forward flexed position and initiates the extension in the thoracic spine first, starting at the lower segments, and sequentially extending until the trunk is in an upright neutral position, avoiding overextension. As the motion moves into the cervical spine, the chin tuck position is maintained as the patient continues to extend segmentally, incorporating a component of slight posterior motion (**Fig. 23-10**). The patient should be cautioned to avoid excessive retraction of the neck as this is not the cervical neutral posture. Maintaining the CV region in flexion until the end of the motion will tend to inhibit the superficial capitis group of the erector spinae muscles. Tactile cues can be given at each level to encourage the segmental nature of the motion.

The extensor recruitment exercise can be progressed by performing the motion in the FPK position to initiate resistance against gravity (**Fig. 23-11**). The patient starts the exercise in the quadruped position with the head hanging into full flexion with the thorax dropped between relaxed scapulae. The patient is instructed to bring the thoracic spine to neutral. While keeping the chin tucked, the patient segmentally draws the head up in line with their body, starting at the lower cervical spine. The final step is to release the chin tuck to neutral, while still maintaining the head back in line with the body. This position is held for 10 seconds, before reversing the movement pattern. The FPK position

TABLE 23-3

Cervical Flexor Exercise Progressions

CERVICAL FLEXOR PROGRESSIONS			
EXERCISE	PURPOSE/AIM	MODIFICATIONS	POINTS
Low Load	Recruitment/isolation/pattern/ down-train superficial		Monitor superficial muscle activity—palpation 10 repetitions/hold 10/2×/d + additional practice throughout day
DNF nod: upright	Gravity assisted	Sit Stand	Head must stay in contact with the wall More difficult if poor posture—sitting position may help this
Supine	Slight gravity load	With pillow and roll No pillow No roll	Practice with PBU in clinic
FPK	Particularly useful to reduce SCM activity		Only activates the upper cervical flexors Also recruits cervical extensors to hold neutral neck posture
Light Load	Early strength for DNF		Reeducate the pattern/balance superficial + deep
Auto-resisted nod		Isometric Isotonic Hand—ball—spring system	Apply resistance under chin to encourage nod pattern Can be very light initially Can also progress to much stronger contraction
Higher Load	Strengthening of flexor synergy with DNF focus	**Choose order of progression individually dependent on which mode is easier to most difficult	No longer palpate superficial muscle activity Instead monitor excessive use causing chin poke or shift Work up to three sets of 10/1×/d
Incline nod lift-off	Isometric neutral hold—less gravity		Progress by lowering the incline
Neutral head lift	Isometric hold		A bit more flexed position than incline lift-off
Segmental flexion curl-up head lift	Isotonic, through range	With/without roll	Larger relative contribution of deeper muscles But need more motor control
External Load	Strengthening	Elastic, pulleys, free weights	Could use light band to be less load than head lift
Neutral forward lean	Isometric hold of neutral	Sit	Watch for anterior translation
Segmental neck flexion	Isotonic, through range	Sit Stand	Watch angle of band to encourage nod pattern
Forward lunge	More perturbations More functional		Start slow and controlled Increase speed Incorporate function—arm movements/ movement patterns

DNF: deep neck flexors; SCM: sternocleidomastoid; PBU: pressure biofeedback unit; FPK: four-point kneeling.

can be considered quite functional for those who lean forward in their jobs or for sports such as cycling. This exercise also encourages dissociation between the neck and thorax which may be difficult for those who have been adopting a protective bracing pattern. Prone on elbows is an alternate position to use. A similar exercise can be performed prone over an exercise ball and arm movements can be added to add a scapular stabilization component.

The exercise can also be performed into further extension of the cervical spine or into the extension quadrant position to target the muscles unilaterally. The chin remains relatively tucked as the head is lifted beyond neutral to prevent the collapse of the mid-cervical spine. Adding arm motion further challenges the maintenance of the cervical neutral posture and with multiple repetitions, would also reinforce the endurance requirements of these muscles.

Elastic band resistance can also be used to load the cervical extensors. The patient can perform a seated neutral lean back against the tension of a band, which is secured in front of them. Additionally, to increase load and add a dynamic component, the patient can perform a backward lunge as described for the cervical flexors.

Table 23-4 outlines possible progressions of exercises for the cervical extensor muscle group.

FIGURE 23-8 Therapist-directed deep extensor recruitment: with the patient sitting, the therapist palpates at the affected level as the patient recruits the segmental extensor against the localized resistance of the therapist.

FIGURE 23-9 Auto-resisted extensor recruitment: retraining a weak right superior oblique muscle by applying auto-resistance to atlantooccipital joint side flexion into extension on the same side.

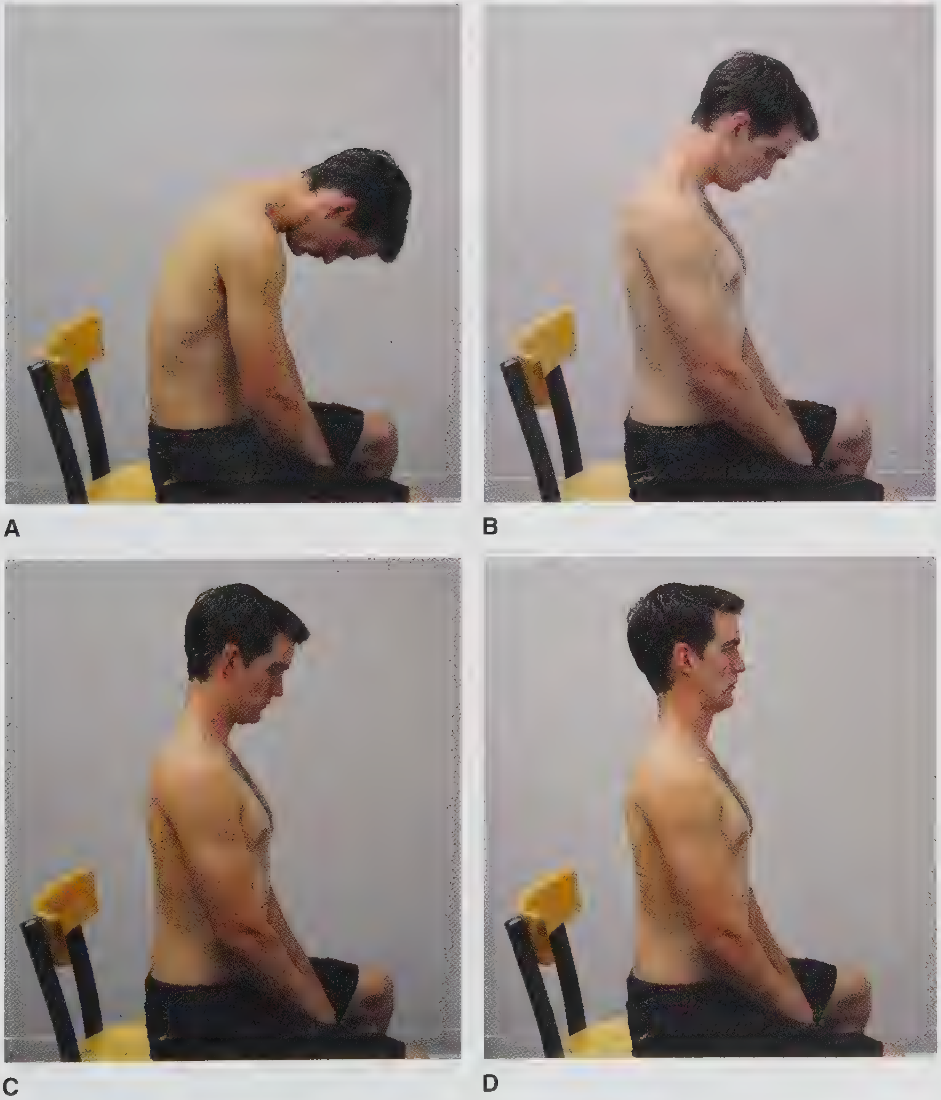

FIGURE 23-10 Return to neutral in sitting: segmental extension movement pattern to recruit the deeper extensors. **(A)** Start in the forward flexed position. **(B)** Keeping the head dropped forward and the chin tucked, initiate segmental extension starting at the mid to upper thoracic spine, lifting up through the sternum. **(C)** Keeping the chin tucked, continue the extension into the lower cervical segments, drawing the head and neck back in line with the trunk. **(D)** Lastly, the chin tuck is released to neutral while avoiding craniovertebral shearing. The pattern is reversed to lower the spine back down to the starting position.

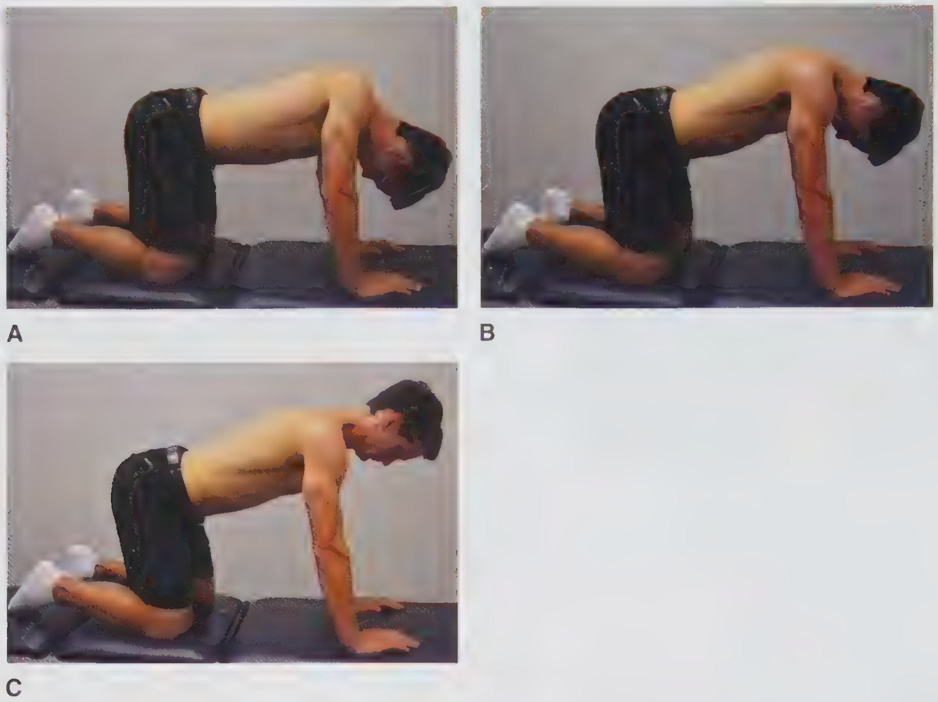

FIGURE 23-11 Return to neutral in four point kneeling (FPK). **(A)** Start position is in FPK with the head hanging and the thorax sagging between the scapulae. **(B)** The patient presses up between the scapulae to bring the thorax into a slight, neutral thoracic kyphosis. **(C)** Keeping the chin tucked the patient draws the head back in line with the trunk and then releases the nod to the neutral position, holding for 10 seconds. The movement pattern is then reversed back to the start position.

TABLE 23-4

Cervical Extensor Exercise Progressions

CERVICAL EXTENSOR PROGRESSIONS			
EXERCISE	**PURPOSE/AIM**	**MODIFICATIONS**	**POINTS**
In clinic options:	Teach patient how to find the extensors		Not as a mobilization—as a segmental muscle recruitment technique
MET			
EMS		+/− simultaneous nod	
Lower Load	Recruitment/isolation/pattern		
Auto-resisted		Segmentally Or a more general multisegmental quadrant motion	Resist at C2 has been found to recruit deeper rather than superficial layer
Resisted nod-retract	Less superficial activity with retract than tip back into extension	Hand/wall/into pillow	Push back pattern rather than tip back
RTN in sitting	Segmental extension followed by eccentric control on segmental flexion	Back on chair or at wall	
Higher Load	Strengthening of extensor synergy with deeper layer focus		
RTN in FPK	Adds scapular control and slight loading against gravity	On elbows On forearms on chair Over end of bed Forward lean on wall/counter	Achieve neutral, not over-retraction
Add extension lift	Focuses on lower cervical extensors, as controls tendency to collapse		Keep CV neutral as extend about an axis at C7—encourages deep vs. superficial
Ball extension lift-off	Includes scapular and thoracic strength	Over end of bed 45° arm lift to focus to scapular stabilizers	Starts with head and neck position, then scapula set, then thoracic extension

TABLE 23-4

Cervical Extensor Exercise Progressions (*continued*)

CERVICAL EXTENSOR PROGRESSIONS			
EXERCISE	PURPOSE/AIM	MODIFICATIONS	POINTS
External Load			
Isometric backward lean		Sit	
Hand hold band		In sit/stand At wall	Retract motion or extend elbows to add tension Watch that relaxation phase doesn't allow excessive anterior shear
Backward lunge	More perturbations More functional		Start slow and controlled—increase speed Incorporate function—arm movements/ movement patterns

RTN, return to neutral; FPK, four-point kneeling; MET, muscle energy type technique; EMS: electric muscle stimulation.

Rotation and Side Flexion Component By exercising into a quadrant position, the muscles that are primarily lateral flexors and rotators are also recruited. In supine, with the head offset on a foam wedge, the slope can be used to apply resistance to combined flexion, side flexion, and rotation of the cervical spine (see **Self-Management 23-1**).

The addition of pure rotation to the exercise in FPK (**Fig. 23-12**) further activates the suboccipital extensor muscles and can be particularly useful for those conditions related to the upper cervical spine such as CHA and dizziness **Table 23-5**.

Elastic resistance can be utilized to provide additional loading to this movement pattern. With the band held in hands placed on the wall, the head is drawn back into neutral, the elbows extended slightly to obtain the desired tension, and then the head rotated in a single plane motion to the right and then left (**Fig. 23-13**). The elbows can then be flexed to release the load and then the exercise repeated. As a true strengthening exercise, building to three sets of 10 repetitions would be appropriate.

In the sidelying position with the head supported on a pillow and a towel roll under the neck, these muscles can also be

SELF-MANAGEMENT 23-1
Side Flexor and Rotator Activation

Purpose: To activate and strengthen the neck side flexors and rotators on each side

Starting Position: Lie on your back with your head supported on the foam wedge. Knees are bent. Move the wedge so your head is resting off to one side on the slope of the wedge (**A**). You will immediately feel that you have to use your neck muscles on the side closest to the peak to hold your head in place.

Movement Technique: Perform a slight nod to activate the deep neck muscles. Hold this nod throughout the exercise.

Slowly, in a controlled fashion, lower your head down the slope to the end of range. Stop before there is any pain. Pause at the end of range, then slowly bring the head back up the slope, maintaining the slight nod throughout (**B**). Go past your center position, continuing up the slope of the wedge to the end of range. Again pause at this point. In a controlled fashion, bring your head back to midline. Relax from the nod position. This is one repetition.

Repeat for the designated number of repetitions, beginning with the pre-set nod for each.

Move the wedge over to have the head resting on the other side of the peak. Repeat the same sequence as above for the designated number of repetitions.

Dosage:

Set/repetitions: ______________________

FIGURE 23-12 Pure rotation in four-point kneeling: the patient first adopts the neutral spine position they were taught to achieve in Figure 23-11. Keeping the chin nodded to neutral, the patient performs isolated rotation to the right and then left, making sure not to collapse into side flexion or extension.

FIGURE 23-13 Elastic resisted pure rotation: holding the elastic band at the wall, the patient draws the head back to neutral, extends the elbows slightly to increase the tension, and then performs pure rotation, maintaining the neutral chin nod position throughout.

TABLE 23-5

Asymmetric Loading and Rotation Control Exercise Options

ASYMMETRIC LOADING AND ROTATIONAL CONTROL			
EXERCISE	**PURPOSE/AIM**	**MODIFICATIONS**	**POINTS**
Low Load			
Wedge pillow: peak	Non–weight bearing but some gravity load		Pre-set a neutral nod prior to rotation, maintained throughout motion
offset	Increase load against gravity	Can angle the pillow to alter amount of combined SF	
Auto-resist rotation	Early rotation loading—can be less than weight of head	Pure rotation Diagonal pattern Can also resist pure SF separately	Neutral nod first to encourage deep component Can start with very low load and progress as appropriate
Higher Load			
Pure rotation in FPK	Extensor/suboccipital focus		Excellent for CHA and CD
Pure rotation in incline nod lift-off	Flexor focus	Start with minimal decline and progress	Much more difficult than FPK—later progression
Diagonal segmental curl-up head lift	Isotonic through range combined flexion/rotation		Watch that the nod continues throughout
Diagonal extensor lift in FPK	Extensor through range extension/ SF/rotation		Watch for any midcervical collapse
SF head-lift in side lying	Isotonic through range strengthening	Use towel roll to encourage proper pattern	Neutral nod first to "set" the deeper muscle system
External Load—Elastic/Pulleys			
Rotation	Pure rotation control	Options: Lean back/forward and then pure rotation Rotation from side attachment Rotate and lean forward/back	Ensure cervical neutral is maintained throughout the exercise Pre-set neutral nod prior to each repetition Or held for multiple repetitions to gain endurance
Side flexion		Options: sideways lean Isotonic SF Sideways lunge	
General asymmetric	Challenges rotation control	Diagonal leans Diagonal lunges—forward/back/sideways Pull back with elastic in mouth—alphabet	

SF, side flexion; CHA, cervicogenic headache; CD, cervicogenic dizziness; FPK, four-point kneeling.

FIGURE 23-14 Side lying head lift: the patient starts in the side lying position, with the head supported on a pillow with a towel roll under the neck. The patient lifts their head toward the ceiling. The deeper muscles are emphasized by ensuring that the neck remains in contact with the roll while the head is lifted.

FIGURE 23-15 Elastic resisted rotation: standing sideways to the attached band, the patient begins with a pre-set neutral nod, then performs pure rotation against the resistance of the elastic. Having the knot of the band anterior rather than posterior will alter the angle of pull and change the emphasis on anterior and posterior muscles.

trained more specifically and at higher load. The head is lifted off the pillow, working against gravity. The roll is used as the fulcrum, and the deeper muscles can be emphasized by ensuring that the neck remains in contact with the roll, decreasing the amount of lateral translation taking place (**Fig. 23-14**). The desired movement pattern is pure side flexion as any rotation during the lift would suggest excessive recruitment of either SCM or scalenes

For both of these exercises, the patient is taught to perform a pre-set nod to activate the deep stabilizing muscles prior to any motion of the head. This would also encourage retraining of the appropriate timing of the motor pattern that is impaired with neck pain.

Again elastic band resistance can be used in sitting during sideways or diagonal leaning movements to produce asymmetrical loading. In addition, a sideways or diagonal lunge can be performed. Standing sideways to the attached band, with the knot at either the front or the back of the head, pure rotation movements can be practiced against load (**Fig. 23-15**).

See Table 23-5 for exercise options in this category.

Mobility Impairment

Impairment of mobility can be classified as hypomobility (i.e., reduced motion) or hypermobility (i.e., excessive motion). In the case of hypomobility, exercises are given to regain and maintain motion. For hypermobility, a stabilization exercise program is used to regain control of the excessive motion.

Hypomobility

Etiology ROM is often reduced in patients with neck pain regardless of cause. There is a decrease in ROM in patients with symptomatic WAD at 1 month post-accident, but this has recovered by 3 months in the subgroups that are classified as either mild or recovered.[57–59] In both the moderate and severe subgroups of WAD, the reduced ROM persists at 3 months. Decrease in ROM is present in subjects with CHA, but not in migraine or tension type headache. As such, a decrease in ROM may be used in the differential diagnosis. Reduction in motion as determined by the flexion-rotation test has been found to correlate highly with CHA related to AA joint rotation restriction.[60] Rosenfeld et al.[61–63] demonstrated that subjects who performed early active repeated rotation movements 10 times hourly, had less pain at both 6 months and 3 years, as well as better mobility and less sick time at 3 years.

Cervical mobility can be reduced for several reasons:

- Segmental articular mobility restriction
- Capsular thickening and contracture
- Degenerative bony changes
- Segmental muscle spasm
- Myofascial restriction
- Adverse neuromeningeal tension

Cervical mobility also can be affected by syndromes involving the shoulder girdle and thoracic spine, and treatment oftentimes requires interventions for impairments in those regions.

Therapeutic Exercise Interventions Even in the early stages of treatment for an acute neck condition, ROM exercises within the pain-free range can be taught for each of the restricted planes of motion. Care must be taken in teaching these exercises to ensure that the normal movement pattern is performed and that this pattern is reinforced with repetition. With the patient lying supine with the head supported on a pillow, the weight of the head is eliminated, decreasing the compression load. This position can be helpful for patients with painful neck motion. The use of rhythmic respiration during the exercise can aid in relaxation of the scalene muscles and create a pumping action to help reduce swelling. This activity can be progressed to rotation exercises with the head positioned on the peak of a foam wedge (**Fig. 23-16**). The amplitude of motion obtained is increased and there is some extension incorporated with the movement on rotation and flexion on return to midline. Once the patient can tolerate the compressive load from the weight of the head, ROM exercises can also be performed in the upright position.

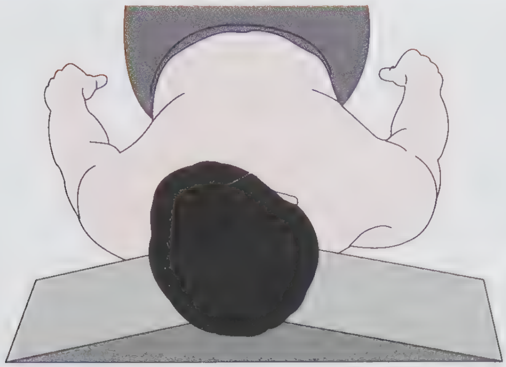

FIGURE 23-16 Foam wedge ROM exercises: allows gravity assisted non–weight-bearing motion, combining rotation and side flexion with flexion-extension.

If a mobility exercise into extension or the extension quadrant is being contemplated, the effects on articular, vascular, and neurologic tissues should be considered. Keep in mind that a considerable weight-bearing force is sustained by the articular facet and the intervertebral foramen is being compressed in these positions.

Segmental Articular Restrictions Segmental articular restrictions generally respond well to manual therapy mobilization techniques unless there is excessive degeneration of the bony structures (see Chapter 7). As the maintenance of the range gained with mobilization is often difficult, self-mobilization exercises are a useful adjunct to this treatment. The patient is taught to localize to the involved segment with his or her fingers or a towel support and perform a specific, sometimes multiplanar motion to mobilize the joint restriction as determined by mobility testing (see **Self-Management 23-2**). A specific AA towel rotation technique (**Fig. 23-17**) as proposed by Mulligan has been shown to be effective in increasing upper cervical motion and decreasing headaches.[64]

Muscle Extensibility Assessment of muscle length is necessary because of muscle imbalances and postural asymmetries that are unique to each individual. Janda[65] states that certain muscle groups in the cervical spine have a greater tendency to shorten. This may be related to the effect of the limbic system on these muscles, the large percentage of afferent fibers supplying these muscles, and the more tonic rather than phasic properties of many of these muscles. According to Janda,[65] the following muscles tend to shorten:

- Posterior suboccipital muscles
- Cervical superficial erector spinae muscles
- Scalenes (anterior, medius, posterior)
- Sternocleidomastoid
- Levator scapula
- Trapezius, upper fibers

A study of cervical musculoskeletal function in postconcussional headache[66] and CHA[67] showed a higher incidence of moderate muscle tightness compared to those with migraines or controls. This finding of tightness was not isolated to any one of the muscles tested (e.g., upper fibers of the trapezius, levator scapula, scalenes, upper cervical extensors), but it was most frequently identified in the upper cervical extensors. In subjects with CHA, many of these muscles were found to be of normal length. A study by Edgar et al.[68] showed a relationship between decreased neuromeningeal extensibility and decreased length of upper fibers of the trapezius, possibly as a protective mechanism. Patients with WAD showed greater electromyography activity of both their ipsilateral and contralateral upper fibers of the trapezius during repetitive upper extremity activity and were less able to relax that muscle following activity as compared with controls.[28] This may suggest that feelings of tightness in patients with cervical spine dysfunction may be more related to overactivity than to true shortening.

Alterations in resting posture may cause a muscle that is of normal length to be placed on tension because of the increased distance between the origin and insertion caused by the posture. For example, a depressed scapular resting position puts tension on the levator scapula, potentially reducing opposite-side flexion and rotation of the cervical spine. The neck motion can be regained immediately upon elevating the scapula, confirming that the tension on the levator scapula, resulting from the depressed position of the scapula, was contributing to the loss of neck ROM. Other muscles may adaptively shorten because of long-standing changes in posture. The sternocleidomastoid, for example, tends to adaptively shorten in response to FHP. When the head is brought back into a more normal position, the muscle may appear to be a tight band, inhibiting attempts to retrain optimal posture. Treatment of both cases consists of postural correction exercises. Chapter 25 illustrates taping techniques to correct scapula position and normalize length–tension properties of the cervical muscles that attach to the scapula (i.e., levator scapula and upper trapezius).

The posterior suboccipital muscle group can be lengthened by using the CV flexion head nod exercise at the wall (**Fig. 23-18**). The stretch can alternatively be localized by supporting the rest of the neck with clasped hands and further localized by side flexion away and rotation toward the tighter side.

Further neck flexion must be incorporated to obtain a stretch into the middle to low cervical erector spinae. CV flexion must be maintained throughout the exercise to maintain the stretch on the long superficial extensors. If any anterior translation is allowed, cervical lordosis is produced, which results in a shortening of these muscles. Performing this stretch with the trunk against the wall helps fixate the cervicothoracic (CT) junction (**Fig. 23-19**). Adding side flexion and rotation to the opposite side biases the stretch to the right or left side.

The scalene muscle group tends to shorten and become overactive, often reinforced by improper breathing patterns. Teaching proper diaphragmatic breathing while palpating the scalenes can decrease recruitment of this group as a secondary muscle of inspiration (see Chapter 22). Exercises designed to stretch this muscle must allow for adequate fixation of the first and second ribs, which can be achieved through manual or belt fixation. The scalene group is lengthened by side flexion away (**Fig. 23-20**). Slight rotation toward the affected side will focus the stretch to the anterior group, and rotation away from the effected side will bias the posterior scalene. Performing pure side flexion at the wall prevents the neck from collapsing into an FHP and will allow a more effective stretch. The patient must be instructed to stop at the point of tension, because the muscle pull can produce an unwanted lateral translation force on the cervical spine.

An effective method of regaining normal SCM length is to correct the FHP. Retraining the use of the deep cervical

SELF-MANAGEMENT 23-2
Self-mobilization for the Cervical Spine

Purpose: To maintain the range gained during treatment at a particular joint.

AO Joint

Starting Position: Sit tall in a chair with back support. Clasp your hands behind your neck with your little fingers just under the base of your skull. Stabilize the neck, but be careful not to drag the neck forward by pulling forward with your hands.

Movement Technique: Flexion on the right (**Fig. A**)

- Nod your head on your neck. The head must tip away (left) from the stiff side, and the chin must deviate toward (right) the stiff side. In other words, tuck your chin toward your armpit on the side of the stiff joint.

Extension on the right (**Fig. B**)

- Tip your head back on your neck over your fingers. Tip the head slightly toward (right) the stiff side and point the chin away from (left) the stiff side. In other words, point your chin toward the opposite elbow.

Dosage:

Hold: ________________________________ count

Repetitions: ________________________________

Frequency: ________________________________

AA Joint

Starting Position: Wrap your hands behind your neck with your little fingers resting at the level of the large bump at the top of the neck below the skull. Stabilize the neck, but be careful not to drag the neck forward by pulling forward with your hands.

Movement Technique:

- Keep eyes level as you rotate the head in the stiff direction, being sure not to let the rest of the neck move with the head.
- If instructed, bias the movement to the joint on one side or the other by
  - Tucking the chin into a bit of flexion as you turn, and slightly pull the supporting hand forward on the side you are turning to (**Fig. C**)
  - Tipping the chin slightly up as you turn, and hold back with the supporting hand on the side opposite to the direction you are turning to (**Fig. D**)
- Do not let the neck collapse as you turn the head; stay tall.

Dosage:

Hold: ________________________________ count

Repetitions: ________________________________

Frequency: ________________________________

Midcervical Joints

Starting Position: Find the stiff joint as instructed. It often will feel tender, or thick under your finger. Hold the bottom bone stable by pushing in gently with your fingers. Alternatively, place the salvage edge of a towel along the affected joint to stabilize it.

Movement Technique: Flexion

- Nod your chin forward until you feel a pull at the stiff joint. Tip the head away from the stiff side and rotate the head away (**Fig. E**). The movement to stretch the joint maximally will be off on the opposite diagonal.
- The fixing fingers should stabilize the bottom bone down toward the floor.
- You should feel a strong stretch on the side of the neck at the stiff joint.

Extension

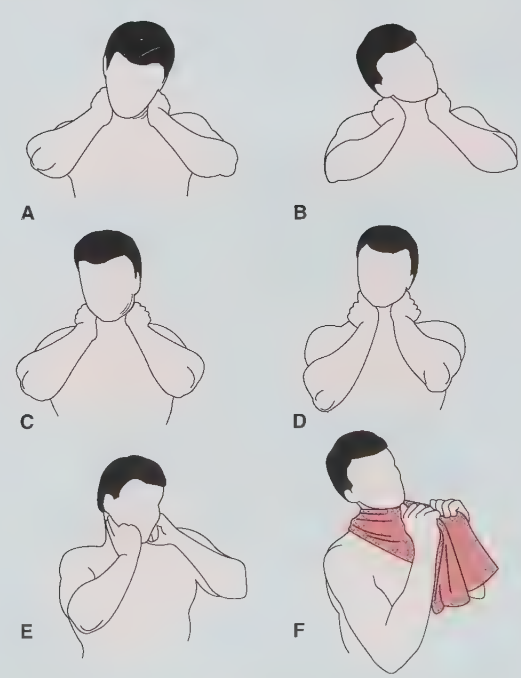
- Tip your head back over the stabilizing fingers or towel. The head should also tip and rotate to that same side on a diagonal (**Fig. F**).
- You can push in and up slightly with the fixating fingers.
- Focus the movement to the level that is stiff. Do not arch your whole neck back over the fingers.

Dosage:

Hold: ________________________________ count

Repetitions: ________________________________

Frequency: ________________________________



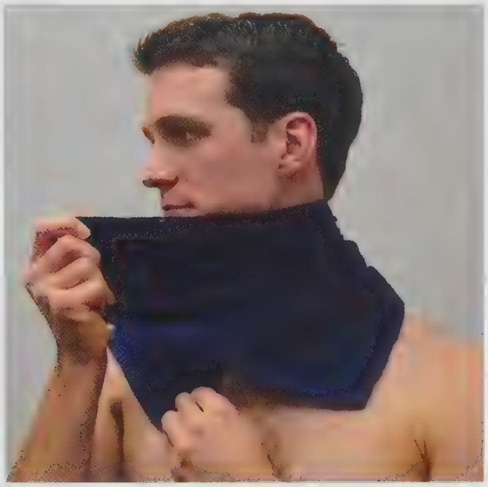


FIGURE 23-17 Atlantoaxial towel rotation self-mobilization: the edge of a towel is placed at the level of C2, the hands crossed with the towel positioned along the edge of the jaw. The towel is used to assist the head and neck motion in pure rotation. The movement should be pain free.

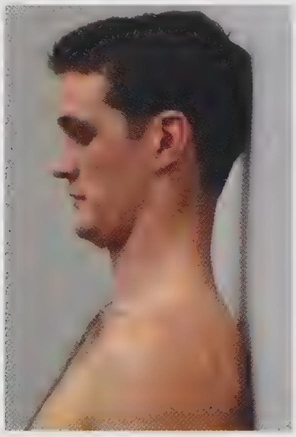

FIGURE 23-18 Posterior suboccipital stretch: using the craniovertebral flexion head nod exercise into full range with head staying on the wall.

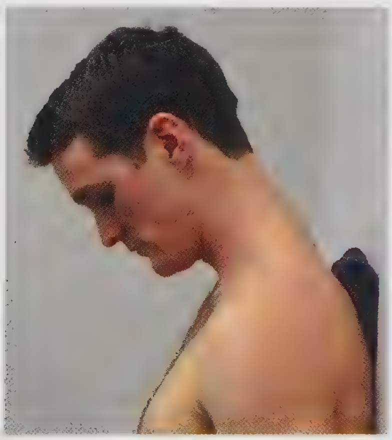

FIGURE 23-19 Long cervical extensor stretch: positioned at the wall to ensure that the upper thoracic spine remains in contact (can use a folded towel as feedback). The chin stays tucked and the head drops forward into full flexion.

FIGURE 23-20 Scalene stretch: first rib fixed, side flexion away, and slight rotation toward the affected side at the wall.

flexors for the habitual movement pattern of neck flexion also decreases overuse tightness of the sternocleidomastoid. If the muscle has become shortened by posttraumatic adhesions, it may be necessary to stretch the muscle. This can be achieved by side flexion away from, and rotation toward the side being treated, keeping the chin tucked, while extending the head behind the trunk. Lordosis must be controlled, because that position shortens the muscle. This effect can be achieved by bringing the CV flexed head on a straight neck back behind the line of the trunk (**Fig. 23-21**).

When attempting to lengthen the levator scapula muscle it is optimal to fix the scapula into both depression and upward rotation. Upward rotation can be achieved by arm elevation, but this shoulder position may be painful for some patients with neck pain. In that case, depression of the scapula can be maintained with the arm positioned in slight abduction to try to include some upward rotation (sitting, holding the underside of the chair). The muscle is then stretched by cervical side flexion and rotation to the opposite side and cervical flexion (**Fig. 23-22**).

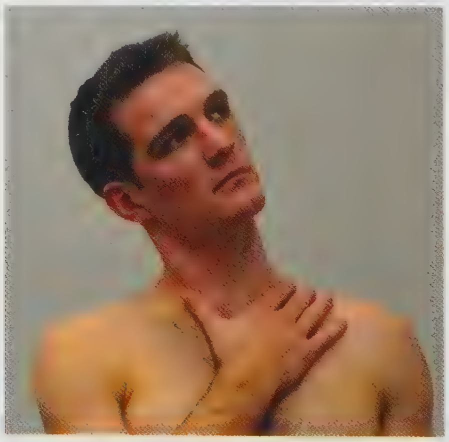

FIGURE 23-21 Sternocleidomastoid stretch: extension, side flexion away from and rotation toward the side being treated.

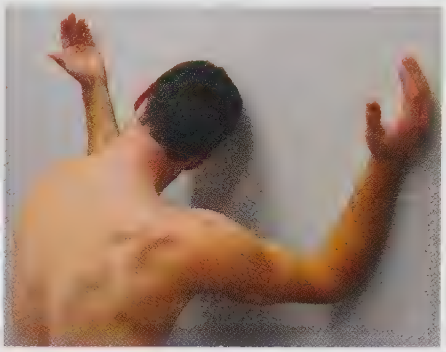
FIGURE 23-22 Levator scapula stretch: arm overhead (scapular upward rotation), scapular depression, side flexion away, rotation away from affected side, and flexion.

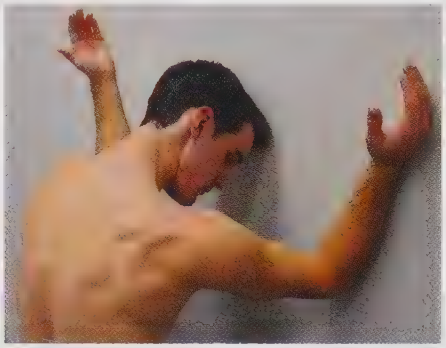
To stretch the upper fibers of the trapezius, the scapula must be fixed into depression, downward rotation, or both. Scapular depression and downward rotation can be achieved by reaching the arm down and behind the back. The stretch is then performed into neck flexion, with side flexion away from and rotation toward the affected side (**Fig. 23-23**).

The concern about the latter two stretches is the resultant forces on irritable zygapophyseal joints from the end-range combined movements. These two muscles and the scalene muscles, because of their angle of pull, may also produce an excessive lateral translation force on the vertebrae when stretched. An alternative exercise is to have the patient face the wall, with the ulnar border of the hands and forearm in contact overhead, and perform a wall slide. The arms are slid downward and slightly inward, creating scapular depression. The cervical spine can then be moved into flexion. From this position, contralateral rotation lengthens the levator scapula muscle, and ipsilateral rotation lengthens the upper fibers of the trapezius muscle (**Fig. 23-24**).

FIGURE 23-23 UFT stretch: scapular depression and downward rotation, neck flexion, side flexion away, and rotation toward the affected side.



A



B

FIGURE 23-24 Alternative wall slide exercise. **(A)** Contralateral rotation lengthens the right levator scapula muscle. **(B)** Ipsilateral rotation lengthens the upper fibers of the right trapezius muscle.

Adverse Neuromeningeal Tension Adverse tension in the neuromeningeal structures of the cervical spine can affect the mobility of the neck, thoracic spine, shoulder girdle, and upper extremity.[69] Signs of decreased extensibility of these structures are found on the upper limb neurodynamic tests, with a median, radial, or ulnar nerve bias. When prescribing an exercise designed to improve neuromeningeal extensibility, the effect on the cervical spine should be considered. Because of direct attachment of dural structures into the cervical vertebrae, tightness in the neuromeningeal system may cause lateral translation of the vertebrae with each attempt to stretch the structures, which can lead to hypermobility of the segment. The affected segment should be manually fixated by the opposite hand supporting under the neck so that the fingers wrap around to the affected side and prevent lateral translation (**Fig. 23-25**). The DNFs can also be used to stabilize the spine through an active nod, setting the spine in neutral.

The stretch can be performed by the patient in supine lying, with a belt wrapped over the shoulder and around the knee to prevent scapular elevation. Median, radial, and ulnar nerves are biased via various arm, elbow, forearm, and wrist positions as shown in **Figure 23-26**. It may be more effective initially to emphasize mobility of the system, by using "slider" exercises that add tension in one component of the movement, while removing tension in another component. For example, tipping the head toward the arm as the elbow is extended for a median nerve bias slider.

For median nerve bias, the arm, flexed at the elbow, is abducted to the tension point and externally rotated, with the

FIGURE 23-25 Dural stretch: with manual stabilization and fixation of lateral shear.

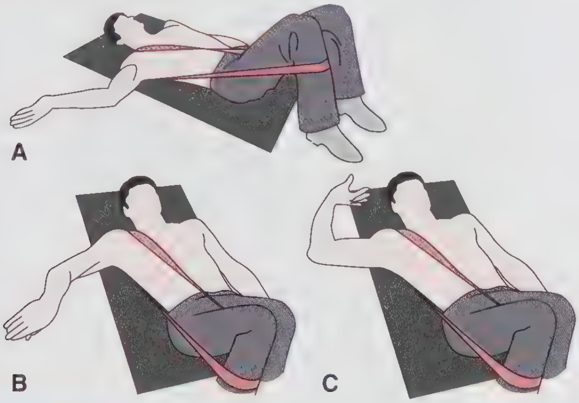


FIGURE 23-26 Dural stretch: in supine lying with a belt wrapped over the shoulder and around the knee to maintain scapular depression. **(A)** For median nerve bias, the arm, flexed at the elbow, is abducted to the tension point and externally rotated, with the forearm supinated and the wrist and fingers extended. The elbow is then slowly extended to produce the stretch. **(B)** For radial nerve bias, the arm, flexed at the elbow, is abducted and internally rotated, the forearm is pronated, with the wrist flexed. The stretch is produced by slowly extending the elbow. **(C)** For ulnar nerve bias, the arm, flexed to a right angle at the elbow, is abducted and externally rotated, the forearm is pronated, with the wrist extended. The stretch is produced through further flexion of the elbow.

forearm supinated and the wrist and fingers extended. The elbow is then slowly extended to produce the stretch (Fig. 23-26A).

Similar stretches can be performed by the patient in standing. The opposite hand is required to maintain depression of the scapula. With each of these exercises, a more intense stretch can be obtained by the addition of contralateral side flexion or rotation of the neck. For more detailed descriptions of these types of exercises, the reader is directed to other sources.[70]

Hypermobility

Etiology Hypermobility is excessive motion of the intervertebral segment. As hypothesized by Panjabi,[4] spinal stability is obtained through three subsystems:

- Passive musculoskeletal subsystem: inert osseoligamentous column, including the vertebra, disk, capsule, and ligament
- Active musculoskeletal subsystem: the muscle and tendon units
- Control subsystem: the neural and feedback mechanisms

The role of the spinal stability system is to provide sufficient stability through all three subsystems to match the demands made on the spine. Within certain limits, deficiencies in one subsystem can be compensated for by the other subsystems. Gross instability, as documented by functional radiographs, may require surgical fixation. Otherwise, hypermobilities are best addressed by conservative measures, including a progressive stabilization exercise program. Exercise programs can be used to enhance both the active and control subsystems.

Specific passive stability testing is performed to determine the degree and planes of laxity. Special attention is given to the amount of translation and the end-feel. This assessment determines the structural integrity of the passive subsystem of the spine. To determine the dynamic stability of the cervical spine, the passive tests can be repeated during an active preset DNF nod to neutral. If recruitment of the deep segmental stabilizers decreases the amount of translation on passive testing, there is a degree of dynamic stability present. The neck can also be observed or palpated during bilateral or unilateral elevation of the arm in the relaxed upright posture and then repeated with the cervical spine under the dynamic control of a pre-set nod (**Fig. 23-27**). If recruitment of the deep segmental stabilizers decreases the amount of translation, there is a degree of dynamic stability present. Because of the large neutral zone in the cervical spine, much of the stability in this region is imparted by the dynamic control of the active muscular system. In the case of loss of integrity of the inert stabilizing structures, training of neuromuscular control may result in a functionally stable spine.

Therapeutic Exercise Intervention For the hypermobile cervical spine, care must be taken in prescribing ROM or stretching exercises that may exaggerate the excessive translation. The neck must be passively fixed at the affected segment during the stretch, or another exercise should be chosen that does not incorporate the unwanted motion. For example, a patient may have a tight right levator scapula muscle but also be hypermobile into right lateral translation at the C3–C4 intervertebral

FIGURE 23-27 Dynamic stability testing: the neck can be observed or palpated during unilateral arm elevation in the relaxed upright posture, and then repeated with the cervical spine under the dynamic control of a pre-set nod.

FIGURE 23-28 Levator scapula stretch: fixing C4 to prevent right lateral translation.

segment. Attempts to stretch the levator scapula muscle by left side flexion encourage right lateral translation at C3–C4. The patient can control the right lateral translation with the left hand cupping behind the neck, offering a counteracting left translation at the C4 vertebra (**Fig. 23-28**). It may be more appropriate in this case to choose the wall slide levator scapula stretch exercise described in the "Hypomobility" section, using contralateral rotation rather than side flexion.

For the patient with lateral translation hypermobility, attempts to incorporate dural stretch exercises cause repetitive lateral translation at the affected joint. A stretch can be performed effectively by first manually stabilizing that segment for lateral translation (see Fig. 23-25).

Postural correction exercises are an integral component in unloading the hypermobile segment in the cervical spine. Any deviation from the optimal posture of the cervical spine increases the translational forces placed upon the spine. The resting posture of the shoulder girdle also plays a role in imparting translational forces to the cervical spine. For example, weakness or poor recruitment of the upper fibers of trapezius leads to a depressed and downwardly rotated scapula, which places the muscle in a lengthened position. Constant pull on the insertion into the cervical spine may eventually lead to hypermobility into lateral translation. In cases of preexisting lateral hypermobility, the continuous lateral force exacerbates symptoms arising from that segment. Exercise should focus on correcting the impairments found on assessment of the shoulder girdle. Taping to reposition the scapula into elevation and upward rotation can reduce this force, allow a more normal movement pattern of the cervical spine, and relieve the increased dural tension caused by the abnormal resting position (see Chapter 25).

Cervical hypermobility can also be addressed through training to facilitate neuromuscular control of the cervical spine with graduated exercise. A series of cervical strengthening exercises can be implemented as determined by specific muscle testing. These exercises, as described in the "Impaired Muscle Performance" section, enhance the active subsystem of the spinal stability system. Alternatively, a cervical stabilization program can be developed to focus on both the active and control subsystem. A stabilization program can be divided into three stages:

- Stage 1: Isolated contraction of the deep segmental flexors and extensors and cocontraction in the cervical neutral position
- Stage 2: Cervical stability during various upper extremity movement patterns
- Stage 2b: Higher load strengthening and endurance
- Stage 3: Cervical stability during functional neck movements

Display 23-1 provides examples of exercise that can be prescribed in each stage.

Throughout the stabilization program, motion at the hypermobile segment must be controlled, particularly for the excessive translation component. In many cases, the patient can be taught to palpate the translation motion of the vertebra and stop moving when it begins. The patient can also be taught to stabilize the affected level manually or through active muscle cocontraction by performing a pre-set nod as an exercise is performed. Progressing in the presence of translation of the affected level does not succeed in developing stability, and through increased stresses on the capsule and ligaments, it may result in painful exacerbation to the point that the program has to be discontinued.

Because of the importance of the role of muscles in dynamic stability of the spine, it can be deduced that, despite the presence of hypermobility, functional stability can be regained through neuromuscular retraining. The key is gradually challenging the cervical musculature over several months while preventing excessive motion at the involved segment. The degree of true strengthening that is required will depend on the demands placed on that particular cervical spine throughout daily, occupational and recreational activities.

Posture Impairment

Etiology

Although posture is affected by the whole of the axial skeleton, the cervical spine plays an important role in the control of posture. The rich supply of mechanoreceptors in the articular capsules and muscles of the cervical spine provides proprioceptive input and feed into the vestibular system.[71] Any attempt to alter cervical spine posture must include an examination and evaluation of the thoracic spine, shoulder girdle, and pelvis. Many of the involved muscles are multijoint muscles. Changes in the lengths of muscles such as the levator scapula, trapezius, pectoralis major and minor, or rhomboids have profound effects on the shoulder complex and the cervical spine. Changes in the strength of these scapular stabilizers also alter the resting posture of the neck. Alterations in the pelvic base in any plane have effects throughout the spinal column, including the cervical spine.

The optimal posture for the cervical spine is the position of cervical neutral or axial extension (**Fig. 23-29A** and **Patient-Related Instruction 23-2**). In cervical neutral, minimal muscle work is required to maintain the position, the spine is in an elongated state, and compressive and translatory forces on the spinal structures are reduced compared with other suboptimal postures. The most common postural impairment of the cervical spine is FHP.

A patient with FHP can present with several variations. In some individuals, the lower cervical spine flexion juts the whole cervical spine forward above that level, and extension mainly occurs at the CV region with little increase in the midcervical lordosis (Fig. 23-29B). In others, the lower cervical spine flexion is compensated for by an exaggerated cervical lordosis that may start abruptly, sometimes as low as the C6–C7 segment. In these cases, the midcervical lordosis tends to be accompanied by an excessive anterior translation that is an unphysiologic coupling of motion, because extension (i.e., lordosis) should couple with posterior translation (Fig. 23-29C). Each individual should be

DISPLAY 23-1

Cervical Spine Stabilization Program

STAGE I

The first goal of the stabilization program is to isolate the deep neck flexors and extensors. The next goal is to perform cocontraction patterns in the cervical neutral position. The following exercises can be used to achieve these goals. The exercises are described in more detail in the "Impaired Muscle Performance" section.

Isolation of the Deep Cervical Flexors

- Cervical core activation (DNF nod) in a variety of positions (Patient-Related Instruction 23-1; Figs. 23-2 and 23-3)
- Auto-resistance to the deep flexors

Isolation of the Deep Cervical Extensors

- Electrical muscle stimulation to the cervical extensors in supine
- Therapist-directed MET recruitment (Fig.23-8)
- Auto-resistance to specific multifidus or suboccipital muscles (Fig. 23-9)
- RTN in sitting (Fig. 23-10)

Rotation and Side Flexion Components

- Supine controlled rotation offset on a foam wedge (Self-Management 23-1)

Cocontraction of the Deep Cervical Flexors and Extensors

- Early cocontraction training can be accomplished in supine lying with the cervical lordosis supported over a towel roll. The extensors are recruited using the electrical muscle stimulator while the patient prevents the extension motion by simultaneously performing the head nod exercise such that the cervical spine remains in neutral.
- Cocontraction of the deep extensors and upper cervical flexors can also be practiced with the patient positioned prone over an exercise ball or in FPK. The RTN in FPK exercise is an example (Fig. 23-11).

STAGE IIa

After the patient is able to achieve cocontraction of the anterior and posterior muscles of the cervical spine in resting positions, the next goal is to be able to maintain cervical stabilization during arm motion. The exercises consist of initial cocontraction of the cervical musculature (a pre-set nod to obtain neutral), which is maintained while the patient performs repetitive motions of the upper extremity in various positions (i.e., supine, FPK, sitting, standing). The pattern of the arm motion, amplitude, and position of the exercise is based on what combination challenges the patient optimally while maintaining neutral position of the affected segmental level(s). The goal is to accomplish segmental cervical stability in a variety of positions with an assortment of arm movements and a range of amplitudes. See **Table 23-6** for Stage II exercise options.

- Because the most stable position is supine, it is used as the initial starting position.
- Various movements of the upper extremity (e.g., flexion, abduction, diagonals) are performed while palpating the affected segment for unwanted translation. Only those motions in which the segment remains neutral can be performed.
- Bilateral arm motions below 90 degrees often are the least challenging. Unilateral, overhead movements place higher demands on the stabilization system. (However, these effects depend on factors such as the plane or direction of the hypermobility, dural tension, and shoulder or thoracic mobility.)
- Progression includes adding hand weights, which increases the resistance, or lying on a half roll, which reduces the stability of the base (**Fig. A**).
- These same exercises can be progressed by having the patient perform them in a sitting or standing position, because these positions are more challenging to spinal stability. To make the transition to upright less challenging, the patient can be instructed to sit or stand with the back to the wall to provide feedback of where the head is in space (**Fig. B**). Upper extremity motion can be altered in direction, amplitude, and pattern.
- The therapy ball can be used as another surface to promote cervical spine stability with upper extremity movements. Ball sitting and the use of elastic band or pulley resistance are beneficial at this stage (**Fig. C**). In prone on the ball, the patient can be taught to maintain a controlled cervical spine position while performing simple rocking motions. Increased demands can be made on the cervical spine by adding unilateral or bilateral arm motions, with or without weights. This can be progressed to more complicated arm and leg lift patterns (**Fig. D**). Similar exercises performed in supine on the ball are of a much higher load to the cervical spine and should be added later in the retraining process, only once a higher level of motor control has been developed.
- The use of proprioceptive neuromuscular facilitation (PNF) patterns or sport- and work-specific movements introduce a more functional approach (**Fig. E**).
- Various wobble board systems can be used; the unstable base can further challenge the control of posture as the patient performs various upper or lower extremity movements.

Figure A: Maintaining axial extension on a half roll with weighted unilateral overhead motion.

DISPLAY 23-1 (continued)

Cervical Spine Stabilization Program

Figure B: Wall posture with pre-set nod and unilateral arm elevation.

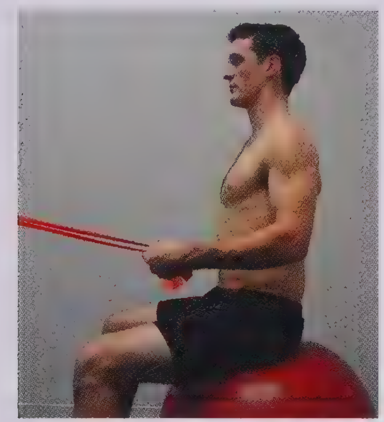

Figure C: Maintaining sitting axial extension on a ball during arm motion (scapular setting) with resistance.

Figure D: Maintaining axial extension prone over a ball during opposite arm and leg lift pattern.

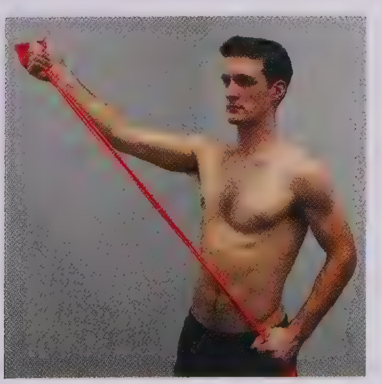

Figure E: Maintaining axial extension with proprioceptive neuromuscular facilitation (PNF) pattern against tubing resistance.

Stage IIb

At this stage, heavier loads can also be added to resist cervical musculature to truly achieve strength gains. Control of the unstable segment must be carefully monitored.

- Nod lift-off on high incline (Fig. 23-5)
- Supine neutral head lift (Fig. 23-4)
- Supine segmental curl-up head lift (Fig. 23-6)
- FPK extension lift
- Sidelying head lift (Fig. 23-14)
- Elastic band resistance leans (Fig. 23-7A), lunges (Fig. 23-7B), and rotation (Fig. 23-13 and 23-15). The lunges are particularly useful for gaining stability control because of the perturbations created during the movement of the body.
- Controlled, non–weight-bearing side flexion and rotation can be initiated in supine using a foam wedge, starting at the peak (Fig. 23-16), progressing to the offset position (Self-Management 23-1).
- Pure rotation and side flexion motions can be practiced with the head at the wall in front of a mirror to give feedback and prevent the tendency to collapse into the hypermobile plane of movement.
- Cervical segmental flexion and RTN from the flexed position are movement patterns that require segmental stabilization during a dynamic movement pattern (Fig. 23-10).
- Pure rotation in FPK challenges the extensor group of muscles, particularly activation of the suboccipital muscles, as well as proprioceptive control (Fig. 23-12).
- A faulty extension movement pattern using excessive anterior translation can be corrected and practiced in either a sitting or FPK position.
- Heavier loaded movement control exercises would include the following:
- Incline nod lift-off (Figs. 23-5).
- Segmental flexion curl-up head lift (Fig. 23-6).
- Sidelying head lift (Fig. 23-14).

Stage III

This stage challenges the patient to maintain segmental control during various neck motions. A pre-set nod activates the deep segmental flexor muscles as stabilizers, permitting the more superficial muscles to perform the movement pattern without excessive segmental translation patterns. Position is based on the ability to control segmental stability during neck motion with gravity-assisted versus gravity-resisted. The amplitude of motion is graded based on the range in which the patient can control segmental stability. See **Table 23-7** for some of the exercise options for this stage.

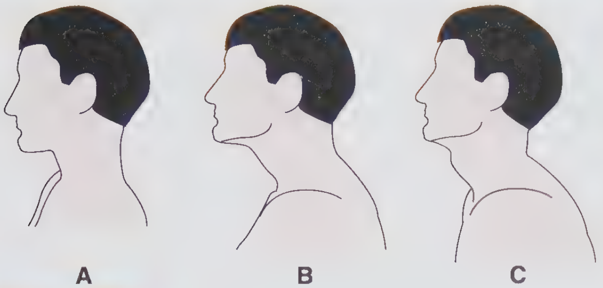

FIGURE 23-29 **(A)** Axial extension. **(B)** Forward head position: minimal midcervical lordosis. **(C)** Forward head position: excessive midcervical lordosis.

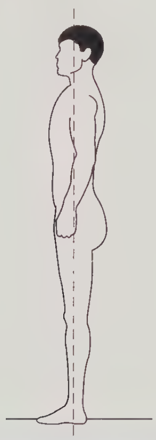
Patient-Related Instruction 23-2

Optimal Posture of the Neck

It is important to practice proper posture of the head and neck. Good posture decreases the stresses on muscles, joints, and ligaments of the cervical spine, which can reduce pain and prevent wear and tear on these structures. Your therapist will instruct you in additional exercises to enable you to achieve and maintain this posture.

The upper back should be straightened, the shoulder blades pulled back together to open up the front of the chest, and the chin brought back so that the head is centered over the trunk. A useful guideline is that the ear should be over the midline of the shoulder. Do not overcorrect, because a slight curve in the neck is normal. Proper posture must be practiced frequently throughout the day so that this position becomes habitual. This posture must also be adopted during exercise for the neck and upper extremity.



assessed to determine the exact components of his or her abnormal posture, the levels at which changes in the spinal curves are taking place, and thus, where the postural correction should focus. **Table 23-8** summarizes alignment findings at various levels of the cervical spine in the optimal position and FHP.

Reversal of the normal cervical lordosis is a less common postural impairment. In this situation, the patient presents with a very straight cervical spine or even a kyphosis. Treatment focuses on regaining extension in the cervical spine to encourage the normal cervical lordosis.

TABLE 23-6

Limb Load Challenge Options

LIMB LOAD CHALLENGES		
COMPONENT	**OPTIONS**	**POINTS**
Upper limb motions	*Motion:* Bilateral Unilateral Reciprocal	
	Plane: Flexion Abduction PNF	Bilateral flexion stresses anterior translation Unilateral flexion stresses lateral translation Abduction: stresses dural mobility and lateral translation
	Position: Below 90 degrees Overhead	
Positioning	*Supine:* Mat Foam: full roll ½ roll	Progressive challenges dependent on individual patient's dysfunction and requirements for their work/sport
	Sitting: Supported at wall Unsupported Ball	
	Kneeling: Knees 4PK	
Resistance	Free weights/ medicine ball/ pulleys/elastic	Start with low load to down-train excessive recruitment
	Isometric/ concentric/ eccentric	Focus on scapular stabilizers and extension patterns

Postural abnormalities may be observed in the frontal plane with the head and neck tilted to one side. This posture can be caused by factors such as muscle imbalance, articular hypomobilities, habitual work or leisure positions, and hearing or sight deficits necessitating altered head position. Treatment should be directed at the cause of the asymmetry.

Therapeutic Exercise Interventions

Treatment for FHP should address muscle imbalance, neuromeningeal extensibility, articular hypomobility, and proprioception. Muscles which require lengthening include the posterior cervical extensors, scalene, upper fibers of the trapezius (UFT), levator scapula, and pectoralis major and minor. Muscles that are weak and require strengthening include the deep, short cervical flexors, the scapular stabilizers (middle and lower fibers of the trapezius, rhomboids, and serratus anterior), and the upper thoracic erector spinae, In addition, abnormal cervical postures may be caused by an attempt to decrease stretch on shortened or mechanosensitive neuromeningeal structures. Ipsilateral side flexion of the cervical spine and elevation of the scapula decrease tension in these structures. Lastly, manual therapy techniques

TABLE 23-7

Segmental Motor Control Exercise Options

SEGMENTAL MOTOR CONTROL			
EXERCISE	**PURPOSE/AIM**	**MODIFICATIONS**	**POINTS**
Single plane movements	Practice corrected movement patterns	Eye level rotation Pure SF at wall Flexion pattern—top down Extension pattern—bottom up from flexion to neutral	Can use wall as feedback Laser pointer may also help with eye level rotation
Lower Load Control			
Wedge pillow	NWB rotation control	Peak → offset	
RTN segmental extension/flexion		Sit → FPK as progression	
Higher Load Control			
Controlled hyperextension: sit	Eccentric/concentric flexors in outer range	Can progress to a lean back position	Focus on motion occurring at CV joints through axis through ears Return with a nod pattern Control any midcervical collapse
FPK—CV extension	Practice pattern of CV flexion—extension		Control tendency to collapse anteriorly in the mid-cervical spine Keep neck back in line with trunk
FPK—CV neutral	Head lift keeping CV neutral	Could add a diagonal quadrant motion	
Pure rotation control: FPK	Rotation control—extensor focus	Prone on elbows	Maintain neutral nod position
Incline lift-off	Rotation control—flexor focus		

FPK, four-point kneeling; CV, craniovertebral; NWB, non-weight bearing; RTN, return to neutral.

TABLE 23-8

Summary of Optimal and Faulty Regional Cervical Spine Positions

OPTIMAL CERVICAL SPINE POSTURE (SEE FIG. 23-25A)	FORWARD HEAD POSITION—MINIMAL MIDCERVICAL LORDOSIS (SEE FIG. 23-25B)	FORWARD HEAD POSITION—EXCESSIVE MIDCERVICAL LORDOSIS (SEE FIG. 23-25C)
CV flexion	CV extension	CV extension
Midcervical spine neutral (slight cervical lordosis)	Midcervical lordosis	Excessive midcervical lordosis, can extend as low as C6–C7. Accompanied by abnormal anterior vertebral translation.
CT extension Upper thoracic neutral (slight kyphosis)	Low cervical and upper thoracic flexion Excessive thoracic kyphosis	Upper thoracic flexion Excessive thoracic kyphosis

CV, craniovertebral; CT, cervicothoracic.

may be indicated in conjunction with mobility exercises to regain the restricted motions of upper cervical flexion, CT junction extension, and upper thoracic extension.

Postural Correction To correct the FHP, the head must be brought back over the trunk. This can often be achieved by directing the patient to "lift the sternum upward," thus decreasing the upper to midthoracic kyphosis. It is important to not allow overcorrection, with patients adopting a flat or even lordotic mid to upper thoracic curve, as they overbrace with their superficial thoracic extensors.

Another primary exercise for achieving many of the goals of postural correction is the head nod exercise. It corrects the upper cervical extension, and because it also tightens ligamentum nuchae, it simultaneously reduces cervical lordosis. In patients with excessive lordosis of the midcervical spine, continuing the head nod into further cervical flexion stretches the posterior structures that have become shortened by the lordotic position.

FIGURE 23-30 Foam roll thoracic extension: lying lengthwise on an Epifoam roll to encourage thoracic extension, with the addition of a "T" position of the arms to further encourage that extension and stretch the tight anterior chest structures.

The head nod exercise can be modified to include posterior displacement (retraction) of the head and neck complex to encourage extension at the lower cervical spine and CT junction when indicated.

One study on the effect of repeated neck retractions in normal subjects found that there was a significant change in resting posture toward a more retracted position after two sets of repeated retractions.[72] Supine is a good position for the patient learning this exercise, because there is more proprioceptive feedback from the contact of the head. Lying lengthwise along an Epifoam roll also encourages the thoracic extension component of postural correction; adding arm movements into a "T" and "Y" position can accentuate that extension and open up the anterior chest (**Fig. 23-30**). Sitting and standing against wall support are natural progressions of the exercise (see Fig. 23-4). The patient must maintain a neutral lumbar spine position, and a towel may have to be used behind the head initially to support the forward head or later to maintain a neutral neck position. The reader is directed to Chapter 24 for additional thoracic spine exercise suggestions. Maintaining this cervical neutral posture while incorporating upper extremity motion is the next progression. Resisted upper extremity exercises can be added through the use of free weights, elastic tubing, or pulley systems. Exercises can be chosen to address strength impairments found on assessment or to simulate work or leisure movement patterns. Various wobble board systems can be used; the unstable base can further challenge the control of posture as the patient performs various upper or lower extremity movements. Because many daily activities require a bent-forward position, maintaining proper axial extension while in FPK or prone over the exercise ball can simulate this position, and upper extremity movements can be incorporated as described previously. The focus should remain on functional movement patterns related to activity limitations and participation restrictions.

Kinesthetic Awareness

Several studies[11,73–77] have shown that subjects with neck pain, particularly those with WAD who complain of dizziness, are less accurate in their ability to perceive a neutral resting posture, and return to a cervical neutral posture after motion in either the horizontal or vertical plane. Standing balance is also impaired in these subject groups.[78,79] Patients were able to improve their kinesthetic awareness following manual therapy, vestibular exercises, or by practicing RTN movements using a laser pointer and target.[80,81]

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON DIAGNOSES

Some of the more common diagnoses of cervical spine disorders are discussed in the following sections. The impairments that occur with each diagnosis are identified, and examples of exercises for treatment are provided.

Disk Dysfunction

Etiology

Although disk herniation is less common in the cervical spine than in the lumbar spine, various dysfunctions of cervical disks do occur. The term *disk dysfunction* is used whenever changes in the disk alter its biomechanical properties and prevent normal function. Included in this grouping are degenerative disk disease, excessive disk clefting, and rim lesions (i.e., separation of the disk from the end plate).[82,83] In the acute stages, disk dysfunction can manifest as an irritable condition, with painful limitation of active ROM in all planes, particularly flexion; pain on cough or sneeze; painful cervical muscle contraction from guarding; and difficulty in maintaining upright postures because of the compressive load of the head on the neck. There may or may not be associated radicular symptoms or neurologic signs, depending on the degree of foraminal encroachment by the disk and the condition of other structures surrounding the foramen, such as the zygapophyseal joint capsule, ligaments, and bone. Radiculopathy is discussed in a subsequent section.

Treatment

Treatment initially is aimed at active rest of the cervical spine, which is achieved through education about proper resting positions that unload the compressive and translatory forces on the cervical spine. Therapeutic modalities may be useful to help alleviate the inflammatory response, decrease the associated muscle spasm, and manage pain. Manual therapy techniques can be used to mobilize the involved segment if segmental hypomobility is found during mobility testing. Muscle energy techniques can also be used to mobilize and alter muscle activity at that segment.

Manual traction techniques help to decompress the disk and increase intervertebral foramen size. If the condition is very irritable, excessive traction may increase symptoms because of the stretch on the nerve and dura. Breathing pattern reeducation is an appropriate exercise during the acute stages, because excessive use of the scalene muscles can add a compressive load to the cervical spine. Instruction in diaphragmatic breathing while monitoring scalene muscle activity through palpation encourages an optimal breathing pattern and unloads the cervical spine. Using postural correction exercises reduces translational forces. Supine exercises, such as gentle head nod (i.e., CV flexion), may be tolerated at this stage and will help improve posture as well as initiate proper recruitment of the cervical stabilizers. Any exercise that causes peripheralization of symptoms must be avoided, while any exercise that results in centralization of the patient's symptoms should be continued.

As the condition improves, impairments that contribute to activity limitations and participation restriction can be identified and addressed. After a period of protected function, the patient will usually exhibit signs of hypomobility. Degenerative changes at that vertebral segment may also decrease mobility. Care must be taken in selecting and teaching ROM exercises that minimize compressive or translatory forces. In addition, any exercises that further narrow the intervertebral foramen should be avoided if there is nerve root involvement.

Because muscle extensibility may be decreased as a result of muscle guarding during the acute phase, stretching exercises should be implemented. Neuromeningeal extensibility should also be assessed at later stages, particularly in cases of neurologic involvement. Exercises to increase the mobility of these structures should not be started while signs of decreased nerve conduction are present, because the movements can easily exacerbate the condition.

The disk is an important structure in the control of motion of the intervertebral segment, and hypermobility impairment may occur as a result of disk dysfunction. Stability testing at the affected segment may detect increased motion because of the loss of the disk's ability to control translational forces in the spine. This impairment must be addressed with a progression of stabilization exercises. The "Hypermobility" section describes these exercises. It is important to progress slowly, as higher load exercises will also load the healing disk.

To prevent further disk degeneration and reduce the incidence of recurrence of an acute episode, it is important to correct all postural impairments of the cervical spine, thoracic spine, and shoulder girdle. Postural asymmetry of the pelvic girdle also influences the cervical spine, and impairments should be addressed as previously discussed.

Cervical Sprain and Strain

Etiology

Any traumatic incident can produce a sprain or strain of the cervical spine. The most common incident is the WAD that occurs after a motor vehicle accident.

The complex injuries sustained by the cervical spine can affect many different tissues. The soft-tissue structures involved may include muscle, ligament, capsule, articular cartilage, and the disk (including rim lesions). Concurrent bony injuries can include fractures of the articular subchondral bone, transverse and spinous processes, lateral masses of the atlas, and the vertebral body.[82] Suspicion of fracture requires referral to the physician for management. Patients exhibiting signs of instability from traumatic injury should also be referred to the physician for further diagnostic tests and appropriate medical intervention. The severity of these injuries varies widely, and the irritability of the condition must be assessed individually. As discussed earlier in this chapter (see "Impaired Muscle Performance" section), patients with WAD have been shown to have decreased recruitment, strength and endurance of their deep cervical flexors, early and excessive recruitment of the more superficial flexors even at low loads, and decreased strength and atrophy of the deep cervical extensors. Motor patterning is altered during upper extremity tasks, and there are prolonged relaxation times for some of the superficial muscles. Subjects with WAD who also complain of dizziness demonstrate impairments of joint position sense, balance, and gaze stability as compared with controls.[73–79]

Treatment

During the acute inflammatory stage, treatment is aimed at reducing pain and inflammation and promoting optimal healing. Education about proper resting positions, limitations of activity, and the use of ice can assist in obtaining these goals. If segmental hypermobility is suspected, bracing should be considered to reduce stresses on the healing structures. Interventions during this phase include breathing exercises and pain-free ROM exercises. The supine position is often best tolerated at this stage, because it unloads the weight of the head. Rhythmic neck rotation movements performed in a supine position in conjunction with relaxed breathing can increase mobility and assist vascular flow. The wedge pillow can be used to assist the mobility exercise. Rosenfeld et al.[61–63] showed that regular rotation ROM exercises in the upright position performed 10 times hourly, resulted in significantly less pain, better mobility, and less time loss from work.

Therapeutic modalities such as ice, interferential current, pulsed ultrasound, or transcutaneous electrical nerve stimulation may also be indicated at this stage to reduce inflammation, decrease muscle spasm, and assist in pain control.

In the subacute stage, it is important to continue to protect the injured structures and to introduce stresses that encourage optimal healing. Grade I and II manual therapy mobilization techniques are effective in pain relief, and grade III and IV mobilizations can help restore motion of the involved segments (see Chapter 7). Impairment of mobility may continue to be the primary dysfunction. Mobility exercises may be progressed into larger arc movements, more specific to the multiplanar articular restrictions found on manual mobility testing. Specific muscle length tests may also indicate that certain muscles are short. However, the effect on the whole spine (e.g., dural stretch, disk compression) must be taken into consideration when choosing mobility exercises. Depending on the degree of ligamentous or disk injury, there may be a mobility impairment of hypermobility. As studies have shown that decreased dynamic stability occurs early in this patient population, stabilization exercises should be included as soon as possible. The Stage I exercises put very little stress on the cervical spine and can be implemented early in the rehabilitation process. Development of a stabilization program must take into consideration the direction, severity, and irritability of the hypermobility (see the "Hypermobility" section). It is also prudent to begin postural reeducation, progressing through the exercises as tolerated. Overhead arm motions are often too stressful on the cervical spine at this stage because of increased translation and compression forces.

During the remodeling phase, as the condition becomes more chronic, other impairments can be addressed. The muscles strained at the time of injury and the segmental muscles related to levels of articular dysfunction often show impairment of force production. A specific strengthening program can be designed to improve muscle function. Higher load Stage II and III stabilization exercises (see Display 23-1) should be taught and progressed as tolerated. It has been shown that the lower load nod type exercises do not regain strength to the same extent as higher load head lift type exercises,[52,84] so these should be included when the healing structures of the neck are able to tolerate the larger forces. In some chronic cases, overactivity of the superficial muscles is the predominant feature, and so continuing to use low load exercises to focus on the downtraining of these superficial muscles may be more appropriate than a focus on strengthening with no consideration given to the motor pattern. Postural impairments continue to be a concern, and treatment interventions should include dynamic exercises that encourage movement patterns that incorporate optimal posture.

Neural Entrapment

Etiology

The cervical nerve roots can become entrapped as they exit at the intervertebral foramen. The foramen is bounded by the zygapophyseal joint, the UV joint, the disk, and the pedicle. Any pathologic condition increasing the size of these surrounding structures can lead to narrowing or stenosis of the foramen, potentially entrapping the nerve root. Foramen size is also reduced by the movements of extension, ipsilateral side flexion, and rotation. Any muscle imbalance producing this resting position of the cervical spine would further aggravate the problem. The FHP can place the upper and midcervical spine into a posture of increased cervical lordosis, decreasing the intervertebral foramen size. Any scapular resting position that encourages this cervical position (e.g., elevated scapula) or stretches the nerve root (e.g., depressed or protracted scapula) would also aggravate the condition. Changes in neural conduction depend on the degree of pressure or traction on the nerve root.

The term *double crush syndrome* or *multiple crush syndrome* has been used to describe the syndrome in which the nerve is affected at multiple sites along its course from the cervical spine to the hand. Common sites of entrapment are the cervical intervertebral foramen, the thoracic outlet, the elbow, and the carpus. Pressure at any one of these sites in isolation may be insufficient to produce symptoms, but there can be a summative effect as subsequent sites add their "crush" to the nerve.

A common example of crush syndrome is carpal tunnel syndrome. There may be decreased space in the carpal tunnel locally, but it may not be as marked as the symptoms suggest. There may be additional proximal symptoms that are unexplained by pressure at the carpal tunnel alone. In the cervical spine, there may be some mild degenerative changes involving the zygapophyseal joint and uncinate process that decrease the intervertebral foraminal dimensions. A superimposed FHP places the upper and midcervical spine into a resting position of extension, further compromising intervertebral foramen size. A short scalene muscle on the same side, because of a faulty respiratory pattern or the habitual crooking of a phone between head and shoulder, causes a side-flexed posture of the cervical spine and further decreases the intervertebral foramen space. At the thoracic outlet, a shortened scalene muscle can also elevate the first rib, decreasing the size of the thoracic outlet and creating another potential site of neural entrapment. A depressed scapular resting position places a traction force on the brachial plexus, which can also decrease neural conduction, and increases tension in the neuromeningeal system in the upper quadrant, which can aggravate the condition.

Treatment

Thorough assessment at each of the sites of entrapment can identify the impairments contributing to the condition. Treatment interventions address the impairments found at the cervical spine, thoracic spine, shoulder girdle, and wrist. If wrist dysfunction is treated in isolation, the symptoms tend to recur or change, often working their way proximally. Exercise treatment interventions for the impairment of posture are particularly useful, as is addressing the findings of neuromeningeal hypomobility.

Cervicogenic Headache

Etiology

CHA can be caused by two mechanisms. First, the posterior aspect of the skull, as far forward as the vertex, is supplied by the greater occipital nerve (a branch of the C2 and C3 posterior rami). Any structure supplied by the second or third cervical nerve can refer pain into that distribution. Second, the spinal nucleus of the trigeminal nerve descends into the spinal cord to at least the level of C3. Branches of the trigeminal nerve supply the mandibular, maxillary, and frontal areas of the face. Afferents from the first three or four cervical nerves converge with afferents of the trigeminal nerve. Any structure supplied by these neurologic segments can refer pain into the head and face, causing headache of cervical origin.[71]

There has been conflicting results in studies that have looked for the presence of FHP in subjects with CHA as compared to other headache types.[8,66,67,85] Hypomobility is a feature of CHA. In particular, symptomatic segmental stiffness in the upper cervical spine has been found in this population.[19,67,85,86] As with other subjects with neck pain, those with CHA demonstrate weakness and lack of endurance of the deep cervical flexors and extensors along with excessive activity of the superficial groups.[19,67,86] Zito et al.[67] found a higher incidence of muscle tightness in these subjects as compared to other headache types, but this tightness was not confined to a specific muscle or muscle group. Jaeger[87] found a significant number of myofascial trigger points on the symptomatic side compared with the asymptomatic side in patients presenting with CHA.

Treatment

Treatment interventions should target impairments of posture, mobility, and muscle performance. Mobility exercises may be performed as generalized ROM exercises or designed as specific articular mobilization exercises to address the segmental mobility restrictions found on manual mobility testing, most often of the upper cervical intervertebral levels (see the "Hypomobility" section). Specific muscle stretches can address the myofascial tightness and trigger points that may be contributing to the headache. Progressive exercises to increase muscle performance and endurance of the deep cervical flexor and extensor muscles should be included in the exercise program. Jull et al.[88] showed that a combination of manual therapy and specific therapeutic exercise gave significant improvement in intensity, frequency, and duration of headaches in a population with chronic CHA as compared to controls. This improvement was maintained at 12 months.

LAB ACTIVITIES

Constructing New Knowledge

- Consider a 45-year-old male patient with long-standing mild neck pain. Examination findings reveal weakness of both the DNF and the superficial flexors. Describe a progression of exercises to first address the deeper muscle weakness and then the more generalized flexor weakness. Be sure to include dosage.
- Consider a 22-year-old-female patient who has resolved from a recent episode of acute wry neck (torticollis). This is her third episode in the past year. Your examination reveals hypermobility on testing at the C4–C5 segment. Outline the progression of exercises you would prescribe to develop dynamic stabilization of her cervical spine.
- A 35-year-old female patient sustained a WAD II injury in a motor vehicle accident 2 weeks ago. She is reluctant to move her neck, and you note excessive bracing of the superficial musculature on many of your tests. Describe three exercises that you could prescribe on this first visit to assist in improving her mobility and relaxation of her superficial muscles. Be sure to provide information about the education component to assist this patient in confidently performing the appropriate dosage for this group of exercises.
- Your patient is a 65-year-old male with poor static resting posture. He has a FHP along with an increased thoracic kyphosis. A number of his neck muscles have shortened because of this constant position, and his SCM muscle is overdominant. List those muscles which are likely to have shortened in this situation. Create an exercise program to address both the muscle length and balance impairments and to gain control over the FHP.
- Consider a patient with a restriction of left side flexion, with the tightness felt on the right side of the neck. List three different types of structures which could be contributing to this restriction of motion. Describe one mobility exercise you could teach to address each one. Give a progression wherever possible.
- Describe the situations in which you would use a higher load neck flexor strengthening exercise as compared to a low load DNF recruitment exercise.
- Your patient presents with an asymmetric loss of strength of rotation/side flexion to the right. Which exercises could you use to specifically target this asymmetric pattern?
- Your patient is a painter with neck pain, aggravated by overhead work, particularly when painting ceilings. You notice that his neck collapses forward into anterior translation in the mid-cervical spine on active neck extension. You have already helped him to retrain and strengthen the DNFs, but you notice that his extension pattern has not really changed. Describe a progression of exercises you could use to retrain an optimal extension pattern, leading to control of the anterior translation tendency while painting ceilings.
- Your patient presents with a diagnosis of thoracic outlet syndrome. On examination, you identify overactivity of her anterior scalene muscles. Describe three exercises you could prescribe to assist in downtraining the excessive activity of this muscle.

KEY POINTS

- The cervical spine examination and evaluation consists of a patient report (subjective history) and the physical (objective) examination. The patient report should include information about the patient's job, sitting position, and type of exercise performed. The physical examination includes visual observation; active and passive movement tests, including myofascial and neuromeningeal extensibility tests; manual muscle testing; neurologic tests; various special tests; and clearing tests of the thorax, shoulder girdle, and TMJ.
- Common impairments of body structures and functions affecting the cervical spine include muscle performance impairment, posture impairment, and mobility impairment (i.e., hypomobility and hypermobility).
- A therapeutic exercise program is developed to address each impairment that is directly related to activity limitations and participation restrictions
- The following are common diagnoses of the cervical spine:
  - Disk dysfunction: Impairments that are often associated with this diagnosis include mobility (i.e., hypomobility and hypermobility) and posture.
  - Sprain or strain: Impairments associated with this diagnosis include mobility, posture, and muscle performance.
  - Neural entrapment: Impairments associated with this diagnosis include mobility and posture.
  - CHA: Associated impairments include mobility, posture, and muscle performance production, particularly endurance.
- For any patient presenting with a particular diagnosis, the associated impairments are identified. They must then be prioritized according to their relative importance as those requiring immediate attention and those most likely to be tolerated by the patient.

CHAPTER 24

The Thoracic Spine

ELIZABETH A. V. BLOOM • CARRIE M. HALL

The thoracic spine is unique in its structure and function from the remainder of the spine because of its articulations with the sternum and ribs and its critical role in ventilation. The thoracic spine's location between the cervical and lumbar spine creates a vulnerability to impairments in these related regions. Conversely, impairments in the thoracic region affect function of the surrounding spinal regions. As a critical link in the kinematic chain, functions of other regions of the body (e.g., shoulder girdle, hip, foot, ankle) affect function of the thoracic spine and vice versa.

Unlike the lumbar and the cervical spine, there is a paucity of literature regarding the management of thoracic spine impairments, particularly regarding interventions for impaired muscle performance. Much of the approach to exercise for the region must be extrapolated from the lumbar and cervical regions, with allowance made for differences because of the thoracic cage. This chapter presents principles and examples of therapeutic exercise prescription for common pathologies and impairments affecting the thoracic region which ultimately contribute to a person's activity limitations and participation restrictions.

As you progress through this chapter, it may be helpful to keep patient scenarios in mind. For each scenario in **Display 24-1**, ask yourself how you would address the patient's impairments, activity limitations, and participation restrictions through an appropriate exercise program. What exercises would you choose? How would you dose the exercises (number of repetitions, sets, speed of movement, amount of rest, progression from initial session to discharge, and so on).

DISPLAY 24-1

Patient Cases

Pain

Orson Buggy is a 60-year-old horse-drawn carriage driver who complains of mid-back pain that limits his work tolerance. He describes an ache that increases the longer he sits, which he must do to drive tourists. He also reports a sharper pain of short duration that occurs when the carriage hits a bump or hole, relatively often in the area he must drive. You observe that he sits in a flexed posture. His pain is aggravated by flexion with overpressure, and vertical compression of his trunk while in his resting sitting position. His pain is less with extension. Compression of his trunk when sitting upright is painfree.

Osteoporosis/Insufficiency Fracture

Viola Fuss is a 64-year-old meditation and stress relief counselor with moderate osteoporosis who complains of mid-back pain. Radiographs reveal a stable compression fracture of the T6 vertebral body; both her orthopedist and radiologist feel it is stable and she is cleared for exercise. Her primary activity limitation is decreased walking endurance because of fatigue and shortness of breath.

Hyperkyphosis/Parkinson Disease

Denton Fender is a 56-year-old auto body mechanic who was diagnosed with Parkinson disease 3 years ago, and is still in the early stages. Individuals with this disorder typically acquire a flexed posture as they age and the disease progresses. In addition, their voice volume is often low, reflecting a decrease in chest and diaphragm excursion because of the resulting hyperkyphosis.

Dustin Dubree is a 72-year-old construction company owner with Parkinson disease who's "on" periods last about 3 hours. He remains active running his company, including overseeing work at job sites. His major complaint at this time is having to take three or more attempts at rising from a chair, and taking up to a minute some times to straighten into an upright posture upon standing. You note on physical exam that he has limited hip flexion and lumbar extension.

Thoracic Outlet

Laura Biden is a 22-year-old policewoman with diffuse neck, shoulder, arm, and hand pain and numbness in the fifth digit. These problems make it difficult to write traffic tickets. You note that she sits and stands with an exaggerated kyphosis and forward, drooping shoulders. Passively or actively holding her shoulders back and straightening her back improves her UE symptoms after several minutes. She notes she is unable to maintain this position for long, however.

EXAMINATION AND EVALUATION

A comprehensive examination, including the history, systems review, and tests and measures, enables the physical therapist to determine the diagnosis (based whenever possible on impairments, activity limitations, and participation restrictions), prognosis, and interventions.[1–3] The physical therapist must follow an organized, sequential approach in order to avoid omitting crucial information that may prevent an accurate interpretation of the findings. In addition, a detailed history must be taken to determine the nature and extent of the dysfunction. Beyond the general data generated from a patient/client history as defined in Chapter 2, the following information is important to obtain from a patient with impairment, activity limitations, or participation restrictions involving the thoracic spine.

History

While primary thoracic spine pain is common in the general population,[4] (**Evidence and Research 24-1**) the thoracic region is also the site of many visceral and pathologic causes and sources of pain (**Evidence and Research 24-2**). Most of the visceral organs are innervated by the thoracic spinal nerves and may refer pain to the thoracic spine and rib cage (e.g., back or chest pain due to acute myocardial infarction or dissecting aortic aneurysm,[5] pain located at the costovertebral angle of the lower thoracic segments that actually originates in the kidneys, chest pain or back pain because of infection or other inflammatory disorders, back pain due to vertebral fractures, referred pain due to neoplasms). Therefore, questions must be asked which will help determine whether or not physical therapy is the appropriate management option for the patient, especially as physical therapists may see patients in a direct access setting. The findings from a thorough history can indicate possible nonmechanical sources of symptoms (see Appendix 1). If the therapist suspects that the pain is derived from nonmechanical or visceral sources, the patient should be referred to the appropriate medical practitioner.

EVIDENCE and RESEARCH 24-1

A systematic review of 33 studies concluded that the prevalence of thoracic back pain was very broad because of many factors, including the duration of thoracic back pain.[4] Prevalence data ranged from 4% to 72% (at any one time), 0.5% to 51.4% (7 days), 1.4% to 34.8% (1 month), 3.5% to 34.8% (1 year), and 15.6% to 19.5% (lifetime). Reports of thoracic back pain were higher in children and adolescents. In children and adolescents, pain was associated with female gender, postural changes associated with backpack use, backpack weight, other musculoskeletal symptoms, participation in specific sports, chair height at school, and difficulty with homework. In adults, pain was associated with concurrent other musculoskeletal symptoms and difficulty in performing activities of daily living (ADLs).

EVIDENCE and RESEARCH 24-2

Ozaki et al.[6] reported on 22 cases of spinal osteoid osteoma or osteoblastoma of which six were in the thoracic spine. Deyo and Diehl[7] reported on 1975 patients in an outpatient primary care setting with spinal pain of which 316 (16%) had thoracic spine pain. Two (0.63%) of these patients had cancer as the cause of the thoracic pain. This was similar to the 0.66% of cancer-related pain for patients with low back pain.

Systems Review

A systems review provides a screen of the pertinent systems. If problems are observed during this review, more detailed tests and measures should be performed as the next phase of the examination process. Information about disorders of other systems (e.g., cardiopulmonary, genitourinary, gastrointestinal) that may mimic thoracic musculoskeletal disorders should be obtained during the medical history portion of the examination, and used to guide the subsequent systems review. For example, a systems review of the cardiopulmonary system includes screens of the lungs (e.g., respiratory rate, breath sounds), heart (e.g., heart rate, heart sounds), and blood pressure.

A systems review of the skeletal system is also called a scan examination. The scan examination is a quick procedure that includes tests and measures listed in **Display 24-2**. Because the thoracic spine spans the upper and lower quadrants, screens of both regions are advisable, particularly as they relate to the transitional zones (i.e., C7–T1 and T12–L1). Chapter 23 provides a more detailed explanation of the upper quadrant scan

DISPLAY 24-2

Outline of a Scan Examination

Observation

- Range of motion
- During trunk flexion observe for rib hump (scoliosis)
- Motor assessment
- Sensory assessment
- Vascular status
- Reflexes
- Palpation
- Clearing tests

Upper Quadrant (see Chapters 23 and 25)

- Foraminal encroachment
- Compression or distraction
- Upper limb tension test (ulnar bias may indicate upper thoracic pathology)
- Thoracic outlet syndrome (TOS) tests

Lower Quadrant (see Chapters 17 and 19)

- Prone knee bend (may indicate low thoracic pathology)
- Straight-leg raising
- Slump test
- Hip flexion, abduction, external rotation (FABER)
- Scour test

examination, and Chapter 17 explains the lower quadrant scan examination.

Individuals with kyphotic postures, especially elder women with a history of osteoporosis, should be screened for vertebral body fractures. In the case of a healthy spine, vertebral body fractures can result from blunt force or injury. Individuals with excessive spinal stiffness should be examined radiographically for ankylosing spondylitis. To be considered significant, radiographic findings must be correlated with the clinical examination findings.

Additional medical screening is highly indicated in individuals whose symptoms do not appear to be mechanical in nature, who have a history of cancer, risk factors for vascular disease, a history of exposure to tuberculosis, or bilateral lower extremity neurologic complaints with or without reports of incontinence (see Appendix 1). It is important to understand the origin of the problem, because the decision to refer on an emergent basis rather than on a routine follow-up visit with the physician will depend upon the system involved, the nature and severity of the complaint, and the clinical findings.

Tests and Measures

The next step in the examination process is the selection of one or more tests and measures to ascertain the impairments, activity limitations, and participation restrictions of the patient. This determination leads to the development of the final diagnosis and the prognosis, which should guide the physical therapist's choice of management options. The selection of tests and measures, like the choice of questions asked, should be driven by the provisional diagnosis list. The choice of performing any tests and measures therefore depends on the results of the history and systems review. Each test or measure should contribute to the process of either confirming or refuting a potential cause of the problem. Proceeding in this manner eliminates unnecessary procedures and streamlines the examination.

Tests for regions other than the thoracic spine, for example, the lumbopelvic, hip, or cervical areas, may be chosen should the provisional diagnosis list require them. **Display 24-3** lists impairments that may require examination in patients with thoracic complaints. The reader is referred elsewhere for a detailed explanation of each test and measure.[8]

DISPLAY 24-3
Component Impairments Related to Thoracic Kyphosis During Gait

Stance Limb

- Initial contact: Hip extensor strength is necessary to prevent backward lean by means of lumbar lordosis. Lumbar lordosis can lead to thoracic kyphosis.
- Terminal stance: Hip flexor length and hip joint extension mobility are necessary to prevent lumbar lordosis and secondary thoracic kyphosis.

Swing Limb

- Hip extensor length, hip joint flexion mobility, and hip flexor strength are necessary to perform proper hip flexion during swing and prevent backward lean by means of lumbar lordosis to advance the limb. Lumbar lordosis can lead to thoracic kyphosis.

Trunk

- Balance between length and performance of oblique abdominal or spinal extensor muscles is necessary to prevent thoracic kyphosis.
- Counterrotation between the pelvis and trunk is necessary to promote optimal trunk function during gait to prevent compensatory thoracic flexion.

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON IMPAIRMENTS OF BODY STRUCTURES AND FUNCTIONS

The basic steps in designing the plan of care for a patient or client are to (1) identify the impairments that relate to the observed posture or movement pattern, activity limitation and participation restriction, and (2) address each causative impairment as necessary. Therapeutic exercise interventions for the thoracic region include activities and techniques that address impairments that directly and indirectly affect thoracic spine function. Comprehensive treatment of thoracic activity limitations and impairments requires treatment of related areas, including the cervical spine, the shoulder girdle, and the lumbopelvic region.

The ultimate goal of all therapeutic exercise interventions should be to regain maximum pain-free function. This requires addressing impairments contributing to the faulty movement that are related to activity limitation and participation restriction. Analysis of complex movements (e.g., gait, forward bending, reaching, rising from sitting, ascending or descending stairs) requires division of the movement into component parts to analyze the contribution from each segment or region involved in the movement. The examination and evaluation should reveal specific regional physiologic impairments such as hypomobility in the hips, restricted mobility of the spine, or impaired muscle performance of the shoulder girdle. Combining the information obtained from movement analysis and specific examination of selected regions can determine which impairments need to be addressed to improve the strategy of movement for the given task. For example, a goal of maintaining a neutral spine while walking for an individual with pain related to thoracic kyphosis may require improving any one or all of the impairments listed in **Display 24-4**.

In an appropriate treatment progression, component impairments are first addressed, followed by integrated movements with relatively simple activities or techniques, progressing to more challenging activities or techniques, and then progressing to complex, integrated functional movement patterns. **Figure 24-1** demonstrates an integrated movement in sidelying, which is gravity-lessened for the hip flexors and gravity-assisted for the oblique abdominal muscles and spinal extensors. This movement pattern can be progressed to the upright position of the swing phase of step-up (**Fig. 24-2**) and eventually into the swing phase of gait (after the stance phase of gait components has adequately improved through another set of exercises).

Because the thoracic spine lies between the shoulder girdle and lumbo-pelvic-hip complex, correction of movement impairments of these regions may be necessary to improve the movement pattern of the thoracic spine. Movement impairments

DISPLAY 24-4

Required Tests and Measures for Thoracic Spine Examination

Aerobic Capacity: Assessment of vital signs may be necessary, particularly when working with patients with a cardiopulmonary disorder or patients at risk of falls.

Ergonomics and Body Mechanics: The ergonomics of the patient's workstation(s) can provide vital information regarding the pathomechanics of the condition. Observation of the ADLs and the patient's occupational and recreational movement patterns can reveal impairments in movement in the thoracic and related regions. For example, when reaching across the body, one might observe excessive thoracic flexion and lateral flexion as compensatory movements for insufficient hip and thoracic rotation.

Gait, Locomotion, and Balance: Assessment of these skills can determine risk for falls.

Joint Mobility and Integrity: Arthrokinematic testing of the zygapophyseal, costotransverse, sternocostal, and sternochondral joints. Motion findings in these tests should correlate with osteokinematic findings. Specific testing of osteokinematic function of the ribs can be assessed during inhalation and exhalation.[9]

Motor Function: Altering impaired movement patterns and observing for an associated change in symptoms will assist in determining the pathomechanics of the symptoms. For example, in the case of compensatory thoracic flexion and lateral flexion because of reduced hip and thoracic rotation, having the patient rotate the hip and thoracic spine to the limit of mobility while thoracic flexion and lateral flexion are restricted should alter the movement. This can be achieved manually by the therapist or actively if the patient is able to make the change from verbal instruction alone. If the symptoms are reduced with the new movement pattern, the flexion or lateral flexion movement patterns are assumed to be contributing to the symptoms.

Muscle Performance: Include muscle performance tests to determine the presence of nerve root dysfunction in the cervicothoracic and thoracolumbar regions. Manual muscle testing can identify imbalances in muscle performance between synergists and agonist–antagonist muscle pairs in the trunk and shoulder girdles (see Chapters 17 and 25).

Pain Tests and Disability Measures: The Functional Rating Index[10] (measures the magnitude of clinical change in spinal conditions), Oswestry,[11] and Roland–Morris Disability Questionnaires[12] (disability scales developed for the cervical and lumbar spines which, although not specific to the thoracic spine, can be used to gain insight into the condition's effect on the patient's life; see Chapters 17 and 23).

Posture: Particularly as it relates to the head and neck and lumbar-pelvic-hip complex in standing, sitting, and recumbent positions, signs of asymmetry and scoliosis.

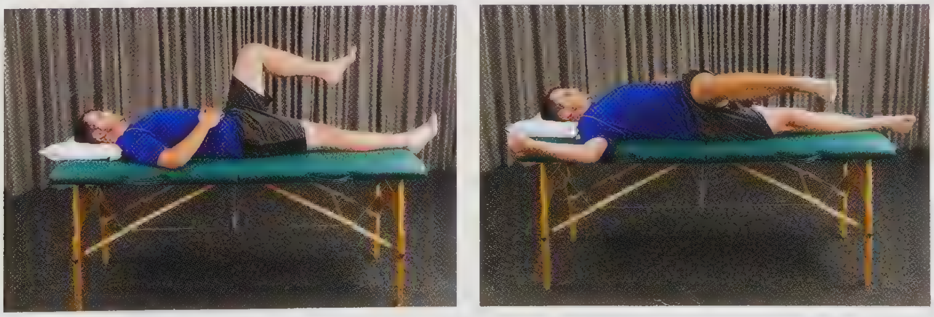
Range of Motion and Muscle Length: Assess the quality and quantity of motion in general as well as intersegmental mobility during active and passive osteokinematic thoracic and upper extremity movements; observe for localized areas of hypermobility with associated areas of hypomobility. Assessment of unilateral upper extremity elevation can assist in the assessment of mobility of the upper thoracic region. For example, upper thoracic extension and rotation to the ipsilateral side should accompany upper extremity arm elevation.[2]

If articular function in a specific joint is found to be normal, and yet overall mobility is limited, lack of myofascial extensibility can be suspected as a primary cause. For example, a stiff or short right external and left internal oblique can limit right thoracic rotation. If this were the case, accessory joint play assessment would reveal normal joint mobility.

Sensory Integrity: Function of the intercostal nerves; special tests, such as those for TOS and neural tension.

Ventilation, Respiration, and Circulation: Observation of breathing patterns can be very useful in fully understanding underlying contributing factors to numerous diagnoses such as kyphosis-related diagnoses and TOS. Assess the quality (e.g., proper pump and bucket handle motions of the rib cage, looking for movement in all three directions) and quantity (rate, inspirometry) of respiration.[2]

Other: Radiographs (diagnosis and curve angle in scoliosis, Scheuermann disease, and kyphosis related to osteoporosis, signs of ankylosing spondylitis); MRI (soft tissue pathology such as herniated nucleus pulposis); additional medical screening for visceral sources of thoracic pain (see Appendix 1).



A B

FIGURE 24-1 This exercise promotes simultaneous hip flexion and trunk counterrotation to prepare for the complex movement of the swing phase of gait on the left. **(A)** The start position is supine with hip and knee flexion. **(B)** The end position is sidelying with hip and knee flexion and left trunk rotation.

FIGURE 24-2 During the swing phase of the step-up, trunk counterrotation can be emphasized to facilitate the complex movement during the swing phase of gait.

at the foot and ankle also can contribute to impairments in the thoracic spine. The link between the foot and the thoracic spine is reviewed in a subsequent section on scoliosis. Chapter 21 details the exercise prescriptions for impairments in the foot and ankle.

Impaired Muscle Performance

Patients with impairments, activity limitations, or participation restrictions related to impaired muscle performance require resistive exercise with dosage parameters targeted toward a goal of increased force or torque production, power, or endurance (see Chapter 5). The cause of the altered muscle performance must be determined to ascertain the appropriate intervention to treat the impairment. The intervention plan developed is specific to the source or cause. There are several possible sources of reduced force or torque production:

- Neurologic impairment or pathology (e.g., peripheral nerve injury, nerve root injury, CNS disorder, impaired neural dynamics)
- Muscle injury or strain
- Disuse resulting in atrophy and general deconditioning
- Length-associated changes resulting in altered length–tension properties

Neurologic Impairment or Pathology Intervention

When muscle performance is impaired because of neurologic injury or pathology, the neural input must be restored in order for muscle performance to improve. If the nerve injury or pathology is permanent and paresis or paralysis is the outcome, the clinician must consider the effect of the resulting muscle weakness and subsequent adaptive shortening or contracture in the opposing muscles. In the case of paresis, the clinician must consider the effect of stretch on the weak muscle because of antagonist action superimposed on the initial weakness caused by the nerve damage. If reinnervation is latent, these same considerations must be heeded during the recovery process. Weak muscles must be protected from overstretch with proper support and stimulated with appropriate-dosage resistive exercise in the short range. The strong muscles must be stretched to maintain proper extensibility and prevent contracture and deformity.

One example of impaired muscle performance related to neurologic injury or pathology is reduced muscle force production in the diaphragm resulting in faulty breathing mechanics. Diaphragmatic breathing exercises cannot be effective until the source of the weakness is appropriately addressed. Because the diaphragm is innervated by the phrenic nerve (C3–C5), treatment of any cervical dysfunction at these levels may be necessary to improve diaphragmatic function. Subsequently, appropriate diaphragmatic breathing must be taught along with stretch of the lateral trunk and intercostal muscles (**Patient-Related Instruction 24-1**; **Fig. 24-3**). The lateral trunk and intercostal muscles may become stiff because of the unilateral rib approximation that may result from inadequate rib expansion, causing weakness in the diaphragm.

In the case of paraplegia with thoracic spine involvement, impaired respiration may result. Full excursion of chest expansion should be encouraged via deep breathing exercises utilizing the diaphragm. Resistance can be applied to the chest walls, diaphragm, and sternum via manual contacts using principles of proprioceptive neuromuscular facilitation (see Chapter 15) or using equipment. For example, inspiration can be facilitated using elastic bands wrapped around the chest. Resistance can be given to the diaphragm by placing weight on the abdomen while in supine (**Fig. 24-4**). The patient should be instructed to take full, deep breaths.

Evaluation of back pain should also include evaluation of neural tissue mobility by conducting upper and lower limb tension tests. Though the evidence is limited, neural tissue dynamics has been reported in clinical orthopedic physical therapy literature and is supported by basic science research and clinical case reports.[13–15] Since the sympathetic chain is positioned anteriorly along the rib heads and costovertebral joints,[16] further tension and stretching of the sympathetic chain can occur with thoracic flexion (e.g., excessive kyphosis, poor posture, or during a slump test) and contralateral side bending. The area from T4–T9 is significant because of the smaller diameter of the vertebral canal; T6 is reported to be a tension point in the nervous system. Butler postulates that during cervical and thoracic flexion, the spinal cord, relative to the spinal canal, moves cranially toward the cervical spine and caudally toward the lumbar spine. Segmental hypomobility of the middle thoracic spine could contribute to signs and symptoms associated with adverse neural tissue dynamics. Therefore, restoring thoracic mobility may help to facilitate treatment goals[14,17–20] related to upper or lower extremity neural tension.[21]

Muscle Strain or Injury

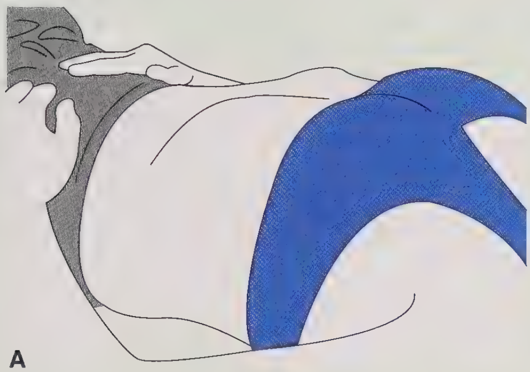
Causes Trauma, such as a blow to the chest or a sudden rotational injury sustained in a motor vehicle accident, can lead to muscle injury. An insidious-onset strain can also occur in muscles surrounding the thoracic region. Possible mechanisms of gradual insidious-onset muscle strain include overuse or overstretch.

One example of overuse in the thoracic region is provided by the scalene muscle group, particularly the anterior scalene. The actions of the anterior scalene include cervical flexion, ipsilateral cervical lateral flexion, contralateral cervical rotation, and elevation of the first rib (i.e., acting as an accessory muscle of respiration). Overuse of the anterior scalene can result from underuse or weakness of the deep cervical flexors (i.e., longus colli and capitis and rectus capitis anterior), other contralateral cervical rotators

Patient-Related Instruction 24-1

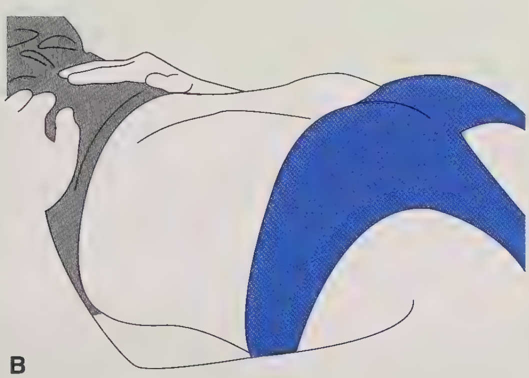
Diaphragmatic Breathing

- Initially, assume a comfortable position on the floor with your hands on your stomach.
- Relax your belly as much as possible.
- During the first third of inhalation, the belly should expand slightly (on its own) in an outward direction as the diaphragm pushes down on the contents of the abdomen.



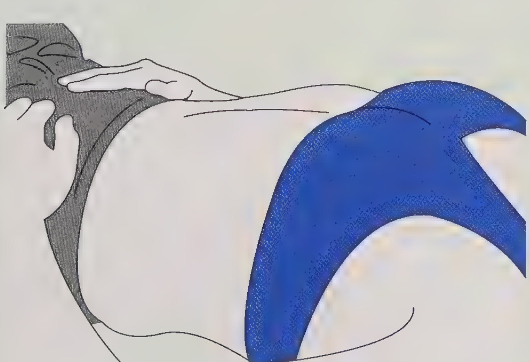
A

- Next, the air should move into the middle portion of the lungs, causing the area of the lower and middle ribs to expand. Complete inhalation means filling the lungs forward, sideways, and backward.



B

- The dimension of breathing often neglected is sideways intercostal breathing.
- Exhalation is largely a passive occurrence. The chest muscles and diaphragm relax, the ribs drop back close together, and the lungs recoil as air is quickly expelled.



C

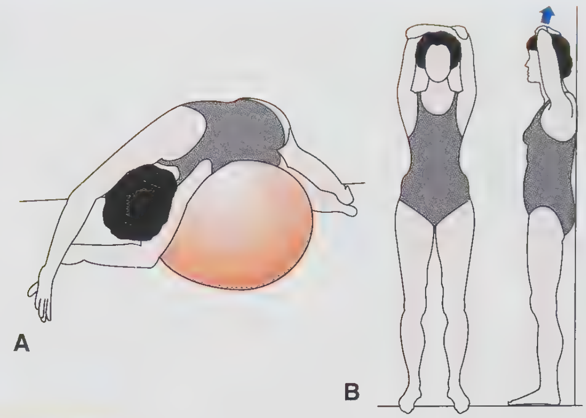


FIGURE 24-3 **(A)** Lateral trunk flexion stretch is assisted by gravity over a gymnastic ball. **(B)** Lateral trunk flexion while standing against a wall with arms overhead. The wall guides movement in the frontal plane. The arms-overhead position facilitates stretch to the intercostals. Diaphragmatic breathing into the stiff region can augment the stretch.

FIGURE 24-4 Resisted diaphragmatic breathing. **(A)** A weight can be placed on the patient's abdomen while in supine to provide resistance to diaphragm excursion. **(B)** Alternatively, by positioning the patient supine with the head inclined downward, the diaphragm must work against the weight of the abdominal contents during inhalation.

(i.e., deep cervical rotators, semispinalis cervicis, sternocleidomastoid, or upper trapezius), or primary muscles of inspiration (i.e., diaphragm, levator costarum, and intercostals). Chronic overuse can lead to stiffness or adaptive shortening of the anterior scalene, which can contribute to elevation of the first rib. Elevation of the first rib can disrupt cervicothoracic joint mechanics and contribute to TOS (see the section "Thoracic Outlet Syndrome").

Another example is middle and lower trapezius strain, which refers to the painful upper back condition resulting from gradual and continuous tension on the middle and lower trapezius muscles.[22] The strain in these muscles is caused by overstretch from a habitual position of forward shoulders (see Chapter 25), kyphosis, or a combination of these two faults. Treatment of the thoracic region must include treatment of the impairments related to the postural fault and/or the kyphosis to reduce the habitual stretch on the tissues (see the sections "Posture and Movement Impairment" and "Kyphosis").

Intervention Treatment of overuse of a particular muscle group must improve muscle performance of underused synergists and address the posture and movement patterns contributing to excessive use. In the anterior scalene example described above, instructing the patient in proper diaphragmatic breathing (see Patient-Related Instruction 24-1) rather than using accessory muscle strategies may be an important intervention to reduce the stress placed on the anterior scalene. The deep neck flexors are often weak, particularly after a neck injury (such as whiplash), and need to be strengthened in isolation of the overused muscle(s). Chapter 23 provides exercises in the "Impaired Muscle Performance" section to address weak cervical flexors. Stretch of the anterior scalene should be performed with caution. Stabilization of the first rib is essential so that gentle active range of motion (ROM) of the cervical spine in ipsilateral rotation can stretch the scalene without rib elevation or cervical anterior shearing (**Fig. 24-5**). The patient should be instructed to avoid chronic postures of cervical flexion or neck ipsilateral side bending and contralateral rotation to avoid overuse of the muscle in the short range (e.g., using a mobile device or talking on the phone for prolonged periods without use of a hands-free accessory (**Fig. 24-6**).

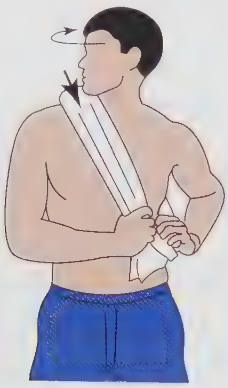

FIGURE 24-5 It is important to stabilize the first rib while stretching the anterior scalene. After the rib is stabilized, *gentle* active ROM into ipsilateral rotation stretches to the same side anterior scalene without undue cervical shear or first rib elevation.

Disuse Resulting in Atrophy and General Deconditioning

Disuse and deconditioning can be caused by illness, immobilization, sedentary lifestyle, or subtle shifts in muscle balance from repetitive faulty movement patterns. Progressive resistive exercises for the upper body can address general disuse and deconditioning. Initially, the weight of the limb alone can provide enough stimulus for strength gains in the severely deconditioned individual. Progression in small increments is recommended because the upper body muscles are small compared with those of the lower body, and excessive resistance added prematurely may promote muscle imbalance by strengthening the dominant synergists or antagonists (see Chapter 25). Abdominal and back extensor strengthening (see **Fig. 24-7**) may be indicated to improve the alignment, movement, and stabilizing function of the thoracic region (**Evidence and Research 24-3**). Chapter 17 describes proper exercise prescription for the abdominal muscles.

A B

FIGURE 24-6 Resting a telephone on an elevated shoulder with the neck in lateral flexion and opposite rotation can cause shortening and overuse of the anterior scalene muscle **(A)**. Prolonged neck flexion can lead to anterior scalene shortening **(B)**.

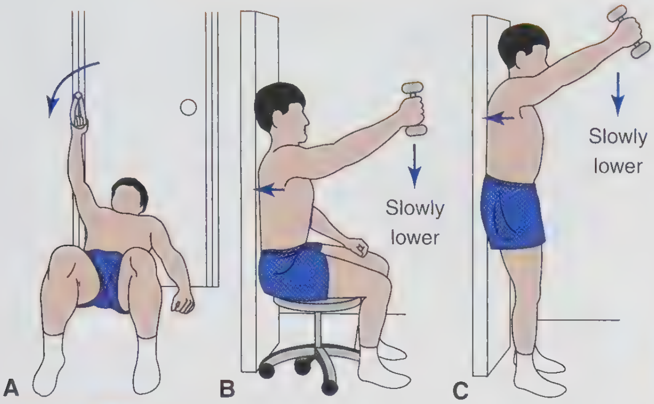

FIGURE 24-7 Activity promoting strength of the thoracic spine extensors in the short range in various start positions. In each position, the patient is instructed to maintain neutral cervical, thoracic, and lumbar spine positions using core activation strategies (see Chapters 18 and 24 for details on core activation strategies for the lumbar and cervical regions, respectively). Supine **(A)**, resisted upper extremity extension from a flexed position using elastic tubing. The thoracic extensors stabilize against the flexion moment. Sitting **(B)** and standing **(C)** upper extremity eccentric lowering from a flexed position stimulates thoracic extensor activity to stabilize against a flexion moment.

EVIDENCE and RESEARCH 24-3

Colado et al.[23] reported that maintaining a neutral posture alignment during exercises that stress the lower back can stimulate core-muscle activation as much or more than exercises involving stability devices.

Muscle function in response to injury has not been as well studied in the thoracic spine as it has in the lumbar spine. However, one can extrapolate lumbar findings to the thoracic spine in an attempt to make educated decisions regarding thoracic spine management (**Evidence and Research 24-4**).

EVIDENCE and RESEARCH 24-4

Many authors have highlighted the importance of the lumbar multifidus muscle in providing dynamic control,[24–27] and there is cumulative evidence that the cross-sectional area of the paraspinal muscles is smaller in patients with chronic[28–31] and postoperative low back pain.[32,33] Furthermore, it has been shown that recovery of multifidi muscle function in the lumbar spine is not automatic following resolution of the pain.[34] This atrophy may permit spinal hypermobility and instability and therefore be an important factor to consider in treatment of persons with spine-related pain.[35]

A study of cadavers found differences in position and mass between lumbar and thoracic multifidi, which may have implications for their function. Compared to the lumbar spine, the thoracic spine multifidi are deeper, thinner, and the fibers are more tendinous and oblique.[36] There is general consensus in the literature supporting the need for active reconditioning exercise in the treatment of spine pain.[37] Add to these findings the natural tendency toward kyphosis and forward shoulder posturing (because of the effects of gravity, aging, and habitual usage patterns), and it seems clear that thoracic extension strength and scapular stabilization should be an emphasis in any plan of care for the region. To improve the role of thoracic extensors and periscapular muscles in supporting posture, any exercise plan should be dosed so as to improve muscular endurance. Unfortunately, there is little agreement on which exercise regimens are most effective. The use of static stabilization training has been advocated[38] as an ideal means of improving the recruitment of back muscles capable of enhancing spinal stability, particularly the multifidus, obliques, and erector spinae (**Evidence and Research 24-5**).

EVIDENCE and RESEARCH 24-5

A study of 30 subjects with chronic low back pain found that pain and Oswestry disability index improved with lumbar stabilization combined thoracic extension exercises.[39] De Ridder et al.[40] observed thoracic and lumbar paraspinals had higher activation with trunk extension movements compared to leg movements and with movements that combined dynamic trunk extension (2 seconds for trunk extension) with a static hold for 5 seconds compared to dynamic trunk extension alone (2 seconds for trunk extension).

Though studies on scapular stabilization exercises are primarily focused on populations with shoulder pain or pathology, these studies also report improvements in posture, specifically in the position of the shoulder and head.[41–43] Postural dysfunction consisting of forward head and rounded shoulders is commonly noted in patients with thoracic pain.

This text describes a series of specific exercises to promote spine stability in Chapter 17 (see Patient-Related Instruction 17-1 and Self-Managements 17-1 and 17-2) and scapular stabilization in Chapter 25. The exercises presented in Chapter 17 can be extrapolated to the thoracic spine by adding the focus on thoracic spine alignment and thoracic multifidus activation. Progression of these exercises to use of thoracic paraspinals and periscapular muscles during ADLs and occupational and recreational activities are necessary for the best functional outcome.

Length-Associated Changes Resulting in Altered Length–Tension Properties

Causes Subtle imbalances in muscle length can lead to length-associated strength changes and positional weakness of one synergist compared with its counterpart or its antagonist muscle group. For example, in the thoracic spine, the erector spinae and upper rectus abdominis are susceptible to length-associated strength changes from chronic kyphotic posture. The thoracic erector spinae are vulnerable to overstretch while the anterior muscles such as pectoralis major, pectoralis minor, and upper rectus abdominis are susceptible to adaptive shortening. Overstretching and shortening can lead to conditions within the thoracic region such as joint impairments and respiratory dysfunction. Muscle imbalance can contribute to conditions in the adjacent cervical and lumbopelvic areas, and soft tissue dysfunction from the kyphosis-lordosis or swayback posture (see the section "Kyphosis").

Intervention Treatment of muscle length imbalance requires a twofold approach of strengthening the weak and overstretched muscle group (e.g., the thoracic erector spinae) in the shortened range (see **Figs.** 24-7 and **24-8**), while concurrently stretching adaptively shortened muscle groups (e.g., the upper rectus abdominis

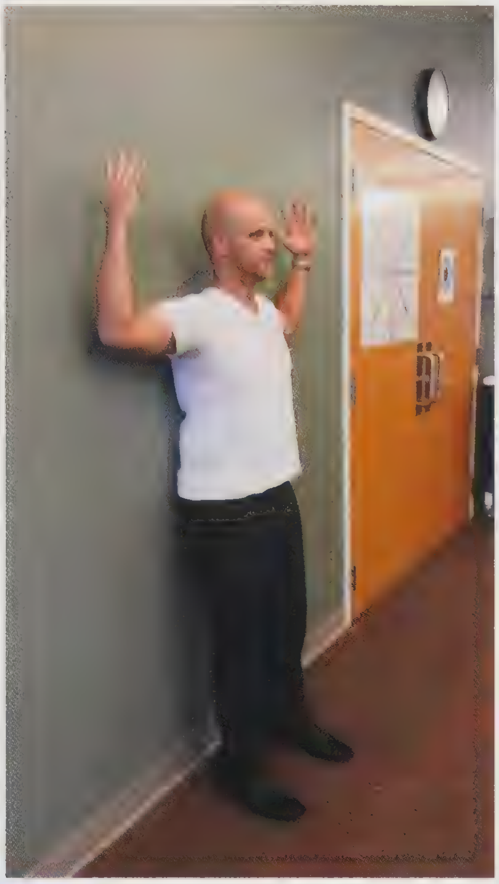

FIGURE 24-8 This exercise stretches superior fibers of the external oblique muscle at the rib angle and the shoulder adductors, and it provides resistance to the spine extensors and scapular upward rotators in the short range. Standing with the back to the wall in a neutral spine position, the patient raises her arms raised in horizontal abduction. The elbows are forward of the wall to maintain the arms in scapular plane. Deep diaphragmatic breathing is performed in this position. The arms can slide up the wall as the length of the pectoralis major allows. The lower abdominals contract to maintain the lumbar spine and pelvis in neutral alignment.

and pectoralis muscles). Supportive taping (see **Fig. 24-9**) can be used as an adjunctive measure to facilitate positive length-associated changes. Patient-related instruction aimed at correcting posture and movement patterns that perpetuate these length-associated changes is required to prevent recurrence of conditions caused by this muscle performance impairment. Instruction in appropriate ergonomic changes for computer or mobile device use is also necessary as use of technology is commonplace.

Impaired ROM, Muscle Length, and Joint Mobility/Integrity

Optimal function of the thoracic region requires full and symmetrical cardinal plane motion as well as combined motions. In addition, full thoracic spine and rib motion during breathing should be a goal. The examination should delineate joint versus soft tissue impairments, and the plan of care be designed appropriately. Lack of motion (hypomobility) can be the result of either joint or soft tissue impairments, and manual intervention will differ in each case (joint mobilization vs. soft tissue mobilization, for example). The exercise intervention, on the other hand, will typically address both causes simultaneously. Furthermore, improving thoracic mobility may restore length–tension relationships and allow more efficient strengthening of postural stabilizers. The general plan for excessive motion (hypermobility) is to stabilize with muscle function while addressing biomechanical factors, such as adjacent hypomobile areas, that transmit increased forces to, and produce excess motion in, the problem area. Finally, optimal function requires trunk stability during extremity movements. Therefore, appropriate thoracic exercise management will progress from active extremity movement to resisted extremity exercise, while demanding concurrent trunk stability.

Hypermobility

Causes A well-designed intervention plan for hypermobility of the thoracic spine must consider the mechanism or cause of the hypermobility. Spinal mobility must be examined both globally (e.g., the thoracic spine as a whole) and locally (e.g., segmentally). Optimal global spinal movement incorporates motion contributions from each spinal level. Lack of motion in one segment will transfer the mechanical stress to adjacent movement segments. The segments experiencing greater stress over time will become hypermobile. Tissue responses to the increased load may render the region symptomatic. In this case, intervention must address the local impairments. If the underlying cause is impairment in habitual posture or repetitive movement, the clinician must consider the integrated relationship between the foot and ankle, pelvic girdle, trunk, and upper extremity in developing a plan of care. If there is a history of macrotrauma but the expected healing time has been surpassed, the clinician must consider issues contributing to delayed or interrupted healing.

Interventions Regardless of the mechanism or cause of the hypermobility, central to the success of a program to improve stability of the thoracic spine is the concept that the trunk muscles must hold the vertebral column stable for independent upper and

A B

FIGURE 24-9 **(A)** Longitudinal tape spanning the kyphosis, applied in four-point kneeling to capture neutral spine alignment, can prevent excessive thoracic flexion. **(B)** Taping to inhibit scapular abduction and protraction, promoting neutral spine positioning of the scapulae.

lower extremity movement to occur. This role must be executed regardless of the speed of movement and any additional load the individual may be carrying. Spinal stability must be maintained without sacrificing adequate chest mobility necessary for respiration. Loads must be transferred from the ground upward in an efficient manner, and this can be done without cumulative microtrauma only if the forces are attenuated through an efficient kinematic chain from the foot and ankle upward through to the thoracic spine.

Improved Motor Control

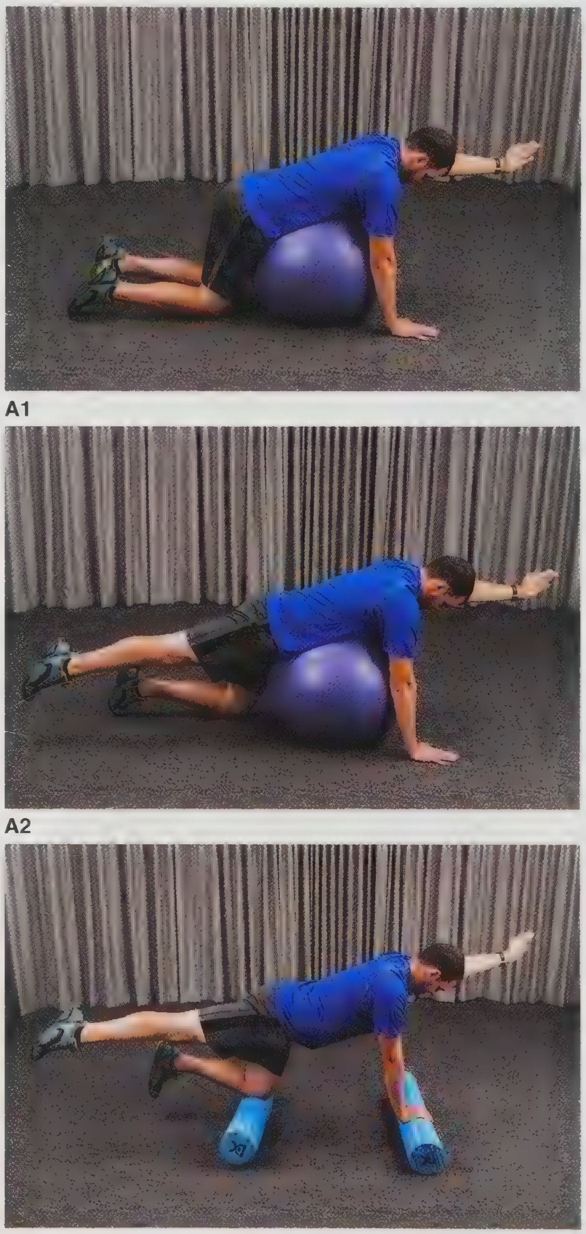
Intervention for hypermobility begins at the stability stage of motor control. Applying an axial load to the thorax and gauging the response can allow the estimation of ideal or optimal alignment in sitting or standing. In the optimal position, axial loading forces are distributed equally throughout the vertebral body and intervertebral disk. In symptomatic patients, the ideal alignment or "neutral spine" position will often allow asymptomatic axial loading. Additionally, in patients and clients alike, the therapist can feel the increased stability of the spine as the load is applied, as the spine does not give way into either flexion or extension. Specific motion segments that demonstrate hypermobility can be identified and exercises promoting stability can be prescribed. Exercises should target the single segment muscles, such as the multifidi, since multi-segment muscles like the semispinalis or iliocostalis promote multi-segmental motion. Since the primary action of the multifidus is rotation, resisted isometric rotation isolated to the hypermobile segment is a rational starting point. This can be initiated in sidelying with manual resistance. Home exercises can be performed using a straight-backed chair for stability and elastic band or tubing for resistance.

To progress the patient into the next stage, controlled mobility, movement is superimposed on a stable spine. The patient is instructed to hold the spine in ideal alignment during movements of the upper and lower extremity. The activity or technique chosen depends largely on the level of intensity the patient can sustain while maintaining ideal alignment with proper recruitment patterns. The prescribed direction of force imposed on the spine depends on the direction of the hypermobility. For example, a patient may present with difficulty in stabilizing against flexion forces such that, when the arm is lowered from a flexed position, the thoracic spine flexes instead of remaining in neutral alignment. A flexion force such as resisted (in some cases, using only the weight of the arm) or rapid upper extremity extension (from an overhead start position) can be used to challenge the spinal extensors. The exercises can begin in sitting with the back against the wall or in supine (see Fig. 24-7), and then progressed to standing. The former positions require stabilization of fewer regions than standing (i.e., sitting eliminates the need to stabilize the foot, ankle, knee, and hips), and the wall or floor provides proprioceptive feedback to enhance stabilization. Similar principles can be used in creating exercises to stabilize against rotational or lateral flexion forces.

As control of the hypermobile segment(s) improves, several variables can be adjusted to progress the difficulty of the controlled mobility exercises and make them more specific to the activity limitations and participation restrictions of the patient. For example, the speed of extremity movement can be altered based on the functional demands of the patient's work or lifestyle. Slow, controlled movements promote stability and endurance while faster movements such as catching a medicine ball promote fast recruitment.

Motor control and motor learning theory, based on findings in normal individuals,[44] suggests that altering the practice conditions and the amount, type, and scheduling of feedback is essential to optimal acquisition of motor skills. Accordingly, exercises and activities should be sequenced in a random fashion, rather than repeating the same activity. Feedback should be provided on an intermittent, rather than continuous, basis. Attention to these details will enhance skill acquisition.

Gymnastic balls, foam rolls, and balance boards can modify stabilization activities to provide a greater challenge by destabilizing the base of support (**Fig. 24-10**). The theory behind the



A1

A2

B

FIGURE 24-10 **(A1** and **A2)** These exercises use the labile surface of the gymnastic ball to stimulate balance and equilibrium reactions. The patient is instructed to maintain axial extension and neutral thoracic and lumbar spine alignment. Teach the patient cervical and lumbopelvic core activation prior to adding any arm or leg movements (see Chapters 18 and 24 for details on lumbar and cervical core activation strategies, respectively). **(B)** The foam rolls further destabilize the base of support.

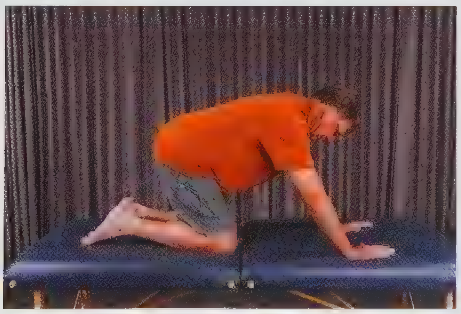
use of these pieces of equipment is that the labile base of support stimulates balance and equilibrium reactions. Continuous postural adjustments are required, facilitating smooth coordination of posture and movement. Care must be taken to ensure that the patient employs proper trunk stabilization strategies when using equipment that destabilizes the base of support.

Adjacent Areas of Hypomobility

Difficulty stabilizing against flexion forces is a common problem for the thoracic spine. The therapist must consider that excessive thoracic flexion may occur because of lack of mobility in related regions. For example, in sitting, a decrease in hip flexion mobility may be compensated for by thoracic flexion with forward-reaching or forward-bending movements. Four-point kneeling with a sit-back movement (**Fig. 24-11**) can promote hip flexion mobility and thoracic spine stability. This movement pattern must eventually be transferred to controlled mobility and skill level activities in sitting and standing positions, such as reaching forward with hip flexion while maintaining neutral spine position (**Fig. 24-12**).

Another common cause of excessive thoracic spine motion is lack of thoracic and hip rotation combined with excessive shoulder girdle protraction. For example, in cross-body reaching tasks, the elbow extends and the shoulder flexes and horizontally adducts until the full length of the arm has been reached. If further reach is required, the thoracic spine should rotate, followed by lumbar spine and hip joint flexion and rotation. If standing, a step toward the object can increase the reach span. The arm can effectively reach across the body if the scapula provides a stable base for arm movement and the thorax provides a stable base for the shoulder girdle. This movement requires appropriate recruitment and length–tension properties of the scapulothoracic, glenohumeral, spinal extensor, and oblique abdominal muscles. There must be ample mobility in the glenohumeral joint for upper extremity horizontal adduction and in the thoracic spine and hip joints for rotation. A prevalent faulty movement pattern is to reach instead with scapular abduction and thoracic flexion (**Fig. 24-13**). Impairments in the shoulder girdle, thorax, and hips may need to be addressed separately to improve the movement pattern of cross-body reaching and thereby reduce the tendency toward excessive thoracic flexion. One useful activity to retrain independent motion among the upper extremity, thoracic spine, and hip joints is shown in **Self-Management 24-1**. The prerequisites for correct performance of this exercise are proper movement patterns at the scapulothoracic, glenohumeral, and hip joints (see Chapters 19 and 25).

A



B

FIGURE 24-11 In four-point kneeling, the patient is instructed to maintain neutral spine position while rocking back toward the heels (**A** and **B**). At the point of hip flexion stiffness, the tendency is to flex in the lumbar and/or thoracic spine. The patient is instructed to stop at the onset of spine flexion.

A

B

FIGURE 24-12 **(A)** The standing subject reaches forward with excessive thoracic flexion. **(B)** The movement pattern is altered such that flexion takes place at the hips, knees, and shoulder, and the thoracic spine remains in neutral.

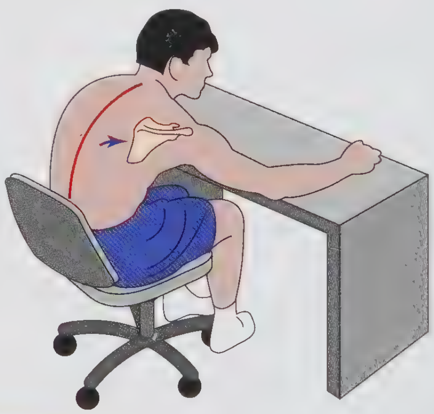


FIGURE 24-13 A prevalent movement pattern is to reach with scapular abduction and thoracic flexion.

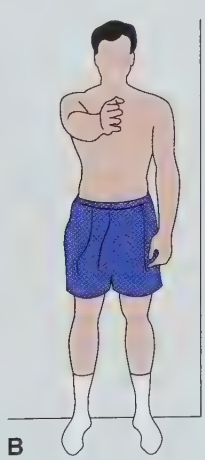
SELF-MANAGEMENT 24-1
Cross-Body Reaching

Purpose: To promote independent motion of the shoulder joint from the shoulder blade, torso, and hip. You should not progress to the next level without mastering the previous level. Use the movement pattern acquired in Level 4 (noted below) when reaching across the body for an object farther away than the span of the arm. Avoid reaching by moving your shoulder blade or flexing in your thoracic spine excessively.

Starting Position: Stand, facing away from the wall, with feet about two in away from the wall and the pelvis and spine in neutral. If your hip flexors are short or stiff, you may need to flex your hips and knees to achieve a neutral spine and pelvis position.

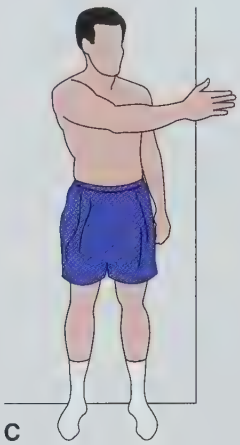
A

Movement Technique: **Level I:** Move your arm across your body to the midline without letting your shoulder blade move from its starting position. This may require a submaximal contraction of your interscapular muscles.



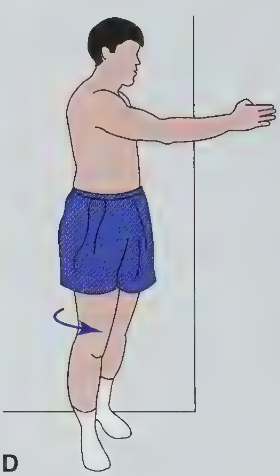
B

Level 2: After you can reach your arm to the midline of your body, rotate your torso as far as you can without moving at the hips, knees, ankles, or feet. Do not move your shoulder blade from its starting position. Do not let your thoracic spine flex; *rotate* it.



C

Level 3: After you have mastered independent rotation of your torso, add hip rotation to the movement. Do not move your feet from the starting position (i.e., do not take a step forward, but allow your ankles and feet to rotate naturally with hip rotation). Do not move your shoulder blades from the original position or allow your thoracic spine to flex forward.



D

Level 4: After you have performed rotation sequentially at the torso and hips, take a step diagonally forward across midline of your body. Do not let your shoulder blade move from its starting position, but achieve a greater reach by stepping across your body.

______________________________ Increase the speed of the movement.

______________________________ Add a weight in your hand.

External Support

Treatment of hypermobility in the thoracic spine may also include supportive devices such as a posture brace (to prevent thoracic flexion; **Fig. 24-14**) and taping. Taping can be used to facilitate and remind against excessive flexion and rotation (Fig. 24-9) and to retrain appropriate scapular positioning (inhibit protraction). As proprioception, strength, endurance, and control improve, the patient can be weaned off the supportive devices.

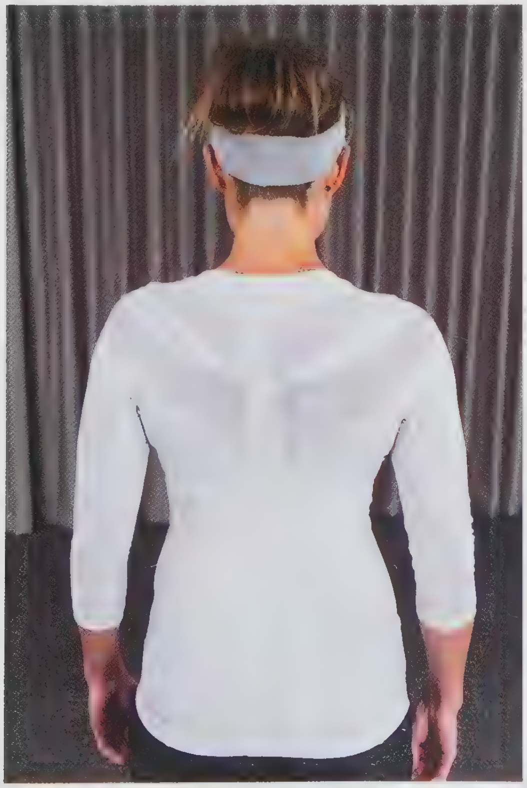

FIGURE 24-14 A posture brace or garment can be used to control excessive thoracic flexion.

Hypomobility

Impaired mobility of the thoracic spine and ribs may manifest as dysfunctions in other regions (**Evidence and Research 24-6**).

EVIDENCE and RESEARCH 24-6

Patients with cervical pain can have decreased pain and increased ROM after manipulation of the thoracic spine.[20,21] The last degrees of end-range shoulder flexion require thoracic extension and rotation; improving thoracic mobility has been shown to decrease shoulder pain.[19] Lumbar spine pain may result from excessive lumbar mobility that is related to relative thoracic hypomobility.[21]

In addition, poor thoracic spine and costovertebral mobility can remain asymptomatic while anteriorly pain can develop at the costosternal joints, resulting in costochondritis. Poor thoracic spine and rib mobility will result in decreased chest expansion and therefore decreased lung capacity. This can result from disease processes such as ankylosing spondylitis,[45] from structural deformities such as scoliosis, or from habitual postures such as seen in the patient with Parkinson's who spends most of his time sitting in flexion. Because of gravity, the tendency is to sit in a flexed posture; therefore, restrictions in extension mobility and a relatively fixed kyphosis are typical findings on examination (see **Building Block 24-1**).

BUILDING BLOCK 24-1

Consider the patient with Parkinson disease in Case No. 3, Display 24-1. You are finding it difficult to hear the patient because of low vocal volume. Describe one postural change and two exercises that would likely improve the patient's vocalization.

Causes Hypomobility can result from pain or altered tone, restrictions in neural or dural mobility, trauma-inducing osteokinematic restriction, degenerative joint changes, disease processes, or generalized stiffness in the joints or myofascial tissues from self-induced or externally induced immobility. Self-induced immobilization can result from pain or repetitive altered movement patterns. Repetitive altered movement patterns can produce sites and directions of relative mobility and concurrent sites and directions of hypomobility. For example, the movement strategy of scapular abduction and thoracic flexion to reach across the body can lead to hypomobility in thoracic rotation. One must consider the effect that postoperatively induced immobility, such as open heart surgery or mastectomy, has on the mobility of the thoracic cage[46] (**Evidence and Research 24-7**).

EVIDENCE and RESEARCH 24-7

Hanuszkiewicz et al.[46] proposed that breast cancer treatment may be a cause of postural dysfunction. They reported significant reductions in thoracic kyphosis and lumbar curvature in post-breast cancer treatment with fitness walking, using poles for postural support as compared to general fitness activities.

Hypomobility can be caused by limitations in myofascial length or mobility. In the case of myofascial restriction in the absence of articular hypomobility, correlating articular glides are normal, but osteokinematic motion is limited in rotation. For example, restriction in right rotation can indicate short or stiff right external and left internal oblique muscles. Hypomobility of the thoracic spine can also be found in relation to breathing, with reduced movement in pump or bucket handle breathing mechanics.

Intervention Patients with long-standing joint mobility restrictions are likely to develop myofascial restrictions, requiring concurrent intervention to both. Treatment of joint restrictions usually requires joint mobilization techniques, and treatment of myofascial tissue requires passive stretching, active ROM exercises, or both. Therefore, to maintain mobility gained with joint mobilization techniques, it is important to teach the patient a self-management exercise program that includes a passive stretch, active ROM exercise, or both. Functional movement patterns should be learned that reinforce the mobility gained through mobilization and specific exercise.

A clinical example may best illustrate this point. A patient presents with left rotation and left lateral flexion restrictions in the thoracic spine at the T7 segmental level. The examination determines that this restriction is articular. The appropriate joint mobilization technique is performed to restore the arthrokinematic glide.[2,3] To maintain the mobility gained, the patient is instructed to perform specific midthoracic lateral flexion, blocking motion at the relatively hypermobile segments below T7, to facilitate motion at the stiff segmental level (**Fig. 24-15**). Repeated thoracic left rotation can also be instructed (**Fig. 24-16**). The patient should be instructed to use left rotation of the thoracic spine frequently throughout the day to further facilitate maintenance of articular mobility. All exercises should be done with high repetitions (up to 20 times) and frequently throughout the day (up to 10 times), and in the pain-free range to prevent aggravation of symptoms.

Proper diaphragmatic breathing is essential to the treatment of numerous impairments in the thoracic spine and related regions (see Chapters 17 and 22). The Patient-Related Instruction 24-1 describes proper diaphragmatic breathing, with an emphasis on pump and bucket handle breathing. After

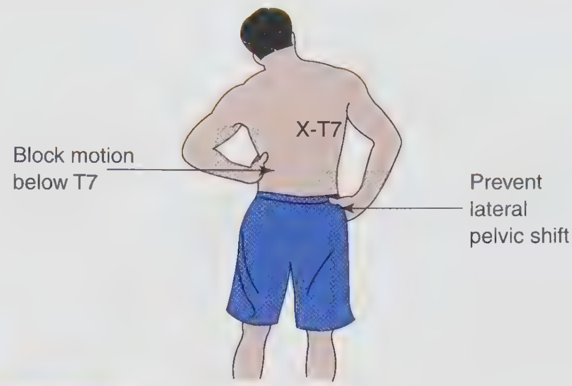

FIGURE 24-15 Left thoracic spine lateral flexion can be encouraged at T7 by blocking excessive lateral flexion below T7.

FIGURE 24-16 Holding onto a light dowel rod can encourage thoracic rotation by keeping the dowel rod level while rotating the torso. The patient is instructed to rotate the sternum. Lower segments can be stabilized by keeping the lower back flat against the back of the chair.

mastering diaphragmatic breathing in a supine position, the patient should progress to sitting and standing while applying the same breathing techniques. The ability to maintain diaphragmatic breathing in different postures is important in isolation, but should also be emphasized during exercise and functional activity (**Evidence and Research 24-8**).

EVIDENCE and RESEARCH 24-8

In older adults, aerobic conditioning may provide significant improvements in spinal mobility, physical function, and overall health.[47] The effects of a 3-month supervised program of spinal flexibility and aerobic exercises was compared to one with aerobic exercise alone on axial rotation, maximal oxygen uptake ($\dot{V}O_2$ max); functional reach, timed bed mobility; and the Physical Function Scale (PhysFunction) of the Medical Outcomes Study SF-36. Both groups improved in all measures although there was no difference between the groups, suggesting that for this population either type of exercise would be beneficial.

Muscle/Myofascial Length

Specific myofascial tissue length impairments may promote poor thoracic mobility and can be assessed via muscle length testing of each muscle. Commonly impaired muscles include

FIGURE 24-17 Rotation stretch for short or stiff right external and left internal oblique muscles.

the pectoralis major and minor, rectus abdominis, and oblique abdominals (limit extension); the paraspinals and the more lateral iliocostalis (limit flexion); and the intercostals, which can limit motion in all directions. Specific soft tissue mobilization and longitudinal stretching techniques are often necessary to restore full mobility but must always be followed by exercises aimed at maintaining the new mobility. Additionally, the patient must work to maintain the newly achieved length in daily postures and activities, which may involve changing major postural habits.

Restrictions in oblique abdominal muscle length can limit thoracic rotation. In the case of myofascial restriction in the absence of articular hypomobility, correlating articular glides are normal, but osteokinematic motion is limited in rotation. Restriction in right rotation can indicate short or stiff right external and left internal oblique muscles. A passive stretch (**Fig. 24-17**) can be used in conjunction with diaphragmatic breathing (see Patient-Related Instruction 24-1) into the right thoracic rib cage. Lying on a foam roller can increase the stretching force. Postural habits and repetitive movement patterns must be analyzed for potential causes of myofascial restrictions. Comprehensive treatment may include changing the ergonomics of the workstation to reduce factors contributing to myofascial restrictions (e.g., rearranging the workstation to reduce sustained and repeated left rotation and promote occasional right rotation). The patient's movement patterns and activities may need to be altered to limit repeated left rotation and promote more activities requiring symmetric rotation. For example, the patient should reduce the time spent playing tennis (an asymmetric activity) and begin walking, jogging, biking, or swimming (symmetric activities) (see **Building Block 24-2**).

BUILDING BLOCK 24-2

Consider the buggy-driving patient in Case No. 1, Display 24-1. This patient, like many large equipment operators, spends much of his day rotating to one side because of the nature of the traffic flow. He is having pain when rotating to the left, the direction he must turn to most frequently at work. Provide some recommendations for his work and leisure activities as well as exercise intervention choices.

Patients who have undergone surgery such as a coronary artery bypass graft (CABG) or mastectomy[47] will develop thoracic spine and rib hypomobility if not exercised properly. Early exercises should focus on maintaining deep inspiration ROM as tolerated by the patient. Diaphragmatic breathing will also assist in lymphatic drainage post-mastectomy. Gentle stretching of the chest musculature should be undertaken, within the confines of postoperative precautions. In general, precautions would follow the typical stages of healing; excessive stretching and resisted exercises that stress the involved musculature and their associated joints should be avoided until such time as allowed by postoperative protocols and the appropriate phases of healing. For example, pectoralis major strengthening after a CABG should not take place until the sternum has healed. As the surgical incisions heal, shoulder ROM exercises should be introduced, gradually progressing to full arcs of motion and adding resistance (Fig. 24-8).

Pain

Pain in the thoracic region has many possible causes or mechanisms. The onset of pain may be the result of joint dysfunction (i.e., thoracic vertebrae or rib articulations), soft tissue injury or strain, or of non-visceral (e.g., osteoporosis, ankylosing spondylitis, Scheuermann disease) or visceral diseases (see Appendix 1).

Treatment must focus on the cause or mechanism of the pain. This chapter provides a theoretical framework and clinical examples of exercises used to alleviate impairments that could be contributing to the causes and mechanisms of musculoskeletal pain.

Impaired Posture and Motor Function

Optimal postural alignment is discussed in detail in Chapter 9. As noted previously, it is important to distinguish between postural faults that are due to permanent changes in the structure of the spine and those that are amenable to change. The impairments of body structures common to the thoracic spine were discussed earlier. This section will address the nonstructural impairments of posture, which are amenable to change.

Head posture is contingent upon thoracic posture which in turn is dependent on the lumbar spine, pelvis, and lower extremities. In addition, as noted earlier, full motion of the upper extremity requires thoracic mobility. Therefore, all aspects of the kinetic chain must be examined and evaluated.

Kyphosis

Causes Postural kyphosis is caused by habitual trunk flexion, for which there are several reasons. An individual with poor postural habits, such as a student who spends most of her time sitting in class in a flexed posture, is likely to develop a kyphosis. Weak trunk extensors can exacerbate already poor posture. A dominant daily activity that encourages thoracic flexion, for example use of a laptop or other mobile devices such as cell phones and tablets, will likely encourage a kyphotic spine. Finally, there are diseases that tend to manifest with thoracic kyphosis as a secondary complication. Parkinson disease is an example of one such disorder, in which there is a lack of movement into extension, and is discussed later in this chapter.

Intervention Any plan of care for kyphosis must consider the structural impairment and pathology in addition to the related impairments in body function. **Display 24-5** lists potential impairments of body functions associated with kyphosis, and **Table 24-1** lists general exercise recommendations to address these impairments.

Neck flexors	Neck flexors
Upper back spinal extensors	Upper back spinal extensors
External oblique	External oblique
Hamstrings	One-joint hip flexors
Middle and lower trapezius	Middle and lower trapezius

**Findings associated with short muscles must be tested by muscle length and manual muscle tests, because not all muscles held in short positions develop shortness.*

Although diseases such as osteoporosis and Scheuermann disease cause structural changes in the vertebrae that create the kyphosis, postural habits and movement patterns can exaggerate the posture impairment. Although exercise cannot correct the structural changes that have occurred in the vertebrae, it can positively influence physiologic factors that exaggerate the kyphosis. Only through a comprehensive program of exercise and patient-related instruction can these contributing factors be properly addressed.

In patients without a structural kyphosis in whom lack of extension ROM is the primary impairment, manual joint and soft tissue mobilization is a key part of successful management. In addition, trigger-point dry needling is another method to achieve soft tissue mobility; early studies show promising results for the utilization of dry needling in treatment of thoracic spine pain.[48–50] Joint mobilization techniques are described and discussed in Chapter 7. Often a kyphotic posture is associated with shortened soft tissues on the anterior aspect of the thorax. Soft tissue mobilization and manual stretching of the pectoralis major and minor is often required, followed by a home stretching program (Fig. 24-8).

Patient-related instruction is indicated to improve posture alignment and avoid positions that contribute to the kyphosis. Support to the lower back may be indicated to help relax the musculature holding the spine in lordosis in the lordosis-kyphosis posture, and a shoulder support such as a figure 8 strap may be indicated to stretch anterior structures while positioning posterior musculature in a proper position (see Fig. 24-14). As illustrated by Table 24-1, exercise prescription for the treatment of kyphosis oftentimes goes well beyond strengthening the thoracic erector spinae. The thoracic spine must function as part of a kinematic chain, and treatment of impairments in each region influencing the kyphosis is indicated. Specific, isolated exercises must progress to functional movements meaningful to that patient. For example, a patient with Scheuermann disease with a desk job needs to maintain a neutral spine when working. As such, the patient would benefit from learning to lean forward and backward from the hip joints ("hip hinge") while maintaining a neutral spine. Thinking about the distance between the symphysis pubis and the base of the sternum and keeping this distance constant during forward and backward

TABLE 24-1

movements at the hip joints can be useful in changing movement patterns that promote thoracic flexion.

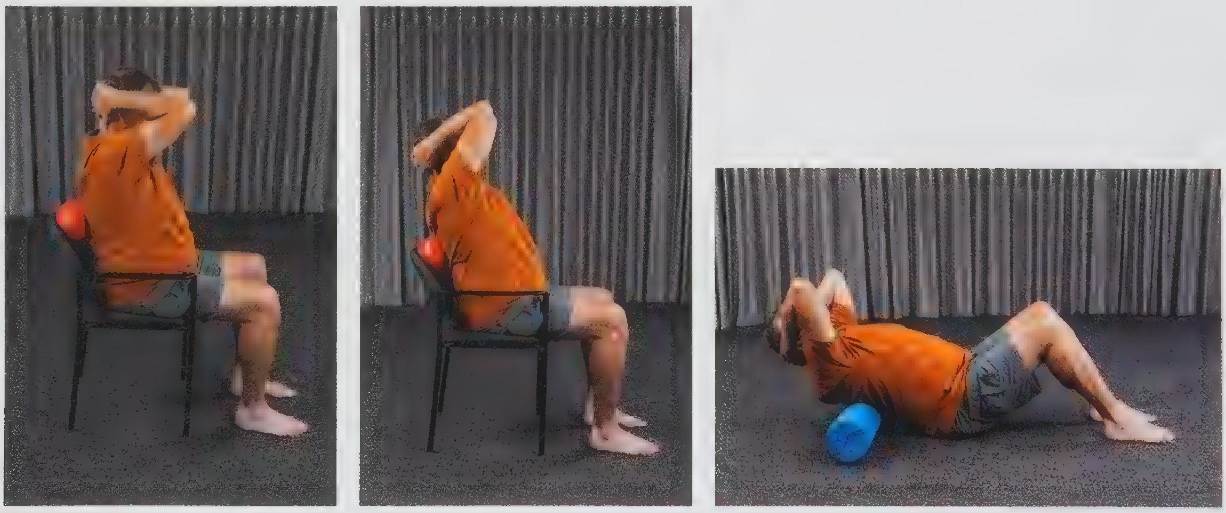
Home exercises that promote extension throughout the thoracic spine may be beneficial. However, if the patient presents with specific hypomobile segments adjacent to hypermobile segments, the patient must be instructed how to segmentally mobilize hypomobile segments while protecting areas of hypermobility. As such, a global approach may exacerbate hypermobile segments, because the hypomobile segments resist movement and transfer the motion to the segments that move easily. It is therefore important to utilize self-management exercises that target the stiff segments while protecting the mobile ones. **Figure 24-18A** to **C** illustrates a progression of effective self-mobilization techniques.

Throughout all these mobility exercises, deep breathing should be emphasized, to incorporate chest mobility. As with the use of tennis balls, the key subsystem in this exercise's potential for success is maintaining the mobilization for a sufficient amount of time (1 minute per segment to start), being consistent (every day without fail), and staying with the program (2 to 4 months). Considering that gravity is forcing the thoracic spine into flexion every second of every day that the patient is upright, encouraging extension 10 minutes per day seems a paltry amount of time in comparison. Asking for more time than this, however, risks losing the patient's compliance. The patient may fare better with dividing the exercise program into parts of the day as a practical strategy for preventing and managing symptoms.

Taping the thoracic spine for proprioceptive feedback and as a reminder to avoid flexion postures is a powerful, inexpensive biofeedback tool. The patient is asked to assume a quadruped position with the thoracic spine in neutral. The tape is applied along the paraspinal region on each side and spans several segments above and below the hypermobile segment or "hinge point" (Fig. 24-9A). Each time the patient flexes from this area the tape will provide proprioceptive feedback in the form of a pull on the skin, reminding the patient to stay in more extension. This type of feedback is very successful when used during symptomatic activities, alerting the patient to how often they are flexing the spine. Similarly, taping to limit scapular protraction and abduction may be helpful (Fig 24-9B). Cue the patient to sit tall (neutral spine) and pull their shoulder blades down and back (adducted and retracted). The tape is applied over the scapula and toward the lower contralateral ribs, in the direction of adduction. This method is a helpful reminder for appropriate scapular position in a neutral spine. Leaving the tape on for several hours at a time helps to counteract the constant force of gravity compressing the spine into flexion. The use of tape is gradually decreased as the patient develops improved awareness and the endurance necessary to actively maintain optimal posture. The benefit of taping over a postural brace is that patients will be more comfortable without anterior chest compression or shoulder discomfort from a brace. This allows the therapist to treat wider variations in body types with minimal cost.

Finally, exercises to address kyphosis need to be prescribed that address muscle performance impairments in the thoracic extensors and in the shoulder girdle complex. This is described in the section on "Muscle Performance Impairment."

Intervention in Patients with Scheuermann Disease In patients with Scheuermann disease, intervention is usually limited to patients with a painful deformity, documented progression, and at least 2 years of growth remaining. Younger children with a mild deformity can be initially treated with a program of exercise to strengthen spinal extensor muscles (see



A B C

FIGURE 24-18 A self-management exercise can be used to mobilize stiff segments in the thoracic spine. A single ball can be placed mid-back in sitting **(A)**. The patient is seated with a small ball positioned at the mid-back and against a chair. Have the patient support the neck and head by clasping the hands together at the back of the head. Instruct the patient to reach the elbows toward the ceiling while extending the thoracic spine over the ball. Active trunk extensors are used to improve thoracic mobility **(B)**. A more advanced progression involves the use of a foam roll on the floor. Lying on the foam roll with it positioned horizontally encourages extension of the thoracic spine but also serves to mobilize the ribs. If positioned in the hook-lying position, rolling the knees to one side encourages trunk rotation. With the roll positioned at 45 degrees, mobilization into extension and rotation is possible **(C)**.

Fig. 24-7) and stretch the hamstrings (see Self-management 19-7), pectoralis major (see Fig. 24-8), superior fibers of the rectus abdominis muscles and anterior longitudinal ligament (see Self-Management 17-7, level II, in Chapter 17) (**Evidence and Research 24-9**).

EVIDENCE and RESEARCH 24-9

Though there is a paucity of research into the effect of spinal exercise on spinal parameters in Scheuermann disease, one study did demonstrate the beneficial effect of regular exercise.[51] During a 12-month study of 103 patients with Scheuermann disease, Somhegyi et al.[51] observed that patients who exercised regularly demonstrated no increase in kyphosis and increased finger to floor distance compared to patients who did not participate in regular exercise. The inactive patients showed a small but significant increase in kyphosis and no change in finger to floor distance.

In adolescents, Scheuermann disease is effectively managed with bracing until skeletal maturity is attained (see the section "Scoliosis"). Contraindications to brace treatment include curves >70 degrees, severe apical wedging, and a rigid curve. Surgery (spinal fusion) is considered as an option for patients with severe deformity and disabling pain; surgical intervention is necessary in cases of neurologic compromise. At any stage in life, management of the resulting kyphosis can be effective in preventing increased postural kyphosis overlaid over the anatomic kyphosis (see the section "Kyphosis").

Scoliosis

Causes Nonstructural scoliosis may result from highly repetitive, asymmetric activities related to hand dominance. A common pattern of muscle imbalance and alignment changes for right-handed individuals is pictured in **Figure 24-19**. The therapist should be aware of the postural habits of a child in various positions such as sitting, standing, and lying, because

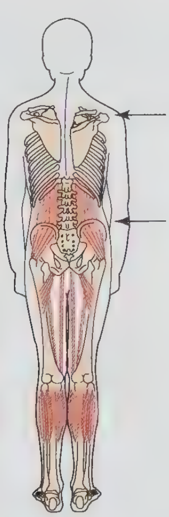


FIGURE 24-19 In a typical dominant right-hand pattern, the right iliac crest is high and the shoulder low. The darkly shaded muscles can develop adaptive shortening, while the lightly shaded muscles can develop adaptive lengthening. (From Kendall FP, McCreary EK, Provance PG. Muscles: Testing and Function. 4th Ed. Baltimore, MD: Williams & Wilkins, 1993:89.)

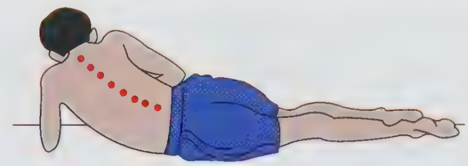

FIGURE 24-20 Children sometimes assume a sidelying position on the floor or bed to do their homework. A right-handed person lies on the left side so that the right hand is free to write or turn the pages in a book. Such a posture places the spine in a left convex curve.

FIGURE 24-21 Sitting on one foot (the left in this illustration) causes the pelvis to tilt downward on the left and upward on the right. This places the spine in a left convex curve.

childhood habits persist into adulthood. A right-handed child may sit at his desk to write in right lateral flexion. If this posture is also assumed in sidelying to perform homework (**Fig. 24-20**), sitting (**Fig. 24-21**), and to carry a backpack slung over the right shoulder, he is prone to develop muscle imbalance problems that can lead to acquired scoliotic deviations of the spine that persist into adulthood.

The pronation of one foot, standing on one leg, or standing with the same knee always bent (these habits often occur together) can contribute to the development of acquired scoliosis. The imbalances in hip musculature, faulty foot alignment, or knee position that result in lateral pelvic tilt are more closely related to primary lumbar or thoracolumbar curves than to primary thoracic curves.

Intervention To develop a comprehensive approach to treatment, a comprehensive musculoskeletal evaluation must be performed. The evaluation should include the tests and measures described in **Display 24-6**. Exercises should be carefully selected on the basis of the examination findings. The general principles of exercise prescription for patients with scoliosis are listed in **Display 24-7**. Exercises to be avoided by individuals with scoliosis include those listed in **Display 24-8**. An alternative exercise is shown in **Self-Management 24-2**. Exercises for muscle imbalances associated with acquired scoliosis have been described previously.

Patients with mild scoliotic curves often do not require treatment, as long as the curve does not progress. Periodic observation is required to make sure the degree of curvature is not increasing. After skeletal maturity has been reached, a curvature (as measured by the Cobb method) of <25 degrees[52] to 30 degrees[53] typically does not progress. In the patient with

DISPLAY 24-6

Tests and Measures Included in a Scoliosis Evaluation

Posture Alignment

- Plumbline views (anterior, posterior, and lateral)

Muscle Length Tests

- Hip flexor (differentiating psoas from tensor fascia lata, rectus femoris, and sartorius)
- Hamstrings
- Standing forward bend for length of posterior muscles
- Tensor fascia lata–iliotibial band
- Teres major and latissimus dorsi

Muscle Strength Tests

- Back extensors
- Abdominal muscles (differentiating trunk curl from pelvic stabilization roles)
- Lateral trunk
- Oblique abdominals
- Hip flexors
- Hip extensors
- Hip abductors (differentiating posterior gluteus medius)
- Middle and lower trapezius

Movement

- Forward bending to determine a structural curve and the location of the curve

DISPLAY 24-7

Principles of Exercise Prescription for Scoliosis

- Symmetric exercises should not be attempted.
- If one group or one muscle within a group is too strong for its antagonist or synergist, that muscle or group should be stretched, and the weaker, longer antagonist or synergist should be strengthened and supported to provide balance to the region.
- The lateral and anterior abdominal muscles, pelvic girdle, and leg muscles usually have asymmetric strength, causing the body to deviate about all three planes of motion with the transverse and frontal planes affected the most. Because the posterior spinal muscles are relatively less affected, the program should emphasize promoting strength of the relatively weak muscle or groups of muscles in the anterior thoracolumbar region and the pelvic-hip complex.

DISPLAY 24-8

Exercises to Avoid in Treating Scoliosis

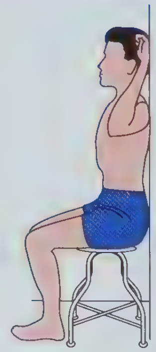
- Exercises that promote flexibility of the spine should be avoided without counterbalancing exercises or support promoting opposing shortening and strength to maintain corrections.
- A subject who is also developing kyphoscoliosis should avoid back extension exercises performed in prone because it promotes further lumbar extension (Self-Management 24-2).
- Trunk curl exercises or sit-ups should be avoided even if the rectus abdominis and internal oblique muscles are weak, because thoracic flexion promotes kyphosis (see Chapter 17 for alternative methods of abdominal strengthening).

SELF-MANAGEMENT 24-2

Postural Exercise with Back to Wall

Purpose: To reduce the tendency for excessive mid-back forward flexion and forward shoulder posture. After this exercise is mastered in sitting, it can be progressed to standing.

Starting Position: Sit on a stool with the lower back nearly flat against the wall. You should be able to fit your hand behind your lower back if your spine is in optimal position. If you have an exaggerated upper and mid-back curve, you may have a larger space between the wall and your back. Try to reduce this space as much as possible by contracting your lower abdominal muscles. *Caution:* Do not let your upper and middle back forward flex more in an attempt to reduce the curve of your lower back. (Note: this exercise can be modified to be performed in supine.)



A

Press your head back with your chin tucked down. If you have an exaggerated curve of your

SELF-MANAGEMENT 24-2
Postural Exercise with Back to Wall (*continued*)

upper or middle back, you may not be able to get your head to the wall. Place one or two towel rolls behind your head with your head as close to the wall as possible and with your eyes and nose positioned horizontally. *Caution:* Do not let your chin rise upward in an attempt to get your head closer to the wall.

Place your thumbs on the wall with your elbows pointing slightly forward. If you have an exaggerated curve of your upper or middle back, you may not be able to get your thumbs to the wall (**Fig. A**).

Movement Technique: Keep your thumbs in contact with the wall; keep your head and low back in the starting position, and slide your arms to a diagonal position overhead. When your head or low back deviates from the start position or your shoulders shrug excessively, stop the movement (**Fig. B**).

an immature spine, if the curve is between 25 and 40 degrees, there is a high risk of further progression. These patients need to be treated using a brace, which in 70% to 80% of the cases will prevent further progression[52] (**Evidence and Research 24-10**).

EVIDENCE and RESEARCH 24-10

In one study, a brace worn 16 or more hours each day was shown to be effective in preventing 90% or more of the curves from progressing, particularly mild curves of 25 to 35 degrees.[54]

Most authorities recommend wearing the brace for 23 hours each day, because using it part time can create compliance problems. When wearing the brace is an established part of a daily routine, it becomes a standard function. However, the brace cannot correct a curve; it can only prevent it from worsening. In adults, the curve may progress slowly over years, and bracing may not be a practical solution.

Early detection and intervention is the key to the treatment of scoliosis. A few carefully selected exercises that help to maintain muscle balance and a kinesthetic sense of good alignment are recommended over a vigorous, complex program. This means providing good patient-related education about how to avoid habitual positions and activities that can increase the curvature. It also means providing incentives that help keep the child, adolescent, or adult interested and motivated in an ongoing program.

The use of exercise in the management of scoliosis is controversial. Muscle imbalance that exists as a result of postural or other nonstructural scoliosis theoretically can be treated through the use of exercise to prevent further exaggeration of the scoliosis beyond that which the disease has caused[55] (**Evidence and Research 24-11**).

EVIDENCE and RESEARCH 24-11

A review of two studies involving 154 patients total evaluating effectiveness of scoliosis-specific exercises in reducing curve progression and postponing or avoiding invasive treatments such as surgery in adolescents with adolescent idiopathic scoliosis found no evidence for or against scoliosis-specific exercises compared to electrical stimulation, traction, and posture training for avoiding curve progression. Scoliosis-specific exercises as the only treatment had similar results as general physical therapy.[56] However, a review of randomized controlled trials and prospective non-randomized controlled trials was also inconclusive in determining the effectiveness of surgical treatment compared to nonsurgical treatments for teens with idiopathic scoliosis.[57]

The message that exercise is of little or no value prevails in the literature, leaving individuals with scoliosis a range of treatment options including doing nothing, bracing, or surgery. Regarding physical therapy intervention, Kendall et al.[22] warn that overemphasis on flexibility is the exercise approach that leads to the view that exercise is of little value or even counterproductive in the treatment of scoliosis. The authors state that adequate musculoskeletal evaluation has been lacking, and as a result, there has been little scientific basis on which to justify the selection of therapeutic exercises. Kendall's premise for using therapeutic exercise is that scoliosis is a problem of symmetry and that restoring symmetry requires the use of asymmetric exercises along with appropriate support. Stretching of stiff or short muscles is desirable only if it is performed with simultaneous exercise and appropriate support to shorten and strengthen what is too long and relatively weak.

The correction of asymmetrical postural habits may be helpful in preventing the development of scoliosis during childhood. Exercises should be carefully selected on the basis of thorough examination findings, and adequate instruction is needed to ensure that the exercises will be performed correctly and with precision. The object is to use asymmetric exercises to promote symmetry. To illustrate this point, consider the following case.

The patient is a gymnast with a right thoracic, left lumbar curve (**Fig. 24-22**). Along with other findings, right iliopsoas and right external oblique weaknesses are diagnosed. An example of an asymmetric exercise is resisted exercise to the right iliopsoas (**Fig. 24-23**). Because the iliopsoas muscle attaches to the lumbar vertebrae, transverse processes, and the intervertebral disks, this muscle can pull directly on the spine. **Figure 24-24A** demonstrates the adverse effect of resisting the left iliopsoas, and Figure 24-24B illustrates the positive effect of resisting the right iliopsoas. A left upper extremity diagonal reaching movement pattern can facilitate right thoracic lateral flexion. Simultaneous right hip flexion and left upper extremity diagonal reaching should promote lateral deviation, correcting both curves (**Fig. 24-25**). If performed as a home program, this movement should be monitored (by an observer or using a mirror) to ensure that the appropriate spine correction occurs.

Kendall et al.[22] describe an exercise in supine to address the weakness of the right external oblique. In the supine position, the subject places the right hand on the right lateral chest wall and the left hand on the left side of the pelvis. Keeping the hands

FIGURE 24-22 This person has a right thoracic and left lumbar curve.

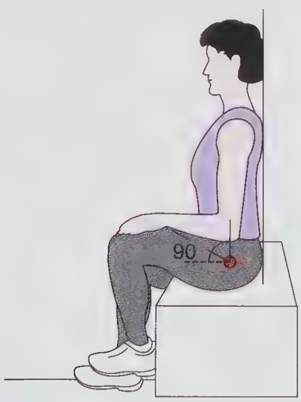

FIGURE 24-23 Resisted end-range hip flexion can isolate the iliopsoas from the other hip flexors that do not attach directly to the spine. The patient is instructed to passively lift the thigh to end range and hold the position against gravity while maintaining a neutral spine position. The patient is instructed to activate the lumbopelvic core prior to letting go of the leg (see Chapter 18 for core activation strategies). Resistance is applied only after the patient is able to hold the limb against gravity without resistance.

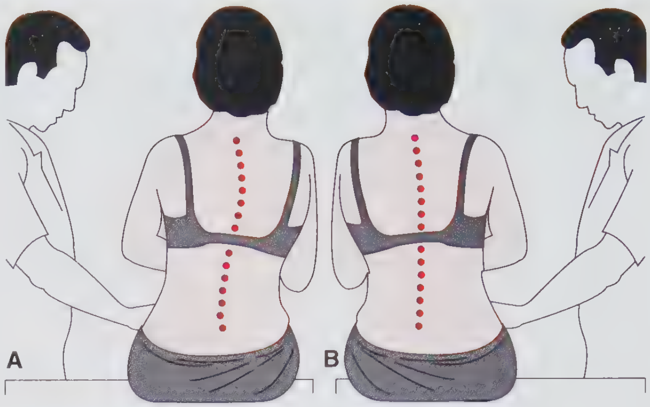

FIGURE 24-24 **(A)** The dotted line shows the adverse effect of resisting the left iliopsoas in a left lumbar curve. **(B)** The dotted line shows the positive effect of resisting the right iliopsoas in a left lumbar curve.

FIGURE 24-25 The dotted line shows the effect of reducing the right thoracic and left lumbar curve by simultaneously reaching diagonally upward with the left arm and resisting right hip flexion.

in position, the object of the exercise is to bring the two hands closer by contraction of the abdominal muscles without flexing the trunk. It is as if the upper part of the body shifts toward the left, and the pelvis shifts toward the right. By not allowing trunk flexion and contracting the posterior lateral fibers of the external oblique, there will be a tendency toward some counterclockwise rotation of the thorax in the direction of correcting the thoracic rotation that accompanies a right thoracic curve.

There is some evidence in small groups that exercise using trunk rotation may inhibit the progression of adolescent scoliosis.[58] However, there was no control group in this trial and there were only 20 subjects. One study has looked at the effect of axial unloading in changing the spinal curvature and found some improvement but without lasting results.[59] Again, the group was small (six subjects) and there was no control group for comparison. A review of the literature found that physical exercise prevents or reduces disabilities, and facilitates the neutralization of postural deficits to produce a stationary or regressive curve.[60]

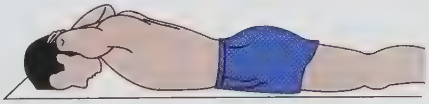
Often adolescents with scoliosis will have impairments in their overall fitness level. This impaired fitness has to do as much with poor self-image and reluctance to participate in activities while wearing the brace as it has to do with impairments in respiratory function. These children must be encouraged to remain as physically active as possible, and the parent must take an active role in this process. If the curve is severe enough, aerobic capacity may become impaired and appropriate endurance exercises should be prescribed. Thirty minutes of bike ergometry four times a week over 2 months produced a significant improvement in aerobic capacity in young girls with scoliosis compared to a control group of girls with scoliosis who did not exercise.[3] Cardiovascular exercise selection for patients with scoliosis is very important. The activity must not strengthen already short, tight muscles; rather it should encourage lengthening of short muscles and strengthening of weak muscles. For example, with the example of the gymnast previously discussed, swimming might be a good option for her. She should be encouraged to swim freestyle and breathe to the left, encouraging left rotation of the thoracic spine.

Consider a case of asymmetry and muscle imbalance found in acquired and structural scoliosis associated with unilateral pronation. For example, the combination of left pronation, shortness of the left tensor fascia lata, left gluteus medius and right hip adductors, and weakness of the right gluteus medius, left hip adductors, and left lateral abdominals can be seen in a person with a right thoracic curve and left lumbar curve. In such cases, along with specific exercises to improve the length of the left tensor fascia lata and strength of the right gluteus medius, left hip adductors, and lateral abdominal muscles (see Chapters 17 and 19), the use of an orthotic to support the left foot may be indicated, but only after all expected strength gains are made (see Chapter 21). Correction of lateral pelvic tilt associated with a lumbar curve can be helped by proper lift on the side of the low iliac crest. However, no lift can help if the patient continues to stand in an asymmetric posture, such as with weight predominantly on the leg with the higher iliac crest and with the knee flexed on the side of the lift.

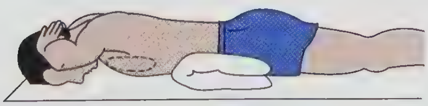
Thoracic Lordosis

Causes Thoracic lordosis is a loss of the normal posterior curve of the thoracic spine, and it can be associated with abnormal postural correction strategies. For example, in an attempt to correct forward shoulders, the individual may extend the thoracic spine, rather than adduct the shoulder girdle on the stable thorax. If this is done habitually, the thoracic spine becomes a site of relative flexibility.

Intervention Attempts to improve impairments of the shoulder girdle with lower trapezius resistive exercises (**Fig. 24-26A**) cause thoracic extension instead of scapular adduction. Use of a support under the sternum (Fig. 24-26B) can somewhat block the undesired thoracic extension to allow resistive exercises to transmit forces to the scapula instead of the thoracic spine.



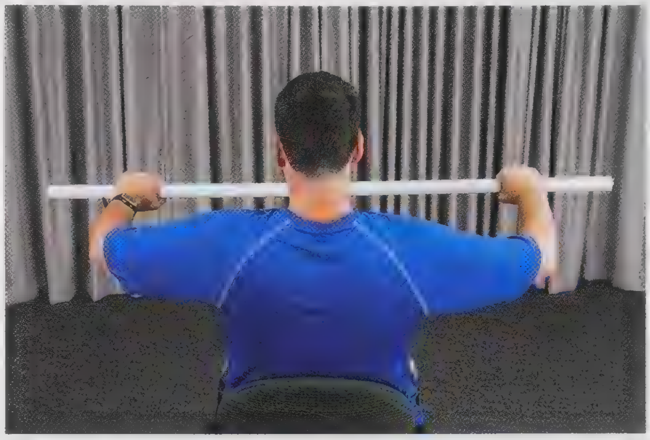
A



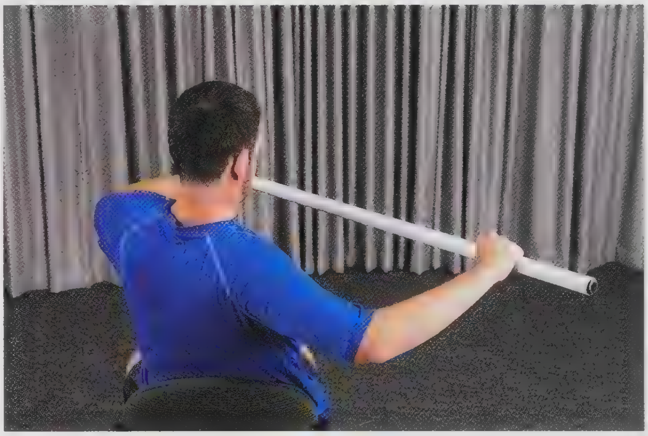
B

FIGURE 24-26 **(A)** In a person with thoracic lordosis, attempts at performing resisted lower and middle trapezius exercises promote thoracic extension instead of scapular adduction. **(B)** Use of a firmly rolled towel placed under the sternum can stabilize the thoracic spine in flexion, allowing the force of the middle and lower trapezius to adduct the scapula instead of extending the thoracic spine.

Applying tape anteriorly as a proprioceptive feedback mechanism to prevent excessive thoracic extension will facilitate movement in the lumbar spine and pelvis. Patient-related instruction is necessary to alter the strategy of posture correction performed by the patient. Self-mobilization into thoracic flexion can be performed, using the back of a firm chair to stabilize caudal segments while the cranial vertebrae are actively flexed (**Fig. 24-27**).



A



B

C

FIGURE 24-27 Blocking motion of the caudal segments by stabilizing against the back of a chair, while mobilizing the segments above. **(A)** Starting position. **(B)** End position, rotation. Be sure to instruct the patient to rotate the spine versus adduct the scapula. **(C)** End position, extension. Be sure to instruct the patient to stabilize the thoracolumbar and lumbar regions to prevent extension.

THERAPEUTIC EXERCISE INTERVENTION FOR COMMON DIAGNOSES

This section contains selected medical diagnoses that have a bearing on the muscular, skeletal, and nervous systems as they relate to the thoracic region. Although numerous musculoskeletal diagnoses are associated with the thoracic region, only a few are discussed to provide examples of therapeutic exercise prescriptions for the related activity limitations, participation restrictions, and related impairments.

Prevention and Intervention in Patients with Osteoporosis

When treating patients with vertebral compression fractures secondary to osteoporosis, the therapist must know the status of the fracture (stable vs. unstable). Most compression fractures, such as those seen with osteoporosis, are stable and typically managed conservatively. Physiologic forces or movement will not displace these fractures. Patients are treated acutely with a short period (no more than a few days) of bed rest. Prolonged inactivity should be avoided, especially in elderly patients. Pain control can be in the form of oral or parenteral analgesics, muscle relaxants, external back-braces, and physical therapy modalities.[61,62] Intervention should focus on strength and flexibility exercises, as well as information on falls risk and assistive devices, balance, and gait training[63] (see **Building Block 24-3**).

BUILDING BLOCK 24-3

Why is extended bed rest and prolonged inactivity to be avoided?

A 77-year-old male spent the last 2 weeks in bed recovering from pneumonia. His cough is nearly gone and his breathing is no longer impaired. He is otherwise healthy. What impairments and activity limitations might be found in this patient? Design an exercise program that will effectively treat his impairments and improve his function, using two in-clinic visits and a home program.[64,65]

Patients who do not respond to conservative treatment or who continue to have severe pain may be candidates for surgical intervention. However, most patients are managed conservatively and make a full recovery or at least significant improvements in 6 to 12 weeks; resumption of a regular exercise program can occur once the fracture has fully healed. A well-balanced diet, regular exercise that includes weight-bearing activity and some form of resistance training, calcium and vitamin D supplements,[66,67] smoking cessation, and medications to treat osteoporosis may help prevent additional compression fractures. Age should never preclude treatment (**Evidence and Research 24-12**).

EVIDENCE and RESEARCH 24-12

There is current evidence that diagnosing and treating osteoporosis does indeed reduce the incidence of compression fractures of the spine.[67-70] Regular activity and muscle strengthening exercises have been shown to decrease vertebral fractures and back pain.[71] Inactivity leads to bone loss, but weight-bearing exercise can reduce bone loss and increase bone mass.

The optimal type and amount of physical activity that can prevent osteoporosis has not been established, but moderate weight-bearing exercise such as walking is recommended. Resisted upper extremity exercise is also recommended to induce weight-bearing stress on the spine and wrist. Exercise to reduce the stress of kyphosis is discussed in a later section of this chapter (see the section "Kyphosis") (see **Building Block 24-4**).

BUILDING BLOCK 24-4

Consider the patient in Case No. 2, Display 24-1. She is currently able to walk half a mile before the onset of pain that requires her to discontinue exercise. She uses yoga as an additional exercise. Design a therapeutic exercise program to help her get back to walking 3 to 4 miles per day. What additional activities might be part of an ongoing prevention program for her?

Measures to prevent falls must be initiated by patients and their caregivers, as a fall in this population can lead to morbidity or death from the secondary effects of immobilization and reduced activity. Specific exercise techniques addressing impairments related to balance are addressed in Chapters 8 and 19. **Table 24-2** lists items that should be assessed when determining what preventive measures should be followed.[72]

Exercise Management of Parkinson Disease

Parkinson disease is a progressive neurologic disorder that results in the loss of L-dopa in the substantia nigra. Clinical findings of the disease include rigidity, facial masking, resting tremor, dyskinesia, bradykinesia, difficulty initiating movement, and a flexed posture.

Intervention

Appropriate treatment for patients with Parkinson disease includes a combination of drug therapy, usually a form of L-dopa replacement, and exercise. A consideration in designing exercise programs in Parkinson disease is the typical waxing and waning of the drug effectiveness, often termed the "on" and "off" periods. The patient may swing from a fully functional and mobile

TABLE 24-2

individual while "on" to one who is immobilized and "frozen," all in a matter of minutes. As the disease progresses, the "on" periods may become very short despite appropriate medication doses (see **Building Block 24-5**). The patient in this situation may not wish to spend this valuable "on" time exercising, opting instead for performing highly valued or necessary tasks. In these cases, the exercise program must be economical in effect given the time needed to perform it. That is, only the few, most effective and broadly useful exercises should be chosen. The patient must be made aware of the importance of the exercises in order to consider them worth the time investment. This can be accomplished in a powerful way if the patient can experience the benefit of performing the exercise. For example, a simple exercise practicing a forward weight shift in sitting using an exercise ball or a stick (**Fig. 24-28**) often will result in dramatic improvement in sit to stand ability (from unable to independent). Experiencing this improvement will make it more likely that the patient will attach importance to it and will therefore increase compliance.

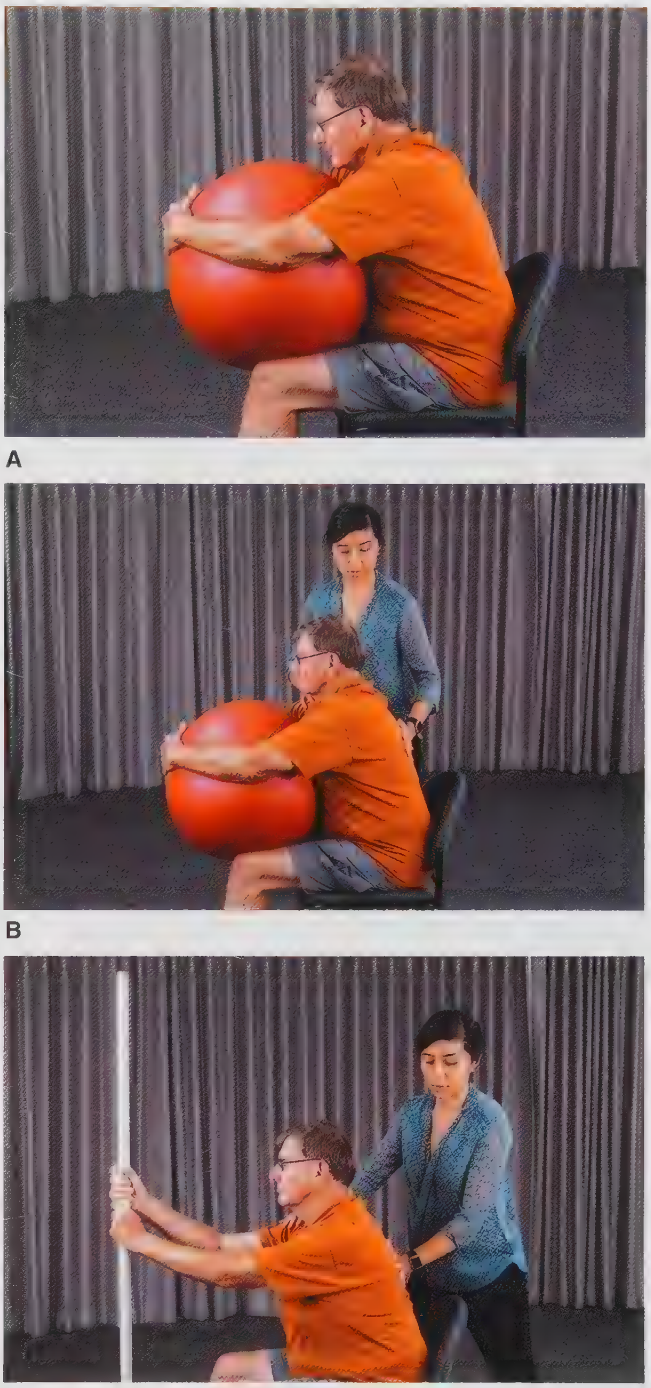
BUILDING BLOCK 24-5

Consider the patient in Case No. 4, Display 24-1. He is a 72-year-old construction company owner with Parkinson disease who has two to three "on" periods per day, each lasting about 2 hours. You note on physical exam that he has limited hip flexion and lumbar extension. Describe how this might limit his ability to arise from a chair, and design an exercise program that he can do at work that will address his impairments while simultaneously working on his function. Include dosage parameters, considering the amount of time he may spend sitting in a truck each day.

There are situations where the "on" periods are so short that it makes it unreasonable to ask the patient to spend it doing exercises. In these cases, the help of a family member or caregiver is crucial, in the form of a program of primarily ROM exercises. Utilizing inexpensive equipment such as exercise balls and wands or canes, combined with instruction in positioning techniques that promote spinal extension, can allow even a frail spouse to assist with exercises (see Fig. 24-28 and **Evidence and Research 24-13**).

EVIDENCE and RESEARCH 24-13

There is growing evidence that exercise can play an important role in the management of Parkinson disease. For example, the effectiveness of an exercise intervention for people in early and midstage Parkinson disease (stages 2 and 3 of Hoehn and Yahr) in improving spinal flexibility and physical performance in a sample of community-dwelling older people was described by Schenkman et al.[73] They compared people with Parkinson disease who received 10 weeks (30 sessions) of exercise instruction with a group of patients who received no exercise instruction and found improved functional axial rotation, functional reach, and timed supine to stand (see **Building Block 24-6**).



A

B

C

FIGURE 24-28 Encouraging thoracic extension coupled with shoulder elevation, using a forward weight shift. **(A)** With the exercise ball resting in the patient's lap and his arms resting on top of the ball, the patient shifts his weight forward, causing shoulder elevation and thoracic extension. **(B)** Assistance with the movement can be provided by a family member or friend. **(C)** A stick, dowel, or broomstick can be substituted for the ball. These exercises can be especially effective in encouraging spinal extension with simultaneous hip flexion as a pre-transfer activity in patients with Parkinson disease. Be sure to instruct the patient to stabilize against lumbar flexion during this motion by activating lumbar erector spinae. The hips must have enough mobility to move into flexion without associated lumbar flexion.

BUILDING BLOCK 24-6

Consider the patient in Case No. 3, Display 24-1. The patient is a 56-year-old auto body mechanic who was diagnosed with Parkinson disease 3 years ago, and is still in the early stages. Develop a preventative home exercise program that would address impairments of decreased extensor strength, endurance, and extension mobility.

Thoracic Outlet Syndrome

TOS was first described by Peet et al.[74] as a syndrome caused by compression or stretching of the brachial plexus and/or the subclavian artery and vein as they transverse the thoracic outlet. All the symptoms attributed to TOS imply compression or stretching of the brachial plexus, subclavian artery and vein, or both areas (see **Building Block 24-7**).

BUILDING BLOCK 24-7

Consider the patient in Case No. 5, Display 24-1. The patient is a 22-year-old policewoman with diffuse neck, shoulder, arm, and hand pain and numbness in the fifth digit. These problems make it difficult to write traffic tickets. She is referred to PT with a diagnosis of neurogenic TOS. List the findings you would expect on her history and physical examination.

Traditionally, the etiology of TOS has been thought to be due to mechanical, nontraumatic brachial plexus compression caused by bony, ligamentous, or muscular obstacles anywhere between the cervical spine and lower border of the axilla. Common sites of compression include the anterior scalene, between the clavicle and first rib, and under the pectoralis minor. Several types of impairments of body structures, such as a cervical rib, a J-curve structural variation of the first rib, and a long transverse process of C7, may predispose the neurovascular bundle to compression. Fibrous bands between the cervical vertebrae and first rib may also be a source of compression. Less commonly, a tumor in the thoracic outlet (such as a Pancoast tumor) may compress the neurovascular bundle.

There are three types of TOS—neurogenic, venous, and arterial. Neurogenic TOS is the most commonly observed condition (95%) while the vascular variety is observed only 5% (venous 3% to 5% and arterial 1% to 2%) of the time. Swift and Nichols[75] reported that some patients with TOS had *droopy shoulder syndrome* suggesting that their symptoms resulted from stretching of the brachial plexus. Nakatsuchi et al.[76] proposed that the symptoms of TOS might be related to increased tension of the brachial plexus and surrounding vasculature because of muscular imbalance and the resultant downward traction.

Diagnosis

A careful evaluation is necessary to diagnose the subsets of TOS and to differentiate it from a spinal tumor, a Pancoast tumor, multiple sclerosis, cervical disk pathology, carpal tunnel syndrome, angina, tendinitis, and other brachial plexus injuries (**Evidence and Research 24-14**). Patients with TOS present with the following signs and symptoms:

EVIDENCE and RESEARCH 24-14

Sanders et al.[81] documented the following frequency of symptoms and symptom locations reported in patients: paraesthesia in the upper limb (98%), neck pain (88%), trapezius pain (92%), shoulder and/or arm pain (88%), supraclavicular pain (76%), suboccipital headache (76%), chest pain (72%), paraesthesia in all five fingers (58%), paraesthesia in the fourth and fingers only (26%), and paraesthesia in the first-third fingers (14%).

- Persistent diffuse pain and/or paraesthesia involving the neck, shoulder, arm, forearm, or wrist and hand
- Sensory and motor loss most commonly involves the C8–T1 segmental level, fine coordination may be affected, and patients may complain of symptoms when holding a newspaper, combing hair, or buttoning clothes
- A positive Tinel sign over the brachial plexus
- Elicitation of reproducible pain and/or paraesthesia by at least one provocation maneuver[77–80] or induction and/or aggravation of symptoms upon pulling downward on the arm and their improvement or elimination upon supporting the arms upward
- Exclusion of diseases of the cervical spine and a peripheral neuropathy.

Treatment

Treatment can be specified toward relieving compression, stretching, or both. Ultimately, the patient must be instructed in self-management techniques that treat the site and cause(s) of TOS and prevent recurrences.[82]

Often, patients with neurogenic TOS present with pain, paraesthesia, numbness, and/ or weakness related to poor posture. The presenting poor posture may include forward head, rounded shoulders, increased thoracic kyphosis, downward rotation and/or depression of the scapulae, and posterior pelvic tilt. Consider the patient in Building Block 24-7 who presents with drooping shoulders and poor posture. The distance between the first thoracic spinous process and coracoid process indicates the stretch placed on the neurovascular bundle. Presumably, the greater the distance, the greater the magnitude of stretch.[83] Therefore, treatment aimed at improving muscle performance and reducing the elongation of the upper trapezius and middle trapezius would be highly beneficial. Supportive taping of the scapula can relievè the stretch on the brachial plexus. General shoulder strengthening exercises to prevent traction on the brachial plexus and posture education is recommended. Conservative treatment is often successful with neurogenic TOS. Thoracic outlet decompression surgery may not be effective in patients whose major symptoms are due to stretching of the brachial plexus[84,85] (see **Building Block 24-8**).

BUILDING BLOCK 24-8

Let us return to Laura Biden, the 22-year-old policewoman with diffuse neck, shoulder, arm, and hand pain and numbness in the fifth digit. Recall that these problems make it difficult for her to write traffic tickets. You note that she sits and stands with an exaggerated kyphosis and forward, drooping shoulders. Passively or actively holding her shoulders back and straightening her back improves her UE symptoms after several minutes. She notes she is unable to maintain this position for long, however. Given the impairments you expected to find in Laura, design an exercise program that addresses these impairments, and progress the dosage parameters from initial visit to discharge from physical therapy.

General Treatment Concepts for Treatment of TOS

- Correct posture and movement impairments relevant to neurovascular compression and/or stretching, such as correcting a depressed and anterior tilted scapula.
- Taping the scapula into elevation (see Fig. 25-21) often reduces compression and alleviates symptoms until the related impairments are remedied.
- Alter sleep habits such as sleeping on the stomach with the neck extended and rotated, or arms overhead.
- Improve diaphragmatic breathing patterns. Accessory breathing patterns using scalenes and pectoralis minor may elevate the first rib and pull the scapula, and therefore the clavicle, closer to the first rib, causing compression of the fibers of the anterior scalene, within the costoclavicular space, or under the pectoralis minor.
- Correct impairments of body functions linked to posture and movement impairments, such as improving the length of the scalenes and pectoralis minor to increase the space of the thoracic outlet and mobility of the first rib; force-generating capacity or length–tension properties of underused synergists or antagonists such as the upper trapezius to alleviate a depressed scapula or lower trapezius to offset a short pectoralis minor.
- Alter movement patterns during instrumental ADLs. Examples include changing workstation ergonomics, body mechanics, or sport-specific movements.
- Appropriately refer for treatment of any patients with cognitive-emotional subsystems or exacerbating health habits that may be causing tension in the relevant musculature. For example, anxiety may cause cervical or brachial tension, or smoking may cause poor breathing habits.

LAB ACTIVITIES

1. Your patient has trouble stabilizing against rotational forces in the upper thoracic region. Develop and teach your partner three sequentially more difficult exercises to improve stabilization skills against rotational forces.
2. Refer to the Patient-Related Instruction 24-1. Assess your partner's breathing in the supine position. Does your partner have integrated pump and bucket handle rib motions? Are they symmetric? Teach your partner proper breathing mechanics.
3. Play the role of a person with Scheuermann disease with a desk job at a visual display terminal. Teach your partner proper ergonomics at the workstation. Teach your partner to reach across the desk and into a file cabinet. Avoid exaggerating the kyphosis.
4. Design an exercise program for a patient with right thoracic and left lumbar scoliosis. Teach each activity to your partner. Can you see or feel the effect of asymmetric exercise on the spine?
5. Referring to Critical Thinking Question 4, what alternative exercise would you prescribe to your patient with osteoporosis if she had weak abdominal muscles? Teach your partner this activity. Which abdominal muscle would you expect to dominate in the exercise you instruct for someone with kyphosis?
6. Referring to Critical Thinking Question 5, what alternative exercise would you prescribe to your patient with osteoporosis if she had weak thoracic erector spinae? Teach your partner this activity. Be sure to role-play someone with moderate to marked kyphosis.

KEY POINTS

- A comprehensive examination of all patients, including the history, systems review, and tests and measures, must be performed to enable the therapist to determine the diagnosis (based on impairments, activity limitations, and participation restrictions), prognosis, and interventions.
- When considering therapeutic exercise interventions for common impairments of body functions of the thoracic region, the therapist must consider the role of the thoracic spine in the kinematic chain and how other segmental levels can affect the physiologic function of the thoracic spine.
- Although few exercises solely address the thoracic region, those that address respiration, mobility, and performance of the trunk, shoulder girdle, and cervical muscles are important for optimal thoracic function.
- Thoracic spine function can be enhanced by treating the cervical and lumbar spine, shoulder girdle, pelvic-hip complex, and foot and ankle complex.
- Therapeutic exercise intervention is thought to affect the course of nonstructural scoliosis if the disorder is treated through asymmetric exercises, patient-related instruction, and movement retraining.
- There are many causes of kyphosis. If the cause is a disease such as Scheuermann's or osteoporosis, exercise intervention cannot reverse the pathology, but it may be able to retard or prevent further exaggeration of the kyphosis.
- Exercises may play an important role in the management of Parkinson disease. Exercises should be chosen carefully to maximize their effect without stealing precious "on" time from the patient.
- Diagnosis and treatment of TOS requires extensive knowledge of the anatomy and kinesiology of the cervical, thoracic, and shoulder girdle regions.

CRITICAL THINKING QUESTIONS

1. Describe how function of the foot and ankle, hip, and shoulder girdle could affect function of the thoracic spine. Provide one example for each region.
2. You have been referred an 18-year-old boy with Scheuermann disease.
   a. What two posture types would this patient probably exhibit?
   b. List the possible shortened and lengthened muscles around the trunk and pelvis for each posture type.
3. You have been referred a 16-year-old female with right thoracic and left lumbar scoliosis.
   a. What are the possible shortened and lengthened muscles in the anterior and posterior trunk and pelvic girdle?
   b. What foot and ankle alignment faults could contribute to this scoliosis?
4. Why would trunk curl exercises be contraindicated for someone with Scheuermann disease or osteoporosis?
5. Why would prone hyperextension exercises be contraindicated for someone with Scheuermann disease or osteoporosis?
6. What five exercises would you choose to teach to a patient with Parkinson disease who complains of an increasingly flexed posture, if he has only 3 hours each day when he is "on?"
7. List common postural impairments found in someone with TOS.
8. Given the list you created in No. 7, what muscles would you want to stretch versus strengthen?

CHAPTER

25

The Shoulder Girdle

CARRIE M. HALL

The shoulder girdle functions with the arm, elbow, forearm, wrist, and hand in a kinetic chain with the trunk and lower extremity. Therefore, dysfunction of the shoulder girdle can affect the function of related regions, and conversely dysfunction of related regions can affect shoulder girdle function. For example, faulty movement patterns and associated impairments of the shoulder girdle can affect the function of the cervical spine and vice versa because of shared musculature (i.e., levator scapula and upper trapezius). In addition, faulty movement patterns and associated impairments of the spine and pelvis can affect function of the shoulder girdle. For example, anterior pelvic tilt, combined with thoracic kyphosis, can result in an anterior tilt to the scapula, leading to subacromial impingement with overhead movements.

This chapter will first present information related to anatomy, kinesiology, and evaluation of the shoulder girdle. This information will set the stage for the sections on therapeutic exercise intervention for common shoulder girdle impairments. As with all other chapters in this book, the goal is to provide the necessary information to become a critical thinker and perceptive problem solver such that you will be prepared with the knowledge necessary to develop an efficient and effective exercise prescription for any case involving the shoulder girdle.

REVIEW OF ANATOMY AND KINESIOLOGY

The shoulder girdle is one of the most complex regions of the body as it pertains to anatomy and kinesiology. The coordinated movements of the three distinct articulations and the involved muscles and periarticular structures allow the arm and hand to be positioned in space for a variety of functions. The result is a range of motion (ROM) that exceeds that of any other joint complex in the body.

The shoulder girdle is composed of the sternoclavicular (SC), acromioclavicular (AC), and glenohumeral (GH) joints. Scapulothoracic (ST) motion occurs through combined SC and AC joint motions over the surface of the rib cage.[1] Therefore, rib structure and function also impact the function of the shoulder girdle. The importance of understanding the complexity of the anatomy and kinesiology of the shoulder girdle as it pertains to therapeutic exercise prescription cannot be underestimated. For that reason, a thorough review can be found on thePoint.lww.com/BrodyHall4e.

EXAMINATION AND EVALUATION

More than 50 physical diagnostic tests have been described for the shoulder girdle.[1–5] Diagnosis of dysfunction in the shoulder girdle is challenging because of the complex anatomy and kinesiology and interrelationships of the AC, SC, and GH joints and the cervicothoracic spine. Furthermore, functions of the elbow, forearm, wrist, and hand are related to the function of the shoulder girdle as part of the upper quarter kinetic chain. Dysfunction in one segment of the chain affects the function of other segments.

A clinical example of the close relationship between upper quarter joints is demonstrated in an individual presenting with reduced forearm pronation ROM. The compensation for this restriction during activities of daily living (ADLs) may be medial rotation and abduction of the GH joint to orient the palm of the hand downward (see **Fig. 25-1**). If this pattern is performed repetitively, particularly in elevated arm positions biased toward the frontal plane, impingement of the subacromial structures of the shoulder may develop.

The descriptive examination and evaluation information discussed in this section is not intended to be comprehensive or reflect any specific philosophical approach. It is presented in alphabetical order and should simply serve as a review of pertinent tests performed in shoulder girdle examinations.

Patient/Client History

In addition to the general data collected from a patient/client history as defined in Chapter 2, several patient-reported outcomes (PROs) have been shown to demonstrate acceptable levels of reliability and validity and can be used as a baseline assessment of how the function of the shoulder is affecting function and quality of life. Of 16 PROs used for the shoulder, disabilities of the arm, shoulder, and hand,[6] Shoulder Pain and Disability Index (SPADI),[7] and Simple Shoulder Test,[8] each have good evidence in support of four of the following five properties—internal consistency, reliability, content validity, hypothesis testing, and responsiveness.[8] The reader is referred elsewhere for a review of each PRO.[9–11]

FIGURE 25-1 Use of arm abduction and medial rotation to orient palm downward versus pure forearm pronation. The former pattern can lead to wrist extensor overuse (aka "tennis elbow") due to using wrist extensors to both extend the wrist and flex the elbow in lieu of using the biceps and brachialis to flex the elbow.

Clearing Examinations

Routine cervicothoracic spine screening should be included during the examination of any patient with shoulder girdle complaints. Dysfunction of the cervicothoracic region may contribute to shoulder dysfunction.[12–14] Additionally, the elbow-wrist-hand complex should be excluded as a source of pain, although it rarely refers pain proximally to the shoulder (**Evidence and Research 25-1**).

EVIDENCE and RESEARCH 25-1

Connection Between Shoulder Girdle Function and Mechanical Neck Pain

Studies using electromyography (EMG) have shown alterations in cervical muscle behavior in patients with mechanical neck pain (MNP) compared with healthy control subjects.[15,16] One muscle group that is intricately related to the mechanical function of the cervical spine is the axioscapular muscle group.[17,18] On a clinical basis, some patients with MNP exhibit alterations in scapular orientation and motion similar to that observed in patients with painful shoulder disorders who report no cervical pain.[19–22] In shoulder conditions such as impingement, scapular dysfunction has been shown to be associated with changes in the behavior of the axioscapular muscles.[21] This, at present, is speculative and underpins the need for studies combining measures of axioscapular muscle behavior with measures of scapular kinematics in MNP as has been performed in patients with shoulder girdle impingement disorders.[21] Nevertheless, the observed changes in trapezius muscle behavior suggest that impairment of the trapezius muscle appears to be a feature of some MNP disorders.[23–27] Certainly, these findings support the literature that suggests evaluation of the shoulder girdle, and therapeutic exercise to improve shoulder girdle function when indicated should be an integral component of the management of MNP.[28–30]

TABLE 25-1

Referred Pain Sites to the Shoulder Girdle

- Abdominal problems, such as gallstones or pancreatitis.
- Pelvic problems, such as a ruptured ovarian cyst.
- Heart or blood vessel problems in which pain is more often felt in the left arm and shoulder, such as heart attack or inflammation around the heart (pericarditis).
- A lung problem, such as pneumonia or Pancoast tumor, where pain may be felt throughout the shoulder, shoulder blade area, upper chest, upper arm, neck, and axilla. Pain is usually felt in the shoulder on the same side as the lung problem.
- Other conditions, such as herpes zoster (shingles), Paget's disease, or thoracic outlet syndrome.
- Other problems, such as gas from laparoscopic abdominal surgery or air entering the vagina under pressure from some gynecologic procedures.

Unexplained shoulder pain that does not change with shoulder or arm movement or that occurs with symptoms elsewhere in the body (such as in the abdomen or chest) may be referred shoulder pain. Causes of referred shoulder pain are listed in **Table 25-1**. A thorough health history can assist in identifying signs of visceral sources of symptoms.

Motor Function (Motor Control and Motor Learning)

Visual observation and palpation of the multiplanar motions of the scapula on the thorax have been developed into scapular dyskinesis tests.[31,32] A comprehensive scapular dyskinesis classification test combining both visual and palpation methods has satisfactory interrater reliability.[32] This type of qualitative testing is important, because active ROM may be within normal limits (WNLs) but have abnormal associated kinematics contributing to shoulder dysfunction (**Evidence and Research 25-2**).

EVIDENCE and RESEARCH 25-2

Evidence of Altered Kinematics Contributing to Shoulder Dysfunction

The mobile scapula is dependent on the synchronous action of all axioscapular muscles, as well as rotator cuff (RC) muscles, to control its multidirectional rotations and translations, particularly during upper limb activities that load the scapula.[33–35] Changes in the orientation of the scapula during upper limb activities could affect the efficiency of the scapular upward rotators (upper and lower trapezius, serratus anterior) due to changes in muscle length–tension relationships as well as lever arms.[17,18] Alterations in scapular kinematics effect the entire shoulder girdle. For example, heightened lower trapezius activity during upper limb tasks is a finding of Ludewig and Cook[21] in patients with impingement of the shoulder. The cause of altered trapezius behavior may be directly due to pain; in addition, it may be reflective of the presence of altered axioscapular muscle function irrespective of pain. Potentially, changes in trapezius muscle behavior may be a contributor to scapular dysfunction or, alternatively, may be compensatory for inadequacies of other axioscapular muscles in an attempt to correctly orientate the scapula during loaded upper limb tasks.[21,30]

Muscle Performance

Impaired muscle performance can result from numerous causes/sources (refer to Chapter 5). Various tests can determine the presence and potential cause or source of impaired muscle performance.

Specific manual muscle testing (MMT) provides information regarding the amount of force or torque that a musculotendinous unit can generate. **Display 25-1** provides a list of muscles that should be included in MMT of the shoulder girdle. MMT is traditionally done, but testing of muscle performance can be performed with a dynamometer, and both types of testing can be performed in conjunction with surface EMG when appropriate. In addition, muscular endurance can be assessed by counting the number of repetitions a patient can perform with a small load. For example, because of the RC's role in stabilizing the humeral head in the glenoid during movement, it functions as a low-load, high-volume muscle. As such, the endurance of the muscle can be assessed via a number of repetitions the patient can successfully perform with a 1 to 2# weight. The number can be expressed as a percentage of the number of repetitions performed on the uninvolved side. This method also helps with dosing of the exercise for home. Texts on manual testing for specific protocols should be consulted.[36,37]

Positional strength testing is a specialized form of MMT that tests the muscle at a specific length; this provides information regarding the length–tension properties of the muscle (see Chapter 5). Positional strength testing is particularly useful in determining whether a muscle is weak because of altered length–tension properties. If a muscle is lengthened, it tests weak in the short range but strong in a slightly more lengthened range. If a muscle is weak because of other causes, it tests weak throughout the range. Sahrmann[38] has provided more information on positional strength testing of muscles in the shoulder girdle.

Selective tissue tension tests combine active and passive ROM with resisted tests of muscles about the shoulder girdle.[39] The sum total of the results of each test assists the practitioner in determining which tissue is the probable source of the shoulder condition.[40,41] Many clinicians use Cyriax's selective tissue tension model for the diagnosis of soft-tissue lesions of the shoulder.[42] The Cyriax model has been shown to be a reliable scheme for assessing patients with shoulder pain.[43] If selective tissue tension test results are positive for a contractile lesion, the resisted test can further diagnose the severity of the lesion. **Table 25-2** highlights the diagnostic findings of resisted tests.

DISPLAY 25-1

Shoulder Girdle Muscles to Include in MMT*

- Anterior, middle, and posterior deltoid
- Glenohumeral lateral rotators
- Glenohumeral medial rotators (with isolation of subscapularis)
- Upper, middle, and lower trapezius
- Serratus anterior
- Rhomboids and levator scapula
- Pectoralis major
- Latissimus dorsi

**The reader is referred to the appropriate reference for specific MMT techniques.*

TABLE 25-2

Diagnosis Based on Resistive Tests

FINDING OF RESISTIVE TEST	LESION
Strong and painless	Normal
Strong and painful	Minor muscle lesion
	Minor tendon lesion
Weak and painful	Gross macrotraumatic lesion such as fracture
	Partial rupture of muscle or tendon
Weak and painless	Muscle or tendon rupture
	Neurologic dysfunction

Pain

Evaluation of pain is done throughout the examination process. Palpation of suspected tissues is used to evaluate tissue tension, temperature, swelling, and provocation of pain.[44] Cyriax[39] and Maitland[45] advocate use of the sequence of pain and resistance during passive movement testing to establish the irritability level of a tissue. This information can guide the aggressiveness with which stretching and mobilization techniques are performed.

Because a subjective report of the pain associated with specific activities can help in the assessment, the clinician should question the patient about which activities are associated with pain. Pain often is latent (i.e., experienced after the activity), which makes it difficult to relate a cause or source. The range of pain, from the least pain to the worst pain experienced, should be examined through some accepted method of pain assessment (e.g., visual analog scale).[46]

The clinician must attempt to determine a mechanical cause of the pain during the course of the examination. This is often quite challenging but necessary to ensure full recovery and prevention of recurrences. For example, although the supraspinatus tendon can be diagnosed as the source of pain through selective tissue tension testing and palpation, the cause of the pain may be excessive scapular anterior tilt.[47] Excessive anterior tilt or insufficient posterior tilt, during arm elevation, can lead to pain because of mechanical impingement of the supraspinatus under the acromion process. Local treatment of the supraspinatus may decrease the pain in the short term. However, treatment of the faulty postures and movement impairment in addition to related intrinsic and extrinsic physiological impairments is essential to manage the condition in the long term. In this case, the clinician should implement stretching of the pectoralis minor and short head of the biceps (both attaching to the coracoid process and exert an anterior force on the scapula) with neuromuscular reeducation of the posterior scapular muscles, particularly the serratus anterior, prior to strengthening the supraspinatus. However, recent advances in pain science have demonstrated that, in general, symptom intensity and the magnitude of disability experienced by the patient seem to be influenced by a variety of factors unrelated to the physical diagnosis, including socioeconomic, emotional, and occupational status.[48–51] Interestingly, these factors have been shown to have a greater impact on symptoms and disability than the severity of the patient's diagnosis[51] (**Evidence and Research 25-3**).

EVIDENCE and RESEARCH 25-3

Biopsychosocial Factors as They Relate to Shoulder Pain and Anatomic Diagnoses

The traditional biomedical model of illness assumes a direct relationship between nociception and pain, and the biopsychosocial model acknowledges the influence of biological, psychological, cultural, and social factors on a patient's experience with his or her own pain.[52] The results of a study by Menendez et al.[53] provide support that biological (body mass index), psychological (pain catastrophizing and ineffective coping strategies), and social (work status) factors were independently associated with symptom intensity and magnitude of disability. However, the primary diagnosis did not independently predict the SPADI, even though one would expect variation in pain and disability between different shoulder conditions. A similar effect has been seen previously in the shoulder, as one study found that tear size, retraction, or humeral head migration did not predict functional scores in patients with RC abnormalities.[54] Interventions to decrease catastrophic thinking and to optimize self-efficacy during treatment hold potential to ameliorate symptom intensity and the magnitude of disability, and merit additional study.

Peripheral Nerve Integrity

Results of thoracic outlet,[55] neural tissue provocation testing,[56] peripheral nerve integrity tests, and resisted tests diagnose a pattern of pain and/or muscle weakness due to peripheral nerve involvement. Tests of shoulder girdle musculature, combined with elbow, forearm, wrist, and hand musculature, can indicate whether a nerve deficit is at the level of the cervical spine (i.e., nerve root), a peripheral nerve lesion, or, possibly forms of myopathy (i.e., facioscapulohumeral muscular dystrophy.[57]

Neural tissue sensitivity tests including upper limb neurodynamic testing and palpation of the courses of the median, ulnar, and radial nerves. The neurodynamic test is considered positive if arm symptoms (at least in part) were reproduced along with positive structural differentiation tests.[58,59]

Posture

Atypical positions of the scapula on the thorax, GH joint, and cervicothoracic spine have been noted in patients with shoulder girdle dysfunction.[12–14,60,61] Although there is inconsistent clinical reliability and validity with tests to objectively measure scapula and humerus resting position,[62] there is research supporting the relationship between the incidence of pain in the shoulder girdle and aberrant scapula and humerus posture[12,13] (**Evidence and Research 25-4**). Therefore, the clinician should observe and document the following:

- Total body alignment—particularly related to symmetry in lower extremity (LE) limb lengths
- Head position, cervical, thoracic, and lumbar spine alignment
- Pelvic position about all three planes
- Analysis of alignment of the scapula, clavicle, and humerus about all three planes

EVIDENCE and RESEARCH 25-4

Evidence for Postural Consideration When Treating a Shoulder Condition

Spinal alignment, especially thoracic curvature, is proposed to be critical for determining the scapular position, which influences overall shoulder function. With excessive thoracic kyphosis, the orientation of the scapula on the thorax is altered. A more anterior tilt and internally rotated scapula position and increased forward head is evident.[63–65] Shoulder flexion, abduction, and external rotation require substantial movements of the scapula into posterior tilting, upward rotation, and scapular external rotation.[66] These are impaired with a scapula resting in anterior tilt and internal rotation. In addition, in the elderly, it was found that subjects with severe thoracic kyphosis at rest had a narrower subacromial space than those with less thoracic kyphosis[67] Interestingly, the statistically significant effects of thoracic kyphosis on shoulder ROMs were found not only between the erect and maximum slouched postures but also between the erect and comfortable slouched postures.[68] These findings highlight that even a subtle increase in thoracic kyphosis of approximately 7.10 degrees such as that occurring in the comfortable slouched posture might require further attention. It was shown that a reduction of 5.80 degrees of thoracic kyphosis could produce greater pain-free shoulder ROMs both in flexion (mean 16.20 degrees) and abduction in the scapular plane (mean 14.70 degrees).[69]

ROM, Muscle Length, Joint Mobility, and Joint Integrity

Elements to include in testing ROM, muscle length, joint mobility, and joint integrity of the shoulder girdle are listed in **Display 25-2**.

DISPLAY 25-2

Elements to Include in Testing ROM, Muscle Length, Joint Mobility, and Joint Integrity of the Shoulder Girdle

- Active and passive osteokinetic ROM of the GH joint and both the cervical and thoracic spine.
- Passive arthrokinematic mobility tests of the SC, AC, GH, cervicothoracic spine, and scapula mobility on the thorax.
- Capsuloligamentous integrity[70–74]
- Glenoid labrum integrity tests[75–78]
- Rotator cuff integrity[77,78]
- Subacromial impingement tests[79,80]
- Muscle length testing for scapulohumeral, axioscapular, and axiohumeral muscle groups. Examples of muscles that fall into each category are summarized in **Display 25-3**. Sahrmann[61] and Kendall et al.[36] have described the appropriate muscle length testing procedures.
- Functional movements should be examined, including reaching behind the back, touching the back of the head and neck, and reaching across to the opposite shoulder.

DISPLAY 25-3

Shoulder Girdle Muscles Prone to Adaptive Length Changes

Adaptive Shortening	Adaptive Lengthening
Rhomboid major and minor	Middle trapezius
Levator scapula	Lower trapezius
Upper trapezius*	Upper trapezius*
Subscapularis**	Subscapularis**
Teres major	Serratus anterior
Latissimus dorsi	
Pectoralis major and minor	
Short head of biceps	
GH lateral rotators	

**Upper trapezius can be short with an elevated scapula and long with a depressed scapula*

***Subscapularis can be short with humeral medial rotation and long with anterior humeral head displacement*

Work (Job/School/Play), Community, and Leisure Integration or Reintegration (Including Instrumental ADLs)

Functional testing, whether in the form of performance testing or subjective grading (PRO), should be included in the examination. See previous section on patient/client history for details regarding specific PROs.

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON IMPAIRMENTS OF BODY STRUCTURES AND FUNCTIONS

After thorough examination and evaluation of the shoulder girdle, the clinician should have a good understanding of the activity limitations and participation restrictions affecting the patient as well as the related body function and structure impairments. A diagnosis and prognosis are formulated, and an intervention is planned. After it is determined which body function impairments should be treated to restore activity and participation level, a plan of care must be developed to treat the appropriate impairments and limitations/restrictions. Therapeutic exercise intervention is vital in the restoration of shoulder girdle function in order to restore the precise coordinated muscular force couples acting on the three integrated joints in the shoulder girdle complex. The following sections provide information about therapeutic exercise interventions for common impairments of body structures and functions. Pain is presented as the first impairment because of the importance of understanding the underlying impairments contributing to and/or causing pain.

Pain

Differential diagnosis of the source of pain experienced in the upper quarter is difficult in part because of the interdependence in the anatomy of the shoulder, elbow, wrist, hand, and cervicothoracic spine. Pain stemming from tissues in the shoulder girdle may be experienced locally or referred distally down the arm as far as the wrist and hand.[81] Confounding the diagnosis of the source of shoulder pain is the fact that the shoulder girdle is a common region for referral from sites extrinsic to the shoulder girdle such as the cervicothoracic spine[82,83] and nonmusculoskeletal sources, such as the heart and diaphragm (see Appendix 1).[84]

The cause of local pain in the shoulder remains elusive, and frequently the level of pain experienced varies substantially among individuals, as previously alluded to in the Evaluation/Examination section. Central sensitization and central motor alterations could contribute to explain this disparity[85] (**Evidence and Research 25-5**).

EVIDENCE and RESEARCH 25-5

Central Sensitization and Central Motor Alterations with Rotator Cuff Tendinopathy

Gwilym et al[85] demonstrated that a significant proportion of individuals with RC tendinopathy have pain radiating down the arm and hyperalgesia to pinprick stimulus of the skin. Furthermore, the presence of either hyperalgesia or referred pain preoperatively is associated with a worse outcome from subacromial decompression 3 months after surgery.[85] Two other studies compared pain thresholds between individuals with and without unilateral RC tendinopathy and found hypersensitivity at local and remote sites bilaterally in the symptomatic population, suggesting central sensitization.[86,87] These findings suggest that central sensitization is present in a proportion of people diagnosed with RC tendinopathy, and that the pain experienced may not always relate to local pathology.

Another potential influence in the development or maintenance of pain is the presence of central motor alterations. Ngomo et al.[88] have shown that individuals with RC tendinopathy demonstrate decreased corticospinal excitability of the infraspinatus muscle on the affected side compared to their unaffected side. Corticospinal hyperexcitability at rest and hypoexcitability during voluntary activation have also been reported for the deltoid muscles in individuals with chronic full-thickness tears of the RC.[89] These altered muscle cortical representations show adaptive changes in the central nervous system associated with RC tendinopathy and may contribute to the neuromuscular deficits associated with this disorder.

If a *source* of the pain is determined to be located in the shoulder girdle, treatment may involve a combination of interventions, including manual therapy, physical agents or electrotherapeutic modalities, neuromuscular reeducation, and therapeutic exercise aimed at the shoulder girdle region. A clinical example can illustrate the use and interaction of physical therapy interventions. **Display 25-4** outlines hypothetical examination and evaluation findings of a person diagnosed with RC tendinopathy. Current research evidence provides considerable confidence for people diagnosed with RC tendinopathy to expect an equivalent outcome to surgical intervention with a well-structured and graduated exercise program, with the additional generalized benefits of exercise, less sick leave, a faster return to work, and reduced health care expenses[94,95] (**Evidence and Research 25-6**).

DISPLAY 25-4

Clinical Case of Rotator Cuff Impingement (Primary Rotator Cuff Disorder)

Examination and Evaluation

History

A 35-year-old, right-handed man complains of right shoulder pain. His occupation requires him to sit at a visual display terminal 8 to 10 hours each day, 5 days each week. He uses his mouse in his right hand. He also engages in cross-country skiing, climbing, and kayaking. A primary activity limitation includes inability to sleep on his right shoulder due to pain at night that awakens him briefly two to three times each week. His participation restrictions include inability to participate in any recreational activity using his right arm overhead. Work is not disrupted at this time, although he does experience a fatiguing discomfort between his shoulder blades while working at the computer about two-thirds into his workday.

Postural Alignment

Moderate forward head, moderate abducted, anterior tilted, and downwardly rotated scapulae, with the right scapula slightly depressed, bilateral humerus in moderate abduction (R > L), and moderate thoracic kyphosis

Cervical Clearing Examination

Slight stiffness in cervical rotation to the right, otherwise negative for shoulder girdle signs or symptoms

Passive ROM

Arm elevation in the plane of the scapula—150 degrees
Lateral rotation at 90 degrees of abduction—90 degrees
Medial rotation at 90 degrees of abduction—40 degrees
Elbow, forearm, wrist, hand—WNL

Active ROM

Active arm elevation in flexion—145 degrees
Active arm elevation in abduction—140 degrees
Total scapular upward rotation is 45 degrees

Scapulohumeral Rhythm

Faulty scapulohumeral rhythm is present. The scapula is slow to elevate from the initial depressed position and is still depressed relative to the left at 90 degrees of flexion, but excessively elevates in the last half of flexion. In addition, the scapula fails to fully upwardly rotate and is only rotated upward 10 degrees at 90 degrees of flexion. The patient experiences pain from 90 degrees to end range. Pain is reduced with manual assistance of elevation and upward rotation of the scapula.

Muscle Length

Moderate shortness in the GH lateral rotators and rhomboids and lengthened right upper trapezius and middle trapezius.

Joint Mobility

Hypomobile GH posterior and inferior glide, ST upward rotation, and AC joint anteroposterior glide

Muscle Performance (Tests Performed on Right Only)

GH lateral rotators: 3+/5 (pain)
GH abductors: 4−/5 (pain)
Supraspinatus (full can test)[90]: 3+/5 (pain)
Subscapularis (lift-off position)[41] 3+/5
Upper trapezius: 3+/5
Middle trapezius: 3+/5
Lower trapezius: 3+/5
Serratus anterior: 3+/5
Rhomboids/levator scapula: 5/5
Biceps: 4−/5
Triceps: 5/5

Resisted Tests

General abduction, end-range lateral rotation, and supraspinatus are weak and painful.

Motor Control

Surface EMG analysis demonstrates latent upper trapezius and serratus anterior activity, when compared to the uninjured side, during scaption.

Palpation

Tenderness was elicited over the tenoperiosteal and musculotendinous junction of the supraspinatus and AC joint.

Special Tests

Neer impingement sign[91] and Hawkins impingement tests[90] are positive
Jobe apprehension test[92] is negative
Negative drop arm test and hornblower's signs[79]
Sulcus sign[93] is negative

Assessment

This patient appears to have primary RC disorder. His body function impairments include:

- Altered mobility in periarticular soft tissues limiting posterior and inferior glide of the GH joint
- Reduced muscular extensibility in GH lateral rotators, further contributing to limited GH posterior glide
- Reduced muscular extensibility in scapular downward rotators, limiting scapular upward rotation
- Lengthened scapular elevator and upward rotator group, affecting length–tension properties of muscles participating in the upward rotator force couple
- Decreased muscle performance of the elevator or upward rotator, affecting the muscle's participation in the active force couples
- Altered motor control patterns in scapular rotators
- Positive signs of injury to subacromial tissue, particularly supraspinatus (i.e., positive impingement sign, weak and painful resisted tests, palpation).

Summary of Pathomechanics

This patient is vulnerable to developing impairments that contribute to impingement syndrome. The prolonged faulty posture he sustains during an 8- to 10-hour workday can lead to altered passive, active, and neural subsystems of the movement system. The faulty joint alignment can contribute to GH impingement because of the altered relationship between the ST articulation and GH joints. Prolonged faulty postures can lead to altered muscle length–tension properties, which can contribute to altered movement and recruitment patterns. For example, if the scapula is chronically abducted, downwardly rotated, depressed, and anteriorly tilted at rest, the axioscapular upward rotators could adaptively lengthen and the axioscapular downward rotators and scapulohumeral muscles could adaptively shorten. When he raises the arm overhead, as is required for rock climbing and kayaking, the patient's scapula may not sufficiently upwardly rotate and the humeral head may translate excessively superior in the glenoid fossa. This movement pattern could result in impingement of subacromial structures against the AC ligament and the acromion process.

EVIDENCE and RESEARCH 25-6

Graded Exercise Versus Surgery for Treatment of Rotator Cuff Tendinopathy

There is evidence in the literature that surgery does not confer additional benefit at 1-, 2-, or 5-year follow-up for the treatment of RC tendinopathy[96–99] and a structured exercise program significantly reduces the need for surgery.[100] Also, surgery (acromioplasty or acromioplasty and RC repair) is not associated with an improved outcome over exercise alone for atraumatic partial-thickness tears (less than 75% thickness tear of the supraspinatus)[101] or atraumatic full-thickness RC tears.[102] All these studies used graduated exercise designed to target the RC musculature, with the number of formal treatment sessions ranging from 6 to 19. Some studies also included motor control exercises, scapular exercises, and shoulder stretches as part of the plan of care. One study specifically permitted and recommended pain up to a level of 5/10 (where 10 represented maximal pain) when performing the exercises, provided that the pain level reverts back to resting pain level experienced *prior* to exercise *by* the next exercise session.[100] In addition, the authors have suggested that it is conceivable that the average of 6 to 12 weeks of relative rest following subacromial decompression surgery for RC tendinopathy and the subsequent graduated rehabilitation may be the beneficial mechanism, and not the actual operative procedure itself.[103–105]

EVIDENCE and RESEARCH 25-7

Injection Therapy for Treatment of Refractory Shoulder Pain

In the United Kingdom, physical therapists have been performing joint and soft-tissue injections to support exercise prescription and manual therapy since the 1990s, and, more recently, physical therapists have started to perform ultrasound-guided procedures.[108–110] Electromyographic studies have shown that shoulder pain inhibits the RC muscles and that effective pain relief from subacromial injection of local anesthetic can improve outcomes of exercise therapy.[111] As these treatments (injection therapy, exercise, and manual therapy) probably work by different mechanisms, the combined treatment approach has been found to be more effective than the single components.[108] Both corticosteroids and analgesics have been shown to reduce tenocyte proliferation[112,113] that may be a feature of irritable RC tendinopathy.[114] However, corticosteroids have been associated with reduced RC tissue strength in rats[115] and potential tendon apoptosis,[116] and as research studies have not demonstrated differences between corticosteroid and analgesic subacromial injections,[117–119] it may be clinically more appropriate, when considering injection therapy, to initially try subacromial analgesic injections followed by graduated rehabilitation.

Guiding principles for the spectrum of RC tendinopathies are modification of painful activities, an exercise strategy that does not trend pain levels upward over time, reeducation of movement patterns that contribute to tissue stress, controlled reloading, gradual progression from simple to complex shoulder movements, education of long-term management and ideally, prevention of future recurrence.

Pain reduction is a priority in managing irritable RC tendinopathy. People with irritable RC tendinopathy commonly report combinations of constant pain, night pain, and persistent pain following minimal activity that continues for a protracted period. It is important to advise people with irritable RC tendinopathy to *temporarily* restrict activities of the affected limb that exacerbate symptoms (relative rest). In addition, any exercise program should be carefully planned and delivered so as not to trend increased pain levels. This may include devising exercises that support the arm, are performed slowly, and are also typically performed through a reduced shoulder ROM. There is evidence to suggest that sustained isometric contractions performed in the direction of the pain and weakness help to control pain.[106,107] If a combination of relative rest, isometric exercises, and carefully graduated exercise is not helpful in reducing symptoms, then injection therapy with the goal to control pain and reduce potential inflammation may be considered as adjunctive intervention[108,109] (**Evidence and Research 25-7**).

Treatment of the source of the pain may include the following interventions:

- Transverse friction massage to the affected RC tenoperiosteal or musculotendinous junctions to assist in the formation of a strong and mobile scar[42]
- Active exercise, electrical stimulation in mid-range, or both to broaden the muscle (serving a purpose similar to that of transverse friction massage)[42]
- Physical agents (e.g., cryotherapy) or electrotherapeutic modalities (e.g., phonophoresis, ultrasound) used to treat the inflammatory (if acute inflammation is present).[120]

Treatment isolated to the *source* of the pain can assist in the healing process and provide relief of discomfort in the short term, but will not be able to manage the condition long term, particularly if the cause of the pain is repetitive microtrauma from faulty postures/movement patterns and/or inappropriate loading of the injured tissue. The clinician must address the underlying *cause* of the pain and functional impairment/participation restriction for long-term resolution of the condition.

It has been shown that there is an association between faulty scapulohumeral kinematics and RC disease.[11,46,47] Treating the *cause* of the RC impingement requires modifying the sustained postures and repetitive movement patterns believed to contribute to or perpetuate the faulty kinetics/kinematics. This training is far more specific than the basic activity modification described under treatment of the *source* of the pain. Altering sustained postures and repetitive movement patterns usually requires prior therapeutic exercise intervention focused on muscle performance, joint mobility, and soft-tissue extensibility. Improved physiologic capabilities provide a better foundation for optimal posture and movement control and tissue loading. For example, lower trapezius and serratus anterior muscles with an MMT grade of 3−/5 cannot fully participate in a muscular force couple to upwardly rotate, posterior tilt, and laterally rotate the scapula during arm elevation against gravity. Therapeutic exercise aimed at improving muscle performance of the upward rotators until they achieve a minimal MMT grade of 3 to 3+/5 is a prerequisite for retraining the coordinated muscular force couples required for functional movement patterns against gravity. As such, training the scapula and normalizing scapular kinematics is important prior to strengthening (loading) the RC musculature.

Shoulder rotation exercises are commonly employed to treat RC tendinopathy. Although these are frequently performed with the arm by the side, evidence derived from electromyographic studies indicates that the RC muscles can be recruited in a more specific manner when rotation is performed with the arm in 90 degrees of abduction[121,122] (see **Self-Management 25-1**). An alternate position to the position described here is in half kneeling with the humerus supported by the plinth in approximately 80 degrees of scaption. In these two positions, the RC can work, but the deltoid does not have to elevate the arm. As the RC functions to counterbalance potential destabilizing humeral head translation forces generated by muscles producing shoulder abduction, flexion, and extension, exercises incorporating these shoulder movements will preferentially target the important dynamic stabilizer function of the RC.[123]

Performing these exercises statically or dynamically in different parts of the available ROM can also address SC muscle function that is required for optimal RC function. Key to the

SELF-MANAGEMENT 25-1
Facelying Shoulder Rotation

Purpose: To strengthen the shoulder rotators and train independent motion between the shoulder blade and the arm

Starting Position: Kneel next to a weight bench; if at home, lie on your stomach adjacent to the edge of your bed. Place two or more rolled towels under your shoulder joint. Position your arm out to the side with the elbow bent to 90 degrees. Keep as much of your shoulder supported on the bench or bed as possible. Your arm should hang from your elbow down, not from your shoulder. Properly positioned, your elbow should be slightly lower than your shoulder and the "ball" of the "ball-and-socket" joint should be well supported with towel rolls.

Movement Technique:

Lateral rotation (target muscles: infraspinatus, teres minor)

- You may perform this exercise just by rotating your arm or with weight. If you are to perform this with weight, see the amount of weight you have been prescribed under dosage.
- Slowly rotate your shoulder so that your forearm moves up toward your head. Stop just short of horizontal.
- Concentrate on letting your arm move independent from your scapula. Your shoulder should "spin" in the socket. There should be no movement of your scapula.
- An alternate activity is to place your forearm on the table in the start position, slowly move your wrist off the supporting surface and hold your wrist and forearm isometrically for 5 to 10 seconds. Return your hand back to the supporting surface. Repeat for the designated number of repetitions.

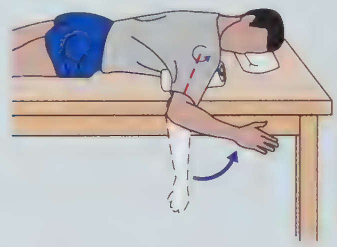
Dosage:

Weight: ____________________

Sets/Repetitions: ____________________

Frequency: ____________________

Lateral Rotation



Medial rotation (target muscle: subscapularis)

- You may perform this exercise by rotating your arm with or without added weight. If you perform this with weight, see the amount of weight you have been prescribed under dosage.
- Slowly rotate your shoulder in the opposite direction (from previously described) so that your forearm moves backward.
- Do not let your shoulder displace into the towel roll. Think of keeping your shoulder "pulled away" from the towel roll, or the "ball" in the "socket."
- Your ROM is more limited in medial rotation than lateral rotation (possibly only 10 to 20 degrees). Remember, it is quality, not quantity, that is important.

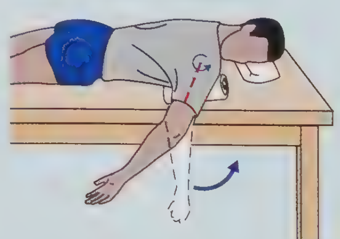
Dosage:

Weight: ____________________

Sets/Repetitions: ____________________

Frequency: ____________________

Medial Rotation



success of any RC exercise is activation of the scapulohumeral muscles (serratus anterior, rhomboid, and trapezius) to provide a stable muscular anchor for the scapula, thus preventing RC muscles, which have their origin on the scapula, from moving the scapula away from the midline into scapular internal rotation.[124]

As exercises are performed dynamically in higher ranges, SC muscles will need to function to not only counterbalance potential destabilizing translation forces produced by RC muscle contraction, but also to reposition the scapula to maintain optimal GH joint articular surface and RC muscle alignment. Active exercise treatment of RC tendinopathy is guided by strategies to manage tendon loading and to progressively restore the complex muscle coordination required for scapulohumeral rhythm and dynamic stability requirements at the shoulder.

Posture and movement education should be initiated as soon as possible to teach the patient internal locus of control over symptoms. To be successful in physical therapist management, patients must be mindful and consciously aware of how even subtle changes in posture and movements can affect symptoms.

Education and lifestyle need to be addressed as part of the treatment of RC tendinopathy. With respect to education, patients need to understand what has happened to the tendon and how this affects shoulder function and the importance of a structured exercise program, appreciating that the management of RC tendinopathy requires close attention to the relationship between pain and tissue healing. Adequate time and appropriate management are mandatory, and controlled movement/graded exercise should not create a trend in increased pain. Gradually, load and complexity of movement are introduced, as they are a necessary part of the rehabilitation process.

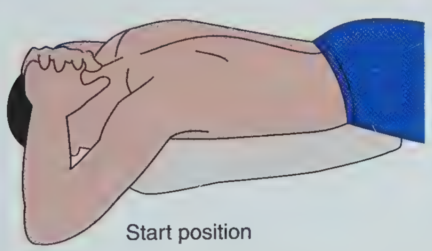
In the case presented in Display 25-4, the following impairments must be addressed to promote optimal posture and movement patterns:

- Muscle performance of the RC (see Self-Management 25-1), scapular upward rotators (see **Self-Managements 25-2** and **25-3**)

SELF-MANAGEMENT 25-2
Facelying Arm Lifts

Purpose: To strengthen the middle and lower trapezius.

Starting Position: Lie on your stomach with at least one pillow under your abdomen. Place your hands on the back of your head. Use this position for levels I through III.



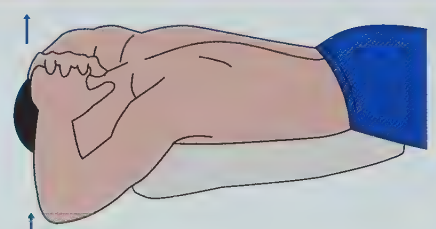
Start position

Movement Technique:

Level I: Stomach-lying elbow lifts (target muscles: middle and lower trapezius)

Barely lift your elbows. Keep your neck muscles (upper trapezius) relaxed, and contract the region between your shoulder blades (lower trapezius). Keep the contraction just enough to lift the elbows so as not to use rhomboids to adduct the shoulder blades.

- Hold the contraction for 5 seconds.
- Lower the elbows and repeat.
- Stop when your neck muscles become more tense; this is an indication that the middle and lower trapezius are fatiguing and that you should stop and rest.



Level I, end position

Dosage:

Sets/Repetitions: ______________________

Frequency: ______________________

Level II: Stomach-lying elbow lift with arms extended (target muscles: middle and lower trapezius)

Barely lift your elbows. Keep your neck muscles (uppter trapezius) relaxed, and contract the region between your shoulder blades (lower trapezius). Keep the contraction just enough to lift the elbows so as not to use rhomboids to adduct the shoulder blades.

- Slowly extend your elbows so that your arms are straight. Bend your elbows so that the hands return to the position behind your head.
- Relax your elbows to the table.
- Stop when your neck muscles become more tense; this is an indication that the middle and lower trapezius are fatiguing and you should stop and rest.

(continued)

SELF-MANAGEMENT 25-2
Facelying Arm Lifts (*continued*)

Level II, mid-position

Dosage:

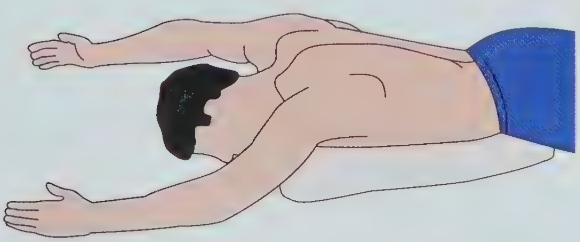
Sets/Repetitions: ______________________

Frequency: ______________________

Level III: Stomach-lying elbow lift with arm extension overhead (target muscles: middle and lower trapezius)

Barely lift your elbows. Keep your neck muscles (upper trapezius) relaxed, and contract the region between your shoulder blades (lower trapezius). Keep the contraction just enough to lift the elbows so as not to use rhomboids to adduct the shoulder blades.

- As you extend your elbows while raising your arms overhead, be sure not to tense your neck muscles (upper trapezius) during this level of exercise. If you are unable to keep your neck muscles relatively relaxed, you may not be ready for this level of exercise.
- Return your hands to your head, lower your elbows, and relax.



Level III

Dosage:

Sets/Repetitions: ______________________

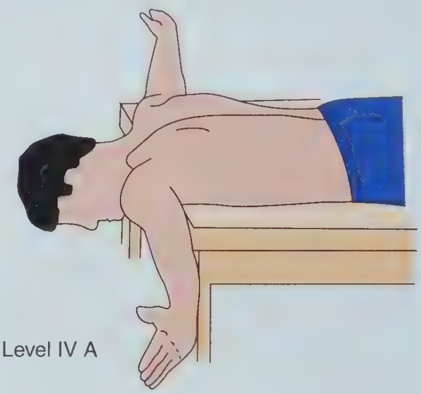
Frequency: ______________________

Starting Position: Lie on your stomach on a weight bench, piano bench, or low bed. Your chest should be suspended off the edge of the bench. Bend your knees if they extend too far off the bench. Pull your abdomen up and in. Your head should be in line with your spine with your chin tucked. Hold dumbbells with palms facing forward and thumbs up. Arms should be relaxed at chest level and resting on the floor or against the bench if the bench is tall. Keep elbows slightly bent.

Movement Technique:

Level IVA: Stomach-lying reverse horizontal fly (target muscle: middle trapezius)

- Raise the dumbbells in a semicircular motion to just below chest height. Do not lift beyond chest level.
- Lower to the starting position using the same path.
- Exhale up; inhale down.



Level IV A

Dosage:

Weights: ______________________

Sets/Repetitions: ______________________

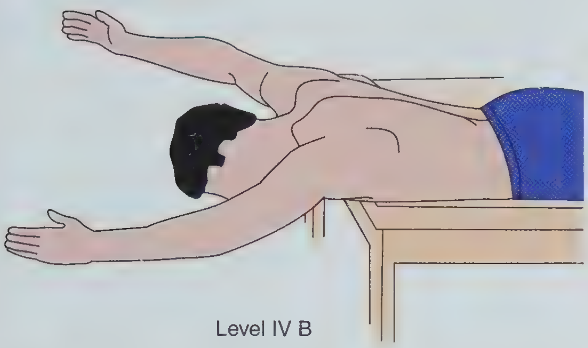
Frequency: ______________________

Level IVB: Stomach-lying diagonal reverse fly (target muscle: lower trapezius)

- Raise your elbows in a semicircular motion, diagonally upward toward the head to just below the level of the head. Do not lift the elbows above the level of the head.
- Lower to the starting position using the same path.
- Exhale up; inhale down.

SELF-MANAGEMENT 25-2
Facelying Arm Lifts (*continued*)

- Repeat in sets of 10 repetitions. Begin using a light weight when you can complete two sets of 10 repetitions maximum with proper technique.



Level IV B

Dosage:

Weight: ___________________________

Sets/Repetitions: ___________________________

Frequency: ___________________________

SELF-MANAGEMENT 25-3
Serratus Anterior Progression

Purpose: To progressively strengthen your serratus anterior

Level I: Backlying Isometric with Arm Overhead

Starting Position: Lie on your back with one to two pillows positioned above (not under) your head.

Movement Technique:
- Raise your arm overhead, close to your ear, until it reaches the pillow.
- Gently but consistently push your arm backward into the pillow and hold for 10 seconds.

Level I

Dosage:

Sets/Repetitions: ___________________________

Frequency: ___________________________

Level II: Sidelying with Dynamic Arm Slide

Starting Position: Lie on your side with two to three pillows in front of your head and shoulders. Bend your hips and knees. Rest your arm on the pillows with your elbow bent. Grasp the prescribed color of elastic band in your hand and attach the other end to your top foot.

Level II

Movement Technique:
- Slide your arm upward toward your head, keeping it in contact with the pillows.
- Slowly lower the arm back down to the starting position. Do not pull the arm back down, but slowly lower it against the resistance of the elastic.

(*continued*)

SELF-MANAGEMENT 25-3
Serratus Anterior Progression (*continued*)

Dosage:

Color of elastic: ______________________

Sets/Repetitions: ______________________

Frequency: ______________________

Level III: Standing Back to the Wall and Arm Lift

Starting Position: Stand with your feet about 2 to 3 inches from the wall. Your head should be against the wall. If you cannot bring your head against the wall, place one or two small, rolled hand towels behind your head. Pull in your stomach to rotate your pelvis backward and reduce the arch in your back. You should be able to place one hand between your lower back and the wall. If there is more space between your back and the wall, bend your hips and knees slightly to reduce the pull from your hip flexors. You should be able to reduce the arch of your back more easily.

Level III

Start

Movement Technique:

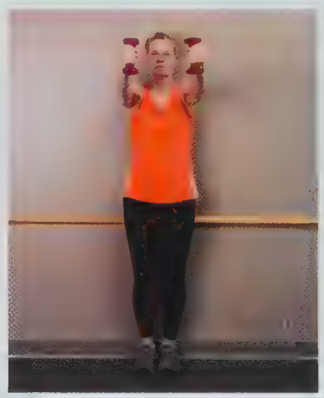
- Lift your arms in front of your body with your elbows straight.
- Try to bring the arms all the way back to the wall, but stop if you feel your back arching or your shoulders shrugging.
- Slowly lower your arms to your side, ensuring your shoulders stay back against the wall and do not roll forward.

Dosage:

Weight: ______________________

Sets/Repetitions: ______________________

Frequency: ______________________



Mid-position

- Muscle extensibility of the pectoralis minor (**Fig. 25-2**), rhomboids and levator scapula (**Fig. 25-3**), and GH lateral rotators (see **Self-Management 25-4**)
- Joint mobility of the AC, SC, GH joints, and the cervicothoracic junction, first rib articulations at T1 and the manubrium, and all thoracic vertebrae.

Often, altered length–tension properties of the scapular upward rotators exist due to prolonged posture habits (i.e., thoracic kyphosis leading to scapular tilt and lengthening of the serratus anterior and lower trapezius), and the exercises prescribed must be initiated at relatively low levels of intensity. For example, the patient should begin with level I of the lower trapezius (see Self-Management 25-2) and serratus anterior progressions (see Self-Management 25-3). Even so, improving the muscle performance of the lower trapezius, serratus anterior, and RC may not translate directly into improved function. Transitional exercises should be prescribed to train the muscle to function with the appropriate magnitude and timing during ADLs or instrumental ADLs. Examples of transitional exercises are shown in **Figure 25-4** (see **Building Block 25-1**).

Ineffective treatment of pain may result from failing to determine that the source of symptoms is not within the shoulder girdle. Even if the source is determined to come from an associated musculoskeletal region, ineffective treatment may nonetheless result from failing to recognize that the shoulder girdle may be contributing to the cycle of pain and dysfunction. For example, a patient may be diagnosed with radicular pain originating from an inflamed C5–C6 nerve root caused by a protruding nucleus pulposus at that level. However, it may be determined that faulty postures and movements of the shoulder girdle are contributing to faulty postures and movements of the cervical spine because of the shared musculature and

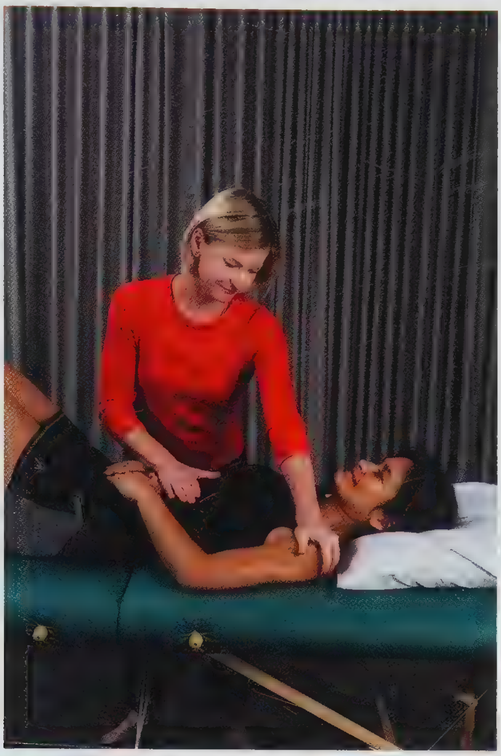


FIGURE 25-2 Manual stretch of the pectoralis minor. The hand applying the stretch force is placed over the coracoid process. A stabilizing hand can be placed over the rib cage. The force applied by the practitioner is in a posterior, superior, and lateral direction.

FIGURE 25-3 Rhomboid and levator stretch. The patient's elbow is resting on the practitioner's abdomen. The practitioner cups her hands around the scapula. By shifting the body weight from the caudal to the cranial positioned foot, a rotational force is transmitted to the scapula. The hands rotate the scapula upward like the scapular force couple.

SELF-MANAGEMENT 25-4
Lateral Rotator and Posterior Capsule Stretch

Purpose: To stretch the shoulder rotators and train independent movement between the shoulder blade and the arm

Starting Position: Slide your arm out to the side, and bend your elbow to 90 degrees. Position your forearm so that the fingers point to the ceiling. Hold your shoulder down with the opposite hand.

Movement Technique:
- Relax and let your shoulder joint rotate, allowing your forearm to move toward the floor.
- Do not let your shoulder come off the floor and move into your hand as your forearm gets closer to the floor.
- You may hold up to a 2-lb weight in your hand to assist in the stretch.

Dosage:

Hold the stretch for ______________ seconds

Sets/Repetitions: ______________

Frequency: ______________

Alternate Position: Lie on the side of your affected arm. Be sure to lie directly over your shoulder joint with your arm positioned perpendicular to your body and your elbow bent to 90 degrees.

Movement Technique:
- Using your free hand, place it on the backside of the wrist of the shoulder you are stretching. Gently perform an isometric contraction into your free hand. Hold for 6 seconds. Relax.
- On relaxing, move your forearm downward in the direction of your feet until you feel a mild stretch. Repeat the isometric contraction. Move your hand to the next barrier. Repeat three to four times.

(continued)

SELF-MANAGEMENT 25-4
Lateral Rotator and Posterior Capsule Stretch (*continued*)

FIGURE 25-4 Transitional rotator cuff (RC) exercises. **(A)** The patient places the ulnar aspects of the hands on the wall and slides the hands up the wall in the sagittal or scapular plane, depending on whether the focus is on the serratus anterior or lower trapezius, respectively. **(B)** Medial rotation bias. The patient places the palm of the hand against the doorframe and slides the hand upward and downward while maintaining a mild pressure into medial rotation against the doorframe. The patient must not push so hard that she recruits the pectoralis major, latissimus dorsi, and teres major. The goal is to use the subscapularis to encourage an increased RC force vector during arm elevation by facilitating subscapularis. **(C)** Lateral rotation bias. The patient places the dorsum of the hand against the doorframe and slides the hand upward and downward while maintaining a mild pressure into lateral rotation against the doorframe.

BUILDING BLOCK 25-1

Describe three more examples of faulty posture habits that alter scapula or humerus positions that can lead to altered length–tension properties. Name the faulty posture, the affected muscles, and which are prone to lengthening versus shortening.

joint articulations.[125] An example is a person with a depressed scapula at rest (**Fig. 25-5**) and insufficient elevation of the scapula during movement, particularly during the first half of the movement. This person may experience excessive tension on the cervical spine because of overstretching of the upper trapezius at rest and levator scapula during upward scapula

FIGURE 25-5 Slightly depressed right scapula.

rotation.[126] This excessive tension may compromise normal movement of the cervical spine and restrict cervical rotation with the arms at the side or simultaneously with movement of the shoulder girdle (e.g., driving a car and needing to look behind the shoulder). In this case, treating the cervical spine in isolation may not result in full functional recovery.[127] However, in this case, adding treatment of the posture and movement patterns of the shoulder girdle and the related shoulder impairments to the plan of care would be critical to treating symptoms originating in the cervical spine (see **Building Block 25-2**).

ROM and Joint Mobility Impairments

This category of impairments covers the scope of osteokinematic and arthrokinematic mobility from excessive ROM or joint hypermobility to reduced ROM or joint hypomobility. An example of extreme loss of mobility is adhesive capsulitis or frozen shoulder, and an example of extreme excessive mobility is GH dislocation. Mobility is a hallmark characteristic of the shoulder girdle. Even a minor alteration in mobility at any of the three joints of the shoulder girdle, cervicothoracic junction, or thoracic spine can disrupt the normal mechanics of the shoulder girdle.

For the purposes of simplifying terminology in this section, we have chosen to use the terms *hypomobility* when referring to either loss of ROM, reduced extensibility in soft tissues, or reduced joint mobility; and *hypermobility* when referring to excessive ROM, excessive muscle length, or excessive joint mobility.

Hypomobility and hypermobility impairments are intimately related. The "chicken and egg" dilemma exists when assigning causative factors; however, hypomobility is usually associated

BUILDING BLOCK 25-2

Intervention for pain originating from the cervical spine with an associated depressed scapula:

- Scapular taping into elevation and upward rotation (see "Adjunctive Interventions: Taping" later in this chapter)
- Upper trapezius and levator scapula strengthening
- Education regarding posture habits (e.g., do not allow the shoulder to assume a depressed position, keep arms supported at work station and during sustained periods of sitting such as during a movie)
- Movement retraining (i.e., initiating with upper trapezius initially to move the scapula to normal level of elevation, then retraining normal movement and recruitment patterns from an improved start position)

Upper trapezius strengthening into the short range. For patients with 3/5 muscle strength: the patient faces the wall and slides the ulnar aspect of the hand up the wall (see Fig. 25-4A). At the end range, scapula elevation is performed through available ROM (not pictured). For patients with 3+/5 to 5/5 muscle strength: patient performs an overhead press technique (start position—**Fig. A**). At end range, scapula elevation is performed through full available ROM (**Fig. B**) with scapula elevation at end range (**Fig. C**).

A B C

with a compensatory increase in motion at another joint in the kinetic chain (i.e., scapular elevation as compensation for lack of independent GH motion)[128] or a compensatory increase in a specific direction of accessory motion at the impaired segmental level (i.e., a stiff posterior GH capsule causing excessive anterior GH translation and anterior hypermobility).[129]

Hypomobility

Hypomobility cannot be treated as an isolated impairment. Numerous examples exist in the shoulder girdle complex depicting the intimate relationship between hypomobility and hypermobility. For example, if the scapula does not fully upwardly rotate during arm elevation, the arm and hand can reach the same endpoint by moving into excessive scapula elevation; or the humerus may compensate by translating excessively inferiorly.[61] When restoring balanced and coordinated motion to the shoulder girdle, mobility must be restored in the specific direction of the relatively less mobile joint. Simultaneously, the relatively more mobile segments must be protected from motion in the offending direction (i.e., external support such as bracing or taping and retraining movement patterns).

The method by which mobility is restored must be highly prescriptive and based on individual examination findings. To choose the appropriate intervention, structures responsible for the loss of mobility (i.e., muscle, periarticular tissue, bony restrictions), the direction of the loss of motion, and the severity of restriction must be determined. Any one or a combination of the three joints (SC, AC, GH) may be restricted in one or numerous directions because of articular or periarticular soft tissue or bony restrictions or loss of extensibility or adaptive shortening of myofascial tissue. If the restrictions are mild and the compensatory movements can be easily minimized, self-stretching, self-mobilization, and active exercise with mindful neuromuscular reeducation may suffice. However, if the restrictions are significant (higher levels of stiffness or involving more than one segment) or affect a specific arthrokinematic motion, manual joint mobilization, soft-tissue mobilization, and/or manual stretching may be indicated (see Chapter 7).

Stretching Stretching short or stiff myofascial tissue with a self-management program can be challenging in the shoulder girdle because of the complexity of the joint system and the ease of moving in compensatory patterns. For example, it is difficult to self-stretch a short rhomboid muscle that is limiting scapular upward rotation, because the compensatory motion may be to elevate the scapula, which does not result in a stretch to the rhomboids. Manual stretching (see Fig. 25-3) may be necessary to restore normal tissue extensibility to the rhomboids. Concurrent strengthening exercises for the scapular upward rotators (see Self-Managements 25-2 and 25-3) are encouraged until normal scapular upward rotation mobility is restored during active motion.

The same challenge can occur in attempting to stretch a short pectoralis minor that is causing excessive scapular anterior tilt during arm elevation. The traditional corner stretch (**Fig. 25-6**) can be ineffective because the head of the humerus can compensate by moving anteriorly into the relatively more flexible anterior capsule instead of stretching a short pectoral muscle. This action reflects a fundamental physical law: objects tend to move through the path of least resistance. In this case, the relatively flexible anterior capsule is the path of least resistance, and it stretches more readily than a short pectoralis minor. Even in the absence of compensatory anterior humeral head translation, research has shown that a posterior shift of the coracoid process with horizontal abduction might not be sufficient to stretch the pectoralis minor.[130] A simultaneous posterior and superior shift of the coracoid is more effective in stretching the pectoralis minor. Manual stretching (see Fig. 25-2) may be necessary until normal extensibility of the pectoralis minor is achieved. Stretching should be combined with strengthening of the lower trapezius (see Self-Management 25-2) and serratus anterior (see Self-Management 25-3) until normal movement is achieved.

FIGURE 25-6 Traditional pectoralis major and minor stretch.

In these examples, stretching the short muscle was combined with strengthening an antagonist muscle. This principle is important to restore muscle balance. In this case, stretching the pectoralis minor, rhomboid, or both muscles can be complemented with active exercise of the middle and lower trapezius and serratus anterior muscles in the shortened range.

Other common muscles in the shoulder girdle that require stretching include the GH lateral rotators and the medial rotator-adductor group. Although these often can be successfully self-stretched, special self-stabilization techniques should be employed to ensure compensatory motions do not occur. These exercises are illustrated in **Self-Managements** 25-4 and **25-5**, and **Figure 25-7**, respectively.

Stretching is ineffective if the improved flexibility does not translate into an improved functional outcome. Posture education is another important aspect to consider when treating mobility impairments. The patient must be educated to avoid postures that adaptively shorten the target soft tissues and lengthen the opposing ones. In the case of a short pectoralis minor, sitting or standing in kyphosis and forward head posture must be gradually reduced (see **Building Block 25-3**). Scapular taping can assist in improving postural habits (see "Adjunctive Interventions: Scapular Taping").

Active exercise through a functional range must be instructed and performed precisely to stretch the short soft tissues and recruit the lengthened and weak muscles with the optimal

SELF-MANAGEMENT 25-5
Latissimus Dorsi and Scapulohumeral Muscle Stretch

Purpose: To stretch the trunk muscles that attach to your arm and the muscles that originate on the shoulder blade and attach to your arm.

Starting Position:
- Lie on your back with your hips and knees bent and feet flat on the floor.

To stretch your scapulohumeral muscles, you need to prevent your shoulder blade from sliding out to the side. To do this, you need to hold the outside edge of your shoulder blade with the opposite hand.

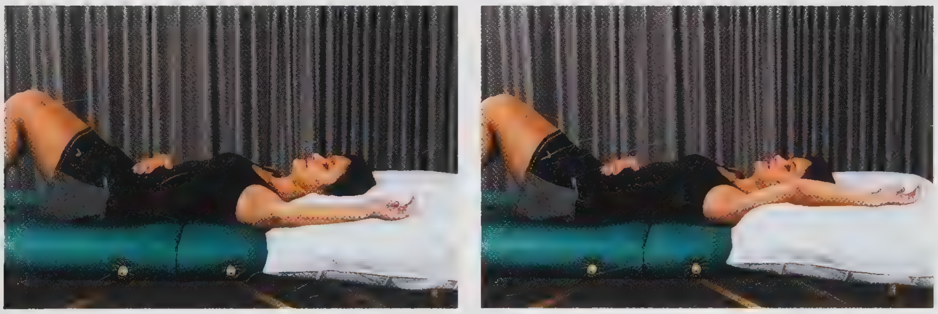
Movement Technique:
- Raise your arm over your head, keeping the arm close to your ear. When you feel your back arch or your shoulder blade slide out to the side, stop the movement.
- Rest your arm on the appropriate number of pillows so that your arm may relax in the position previously determined.
- Hold the stretch for the prescribed amount of time, and lower your arm back to your side. Keep your shoulder back as you lower your arm, and do not let it roll forward.

Dosage:

Hold the stretch for ______________________ seconds

Sets/Repetitions: ______________________

Frequency: ______________________



A B

FIGURE 25-7 Active pectoralis major stretch. **(A)** The patient rests her abducted and laterally rotated arms on pillows in the scapular plane. The pillows should be of sufficient height to prevent glenohumeral anterior translation. **(B)** The patient slides her arms upward until she feels a stretch across the pectoralis region. A static stretch can be maintained at the end position.

BUILDING BLOCK 25-3

What posture(s) would contribute to adaptive shortening of the pectoralis minor? Provide one tip to alter a postural habit to assist with long-term tissue changes for the pectoralis minor.

length–tension relationships. Though originally depicted as an exercise to promote function of the RC, Figure 25-4 can also be used to orient the scapula into upward rotation, placing the rhomboid in an elongated position. The kinematics of the scapula must be closely observed, and biofeedback provided to the patient regarding any deviation from the optimal scapular motion to ensure a lengthening stimulus is applied to the rhomboid muscle.

Effects of Immobilization Loss of ROM due to reduced muscle extensibility and joint hypomobility can occur as a result of imposed immobilization following an injury or self-immobilization resulting from pain, fear, or a deconditioned state. Immobilization should never be prolonged because of the tendency to develop myofascial shortening,[131] loss of capsular extensibility,[132] muscular,[133] tendon,[134] cartilage[135] changes, and disturbed motor control.[136] Immobilization resulting in hypomobility can cause widespread tissue changes, activity limitation, and participation restriction.

Movements associated with (increased) pain tend to be avoided, leading to increasing disability in the long run. To prevent self-imposed immobilization during painful periods or during the "rest" phase of healing, a cognitive-behavioral approach can be combined with carefully prescribed ROM exercises. Though it is beyond the scope of this text, a comprehensive review of the literature by Craske et al.[137] discusses exposure therapy, an inhibitory learning approach. Many techniques discussed can be used in combination with graded exposure from a mechanical perspective to reduce fear associated with movement.

Pain and fear avoidance can lead to deconditioning and incoordinated motor control which can lead to further pain during arm movements. In the early phases of tissue healing, a traditional gravity-lessened exercise in which GH motion is achieved is the Codman exercise, also called the pendulum exercise (**Fig. 25-8**). This exercise adds traction to the GH joint, stretches the capsule, avoids active abduction, and minimizes the common faulty movement pattern of scapular elevation during exercise against gravity. The rhythmic pendulum movements are believed to modulate pain.[138]

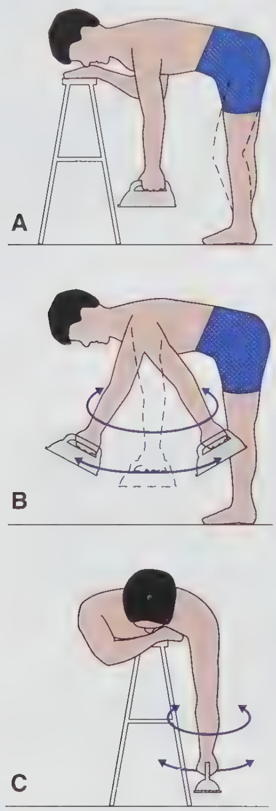


FIGURE 25-8 Pendulum exercise. **(A)** The patient should bend forward at the hips approximately 90 degrees, and his knees should be slightly bent to allow greater hip flexion and minimize stress to the low back. The patient should place the hand not being used in the exercise on a firm surface (e.g., stool) and place his head on the hand. This permits relaxed movement and concentration on the indicated movement of the involved shoulder. The involved arm should dangle freely, and a weight can be held in the hand. Use of an iron as a weight is suggested for home exercise. A weight adds traction to the glenohumeral (GH) joint and widens the pendulum arc. The patient should maintain the thoracic spine in neutral to prevent excessive scapula abduction, so as to transmit the forces from the weight to the GH joint rather than the scapulothoracic joint. **(B** and **C)** Pendulum exercises are done passively; no muscular action of the GH joint is required. Instead, muscular effort of the trunk and hips allows the body to sway and the arm to swing in sagittal, frontal, and transverse planes of motion. The exercise can be progressed to active exercise by actively swinging the arm in the same planes and arcs of motion. (Adapted from Cailliet R. Shoulder Pain. Philadelphia, PA: FA Davis, 1966.)

Hypermobility

Glenohumeral joint stability is provided by several mechanisms: static stabilizers including bony surfaces, the capsuloligamentous structures, the glenoid labrum, the negative intraarticular pressure, and the dynamic stabilizers (the RC) that actively center the humerus in the glenoid.[139–142]

To effectively treat hypermobility or instability in the absence of a traumatic onset, the hypomobile segments must also be identified. Hypermobility does not improve despite aggressive exercise protocols if it is occurring in response to a less mobile segment. For example, the GH joint may become hypermobile in the anterior direction in response to a hypomobile scapula in the direction of SC retraction. Consider all the shoulder girdle and thoracic segments that must move in harmony to achieve functional movements. If one of the segments is hypomobile, this will impose excessive motion on one or more other segments. Consider the scenario of reaching behind the back (see **Building Block 25-4**).

When reaching behind the back, if the scapula fails to move three-dimensionally into a more adducted and downward rotated position, it becomes a barrier to the head of the humerus. If the goal is to reach behind the back, the humerus may compensate by translating into the anterior capsule. Lack of scapular adduction is the result of reduced SC retraction and/or AC lateral rotation; lack of scapular downward rotation is the result of reduced SC depression and/or anterior/inferior rotation and/or AC downward rotation. Attention to restrictions in these joints in the related directions is pivotal to treatment of the anterior GH hypermobility.

This is just one functional example of how the humerus may compensate with excessive anterior translation, but if this compensation is repeated throughout daily activities, hypermobility results in the GH joint in the anterior direction. Treatment must focus on the underlying *cause(s)* of the hypermobility by improving mobility of the relatively less mobile segments and concurrently reducing mobility at the relatively more mobile segments. Improving the muscle performance, length–tension properties, and motor control of the dynamic stabilizers in the relatively more mobile direction is the recommended approach to decrease excessive or abnormal mobility. Specific exercise to remedy impairments associated with faulty movement patterns must be included in the plan of care. Ultimately, the functional movement patterns causing the hypermobility must be addressed (e.g., retraining scapular adduction and downward rotation at the appropriate time in the coordinated hand behind back movement pattern).

An impairment commonly associated with a faulty movement pattern that contributes to an anterior GH hypermobility is impaired muscle performance and altered length–tension

BUILDING BLOCK 25-4

Break down the composite motions at the GH, AC, and SC joints necessary to achieve the hand behind the back position.

properties of the GH medial rotators. Among the dynamic stabilizers, the subscapularis provides the greatest degree of stabilization of the abducted and externally rotated humerus (i.e., cocking phase of pitching), a position known to be critical for shoulders with anteroinferior instability.[143–145] This contention is supported by electromyographic findings.[146–148]

To isolate subscapularis function from the other medial rotators (i.e., pectoralis major, latissimus dorsi, and teres major), its unique function must be promoted by carefully prescribing the posture and movement parameters of the activity chosen.

An exercise to improve the muscle performance and length–tension properties of a lengthened subscapularis is prone medial rotation (see **Self-Management 25-6**). If the subscapularis can produce enough force to rotate the arm against gravity, prone is the desired position for the patient to perform medial rotation.[61] Prone medial rotation poses a greater challenge to the subscapularis to prevent the humerus from translating anteriorly than a supine position, in which gravity assists the humerus posteriorly. Theoretically, if the other medial rotators dominate the subscapularis during this exercise, anterior translation during medial rotation will occur. Decker et al.[149] demonstrated that internal rotation (IR) at 90 degrees of abduction produced less pectoralis major activity compared to 0 degrees of abduction. Pectoralis major and latissimus dorsi activity increase when performing IR exercises in an adducted position or while moving into an adducted position during the exercise.[150] Thus, IR at 90 degrees of abduction is recommended if attempting to strengthen the subscapularis while minimizing larger muscle group activity.

The goal in this case is to strengthen the subscapularis to prevent abnormal or excessive anterior translation of the head of the humerus during GH medial rotation and during other functional movement patterns. Resolution of this impairment does not necessarily translate into a functional outcome unless the muscle is specifically trained during functional activities. The subscapularis muscle is kinesthetically limited, and it cannot be palpated or recorded with surface EMG. The clinician's best indication that it is working is to observe or palpate movement of the head of the humerus during functional activities. Because movement occurs rapidly and the movement is difficult to observe, videotaping the movement can be useful for carefully analyzing movement.

If the humeral head appears to be translating excessively anteriorly during function, particularly if symptoms of instability or pain are present, the clinician must determine whether the problem is caused by impairments in active range of motion (AROM), passive range of motion (PROM), or neuromuscular coordination, or some combination (most typical). An active impairment may be caused by insufficient subscapularis force capability and/or length–tension properties.

Poor neuromuscular coordination (motor control) may be due to poor timing between the cuff muscles and torque producers. Methods to improve motor control include verbal, visual (e.g., patient views a videotape of their performance to gain understanding of the movement pattern), or tactile feedback to provide knowledge of results. Verbal cueing might include "think of sucking the ball into the socket," or "imagine the ball is on a skewer and you are sliding it into the socket." These verbal cues might augment the concavity compression role of the subscapularis and improve GH stability.

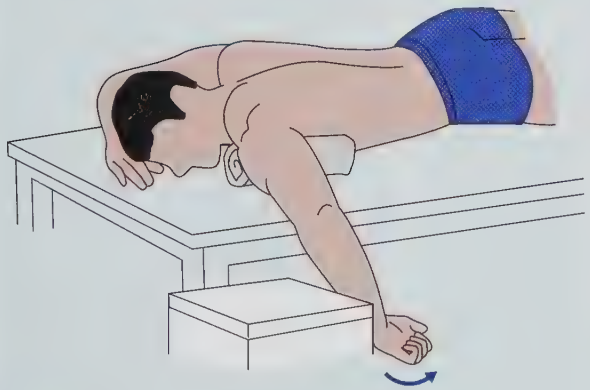
Passive impairment may include laxity in the anterior capsuloligamentous structures with correlating relative stiffness in the posterior structures. Postural faults may include increased thoracic flexion preventing adequate scapular adduction during horizontal arm abduction, or limited thoracic rotation in a more global movement (such as with the cocking phase of pitching), and thereby leading to excessive GH anterior translation. Attention to the posture and associated movement of the thoracic spine may be critical to ultimately improve the GH movement pattern.

SELF-MANAGEMENT 25-6
Subscapularis Isometric Exercise

Purpose: To strengthen the subscapularis in the short range

Starting Position: Kneel next to a weight bench; if at home, lie on your stomach adjacent to the edge of your bed. Place one or two towels rolled under your shoulder. Position your arm out to the side with elbow bent to 90 degrees. Keep as much of your shoulder supported on the bench or bed. Your arm should hang down from your elbow, not your shoulder. Rotate your arm backward as far as you can before you feel the "ball" drop out of the socket. Position a garbage can or another object sufficient to support your arm.

Movement Technique:
- Raise your hand ½ in off the garbage can, and hold it for 10 seconds.
- Be sure the "ball" does not drop out of the socket.
- Lower your hand back to the garbage can.



Dosage:

Sets/Repetitions: ____________________

Frequency: ____________________

Impaired Muscle Performance

As discussed in the examination/evaluation section, impaired muscle performance can result from numerous causes. This section discusses therapeutic exercise intervention for each major cause of impaired muscle performance.

Neurologic Pathology

Neurologic pathology can lead to sensory or motor changes and can occur at the nerve root level or as a result of a peripheral nerve injury. Thorough examination and evaluation can determine the anatomic site of the neurologic deficit. A thorough discussion of thoracic outlet syndrome can be found in Chapter 24.

Alterations in neurologic function at the nerve root level from cervical involvement can be a source of impaired muscle performance in the shoulder girdle musculature. For example, mechanical dysfunction of the C4 or C5 levels can affect the C5 nerve root, and may result in weak abduction, flexion, medial, or lateral rotation.[151] Strength-related activities will not improve muscle performance in the shoulder until the cause of neural impairment at the level of the cervical spine is addressed (see Chapter 23, The Cervical Spine, for concepts related to therapeutic exercise intervention of the cervical spine). If the underlying cause of impaired muscle performance is due to impairment of the nerve root, the position of the cervical spine with respect to the trunk and the shoulders is extremely important when performing shoulder exercises.

Another common neurologic deficit involving the shoulder girdle is injury of a peripheral nerve resulting from traction, compression, trauma, or surgery. Nerves that are vulnerable to injury are depicted in **Display 25-5**. Nerve injury often results in weakness of the innervated muscles. Injury to the long thoracic nerve is discussed to demonstrate the resulting muscle performance impairments and the related therapeutic exercise intervention.

Long Thoracic Nerve Injury The long thoracic nerve is purely a motor nerve that originates from the ventral rami of the fifth, sixth, and seventh cervical roots. It is the sole innervation to the serratus anterior muscle. The fifth and sixth cervical roots, along with the dorsal scapular nerve, pass through the substance of the scalenus medius muscle, whereas the seventh cervical root passes anterior to it.[158] The nerve then travels beneath the brachial plexus and clavicle to pass over the first rib. From there, it descends along the lateral aspect of the chest wall, where it innervates the serratus anterior muscle. The nerve extends as far inferior as the eighth or ninth rib. This long, relatively superficial course makes it susceptible to injury (**Evidence and Research 25-8**).

Spinal accessory	Jugular foramen or posterior triangle[156,157]

EVIDENCE and RESEARCH 25-8

Mechanisms of Nerve Injury to the Long Thoracic Nerve

The stretching capacity of a peripheral nerve is estimated at 8% to 15%.[159–160] In research into human cadavers, in which the head was turned to the opposite shoulder while elevating the ipsilateral arm, the long thoracic nerve could be stretched twice its length.[161] Pathomechanics postulated to cause injury to the long thoracic nerve include entrapment of the fifth and sixth cervical roots as they pass through the scalenus medius muscle, compression of the nerve during traction to the upper extremity by the undersurface of the scapula as the nerve crosses over the second rib, and compression and traction to the nerve by the inferior angle of the scapula during general anesthesia or passive abduction of the arm.[159,162,163]

One additional plausible cause of injury is traction to the nerve in the presence of a depressed scapula on the rib cage (e.g., carrying a heavy bag with the strap over the shoulder). Depressed scapula is often seen as a sequela in cervical dysfunction to the C5, C6 segmental levels.[164]

Injury to the long thoracic nerve manifests as weakness of the serratus anterior, a critical muscle for normal scapular mechanics. A hallmark sign for long thoracic nerve injury is scapular winging at rest that is exaggerated during arm elevation, arm lowering, or pushing. The pathomechanics that contributed to the injury must first be resolved before strength-related activities can be effective. In the case of a traction injury to the long thoracic nerve, the postures and body mechanics that cause depression of the scapula must be addressed. Strength exercises for the scapular elevators (e.g., upper trapezius) are often necessary. Taping the scapula into elevation may also be required to relieve the tension on the nerve (see Adjunctive Interventions: Scapular Taping).

To develop a working prognosis, one must consider the anatomy of the long thoracic nerve. From its origin at the root of C5–C7 to the insertion into the serratus anterior, the nerve travels approximately 35 cm. Recovery of the nerve is a very slow process: about 1 cm per week. Recovery may occur between a few months and 2 years.[159] Initially, neuromuscular electrical stimulation (NMES) can be used to prevent muscle atrophy.[165] NMES can be used with biphasic pulses in burst mode applied via electrodes over the motor points of the affected serratus anterior.[166] Self-Management 25-3 can be used in conjunction with NMES for the prevention of atrophy initially and later to reeducate the serratus anterior as motor function returns.

Passive ROM exercises can be prescribed and manual joint mobilization techniques can be applied to the GH joint and ST articulation to prevent loss of mobility in the early stages. As reinnervation of the muscle occurs, a progressive strengthening exercise program must be introduced. Several exercises elicit high serratus anterior activity.[167–171] **Display 25-6** lists commonly prescribed exercises.

A general rule of thumb to consider in functionally strengthening the serratus anterior is that its activity tends to increase in a somewhat linear fashion with arm elevation.[35,168,170–173] Though one would not initially consider performing shoulder IR and ER at 90 degrees of abduction (see Self-Management 25-1) to generate serratus anterior activity, these are excellent choices

DISPLAY 25-6

Commonly Prescribed Serratus Anterior Exercises

- D1 and D2 diagonal proprioceptive neuromuscular facilitation (PNF) pattern flexion (see Chapter 15)
- D2 diagonal PNF pattern extension (see Chapter 15)
- Supine scapular protraction
- Supine upward scapular punch
- Military press
- Push-up plus
- GH, IR, and external rotation (ER) at 90-degree abduction
- Shoulder flexion, abduction, and scaption with ER above 120 degrees.

because the role of the serratus is to stabilize the scapula against the forces exerted by the RC.[168] For example, the force exerted by the supraspinatus at the supraspinous fossa has the ability to downwardly rotate or internally rotate the scapula if this force is not counterbalanced by the ST musculature. Following the principle of specificity of training, when possible, the exercise should duplicate the function of the serratus anterior.

Decker et al.[167] compared several common exercises designed to recruit the serratus anterior. The authors identified that the three exercises that produced the greatest serratus anterior EMG signal were the push-up with a plus, dynamic hug (see **Fig. 25-9**), and punch exercises (similar to a jabbing protraction motion; see **Fig. 25-10**).

Despite the high activation levels of the serratus anterior during protraction patterns, this author recommends caution in promoting the protraction function of the serratus anterior. Normal upper quarter (UQ) kinematics involve a combination of scapula upward rotation, posterior tilt, and external rotation.[35] The clavicle retracts during normal UQ elevation, which is coupled with scapula external rotation (an important function of the serratus as well as an important kinematic to prevent subacromial impingement).[21,35,63,170–174] Training scapular protraction movement patterns could be detrimental to restoring ideal shoulder girdle kinematics.

An alternative exercise that has been shown to be an effective method to strengthen the serratus anterior is the wall slide (see Fig. 25-4).[173] Interestingly, the wall slide produces similar serratus anterior activity compared to scapular abduction above 120-degree abduction with no resistance.[173] One advantage of the wall slide compared to scapular abduction is that, anecdotally, patients report that the wall slide is less painful to perform. This may be because during the wall slide, the upper extremities are supported against the wall, making it easier to perform while also assisting with inferior glide and compression of the humeral head within the glenoid. Thus, this may be an effective exercise to perform during the earlier protective phases of rehabilitation.

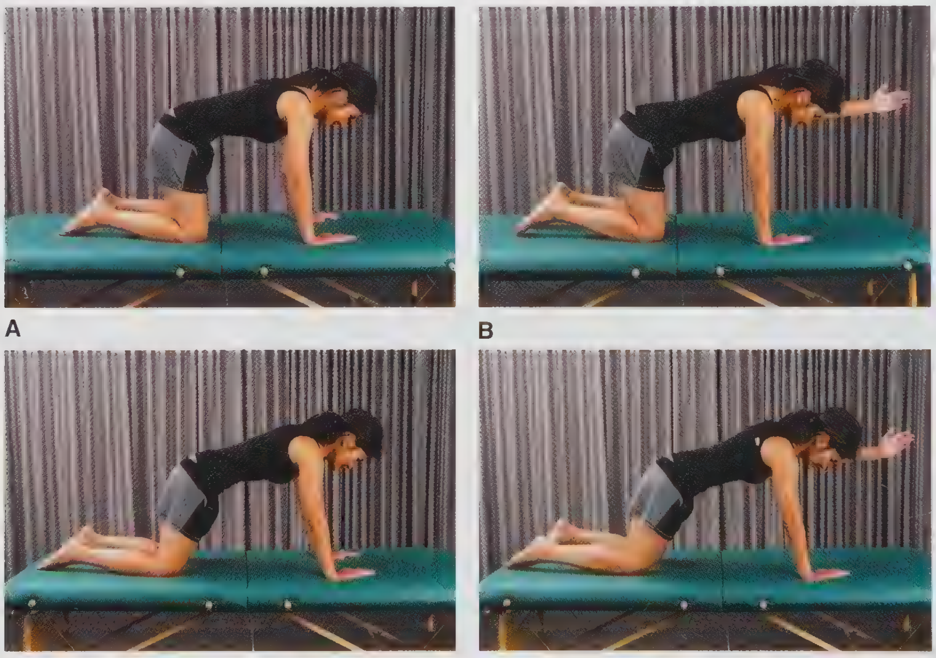
The hand-knee position is an alternative position to provide resistance to the serratus anterior. **Figure 25-11** illustrates an initial progression on hands and knees. The goal with this exercise is to support the body weight through the affected upper extremity without scapular adduction or winging. Stepping the knees behind the hips increases the weight the arms must support, thus increasing the strength demand on the serratus anterior (see Fig. 25-11C and D). This exercise can be progressed to a push-up position. The desired position for a "serratus push-up" is modified from the traditional "pectoral push-up" by positioning the olecranon and antecubital fossa in the sagittal plane. This modified position is also called a "triceps push-up" or a "pilates"

A B C

FIGURE 25-9 Dynamic hug for the serratus anterior begins with elbows flexed 90 degrees and arms at side **(A)**. The next motion is elbow extension with humeral internal rotation **(B)**. The ending position is with the humerus in full internal rotation, elbows flexed slightly, and humerus moving into horizontal adduction similar to a "hugging" motion until full acromioclavicular protraction is reached **(C)**.

A B

FIGURE 25-10 Bilateral serratus anterior punch to 120-degree abduction begins with hands by the side **(A)** before extending elbows and elevating shoulders up to 120 degrees of elevation and full protraction **(B)**.



A B C D

FIGURE 25-11 Progressive serratus strengthening exercises. **(A)** The patient assumes a quadruped position, with the hips directly over the knees and the shoulders directly over the hands. The scapula should be flat against the rib cage in neutral position. **(B)** The patient then lifts the opposite hand slightly off the ground. The supporting shoulder girdle should not demonstrate any alteration in scapular position. **(C)** The patient assumes a quadruped position, with the hips slightly in front of the knees and shoulders directly over the hands. The scapula should be flat against the rib cage in neutral position. **(D)** The patient then lifts the opposite hand slightly off the ground. The supporting shoulder girdle should not demonstrate any alteration in scapular position. **(E)** "Serratus push-up." The patient assumes the position shown. The hips should be in neutral with respect to the sagittal plane. This subject is in more hip flexion than is desirable. The scapula should be resting against the rib cage in a neutral position. The elbows should be in the sagittal plane with the olecranon process facing posteriorly and the antecubital fossa facing anteriorly. The fingers should be directed forward with the wrist in extension; a small towel roll may be placed under the palm of the hand to reduce the amount of wrist extension if full wrist extension is uncomfortable. **(F)** The patient slowly lowers his body toward the floor while maintaining neutral pelvis and spine alignment. The elbows should flex in the sagittal plane (sometimes called a triceps push-up). The scapula should abduct and adduct during the movement. Evidence of winging or lack of abduction indicates the load is too great or the muscle has fatigued. **(G)** The patient is positioned as in **(E)** and **(F)**, but the legs are straight. **(G,H)** The exercise proceeds as in **(E)** and **(F)**.

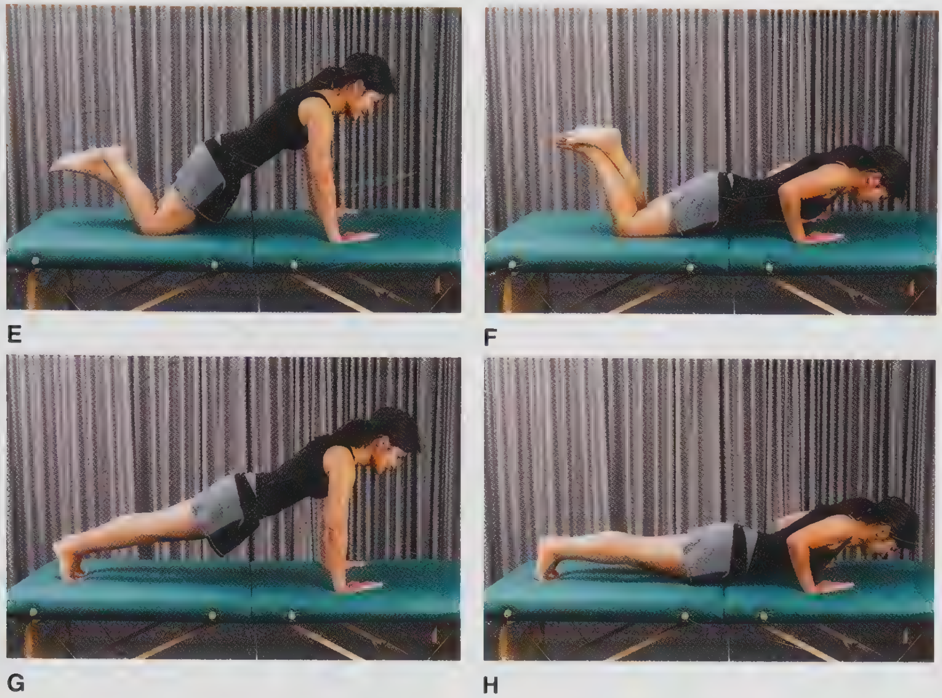


FIGURE 25-11 (*continued*)

push-up. To progress the level of difficulty, the exercise can be performed first in the bent-knee position (see Fig. 25-11E and F) and then progressed to a straight-body position (see Fig. 25-11G and H) if higher levels of performance using the serratus anterior are required. Though the "plus" movement of the scapula during a push-up does generate high serratus activation levels,[167–171,175] caution is recommended in promoting this additional movement due to the aforementioned reasons.

The clinician must consider the most critical function(s) to restore and consider the posture, mode, movement, and dosage parameters based upon the examination findings. A clinical example detailed in **Display 25-7** can provide a platform for prescribing a therapeutic exercise intervention (see **Building Block 25-5**).

DISPLAY 25-7

Clinical Scenario for Traction Injury to Long Thoracic Nerve

A 39-year-old female homemaker injured her long thoracic nerve from constantly carrying a diaper bag and her 25-lb toddler on her left side. The MMT grade of her serratus anterior at the time of initial examination is 3/5. Her functional goals are to be able to perform ADLs and instrumental ADLs of a full-time homemaker. She is not involved in any upper extremity sports or recreational activities.

BUILDING BLOCK 25-5

Based upon the clinical example described in Display 26-7, outline three progressive exercises for the serratus anterior for this patient, starting with her baseline muscle performance up to a grade of 4/5.

Muscle Strain

Muscle strain results from an injurious tension. Muscle strain can result from a sudden and excessive tension (macrotrauma) or from a gradual and continuous tension imposed on a muscle (microtrauma). Both types of muscle strain commonly occur in the shoulder girdle.

An example of a muscle strain caused by sudden and excessive tension imposed on a muscle is a sudden fall onto the shoulder or outstretched arm, resulting in a RC strain or complete tear. The examination may reveal weakness in some or all portions of the RC. Selective tissue tension tests may also reveal pain with resistive testing and stretch, depending on the severity of the strain.

Treatment of strains should follow the guidelines for tissue healing outlined in Chapter 11. After a short period of rest during the early repair phase (5 to 7 days),[176–178] low-load muscle contraction can be introduced in the repair-regeneration phase to impose a load on the healing tissue along lines of stress. Exercise during this phase is crucial for the regeneration on the molecular level and for correct orientation of the regenerating myofibers.[179–183] Initially, submaximal isometric contractions at various positions within the pain-free range can be prescribed (2 to 7 weeks)[182,183] Alternatively or in addition, concentric-eccentric dynamic exercise can be prescribed. Dosage parameters related to the load, starting, and ending positions, and ROM depend on the severity of the strain. More aggressive strength regimens can be gradually introduced in the later stages of the repair-regeneration phase to prepare the muscle for the final phase of healing (**Fig. 25-12**). The type of contraction and specific movement pattern required of the muscle should be trained as early as possible. For example, prevention of excessive humeral head superior translation is a specific and necessary function for the RC during arm elevation (concentric) and the

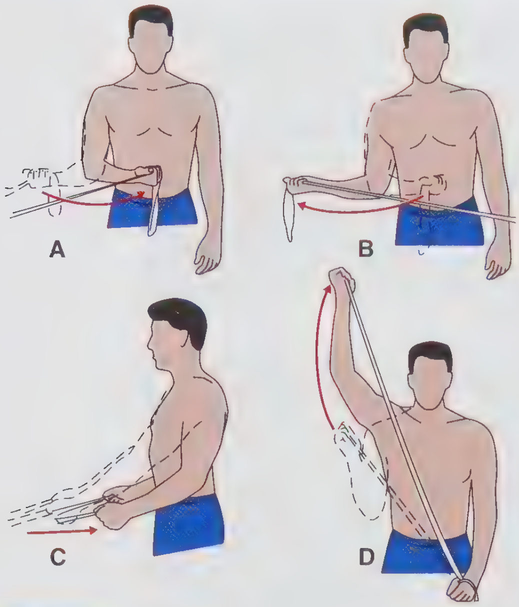

FIGURE 25-12 Higher-level rotator cuff exercise using elastic tubing. The therapist must ensure precise motion at the glenohumeral (GH) joint and provide biofeedback to the patient regarding the path of instant center of rotation (PICR) of the scapulothoracic (ST) joint during these movements. **(A)** Medial rotation. Caution must be taken to prevent scapula abduction and medial rotation during GH medial rotation. **(B)** Lateral rotation. Caution must be taken to prevent scapula adduction during GH lateral rotation. **(C)** Extension. Caution must be taken to move the elbow only slightly posterior to the midaxillary line to prevent excessive anterior displacement of the humeral head. **(D)** Flexion. Caution must be taken to ensure optimal PICR of the ST joint during arm elevation and control over superior translation of the humeral head.

return from arm elevation. The final phase of healing (7+ weeks) should include activity-specific exercises related to the patient's functional goals. Complex functional movement patterns can be trained, and a gradual return to sport-specific activities, such as returning to a pitching program (**Display 25-8**),[184,185] can be accomplished. Quality of movement during exercise and functional activities must be emphasized and used as a guide for progression at any stage.

Another form of strain common in the shoulder girdle is the type resulting from gradual and continuous tension (microtrauma). For example, strain to the middle and lower trapezius often results from a habitual position of abducted and downwardly rotated scapulae found in thoracic kyphosis. Subjective and objective characteristics of middle/lower trapezius strain include[61]:

- Symptoms of "burning" pain along the course of the middle or lower trapezius may be experienced. If the strain is not accompanied by adaptive shortening of the anterior muscles, pain is not constant and can be relieved in the recumbent position. However, change of position does not affect the symptoms of a person with associated adaptive anterior shortness.
- Heavy breasts that are not adequately supported.
- Positional weakness in the middle and lower trapezius.
- Adaptive shortening of the pectoralis major and minor and other internal rotators.

DISPLAY 25-8

Nine-Level Rehabilitation Throwing Program*

Level	Throws/Feet	Throws/Feet	Throws/Feet

**This program is designed for athletes to work at their own pace to develop the necessary arm strength to begin throwing from a mound. The athlete is to throw 2 days in a row and then rest for 1 day. It is not important to progress to the next throwing level with each outing. It is preferred that a number of outings at the same level be completed before progressing. It is important to throw with comfort, which may necessitate moving back a level on occasion.*

DiGiovine NM, Jobe FW, Pink M, et al. An electromyographic analysis of the upper extremity in pitching. J Shoulder Elbow Surg 1992;1:15–25.

Treatment in the early healing phase should include support in the form of taping (see the "Adjunctive Interventions: Taping" section), posture garment (**Fig. 25-13**), or supportive brassiere to relieve the tension on the middle and lower trapezius. If shortness affects the shoulder medial rotator and adductor group, gradual stretching (see Fig. 25-7, Self-Managements 25-2 and 25-4) is indicated before strengthening the middle and lower trapezius. Stretching allows the middle and lower trapezius to be strengthened at the appropriate length.

Exercises to strengthen the middle and lower trapezius muscles should not only consider the function of these muscle fiber directions, but also the length at which the muscles are being strengthened. The lengthened range must be avoided to prevent further strain to the muscle. Lengthened muscles produce less force or torque in the short range; therefore, initial exercises may need to be performed in gravity-lessened positions. The gravity-lessened position decreases the load on the lengthened muscle so it can produce sufficient force or torque in the short range. **Figure 25-14** depicts a strengthening exercise for the lower trapezius in a gravity-lessened position. Prone horizontal abduction between 90 and 135 degrees of abduction in ER has been shown to demonstrate high levels of middle and lower trapezius activation.[168] The progressive exercises shown in Self-Management 25-2 demonstrate a progression of load using these positions to activate the middle and lower trapezius fibers. Exercise prescription can proceed to this progression once when force capability can be produced in the short range against the higher loads imposed by longer lever arms and the introduction of gravity. Figure 25-4 and Self-Management 25-4, Level III can be used, with the emphasis on optimal length–tension properties of the lower trapezius, timing of activation with respect to the

FIGURE 25-13 Posture garment.

upper trapezius and serratus anterior optimal ST kinematics, and concentric/eccentric control.

One of the ultimate goals is to alter length–tension properties of both lengthened and shortened muscles. New length–tension properties of the affected musculature should be achieved if the following conditions are met:

- Strengthening in the shortened range is combined with proper support for the middle and lower trapezius.
- Stretch is applied to the anterior musculature (i.e., pectoralis minor, pectoralis major, short head of biceps).
- Education is provided regarding improved postures, movement patterns, workstation ergonomics, and body mechanics.

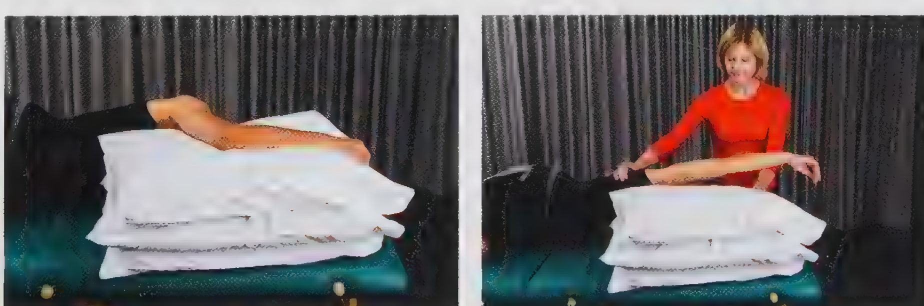
Use of these concepts and principles will result in alleviating the precipitating pathomechanics to allow the strain to heal.

Disuse, Deconditioning, and Reduced Conditioning

In some cases, muscles become weak because of disuse or deconditioning or may not be able to produce enough force or torque to enable an individual to achieve higher levels of performance. Impaired muscle performance due to disuse or lack of conditioning can manifest as alterations in performance of ADLs, instrumental ADLs, recreation, leisure activity, or sports. Muscle performance impairments can be caused by many forms of disuse or deconditioning:

- Gradual development of subtle alterations in agonist–antagonist relationships caused by habitual postures or repetitive movement patterns, which can create problems related to muscle balance (e.g., insidious onset of shoulder impingement without evidence of anatomic impairments as a precipitating factor)[61]
- Generalized weakness from prolonged rest or reduction in activity, preventing performance of ADLs and instrumental ADLs (e.g., dressing, meal preparation, housework)
- Decreased power output preventing maximal performance of a high strength-demand sport, such as swimming, tennis, or baseball/softball.

The shoulder girdle poses a challenge for the clinician prescribing a general strength-conditioning program because of the potential for creating muscle imbalances. A conditioning program should include exercises for all major muscle groups. The posture and movement of the technique are critical to a successful program. For example, if a biceps curl is done with poor technique (i.e., anterior scapular tilt is increased during the elbow flexion motion) rather than optimal technique (i.e., scapula remains neutral with respect to tilt during the elbow flexion motion with proper stabilization from the axioscapular muscles), the patient risks development of impaired muscle length–tension properties of the scapular stabilizers, which could cause secondary impairments or pathology (e.g., subacromial impingement from a scapula functioning in excessive anterior tilt). This risk increases if the same faulty posture is used during a variety of other exercises. **Display 25-9** summarizes exercises that are recommended for inclusion in a general shoulder girdle conditioning program.



A B

FIGURE 25-14 Gravity-lessened position to strengthen lower trapezius. **(A)** Position the patient in sidelying with as many pillows as necessary to support the arm in the sagittal or scapular plane. The arm rests on the pillow at 90 degrees of elevation with the elbow bent. **(B)** Slide the arm upward toward full elevation. The scapulothoracic and glenohumeral joint path of instant center of rotation should be monitored for any deviations. Once full available upward rotation is achieved, the patient lifts the arm 1 to 2 in off the pillow. An isometric contraction of the lower trapezius is held for the specified duration. Care must be taken to lift the entire arm, and not just the elbow.

In the case of a high-level athlete or strenuous industrial worker, general conditioning exercises may not be enough to improve performance of the desired activity. The choice of exercise (e.g., dynamic, isokinetic, isometric) used in training depends on the performance level and the specific activities to which the individual wishes to return. The prescription of high-level strength-conditioning exercises must be specific for mode, contraction type, and velocity whenever possible. For example, when strength training the medial rotators in the pitching athlete, the type of contraction should duplicate the eccentric contraction used in the cocking phase to decelerate motion and a concentric contraction used in the acceleration phase to create pitching velocity.[185] Examples of techniques or activities that can provide concentric and eccentric contraction training include manual resistance by the physical therapist in the clinic, plyometric equipment, and a home program using elastics (**Fig. 25-15**).

Prevention of injury is a major concern for the athlete or industrial worker. In designing a training program for these persons, the clinician should prescribe exercises to improve the muscle performance of the muscles required for the sport or occupation and prescribe exercises to strengthen opposing muscles to prevent muscle imbalances. For example, sports such as baseball may require training for the shoulder medial rotators. If strengthening for the opposing lateral rotators and scapular adductor and upward rotators (i.e., middle and lower trapezius) is not performed, muscle imbalances may develop and lead to impairments.[61] In addition, the clinician should ensure that all the medial rotators are stimulated in a conditioning program and that the larger pectoralis major and latissimus dorsi do not predominate and create an imbalance within the medial rotator group. Specific exercise for the subscapularis as shown in Self-Management 25-6 can be prescribed along with more general medial rotation exercises to maintain muscle balance.

One important component of muscle performance includes muscle endurance. Postural faults in the upper quadrant are often attributed to lack of muscle endurance. However, little or no muscle activity has been found in upper quadrant muscles during relaxed standing posture.[186] Postural faults are commonly caused by alterations in muscle length whereby some

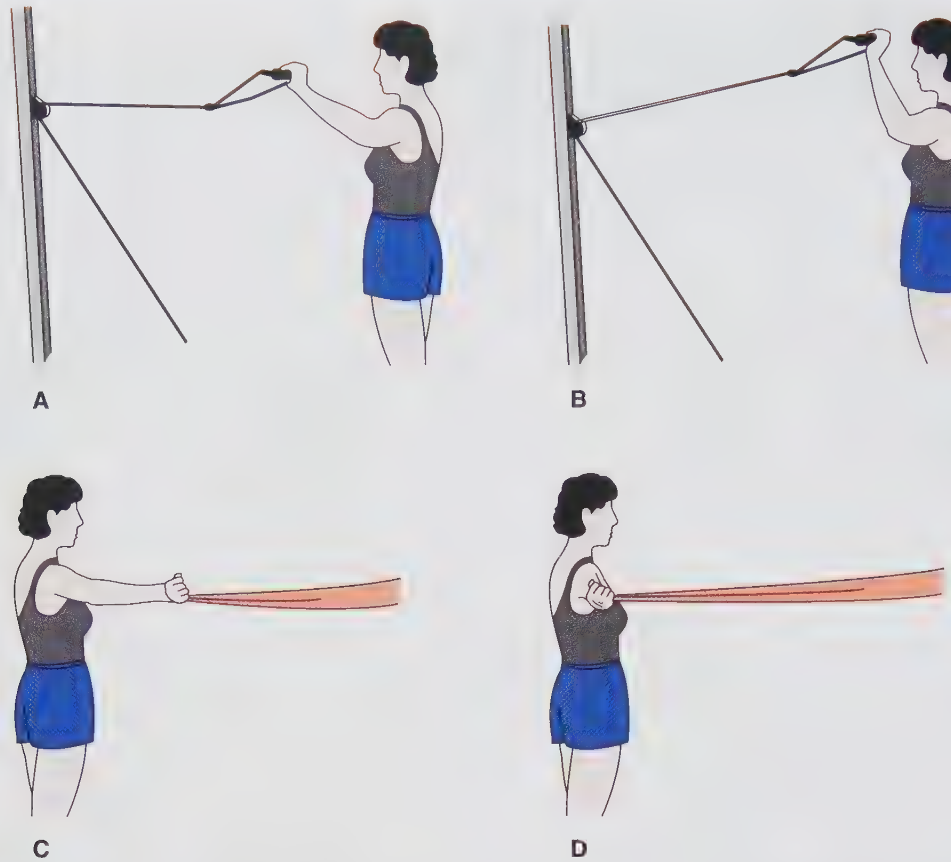

FIGURE 25-15 Plyometric exercise for rotator cuff. **(A** and **B)** Starting and ending positions for dynamic plyometric shoulder external rotation (using Impulse Inertial Exercise System). **(C** and **D)** Starting and ending positions for dynamic plyometric horizontal abduction using elastic tubing. Monitor the patient to prevent excessive anterior translation of the head of the humerus during horizontal abduction.

muscles become adaptively lengthened and others adaptively shortened. The altered lengths of muscles do not provide the optimal support to the shoulder girdle structure.

Impairments in muscle endurance have also been implicated in shoulder and neck symptoms. However, despite the methodologic problems associated with quantifying muscle fatigue,[187] most authorities agree that muscle fatigue is not solely responsible for occupational neck and shoulder complaints.[188,189] Indeed, it has been shown that the trapezius, for example, is under constant muscle tension in myalgic subjects,[190] but that a combined program aimed at restoring ideal muscle length–tension properties, muscle force, endurance, and coordination is more applicable than focusing on muscle endurance alone.[191]

Generally, research indicates that prevention and treatment of neck and shoulder symptoms require a multidimensional approach to reduce the workload on muscle.[192–195] Suggested interventions include ergonomic changes in the workstation and appropriate pacing of activity combined with rest[196]; additionally, measures to reduce stress and anxiety in the work place should be employed.[196,197]

In the case of recovery from injury, starting a new job with greater workload demands, or trying to improve performance levels in an upper extremity for a sport, endurance may need to be developed in the upper extremity musculature. Local muscle fatigue has been shown to affect the kinematics of the joints in the shoulder girdle complex.[198] When the ADLs or instrumental ADLs require more endurance than the muscles possess, endurance must be considered while making decisions about exercise dosage. Chapter 5 provides specific dosage recommendations, but generally, resistance is modified to allow for higher repetitions of a given exercise.

Posture and Movement Impairment

Restoring optimal posture and movement patterns (motor control) to the shoulder girdle complex and the entire upper quadrant (and in many cases, the lower quadrant) should be an integral component of any exercise prescription for the shoulder girdle. Attention to posture and movement patterns is a required component of exercise to remedy-related impairments. The etiology of an overuse injury may be a result of poor structure or function in any of the joints included in the shoulder complex. Additionally, function of the cervical and thoracic spine is important to the maintenance of shoulder girdle complex function. Examination of the structure and function of each of these related regions joints will lead the clinician to the pathomechanics underlying the overuse injury.

Posture

Optimal resting alignment of the shoulder girdle is described in Chapter 9. This alignment facilitates ideal joint positions and resting lengths of the axioscapular, scapulohumeral, and axiohumeral muscles. The resting length of a muscle can be a factor in its participation in active force couples.[61,199] Head, spine, and pelvis alignment affect alignment of the shoulder girdle. For example, forward head, kyphosis, lordosis, and anterior pelvic tilt encourage protracted clavicular position and anterior tilt, and downwardly rotated scapulae.[61] Habitual faulty alignment such as this places the middle and lower trapezius on stretch. Adaptive lengthening can ensue, in turn affecting the length–tension properties of these muscles and thereby affecting their performance in scapular force couples.[47,200]

Optimal alignment of the shoulder girdle complex requires education of habitual cervical, thoracic, and even lumbar and pelvic postures during standing, sitting, and sleeping. Equally important is the education of preferred postural patterns in the patient's environment, such as factory assembly line, desk and chair, kitchen counter, car, baby changing table, are critical to successful postural changes. Support through bracing, taping, and supportive brassieres may be necessary to facilitate the reeducation process and reduce strain on lengthened muscles.

Movement

Restoration of the optimal kinematics during active motion requires knowledge about the kinesiology of the shoulder girdle complex. If the ideal is known, the clinician can devise a program of exercises to alleviate impairments and retrain movements to approach the ideal standard. The goal is to achieve movement as close to the ideal kinematics as possible to enhance the health and longevity of the biomechanical system. The references and reading list at the end of the chapter provide sources for more information about electromyographic or cinematographic analysis of the shoulder girdle during common movement patterns, sport activities, and therapeutic exercises.

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON DIAGNOSES

Although comprehensive descriptions and intervention plans for all diagnoses affecting the shoulder girdle are beyond the scope of this book, a few diagnoses are discussed. An overview of the pathogenesis or pathomechanics, examination findings, and proposed treatment plan, with an emphasis on exercise, is provided for each selected diagnosis.

Rotator Cuff Disorders

For the purposes of this text, the broad category of RC disorders includes such medical diagnoses as subacromial impingement syndrome (SIS), posterior superior impingement (PSI), anterior superior impingement (ASI), and functional/microinstability leading to RC tendinosis/tendinopathy. Although each of these classifications merits a separate detailed review of pathogenesis and pathomechanics, associated impairments, and treatment concepts, it is beyond the scope of this text to do so. Comprehensive understanding of RC disorders can be established by means of reviewing the literature cited in this section.

Rotator cuff disorders can be broadly classified as acute or chronic in origin, though acute, avulsive tears of healthy rotator cuff tendons (RCTs) are considered to be rare.[201–203] Most authors believe that RC tears that appear to be of sudden onset after trauma are extensions of underlying chronic tears or tears of previously degenerated tendons.[201–203]

Tendinopathy predominantly develops from excessive compression, tensile load, or a combination of both. Analysis of the possible underlying drivers will direct not only the mechanical intervention, but also assist with addressing the stage of pathogenesis, both of which will be discussed in subsequent sections (**Evidence and Research 25-9**).

EVIDENCE and RESEARCH 25-9

Rotator Cuff Pathology and Pain

It is important to understand that observed structural failure in the RCTs is not always symptomatic. Frost et al.[204] reported that people with and without symptoms of RC tendinopathy demonstrated equivalent RC pathological changes. Asymptomatic professional baseball pitchers demonstrate substantial RCT pathology in their pitching and catching shoulders,[205] and ultrasound studies of men without symptoms identified structural changes in 96% of those scanned including subacromial bursal thickening, supraspinatus tendinosis and partial-thickness tears, as well as labral pathology.[206] Reasons why some people experience pain as well as the source of the pain remain uncertain.

Numerous classification systems have emerged in an attempt to logically categorize staging and mechanistic factors of RC disorders.[104,207–212] There is considerable overlap and opposing models within these systems, and their terminology is not synonymous; therefore, these systems cannot be used interchangeably to discuss classification of RC disorders. For the purposes of this chapter, the following summary will be used for terminology.

Pathomechanics

Three common types of chronic RC disorders have been described in the literature: (1) extrinsic or subacromial (compression), (2) intrinsic (tensile), and (3) extrinsic internal impingement (compression/tensile).

Extrinsic or subacromial (also known as primary impingement) includes diagnoses that can be attributed to mechanical compression of the subacromial structures. Medical diagnoses that are included in this category are primary or *SIS* and bursal surface RC tears.[207] The prevalence of a compression mechanism for the RC is less frequent than initially proposed, and not likely the predominant mechanism.[213] This has led to the evolution in terminology from *subacromial impingement syndrome* to the label of *subacromial pain syndrome*. Underlying mechanisms leading to SIS could include faulty scapular mechanics such as insufficient posterior tilt, external rotation, or upward rotation of the scapula; or excessive superior glide of the humeral head.[214]

The second type includes those disorders that can be attributed to tensile overload of the RC and is commonly referred to as **intrinsic** RC pathology. Throwing or racket sport athletes are at high risk for this type of RC injury because of the high, repetitive eccentric forces incurred by the posterior RC musculature during the deceleration and follow-through phases of overhead sport activities.

Another possible mechanism of tensile loading is chronic loading that occurs in a depressed and downwardly rotated scapula from weak serratus or upper trapezius. In this posture (see Fig. 25-5), the cranial orientation of the scapula is lost and the superior capsuloligamentous structures and cuff tendons are placed under tensile load to support the head of the humerus (**Fig. 25-16**).[215,216]

A common medical diagnosis that is included in this category is undersurface RC tears.[217] Tears can be classified as partial or incomplete, complete, or massive.[103] Incomplete tears do not extend through the entire thickness of the tendon. Complete tears extend through the full thickness of the tendon or muscle. A massive tear indicates more than one RCT or muscle is torn.

Another term, extrinsic **internal** impingement, has been used in the literature to describe a third mechanism of RC disease. This pathomechanic is differentiated from SIS or intrinsic impingement in that this condition implies that there is a problem with keeping the humeral head centered in the glenoid fossa during movement of the arm.[218] This is generally caused by weakness in the RCT muscles (functional instability) combined with a GH joint capsule and ligaments that are too loose (microinstability). Two types of external/intrinsic impingement have been described: (1) PSI and (2) ASI.

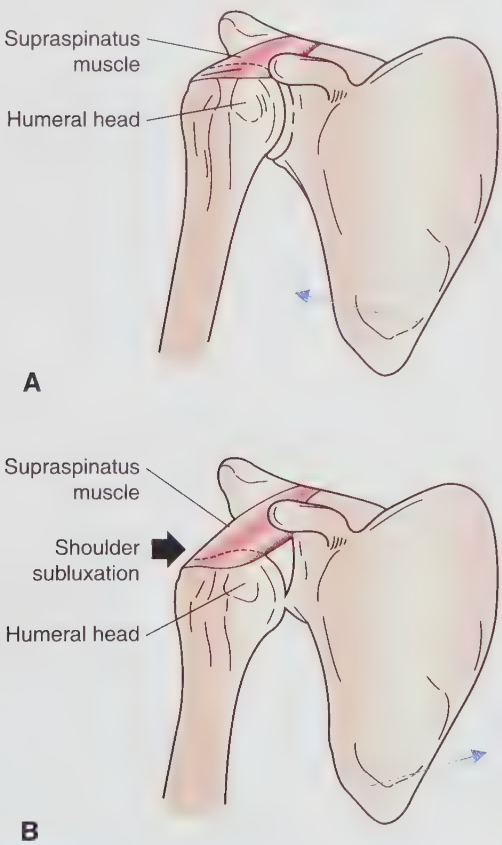

FIGURE 25-16 **(A)** The humeral head is maintained in the glenoid via slight upward orientation of the glenoid and the supraspinatus muscle. **(B)** Chronic tensile loading of the supraspinatus when the scapula rotates downward and the glenoid fossa loses its cranial orientation.

Posterior superior impingement is described as an intra-articular impingement that occurs in all shoulders in the abducted externally rotated position. In this 90–90 degree position, the undersurface of the posterosuperior RC contacts the posterosuperior glenoid labrum and may become pinched (compressed) between the labrum and greater tuberosity implying a labral impingement as opposed to subacromial impingement.[219–221] Jobe[222] hypothesized that the internal impingement in throwers might progressively worsens because of anterior microinstability created by gradual repetitive stretching of the anterior capsuloligamentous structures.

In contrast to PSI, the anterosuperior impingement is significantly less common. It involves an impingement of the subscapularis tendon between the anterior humeral head and the anterosuperior glenoid and labrum during forward flexion of the arm. Habermeyer et al. stated that a forcefully stopped overhead throwing motion might generate a RC lesion.[223] For a detailed etiology of these two types of impingement, the reader is referred to Kirchhoff et al.[224] It is important to treat the underlying "micro-instability" in patients with extrinsic/internal impingement. See summary of RC disorders in **Display 25-10**.

Because the position of the glenoid is directly related to the position of the scapula, relatively small changes in the action of the axioscapular muscles can affect the alignment and forces involved in movement around the GH joint.[61] Optimal 3D mechanics of posterior tilt, external rotation, and upward rotation are vital for optimal centering of the humeral head during elevation. With respect to humeral horizontal abduction and external rotation, the scapula moves into retraction and external rotation to maintain humeral head centering. Conversely, during humeral horizontal adduction and internal rotation, the scapula moves into protraction and internal rotation for humeral head centering.

Athletes with shoulder pathology consistently demonstrate abnormalities in scapular positioning, suggesting that motor control is an important factor to consider in extrinsic etiology of RC disorders.[175,225–229] Muscle function has been investigated in healthy shoulders[170,172,175] and in shoulders with GH instability[227,228] or impingement.[175,229] Most authors suggest that alterations exist in muscle activity of the scapular muscles in persons with RC disorders.

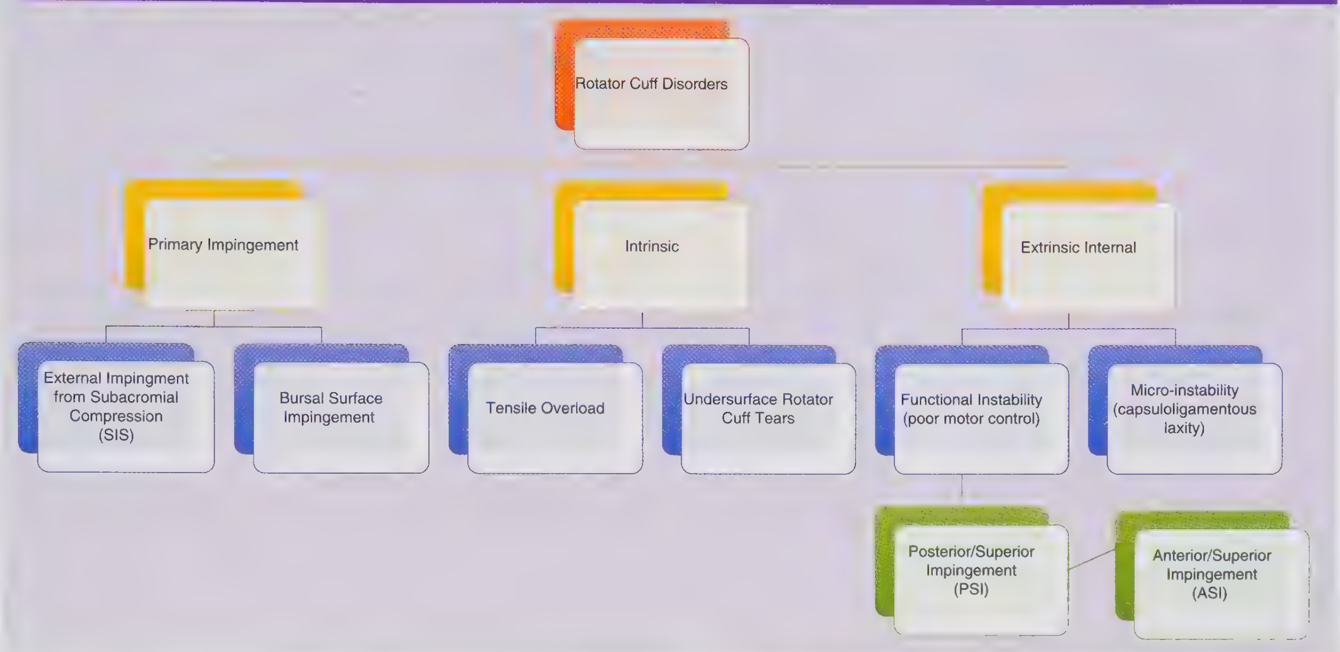
Research supports[226] a relationship between shoulder injury and the temporal recruitment patterns of the scapular rotators, suggesting that injury reduces the consistency of muscle recruitment. In addition, they suggest that injured subjects have muscle function deficits on their unaffected side, indicative of the possibility that muscle function deficits may predispose athletes to injury. Hence, promotion of motor control of scapular mechanics may be an important factor in the prevention of RC disorders.

Muscle dysfunction has also been investigated in the integrated deltoid–RC mechanism in persons with subacromial impingement.[230] The middle deltoid and RC muscles were evaluated during isotonic scaption from 30 to 120 degrees. Overall, the impingement group demonstrated decreased mean muscle activity in comparison with the group of normal subjects, particularly in the infraspinatus and subscapularis during the first portion of arm elevation. The inferior force vector is provided by the infraspinatus and subscapularis, thus humeral head depression during the critical first portion of elevation may be insufficient in persons with subacromial impingement.

This body of research suggests that dysfunction in scapular mechanics or deltoid–RC muscle function is present in persons

DISPLAY 25-10

Rotator Cuff Disorders



with RC disorder. Yet, it must be considered that many RC disorders involve more than one etiologic factor. Consequently, it is critical for the physical therapist to identify all intrinsic and extrinsic factors to effectively manage RC disorders.

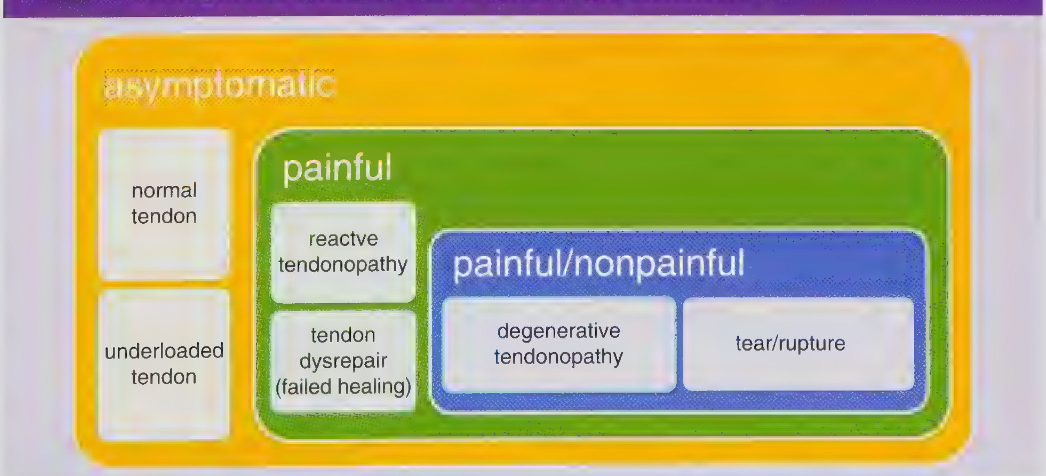
Pathogenesis

Recently, research into tendon pathology has both broadened and confused our understanding of tendon pathology. The new term "tendinopathy" has replaced the old term of "tendonitis" as a result of this research and a better understanding of pathophysiological mechanisms. Inflammatory cells have not been detected in tendinopathy tissue.[231] It is not possible for this text to provide a comprehensive review of current tendon research, but rather provide a synthesis of a continuum as is currently accepted. Understanding pathogenesis helps the clinician in clinical decision-making regarding the most appropriate intervention based on the stage of tendon pathology combined with the underlying pathomechanics leading to the pathology.

Numerous researchers have presented various theories regarding the pathogenesis of tendinosis/tendinopathy. Cook and Purdam[211] presented a model to define the continuum of tendon pathology. Although the continuum was based on evidence from lower limb tendons, it has been adapted for RC pathology.[114] This continuum may involve normal or underloaded tendons (see **Display 25-11**). The normal RCT and the underloaded tendon

DISPLAY 25-11

Pathogenesis of Rotator Cuff Disorders: The Continuum



may be subject to tissue overload if subject to an activity level in excess of that normally placed on the tendon. If this load is transient, the tendon can return to its preload state. This state is termed normal tendon overload and is a normal response to loading RC tissue through activity and exercise.

If the applied load exceeds the physiological capacity of the RC, the effect may be tendon upregulation. The first stage may be *reactive tendinopathy* and is predominantly seen in an acutely overloaded tendon where there is increased swelling within the tendon, and possible bursal effusion. Pain may be present, and this may be constant or intermittent and is position and activity dependent.

The RC may fail to control superior translation of the humeral head, which may lead to a secondary compression and irritation of the superior fibers of the tendon against the coracoacromial ligament and the undersurface of the acromion.[232] Cook and Purdam[211] defined the next stage in the continuum as *tendon disrepair*, which manifests similarly to reactive tendinopathy. Tendon disrepair may be characterized by substantial areas of swelling and tendon degeneration.

Cook and Purdam[211] have classified the final stage as *degenerated tendon*, and is associated with substantial structural failure in the form of large partial-thickness, full-thickness, and massive RC tears.[233]

Therapeutic Exercise Intervention of Rotator Cuff Disorders

Treatment principles for nonoperative RC disorders are based on the underlying pathomechanics combined with pathogenesis, presenting impairments, and activity limitations. Treatment for secondary RC disorders should consider impairments related to hypermobility and instability problems in addition to impingement. Patient education, pain reduction, appropriate tendon loading, and reinjury prevention form the basis of symptomatic RCT rehabilitation.

The following section will focus on rehabilitation concepts related to tendon loading.

Healthy or Underloaded Tendons To maintain optimal health and function, tendons require appropriate ongoing mechanical stimulation (**Evidence and Research 25-10**). Chronically underloaded tendons in a sedentary population may result in asymptomatic degeneration and tears, which undoubtedly will increase with age.

EVIDENCE and RESEARCH 25-10

Training and Repetitive Strain and Tendinopathy

Habitual loading (as occurs in response to training) will result in a higher rate of collagen synthesis for 24 to 48 hours. This results in tendon hypertrophy.[234] The rate of degradation also increases with training to ensure that the overall turnover is high, but not to the same extent as the increase in synthesis, which allows for a small—but consistent—positive net balance of collagen.[235] Habitual training thus results in a higher turnover of collagen whereas inactivity lowers collagen synthesis and turnover.[236] This result illustrates why activity even in the presence of tendinopathy might be better for the regeneration of the tendon tissue than complete inactivity.

Treatment for an underloaded RC involves gradual, controlled loading of the tendon. To maximize the benefit of tendon-loading activities, the load, duration, and intensity of activity placed on the RCTs must be carefully controlled, structured, and monitored. In addition, the therapist's role is to promote ideal biomechanics by instruction in optimal thoracic, scapular, and humeral movement patterns.

Reactive Tendinopathy Load reduction, together with pain management, is a key component in the management of reactive tendinopathy. Attention to remediating pathomechanics leading to compressive or tensile loading will assist in decreasing irritability of the reactive tendon. Examples include patient education, exercise prescription, and training modifications such as altering sustained postures of scapula downward rotation (tensile loading) with exercise and taping; reducing superior or anterior humeral glide relative to the scapula (compressive loading) with appropriate scapular and RC training; and avoiding more vigorous activities that involve the stretch shortening cycle (compressive and tensile loading).

Pain management requires reeducation of activity with "controlled stress" to maintain pain levels to 1 to 2 out of 10 (worst imaginable pain) on a visual analog scale of pain. Additionally, pain should not be trending worse and pain should not be worse upon waking. Sleep should supply restorative/repair processes reflected in reduced pain levels upon waking.

Isometric exercises can help to reduce pain in reactive tendinopathy. Naugle[237] reviewed the evidence of the role of exercise in reducing pain and found that, "isometric exercise appears to exert a generalized pain inhibitory response." The author found that long duration, low to moderate intensity contractions (25% to 50% maximal voluntary contraction) had optimal analgesic effect. Although there are limitations of utilizing these suggestions on tendinopathy, Cook and Purdam[238] discuss isometric exercises relative to tendon loading; ". . .these loads can be repeated several times a day, utilizing 40 to 60 seconds holds, four to five times, to reduce pain and maintain some muscle capacity and tendon load. In highly irritable tendons, shorter holding time and fewer repetitions per day may be indicated."

This contraction should be done in a position where there is no tendon compression, usually in the mid-range of the muscle (see **Fig. 25-17**).

During this period of relative rest, adjunctive therapies such as modalities, taping (see Adjunctive Interventions: Taping in subsequent section), and manual therapy (see Chapter 7) may be considered to reduce pain and restore shoulder movement and function.

Tendon Dysrepair Ongoing pain management and the other components of management for reactive tendinopathy remain important components for the treatment of tendon dysrepair. Graduated tendon reloading including concentric, isometric, and eccentric exercise is introduced during this stage. Evidence supports opposing effects of GH external and internal rotation on subacromial pressure with external rotation lowering pressure.[239] Given this evidence, consideration should be given to pain levels during movements into flexion, abduction, and/or internal rotation. Additionally, exercises that activate the RC to depress the humeral head may also be warranted (see Fig. 25-4).[240]

Degenerative Tendon Pain control and restoring normal movement are the principal aims of managing the degenerated tendon.[241] Clinical investigations have suggested that even in

A B

FIGURE 25-17 Exercises that involve pressing your arm against a wall can help reduce pain related to the tendons that make up the rotator cuff. With the arm forward flexed 45 degrees and elbow at a 90-degree angle, put the palm of your hand on the side of a wall or doorframe that's in front of you **(A)**. Press your palm against the wall or doorframe for several seconds. For the second exercise, move your hand so that the backside of the hand is facing the wall **(B)**. With your arm flexed to 45 degrees and elbow at a 90-degree angle, press your hand against the wall for 40 to 60 seconds. Repeat each exercise four to five times several times a day.

the presence of substantial structural pathology, range of movement and power may be improved when pain is reduced.[242–244] Subscapularis contributes 30% and infraspinatus contributes 10% of the abduction torque during arm elevation, so even in a full-thickness tear to the supraspinatus, arm elevation can be achieved with improved function in those two cuff muscles (see Self-Management 25-1).[245]

Movement Impairment Because shoulder movement requires normal scapular mechanics,[246–250] the ability to effectively strengthen the serratus anterior and all portions of the trapezius is vital for effective management of RC disorders (see Display 25-12). EMG analysis of the trapezius and serratus anterior muscles have been performed during therapeutic exercises.[167–169,250–253] The EMG data presented in **Display 25-12** may assist physical

DISPLAY 25-12

Activation Exercises for Trapezius and Serratus Anterior Based on EMG Analysis

Exercises for Upper Trapezius

- Shoulder shrug (**Fig. 1**)[168]

Exercises for Middle Trapezius

- Prone arm lift with arm overhead (Self-Management 25-2, Level IV B)[168]
- Prone horizontal extension with lateral rotation (Self-Management 25-2, Level IV A)

Exercises for Lower Trapezius

- Prone arm lift with arm overhead (Self-Management 25-2, Level IV B)[168]
- Prone shoulder lateral rotation at 90-degree abduction (Self-Management 25-1)[168,253]
- Prone horizontal extension with lateral rotation (Self-Management 25-2, Level IV A)[168]

Exercises for Serratus Anterior

- *Note*: In general, exercises that create upward rotation of the scapula were found to produce much more EMG activity in the serratus anterior than straight scapular protraction exercises.[167–169]
- Shoulder abduction in the plane of the scapula above 120 degrees.[168,169]
- Diagonal exercise with a combination of flexion, horizontal flexion, and external rotation.[168]

Exercises for Simultaneous Activation of the Trapezius and Serratus Anterior

- Prone arm lift with arm overhead (Self-Management 25-2, Level IV B)[168]
- Shoulder abduction in the plane of the scapula[168]

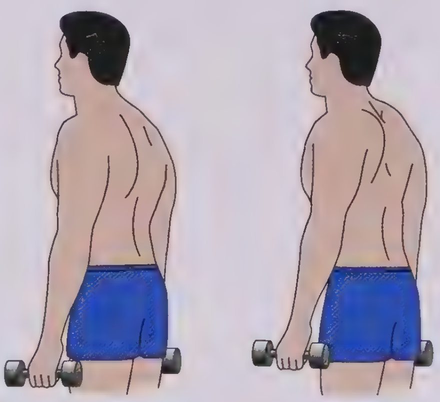


FIGURE 1 Shoulder shrug.

therapists in developing exercise programs that will optimally activate the trapezius and serratus anterior muscles. Because the results of the studies presented were obtained by studying subjects without pathology of the shoulder girdle rather than patients with RC disorders, caution is warranted in extrapolating these findings to a patient population. Exercises may need to be modified to accommodate a painful shoulder. **Display 25-13** summarizes additional exercises for activation of the scapular rotators that are illustrated in this chapter. A clinical example of RC disorder is provided in Display 25-4 with general treatment guidelines presented in **Displays 25-14** and **25-15**, and more specific exercise recommendations in **Display 25-16**.

Treatment Principles for Postoperative Rotator Cuff Disorders

Tears of the RC can be managed with nonsteroidal anti-inflammatory drugs, intra-articular or subacromial glucocorticosteroid injection, oral glucocorticosteroid treatment, physical therapy, and open or arthroscopic surgery. To date, there is little evidence to support or refute the efficacy of common interventions for tears of RC in adults.[254] Rowe[255] stated, "the majority of RC lesions should respond satisfactorily to conservative measures," noting a few exceptions. According to Mantone et al.,[256] there are instances in which early surgical management would be indicated. The first is the 20- to 30-year-old active patient with an acute tear and severe functional deficit from a specific event. The second is the 30- to 50-year-old patient with an acute RC tear secondary to a specific event. These patients are best treated with early operative intervention. The third instance is the highly competitive athlete, particularly one who is involved in overhead or throwing sports. These patients need to be treated operatively because RC repair is necessary for restoration of the normal strength required to return these athletes to the same competitive preoperative level of function.

Patients who fail conservative management may require some sort of surgical intervention. Surgical intervention occurs along a continuum, ranging from arthroscopic debridement to an open RC repair. A decision to attempt a surgical repair of the tear should be informed on an assessment of the (1) individual patient's functional requirements, (2) size of the tear, and (3) the amount of fatty infiltration into the muscle;

DISPLAY 25-13

Additional Exercises Designed for Isolation of Scapular Rotator Muscles

Exercises for Upper Trapezius

- Upper trapezius strengthening (Building Block 25-2)

Exercises for Middle and Lower Trapezius Activation

- Facelying arm lifts (Self-Management 25-2)
- Wall slides (Fig. 25-4)
- Back-to-wall arm slides in abduction (**Fig. 1**)
- Isometric scapula upward rotation (**Fig. 2**)

Exercises for Serratus Anterior

- Serratus anterior progression (Self-Management 25-3)
- Progressive serratus strengthening exercises (Figs. 25-9, 25-10, 25-11)

FIGURE 1 Back to wall, arm slides in abduction. With the back to the wall, the elbows and humerus should be in the scapular plane. Thumbs can touch the wall to ensure that the humerus remains in the scapular plane. The patient slides the arms up the wall, and stops when the scapula deviates into excessive elevation. The goal is to achieve full scapular plane elevation with the ideal arthrokinematics at the GH joint and ST articulation.

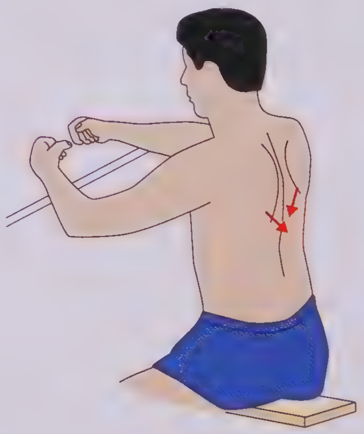

FIGURE 2 Alternative isometric scapular upward rotation. The arms can be positioned in as much elevation as is available. The cue should be to "gently squeeze your shoulder blades together." Caution should be taken to prevent excessive rhomboid or latissimus dorsi contribution.

DISPLAY 25-14

Phases of Rehabilitation for Rotator Cuff Disorders

Phase 1

Decrease Pain	Mid-range isometrics, reduce compressive and tensile loads, avoid SSC

Phase 2

Increase Strength	Heavy slow resistance in non-compressive positions

Phase 3

Increase Functional Stregnth	Progress into functional tasks with focus on optimal movement patterns

Phase 4

Increase Power	Reduce repetitions and increase speed

Phase 5

Develop Stretch Shortening Cycle	Add plyometrics

Phase 6

Sport Specific	Add sport specific drills in OKC or CKC as appropriate

Normal tendon overload is pain-free and is a normal response to loading rotator cuff tissue through activity and exercise.

DISPLAY 25-15

Adjunctive Interventions for Reactive Phase of Rotator Cuff Disorders

Phase 1
Reactive Phase – 1-Degree Goal is pain reduction

Analgesic [illegible] (CS) injection (primarily for pain control, CS may decrease cell proliferation and protein production)	Reduce Swelling [illegible]	[illegible]

DISPLAY 25-16

Specific Therapeutic Exercise Intervention for Rotator Cuff Disorder

Muscle Length

- Passive manual stretch to rhomboids (see Fig. 25-3)
- Self-stretch to GH lateral rotators (see Self-Management 25-4)

Muscle Performance

- Strengthen middle and lower trapezius in the short range (see Self-Management 25-2)
- Strengthen serratus anterior in the short range (see Self-Management 25-3)
- Strengthen RC (see Self-Management 25-1)

Posture and Movement

- Ergonomic modifications at workstations
- Transitional exercises to improve kinematics of GH and ST joints in elevation (see Fig. 25-4)
- Surface EMG training during simple elevation movements to restore temporal relationships in scapular rotators
- Functional retraining for ADLs with focus on motor control and integrated scapula and deltoid–RC function
- Functional retraining for instrumental ADLs (sports and recreation) with focus on motor control and integrated scapula– and deltoid–RC function
- Alter sport-specific training as needed to promote optimal motor control and biomechanics

the presence of fatty streaks has been associated with negative surgical outcomes.[257,258]

Based upon the review of 14 trials in a Cochrane Database of Systematic Reviews for surgical repair for RC tears, no firm conclusions about the effectiveness or safety of surgery for RC disease could be made.[259] There is "Silver" level evidence from six trials that there are no significant differences in outcome between arthroscopic and open subacromial decompression, although four trials reported earlier recovery with arthroscopic decompression.[259]

If surgery is performed, the postoperative exercise regimen after anterior acromioplasty and repair of the RC is determined by the strength of the RC. Methodical planning and cooperation by the patient, surgeon, and physical therapist are necessary to plan a program with a successful outcome. The patient will have greater confidence if clear objectives are developed. Preoperatively, the surgeon and physical therapist should explain to the patient that it will take up to 12 months for mature healing of the tendons. However, during this time, activities will be progressively advanced, and strict adherence to the physical therapist's instructions will ensure the most successful outcome. The physical therapist must understand the specific anatomic considerations and limitations to plan a safe and effective postoperative rehabilitation program. Only the surgeon knows the strength and stability of the repair and therefore should work closely with the physical therapist in developing the aftercare program of each patient.

The algorithm shown in **Display 25-17** provides guidance for rehabilitation after a standard RC repair.[103] Because of the unique anatomic arrangement and function of the RC,

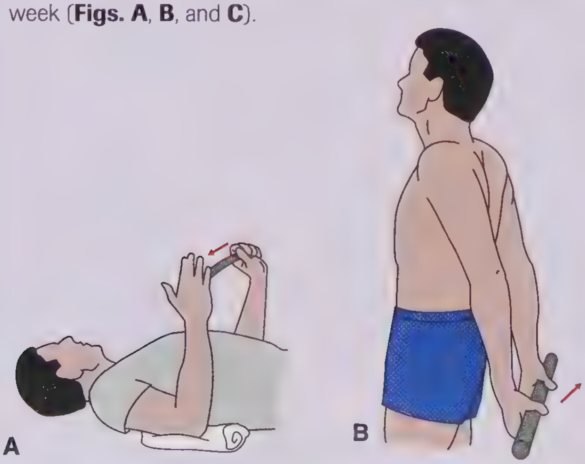
DISPLAY 25-17

Rehabilitation After Rotator Cuff Repair

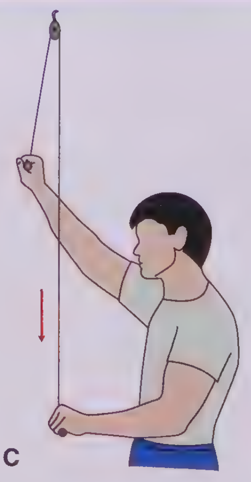
This protocol is a guideline only; actual progression will be based on clinical presentation.

Protective Phase (1 to 4 weeks)

- Sling protection is used for 2 to 3 days and up to 6 weeks at night.
- Pendulum exercises (see Fig. 25-8) are initiated within the first 48 hours and should be performed three times a day.
- Self-assisted ROM exercises are initiated at the end of the first week (**Figs. A**, **B**, and **C**).



A B

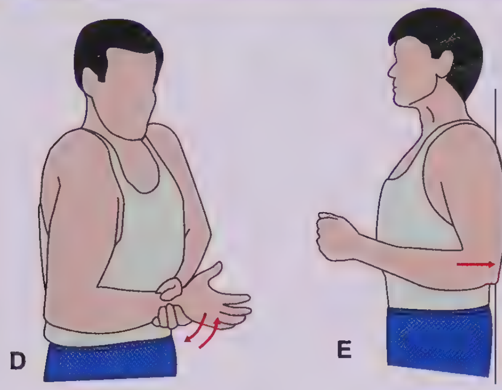


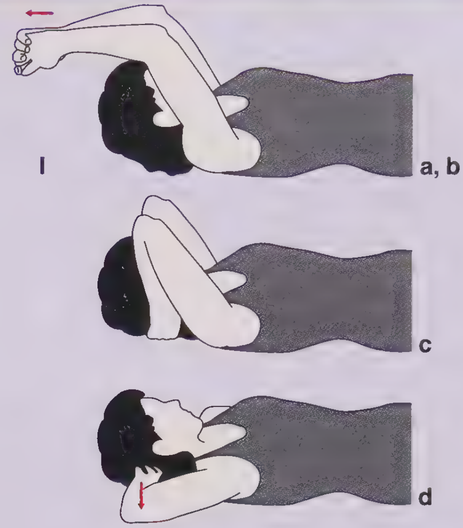
C

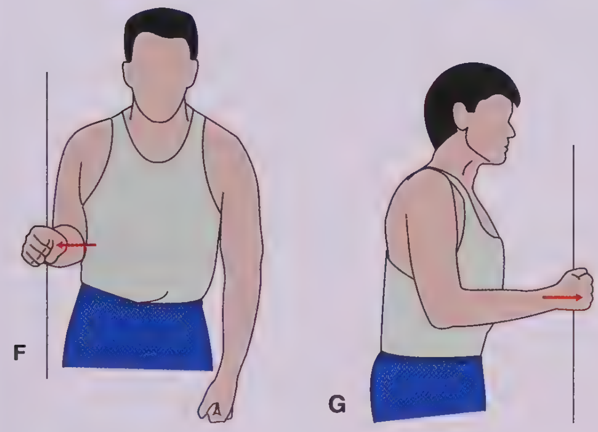
- Most surgeons DO NOT want the surgical arm elevated above 70 degrees in any plane for the first 4 weeks postoperatively.
- Gentle isometric exercise may be introduced as early as 1 week postoperatively, but is highly dependent on the extent of the surgery (**Figs. D–G**).

DISPLAY 25-17

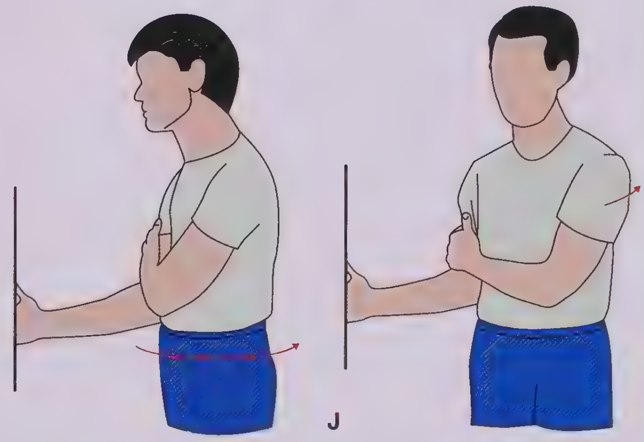
Rehabilitation After Rotator Cuff Repair (*continued*)





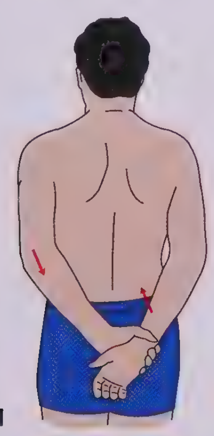


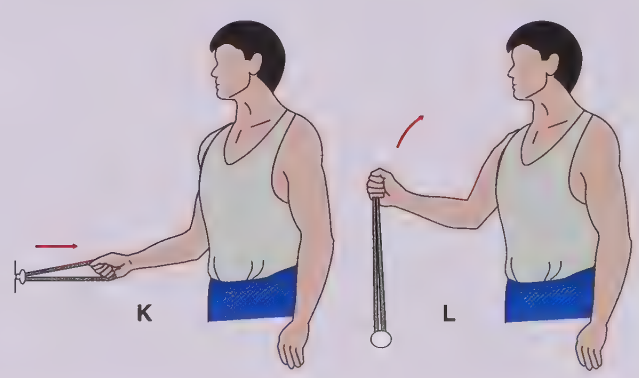
- Consult the surgeon for timing on introducing isometrics.
- Scapular pinches every hour with good upright posture.
- Maintain good upright shoulder girdle posture at all times—especially during sling use.



Early Intermediate Phase (4 to 8 weeks)

- Additional self-assisted ROM exercises are prescribed 6 weeks after surgery (**Figs. H, I, J**).
- If motion is restricted at this time, gentle passive stretching by the physical therapist is indicated.
- Mobilization of GH, SC, AC joints as needed to restore joint mobility (this may be started earlier if needed).
- ROM goals should be up to 90 degrees of flexion and abduction without excessive clavicular elevation.
- Isometric exercise is progressed to active ROM as patient symptoms permit (**Figs. K** and **L**).





(*continued*)

DISPLAY 25-17

Rehabilitation After Rotator Cuff Repair (*continued*)

Late Intermediate Phase (8 to 12 weeks)

- ROM goals should be full ROM in all planes, flexion, abduction, external rotation, internal rotation.
- Continued mobilization of GH, SC, AC joints as needed to fully restore joint mobility.
- Light resistance with resistive tubing is added to dynamic exercise for flexion, extension, ER, and IR.
- More aggressive exercise for serratus anterior and trapezius (Display 25-13) is introduced.

Advanced Rehabilitation Phase (12 weeks and beyond)

- A more aggressive RC strengthening program is introduced (Self-Management 25-1).
- Add weights to all exercises as tolerated.
- Continue to seek full ROM in all planes with attention to motor control and scapulohumeral rhythm.
- Swimming is allowed at 5 months after surgery.
- Submaximal sport-specific training is progressed to maximal training by the end of 1 year after surgery.

General Precautions and Contraindications

- Flexion should precede abduction when restoring active motion.
- The patient should avoid leaning on the arm or carrying more than 5 lb of weight in the early and intermediate phases of rehabilitation.
- Patients with complete tears of the supraspinatus should avoid lifting more than 15 lb in the first year postoperatively.
- Skiing, skating, roller-blading, and other such activities are forbidden in the first year after surgery to avoid reinjury from a fall.

(A) Assisted lateral rotation in supine. A towel is placed under the elbow to keep the humerus in neutral and prevent excessive anterior displacement. The patient pushes the involved arm into lateral rotation, using the uninvolved arm to supply the power. **(B)** Assisted extension. The patient pushes backward into extension, using the uninvolved arm to supply the power. Caution should be used to prevent excessive GH extension and anterior displacement of the GH joint. **(C)** Pulley-assisted elevation in both flexion and scaption planes. The uninvolved arm supplies the power to raise the involved arm. Caution should be used to prevent excessive scapular elevation as compensation for lack of GH mobility. The motion should be stopped as soon as a deviation in the path of instant center of rotation (PICR) of the GH joint or ST articulation is noted. This exercise can be progressed to active assisted elevation when directed by the physician. **(D)** Assisted medial rotation. The patient is instructed to medially rotate the arm by pushing the arm backward, followed by pulling the hand upward toward the scapula. Caution should be used to prevent excessive scapular anterior tilt and GH anterior displacement. **(E)** Assisted abduction. The patient is instructed to (a) lie on the back, (b) lock the fingers together and stretch the arms overhead (the uninvolved arm powers the involved arm), (c) bring the hands behind the neck, and (d) flatten the elbows (reverse by sliding the hands overhead and down). Caution should be taken while abducting to ensure the scapulae are in a neutral position and the clavicle retracts as the arm abducts. **(F)** Assisted lateral rotation in a doorway. The patient is instructed to stand in a doorway facing the doorframe. The elbow is flexed to 90 degrees. The palm is on the wall. The elbow is held in adduction. The body turns gradually until the patient faces into the room. Caution should be taken to ensure proper scapular alignment during the lateral rotation process. **(G)** Isometric medial and lateral rotation. **(H)** Isometric extension. **(I)** Isometric abduction. **(J)** Isometric flexion. **(K)** Resistive exercise for shoulder extensors. Caution should be taken to prevent thoracic flexion or scapular anterior tilt. The range should be limited to extension to the midaxillary line to prevent contractions of the rhomboid in the short range. **(L)** Resistive exercise for shoulder flexion. The motion is upward into flexion as if throwing an "upper cut" punch. Caution should be taken to monitor the ST kinematics.

rehabilitation after surgery is considered to be more difficult than that of any other joint. In most patients, the muscles involved in the precisely integrated force couples used in upper extremity movements have suffered from months of atrophy and disuse. Early in the rehabilitation process, careful exercises may be prescribed to prevent significant atrophy of key scapular muscles that perform upward rotation, posterior tilt, and/or external rotation functions (Fig. 2 in Display 25-13). Toward the latter stages of rehabilitation, precise integration and coordination of motor control must be restored to all the muscles involved in the functional movements used by the individual. Postoperative care after repair for a massive RC tear is far more conservative, requiring longer periods of immobilization and slower return to function.

Often repair of a torn RC effectively improves comfort, active motion, and strength in most patients. According to Romeo et al.,[260] female patients 66 years of age and older are more likely to have an unsatisfactory result. In addition, an associated biceps tear in female patients is a poor prognostic factor.[260] Overall, better results are seen in patients with less than 5 cm^2 tear, in patients with an intact biceps tendon,[260] with minimal fatty degeneration in each cuff muscle (particularly the infraspinatus and subscapularis), and with a low index of global fatty degeneration.[257,258]

Glenohumeral Hypermobility/Instability

It is not within the scope of this text to discuss diagnoses and treatments of the entire spectrum of GH joint hypermobility/instability; therefore, this section focuses on anterior GH hypermobility leading to GH subluxation. Hypermobility and subluxation are difficult to diagnose and terminology can best be understood if joint stability is considered in terms of a continuum of stability (**Fig. 25-18**).[259] Jobe et al.[104] first described the etiology of secondary RC disease, or hypermobility, as a continuum (see **Display 25-18**).

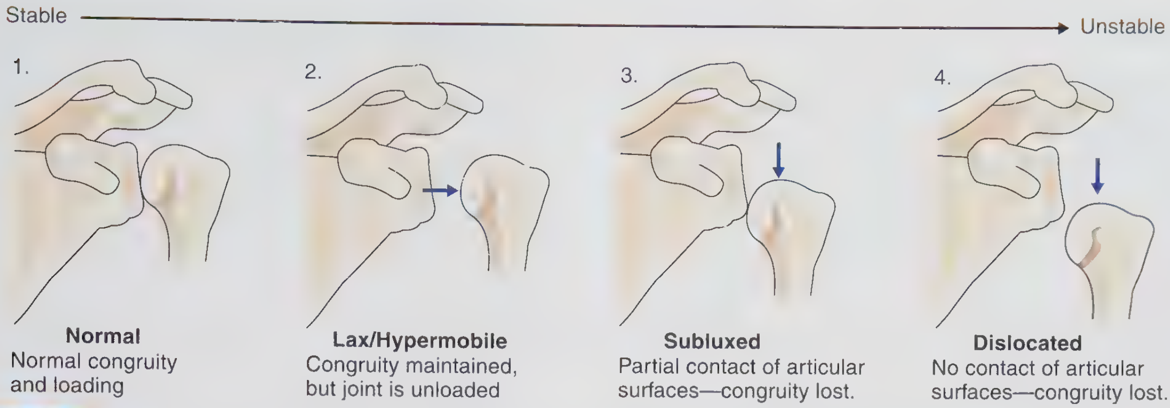


FIGURE 25-18 Continuum of shoulder stability. (Adapted from Strauss MB, Wrobel LJ, Neff RS, Cady GW. The shrugged-off shoulder: a comparison of patients with recurrent shoulder subluxations and dislocations. Physician Sports Med 1983;11:96.)

DISPLAY 25-18

Jobe's Instability Continuum[104]

- RTC weakness
- [illegible]
- [illegible]
- subluxation (inability of the humeral head to center in the glenoid during motion)
- RTC/labral tearing (late stage)

In the absence of trauma, the etiology of GH hypermobility is a circular cause and consequence scenario. Whether the cause or consequence, one should consider that habitual impairments in posture and repetitive movement patterns can result in microtrauma to static and dynamic stabilizers and dysfunction in the relationship between the GH, AC, and SC joints. Attenuation of the static and dynamic stabilizers contributes to mild hypermobility, increasing the demand on the stabilizing function of the RC. This may lead to a vicious cycle of excessive translation of the humeral head, mechanical impingement, and attenuation of the subacromial structures.[193,194,202,261] Left unchecked, mild hypermobility can progress to subluxation and dislocation.

Glenohumeral stability is achieved through a number of different mechanisms, involving the articular geometry, the static capsuloligamentous complex (CLC), the dynamic (muscular) stabilizers, and neuromuscular control.[210] The specific contributions of the shoulder musculature to joint stability are listed in **Display 25-19**.[246,266–270]

DISPLAY 25-19

Contributions of the Shoulder Musculature to Joint Stability

- Passive muscle tension from the bulk effect of the RC muscle
- Rotator cuff contraction causing compression of the articular surfaces
- Joint motion that secondarily tightens the passive ligamentous constraints
- Barrier or restrain effect of the contracted RC muscle
- Redirection of the joint force to the center of the glenoid surface by coordination of muscle forces from both GH and ST joints
- ST muscle balance
  - Efficient compressive forces on the RC are partially dependent upon the stability of their origins on the scapula[262]
  - Scapular position affects length–tension properties of the RC
  - Scapula upward rotation, posterior tilt, and lateral rotation is necessary to maximize subacromial space[263–265]

Diagnosis of Hypermobility/Instability

Early diagnosis and treatment of GH hypermobility can prevent serious pathology resulting from dislocation or impingement. However, mild GH hypermobility is difficult to diagnose, because the "microinstability" of the humeral head occurs during active movement without the signs or symptoms associated with subluxation or instability (i.e., positive apprehension or relocation signs). Excessive passive joint mobility in specific directions combined with displaced kinematics of the GH joint during active arm elevation or GH rotation confirm the diagnosis of hypermobility. The most common abnormal GH motions are excessive superior translation during arm elevation, excessive anterior translation during lateral rotation and arm horizontal abduction,[271] and abnormal anterior translation during medial rotation. Excessive translation can be confirmed by palpating the humeral head during active motions and comparing the motion to that on the unaffected side.

The diagnosis of unidirectional instability or multidirectional instability is based on complaints of pain and activity limitation combined with positive apprehension, relocation, and/or sulcus signs.[272,273]

Treatment for Glenohumeral Hypermobility/Instability

Treatment of hypermobility involves addressing the hypomobile adjacent segments simultaneously. For example, a common examination finding for the anterior hypermobile or subluxating shoulder is posterior capsular stiffness (indicated by restricted GH medial rotation and restricted posterior glide of the humerus) and possibly a coexisting anteriorly displaced humerus at rest. The stiffness of the posterior capsule can restrict posterior translation of the humeral head, occurring primarily during the osteokinematic motions of medial rotation and flexion. The posterior capsular stiffness can also contribute to an anteriorly displaced rest position of the humeral head. In this position, it is more vulnerable to moving into an excessive anterior translation during lateral rotation and abduction. Specific joint mobilization of the posterior capsule combined with passive self-stretching of the GH lateral rotators is the best treatment for hypomobility (see Self-Management 25-4).

As passive mobility is restored, the restoration of precise active mobility must closely follow. The GH joint needs to be trained to move in a precise kinematic pattern without abnormal or excessive anterior translations. This often must occur in conjunction with restoring the normal kinematics of the ST articulation (explained later in this section). The subluxating shoulder may require a period of immobilization to decrease pain. Abduction and lateral rotation positions must be avoided to prevent stretching of the anterior capsule. Pain-free isometric exercises for the scapulohumeral and axioscapular muscles should begin as soon as tolerated to avoid the disuse or deconditioning effects of prolonged immobilization.

Active ROM exercises can be initiated against gravity as the patient regains strength and motor control. Abnormal movement patterns, such as excessive scapular elevation, should be discouraged.

Gradually, resistive exercises can be initiated targeting the pectoralis major, latissimus dorsi, teres major, and subscapularis to provide dynamic restraint to anterior translation into the anterior capsule. However, the main target muscle should be the subscapularis because of its insertion anterior to the GH joint and its proximity to the axis of rotation of the GH joint. Careful observation of the humeral head PICR during medial rotation is a good indicator of the participation of the subscapularis in the medial rotation force couple. Anterior translation of the humerus during medial rotation indicates a lack of subscapularis participation. In addition, proper scapular stabilization by the serratus anterior and lower trapezius will prevent excessive anterior tilt of the scapula. Exercises should be prescribed to isolate subscapularis function as much as possible (see Self-Management 25-6).

Infraspinatus and teres minor strengthening can also be targeted to prevent excessive anterior translation of the head of the humerus.[274] For the infraspinatus and teres minor to provide a stabilizing force on the GH joint, stability of the ST articulation is a prerequisite. If the scapula is not stabilized by the axioscapular muscles, when the infraspinatus and teres minor contract, instead of providing a posterior force to the GH joint, contraction of the infraspinatus and teres minor can contribute to further anterior displacement. This occurs by reverse action on the scapula; instead of compressing the GH joint into the glenoid fossa, the resultant force pulls the scapula toward the humerus and forces the head of the humerus anteriorly. During any lateral rotation exercise, care must be taken to ensure scapular stability exists by encouraging serratus anterior, middle, lower trapezius, and rhomboid activity. This will result in lateral rotation of the humerus without excessive scapular movement.

Isokinetic or plyometric upper extremity exercises (see Fig. 25-15) can be incorporated into the resistive training program of individuals returning to a high level of function. Again, it is recommended that the clinician closely monitor proper stabilization of the scapula during resisted movements at the GH joint. Initial movements should be slow and controlled, with a gradual increase in speed of movement.

If the kinematics are closely monitored, movements into full lateral rotation and abduction should not be contraindicated. If excessive anterior translation occurs because of lack of force-generating capability from the axioscapular or RC muscles and poor motor control, extremes of ROM should be avoided. More neuromuscular reeducation of the movement in a slow, controlled manner is indicated.

Sport-specific exercises can be gradually incorporated into the treatment program to prepare the patient for transition to functional activity (**Fig. 25-19**). Muscle fatigue and close attention to the kinematics of the GH joint is the guide to progression. Control over the translatory motions of the GH joint should be emphasized over general strength gains.

The literature supports the notion that motor control is critical in restoring function to the unstable shoulder.[275–278] Research indicates that peak torque gains occur in persons trained with EMG biofeedback in purely functional patterns with no emphasis on "strength exercising." Functional gains and abolition of pain were greater and occurred earlier in the group trained functionally with EMG biofeedback than the group trained in more traditional strength regimens.[275]

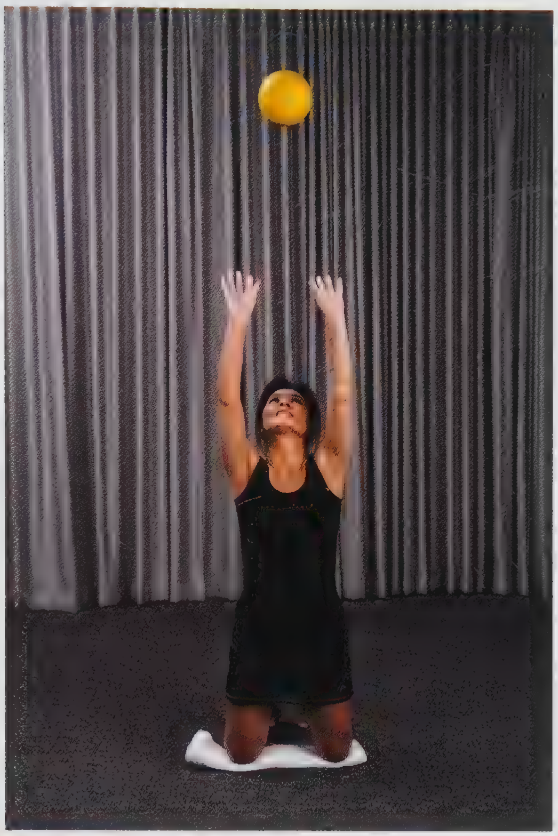

FIGURE 25-19 Sport-specific exercise for a person with glenohumeral hypermobility: ball tossing upward to simulate a set in volleyball.

Frozen Shoulder

Frozen shoulder is defined as slow onset pain near the insertion of the deltoid muscle with loss of internal rotation initially followed by more than 50% loss of external rotation and abduction of less than 90 degrees.[279] The pathophysiology of frozen shoulder is capsular fibrosis and inflammation with chondrogenesis.[280] Although inflammation may be present at the onset of the condition, signs and symptoms last long after the inflammatory process has subsided. As such, the term "adhesive capsulitis" has come into question, with the preferred term describing this condition being "frozen shoulder."[280] Factors associated with frozen shoulder include female gender,[281] older than 40 years,[281] trauma,[282] diabetes,[283] prolonged immobilization,[284] thyroid disease,[285] stroke or myocardial infarction,[286,287] RC disease,[288] cervical radiculopathy,[288] suprascapular nerve entrapment,[288] and the presence of autoimmune diseases.[289] The prevalence of frozen shoulder in the general population is slightly >2%,[290] increasing to 10% to 38% in patients with diabetes and thyroid disease.[291,292] Seventy percent of patients with frozen shoulder are women, and 20% to 30% of those affected subsequently develop a frozen shoulder in the opposite shoulder.[293]

Numerous authors have described classification systems to further define frozen shoulder.[170,171] Most recently, Itoi et al[280] recommend utilizing two categories (see **Table 25-3**):

- The primary idiopathic stiff shoulder develops without any trauma. It results in limited motion and use of the arm.[280] Inflammation and pain can cause reflex inhibition of the shoulder muscles, similar to inhibition of the quadriceps after injury to the knee. There is disagreement in the literature as to whether the underlying pathologic process is an inflammatory condition[294–296] or a fibrosing condition.[297] It appears that synovial inflammation may start the cascade of excessive collagen formation, resulting in a stiff, fibrotic shoulder.[289,296,298,299]
- Secondary stiff shoulder describes stiffness and loss of motion that is due to a known cause, such as after a surgery, trauma, or immobilization.[280]

Diagnosis

Frozen shoulder has been staged based upon arthroscopic findings as described in **Table 25-4**.[300,301] These stages represent a continuum of the disease rather than discrete, well-defined stages. The course associated with frozen shoulder typically lasts from 1 to 3 years.[284,302] There is a relationship of the length of each stage to the length of the remaining stages in that the shorter the initial inflammatory component, the shorter the second and third stages and overall course of the condition. Thus, early intervention can reduce the overall duration of the condition. The role of the physical therapist is to hasten the progression through the stages and limit the severity of the earlier stages so that the patient can move to the final stages as quickly as possible with the least amount of impairment, activity limitation, and participation restrictions.

TABLE 25-3

Classification of Frozen Shoulder

CLASSIFICATION	CAUSE	EXAMPLES
Frozen shoulder (primary stiff shoulder)	Unknown Predisposing conditions	Diabetes mellitus, Dupuytren contracture, thyroid disorders, myocardial infarction, Parkinson disease
Secondary stiff shoulder	Intra-articular	Chondral lesion, labral tear, loose bodies
	Capsular	After capsular injury, surgery, joint immobilization
	Extra-articular	Muscle tightness, heterotopic ossification, skin scarring of burns
	Neurologic	Injuries to the cervical spine or brachial plexus

Itoi E, Arce G, Bain GI, et al. Shoulder stiffness: current concepts and concerns. Arthroscopy 2016;32(7):1402–1414. doi:10.1016/j.arthro.2016.03.024.

TABLE 25-4

Frozen Shoulder Stages Based on Arthroscopic Findings

STAGE	FINDINGS
Stage 1: pre-freezing stage	■ Duration of symptoms is 0–3 months ■ Pain with active and passive ROM ■ Examination under anesthesia: normal or minimal loss of ROM ■ Arthroscopy: diffuse GH synovitis, most pronounced in anterosuperior capsule ■ Pathologic changes: hypertrophic, hypervascular synovitis, rare inflammatory cell infiltrates, normal underlying capsule
Stage 2: freezing stage	■ Duration of symptoms: 3–9 months ■ Patient presents with continued pain ■ Severe loss of ROM in all planes ■ Examination under anesthesia: ROM same as without anesthesia ■ Arthroscopy: dense, proliferative, hypervascular synovitis ■ Pathologic changes: hypertrophic, hypervascular synovitis with perivascular and subsynovial scar, fibroplasias and scar formation in the underlying capsule ■ Duration of symptoms 5–9 months
Stage 3: frozen stage	■ Continued severe loss of ROM with minimal pain ■ Examination under anesthesia: same as Stage 2 ■ Arthroscopy: No hypervascularity seen, remnants of fibrotic synovium can be seen. The capsule feels thick in insertion of the arthroscope and there is diminished capsule volume ■ Pathologic changes: "burned out" synovitis without significant hypertrophy or hypervascularity. Underlying capsule shows dense scar formation ■ Duration of symptoms: 15–24 months
Stage 4: thawing stage	■ Minimal pain ■ Progressive improvement in ROM

ROM, range of motion; GH, glenohumeral joint.

Treatment

Neviaser and Neviaser[300,301] stress the importance of an individualized treatment plan based upon the underlying etiology and stage of the disease. Patient-related instruction is a critical component in educating the patient as to the underlying etiologic factors contributing to the condition, the stage and progression of the condition, and the necessary commitment to self-management for the best outcome. The use of therapeutic exercise has been shown to be a common and effective component of intervention used for frozen shoulder.[286,303–307] The determination of the type and intensity of exercise depends on the patient's specific strength, ROM, joint mobility, motor control needs, and level of irritability. Kelley et al.[308] propose an irritability classification to assist the practitioner in clinical decisions regarding intervention.

Nonoperative Interventions The best approach to frozen shoulder is prevention. Although this syndrome is considered a self-limited process, complete recovery with no residual limitation and disability is neither ensured nor common. Fibrosis, secondary arthritis, myofascial contracture, disuse atrophy, and altered motor control patterns may be permanent. Only active use of the arm and full maintenance of GH and ST active mobility with precise shoulder kinematics at all three shoulder girdle articulations can reverse these changes.

Table 25-5 outlines basic interventions for each stage of frozen shoulder.

Stage 1 Patient-related instruction about the underlying causes of presenting signs and symptoms and the natural history of frozen shoulder is important to allay the patient's fears of more serious disease. Discussing how the painful stage progresses to painless motion restriction prepares the patient for an extended recovery. Instruction in the importance of adherence to a self-management program is vital to positive long-term outcomes.

Patients who present with painful limitation of motion are recommended oral nonsteroidal anti-inflammatory medications that are supplemented with other analgesics as necessary.[309–311] An intra-articular injection of steroid and local analgesic can be extremely useful both in the diagnosis and treatment of frozen shoulder.[312–316] In the presence of cervical discogenic pain as the genesis of the painful limitation of motion, a systematic review shows Level II evidence for the efficacy of cervical interlaminar epidural injections with local anesthetic with or without steroids vs. injection into the shoulder.[317]

After injection, passive GH ROM is reevaluated. If the patient has significant decrease in pain and increased ROM, the diagnosis of Stage 1 is confirmed. If, however, pain is improved, but ROM has not changed significantly, the diagnosis of Stage 2 is confirmed.

Patients should also be started on a supervised therapeutic exercise program to restore function by decreasing the pain and inflammatory response, increasing ROM, improving muscle performance, and reestablishing normal shoulder mechanics. The primary goal of treatment of patients with Stage 1 frozen shoulder is to interrupt the cycle of pain and inflammation.

Though little data exist to support the use of therapeutic modalities, modalities are suggested to influence pain (high-voltage galvanic stimulation, transcutaneous electrical stimulation,[311] iontophoresis, cryotherapy), reduce inflammation (iontophoresis, phonophoresis, cryotherapy), and to promote relaxation (moist heat, ultrasound).[318] Hydrotherapy can also be effectively used to break the cycle of pain (see Chapter 16).[319]

Applying the correct tensile stress to the tissues is based upon the patient's level of irritability (see **Table 25-6**). In patients with high irritability, such as the case in Stage 1, low intensity and short duration joint mobilizations are performed to alter the joint receptors' input, reduce pain, decrease muscle guarding, and increase motion.[320] Grade I and II joint mobilizations and physiologic movements (active assisted ROM) within a pain-free ROM can be used in this stage (see Chapter 7).[321]

Closed chain exercises can be performed to promote the RC function of GH stabilization (i.e., wall slides),[322] and improve

TABLE 25-5

Physical Therapy Intervention During Stages 1 to 4 of Frozen Shoulder

STAGE/GOAL	PATIENT EDUCATON	MODALITIES	STRENGTHENING	STRETCHING AND ROM	JOINT MOBILIZATION
Stage 1					
Goal: interrupt pain and inflammation; promote relaxation	Educate (pathogenesis, posture, activity modification)	As needed to control pain, inflammation, and promote relaxation	Early closed chain exercises (i.e., wall slides)	AAROM in pain-free ROM, aquatic exercise, gentle PROM, pendulum exercise	Grade I and II mobilizations
Stage 2					
Goal: minimize pain, inflammation, capsular adhesions, and restriction of ROM	Posture, necessity for HEP	As needed to decrease pain and inflammation and improve tissue extensibility	More advanced scapular training, specific RC strengthening	AROM, PROM	Grade II and III mobilizations
Stages 3 and 4					
Goal: Increase ROM	Posture, necessity for HEP	To promote relaxation, tissue extensibility, and reduce treatment discomfort	More specific scapular training to reestablish force couples, continued RC strengthening	More specific AROM to reestablish scapular and GH mechanics; more aggressive stretching (PNF, STM, low-load, prolonged stretch)	Grades III and IV

AAROM, active assisted range of motion; AROM, active range of motion; PROM, passive range of motion; HEP, home exercise program; PNF, proprioceptive neuromuscular facilitation; RC, rotator cuff; STM, soft-tissue mobilization.

TABLE 25-6

Irritability Classification

HIGH IRRITABILITY	MODERATE IRRITABILITY	LOW IRRITABILITY
High pain (≥7/10)	Moderate pain (4–6/10)	Low pain (≤3/10)
Consistent night or resting pain	Intermittent night or resting pain	No resting or night pain
Pain prior to end ROM	Pain at end ROM	Minimal pain at end ROM with overpressure
AROM less than PROM secondary to pain	AROM similar to PROM	AROM same as PROM

ROM, range of motion; AROM, active range of motion; PROM, passive active range of motion.
Modified from Kelley MJ, McClure PW, Leggin BG. Frozen shoulder: evidence and a proposed model guiding rehabilitation. J Orthop Sports Phys Ther 2009;39:135–148.

extensibility of the affected muscles, capsule, and ligaments. Stretching should be done in the pain-free range and may be held from 1 to 5 seconds, two to three times a day. Scapular stabilization exercises can be modified to allow the patient to activate the scapular muscles in pain-free positions (see Display 25-14, Fig. 2, and Self-Management 25-3, Level 1, can be modified with more pillows to allow the patient to work in a less extreme range of upper extremity elevation). This type of exercise should be initiated as early as possible to promote GH stability and optimal ST force couple recruitment. Scapula taping (see "Adjunctive Interventions: Taping") can be used to help promote scapular stability and GH mobility. The home exercise program should include passive ROM exercises in *pain-free* ROM and pendulum exercises to promote capsular stretch (Fig. 25-8).

Postural training is incorporated to discourage forward head and thoracic kyphosis, which places the scapula in anterior tilt, internal rotation, and clavicular protraction.

Stage 2 The continuum of symptoms presenting in this stage may include pain in the paracervical and periscapular region as a result of compensatory scapular elevation. In this stage, the individual may learn to use ST, elbow, or trunk motions to substitute for lost GH motions.[149] "Hiking" of the shoulder girdle is evident during elevation of the arm as a result of capsular stiffness and RC weakness disallowing normal GH mechanics.[149] Anterior and superior translation of the humeral head may result from a decrease in capsular volume.[323] The limitation of ROM is in a capsular pattern with lateral rotation the most limited, followed by abduction and medial rotation.[324]

The goal of the second phase of rehabilitation is to continue to decrease inflammation and pain, and to minimize capsular restriction and secondary weakness of the RC and scapular upward rotator force couple. Passive joint mobilizations are used to stretch the CLC to allow normal GH mechanics. Contracture of the rotator cuff interval (RCI) has been shown in patients with frozen shoulder.[325–327] The RCI forms the triangular-shaped tissue between the anterior supraspinatus tendon edge and the upper subscapularis border, and includes the superior GH ligament and the coracohumeral ligament. Stretching, soft tissue and joint mobilization should target the RCI and the CLC. It has been proposed that an inferior glide with the arm at the side, while in external rotation, stretches the RCI.[308]

Johnson et al.[328] found significant improvement in external rotation ROM in patients with frozen shoulder after performing posterior glide mobilizations for 1 minute at end range of abduction and external rotation. High-grade mobilizations (Grade III and IV) are used to promote elongation of shortened fibrotic soft tissues. High-grade mobilizations should be performed with the joint positioned at or near its physiologic end range. It should be noted that immediate gains with mobilization represent transient tissue preconditioning and must be followed up with a self-management program.[329,330] Stretching passively or with hold-relax techniques to the posterior capsule can be addressed with a home exercise as shown in Self-Management 25-4.

Once passive motion is improved, it must be followed up with active exercises to maintain the ROM. If strength is fair or above, active exercises against gravity can be introduced in the sagittal and frontal planes as well as the plane of the scapula. The therapist must pay careful attention to ensure restoring motor control patterns to promote 3D scapular kinematics (versus elevation or excessive upward rotation) and control over GH superior glide.[149] Careful isolated strengthening of the RC, serratus anterior, middle, and lower trapezius is indicated (see Self-Managements 25-1, 25-2, and 25-3).

Taping the ST articulation can significantly help to limit scapular substitution patterns and force greater mobility at the GH joint during functional activity (see "Adjunctive Interventions: Taping" section).[331] Taping the ST articulation may transfer improvements made in mobility and force or torque production with specific exercise to ADLs and instrumental ADLs, including specific movement patterns necessary for sport.

Stages 3 and 4 In these stages, pain may resolve spontaneously.[332] Physical examination will reveal a stiff shoulder with faulty SH kinematics.[333] The goal of physical therapy is to improve GH mobility and restore SH rhythm. In this phase, irritability level reduces and more aggressive stretching and joint mobilization are tolerated and should be a focus of treatment. **Figure 25-20** provides an example of a self-mobilization technique. Full active ROM is the goal, because any residual limitation may reinitiate the cycle. Low-load, prolonged stretch produces plastic elongation of tissues as opposed to high tensile resistance seen in high-load, brief stretch.[334,335] Heat may be used for relaxation, ultrasound may be used to promote tissue extensibility in the axillary fold, and cryotherapy may be used to reduce treatment discomfort. It is important to note that biologic remodeling occurs over long periods (months) as opposed to mechanically induced change which occurs within minutes.[336] Strengthening of the RC and SH muscles continues in this phase to reestablish coordinated force couples (see Self-Managements 25-1, 25-2, and 25-3), although positions

FIGURE 25-20 Self-mobilization of the glenohumeral joint into lateral distraction.

may still require modification because of ROM limitations in the GH joint.

Operative Treatment Conservative treatment will often be successful in patients with Stage 2 frozen shoulder; however, some patients in late Stage 2 and Stage 3 may have a refractory motion loss. In patients who continue to have a refractory motion loss that creates disability, operative treatment may be considered. Operative treatment is demanding, and proper patient selection, anesthesia, and postoperative analgesia are critical to its success. Operative treatment of patients with frozen shoulder includes closed manipulation and arthroscopic release. Closed manipulation is contraindicated in patients with significant osteopenia, recent surgical repair of soft tissues about the shoulder, or in the presence of fractures, neurologic injury, and instability.

Historically, arthroscopy has been of little diagnostic and therapeutic value in patients with frozen shoulder.[282] However, it has been suggested that the arthroscope may be helpful for delineation of disorders, documentation of the result of closed manipulation, and treatment of concomitant intra-articular and subacromial disease.[296,323,337,338] The goal of physical therapy treatment after surgery is to maintain ROM achieved under anesthesia and to decrease pain and inflammation. In the recovery room, the arm is placed in the quadrant position while the patient is still under scalene block anesthesia. A second scalene block is administered during an overnight hospital stay so the patient can tolerate exercise through the ROM.[339,340] Continuous passive motion is recommended throughout the night.[341] After discharge, the patient should receive outpatient physical therapy 5 days per week for the next 2 weeks, then three times per week until treatment is completed. Treatment includes high frequency of interventions directed toward ROM, modalities for pain and inflammation, and hydrotherapy. Strengthening exercises are gradually incorporated into the program, as outlined previously.

ADJUNCTIVE INTERVENTIONS: TAPING

Complex muscular relationships exist among the scapula, humerus, cervical, thoracic spine, lumbar spine, and pelvis. Faulty scapular alignment contributes to a variety of syndromes affecting the upper quadrant. Scapular taping can improve the resting alignment of the scapula on the thorax, thereby improving joint alignment of the related joints and length–tension properties of the shared musculature between the scapula and other regions of the upper quadrant. Scapular taping can be a useful adjunctive intervention when used with therapeutic exercise for the treatment of many upper quadrant diagnoses.[55,342]

Patients can perform exercises and ADLs or instrumental ADLs while taped with the added benefit of improved joint alignment and length–tension properties of the scapular musculature as well as tactile biofeedback. The benefit of scapular taping over an off-the-shelf brace is that taping allows the specific three-dimensional correction of each patient's unique alignment faults. Short-term taping (2 to 3 weeks) may assist in improved neuromuscular control of faulty movement patterns, whereas long-term taping (8 to 12 weeks) may affect muscle length–tension properties. Taping the ST articulation has several goals:

- To improve initial alignment, which promotes improved movement patterns
- To alter length–tension properties by stretching tissues that are too short and reducing tension placed on tissues that are too long
- To provide support and reduce stress to myofascial tissues under chronic tension
- To provide kinesthetic awareness of scapular position during rest and movement
- To guide the kinematics during movement

Each piece of tape provides a specific corrective force on the scapula. Any one piece can be used in conjunction with other directional pieces to provide a multidimensional correction of the alignment of the scapula. The goal is to tape the scapula into improved alignment. If, however, the patient has significant kyphosis, forward-head, or forward-shoulder posture, 100% correction should not be attempted. It is instead recommended to moderately correct the faulty alignment, because too much change in a short period may not be well tolerated by an individual with a chronic postural problem.

The tape product is specialized for taping the body for alignment and movement. It has the best combination of adhesive, extensible, yet stiff properties. The undertape is called Cover-Roll stretch, a hypoallergenic tape applied to protect the patient's skin from the overtape, called Leukotape (Beirsdorf Inc., Norwalk, CT). On the shoulder girdle, the Cover-Roll stretch often is adequate alone, particularly on a small-framed person with minimal to moderate postural faults.

The description of taping that follows details one method of taping, but other methods of taping can be used on the scapula and the humerus.[76] The goals of improved alignment and function are common to various techniques. Improved alignment and function during ADLs and instrumental ADLs and exercise can be achieved with proper taping techniques, and therefore taping can be a useful adjunctive intervention to therapeutic exercise and functional retraining.

Scapular Corrections

The following illustrations depict corrections of scapula position.

- Correcting scapular depression and improving scapular elevation (**Fig. 25-21**)
- Correcting scapular downward rotation and improving scapular upward rotation (**Fig. 25-22**)
- Correcting scapular abduction and improving scapular adduction (**Figs. 25-23** and **25-24**)
- Correcting scapular winging
  - Tape as for correction of scapular downward rotation (see Fig. 25-21) and abduction (see Fig. 25-23)
- Correction of scapular anterior tilt (**Fig. 25-25**)
- Correcting scapular elevation (see **Fig. 25-26**)

Prevention of Allergic Reaction

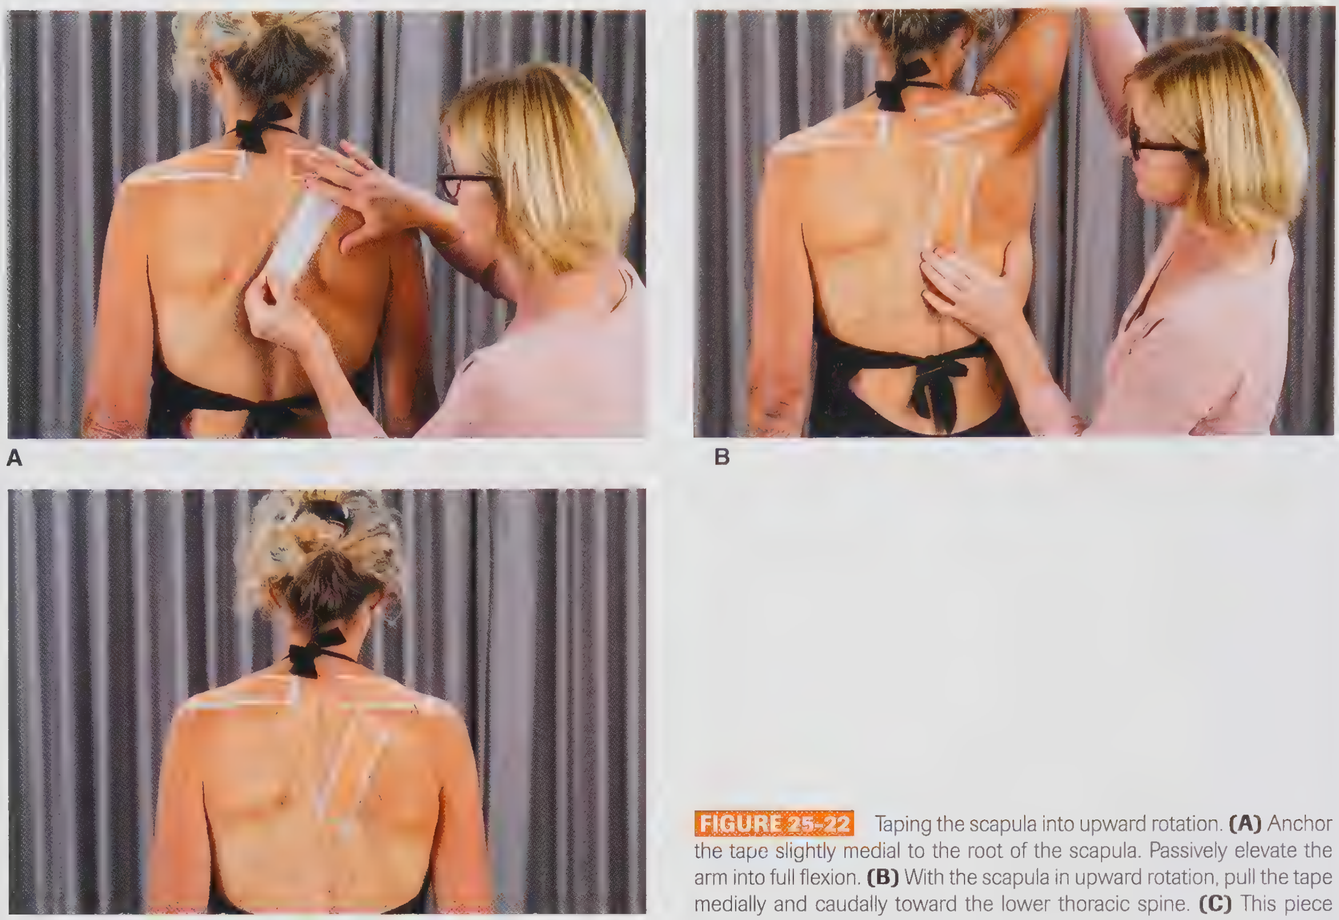
A common side effect of taping is an allergic reaction to the tape adhesive or skin breakdown. The following are troubleshooting tips to help prevent adverse reactions to taping:

- Use only Cover-Roll stretch, which is hypoallergenic. The allergic reaction is usually to the adhesive in the Leukotape.
- Use a skin preparation solution before application of the tape. A recommended skin preparation solution is milk of magnesia. A thin coat applied to the skin should completely dry before the tape is applied to allow easier tape removal.
- Ensure that all tape residue is removed before the next tape application.
- Warn patients of potential skin irritation. Instruct patients to remove the tape immediately if any itching or burning sensations develop.

A

B

FIGURE 25-21 Correction of scapula depression. **(A)** Anchor the tape to the lateral edge of the acromion process. Passively elevate the scapula, ensuring the acromial end rotates upward. Pull the tape medially toward the cervical spine along the suprascapular space, following the fiber direction of the upper trapezius. Do not cross the cervical spine. Apply a piece in a similar direction on the opposite side to prevent lateral shearing across the cervical spine. **(B)** Repeat the application until the correction is made. Often, if tape is applied to correct additional alignment faults, this piece needs to be repeated to ensure that other tape applications have not pulled the scapula into depression.



A B C

FIGURE 25-22 Taping the scapula into upward rotation. **(A)** Anchor the tape slightly medial to the root of the scapula. Passively elevate the arm into full flexion. **(B)** With the scapula in upward rotation, pull the tape medially and caudally toward the lower thoracic spine. **(C)** This piece provides a center of rotation for scapular upward rotation.

FIGURE 25-23 Taping the scapula into adduction. Tape as in Figure 25-22, but add a piece following the fiber direction of the middle trapezius as shown on the left scapula of this subject.

Prevention of Skin Breakdown

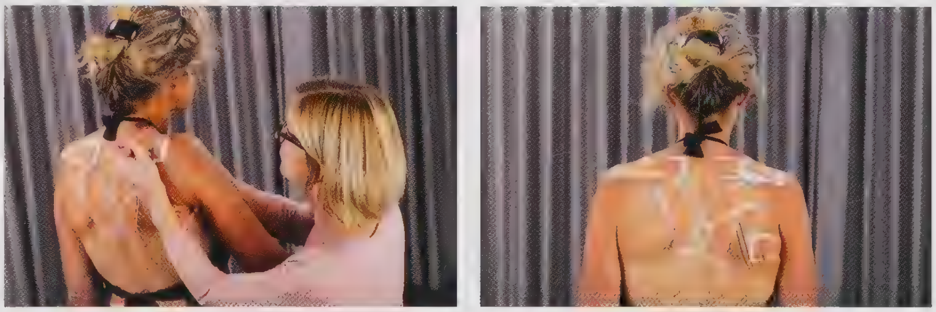
Skin breakdown often occurs because of excessive friction between the skin and the tape. Follow these guidelines to minimize skin breakdown:

- Do not cross the midline of the spine with the tape.
- Do not cross more than one joint at a time.
- Tape the scapulae bilaterally, particularly in elevation.
- Use a skin preparation solution before taping.
- Remove all tape residue before the next taping. Use Leukotape to dab off most of the residue, and follow up with adhesive tape remover.
- If skin breakdown occurs, allow the skin to heal fully before reapplying the tape. This may take 1 week or longer.

If taped properly, patients can often tolerate taping for 3 to 5 days. Showering with the tape is allowed, but soaking the tape is not recommended. For a person engaged in aggressive activities, the tape is more likely to loosen and not be as effective for as many days as it is for a less active individual.

A B C

FIGURE 25-24 This is an alternative or adjunctive technique for taping the scapula into adduction. A second piece of tape can be used to prevent excessive abduction. **(A)** Anchor the tape proximally in the axilla and just anterior to the lateral border of the scapula. **(B)** Pull the tape posteriorly and caudally while adducting and upwardly rotating the scapula. **(C)** Attach the tape to the medial border of the inferior scapula. As the patient elevates the arm, a pull is felt in the axilla if the scapula begins to abduct.



A B

FIGURE 25-25 Taping the scapula into posterior tilt. **(A)** Anchor the tape to the coracoid process. While tilting the scapula posteriorly, pull the tape posteriorly, caudally, and medially (opposite to the direction of pull of the pectoralis minor). **(B)** Anchor the tape to the spine of the scapula. Place another piece of tape as for correction of downward rotation (see Fig. 25-22) and scapular abduction (see Fig. 25-23), being sure to cover the inferior pole of the scapula to control tilt.

FIGURE 25-26 Taping scapula into depression. Use this technique to correct scapula elevation. Anchor the tape to the anterior border of the upper trapezius (not shown). Pull the tape posterior and caudal and anchor to the spine of the scapula.

KEY POINTS

- Critical to the management of the shoulder girdle complex is a thorough understanding of the anatomy and kinesiology of each of the four articulations comprising the complex.
- Precise kinematics at each of the four articulations and the integration of all four articulations with respect to joint function, force couples, and precise motor control to coordinate motion are required for optimal function of the shoulder complex.
- Because the shoulder girdle is one link in a kinetic chain, the function of the shoulder girdle affects and is affected by the function of other regions of the upper and lower quadrants.
- Treatment of impairments, although often necessary for improved function, should be complemented by functional retraining modified to the level of ability at a given time in the rehabilitation process.
- Ideal total body posture is a prerequisite for optimal movement in the shoulder girdle complex.

- A thorough understanding of the integrated approach to therapeutic exercise in the shoulder girdle is key to successful outcomes of shoulder girdle conditions.
- Three common types of chronic RC disorders have been described in the literature: (1) extrinsic or subacromial (compression), (2) intrinsic (tensile), and (3) extrinsic internal impingement (compression/tensile).
- Rotator cuff disorders can be broadly classified as acute or chronic in origin, though acute, avulsive tears of healthy RCTs are considered to be rare. Most authors believe that RC tears that appear to be of sudden onset after trauma are extensions of underlying chronic tears or tears of previously degenerated tendons.
- Frozen shoulder has been staged based upon arthroscopic findings as described in Table 25-4.
- Treatment of frozen shoulder should be individually based on the etiologic causes and stage of the disease (Table 25-5).
- Early intervention is key to successful outcome of frozen shoulder. Complete recovery with no residual limitation or disability is neither ensured nor common.
- Scapular taping can improve resting posture and proprioception, and thereby affect movement of the shoulder girdle complex.

CRITICAL THINKING QUESTIONS

1. What are the 3D kinematics of the scapula during arm elevation?
2. What are the 3D kinematics at the AC joint?
3. What are the coupled motions of the scapula during:
   a. Clavicle elevation
   b. Clavicle posterior rotation
   c. Clavicle retraction
4. What conjunct GH motion is a prerequisite to restoring full upper extremity elevation?
5. Why is the RC–deltoid function contingent on the scapular upward rotation force couple?
6. Which muscles can limit scapular upward rotation mobility?
7. Which muscles must have normal force or torque and length–tension relationships to achieve full upward scapular rotation ROM?
8. What is the timing of onset of the scapular muscles during scapular upward rotation to produce the ideal kinematics for scapular rotation?
9. What musculature is shared by the shoulder girdle and cervical spine? What joints are linked by the shared musculature?
10. If the upper trapezius is overstretched, as in a depressed scapula, in what direction is cervical spine rotation limited? What treatment do you propose to correct this problem?
11. If the levator scapula is adaptively shortened, as in a downwardly rotated scapula, in what direction is cervical spine rotation limited? What treatment do you propose to correct this problem?
12. How can cervical nerve root involvement affect the function of the shoulder girdle?
13. Using the case described in Display 25-4, determine the dosage parameters for improving muscular force or torque of the RC (using the exercise described in Self-Management 25-1).
14. What is the most critical intervention to promote healing of a strained muscle caused by adaptive lengthening from faulty postures?
15. How can poor technique during a biceps curl contribute to an anterior tilted scapula?
16. Adapt Self-Management 25-1 dosage parameters to focus on endurance.
17. In what alignment does the scapula rest to develop an elongated serratus anterior? How does this elongation contribute to a faulty kinematics of the scapula during scapular upward rotation?
18. Why is restoring the scapular kinematics important in the long-term recovery of impingement syndrome?
19. How can taping the scapula help adhesive capsulitis to recover? What taping techniques would you use?
20. Using Case Study No. 4 in Unit 7, develop a comprehensive exercise program. Describe each exercise according to the therapeutic exercise intervention model described in Chapter 2. You can follow the format used in the Selective Intervention at the end of Chapter 26.

CHAPTER

26

The Elbow, Forearm, Wrist, and Hand

LORI THEIN BRODY

Therapeutic exercise texts have often minimized or excluded the elbow, wrist, and hand, deferring evaluation of this region to other health care providers. This complex region is a challenging and specialized area of rehabilitation. Although numerous texts describe the anatomy, kinesiology, pathology, and surgical repair of this area, few sources relate pathology, impairments, and activity limitations with physical therapy intervention at the distal upper extremity level.[1] This chapter discusses common impairments and activity limitations of the elbow, wrist, and hand and the related therapeutic interventions. A brief review of anatomy and kinesiology provides the basis for the interventions chosen. Further details on the anatomy and kinesiology of this region can be found on thePoint.lww.com/BrodyHall4e.

ANATOMY*

Although the anatomy of a given joint is closely related to anatomy of adjacent joints, the elbow, wrist, and hand are discussed separately in the following sections.

Elbow and Forearm

Osteology

The primary osteologic considerations at the elbow and forearm are the humerus, radius, and ulna (**Fig. 26-1**). The articulation of the humerus with the ulna and the radius forms the elbow joint.[2] The key aspects of elbow and forearm osteology include:

- The spool-shaped trochlea of the humerus articulates with the trochlear notch of the ulna medially, and the rounded humeral capitulum articulates with the radial head laterally.
- The humeral medial epicondyle is a subcutaneous, blunt projection, easily palpable during elbow flexion, with a posterior shallow groove accommodating the ulnar nerve.
- The lateral epicondyle is also subcutaneous, with its anterolateral surface serving as the origin of the wrist extensor muscles.

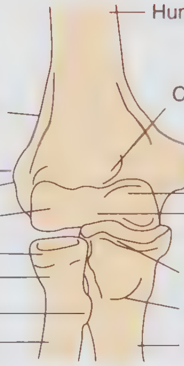

FIGURE 26-1 Elbow osteology with significant bony landmarks. (From Stroyan M, Wilk KE. The functional anatomy of the elbow complex. J Orthop Sports Phys Ther 1993;17:280.)

- The radius is the shorter and more lateral of the two forearm bones, with the radial tuberosity serving as the distal insertion of the biceps brachii.
- The ulna is the longer of the two forearm bones and serves as the major distal component of the elbow joint proper, with its hook-shaped anterior surface articulating with the humeral trochlea.

Arthrology

The elbow joint is comprised of several articulations: the humeroulnar, the humeroradial, and the proximal and distal radioulnar. Because of these multiple articulations, it is considered to be a compound synovial joint. The major ligamentous structures are as follows:

- The ulna deviates laterally relative to the humerus due to the asymmetry in the trochlea. This results in a slight frontal plane valgus angle, often called the carrying angle. This angle allows objects to be carried away from the side of the body while walking. Normal carrying angle can range anywhere from 7 to 20 degrees.[2]
- The ulnar collateral ligaments (UCLs), with anterior, posterior, and oblique components.[3] (see **Fig. 26-2**).
- The thick, cordlike anterior portion of the UCL is the primary stabilizer against valgus forces from 20 to 120 degrees of motion.

*Portions of this section are from Brody LT. Athletic injuries about the elbow. In: Wadsworth C, ed. The Elbow, Forearm, and Wrist [home study course]. LaCross, WI: Orthopedic Section, APTA, 1997. Reproduced with permission.

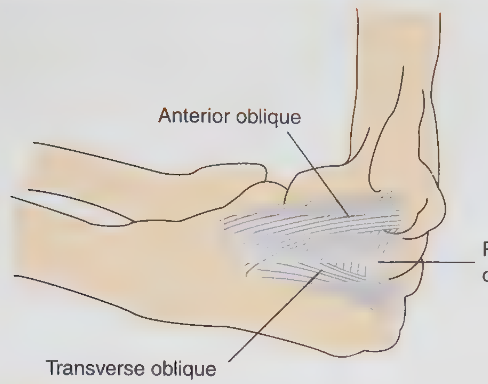

FIGURE 26-2 Ulnar collateral ligaments of the elbow. (From Zarin B, Andrews J, Carson W. Injuries to the Throwing Arm. Philadelphia, PA: WB Saunders, 1985.)

- The radial collateral ligament is a triangular, fan-shaped band blending distally with the annular ligament (surrounding the radial head) and the origins of the extensor carpi radialis brevis (ECRB) and supinator muscles.[3]
- The interosseus membrane is a broad fascial sheath running distomedially, connecting the radius and ulna and providing attachments for the deep forearm muscles.

Myology

Despite only a few muscles having a direct action at the humeroulnar joint, numerous muscles attach about the elbow and can be a source of pain and disability. Although many muscles perform multiple actions, they are classified by the articulation of their primary action. Muscles and their innervation can be found in **Table 26-1**.[4]

Wrist

The bony features of the carpal bones reflect their function. The inner surfaces of the outer carpals are covered with articular cartilage while their outer surfaces are rough, providing attachment for connective tissues. The inner bones have two-thirds of their surfaces covered by articular cartilage, and only the palmar and dorsal surfaces are irregular, providing for ligamentous attachments. A brief overview of anatomy and kinesiology is expanded on thePoint.lww.com/BrodyHall4e.

Osteology

The wrist joint is a complex area that includes eight carpal bones, the distal radius and ulna, and the bases of the metacarpal bones (**Fig. 26-3**). Proximally, the distal radius and radioulnar disk articulate with the scaphoid, lunate, and triquetrum. Laterally, the scaphoid is the largest bone in the proximal carpal row. The distal carpal row consists of the trapezium, trapezoid, capitate (the most central and largest of all carpal bones), and the hamate (**Fig. 26-4**). Key aspects of wrist osteology include the following.

- The scaphoid spans the intercarpal joint, linking the proximal and distal rows, making this bone prone to injury.
- The proximal pole of the scaphoid is susceptible to avascular necrosis following a fracture, as vascular innervation comes from the proximal portion of the scaphoid.[5]
- The lunate bone is the most frequently dislocated bone in the wrist, and perilunate instability following a wrist injury must be evaluated.[6,7]
- The triquetrum articulates with the lunate laterally, the hamate distally and laterally, and the pisiform medially and the articular disk proximally.
- The pisiform is a small pea-shaped bone that is sesamoid in nature and has several soft-tissue attachments.

TABLE 26-1

Muscles of the Elbow and Forearm

MUSCLE	ORIGIN	INSERTION	ACTION	SPINAL LEVEL	PERIPHERAL NERVE
Pronator teres	Medial epicondyle and coronoid process of ulna	Middle lateral radius	Forearm pronation	C7	Median
Supinator	Lateral epicondyle	Lateral upper ⅓ of radius	Forearm supination	C6	Radial
Biceps brachii	Coracoid process; scapular supraglenoid tubercle	Radial tuberosity	Shoulder flexion; elbow flexion	C5–C6	Musculocutaneous
Brachialis	Distal ½ of anterior humerus	Coronoid process of ulna	Elbow flexion	C5–C6	Musculocutaneous and radial
Brachioradialis	Proximal ⅔ of lateral supracondylar ridge of humerus	Lateral radial styloid	Elbow flexion	C6	Radial
Triceps	Infraglenoid tubercle of scapula; proximal posterolateral humerus; distal ⅔ or posteromedial humerus	Olecranon process	Elbow extension	C7–C8	Radial

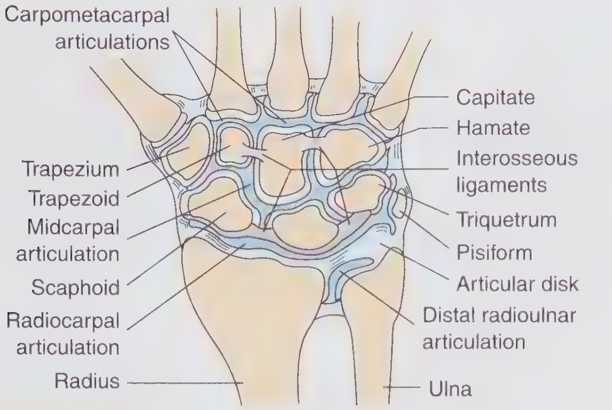

FIGURE 26-3 Wrist osteology. Cross section of the wrist and pertinent bony and soft tissues.

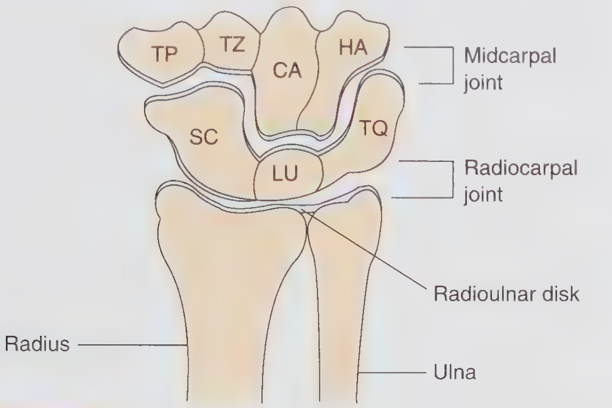

FIGURE 26-4 Wrist complex. The radiocarpal joint is composed of the radius and the articular disk, with the scaphoid (SC), lunate (LU), and triquetrum (TQ) bones. The midcarpal joint is composed of the scaphoid, lunate, and triquetrum with the trapezium (TP), trapezoid (TZ), the capitate (CA), and hamate (HA) bones.

- Distally, the trapezium articulates with the first and second-metacarpals, while lateral and adjacent to it, the trapezoid also articulates with the second metacarpal.
- The capitate is the central and largest of all carpal bones (the "keystone" of the proximal transverse arch), with a central position allowing articulation with seven other bones and serving as a central site for ligamentous attachment.[8] The capitate is convex on all sides; as such, all carpal bones roll and glide anteriorly around the capitate to create a concavity in the palm of the hand, allowing ease in gripping objects.
- The hamate is the most lateral bone of the distal carpal row, articulating with the fourth and fifth metacarpals and containing a palmar hook which protects the ulnar nerve passing beneath.

Arthrology

The wrist is generally divided into radiocarpal, midcarpal, carpometacarpal (CMC), and intercarpal joints. The radiocarpal joint is surrounded by an articular capsule that is lined with a synovial membrane, and this joint is formed by the articulations of the distal radius and the triangular articular disk with the scaphoid, lunate, and triquetrum bones[9,10] (see Fig. 26-4). The key aspects of wrist arthrology are as follows:

- The medial portion of the radiocarpal joint includes a network of structures called the triangular fibrocartilage complex (**Fig. 26-5**).[10]
- The radiocarpal joint is reinforced by several ligaments which are true intracapsular ligaments. The radiocarpal and ulnocarpal joints are considered to be extrinsic because of attachments outside the wrist (**Fig. 26-6**).[9]
- The intercarpal joints consist of articulations between individual bones within the proximal carpal row and the distal carpal row.
- The midcarpal joint is the articulation between the proximal and distal rows. The ligaments in this area are considered to be intrinsic and are divided into interosseous and midcarpal ligaments.[11] The specific ligaments are listed in **Table 26-2**.

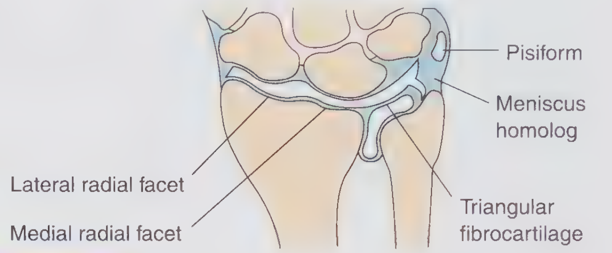

FIGURE 26-5 The proximal surface of the radiocarpal joint is formed by the medial and lateral facets of the distal radius and by the triangular fibrocartilage or articular disk. The articular disk and meniscus homologue are together part of the triangular fibrocartilage complex.

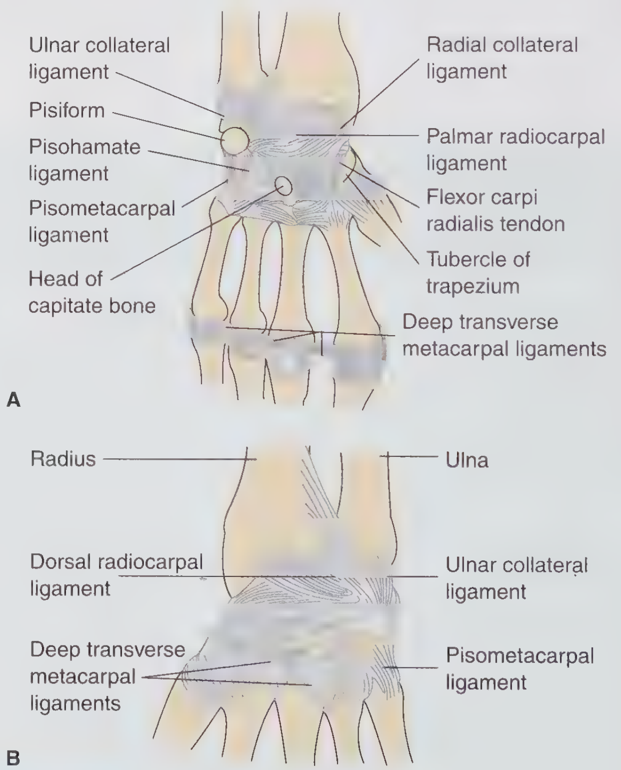

FIGURE 26-6 **(A)** Palmar aspect of the ligaments of the left wrist and metacarpal area. **(B)** Dorsal aspect of the ligaments of the left wrist.

TABLE 26-2

Intrinsic Ligaments of the Wrist

CLASSIFICATION OF INTRINSIC LIGAMENTS	LIGAMENT NAMES
Interosseous	
Distal row	Trapezium-trapezoid
	Trapezoid-capitate
	Capitohamate
Proximal row	Scapholunate
	Lunotriquetral
Midcarpal	
Dorsal[a]	Scaphotriquetral
	Dorsal intercarpal
Palmar[a]	Scaphotrapeziotrapezoid
	Scaphocapitate
	Triquetrocapitate
	Triquetrohamate

[a]Midcarpal ligaments span the proximal and distal rows on the palmar or dorsal surfaces.

From Berger RA. The anatomy and basic biomechanics of the wrist joint. J Hand Ther 1996;9:84–93.

- The CMC joints are also enclosed in a loose articular capsule, and are joined by dorsal, palmar, and interosseous ligaments.
- The first CMC joint has unique properties, as it is a saddle joint, affording great mobility of the thumb. This will be discussed in the *Hand* section.

Myology: Muscles Acting at the Wrist Joint

Several important muscles that function at the wrist have their origin at the elbow. These are the major wrist flexors and extensors. These muscles can be a source of epicondylitis from overuse activities at the wrist. Interventions should be directed at the muscle function at the wrist. A list of the key muscles can be found in **Table 26-3**.

Hand

Osteology

The key aspects of the osteology of the hand are as follows:

- Five metacarpals and 14 phalanges provide the hand's bony structure.
- Each metacarpal has a distal head, shaft, and base.[9]
- The medial four metacarpals articulate proximally with each other and with the distal row of carpal bones while the first and second metacarpals do not articulate with each other.
- The first metacarpal is saddle shaped proximally to articulate with the trapezium.
- There are three phalanges in each finger and two in the thumb.
- Each phalanx has a distal head, shaft, and proximal base.
- The thumb contains two sesamoid bones at the metacarpophalangeal (MCP) joint.

Arthrology

The MCP and interphalangeal (IP) joints have similar arthrologic structures. Each is composed of an articular capsule and synovial lining. The MCP joints contain volar ligaments, which are thick and fibrocartilaginous, loosely attached to the metacarpal, and firmly attached at the phalangeal bases.[9] Because of the incongruence of the MCP joints, the volar ligament (i.e., volar plate) does more than reinforce joint capsule. Its fibrocartilaginous structure adds surface area to the base of the proximal phalanx to more closely approximate the size of the larger metacarpal head. The volar plate also checks hyperextension. Its flexible attachments permit motion

TABLE 26-3

Muscles of the Wrist

MUSCLE	ORIGIN	INSERTION	ACTION	SPINAL LEVEL	PERIPHERAL NERVE
Extensor carpi radialis longus	Distal $^1/_3$ of lateral supracondylar ridge	Base of second metacarpal	Wrist extension and abduction	C6–C7	Radial
Extensor carpi radialis brevis	Common extensor tendon, lateral epicondyle	Base of third metacarpal	Wrist extension and abduction	C6–C7	Radial
Extensor carpi ulnaris	Common extensor tendon	Base of fifth metacarpal	Wrist extension and adduction	C7–C8	Radial
Flexor carpi radialis	Common flexor tendon of medial epicondyle	Base of second metacarpal	Wrist flexion and abduction	C6–C7	Median
Flexor carpi ulnaris	Common flexor tendon; proximal posterior ulna	Pisiform bone, hamate, fifth metacarpal	Wrist flexion and adduction	C8–T1	Ulnar
Pronator quadratus	Medial anterior distal ulna	Lateral anterior distal radius	Forearm pronation	C8–T1	Median

Other muscles with primary function at the hand also assist function at the wrist. These will be included in Table 26-4.

into flexion without restricting motion or impinging the long flexor tendons.[9] The transverse metacarpal ligament connects the volar ligaments of the second through fifth MCP joints. Collateral ligaments are found on either side of the joint and are strong, rounded cords.[10] The capsular, volar, and collateral ligament arrangement at the MCP joints is the same structure found in the IP joints (**Fig. 26-7**).

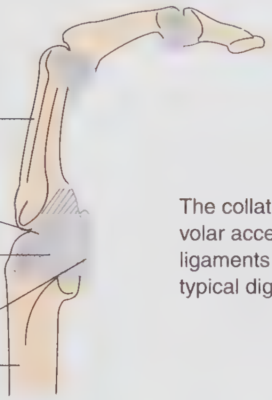

FIGURE 26-7 Ligaments of the fingers.

Myology: Muscles Acting at the Hand

The muscular anatomy of the hand can be classified as thumb and finger musculature. Many muscles contribute to the fine motor function of the wrist and hand. Although a mere listing of the muscles along with their anatomy does not address the fine motor skill necessary for hand function, it is a place to begin consideration of hand function. A listing of muscles as well as figures of some key musculature can be found in **Tables 26-4 and 26-5**, and **Figures 26-8** and **26-9**.

Regional Neurology

Several important nerves serve the elbow, wrist, and hand. These nerves may be injured locally by trauma, stretched during activities, or compressed within a confined space. For example, both the ulnar and median nerves can be entrapped at the ligament of Struthers, and elbow flexion narrows the cubital tunnel by 55%, compressing the ulnar nerve.[12] The median nerve is commonly compressed in the carpal tunnel. Compression of the radial nerve in the forearm can by caused by casts, watchbands, and similar items.[13] Understanding the area anatomy aids the clinician in determining the source of symptoms. The regional neuroanatomy and common site of compression can be found in **Table 26-6**.

TABLE 26-4

Muscles Functioning Primarily at the Hand

MUSCLE	ORIGIN	INSERTION	ACTION	SPINAL LEVEL	PERIPHERAL NERVE
Extensor digitorum	Common extensor tendon of lateral epicondyle	Middle and base of distal phalanx of digits 2–5	Extends MCP joints and assists extension of IP joints	C6–C8	Radial
Extensor indicis	Posterior ulna	Extensor expansion of index finger	Extends MCP joint and assists IP joint extension	C7–C8	Radial
Extensor digiti minimi	Common extensor tendon	Extensor expansion of fifth digit	Extends MCP joint and assists with IP joint extension	C7–C8	Radial
Palmaris longus	Common flexor tendon	Flexor retinaculum, palmar aponeurosis	Tenses palmar fascia	C7–C8	Median
Flexor digitorum superficialis	Common flexor tendon; coronoid process; radius	Middle phalanges of digits 2–5	Flexes proximal IP joints, assists MCP joint and wrist flexion	C7–C8	Median
Flexor digitorum profundus	Anteromedial ulna	Bases of distal phalanges digits 2–5	Flexes DIP joints; assists flexion of IP and MCP joints		
Flexor digiti minimi	Hook of hamate	Proximal phalanx of fifth digit	MCP flexion of fifth finger	C8	Ulnar
Opponens digiti minimi	Hook of hamate	Length of fifth MC	Opposes CMC of fifth finger	C8–T1	Ulnar
Dorsal interossei	Metacarpal bones	Radial and ulnar sides of fingers	Digit abduction and assists flexion and extension	C8–T1	Ulnar
Palmar interossei	Metacarpal bones	Ulnar and radial sides of fingers	Adduction of fingers	C8–T1	Ulnar

IP, interphalangeal joint; MCP, metacarpophalangeal joint; DIP, distal interphalangeal joint; CMC, carpometacarpal joint.

TABLE 26-5

Muscles Functioning at the Thumb

MUSCLE	ORIGIN	INSERTION	ACTION	SPINAL LEVEL	PERIPHERAL NERVE
Adductor pollicis	Capitate; second and third MC	Proximal phalanx of thumb	Adduction of CMC joint	C8–T1	Ulnar
Abductor pollicis longus	Posterior ulna and radius	First MC	Abducts and extends CMC joint	C7–C8	Radial
Abductor pollicis brevis	Trapezium and scaphoid	Proximal phalanx of thumb	Abduction of CMC and MCP joints	C6–C8	Median
Opponens pollicis	Trapezium	First MC	Opposes CMC of thumb	C6–C8	Median
Flexor pollicis longus	Interosseus membranes, medial epicondyle	Distal phalanx of thumb	Flexes IP joint	C8–T1	Median
Flexor pollicis brevis	Trapezius, trapezium, and capitate	Proximal phalanx of thumb	Flexes MCP and CMC joints of thumb	C6–C8, T1	Median and ulnar
Extensor pollicis longus	Posterior ulna	Distal phalanx of thumb	Extends IP joint	C7–C8	Radial

Kinesiology

Elbow and Forearm

Normal range of motion (ROM) at the elbow joint is 0 to 135 degrees actively and 0 to 150 degrees passively. Much of this mobility is necessary for normal activities of daily living (ADLs). However, unlike the knee, where full knee extension is imperative for ADLs such as ambulation, full elbow extension is not frequently utilized during daily activities. For example, putting on a shirt requires a range of 15 to 140 degrees, and drinking from a cup requires a range of 72 to 130 degrees.[14] ROM in flexion is limited by anterior muscle bulk, and ROM in extension is limited by the bony articulation of the olecranon in the olecranon fossa. The extended position of the humeroulnar joint is the close-packed position, but interestingly, is the loose-packed position of the humeral radial joint. Osseous stability also occurs

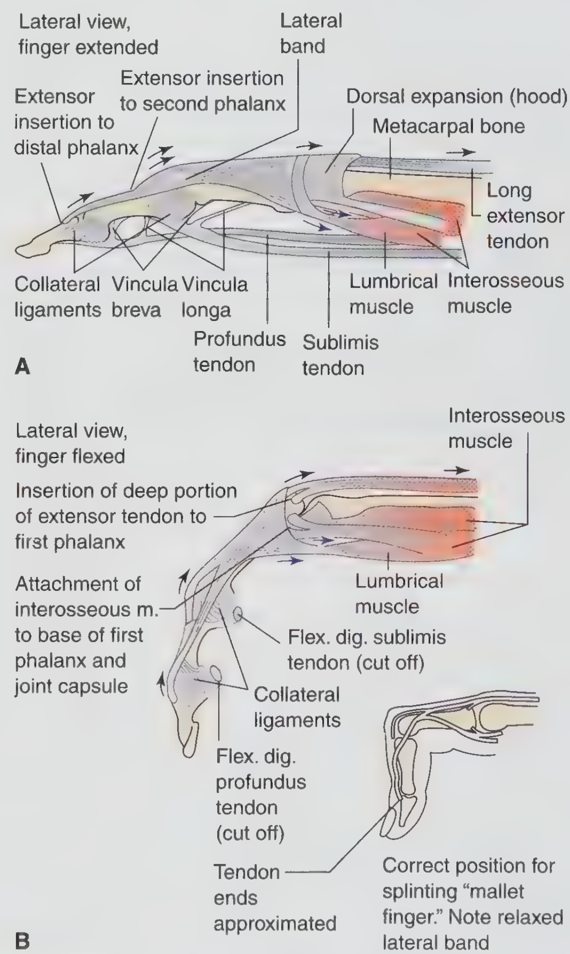

FIGURE 26-9 Intrinsic muscle anatomy. **(A)** Extended position. **(B)** Flexed position.

TABLE 26-6

Regional Neurology of the Forearm, Wrist, and Hand

	MEDIAN NERVE	ULNAR NERVE	RADIAL NERVE
Origination	Two roots from the lateral (C5–C7) and medial (C8–T1) cords	Medial cord (C8–T1) of the brachial plexus	The posterior cord (C5–C8) and is the largest branch of the brachial plexus
Upper arm	Descending along the brachial artery to enter thecubital fossa passing between the brachialis posteriorly and the bicipital aponeurosis anteriorly	Distally through the axilla along with the axillary artery and vein and the brachial artery. At the middle of the humerus, it moves medially, descending anterior to the medial head of the triceps. The ulnar nerve can become entrapped here by *the ligament of Struthers, approximately 8 cm proximal to the medial epicondyle*	Courses distally between the medial and long heads of the triceps and then passes obliquely posterior to the humerus and deep to the lateral head of the triceps to the lateral aspect of the humerus to penetrate the anterior compartment
Elbow	Passes under the *ligament of Struthers* and the *lacertus fibrosus* and enters the forearm between the *heads of the pronator teres (PT)*	Passes superficially through a groove on the dorsum of the medial epicondyle, entering the forearm in the *cubital tunnel* between the two heads of the flexor carpi ulnaris (FCU)	Passes anterior to the lateral epicondyle
Forearm	Behind and adhered to the flexor digitorum superficialis and anterior to the flexor digitorum profundus. Passing the distal margin of the PT muscle, the median nerve gives rise to two branches: the anterior interosseous nerve and the palmer cutaneous nerve	Passes superficially through a groove on the dorsum of the medial epicondyle, entering the forearm in the cubital tunnel between the two heads of the FCU. Just proximal to the wrist, it sends off a dorsal branch that continues distally across the flexor retinaculum	It bifurcates to become the posterior interosseous (only motor) and superficial radial (only sensory) nerves. The posterior interosseous nerve passes through the supinator muscle under *arcade of Frosche*, around the proximal radius, and beneath the extensor muscle mass to interosseous membrane of forearm and ends at dorsal wrist capsule; the superficial radial nerve passes beneath the brachioradialis muscle and continues distally along the *anterolateral aspect of the forearm*
Wrist	Distally, it lies deep to the flexor retinaculum passing through the *carpal tunnel*	Continues distally with the ulnar artery, beneath the most superficial aspect of the *flexor retinaculum*, and divides into superficial and deep terminal branches	Proximal to the wrist, the superficial radial nerve passes deep to curve around the radius and divides into four or five dorsal digital nerves
Hand	After passing through the tunnel, the median nerve divides into five or six branches, providing motor and sensory innervation to the hand	Superficial and deep branches provide motor and sensory innervation to the hand	Superficial radial nerve provides sensory innervations to most of the dorsum of the hand and the thumb and index fingers.

Italicized structures are areas of potential nerve entrapment.

in extreme flexion. Mid-range stability comes from ligamentous support. Motion at the humeral ulnar joint occurs primarily by gliding of the ulna on the trochlea.

Pronation and supination technically occur through the forearm at the proximal and distal radioulnar joints. The normal range of pronation and supination is 0 to 80 degrees in each direction. Pronation occurs as the radius crosses over the ulna at the proximal radioulnar joint. Although most ADLs occur with the forearm in a middle position, some activities, such as receiving change in the palm of the hand, require full supination.

Resistance to varus in full extension is provided by the bony congruity of the humeral ulnar joint on the medial side , by the radial collateral ligament laterally, and the capsule, which surrounds both joints.[10] Resistance to distraction is provided by soft-tissue components, and the anterior portion of the joint capsule provides the primary resistance to anterior displacement.

Resistance to valgus at the elbow is important due to the many throwing sports and activities that stress the medial side of the elbow. The UCL is the primary medial stabilizer; the flexor and pronator muscle groups offer a small amount of additional support. In addition, compression of the humeroradial joint offers approximately 50% of the resistance to valgus stressing.[2] Resistance to valgus stress in full extension is limited equally by the UCL, bony congruity, and the anterior capsule.[9] As the elbow moves into flexion, most of the resistance to valgus stress is provided by the anterior band of the UCL (**Evidence and Research 26-1**).

EVIDENCE and RESEARCH 26-1

A cadaveric study of the flexor pronator group relative to the UCL throughout the ROM has significant implications for rehabilitation of individuals with medial elbow injuries. At 30 degrees of elbow flexion, the pronator teres (PT)and flexor carpi radialis (FCR) muscles were entirely anterior to the UCL, and the flexor carpi ulnaris (FCU) muscle was found over or posterior to the UCL. The flexor digitorum superficialis (FDS) muscle was over the UCL in most cases. The findings were similar at 90 degrees, except the FCU muscle was completely over the UCL, and the FDS muscle was anterior to the UCL in most cases. At 120 degrees, the PT, FCR, and FDS muscles were all anterior to the UCL, and only the FCU muscle was over the UCL. This pattern suggests that the *FCU muscle is the primary dynamic medial elbow stabilizer throughout the ROM* and particularly at 120 degrees of flexion.[15,16]

Wrist

Wrist Flexion and Extension

The normal wrist ROM is from 80 degrees of flexion to 70 degrees of extension. The resting position of the wrist is between 20 and 35 degrees of extension and 10 to 15 degrees of ulnar deviation while in the close-packed position.[17] The wrist functions primarily through a range of 10 degrees of flexion to 35 degrees of extension when performing most ADLs.[18] However, some activities, such as rising from a chair, require significantly more extension.[18] Movement at the radiocarpal joint is predominantly movement of the convex proximal carpal row on the concave distal radius and articular disk, as many functions of the upper extremity are open kinetic chain. In addition, simultaneous movement of the distal carpal row on the proximal carpal row occurs and contributes to overall movement. The distal row is considered convex and articulates with the proximal carpal row in the exact same fashion that the proximal carpal row articulates with the radius.[2] Because of this, the proximal carpal row is considered to be an intercalated segment, a relatively unattached middle segment of a three-segment link, because of its position between the radius and distal carpals.[10]

Mechanically, the scaphoid plays a critical role in stabilizing the wrist by means of its position bridging the proximal and distal carpal rows (i.e., the midcarpal joint). The radiocarpal and midcarpal joints provide variable proportions of the motion during wrist extension and flexion. When the proportion contributed by radiocarpal joint exceeds that of the midcarpal joints in one direction, this pattern reverses in the other direction.[10] Wrist extension is initiated at the distal carpal row, with this row gliding on the relatively stable proximal row. As the wrist passes into extension, these rows begin to move together, with the scaphoid intervening as the bridge to this process.[10] Full extension is the close-packed position of the wrist.

In general, the distal carpal row functions as a unit because of the interlocking of articular surfaces and the ligamentous connections between the distal carpal row and the metacarpals distally.[11] The distal row tends to move in unison with the second and third metacarpals, palmar flexing when these metacarpals palmar flex and dorsal flexing when they dorsally flex. The proximal carpal row differs in its movement pattern from the distal row. In general, the bones in the proximal row move together, although greater motion occurs between the bones in the proximal row than in the distal row. This is true of the direction and magnitude of motion between the bones in the proximal row. The proximal row tends to move in the same direction as the distal row and therefore in the same direction as the second and third metacarpals.[11] Between-bone motion also occurs, and, during wrist extension, the scaphoid supinates while the lunate pronates, functionally separating these bones. This motion underlies perilunate instabilities occurring as a result of forceful extension.

Wrist Ulnar and Radial Deviation

Frontal plane motion is normally from 15 degrees of radial deviation to 30 degrees of ulnar deviation. The ulnar styloid is shorter than the radial styloid, accounting for the greater range in ulnar deviation than radial. Greater ulnar and radial deviation is possible when the wrist is in a neutral flexion-extension position. Arthrokinematic motion in radial and ulnar deviation is more complex than in flexion and extension. During radial deviation, the proximal carpal row glides ulnarly and flexes while the distal row pivots radially. During ulnar deviation, the proximal row glides radially and moves into extension while the distal row moves ulnarly.[11]

Wrist Function

The mobility of the wrist depends on the position of the fingers because of the length of extrinsic tendons crossing the wrist and hand joints. For example, wrist flexion is decreased when the fingers are simultaneously flexed because of the length of the extrinsic finger extensor muscles. Likewise, the mobility of the fingers depends on the position of the wrist, as evidenced by the inability to fully flex the fingers when the wrist is flexed.

Load transmission across the wrist is significant and varies with wrist position. With the wrist and forearm in neutral, approximately 80% of the force is transmitted across the radiocarpal joint and 20% across the ulnocarpal joint.[19] Further breakdown of the radiocarpal loads shows that approximately 45% of these forces are transmitted across the radioscaphoid joint and 35% across the radiolunate joint.[19] Forearm pronation increases the load transmitted across the ulnocarpal joint to approximately 37%, with a proportional reduction in load at the radiocarpal joint. Radiocarpal forces increase to 87% when the wrist is in radial deviation.[11]

Hand

Carpometacarpal Joints

Carpometacarpal joints two through five are similar in structure and function, but the first CMC is unique. The second through fourth CMC joints permit one degree of freedom in flexion and extension, and the fifth CMC allows some abduction and adduction as well. Motion at the CMC joints is limited primarily by the ligamentous structure. Motion increases at the CMC joints from the radial to the ulnar side of the hand.[10] Almost no motion occurs at the second and third CMC joints, the fourth is slightly more mobile, and the fifth moves through a range of nearly 10 to 20 degrees.[10] This allows the hypothenar eminence to cup and grip objects, increasing the palmar contact with the object.

The first CMC joint is saddle shaped and has two degrees of freedom and some axial rotation. This mobility allows for opposition, a key function of the thumb. The thumb is involved in nearly all forms of prehension, or handling activities, and loss of the thumb accounts for the greatest portion of disability in the hand, as approximately 70% of hand function involves the thumb.[20] ROM is approximately from 20 degrees of flexion to 45 degrees of extension and from 0 degrees of adduction to 40 degrees of abduction. Mobility at the CMC is limited by the ligamentous and interposed soft tissues.

A primary role of the CMC joints is to contribute to cupping of the hand, forming palmar arches. This hollowing allows the hand to conform to the shape of the object being held (**Fig. 26-10A** and **B**). Two arches are visible: the longitudinal arch that spans the length of the hand and the metacarpal arch that transverses the palm.

Metacarpophalangeal Joint

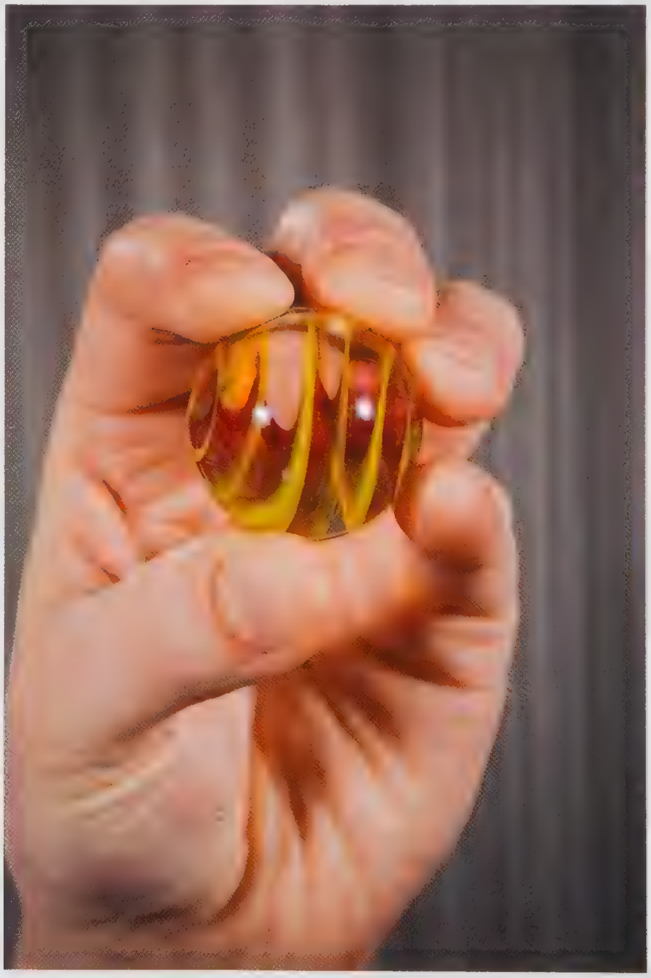
The four medial MCP joints possess two degrees of freedom, flexion and extension, and abduction and adduction. The mobility at these joints increases from the radial to ulnar sides of the hand, with an active ROM (AROM) from 90 degrees of flexion to 10 degrees of extension. Passively, variable amounts of extension are available. Functional flexion at the MCP joint is approximately 60 degrees.[17] The range in abduction and adduction is approximately 20 degrees in each direction. The range in the frontal plane is limited by articular surface geometry, and the range in flexion is limited by joint geometry and capsule, and the range in extension is limited by the volar plates.

The MCP joint of the thumb also possesses two degrees of freedom. The ROM is more limited here than in fingers 2 through 5. Almost no hyperextension is available in normal hands, and only approximately 50 degrees of flexion can be obtained. Extension at this joint is further limited by the presence of two sesamoid bones, stabilized by collateral and intersesamoid ligaments. The primary function of MCP mobility of the thumb is providing additional range for opposition and prehension activities.

Interphalangeal Joints

The IP joints of the fingers and thumb are similar in function. Each is a hinge joint with one degree of freedom. ROM at the IP joints, as with the other joints in the hand, increases from

A



B

FIGURE 26-10 **(A** and **B)** Hollowing of the hand allows it to conform to different size and shape objects.

the radial to the ulnar side of the hand. This is easily observed when making a fist. The ROM at the proximal interphalangeal (PIP) is from 0 degrees of extension to 100 degrees of flexion at the radial side of the hand and nearly 135 degrees of flexion at the ulnar side. Little hyperextension is available because of the volar plates. The distal interphalangeal (DIP) joint demonstrates less ROM, from 10 degrees of extension to 80 degrees of flexion. Functional flexion at the PIP joints is approximately 60 degrees, and functional flexion at the DIP joints is 40 degrees.[17]

Extensor Mechanism

The extensor mechanism of the fingers is composed of the extensor hood (i.e., extensor expansion or dorsal aponeurosis) and the extensor digitorum (ED), palmar interossei, dorsal interossei, and lumbrical muscles. Each finger contains a similar mechanism that is necessary for successful extension of the finger. As the ED courses distally, it flattens into an aponeurotic hood over the metacarpal, and just distal to the MCP joint, the ED is joined by tendon fibers from the interossei muscles. The interossei arise from the lateral borders of the metacarpals (see Fig. 26-9). This aponeurosis formed by the ED and interossei continues distally, where, proximal to the PIP, the hood splits into three branches. All three branches receive fibers from the interossei, and the medial branch also receives fibers from the lumbricals. A central tendon continues distally and crosses the PIP to insert at the base of the middle phalanx. Two lateral bands on either side continue distally, cross the PIP joint, and reunite into a single tendon that terminates at the distal phalanx. Several local ligaments attach to the extensor hood and prevent bowstringing during movement. The oblique retinacular ligaments are important in simultaneous PIP and DIP extension.

A complete description of the mechanics of the extensor hood is beyond the scope of this text, but a few generalizations can be made. At the MCP joint, contraction of the ED produces extension while activation of the lumbricals and interossei produces flexion. The torque produced by the ED exceeds that of others, and extension results. At the PIP joint, the ED, interossei, and lumbricals together produce extension (**Fig. 26-11**). Isolated contraction of the ED causes the finger to claw or to produce MCP hyperextension with IP flexion[10] because of the passive pull of the long finger flexors at the IP joints. Extension of the PIP joint also produces DIP extension (and vice versa), and when the PIP is held in flexion, the DIP is incapable of isolated extension. This mechanism is fine-tuned to produce fine movements and strong grip. Any imbalance in the lateral slips disrupts this mechanism and significantly alters hand function.

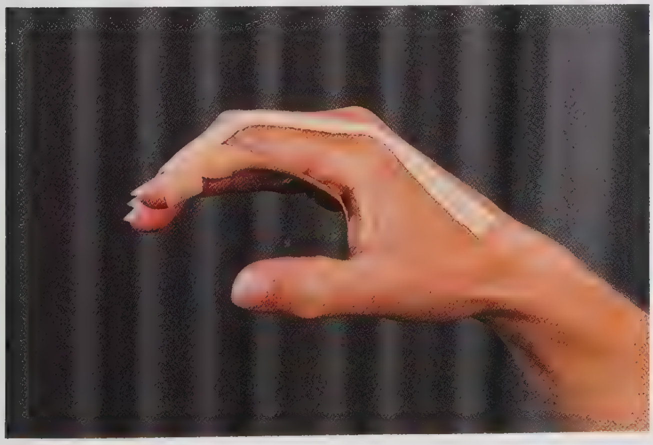


FIGURE 26-11 Patient with a lumbrical strain who improved with kinesiotaping.

Prehension

The hand is well suited for the major task of grasping, gripping, and manipulating objects. Prehension is the global term for the usual tasks of grasping, holding, and manipulating objects. Many terms are commonly used to describe hand functions. Most functions can be grouped into the categories of grip and pinch. These can be further subdivided into categories such as power grip, precision grip, hook grip, key pinch, and precision pinch. The power grip is used for developing firm control, while the precision grip is used when accuracy and precision are needed. The precision grip allows the hand to conform to different size and shape objects. Examples of power grip include hook, spherical, cylinder, and fist grasps. These grips utilize primarily the medial side of the hand. Examples of pinch types include the key, and tip-to-tip and pulp-to-pulp pinches, which use more of the lateral side of the hand.

Grip activity has been broken down into four stages. In the first step, the hand opens by simultaneous action of the long extensor and hand intrinsic muscles. The fingers then close about the object, requiring activity of the intrinsic and extrinsic flexor and opposition muscles. The third step is an increase in force in these same muscles to a level appropriate for the task. Lastly, the hand again opens to release the object.[17] While the flexors are grasping the object, the wrist extensor muscles must fire simultaneously to prevent the long flexors from producing wrist flexion.

The innervation of the hand is related to the two types of grip. The ulnar nerve controls the motor and sensory distribution of the medial digits, and these digits are used more for the power grip. The median nerve controls the lateral digits, which are used more for the precision grip. The thumb musculature, used in both types of grip, is innervated by both nerves.[17]

The power grip is used when force generation is the primary objective (**Fig. 26-12A**). Carrying a suitcase, climbing on a jungle gym, making a fist, and grasping a baseball to throw are all examples of power grip. In this situation, the ulnar digits stabilize the object, holding it against the palm, with or without the assistance of the thumb. The fingers are fully flexed while the wrist is extended and ulnarly deviated.

The precision pinch is used when fine control is necessary. This grip is used when holding a writing instrument, putting a key in the door, holding playing cards or a piece of paper between two fingers (Fig. 26-12B and C). The precision pinch includes primarily the MCP joints and the radial side of the hand. The index and middle fingers work with the thumb to create a tripod. In contrast with the power grip, the object in a precision pinch may never come in contact with the palm.

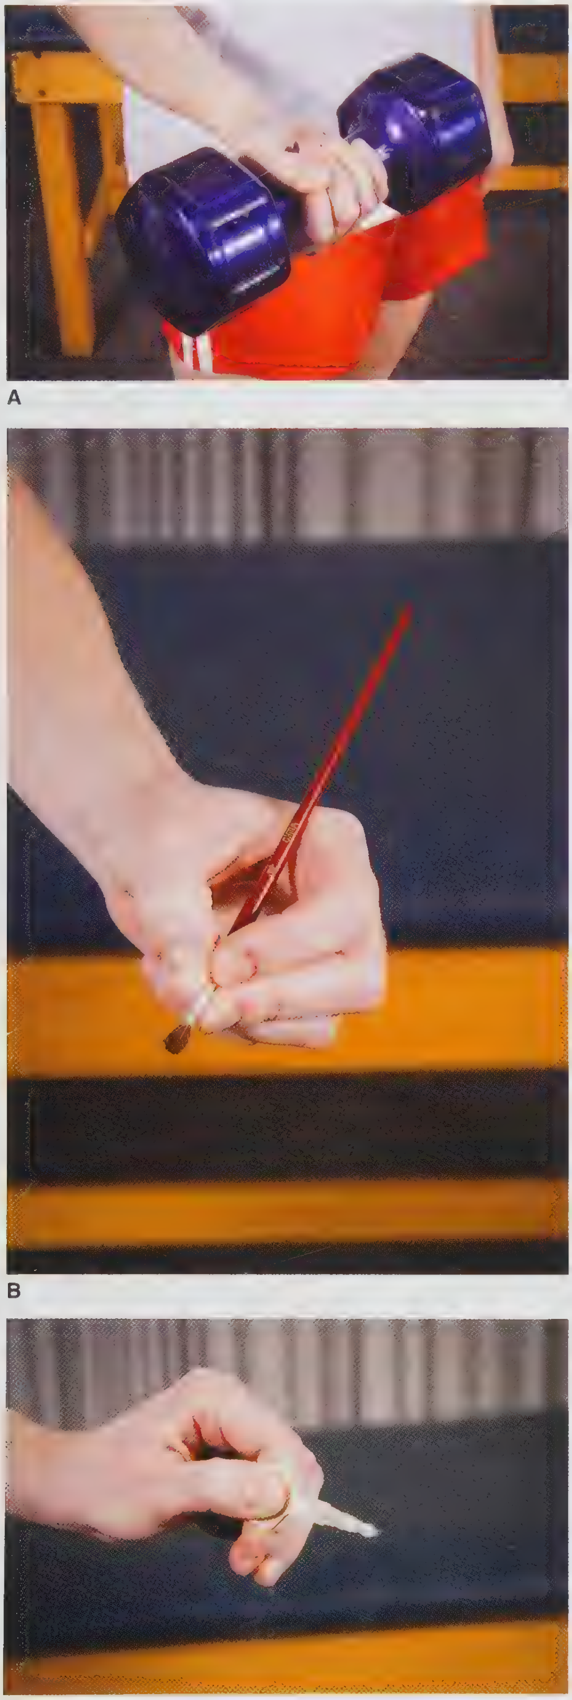

FIGURE 26-12 **(A)** Power grip. **(B)** Precision grip. **(C)** Key grip.

EXAMINATION AND EVALUATION

Examination and evaluation of the elbow, wrist, and hand must include a comprehensive assessment of the upper quarter. The upper extremity relationships between the cervical spine and distal joints require a full examination to ensure identification of the problem source. Many of the examination techniques depend on the situation. The presence of comorbidities such as diabetes or rheumatoid arthritis (RA) necessitates different examination techniques from those used for the patient without such additional issues. The following sections address the key aspects of elbow, wrist, and hand examinations.

History and Observation

The history and subjective information focuses the remainder of the examination. In addition to the medical history and evaluation of the current problem, subjective information about the signs and symptoms after the injury is valuable. Information is gathered about the activity limitations (e.g., inability to manipulate buttons, zippers, and other small objects, inability to carry out hygiene activities, difficulty writing or typing, problems opening jars) and participation restrictions (e.g., unable to work because of inability to type, unable to care for child because of pain and weakness in elbow) associated with the current complaint. Information to differentiate primary elbow, wrist, and hand problems from those referred from the cervical spine must be ascertained.

The resting position of the hand also should be observed, including these deformities:

- Swan-neck deformity
- Boutonnière deformity
- Ulnar drift (commonly observed in patients with RA)
- Clubbing of DIPs
- Heberden or Bouchard nodes
- Claw fingers
- Dupuytren contracture
- Mallet or trigger finger

Mobility Examination

Mobility examination of the elbow, wrist, and hand includes osteokinematic and arthrokinematic testing as well as tests of muscle extensibility. It is particularly important to find the sources of mobility loss in the hand, because this impairment is associated with significant activity limitations, participation restrictions, and disability. Examination procedures should distinguish between contractile and noncontractile tissues and between intrinsic and extrinsic muscle limitations. In most cases, both osteokinematic and arthrokinematic tests of mobility should be performed, as well as tests of muscle flexibility.

Muscle Performance Examination

Muscles functioning at the elbow, wrist, and hand should be tested in a logical order on the basis of the subjective information provided, history, and the results of the examination.

Many of the hand muscles are quite small, and therapists must consider their relative strength when applying traditional manual muscle testing criteria. Stabilization, particularly when trying to isolate small intrinsic muscles of the hand, ensures that the muscle of interest is being tested. Kendall[4] has described the testing procedures for the relevant muscles in the region. Grip and pinch (tip pinch and key pinch) force measurements are commonly used and have high reliability. However, large changes (i.e., improvements) in these measures are necessary before they can be reliably detected with standard measuring devices.[21]

Other Tests

Many special tests assess the integrity of tissues throughout the upper quarter. These tests examine ligament stability, soft-tissue mobility, neurologic status, and functional tasks. Magee[17] has provided a complete listing and description of special tests. Some of the more common tests used are listed in **Display 26-1**.

DISPLAY 26-1

Special Tests at the Elbow, Wrist, and Hand

Elbow

- Valgus stress test (0 and 30 degrees)
- Varus stress test (0 and 30 degrees)
- Tinel sign
- Pinch grip
- Tennis elbow tests
  - Resisted wrist extension
  - Passive wrist flexion
  - Resisted third finger extension (biases ECRB)
- Golfer elbow
  - Resisted wrist flexion
  - Passive wrist extension

Wrist and Hand

- Carpal tunnel tests
  - Phalen test
  - Reverse Phalen test
  - Tinel sign
  - Three jaw chuck test
- Allen test
- Finkelstein test
- Brunnel-Littler test
- Retinacular test
- Froment sign
- Ligamentous instability testing for the fingers
- Thumb ulnar collateral ligament testing
- Lunotriquetral ballottement test
- Scaphoid stress test
- Hand function tests
- Grip strength test
- Reflexes and sensation
- Upper limb tension tests

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON IMPAIRMENTS OF BODY FUNCTIONS

Mobility of Joint Functions: Impaired Range of Motion

Impaired mobility in the distal upper extremity can be very disabling. Fine motor skills are necessary for the simplest of daily activities. Mobility activities must restore full ROM throughout the distal segments to maintain independence in many household tasks. Impaired mobility in this region is treated with a combination of therapeutic modalities, exercise, and splinting.

Hypomobility

Hypomobility in this region can occur for a number of reasons. Injuries that necessitate a period of immobilization can produce profound mobility loss. Surgery, neurologic injuries, burns, and falls can significantly impair mobility. Because of the mobility required for functional use of the upper limb, loss of motion in this region can be quite disabling. Lack of mobility in the distal upper extremity can result in faulty movement patterns, resulting in overuse and pain in the proximal upper extremity, such as the shoulder.

Intervention for mobility loss requires a thorough evaluation to determine the structures responsible for or contributing to the motion loss. The joint capsule, short musculotendinous structures, immobile fascial tissues, or restricted nervous tissues are a few examples of tissues that may be at fault. Evaluation techniques aimed at differentiating contractile from noncontractile tissues, followed by specific tension testing, can pinpoint the source of limitation. Only then can appropriate intervention be initiated.

Mobility impairment at the ***elbow*** includes loss of flexion and extension. Loss of elbow extension occurs frequently after fractures or dislocations at the elbow, or with prolonged use of a shoulder sling. The elbow is also at risk of the development of heterotopic ossification following injury or trauma.[22] Loss of motion occurs rapidly at the elbow, and therefore immobilization is kept to the minimum acceptable time. Degenerative joint disease has a lower impact on the upper extremity joints than the lower, and loss of motion because of arthritic changes at the elbow therefore is less much common than at the knee. Loss of motion at the elbow is often compensated by trunk, shoulder, and wrist motion, all of which may place additional loads on these structures.

Mobility loss at the ***forearm*** includes loss of pronation and supination. The capsular pattern shows equal loss of pronation and supination. Loss of motion at the forearm is common after immobilization for wrist and hand fractures. Loss of pronation and supination results in difficulties with turning knobs, opening jars, receiving change, and turning a key. These motions are frequently transferred to the shoulder, with the person performing external and internal rotation to compensate. Restoration of motion is important to prevent secondary injury to the shoulder.

Loss of motion at the ***wrist*** is common after falls or fractures injuring the wrist. Fractures of the distal radius or ulna require immobilization and potentially surgical stabilization. Scaphoid fractures are prone to avascular necrosis due to the local blood supply, and therefore require surgical fixation and/or immobilization. This immobilization leads to loss of mobility at all joints of the forearm, wrist, and hand. RA also affects the wrist joint causing deformity, pain, and loss of hand function.

Loss of motion in the ***hand*** is frequently caused by rheumatoid arthritic changes. Loss of motion in the hand may also result from osteoarthritis (OA), and this process tends to affect the PIP and DIP joints but not the MCP joints (see **Self-Management 26-1**). The thumb CMC is significantly affected by OA and RA. Injuries such as fractures, dislocations, and burns produce limitations in mobility after treatment. Dupuytren contraction, or contraction of the palmar fascia, usually affects the fourth or fifth fingers, where the skin is adherent to the underlying fascia. This progressive fibrosis of the palmar fascia has no known cause and affects men older than 40 years of age more than women.[17] These impairments can lead to activity limitations (e.g., inability to grasp a pen) and therefore participation restrictions (e.g., unable to work because of inability to grasp objects).

SELF-MANAGEMENT 26-1
Proximal and Distal Interphalangeal Joint Flexion

Purpose: To increase the mobility in the joints and tendons of your fingers

Starting Position: Start with all the joints of your fingers as straight as possible.

Movement Technique: Keeping your knuckle joints (MCP) straight, bend the middle and fingertip joints (PIP and DIP) as far as possible. Return to the starting position.

Dosage:

Repetitions: ______________________

Frequency: ______________________

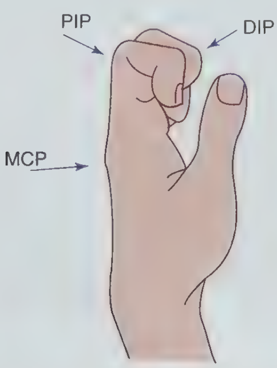

FIGURE 26-13 Elbow joint mobilization. Distal traction at humeroulnar joint to increase elbow flexion and extension range of motion.

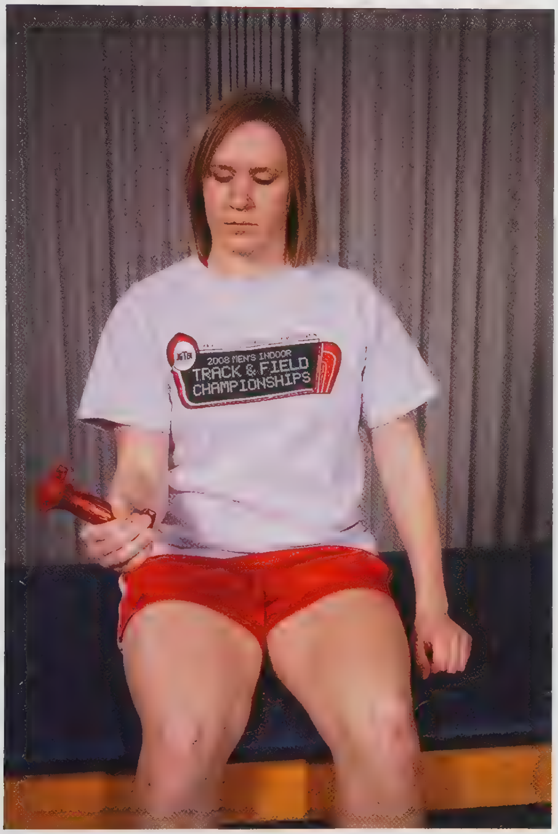
Activities to increase mobility begin with an intervention to warm the tissue (i.e., active exercise, superficial, or deep heat), followed by stretching the musculotendinous tissue, or mobilizing the joint depending upon the source of the restriction. For example, limited motion because of capsular restriction at the elbow may be treated with humeroulnar distraction techniques and some anterior and posterior glides (see Chapter 7; **Fig. 26-13**). After mobilization techniques, passive prolonged stretching in the direction of limitation may be performed along with concurrent application of heat or cold. Active mobility in the new range should follow (**Fig. 26-14 A** and **B**). For example, active pronation and supination may be followed by active hand to mouth exercises or active forward reaching. When immobility is caused by a short or stiff muscle, traditional stretching techniques may be employed. At the same time, postural correction and strengthening of the antagonist (which is often weak because of its lengthened position) must occur. Immobile fascial connective tissues are mobilized by manual techniques such as massage and manual deep pressure application. As with stretching, this intervention should be followed with active use of the limb (see **Self-Management 26-2** and **Building Block 26-1**).

Treatment for immobility of the hand of a patient with RA depends on the acuteness of the situation and the degree of deformity. Immobilization may be the treatment of choice in some phases of this disease process (see the "Stiff Hand and Restricted Motion" section). Neural gliding techniques are employed when neural tension test reveals immobility of neural tissue to be the source of the patient's symptoms.

Hypermobility

Hypermobility is an uncommon problem at the elbow and forearm. The humeroulnar joint is a very congruent joint; as such, hypomobility is a much more common complaint. Elbow hyperextension ROM is one criterion for a diagnosis of systemic hypermobility. However, hypermobility at this joint is rarely symptomatic because of the limited weight bearing occurring in

A



B

FIGURE 26-14 **(A)** Contract-relax stretching of the forearm into supination, followed by **(B)** active use of the forearm into elbow flexion with forearm supination.

the upper extremities. Individuals participating in upper extremity weight-bearing sports such as gymnastics or wrestling may have difficulty associated with elbow hyperextension during sports.

Similarly, hypermobility is uncommon at the wrist and hand. Hypermobility should not be confused with instability. Instabilities occur in the wrist and the hand. Lunate dislocation with perilunate instability and scapholunate dissociation (SLD) are common, and instability in the fingers is evident in the hand of the patient with RA. However, physiologic hypermobility rarely exists without pathology or injury, and if hypermobility is present, it rarely produces symptoms.

SELF-MANAGEMENT 26-2

Metacarpophalangeal and Proximal Interphalangeal Joint Flexion with Distal Interphalangeal Joint Extension

Purpose: To increase the mobility of your finger joints and tendons

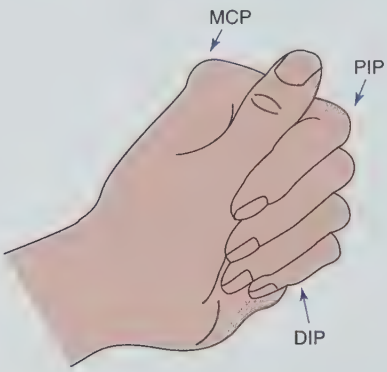
Position: Start with all joints of your fingers as straight as possible.

Movement Technique: Bend your knuckle (MCP) and middle (PIP) joints while keeping the fingertip joints (DIP) straight. Return to the starting position.

Dosage:

Repetitions: ____________________

Frequency: ____________________



BUILDING BLOCK 26-1

A 56-year-old forklift driver has pain with active pronation and supination following a radial head fracture which is now healed. Outline a typical treatment session for this patient in the early phase.

Impaired Muscle Power Functions

Several injuries or pathologies can impair a patient's ability to produce torque in the distal upper extremity. Fractures, dislocations, contusions, sprains, tendon lacerations, burns, nerve entrapments, and crush injuries are some of the conditions that can limit a person's torque-producing ability. The relationship between the force impairment and activity limitations or participation restrictions should justify and guide treatment. The clinician should progress specific muscular strengthening exercises to activities that reproduce the function of the upper extremity. This includes *self-care activities* such as dressing, grooming, and bathing and *work activities* such as pushing, pulling, grasping, pinching, typing, and other dexterous movements.

A B

FIGURE 26-15 Resisted wrist extension. **(A)** Gripping free weights; **(B)** Use of a cuff weight without grip.

Any strengthening exercises for the elbow, wrist, and hand must consider the kinetic chain relationship across these joints. The joints are interconnected and functionally related, and the muscular anatomy often crosses several joints. Strengthening exercises for the elbow often load the wrist and finger muscles as the individual holds a weight or other resistive equipment in the hand. Strengthening exercises requiring a grip differ from those using resistance around the wrist (e.g., a cuff weight). For example, strengthening exercises for lateral epicondylitis focus on strengthening the wrist extensor muscles in their roles as active wrist extensors (concentrically and eccentrically) and as stabilizers against finger flexor activity such as gripping or shaking hands. Any wrist extension exercise that concurrently requires gripping may overload these muscles (**Fig. 26-15**). This relationship is one reason why prescribing shoulder exercises while holding a 16-oz can in the hand can produce lateral epicondylitis in previously asymptomatic individuals.

Neurologic Causes

Neurologic pathology or injury is a common source of impaired muscle function in the distal upper extremity. Cervical degenerative joint disease, degenerative disk disease, foraminal stenosis, and cervical spine injuries can cause symptoms distally in the respective nerve root distributions. After exiting the cervical spine, the nerves may be entrapped in a number of locations throughout the neck, thorax, and arm. Entrapment may produce distal neurovascular symptoms such as thoracic outlet syndrome. In this situation, the neurovascular bundle is compressed at one or more sites (e.g., cervical rib, scalene muscles) producing a variety of intermittent to constant symptoms. The ulnar nerve is also subject to traction injuries at the medial elbow in the thrower. Similarly, the mobility of any nerve within its nerve sheath may become restricted (**Fig. 26-16**; see Table 26-6).

Injury, compression, traction, or ischemia of these nerves, proximally or distally, results in various symptoms, such as loss of torque production in the muscles served by the damaged nerve. Treatment for this inability to produce torque depends on the specific situation. For example, when distal weakness is caused by cervical spine disk herniation, traction, postural retraining, and cervical spine exercises are initiated, followed by progressive resistive exercises for distal musculature after the proximal symptoms have improved. Nerve entrapments at the elbow, wrist, or hand are initially treated by release techniques to mobilize the nerve. In contrast, traction injuries to the ulnar nerve at the elbow are initially treated with stabilization techniques followed by strengthening exercises. Perform these exercises in positions or postures that minimize the traction or compressive forces on the nerve. Progression to more provocative and functional patterns should follow (see **Building Block 26-2**).

FIGURE 26-16 Neural gliding techniques with an emphasis on median nerve.

BUILDING BLOCK 26-2

A 16-year-old softball pitcher experiences weakness in the muscles innervated by the ulnar nerve due to valgus stress traction injury. She has been taken off pitching until symptoms resolve and needs to rehabilitate key musculature. What are the key muscle groups to consider for rehabilitation? What types of exercises might be recommended?

Muscular Causes

Muscle injuries in this region range from muscular overuse injuries to tendinopathies at the elbow (i.e., medial and lateral epicondylitis) and wrist (i.e., de Quervain tenosynovitis) to tendon lacerations in the hand. Interventions to improve torque production after muscular injury depend on the location and severity of injury, the role of that muscle in functional activities, and the stages of healing. The first muscle loading following a muscle injury may be in the form of stretching, AROM, or isometric exercise. As these loading techniques are tolerated, progression ensues.

After the appropriate level of load is determined, progress isometric to dynamic exercises the involved musculature at the elbow, forearm, wrist, and/or hand. Exercises may be performed in an open chain, using light weights, bands, or other functional objects (**Fig. 26-17**). Closed chain activity such as leaning against a wall or on a countertop to provide resistance is also appropriate. In the hand, manual resistance, specific muscle activation exercises or simple gripping exercises using sponges, putty, or other small resistive objects are often used (**Fig. 26-18**). Resistance to extension can be provided manually or by using small resistive bands or rubber bands. In addition to restoring torque-producing abilities, the fine motor function of the muscles must be retrained. Several dexterity tasks are available for training these skills (see **Self-Management 26-3**).

FIGURE 26-17 Resisted wrist flexion combined with grip strengthening using a resistive band.

FIGURE 26-18 Grip strengthening using putty.

SELF-MANAGEMENT 26-3
Finger Pinch with Putty

Purpose:	To increase the strength of the muscles used to pinch
Starting Position:	Form the putty into the shape of a ball. Hold it between your fingertips.
Movement Technique:	Pinch the putty between your fingertips and your thumb until your fingers press through the putty. Reshape the putty and repeat.

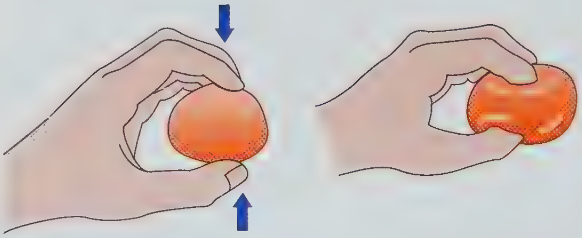
Frequency: ____________________



Deconditioning, Disuse, and Overuse

Proximal muscle deconditioning can lead to distal muscle overuse injuries. For example, as the rotator cuff fatigues during a repetitive lifting task, more of the lifting may be performed by the elbow flexors and wrist extensors, predisposing the individual to lateral epicondylitis. This occurs with repetitive work or leisure activities and reinforces the importance of a thorough upper quarter examination. Effective repetitive wrist and hand activity requires proximal stabilization. When the proximal muscles fatigue, posture is compromised, and a greater load is placed on the distal muscles. As one group of distal muscles fatigues, the load is shifted to alternate muscle groups, overworking these muscles. Ensure sufficient muscle endurance for the required task throughout the kinetic chain (**Evidence and Research 26-2**).

EVIDENCE and RESEARCH 26-2

Researchers performed electromyography of the wrist musculature before and after inducing delayed onset muscle soreness in the upper trapezius muscle. Following the onset of trapezius muscle pain, the ECRB showed decreased activity, while the FCU showed a decrease in the relative rest time. Results suggest that shoulder pain impacts coordination of distal musculature during computer work.[23]

Endurance Impairment

Muscular endurance impairment is often seen at the wrist and hand in individuals who perform repetitive work with their hands. Imbalance between the endurance of wrist flexors and extensors, along with a number of other factors (i.e., posture, tool design, volume of activity, temperature, vibration, etc.), contribute to forearm, wrist, and hand pain. Overwork of the wrist and finger flexors during repetitive gripping or typing can contribute to overuse problems of the forearm, wrist, and hand. The use of smartphones has led to new problems in the hand (see **Evidence and Research 26-3**). Forms of epicondylalgia at the elbow may be considered forms of endurance impairment as well. Epicondylitis may develop as an acute injury because of a muscular strain, or it may result from fatigue of the overworked musculature. In this situation, impaired muscle endurance is contributing to the situation.

EVIDENCE and RESEARCH 26-3

Texting and the use of smartphones has led to tendon and nerve problems in the wrist and hand. Smartphone overuse has led to decreased hand function, increased median nerve size, thumb pain, and decreased pinch strength,[24] while repetitive gaming has resulted in tendon rupture.[25] Ultrasound shows that the flexor pollicis longus (FPL) tendon is thicker in frequent smartphone users as compared to low use individuals.[26] Ergonomic analysis of smartphone use suggests that the tendon load varies by the activity, and that smaller buttons place a greater load on the thumb musculature.[27]

Particular attention should be given to the posture assumed during performance of these exercises. Wrist extensor strengthening exercises should focus on the position of interest; if the individual functions at work with the wrist in a specific posture, that posture should be assessed and corrected if necessary. Subsequent exercises should focus on strengthening the muscle at the length it will be during functional activity. In contrast, training the wrist extensor muscles in the case of lateral epicondylitis will likely use a dynamic range of strengthening, given the wide ROM for most activities producing lateral epicondylitis (e.g., tennis, painting, hammering; see **Self-Management 26-4** and **Building Block 26-3**).

Pain and Inflammation Impairment

Pain and inflammation occur throughout the distal upper extremity for a variety of reasons. Injury or surgery can result in pain and inflammation at the specific site, while central

SELF-MANAGEMENT 26-4

Wrist Extension Exercise with Resistive Band

Purpose: To increase the strength of your forearm, wrist, and hand muscles

Starting Position: Use a resistive band of appropriate tension. Place the band across the back of the hand of your painful wrist with the palm down, forearm supported. Hold the band ends with your opposite hand and pull down creating tension in the band. Pull just hard enough to feel tension in your involved wrist that you can hold for 10 seconds; then release the tension and let your wrist relax.

Movement Technique: Level 1: Hold resistance for a count of 10. Rest by removing the band tension.

Level 2: Raise and lower the involved wrist through a comfortable range.

Level 3: Grasp the band in your involved hand and repeat, incorporating grip into the exercise.

Dosage:

BUILDING BLOCK 26-3

An artist specializing in pottery complains of fatigue in her wrist and finger flexors after a day of working at the pottery wheel. She reports that this is due to putting in long hours preparing for a show. She has no neurologic symptoms nor signs of systemic disease. Design an initial therapeutic exercise program for her. Her show is completed, but she would still like to work at her wheel to keep up her inventory. What advice do you have regarding her work at the wheel?

or local nerve compression usually produces pain locally and pain radiating from the site of compression. Inflammatory conditions such as RA or OA produce pain and inflammation in the affected joints, and tendinopathies in their respective tendons.

Inflammation is easily detected in this region because of the superficial nature of the structures. The MCP, PIP, and DIP joints in the hand are easily observed for swelling and redness and palpated for warmth and tenderness. Crepitus in tendons such as the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons in a person with de Quervain syndrome is readily palpable, as is the local tenderness associated with medial and lateral epicondylitis.

Intervention for inflammation is based on the acuteness of the inflammation (see Chapter11). Gentle active, active assisted, or passive motion to maintain mobility during the acute phase may be indicated. In some situations, immobilization with splints may be necessary, with occasional removal for gentle mobility activities. After the acute phase has passed, more aggressive activities may be initiated.

Gentle grade I and II joint oscillations may be used to decrease pain in some situations. This approach along with ice and other adjunctive agents can decrease pain enough to allow resumption of a therapeutic exercise program.

Muscle Endurance Functions: Impaired Posture and Movement

The most common posture and movement impairments in this region are work- and hobby-related cumulative injuries. Lateral and medial epicondylitis at the elbow and carpal tunnel syndrome (CTS) and de Quervain tenosynovitis at the wrist result from impairments in posture and movement. Grasping and pinching always cause a flexion moment at the wrist that must be offset by extensor muscle activity, loading the common extensor origin at the elbow.

Hand grip strength is a function of the object's size and the posture of the wrist. For a given size of object, an optimal wrist position for maximum grip strength exists.[28] When examining an individual with a work- or hobby-related disorder, consider the size of the tool and its impact on elbow, wrist, and hand posture. These tools can be hobby-related (e.g., golf club, racquet, gardening tools, knitting needles) or work-related (e.g., hammers, screwdrivers, shovels, welding tools, sewing tools). When grip is involved, the posture of the upper quarter relative to that tool must be examined. Posture during non-grip activities such as keyboard operating also is important. The guidelines for posture while sitting at a computer work terminal can be found in **Patient-Related Instruction 26-1**.

Movement factors may contribute to injuries in this region. Fatigue during repetitive activity produces changes in movement patterns and subsequent overuse injuries. As muscles begin to fatigue, the individual has more difficulty controlling force production, and substitution occurs. Substitution may occur with a synergistic muscle or a muscle group more proximal or distal in the kinetic chain. In either case, the primary muscle and the substituting group are vulnerable to overuse injuries. Allowing adequate rest time, using proper tool size, reinforcing good posture, and controlling cycle time, recovery time, and exertion frequency can decrease repetitive loads (**Evidence and Research 26-4**).

Patient-Related Instruction 26-1

Computer Workstation Posture

The following information can help you to evaluate your computer workstation. If you have specific medical problems, consult your clinician for any special needs you may have.

Computer

Correct keyboard position

- Elbows bent at 90 degrees
- Wrists straight or slightly bent up
- Keyboard downwardly sloped
- Try placing the keyboard on a commercially available keyboard tray with a wrist rest.

Correct monitor position

- About 16 to 22 in away (about an arm's length)
- Top of the screen even with top of forehead
- Use a stand or adjustable monitor arm to regulate height.

Mouse

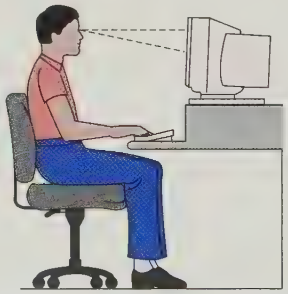
Correct mouse position

- Elbows bent at 90 degrees
- Wrist straight or slightly bent up
- Shoulders relaxed and arm at your side
- Elbow supported on armrest if available

Your Work

- Your document and screen should be at similar heights.
- Use a document holder.
- Sit directly in front of the keyboard, monitor, and document holder.

Sitting posture



EVIDENCE and RESEARCH 26-4

Increased use of smartphones and other digital media has led to new concerns about neck, shoulder, and arm pain. Electromyographic activity of six hand muscles of 56 young adults was obtained while texting from a mobile phone. A higher proportion of those in the asymptomatic group used back and forearm support with a more neutral head position than those in the symptomatic group. Looking at specifics of texting, those using a physical keypad used more thumb, finger flexor, and wrist extensor activity than those using a touchscreen using a device of similar dimensions.[29] More wrist extensor muscles were used with one hand texting compared with both, and there was greater finger flexor and wrist extensor activity as the screen size increased.[30] Holding the phone higher or lower impacts neck and elbow posture and symptoms[31] and varies with one- versus a two-handed texting technique.[32]

THERAPEUTIC EXERCISE INTERVENTIONS FOR COMMON DIAGNOSES

Osteoarthritis and Rheumatoid Arthritis

OA and RA commonly affect the wrist and hand.[33,34] The hands are the most frequent site of OA in the elderly, and can have a significant impact on function and disability in this population.[33] The prevalence of radiographic hand OA ranges from 29% to 76%. The wide variation is due to genetic and environmental differences.[35] Hand OA can have different presentations depending upon individual factors with predictors such as older age, genetics, female sex, menopausal, manual labor with pneumatic vibratory tools and metal, high impact physical activity, and repetitive use of the hand.[33] In patients with RA, hand and wrist dysfunction are common, with 75% of patients with a 15- to 20-year history of RA having erosive wrist disease.[36]

Hand osteoarthritis affects the second and third DIP, the first IP, and the first CMC joint the most frequently. The PIP has the lowest OA prevalence. Symmetry of OA between rows of joints was the most common pattern of interrelationship found.[37] Hand OA is associated with pain and loss of function, particularly when both the thumb and fingers are involved.[38,39] Pinch and grip strength and hand function measures are decreased with hand OA, while the high grip strength appears to be a predictor of the development of OA in the proximal hand joints but not the DIP joints.[40]

Rheumatoid arthritis is a chronic, systemic inflammatory disease affecting multiple joints, with its greatest impact on the synovial membranes. The wrists and hands are typically involved, and strength and mobility impairments can significantly impact the patient's quality of life.[41] At the *wrist*, the distal radioulnar joint is affected causing the ulna to dorsally subluxate on the radius at the distal radioulnar joint. The patient with RA often has a wrist deformity of flexion, radial deviation, and volar subluxation of the carpal bones.[20] Ankylosis may eventually ensue, severely restricting mobility at the wrist. This motion loss is particularly disabling for the individual with RA, because adjacent joints are also affected and unable to compensate for wrist immobility.

At the *hand*, RA causes MCP joint ulnar deviation and volar subluxation of the proximal phalanges. The synovial changes associated with RA weaken connective tissues surrounding the joints, leading to joint subluxation and/or dislocation. For example, swan-neck deformity, or hyperextension of the PIP and flexion of the DIP, results from flexor and extensor imbalance and PIP joint laxity.[20] A boutonnière ("buttonhole") deformity arises when the extensor mechanism fails over the PIP joint causing hyperextension of the DIP and flexion of the PIP with failure of the extensor mechanism. At the thumb, a "zig-zag" deformity can cause significant functional impairments for people with RA (**Fig. 26-19**). Additionally, mucous cysts and nodules impact the function of tendons, causing "trigger fingers" in tendons with sheaths.

Intervention for patients with RA affecting the wrist and hands typically consists of therapeutic exercise to maintain joint mobility and musculotendinous strength and integrity, night splinting, as well as patient education in joint protection.[42,43] A program that includes education in joint protection along with a strengthening program has been shown to produce outcomes that are clinically meaningful and cost-effective.[44] Programs consisting of strengthening exercises have shown improvements in strength and hand function at 6 weeks, that was further improved by 12 weeks.[45] The dosage of therapeutic exercise needs to be individualized based upon the stage and severity of the disease. Research has shown that intense exercise is tolerated in some patients with RA. Mobility, hand pain, and functional ability improved in patients undergoing an intense rehabilitation program compared with a conservative program.[46] However, for those with significant loss of hand function, surgical intervention can improve the quality of life (**Fig. 26-20** and **Evidence and Research 26-5**).

FIGURE 26-19 Arthritis can affect multiple joints of the wrist and hand.

FIGURE 26-20 Rheumatoid arthritis of the hands before and after surgery to correct deformities.

EVIDENCE and RESEARCH 26-5

A number of studies have found improvements in hand function and quality of life in patients with RA who complete a supervised hand rehabilitation program. A systematic review found that grip strength in various grip types was improved and transferred to daily functioning following hand therapy.[47] A 6-week program of isometric and isotonic hand exercise resulted in decreased pain and disease activity and improved hand function, dexterity, and quality of life in women with RA.[48] Group education about the disease process and self-management training also improves outcomes.[44]

FIGURE 26-21 A night splint is used to rest and maintain the position of the wrist and hand.

Splints or orthoses used for RA include resting hand splints, wrist supports, and finger splints.[49] A variety of splints are available and can be customized for use during functional activities or at night or other times of rest. Splinting should be accompanied by an appropriate therapeutic exercise program to ensure optimal mobility, strength, and function of the hand (**Fig. 26-21**).

Cumulative Trauma Disorders

Most musculoskeletal injuries that occur in the workplace are not caused by accidents or acute injuries that sprain ligaments; they result from wear and tear stresses on the musculoskeletal system. Wear and tear injuries are frequently referred to as cumulative trauma disorders (CTDs). The most common CTD is CTS which will be discussed in further detail in a subsequent section. Lateral epicondylitis, deQuervain's tenosynovitis, and other wrist and hand tendinopathies as well as neck, shoulder, and low back problems have been classified by the National Institute for Occupational Health and Safety[50] (**Display 26-2**).

CTDs are by definition work-related phenomena, although these disorders may also occur with certain hobbies and other nonwork-related activities. The World Health Organization has defined CTDs as being multifactorial in nature, indicating that a number of risk factors contribute to these disorders, including physical risk factors, environment, work organization, and psychosocial, sociocultural, and individual risk factors. Because of the multifactorial nature of CTDs, there is some controversy about the role these risk factors play in the development of CTDs.

Physical risk factors include repetition, awkward postures, prolonged activities, forceful exertions, and fatigue (**Display 26-3**).[41] Specific modifiable factors include work tasks with high vibration, working in flexion or extension for prolonged periods of time, tasks demanding heavy resistance, lack of variability in tasks, insufficient break time, and work that is highly repetitive.[26,51–53] The magnitude, duration, and repetition need to be considered for each of these risk factors. Environmental risk factors, such as vibration and cold, may also be present, further complicating the picture. The worker exposed to these factors and not given adequate recovery time may develop a CTD. The worker is unable to recover from the microinjuries or microtrauma that occurs at the tissue level over time. CTDs typically have a slow onset, with only minimal symptoms noticed initially. Many people ignore the early symptoms and do not seek medical attention until the symptoms prevent them from participating in work or in recreational or home activities.

Work may also aggravate or exacerbate an existing health or musculoskeletal problem. For example, forceful gripping at work may aggravate a previous sport injury at the elbow, such as lateral epicondylitis. The diagnosis of lateral epicondylitis is frequently used to describe a CTD injury at the elbow involving the lateral extensor mechanism.

Acting alone or in combination, awkward postures, excessive forces, and frequent repetitions may cause mechanical and physiologic stress on the soft tissues. When a person is positioned in an awkward posture, the body is unable to function at an optimal level. For example, wrist postures may shorten or elongate some muscle groups altering force production (**Evidence and Research 26-6**). When in a lengthened position, the wrist muscles may be unable to exert the required force for the task. Adopting a flexed wrist posture during typing and other hand activities is associated with wrist CTDs potentially due to the sustained work of the wrist extensors.[54,55] The individual may be functioning at a greater percentage of their maximum capabilities. Fatigue is more likely to occur when functioning at a higher percentage

DISPLAY 26-2

Factors Contributing to the Increase in Cumulative Trauma Disorders

- Work pace
- Same task, little variability
- Concentrated forces on smaller physiologic elements
- Decreased time for rest
- Increase in service and high-tech jobs
- Aging workforce
- Reduction in staff turnover
- Increased awareness of the problem

DISPLAY 26-3

Common Characteristics Associated with Cumulative Trauma Disorders

- Work-related: intensity, duration, repetition or cycle time, posture, vibration, force, contact stress, tool geometry
- Mechanical and physiologic processes
- Exacerbation of an existing health problem (e.g., RA, OA)
- Recovery requiring weeks, months, or years
- Multifactorial: work + recreational activity + hobbies
- Fatigue
- Symptoms often poorly localized, nonspecific, and episodic

EVIDENCE and RESEARCH 26-6

Research into the electromyographic (EMG) activity of wrist flexor and finger extensor musculature in both neutral and shortened positions showed that muscle shortening caused by changing the wrist posture changed the relationship between the time and frequency of EMG activity in both muscle groups.[54]

of the maximum voluntary contraction. Fatigue, coupled with excessive repetitive motions, may exceed the tendon sheath's capacity to lubricate the tendon, causing increased friction and eventual wear and tear of the tendon.

Vibration is a significant stressor contributing to a variety of wrist and hand musculoskeletal disorders. Termed *hand-arm vibration syndrome*, this primarily work-related musculoskeletal disorder is comprised of vascular, neurologic, and musculoskeletal components seen in people regularly exposed to high frequency vibratory tools (i.e., spinning/rotating tools, saws, grinders, and jackhammers).[56,57]

Workplace design and ergonomics must be carefully evaluated when a patient is diagnosed with a CTD. Ergonomics is the study of fitting the job to the individual. A job analysis or ergonomic analysis should be completed to assess the risk factors present in the individual's work environment. Certain occupational risk factors such as repetitive gripping or forceful pushing with the wrist in an ulnar-deviated position may prevent the person from successfully returning to that job without symptoms recurring. An example is an individual grasping a straight-handled tool such as a knife. This tool and activity places the wrist in an ulnar-deviated position. By angling the tool handle instead of the wrist, the wrist's position is improved. By ensuring appropriate preventive maintenance (e.g., sharpening the knife on a timely basis), the stress on the tool operator is decreased.

Nerve Injuries

A variety of nerve injuries occur throughout the elbow, wrist, and hand because of the anatomic structures in the upper extremity and the functional demands in the region. A thorough knowledge of the local anatomy provides a foundation for understanding the impairments found with these nerve injuries.

Carpal Tunnel Syndrome

CTS at the wrist is the most common peripheral compression neuropathy, affecting a greater proportion of women than men.[20,58,59] The prevalence of CTS in a population of adults has been estimated between 3.6% in those who never worked and 12.2% among former workers with an 8% lifetime risk of development.[59,60] The Bureau of Labor Statistics found a prevalence of current work-related CTS of 2.1% among current or recent workers in its 2010 survey.[36] The three occupational groups with the highest rate of days lost from work due to CTS include production, office and administrative support and installation, and maintenance and repair.[24] CTS in the working population is associated with significant costs at many levels (individual, employer, third-party payer, etc.). The average cross-sectional area of the carpal tunnel is 1.7 cm^2 with the wrist in neutral. CTS is caused by a decrease in the size of the carpal tunnel or an increase in the size of its contents, which compresses the median nerve (**Evidence and Research 26-7**). A single insult (e.g., Colles fracture), systemic conditions or disease (e.g., pregnancy, diabetes, RA), anomalous anatomy, and cumulative trauma within the carpal tunnel (e.g., flexor tenosynovitis) can compress the median nerve. Physical factors associated with CTS include repetitive motion, force, mechanical stresses, posture, vibration, and temperature.

EVIDENCE and RESEARCH 26-7

Pressure in the carpal tunnel varies with wrist position. Carpal tunnel pressure increases with non-neutral wrist positions, forearm and finger positions, and finger pressure.[61] Passive flexion and extension of the wrist has been shown to increase carpal tunnel pressure significantly. The mean wrist position associated with the lowest carpal tunnel pressure is approximately 2 degrees of flexion and 3 degrees of ulnar deviation. Wrist extension increases carpal tunnel pressure more than wrist flexion.[62]When typing, avoid positions of wrist extension greater that 30 degrees and radial deviation greater than 15 degrees. Digital fingertip pressure also increases carpal tunnel pressure beyond that of wrist position.[61]

CTS can manifest with sensory or motor impairments of the median nerve. Diagnosis is based on the presence of one or more common symptoms and on the results of provocative tests. Electrodiagnostic studies can be valuable in confirming the diagnosis and detecting other neuropathies. Associated impairments can include nocturnal pain and numbness, clumsiness when holding small objects or performing prehension grips, paresthesias in the median nerve distribution, and occasionally pain that radiates proximally. Symptoms of shoulder pain or upper arm pain are not uncommon.[26] Diagnosis is based on the history, a positive Tinel test result, direct compression tests, Phalen sign, manual muscle testing, sensation testing, upper limb tension tests, and extrinsic muscle length tests. The most commonly assessed outcomes include sensory functions, muscle functions, sensations of pain in the median nerve distribution, sleep functions, structure of the median nerve, structures of the area of the skin (ICF Body Structures and Functions impairments); self-care, domestic life, hand and arm use, fine hand use (ICF Activities limitations); and, participation in work and employment (ICF Participation restrictions).[63]

Conservative treatment for CTS is multifaceted and may include a variety of interventions. Review of conservative management has shown limited or no benefit to the use of nonsteroidal anti-inflammatory medications (NSAIDs). Oral corticosteroids show greater benefit than NSAIDs, but are associated with greater side effects.[59,64,65] Local cortisone injections have shown significant but short-term (<6 months) relief.[66,67] Night (and occasionally day) wrist splints positioned at 0 to 15 degrees of extension have been advocated (**Fig. 26-22**)[68–70] (**Evidence and Research 26-8**). Full-time splinting may be better than nighttime splinting only, but compliance may be difficult.[68] Splinting in neutral may be better than extension due to decreased tension on the median nerve in the neutral position.[69]

FIGURE 26-22 A wrist splint is used to rest the forearm and wrist musculature.

EVIDENCE and RESEARCH 26-8

A Cochrane review of the effectiveness of splints for CTS concluded that there is limited evidence that a splint worn at night is more effective than no treatment in the short term. While a number of studies reported significant improvement in outcomes following use of a night splint, the quality of these studies prevented firm conclusions on their efficacy.[71]

Exercise intervention for CTS has been shown to have limited effectiveness[51,52] (**Evidence and Research 26-9**). Therapeutic exercises focus on maintaining mobility and function without producing an exacerbation. Although not curative, therapeutic exercise may be beneficial for maintaining the integrity of associated soft tissues. Stretches for the extrinsic and intrinsic muscles are prescribed for several times each day (**Fig. 26-23**).[72] If working, a patient should perform them before work, on breaks, and after work. They should be performed slowly and gently; the patient should feel only a gentle stretching sensation. Differential tendon gliding exercises are performed to lubricate and increase gliding of the FPL, FDS, and flexor digitorumprofundus (FDP) tendons, all of which travel through the carpal tunnel. These are best performed with the hand elevated to concurrently control local edema. Carpal bone mobilization techniques may also be helpful in decreasing CTS symptoms.[73]

Median nerve gliding exercises and the upper limb tension test with median nerve bias can be used as treatment techniques, although research has not found consistent improvement in CTS with the addition of nerve gliding exercises.[58,75,76] The upper limb tension test with median nerve bias requires a position of shoulder girdle depression, shoulder abduction to approximately 110 degrees, forearm supination, wrist and finger extension, and shoulder lateral rotation.[1] After assuming this stretch position while standing, the patient should perform repetitions of elbow flexion and extension or wrist flexion and extension. Strengthening is generally not prescribed for patients with CTS who also have flexor tenosynovitis. If the precipitating factors have been eliminated and weakness creates a functional limitation, resistive exercises are closely monitored. The focus should be on balancing mobility and strength about the wrist.

EVIDENCE and RESEARCH 26-9

A Cochrane systematic review of exercise, neurodynamic mobilization, and carpal bone mobilization found limited evidence for the use of these interventions in people with CTS. The quality of the research in this area was very low, preventing any positive conclusions about the efficacy of these interventions.[74]

Patient education is a key intervention in the treatment and prevention of CTS. Patients are instructed to maintain a neutral upper extremity joint position during seated or standing work. This position is accomplished with the wrist in neutral, elbow flexed to approximately 90 degrees, shoulders relaxed in adduction, scapula slightly depressed and adducted, and the cervical spine positioned with the earlobe in line with the glenohumeral joint. The patient is also instructed to avoid a sustained pinch and grip, especially with the wrist in flexion, and to avoid repetitive overuse of the wrist and fingers. Patients should avoid direct pressure over the carpal tunnel by using a wrist rest or padded table edge or use a downwardly sloped keyboard. This type of keyboard has been shown to decrease the wrist extension angle and decrease muscle activity[77] (see Patient-Related Instruction 26-1).

Ergonomic intervention includes use of ergonomic tools that are padded with appropriately sized grips and handles. Data processing station revision should allow an adjustable chair height and keyboard height and tilt. Antivibration gloves are helpful for preoperative and postoperative carpal tunnel release to pad and protect the carpal tunnel and flexor tendons (**Fig. 26-24**).[75,78]

Patients treated acutely for CTS related to flexor tenosynovitis often respond well to conservative treatment without recurrence of symptoms if finger and wrist position and activities are monitored.[75] Conservative treatment is recommended for patients with transient symptoms and negative nerve study results. Patients who fail conservative treatment (usually a 3-month trial) often require carpal tunnel release surgery.[79] Studies have shown that the carpal tunnel increases in size with the release of the volar carpal ligament. Symptoms often improve immediately after surgery in mild to moderate cases. Because of the progressive nature of CTS, surgical outcomes appear to be improved by earlier surgical intervention (within 3 years of diagnosis). Carpal tunnel release offers good symptom relief for most patients.[80,81]

Cubital Tunnel Syndrome

Cubital tunnel syndrome is the second most common entrapment neuropathy in the upper extremity.[60] This syndrome is characterized by ulnar nerve pathology at the elbow in the absence of trauma. The cubital tunnel is formed by the medial epicondyle, olecranon, medial collateral ligament of the elbow, and a fibrous band called the arcade of Struthers.[82] Several muscles in the wrist and hand are innervated by the ulnar nerve, and the ulnar nerve provides sensation to the dorsal and volar ulnar side of the hand, the fifth finger, and the ulnar half of the fourth finger.

Ulnar nerve entrapment may produce nerve injury through ischemia or mechanical deformation of the nerve. These forces can occur from trauma to the elbow, external compression, repetitive elbow motion, osteophytes due to elbow osteoarthritis

FIGURE 26-23 Tendon gliding for flexor digitorum superficialis (FDS) and profundus (FDP). **(A)** Start; **(B)** glides FDS and FDP; **(C)** biases FDS; **(D)** biases FDP; **(E)** maximal FDS and FDP.

FIGURE 26-24 Antivibration gloves.

or prolonged elbow flexion. With elbow motion, normal nerve excursion has been reported to be as great as 10 mm. Traction on the nerve may occur with repetitive activities such as throwing. The nerve may also undergo increases in traction forces when its excursion is limited by posttraumatic adhesions.[38] As the elbow moves from extension to flexion, intraneural pressure in the cubital tunnel increases significantly (**Evidence and Research 26-10**). Pressure as high as 209 mm Hg has been recorded in a patient with cubital tunnel syndrome with elbow flexion and FCU contraction.[39]

EVIDENCE and RESEARCH 26-10

Studies of cubital tunnel pressure have found progressively increasing cubital pressure as the elbow moves into flexion, and the pressure increase has correlated with patient symptoms.[83–85] Additionally, ulnar nerve strain is increased when the shoulder is in internal rotation compared with a neutral position.[86]

Symptoms of cubital tunnel syndrome can include aching in the medial forearm and ulnar side of the hand. The aching can radiate proximally or distally. Paresthesias or anesthesias in the ulnar nerve distribution often accompany the pain.[39] Prolonged or repeated endrange elbow flexion tends to exacerbate symptoms. Functional activities eliciting symptoms include sleeping with the elbow flexed at night, combing the hair, driving, or holding the telephone. Leaning on the medial elbow can directly compress the ulnar nerve. Early in the syndrome, patients typically control the paresthesias by repositioning the elbow in a more extended position. As the syndrome progresses, activity limitations caused by motor changes cause activity limitations such as difficulty in turning keys, a weak grip and pinch, and dropping objects held in the ulnar side of the hand.

Focused physical examination techniques include Tinel testing over the ulnar nerve, provocative elbow flexion testing (including direct compression over the cubital tunnel), upper limb tension testing with ulnar nerve bias, observation of muscle bulk and clawing in the fourth and fifth digits, muscle testing, Froment sign, and sensory testing. The differential diagnoses include C8–T1 nerve root pathology, thoracic outlet syndrome, and compression of the ulnar nerve at Guyon canal.

Conservative management of cubital tunnel syndrome consists of eliminating all sources of external and dynamic ulnar nerve compression at the elbow, anti-inflammatory medication, elbow splinting in 40 to 60 degrees at night, elbow pads, and stretching exercises.[87] Stretching exercises focus on extrinsic flexor and extensor muscles along with ulnar nerve–innervated intrinsic muscle stretches. Nerve gliding techniques may be appropriate for patients with intermittent symptoms. The ulnar nerve's normal longitudinal excursion can be limited by adherence to adjacent structures. Nerve gliding can be achieved by assuming a modified ulnar nerve bias tension test position while standing.[88] This position requires shoulder depression and abduction, wrist extension, and forearm supination, followed by elbow extension.[1] Several repetitions of elbow or wrist flexion and extension can be performed. Due to rapid onset of ischemia with prolonged stretching, nerve mobilization performed intermittently is usually better tolerated than a prolonged stretch (**Fig. 26-25**).

Key adjunctive interventions are focused on patient education. Posture correction and proximal stretching or strengthening to maintain posture is indicated when the patient has faulty posture. Short pectoralis minor and weak scapular stabilizer muscles are often observed in individuals working at computers or on assembly lines. Although ADLs can be modified to allow rest of the involved arm, it is more challenging to modify work conditions. Use of the uninvolved arm is encouraged to wash and comb hair, eat, or perform any activity requiring prolonged or repeated elbow flexion. Use of a telephone headset is helpful in cases of frequent or prolonged telephone use. If conservative treatment of cubital tunnel syndrome does not reduce or resolve symptoms in 3 months, surgical treatment may be considered. In the absence of clinically identifiable sensory loss or muscle weakness, conservative treatment may be continued indefinitely in the form of a home exercise program. Ulnar nerve transposition surgery involves mobilizing the ulnar nerve at the ulnar groove and anteriorly transposing it subcutaneously, intramuscularly, or submuscularly to the flexor pronator muscle group.[89] This procedure is commonly performed as part of a reconstruction of the UCL.

FIGURE 26-25 Nerve gliding stretch with elbow extension, forearm supination, and wrist extension.

Radial Tunnel Syndrome

Radial nerve entrapment at the elbow, also called radial tunnel syndrome, is entrapment of the posterior interosseous nerve in one of five locations within the radial tunnel[90]:

- The entrance to the tunnel where fibrous bands encircle the nerve
- The leash of Henry, where the radial recurrent vessels supply the brachioradialis and the extensor carpi radialis longus (ECRL) muscles
- The fascia and medial portion of the ECRB tendon
- The arcade of Frohse
- Distally between the tendinous origins of the supinator muscle[91]

Radial nerve entrapment occurs much less frequently than median and ulnar nerve compressions. The annual incidence is estimated at 0.03%.[90] Radial nerve compression may be caused by direct trauma or anatomic structures compressing the nerve. Nerve compression commonly results from repetitive pronation and supination or wrist flexion and extension activities. Occasionally, a single strenuous effort initiates the problem, and subsequent repetitive motion perpetuates it.

The patient with radial tunnel syndrome often has symptoms similar to those produced by lateral epicondylitis and the two can coexist, complicating diagnosis and treatment.[92] Frequently, these persons have undergone unsuccessful treatment for lateral epicondylitis and use of tennis elbow straps may increase symptoms due to compression. The most common symptom is that of aching in the extensor supinator muscle mass that is distal to the lateral epicondyle, a nonspecific symptom that makes differential diagnosis difficult. Tenderness is approximately 2 to 3 in (5 to 7 cm) distal to the lateral epicondyle, with occasional pain radiating distally. No overt sensory deficits are found, because the posterior interosseous nerve contains only motor fibers. Imaging studies and electromyography and nerve conduction studies are typically normal.[90] The upper limb tension test with radial nerve bias may provide additional information. A brachial plexus or C7 nerve root injury should be excluded in the differential diagnosis.

Intervention for radial tunnel syndrome is initially conservative, followed by surgical decompression if conservative measures are not successful. Conservative measures include activity modification, anti-inflammatory medication, therapeutic exercise, and wrist cock-up splinting for 3 to 6 months. The goal of stretching is to restore full extrinsic wrist extensor and flexor muscle length and tendon excursion. If extensor stretches are painful, initial stretches can be performed with the elbow flexed and forearm supinated, followed by fisted wrist flexion. The exercise is progressed until full elbow extension and forearm pronation are achieved with fisted wrist flexion without forcing through pain. Radial nerve gliding techniques may be helpful to encourage adequate nerve gliding from the cervical spine to the wrist and hand level. Soft-tissue massage to the forearm flexors and extensors may help to relax involved muscles and improve the extensibility and circulation in the area. However, there are no randomized clinical trials examining conservative interventions for radial tunnel syndrome.

Upper extremity activities should be performed with the forearm in neutral to prevent prolonged stretching or overuse of the supinator muscle. This activity modification is particularly important in lifting tasks. Job rotation or diversification can prevent prolonged use of the extensor supinator muscle group.

Functional outcomes after conservative management of radial tunnel syndrome are difficult to determine because of the challenge in identifying the correct diagnosis, the relative rarity of the syndrome, and the frequent surgical intervention in clearly diagnosed cases. The clinician should be alert to radial tunnel syndrome as a differential diagnosis in cases of recalcitrant lateral epicondylitis. When radial tunnel is properly diagnosed, surgery is often the treatment of choice and produces good outcomes.[93] Patients commonly are seen postoperatively for scar and pain management, stretching, and strengthening programs.

Musculotendinous Disorders

Lateral Epicondylar Tendinopathy

Tendinopathy of the common wrist extensor musculature is the most frequent problem seen in the lateral elbow. The incidence of this syndrome in recreational and professional tennis players is 39% to 50%.[94] The prevalence of lateral epicondylar tendinopathy (LET) in the general population has been found to be approximately 1.3%.[95] Any individuals using hand tools for work or hobbies are susceptible to developing symptoms. The combination of continuous grip along with repeated wrist and elbow activity precipitates symptoms. Repetitively handling tools weighing >1 kg, repetitive movements, low job control, and low social support have also been shown to increase the risk of lateral epicondylitis.[96,97] Additionally, smoking has been found to be a risk factor for lateral epicondylitis.[95]

Wrist extension is accomplished by the combined actions of the ECRL, ECRB, and extensor carpi ulnaris. These muscles all originate on the lateral epicondyle and supracondylar ridge of the humerus. The lateral epicondyle is also the origin of the ED and extensor digiti minimi. Of the extensor muscles involved in LET, the ECRB is generally the greatest contributor to symptoms.[98] This is most likely due to its insertion along the central column of the hand, which is formed by the lunate, capitate and the third metacarpal. This creates the "keystone" of the longitudinal arch, rendering the ECRB as a frequent stabilizer. The wrist is stabilized by the extensors working in synergy with the flexors. Biomechanical models have shown that grasping and pinching tasks always produce a flexion moment at the wrist that must be countered by the wrist extensors. Many tasks requiring use of hand tools or writing instruments require wrist extensor activity. Because optimal hand function occurs when the hand is in a complete fist and the wrist is extended 15 to 20 degrees, the grip size of the implement and the resting posture of the wrist can have a great impact on producing and alleviating symptoms. These factors are important aspects of patient education.

Individuals with LET describe pain with any activity that requires gripping and lifting, such as shaking hands, lifting a carton of milk, or turning doorknobs. Use of hand tools, writing, and lifting bags also produce symptoms. Tenderness to palpation over the lateral epicondyle is common, and resisted wrist, middle finger, or index finger extension is painful. Despite these consistent findings in patients with LET, a number of factors will influence the intervention choices and the prognosis. Coomes et al.[98] have proposed an algorithm for the management of subgroups of patients with LET. Those in the low-risk subgroup may begin with a "wait and see" approach with general advice and education. If they do not improve with this regimen, they move into the moderate-risk subgroup. Here patients undergo a multimodal physical therapy program including relative rest/activity modification/advice, occasional bracing or taping, pain control, manual therapy, and therapeutic exercise. If no better following appropriate physical therapy, then diagnostic imaging to confirm LET is performed, and additional adjunctive treatment, work/activity modification, and surgical/medical referrals are considered.[98,99]

Multimodal intervention includes isometric, concentric, and eccentric exercise, combined with manual therapy.[99] Strengthening should focus on the role of the wrist extensors in upper extremity function. The wrist extensors function to stabilize the wrist against the wrist and finger flexors as well as functionally extending the wrist. Because the wrist extensors work during wrist extension and gripping, the clinician must approach use of handheld weights cautiously. The initial strengthening program may include gripping and wrist extension as separate exercises, gradually progressing to concurrent wrist extension and gripping (**Fig. 26-26**). Depending on the symptoms, the program may begin with isometric muscle contractions and progress to dynamic concentric and eccentric exercises. Wrist exercises may begin in a flexed elbow position to decrease tension on the common extensor tendon at the elbow.

There is a growing body of literature supporting the use of eccentric exercise in the treatment of tendinopathy.[100–103] It is theorized that chronic tendinopathy-related pain may be due to neovascularization that occurs in this disorder. The eccentric exercise is suggested to hinder the angiogenesis found with chronic tendinopathy. A growing body of research is examining the effectiveness of different exercise regimes on outcomes in LET. In general, it is difficult to conclude that one type of muscle contraction is superior to others due to differences in dosage parameters (**Evidence and Research 26-11**). Differences in outcomes are not only related to exercise dosage, but also to complicating factors such as the extent of tendon damage, severity and duration of symptoms (possibly associated with central sensitization), associated neck or other arm pain, motor control impairments, work-related factors, and psychosocial impairments.[98]

Adjunctive interventions include therapeutic modalities such as ice, cross-friction massage, prolotherapy, patient education, and bracing. Bracing may include a counterforce brace such as a tennis elbow strap or a wrist splint (**Fig. 26-27**). A counterforce brace decreases loads on the extensor origin by creating a new origin of the muscle that bypasses the inflamed portion of the tendon. A wrist splint can limit wrist extensor

FIGURE 26-26 Wrist extension exercises using a band. **(A)** Without grip. **(B)** With grip.

EVIDENCE and RESEARCH 26-11

Recent literature reviews suggest that strength training is effective for treating LET. Peterson et al.[104] studied 120 subjects with LET and found that those treated with eccentric exercise decreased pain and improved muscle strength more effectively than those treated with concentric exercise. Olaussen et al.[105] randomized 177 (157 completed) subjects into three different groups (physiotherapy with two corticosteroid injections, physiotherapy with two placebo injections, or wait-and-see). The corticosteroid plus physiotherapy group had a 10.6× greater odds of success than the placebo plus physiotherapy group at 6 weeks, a benefit that was lost by 12 weeks. By 52 weeks, there was no clear benefit to any group. Cullinane et al.[106] found the addition of eccentric exercise to a multimodal program for LET to be beneficial. However, eccentric exercise was not compared against any other type of exercise.

FIGURE 26-27 Tennis elbow strap.

activity necessary by providing an external stabilization to the wrist. Patient education regarding home and work ergonomics should be provided. Lifting with the forearm supinated and the elbow flexed decreases wrist extensor muscle activity. Tasks should be modified to limit repetitive elbow and wrist motion when possible.

When conservative management of lateral epicondylitis fails, surgical management, typically consisting of debridement of scar tissue, may be considered. Good documentation and appropriate follow-up care are necessary to ensure that all conservative measures have been appropriately exhausted before surgery is considered.

Medial Epicondylitis

Medial epicondylitis is encountered less frequently than lateral epicondylitis and accounts for 10% to 20% of all epicondylitis cases.[39] Its prevalence in the general population has been estimated at 0.4%.[95] The muscles involved are the flexor pronator group, including the FCR, palmaris longus, PT, and FCU. Repetitive wrist flexion at work or in recreational activities such as golf or fly fishing subject the common wrist flexors to overuse. Repetitive movements, high hand grip forces, and working with vibrating tools have been associated with medial epicondylitis.[52,97] Smoking, obesity, repetitive movements, and forceful activities are also significantly associated with medial epicondylitis.[95] Approximately 20% of cases are associated with concurrent ulnar nerve symptoms.[107] Affected persons usually describe pain at the medial epicondyle with resisted wrist flexion and forearm pronation. Passive stretch into extension and supination also may reproduce symptoms.

Management of medial epicondylitis is conservative, with a focus on controlled activity matched with appropriate rest, stretching and strengthening exercises, and interventions to reduce pain and inflammation.[108] Therapeutic exercises include

FIGURE 26-28 Wrist flexor stretch.

stretching for the flexor and pronator muscles, as long as stretching does not reproduce elbow symptoms (**Fig. 26-28**). As symptoms resolve, a progressive strengthening program with an emphasis on the demands specific to the individual patient is implemented. Like LET, similar symptoms at the medial elbow can be successfully treated with isometric, concentric, and/or eccentric exercise.[109] Braces are not as commonly used in the case of medial epicondylitis as compared to LET. When conservative management fails, surgical resection of the diseased portion of the tendon may be undertaken.[107]

de Quervain Syndrome

de Quervain syndrome, also called stenosing tenosynovitis, is an inflammation of the tendons of the first dorsal wrist compartment. The muscles in this compartment are the EPB and APL; they share a tendinous sheath. The most common cause is overuse of the hand and wrist, particularly in movements requiring radial deviation while the thumb is stabilized in a grip.[110] An example is a hairdresser using scissors to cut hair. Women are affected about 3 to 10 times more often than men.

Persons with de Quervain syndrome notice pain on the radial aspect of the wrist in the region of the radial styloid. Flexing the thumb across the palm is quite painful, especially when combined with ulnar deviation. In addition, resisted extension and abduction may be painful as well. Palpable tenderness and bogginess may be noticed over the tendons of the first compartment. Radial and ulnar deviation may produce clicking or pain. The Finkelstein test is the most commonly used test to diagnose de Quervain syndrome. Measurements may reveal that pinch and grip are weak and painful.

A Delphi panel recommended instructions, splinting, NSAIDs, corticosteroid injections, and surgery as primary interventions.[111] Adjunctive interventions included exercise therapy and kinesiotaping. Therapeutic exercise intervention for de Quervain syndrome includes stretching for the EPB and APL and the extrinsic wrist flexor and extensor muscles. Strengthening should be initiated after full pain-free ROM has been achieved. Strengthening includes the thumb and wrist musculature and full gripping exercises. To prevent further overuse to these tendons during the initiation of a rehabilitation program, immobilization using a forearm base thumb spica splint may be necessary. The splint should be worn during symptomatic times or periods of high activity. The splint is removed to perform exercises throughout the day.

Other adjunctive measures include advice and patient education about pain, function, and activity modification.[111] Work, hobby, or sport modifications to decrease the frequency and forces involved in wrist and thumb motion may be necessary to allow the rehabilitation program to succeed. Therapeutic modalities to reduce inflammation such as ice and iontophoresis may be helpful. The physician may place the patient on an anti-inflammatory medication, inject the area with steroid or analgesic medication, or surgically release the first dorsal compartment. Patient education to avoid or limit situations contributing to the symptoms is essential to prevent recurrence.

Trigger Finger

Trigger finger is a result of thickening of the flexor tendon sheath. Thickening causes catching of the tendon as the finger actively flexes.[17] The flexor tendons of the fingers have an intricate anatomy that includes a synovial sheath extending from the mid-metacarpal area to the DIP joints. Overlying the sheath is a series of annular and cruciform fibrous bands or pulleys. These pulleys hold the flexor tendons close to the metacarpals and phalangeal bones, thereby improving the efficiency of motion. Thickening of the sheath at the A-1 pulley (i.e., fibrous band that overlays the synovial sheath at the MCP joint level) and enlargement of the flexor tendons are the basis for the symptoms found with this condition. This thickening may be caused by repetitive trauma or by direct pressure over the MCP joint in the palm, as when grasping.

Impairments associated with trigger finger include pain and tenderness in the finger from the volar MCP to the PIP level and intermittent triggering or "snapping" of the finger. The triggering usually occurs with flexion, and it may require passive assistance to fully extend the finger.

Intervention for trigger finger is usually conservative and involves active IP flexion and tendon gliding exercises on an hourly basis. Splinting is common, and the hand-based splint or digital splint holds the MCP joint at full extension while leaving all other joints free. The splint is worn at all times for 1 to 3 weeks. Thereafter, it is worn for periods of high activity. The splint prevents triggering at the A-1 pulley and rest to minimize inflammation. The physician may inject into the synovial sheath at the level of the A-1 pulley to decrease local inflammation. Corticosteroids are commonly injected, besides NSAIDs and hyaluronic acid injection options.[112]

If conservative management is unsuccessful, surgery may be performed to release the A-1 pulley. Postoperative therapeutic intervention includes the same active exercise program and potential splinting as conservative management. Progressive grip strengthening may be required to return the patient to full functional use of the hand for work and ADLs. Education and work modification to avoid or limit repetitive grasping and releasing activities of the hand also are necessary.

Tendon Laceration

Tendon lacerations and repair require a complex series of treatments that must account for wound healing, tendon healing, and surgical techniques. Tendon repair treatment is complicated by the need for tendon excursion to prevent adhesions while allowing stability and protection to the healing tendon. Controlled motion helps prevent tendon adhesion, which limits motion and therefore limits function. Too much motion may compromise the repair. The clinician must provide a system of controlled motion, based on physician preference, surgical technique, mechanism of injury, and patient adherence

The extensor tendons are divided into eight zones that determine treatment protocol used. Because of the extensiveness of each protocol, we review only the highlights for each zone (**Fig. 26-29A**).[113] In zones I and II, laceration causes a mallet finger. A mallet finger splint is fit to the patient's DIP joint in 0 to 15 degrees of hyperextension from postoperative day 1 through 6 weeks. The PIP joint is left free to allow movement at the PIP level and proximally. The DIP joint should not be allowed to flex during this time. AROM exercises at the PIP joint are initiated at 4 to 6 weeks with flexion to 25 degrees. Strengthening is started at 6 to 8 weeks with monitoring for an extensor lag. If a lag is present, the patient returns to wearing the splint and AROM.

For zones III and IV, a digital gutter splint is fabricated to include the DIP and PIP joints (MCP is left free) at 2 weeks after surgery. If the lateral bands were not repaired, mobilization of the DIP may begin at 10 to 14 days. If the lateral bands were repaired, the DIP should be immobilized for 4 weeks. The PIP joint may be immobilized for up to 6 weeks. At 6 to 8 weeks, AROM is begun, with progressive flexion and extension exercises. Treatment must be modified if an extensor lag develops and will be individualized based upon consultation with the hand surgeon. Gentle strengthening is begun after 8 weeks.

For zone V (distal to tendineae junctionae), a hand-based splint is custom fabricated at 3 days to 1 week. This hand-based splint holds the MCP in 70 to 80 degrees of flexion and the digit in full extension. This position prevents contracture of the lateral bands at the MCP. AROM, passive ROM (PROM), and strengthening are continued as for zones III and IV.

For zones V (proximal to tendonae junctionae), VI, VII, and VIII, a volar forearm splint is fabricated at 3 to 5 days postoperatively. This splint extends from just proximal to the PIP joint, crosses the MCP joint, and continues two-thirds of the way up the forearm, with the wrist positioned in 30 degrees of extension. This allows controlled movement of the extensor tendons through PIP and DIP joint movement, which prevents tendon adhesions. AROM, PROM, and strengthening exercises are continued as for the more distal zones.

Flexor tendon repairs also rely on zones to determine the appropriate protocol. There are five flexor tendon zones (see Fig. 26-29B). Current treatment protocols focus on controlled motion to prevent scar adhesions that limit functional movement. They also rely on the use of a dorsal blocking splint to prevent disruption of the surgical repair. This dorsal blocking splint is custom fabricated with the wrist in 20 degrees of flexion, the MCPs in 50 degrees of flexion, and the PIP and DIPs in full extension (**Fig. 26-30**).[43]

The program for zones I, II, and III consists of passive flexion and extension motion at the PIP and DIP joints and composite passive flexion and extension at the MCP, PIP, and DIP joints within the confines of the splint. This program is started on postoperative day 1 or 2 and continued through week 5.[43] AROM is started at 3½ weeks, PROM into extension is begun at 6 weeks, and strengthening is started at 8 weeks. Full functional use is allowed at 10 to 12 weeks postoperatively. The program for zones I, II, and III uses the dorsal blocking splint

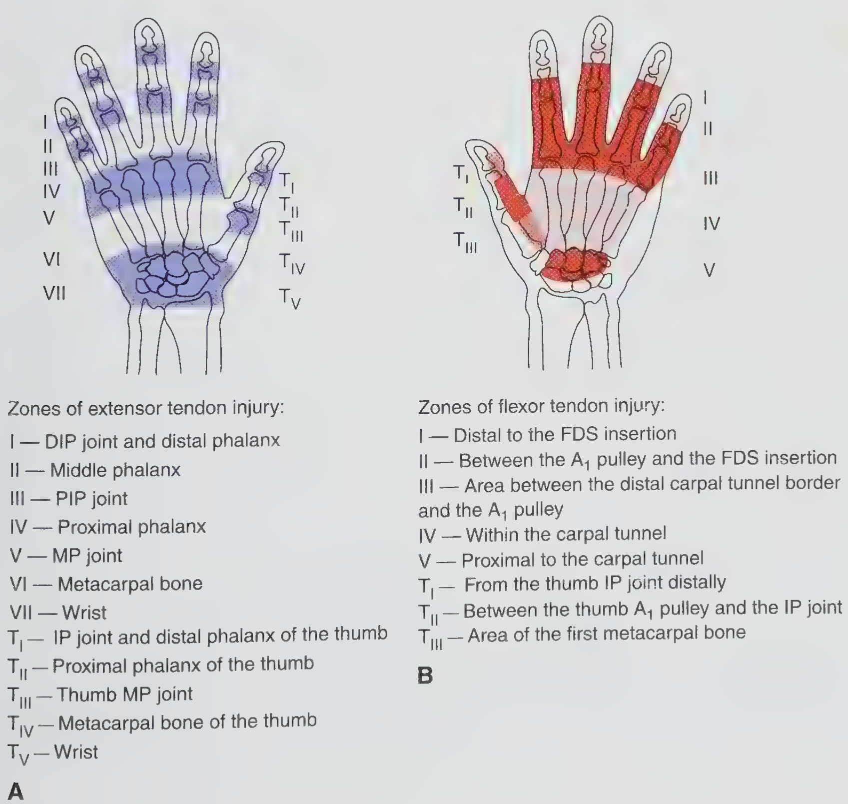


FIGURE 26-29 **(A)** Extensor tendon zones of the hand. **(B)** Flexor tendon zones of the hand.

FIGURE 26-30 A dorsal blocking splint.

with rubber band traction. The addition of a palmar pulley allows for greater FDP tendon excursion. The rubber band traction holds the digit into near full composite flexion, and the patient is instructed to extend the finger against the force of the rubber band to the dorsal blocking splint. The patient is instructed to do this 20 to 30 times per hour. This protocol is initiated 2 to 6 days postoperatively. AROM is started 5 weeks postoperatively, with PROM into extension started 7 to 8 weeks postoperatively. Strengthening is performed after 8 weeks.[43] The outcomes for flexor tendon repairs with early active mobilization are good.[114–117] **Table 26-7** provides guidelines following flexor tendon repair. However, current clinical practice patterns vary widely and often differ from those reported in the literature[117] (see Table 26-7).

TABLE 26-7

Flexor Tendon Repair Postoperative Protocol with Early Passive Motion

STAGE	PRECAUTIONS	GOALS	INTERVENTION
Early: weeks 1–3	No active flexion No wrist motion Active extension only to DBS Splint at all times	Protect healing structures Decreased edema and pain Minimize tendon adhesion Full protected IP joint extension Decreased PIP joint contracture Maintain ROM of uninvolved joints HEP independence	*Dorsal Blocking Splint*: Wrist flexion 20–30 degrees MP flexion 60–70 degrees IPs 0 degree Dynamic traction of fingers into flexion Palmar pulley at DPC to attain increased IP flexion Night block to hold IPs in extension *Exercise*: 1. Active extension to DBS with passive flexion 2. Protected PROM 3. Edema control 4. Scar massage 5. Sensory education
Intermediate: weeks 3 or 4–6	Guarded AROM No composite digit and wrist extension No passive composite extension Protect repaired pulleys	1. Protect healing structures 2. Decrease edema and pain 3. Restore tendon glide 4. Decrease scar adherence 5. Restore PROM of restricted joints 6. Maintain ROM of uninvolved joints 7. Gradually increase active/passive extension to full range	1. Gentle AROM 2. Isometric exercise 3. Active assisted flexion 4. Progress to tendon gliding exercise *Blocking exercise*: (if tendon restricted) FDS at 4 wk. FDP at 6 wk. *Splinting* with wrist in neutral to increased extension 5. Edema control 6. Scar management 7. Progress to light prehensile activity
Late: weeks 6–12	Prevent tendon rupture Prevent tenosynovitis of repaired tendons	1. Maximize full tendon glide and musculotendinous length 2. Maximize grip and pinch strength 3. Resume work and avocational activity	*Splinting*: 1. Phase out of protective splint 2. To decrease contractures 3. To increase excursion of long flexors or extensors *Exercise*: 1. Blocking, if needed 2. Isolated FDS glide 3. Muscle tendon unit stretching 4. Sustained gripping 5. Progress to strengthening Gradually resume full ADLs, return to work and avocational activities

DBS, dorsal blocking splint; IP, interphalangeal joint; PIP, proximal interphalangeal joint; ROM, range of motion; HEP, Home exercise program; DPC, dorsal palmar crease; PROM, passive range of motion; AROM, active range of motion; FDS, flexor digitorum superficialis; FDP, flexor digitorum profundus; ADLs, activities of daily living.

For zones IV and V, both protocols are overall as previously delineated, but they progress faster. AROM is initiated at 3 weeks within the dorsal blocking splint. AROM out of the splint occurs at 4 weeks. PROM into extension and strengthening is initiated at 6 weeks. A four-strand suture technique allows controlled active movement beginning on postoperative day 2. A wrist-hinged dorsal blocking splint is used to allow a tenodesis movement in which the digits are held at the end range by active digit contraction. PROM may be used to achieve full composite flexion. This splint and active motion is continued until week 8, with full active and passive exercise and strengthening started at that time.[43]

Bone and Joint Injuries

Injuries to the bones and joints of the elbow, wrist, and hand can cause significant impairments, activity limitations, and participation restrictions. Fractures of the hand are the most common fractures in the body.[118] Fracture management requires an understanding of the fracture's stability, healing process and potential, and need for surgery to establish stability and healing potential.[119] It is essential that these injuries are properly evaluated and appropriate interventions applied.

Medial Elbow Instability

Medial elbow instability is seen in children and adults, and is found most often in individuals involved in throwing. High forces on the medial elbow structures during the cocking and acceleration phases of throwing can result in attenuation and rupture of the static ligamentous structures. During the acceleration phase of throwing, elbow extension speeds can reach 2,300 degrees per second.[120] In the adult, acute rupture of the UCL can occur. More often, continued valgus loading and loss of dynamic muscular support places loads on the UCL, leading to gradual instability. Progressive instability can lead to rupture or tension of the ulnar nerve. In some cases, this progressive instability and load on the ulnar nerve leads to surgical reconstruction of the UCL. Approximately 25% of major league pitchers and 15% of minor league pitchers have a history of UCL reconstruction.[121] The majority of these athletes successfully return to their previous level of sport.[122,123] **Table 26-8** provides

TABLE 26-8

Rehabilitation Guidelines Following UCL Reconstruction

PHASE	PRECAUTIONS	GOALS	INTERVENTIONS
Early: weeks 4–6	Brace: Week 1: immobilization fixed at 90 degrees Week 2: hinged brace from 30 to 100 degrees Week 3: hinged brace from 15 to 100 degrees Week 4: hinged brace from 10 to 120 degrees	1. Protect healing tissues 2. Decrease pain and inflammation 3. Prevent muscular atrophy 4. Initiate elbow ROM	1. Gentle A/AAROM for elbow and wrist 2. Gentle mobility to achieve ROM goals 3. Submaximal isometric for shoulder IR, abduction, elbow flexion and wrist flexion/extension at week 2 4. Gripping exercise 5. Cervical spine and shoulder ROM
Intermediate: weeks 6–12	Week 5: hinged brace from 0 to 130 degrees Week 6: discontinue brace except in risky environments Avoid all valgus positions and minimize valgus stress to elbow during rehabilitation	1. Increased ROM to nearly full ROM by week 10 2. Prevent re-injury 3. Increased total arm strength	1. Gentle A/AAROM for elbow and wrist 2. Light dynamic resistance for shoulder IR, abduction, elbow flexion and wrist flexion/extension 3. Scapular strengthening and stabilization 4. Core, hip, and lower extremity strengthening 5. Continued upper quarter mobility
Late: weeks 12–20	No pain with strengthening exercises Postexercise pain should be minimal and resolve within 24 hr	1. Maximize shoulder strength in key muscle groups and functional activities 2. Increased distal muscle function and strength	1. Shoulder and elbow strengthening in functional movements and activities, controlling valgus force at elbow 2. Progressive scapular strengthening 3. Rhythmic stabilization for elbow and shoulder with progressively less protected positions 4. Core, hip, and lower extremity strengthening 5. Address any remaining impairments
Return to activity: weeks 20–36	No pain with strengthening or functional progression; postexercise pain should resolve within 24 hr	1. Good dynamic neuromuscular control in functional activities 2. Biomechanically sound functional activities to minimize medial elbow stress 3. Return to pain-free activity	1. Multi-joint, multi-plane strengthening program 2. Shoulder and elbow strength and stabilization drills, specific to work or sport 3. Plyometric program using ball or other tools specific to the work or sport tasks 4. Functional progression, including interval throwing program in thrower, or other sport- or work-specific activities

UCL, ulnar collateral ligament; ROM, range of motion; A/AAROM, active/active assisted range of motion; IR, internal rotation.

guidelines for rehabilitation following UCL reconstruction. However, rehabilitation to the level of competitive sports such as baseball requires additional consideration of the demands of these sports.[123,124]

In the child or adolescent, medial elbow instability is commonly known as "little league elbow." The growth plate and associated ligamentous and tendinous structures are at risk until the fusion at the growth plate is complete, which occurs roughly at age 14 to 15 years.[125] In the child, the valgus stress on the medial side of the elbow is countered with a compressive force on the lateral side at the radiocapitellar joint. This can lead to compression and shearing of the radial head on the capitellum. Osteochondrosis of the capitellum can occur with loose body formation (**Evidence and Research 26-12**).

EVIDENCE and RESEARCH 26-12

A number of factors predisposing young baseball players to elbow injuries have been found including: age older than 11 years, height, pitching position, number of days of training, grip strength, arm fatigue, and shoulder external rotation range of motion.[126–128] Matsuura et al.[129] found that of the 449 youth baseball players (ages 7 to 11 years) studied, 30% reported an episode of elbow pain during the season. Of these, 72% had abnormal elbow examinations and 81% had radiographic abnormalities.

Treatment of the child or adult with valgus instability depends on the pathologic stage. Controlled rest is essential, along with strengthening exercises for the involved musculature. Dynamic support of the medial elbow to minimize loads on the static structures is a critical component of the treatment program. This approach includes strengthening the trunk, shoulder, elbow, forearm, and wrist muscles (**Fig. 26-31**). Proximal weakness can transfer loads distally, and a rotator cuff problem can produce instability problems at the elbow. In addition to strengthening, consideration of throwing form and the throwing schedule (e.g., number of throws, games, innings) is important to prevent a recurrence of the problem.

FIGURE 26-31 Therapeutic exercise on a ball, weightbearing on the upper extremity to strengthen in a closed chain.

Elbow Dislocations

Elbow dislocations are second in incidence only to dislocations of the shoulder in the adult population with an annual incidence of 5.2/100,000.[130] The elbow is the most frequently dislocated joint in children younger than 10 years of age.[131] Elbow dislocations are classified by the direction of movement of the radius and ulna on the humerus, and most are posterior. Elbow dislocations are also classified as "simple" where only a dislocation occurs and closed reduction is successful, and "complex" where the dislocation may be associated with a fracture, and surgery may be necessary. A fall on an outstretched hand or hyperextension are the most common mechanisms of injury. Dislocation also can injure the UCL, the lateral collateral ligament, the anterior capsule, and common flexor and extensor muscle origins or fracture the medial epicondyle. The ulnar, median, or radial nerves may be injured. After dislocation, the elbow is reduced (and stabilized if necessary) and may be immobilized for 1 to 3 weeks due to concerns of long-term instability. Stabilization can be in a hinged external fixator or cross-pinning with supplemental cast immobilization. Both interventions have yielded similar ROM outcomes, while external fixation has been associated with higher complications.[132,133] Other research shows that patients with simple dislocations randomized to early mobilization returned to work earlier and had improved early ROM compared with a group immobilized for 3 weeks.[134] Patients in the early mobilization group used a sling for comfort the first week and performed AROM within comfort limits starting at day 2. No passive stretching was performed for the first 3 weeks.

Impairments after dislocation include loss of motion, pain, inability to produce torque, potential instability, and occasionally neurovascular problems. Restoration of full motion may be difficult and should be a priority in the treatment program. Many patients retain a residual loss of extension of 10 to 15 degrees, and full recovery of motion and strength takes 3 to 6 months for most patients.[135]

Intervention after dislocation includes AROM and active assisted range of motion (AAROM) initiated 2 to 7 days after the dislocation and PROM 3 weeks after the dislocation. Motion should be performed in a variety of shoulder positions with some describing an overhead position to improve congruency and stability in the early healing phase.[130] Dynamic splinting may be necessary to restore motion. Prefabricated splints are available to restore flexion or extension. A static night splint can maintain current range if a dynamic splint cannot be tolerated all night. Caution is necessary to avoid overly aggressive PROM, because it may contribute to heterotopic bone formation. Individuals with head injuries or those with a combined fracture dislocation with prolonged immobilization face the greatest risk of heterotopic bone formation, particularly in the brachialis muscle.

Isometric muscle contractions are initiated early and progressed to dynamic contractions as tolerated (**Fig. 26-32**). Open and closed chain exercises and proprioceptive neuromuscular facilitation techniques are useful for restoration of function. If instability is present, a hinged elbow support with extension blocks may allow functional use of the elbow within a limited range. Exercises are performed throughout the day, in or out of the brace. If the patient has hypomobility, joint mobilization techniques can help restore full elbow and forearm mobility (see Chapter 7). Patients undergoing surgery for chronic elbow instability need to initiate rehabilitation immediately after surgery and continue for at least 6 months to obtain the best outcome.[136]

Carpal Instability

The bony and ligamentous anatomy of the wrist is intricately balanced to allow for concurrent flexibility and stability. Williams et al.[9] observed that the carpal bones are spring loaded like a jack-in-the-box and kept under control by ligament restraints. The palmar ligaments are very substantial compared with the dorsal wrist ligaments. An area between the capitate and lunate where no ligamentous support is maintained is an area of potential weakness. A fall on an outstretched hand can result in damage to the scapholunate ligament and produce instability. This instability may result in dislocation of the lunate where its dorsal surface faces dorsally, called *dorsal intercalated segment instability*. Injury resulting in a volarly facing distal lunate is called *volar intercalated segment instability*.

Many types and descriptions of static and dynamic carpal patterns exist. *Static instability* patterns demonstrate radiographic changes such as abnormal gapping between carpal bones. A static instability generally indicates a significant injury such as a complete ligament tear. Dynamic instability patterns are detected during the physical examination or with special imaging techniques. *Dynamic instability* patterns generally indicate increased laxity or partial ligament tears.

Scapholunate dissociation (SLD) is the most common form of carpal instability and occurs when ligaments from the proximal pole of the scaphoid are torn. This injury can occur from a fall on an extended, ulnarly deviated wrist; degeneration resulting from RA; a direct blow to the wrist; or in association with a distal radius fracture, carpal fracture, or carpal dislocation. Scapholunate instability is the most frequent cause of carpal instability and accounts for a large proportion of impairments, activity limitations, and time lost from work.[137] The severe form of instability is termed the SLAC (scapholunate advanced collapse) wrist and may be the result of the undetected or untreated injury. Isolated injury to the scapholunate interosseous ligament may be difficult to detect with standard clinical examination or radiographs, and may be the first step in progressive decline to degenerative changes (**Fig. 26-33 A** and **B**)[137] (**Evidence and Research 26-13**).

Impairments associated with a SLD include point tenderness over the involved ligament, swelling of the dorsal wrist, pain or limited AROM and PROM of the wrist, a painful click or clunk with radial deviation, grip weakness, and decreased wrist and hand function because of pain. In addition to routine examination procedures such as documentation of pain with rest and functional activities, ROM, and strength of the forearm, wrist, and hand musculature, the clinician should assess grip and pinch

FIGURE 26-33 **(A)** Scapholunate advanced collapse (SLAC) wrist before surgery. **(B)** SLAC wrist after proximal row carpectomy.

EVIDENCE and RESEARCH 26-13

A recent study calls into question the assumptions about SLD and its prognosis.[138] In a study of 124 patients, the majority were unable to recall any specific wrist injury. While the majority had pathologic measurements on radiographs on their symptomatic side, on the asymptomatic side, 52% of the gap measurements and 70% of the angle measurements were pathologic. While 80% had abnormal radiographs bilaterally for at least one of the variables, only 11% had a clinical instability pattern typical of SLD and 50% had degenerative changes. Thus, the recommendations for interventions based upon radiographs and the assumptions about progression to arthritis should be reexamined.

strength. Grip strength is performed with a dynamometer at the standard setting, with five settings used to demonstrate a bell-shaped curve and rapid alternating grip strength. Lateral and three-point pinch strength is also assessed.

Severe instabilities are treated with surgical reduction and ligament reconstruction. Fusions may also be performed for a number of carpal instability patterns. After surgery or for mild cases of instability, the patient is referred for rehabilitative management.[137,139]

Therapeutic exercises for carpal instability include grip and pinch strengthening exercises. Putty exercises and isolated muscle strengthening exercises are incorporated to restore strength and dynamic function throughout the region. With a lunate dislocation and ligament injury, a painful grip may indicate instability leading to lunate destruction. In this situation, grip strengthening should be avoided. Any mobility deficits are treated with AROM, PROM, and AAROM.

Intervention for carpal instability also includes protective splinting of the wrist. The thumb MCP is included in cases of scaphoid involvement, such as SLD. If the ligament disruption is on the ulnar side of the wrist, a wrist cock-up or ulnar gutter splint suffices. Therapeutic modalities may be used for pain and inflammation, and patient education is a critical component of successful management.

Ulnar Collateral Ligament Injuries of the Thumb

The MCP joint of the thumb functions primarily in flexion and extension because of the condyloid shape of the joint surface. Small degrees of abduction, adduction, and rotation also occur. Tautness in the UCL limits abduction and extension and adds stability to the joint in a functional position. However, this functional position also places the UCL at risk of injury. The most common injuries to the thumb MCP involve the UCL.

Skier's thumb, or an acute sprain (macrotrauma) to the UCL of the MCP joint, is the result of abduction or hyperextension forces. This injury occurs frequently in skiing when a fall catches the thumb in the strap of the ski pole, pulling the thumb into abduction. Complete ruptures lead to instability and significant disability. Gamekeeper's thumb is an overuse injury resulting from repetitive microtrauma in the form of valgus stress to the MCP joint, similar to the repetitive valgus stress at the elbow seen in throwers.[140,141]

A thorough examination, with valgus stress performed in extension (collateral ligament and volar plate) and flexion (collateral ligament only), should be done to differentiate partial from complete tears due to differences in treatment based upon severity. Impairments associated with gamekeeper's thumb include tenderness along the ulnar aspect of the MCP joint, localized edema, and instability of the joint. Clinically, joint instability manifests as difficulty gripping items, particularly with a spherical or cylindrical grip.

Rhee et al.[140] have outlined an algorithm to guide treatment of UCL injuries. For those injuries with significant laxity or displaced or rotated fractures, operative repair offers the best outcome. For injuries with equivocal exams, advanced imaging is recommended followed by operative treatment of complete ruptures and conservative management of incomplete ruptures.

Treatment of partial tears requires immobilization in a thumb spica cast for 4 weeks depending upon the degree of injury, followed by a thumb spica splint (**Fig. 26-34**). The splint is removed throughout the day to allow exercise of the wrist and hand, and ensuring appropriate mobility of the IP joint.[142] Athletes are allowed to compete if their sport allows use of a splint. At 4 weeks, formal therapy is initiated, with strengthening at 6 to 8 weeks and return to full activity at 12 weeks.

Acute grade III injuries with instability require surgical stabilization. For patients with chronic UCL instability, surgical reconstruction is advised.[143] Both of these procedures demonstrate excellent outcomes. Therapeutic exercise after immobilization after surgical and nonsurgical treatment include pain-free thumb MCP flexion and extension and gradually adding pain-free rotation and opposition. After 4 to 6 weeks, grip and pinch strengthening exercises are initiated with putty or gripper equipment (see **Self-Management 26-5**). Lateral (key) pinch is initiated, but the patient should be instructed to limit or avoid tip pinch stress until 6 to 8 weeks. Exercises should be progressed to activities pertinent to the patient's lifestyle as quickly as possible within the constraints of healing.

SELF-MANAGEMENT 26-5
Thumb Press

Purpose: To increase the strength of your thumb muscles

Starting Position: Form the putty into a barrel shape, and place it in the palm of your hand, resting against your thumb.

Movement Technique: Press your thumb into the putty with as much force as is comfortable until your thumb has pressed through the putty into your hand. Reshape the putty and repeat.

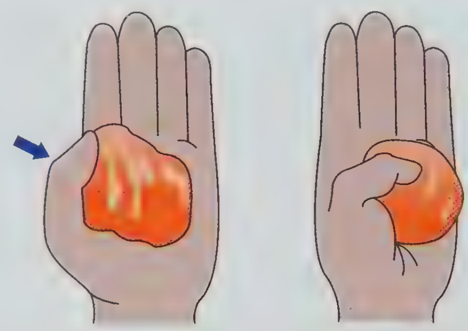
Frequency: ______________________



Olecranon Fractures

Olecranon fractures are generally the result of a direct blow or a fall. A fall on an outstretched hand with the elbow in flexion, followed by a strong contraction of the triceps, can cause an olecranon fracture. A nondisplaced fracture is immobilized in 45 to 90 degrees of flexion for a short time. A displaced fracture may be treated with open reduction and internal fixation (ORIF) using tension band wiring or plate and screw fixation. A small comminuted fracture may be excised with reattachment of the triceps tendon. Excision of loose bodies is required during surgery to prevent a loss of mobility from these fragments. The impairments seen after fracture or surgery are pain, limited ROM, and loss of the ability to produce torque. Because of the close proximity of the ulnar nerve to the olecranon, it is vulnerable to injury. Close examination is necessary to assess the status of the nerve.

FIGURE 26-34 Thumb spica splint.

Intervention after fracture begins with AROM in a forearm neutral position. AROM and AAROM may be initiated as early as 2 days after fracture. These individuals usually are immobilized, and the immobilization is removed for ROM activities. The length of immobilization is decreased for the elderly, and ROM exercise is initiated sooner.[144] AROM is progressed to PROM and stretching.

The biceps muscle often shortens because of the flexed elbow position during immobilization or protection periods. Suggested forms of exercise to restore muscle length include elbow and shoulder extension, walking with a normal arm swing, and contract-relax stretching.

The adaptive shortening may result in weakness, and strength should be addressed concurrently. Suggested strengthening exercises include isometric contractions throughout the available range for all major muscle groups, resistive band exercises for shoulder musculature, resisted elbow flexion in a variety of forearm positions, resisted elbow extension, and resisted wrist and forearm exercises. A stationary bicycle with combined arm movements or a cross-trainer allowing repetitive elbow flexion

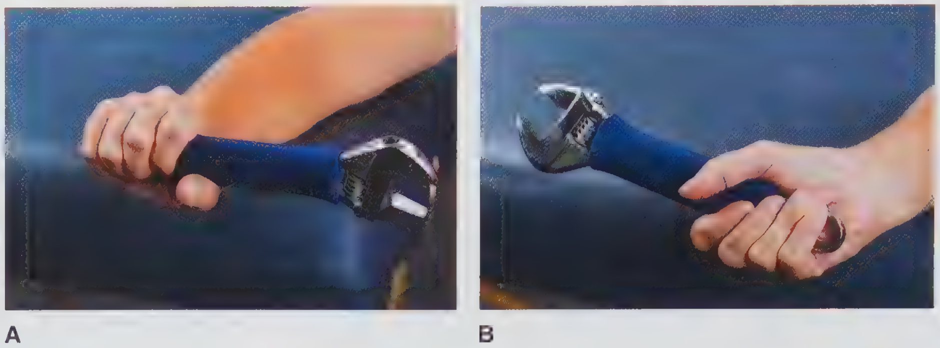


FIGURE 26-35 Range of motion of the forearm using a household object such as a wrench or hammer. **(A)** Supination. **(B)** Pronation.

and extension is helpful to restore motion and strength. If forearm rotation strength is limited, a light hammer can be used to train pronation and supination (**Fig. 26-35**).

Adjunctive interventions include elevation, ice, and active shoulder, wrist, and finger exercises to control edema. Scar massage should be initiated early after surgical stabilization. Generally, the scar is mature enough to tolerate massage 10 to 14 days postoperatively. The triceps may become adherent to the scar and should be treated with cross-friction massage and triceps-resistive exercises. Joint mobilization with distraction may be initiated in later stages if loss of motion is a problem. The prognosis after an olecranon fracture is good, but loss of terminal extension is a common residual impairment.

Radial Head Fracture

Radial head fractures occur most often as a result of falls on an outstretched hand with the forearm in supination. These fractures also occur in combination with dislocation. The individual with a radial head fracture has pain over the radial head in the lateral elbow, and forearm rotation is painful. A nondisplaced fracture can be treated with sling immobilization for 1 to 2 days, whereas a displaced fracture may be treated with ORIF. For severe fractures, the radial head may be excised. Any pathology at the distal radioulnar joint can complicate this form of treatment. The patient may be immobilized with the forearm in neutral but allowing elbow ROM (i.e., sugar tong or Muenster splint) for 2 to 3 weeks.

The most common impairment after a radial head fracture is a loss of 10 to 20 degrees of elbow extension. Crepitus or clicking at the radial head may occur with supination and pronation.

Treatment of a nondisplaced radial head fracture includes initiation of elbow and forearm AROM 1 week after injury. Successful treatment demands early ROM. The progression is similar to that for olecranon fractures. After ORIF of displaced fractures, motion may begin immediately postoperatively, barring any secondary injuries. Strengthening and functional use of the limb should be progressed as for other upper extremity injuries.

Colles Fracture

The distal radius is fractured more frequently than any other bone in the body.[20] The Colles fracture is a dorsally angulated fracture of the distal radius with or without concurrent ulnar fracture. This fracture occurs most often from falling on an outstretched hand. The volarly angulated distal radius fracture is known as a Smith fracture. The Colles fracture is initially treated with closed reduction and cast immobilization in an above-elbow cast to prevent pronation and supination or with ORIF. The cast allows motion at the MCPs of digits 2 to 5 and movement at the IP joint of the thumb. If healing is progressing well, a short forearm cast may be applied after 2 weeks.

The major impairments after cast removal are pain, decreased mobility and strength, and swelling. Control of edema is critical to prevent a stiff hand. Elevation, ice, edema massage, and compression garments can be used to reduce edema. Education about controlling edema must be emphasized to prevent further complications.

Restoration of mobility is essential for full functioning of the hand. The priority in the early phase of mobility exercises should be to regain wrist flexion, extension, and supination, because these are usually the most limited motions and important for a functional outcome (see **Self-Management 26-6**). Exercises should include AROM and self-PROM techniques using the opposite extremity. If mobility remains limited, joint mobilization may facilitate gains

SELF-MANAGEMENT 26-6
Finger and Wrist Flexor Stretching

Purpose: To increase the mobility of the soft tissues in your wrist and hand

Starting Position: With your palm facing up and wrist at the edge of a table

Movement Technique: Using your other hand, gently press your wrist and fingers down toward the floor. Hold 15 to 30 seconds, relax, and repeat.

Dosage:

FIGURE 26-36 Wrist extension exercise after Colles fracture. Wrist stabilization is necessary to prevent substitution by finger extensor muscles.

in ROM (see Chapter7). When dealing with complicated Colles fractures, splinting may be necessary to maintain gains in ROM achieved while at rest or at night or to assist in increasing mobility. Static splinting provides support and maintains mobility between exercise sessions. This intervention may be supplied by prefabricated wrist supports or custom-made splints. Dynamic splinting may also be of value in cases of limited mobility. These splints include a constant or variable tension across the wrist, forearm, or both areas to facilitate increasing motion in the direction desired. Many commercial devices are available, or a custom splint may be fabricated.

Strengthening exercises may be initiated with isometric contractions, grip strengthening, and resisted elbow exercises. Watch for substitution, and utilize proximal stabilization to ensure motion at the joint(s) of interest (**Fig. 26-36**). As mobility improves, dynamic exercise for the wrist and hand may be initiated (**Fig. 26-37**). The clinician must consider the patient's pre-injury status to establish relevant goals.

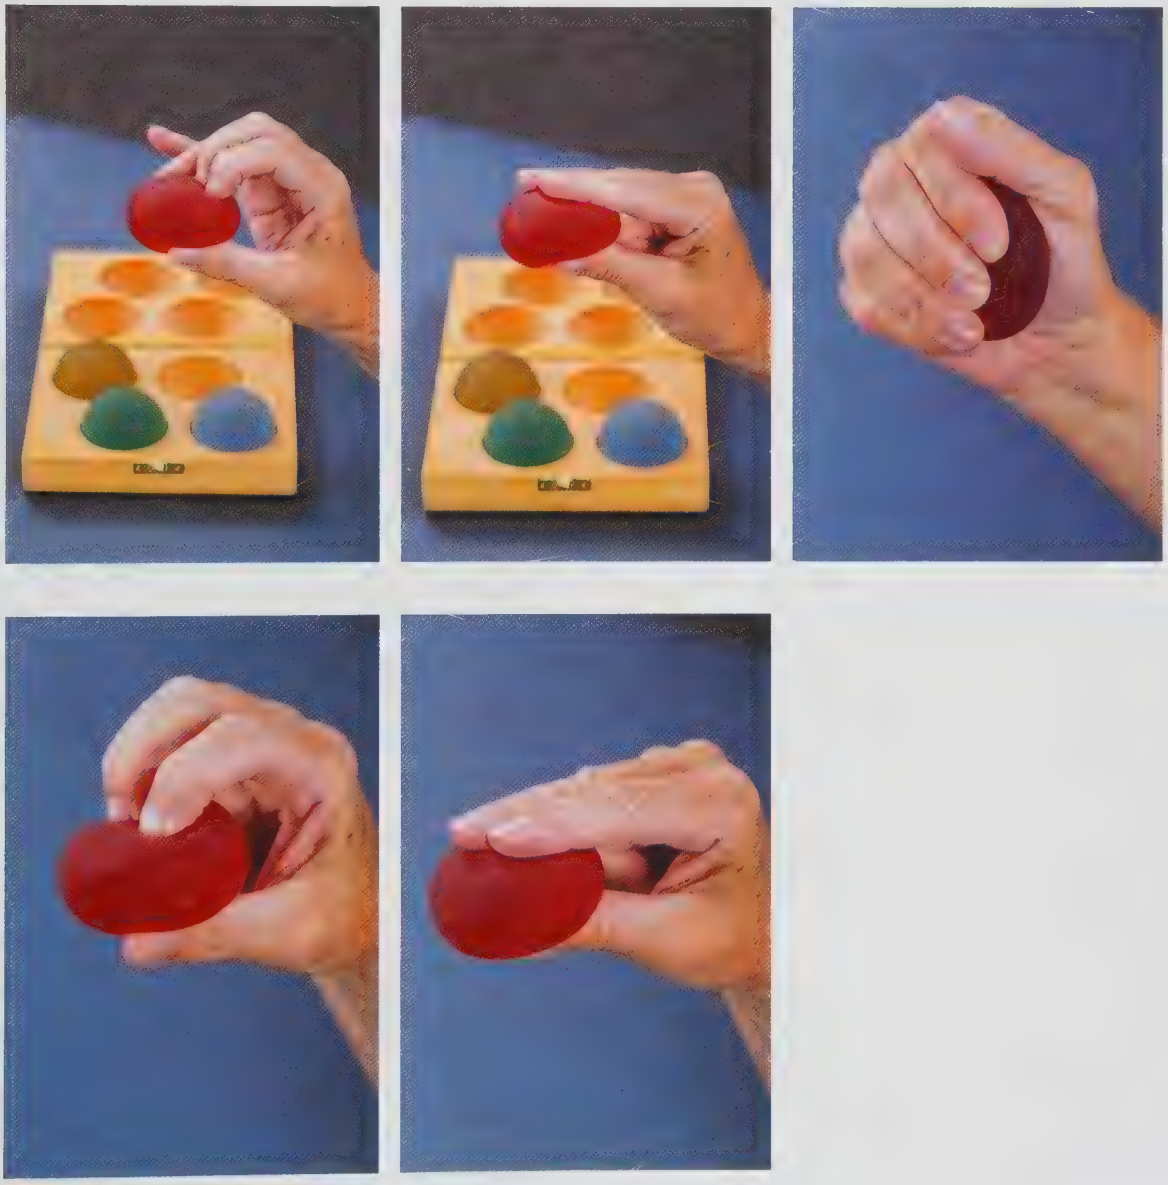

FIGURE 26-37 Grip strengthening exercises requiring concurrent wrist stabilization. Resistance is easily altered by changing the color resistance ball.

Scaphoid Fracture

The scaphoid is often fractured as a result of a fall on an outstretched hand but frequently goes unrecognized. Individuals often pass these fractures off as sprains because of the lack of obvious deformity. The scaphoid is highly susceptible to injury because of its shape and its position. Its narrow midline makes it more vulnerable to stress, and its position crosses the two rows of carpal bones, predisposing it to more frequent injury.

The individual with a scaphoid fracture relates a history of a fall on or other trauma to an extended wrist, with subsequent pain and loss of motion. Pain is particularly apparent with any overpressure in extension, such as in pushing a heavy door open. Athletes are unable to bench press because of the pressure into wrist extension. Palpable tenderness over the anatomic snuffbox and painful extension warrant medical evaluation.

Medical intervention for scaphoid fractures is immobilization for 8 to 12 weeks. Because the poor vascular supply predisposes the scaphoid to nonunion, these fractures are treated conservatively. If the fracture is severe or displaced, ORIF with a Herbert screw may be used. Because of the importance of the scaphoid in providing stability to the wrist, healing of this fracture is important. A bone stimulator may be used to facilitate bone healing. The thumb is immobilized along with the wrist because of its involvement in thumb mobility.

The rehabilitation after immobilization is similar to that for a Colles fracture. Edema control and restoration of mobility, strength, and function relative to the individual's needs are the primary goals. Self-stretching exercises, mobilization, and strengthening exercises are indicated (**Fig. 26-38**). Specific thumb AROM and PROM exercises should also be included. Specific grip, pinch, and thumb opposition strengthening exercises also are important after a scaphoid fracture. Putty or other household products (e.g., racquetball, Nerf ball, clothespin, rubber bands) may be used. Include the patient in discovering objects at home or work that may be used to accomplish the established goals (**Fig. 26-39**).

FIGURE 26-38 A variety of dexterity exercises can improve hand function.

FIGURE 26-39 Resisted pinching using a clothespin.

Metacarpal Fracture

Metacarpal fractures account for 30% to 50% of all hand fractures.[118,145] Metacarpal fractures can occur from a fall onto an outstretched hand with initial ground contact along the metacarpals, from industrial accidents (e.g., punch press machines), or from fist fights. When the fifth metacarpal is the only involved bone, it is commonly referred to as a boxer's fracture. Metacarpal fractures can occur at the base, shaft, neck, or head. Tension in the long finger flexors can cause angulation, shortening, and/or rotation of metacarpal fractures. Importantly, these tendons must be considered during the healing process to avoid adhesions and loss of tendon mobility during the fracture healing process.[119]

Impairments associated with fracture in the acute stage include pain, swelling, loss of motion and strength, and deformity. The MCP joints of fingers 2 through 5 are essentially ball and socket joints with a slack joint capsule in extension and taut collateral ligaments in flexion. The dorsal and palmar interossei muscles arise from the metacarpal bones and insert into the extensor mechanism. These muscle groups need special attention during evaluation, because their length and strength may be affected after injury or immobilization for metacarpal fractures.

Medical intervention depends on the severity of the fracture. If the fracture is nondisplaced, it is usually casted for 2 to 3 weeks. A custom static splint that crosses the wrist and includes only the affected MCP joints up to the level of the PIP joint may be worn for 2 to 3 weeks. Radial or ulnar gutter splints allow immobilization of only the affected metacarpals and permit passive ROM while in the splint. If the MCP joint is flexed during immobilization, the position can prevent collateral ligament contracture. If the fracture is displaced or unstable, surgical fixation with pins, Kirschner wires, or a plate is indicated.

The start of rehabilitation depends on the medical intervention. If the fracture is surgically stabilized, treatment begins as early as 1 to 3 days after surgery. Early intervention avoids associated impairments of dorsal hand edema, extensor tendon adhesions, MCP collateral ligament adhesions, and intrinsic muscle contractures. Exercises in the first phase emphasize gentle AROM of the wrist and all fingers and blocked MCP flexion and extension exercise (see **Self-Management 26-7**). This specific exercise prevents collateral ligament adhesions and encourages extensor tendon gliding with minimal stress placed on the fracture site. Aggressive interosseous and lumbrical stretching along with thumb-index web space stretching also should be initiated in this phase. Intrinsic muscle stretching can only be accomplished by maintaining the MCP in neutral or hyperextension while flexing at both IP joints (**Fig. 26-40**).

At 2 weeks, scar mobilization may begin, and at 4 to 6 weeks after surgery, passive MCP flexion may be initiated. At 6 to 8 weeks after surgery, intervention may focus on aggressive MCP flexion (i.e., joint mobilizations), wrist strengthening, and grip and pinch strengthening, including the intrinsic muscles (e.g., putty exercises for finger abduction and adduction).

The patient treated with immobilization may begin after cast removal at 2 to 3 weeks after the injury. Gentle AROM of the wrist and MCP joints is initiated at this time. PROM is initiated after 4 to 6 weeks. All other noninvolved joints and fingers should be completing AROM exercises from the beginning of immobilization to prevent functional loss. The program is progressed similar to that for surgical management.

FIGURE 26-40 Stretching exercises at the proximal and DIP joints.

SELF-MANAGEMENT 26-7
Metacarpophalangeal Joint Extension with Proximal and Distal Interphalangeal Joint Flexion

Purpose: To increase the mobility in your finger extensor tendon

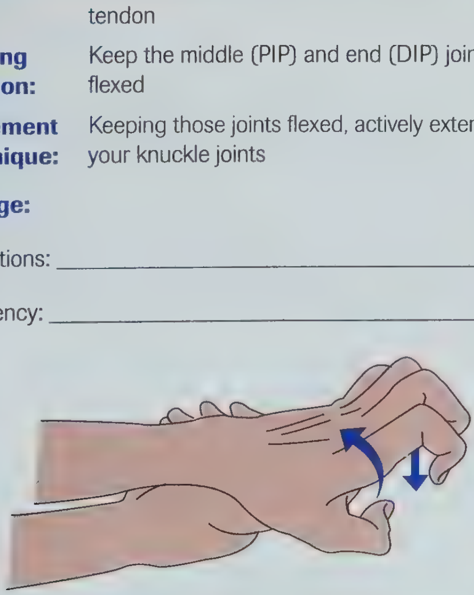
Starting Position: Keep the middle (PIP) and end (DIP) joints flexed

Movement Technique: Keeping those joints flexed, actively extend at your knuckle joints

Dosage:

Repetitions: ____________________

Frequency: ____________________



Adjunctive agents include education, elevation, ice, and compression garments to control edema. Dynamic splinting may be used to promote passive stretching of the MCP joints for 20-minute sessions performed six to eight times per day. Massage is used to manage scar formation in the operative cases.

Phalangeal Fracture

Phalangeal fractures usually occur as a result of trauma. Approximately 45% to 50% of all hand fractures involve the distal phalanx, 15% to 20% the proximal phalanx, and 8% to 12% the middle phalanx.[118] Unlike metacarpal fractures, phalangeal fractures are more often unstable due to the lack of soft-tissue support and the additional tension in the long finger flexors.[119] Additionally, immobilized phalangeal fractures result in loss of motion at a higher rate than metacarpal fractures, in both the injured and adjacent fingers.[119]

Impairments observed in the acute stage include localized swelling, pain, and tenderness over the fractures; hypomobility at IP joints and possibly MCP joint; and abnormal alignment of the IP joint. Patients may also experience lateral instability. Associated impairments after immobilization usually include restricted PIP joint flexion and extension (from volar plate contracture), DIP flexion and extension, and flexor tendon adhesions.

As with metacarpal fractures, the intervention depends on the severity of the fracture. If nondisplaced, the immobilization is accomplished by a custom splint or foam-covered metal splint. The period of immobilization varies according to the location of the fracture. If located at proximal or distal ends, only 3 to

4 weeks are required because of the good vascularity in cancellous bone. Midshaft middle phalangeal fractures require 10 to 14 weeks or longer because of the poor blood supply in the bony cortex. Displaced fractures require internal fixation with Kirschner wires or pinning. Extreme care is taken to avoid rotation, and often a buddy splint or buddy taping technique is used to help minimize this complication.

Intervention after nonsurgical postimmobilization care of phalangeal fractures is usually initiated at 3 to 6 weeks after injury or when immobilization is no longer necessary. Exercises of active and passive motion for all MCP, PIP, and DIP joints should be initiated along with tendon gliding exercises. For PIP joint restrictions of 20 degrees or more, dynamic PIP extension splinting may be required. Several commercial prefabricated splints are available, or custom splints can be fabricated. Static progressive splinting can be used at night. The finger splint is fabricated in full extension, and tension-adjustable straps are used to allow gradual finger extension toward the splint.

After surgical internal fixation, intervention may begin as early as 2 days after surgery. Gentle AROM of the MCP, PIP, and DIP joints, with emphasis on full PIP joint motion, is initiated. Tendon gliding, scar management, and edema control also should be encouraged. At 4 to 8 weeks after surgery, dynamic PIP extension splinting may be initiated, along with buddy taping during exercises or ADLs. Again, these general guidelines will vary depending upon the phalanx fractured, as well as the fixation, healing, and associated considerations.

Therapeutic exercise interventions include AROM, joint mobilization techniques, and continuous passive motion devices. Exercise is best tolerated if initiated at proximal and less painful joints. Supine shoulder flexion or simple posture correction with the patient's back against a wall promotes upper extremity blood flow and improved proximal joint alignment. Active exercise of the wrist and hand should be performed elevated and directed to individual joints and motions. Blocked finger flexion exercises encourage more complete joint motion and specific tendon gliding (see **Self-Management 26-8**). Holding a towel or soft ball while gripping can improve motor function by the assistance of palmar sensory stimulation (**Fig. 26-41**). Patients are encouraged to keep the wrist in slight extension during gripping exercises to ensure maximal efficiency of the flexor tendons.

SELF-MANAGEMENT 26-8
Blocked Finger Extension

Purpose: To increase the mobility of your finger joints and tendons.

Starting Position: Level 1: Hold the knuckle joint of your finger straight.

Level 2: Hold the knuckle and middle joints of your finger straight.

Movement Technique: Level 1: Bend your middle joint, keeping your fingertip joint straight.

Level 2: Bend only your fingertip joint.

Dosage:

Stiff Hand and Restricted Motion

The diagnosis of the "stiff hand" is often used to describe joint limitation from a variety of causes. The primary diagnosis can include lacerations, burns, fractures, soft-tissue crush injuries, and nerve and vascular trauma. The common cause is tissue trauma resulting in an inflammatory response. The resulting edema, fibrosis, and collagen alteration limit tissue gliding (i.e., tendons) and extensibility (i.e., skin, ligament, and joint capsule). Restricted motion is categorized as intra- or extraarticular by the tissue causing the limitation. Joint stiffness that follows simple immobilization is attributable to fixation of the joint ligaments to bone in areas normally meant to be free from such fixation, as well as shortening of the ligament by new collagen synthesis.

Knowledge of the normal anatomy and kinesiology of the wrist and hand help to understand, predict, and effectively treat limited mobility. At the MCP joints, the capsule is very elastic dorsally to allow for full MCP joint flexion. The extensor expansion glides over the dorsal capsule. With dorsal hand swelling, the MCP joints often lose joint flexion. This is initially caused by limited extensibility of the dorsal skin and progressively by adhesions of the collateral ligaments in their position of joint extension. The PIP and DIP joints are similar to the MCP joints with two exceptions. First, the collateral ligaments at the IP joints do not become slack in flexion; they remain taut throughout joint range, preventing lateral motion of the IP joints. Second, unlike the MCP joint, the loose-packed position for the IP joints is flexion. The volar plate becomes slack with IP joint flexion and taut in extension, preventing hyperextension, as seen at the MCP joint. After prolonged local swelling, the IP joints tend to lose joint extension, and the volar plate can become adhered in its slack position, preventing the necessary lengthening for full IP joint extension.

Structures outside the joint such as muscle, tendon, or skin adhesions can also limit joint motion. After prolonged immobilization in wrist and finger flexion, the flexor muscles become shortened. After tendon repair or fractures adjacent to tendons, tendon gliding is often limited by scar tissue or fracture calluses. For complete finger flexion, 7 cm of excursion is needed in the FDP tendons.[3] After a dorsal hand burn, metacarpal fracture, or prolonged dorsal hand edema resulting in decreased skin mobility, adjacent joint motions may be lost. Approximately 4 cm of dorsal skin laxity is needed for full MCP joint flexion and complete fisting.

Patients with articular and extraarticular tissue restriction describe activity limitations such as an inability to hold a fork or grip a steering wheel and difficulty getting their hands into their pockets. Examination must distinguish between articular and extraarticular sources of limited motion. A thorough evaluation, performed with an understanding of the local anatomy and kinesiology, can result in effective intervention.

Interventions for articular limitations include heat before joint mobilization, strengthening, and splinting. Splinting can include dynamic splints (worn for 20 to 30 minutes six to eight times each day or 2 to 3 hours for one or two times each day) or static splints (worn at night). A flexion glove can apply nonspecific tension to the dorsal tissue of the fingers, with an elastic strap used to increase forces at the IP joints (**Fig. 26-42**).

Extraarticular restrictions rely heavily on tendon gliding activities such as differential tendon gliding and blocked IP flexion. As with articular restrictions, static or dynamic splinting plays a role in improving mobility. When intrinsic muscles are shortened or the tendons adhere to surrounding tissues, stretching, gliding, and splinting are the treatments of choice. Along with exercise and splinting, edema can be controlled with compression gloves, compression pumps, elevation, and wraps. Scar massage is important in treating surgical or burn cases.

FIGURE 26-42 A flexion glove can improve the range of motion into flexion.

KEY POINTS

- The ulnar nerve may become entrapped in the cubital tunnel, the median nerve compressed in the carpal tunnel, and the radial nerve entrapped in any of several locations at the lateral elbow.
- The UCL is the primary static stabilizer and the FCU muscle the primary dynamic stabilizer of the medial elbow.
- The carpal tunnel is located on the volar aspect of the wrist and contains nine tendons (4 FDS, 4 FDP and FPL) and the median nerve.
- Grip is generally divided into power grip, used when force generation is the primary objective, and prehension grip, used when precision is the main goal.
- Activities to increase mobility include traditional stretching exercises, joint mobilization, and tendon and nerve gliding exercises.
- CTDs are usually the result of a combination of factors such as work pace, decreased rest intervals, and little variability in the task.
- Conservative management of CTS is often successful if hand and wrist postures and hand activities are monitored.
- Radial tunnel syndrome is often misdiagnosed as lateral epicondylitis.
- Cases of lateral and medial epicondylitis often result from repetitive wrist and hand activities at work, at home, or during recreation.
- Medial elbow instability occurs in children and adults who participate in throwing sports. Progressive instability in the child can lead to osteochondrosis of the capitellum and loose body formation.
- Sprain of the thumb's UCL (skier's or gamekeeper's thumb) can result in degenerative joint disease of the CMC joint if instability continues.
- The anatomy of the scaphoid predisposes it to nonunion after a fracture. Any individual with wrist pain and wrist extension loss after a fall on an outstretched hand should be evaluated for fracture of the scaphoid.
- Interventions for individuals with a stiff hand include mobility activities, splinting, and strengthening exercises.

CRITICAL THINKING QUESTIONS

1. Consider Case Study No. 8 in Unit 7. Design a workstation for this individual given his physical examination and subjective history. How would your treatment differ if the patient's occupation was
   a. A carpenter
   b. A house painter
   c. A portrait painter
   d. A violinist
   e. A pianist
2. Consider potential reasons why this patient's symptoms did not resolve after his workstation update several months ago.
3. Discuss the relationship between this patient's head and neck examination and his distal complaints.

SELECTED INTERVENTION 26-1

Upper Quadrant

See Case Study No. 8

Although this patient requires comprehensive intervention, one specific exercise addressing motor control is described.

ACTIVITY: Simulated typing with surface electromyography (SEMG).

PURPOSE: Develop motor control strategy to use appropriate levels of wrist extensor activation, wrist flexor relaxation, production of microrests, and complete baseline recovery between timed bouts of data entry.

RISK FACTORS: Watch for cervical posture as part of repetitive strain; injury to extensor group may be secondary to cervical dysfunction.

SUBSYSTEM EMPHASIZED: Neural

STAGE OF MOTOR CONTROL: Skill

MODE: Isometric wrist extensor and flexors, concentric and eccentric finger flexors and extensors.

POSTURE: Sitting at a simulated workstation in optimal ergonomic posture, with SEMG appropriately placed on right and left forearm flexor and extensor groups.[41]

MOVEMENT: While simulated typing is performed on a keyboard using a palm and wrist rest and optimal ergonomic posture, SEMG monitors forearm flexor and extensor activity bilaterally. The right forearm attempts to follow the template developed by the left forearm. Random stopping is called out to determine the spontaneous speed and level of recovery to baseline. Timed rest breaks are scheduled to determine planned speed and level of recovery to baseline.

SPECIAL CONSIDERATIONS: Closely monitor cervical position and paracervical muscle tension.

DOSAGE

Special Considerations

Anatomic: Lateral epicondyle, musculotendinous and tenoperiosteal junction of wrist and finger extensor group.
Physiologic: Subacute strain.
Learning capability: May be difficult as patient works up to 60 hours a week at visual display terminal. Probably has strong patterns of overuse of wrist and finger extensors.

Repetitions/sets: Five minutes of typing form one repetition. Perform up to five sets.

Rest period: Random 5-second rest breaks are called out during each repetition; 15-second breaks are taken after each 5-minute bout of exercise.

Frequency: If SEMG is rented, practice should be twice daily for 2 to 4 weeks. If only used in clinic, recommend three times a week for 3 to 6 weeks. For cost-effectiveness, unit rental is preferred.

Sequence: Perform after stretching exercises are performed, but not after muscle performance exercises so as not to overly fatigue muscles.

Speed: Functional speed.

Environment: Initially in quiet home environment, then progress to work environment.

Feedback: Initially, continuous audio feedback from the SEMG unit. Threshold is set so as not to exceed left side wrist and finger extensor activity. Visual feedback is used to see the speed and level of recovery to baseline during microrests and rest breaks. The patient is reassessed once each week, and the decision to progressively fade feedback is based on performance. Progressive fading of feedback occurs during exercise sessions to eliminating either audio or visual feedback every third set, to every other set, and so forth. A second party relaying the results between sets provides verbal knowledge of the results.

Functional Movement Pattern to Reinforce Goal of Exercise: In addition to using an improved motor strategy during data entry, the patient is encouraged to use elbow flexors instead of forearm extensors during lifting tasks (e.g., lift in forearm supination vs. pronation) to reduce the strain to the wrist/finger extensors.

Rationale for Exercise Choice: This exercise was chosen as a skill-level activity to reduce the overuse of the wrist and finger extensors during a highly repetitive functional activity. Through the use of SEMG feedback with a proper faded feedback schedule,[42] the patient can develop an intrinsic reference for muscle activation and error detection to improve motor control strategies to reduce recruitment effort and improve the speed and level of relaxation to baseline.

SELECTED INTERVENTION 26-2

Total Body

See Case Study No. 10

Although this patient requires comprehensive intervention, one specific exercise prescribed in the intermediate stage of recovery is described.

ACTIVITY: Step-ups; swing phase, with counterrotation.

PURPOSE: Incorporate proper total-body movements in a functional context.

RISK FACTORS: None

SUBSYSTEM EMPHASIZED: Neural.

STAGE OF MOTOR CONTROL: Controlled mobility.

POSTURE: Standing in front of a 6-in step in front of a mirror.

MOVEMENT: Lift the right leg onto the step with simultaneous right thoracic rotation and left forward arm swing.

SPECIAL CONSIDERATIONS: Be sure the patient does not hike his right hip during the hip flexion phase and does not drop his right shoulder (right thoracic lateral flexion) or adduct his right scapula instead of right thoracic rotation during the upper body counterswing maneuver.

DOSAGE

Special Considerations

Anatomic: Right hamstring and adductor, right subscapularis, right glenohumeral joint.

SELECTED INTERVENTION 26-2 (*continued*)

Physiologic: Chronic moderate strain and tendinitis, questionable instability of right glenohumeral joint.
Learning Capability: Very ingrained movement pattern from a long history of high-mileage running; may require high repetitions and significant feedback in early stages of learning.
Repetitions/sets: Initially to form fatigue as evidenced by hip hike, shoulder drop, and scapula adduction; work up to three sets of 20 to 30 repetitions.
Frequency: Six to 7 days each week.
Duration: Expect at least 2 weeks before evidence of motor control changes and 6 to 8 weeks before skill level is achieved.
Sequence: Perform after specific exercises for psoas muscle performance, thoracic rotation mobility, and abdominal muscle performance exercises have been performed. Follow with step-up: stance phase.
Speed: Slow progressed to functional speed.
Environment: Home in front of a mirror.
Feedback: Initially in clinic with mirror providing visual feedback and clinician providing verbal feedback. Taper to continued use of mirror, but with knowledge of results of verbal feedback after every three to four repetitions. Withdraw mirror and verbally provide knowledge of results every three to four repetitions. Progress toward skill.
Functional Movement Pattern to Reinforce Goal of Exercise: Ascending stairs, gait.
Rationale for Exercise Choice: The total-body movement pattern of right hip hike and right shoulder drop during swing phase of gait may be perpetuating the upper and lower extremity conditions. Without adequate hip flexion, the gluteus maximus is less efficient at assisting the stance phase of gait or step-up; the persistent right shoulder drop and scapula adduction and downward rotation can perpetuate posture and movement impairments consistent with glenohumeral impingement and hypermobility. As a result, this pattern of movement must be altered to fully recover from the upper and lower body conditions.

LAB ACTIVITIES

For each of the following case scenarios, evaluate your patient and design and execute an exercise program. Teach your patient a home exercise program.

1. A 56-year-old woman sustained an ulnar shaft fracture when she slipped and fell on the ice 6 weeks ago. She was casted for 3 weeks above the elbow and then recasted with a below-elbow cast. Her cast was removed 3 days ago. Evaluation reveals loss of AROM and PROM for elbow extension, pronation, and supination, wrist flexion and extension, and radial and ulnar deviation. Strength testing was not performed. She had no edema. Joint play assessment was not performed, but atrophy was visible.
2. A 12-year-old boy complains of medial elbow pain. He is active in Little League and pitched 14 innings over the weekend. He complains of pain along the medial collateral ligament, pain with passive elbow extension, flexion, pronation, and supination (with a guarded end-feel). A mild effusion is observed, and there is increased laxity with valgus stressing. Radiographic findings are negative.
3. A 44-year-old patient presents with lateral elbow pain after shoveling wet, heavy snow. He complains of pain with activities such as picking up his briefcase, turning the doorknob, and grasping objects. He also has difficulty using the mouse on his computer. Examination reveals a loss of AROM and PROM of wrist flexion (and finger flexion increases symptoms), decreased strength with wrist extension and supination, and pain with palpation at the lateral epicondyle. There is no effusion, but slight warmth is noticed.
4. Three weeks ago, a 22-year-old collegiate gymnast dislocated her elbow (the olecranon displaced posteriorly) from a fall on an outstretched hand when she missed grasping the high bar and fell to the floor. She was in a sling for 2 weeks and has been out of the sling for 1 week, but she is carrying her arm in a guarded position. Examination reveals a loss of elbow extension (actively and passively with a springy end-feel), full anteroposterior flexion, and a loss of pronation and supination anteroposteriorly. Joint play assessment reveals decreased humeroulnar joint distraction.
5. A 70-year-old woman fell on the ice and sustained a Colles fracture 8 weeks ago. She underwent a closed reduction and was immobilized in a series of casts. She also has insulin-dependent diabetes mellitus and has decreased sensation over the distal forearm, wrist, and hand. Examination reveals a loss of all active and passive wrist motion, decreased joint play in the inferior radioulnar joint, visible atrophy, and a loss of strength with resisted movements in neutral.
6. A 32-year-old man sustained a scaphoid fracture 10 weeks ago when he fell on an outstretched hand while skiing downhill. He was casted for 8 weeks, and periodic radiographs revealed nonunion of his scaphoid. He underwent surgical stabilization of the fracture using a bone graft from his iliac spine. He has been immobilized for 12 weeks since surgery. He is referred to physical therapy to begin ROM out of the splint four times each day. Examination reveals a loss of all wrist motions, decreased thumb flexion and extension, and decreased opposition.
7. A 40-year-old meat cutter sustained a laceration of his finger extensors (proximal to his MCP joints) while working. He underwent surgical fixation and was allowed to actively contract only the finger flexors. He has been removed from his splint and is allowed to begin active finger extension. Examination reveals decreased active finger extension (at the MCP joints) from weakness but full passive finger extension. Mobility of the MCP joints is decreased.
8. A 50-year-old man sustained a crush injury to his hand when his shirt sleeve got caught in a printing press and pulled his hand in. He sustained multiple metacarpal and carpal fractures, some of which were surgically stabilized through pinning. He has been casted for 8 weeks and presents to physical therapy today. Examination reveals a massive loss of motion of all wrist and fingers joints, atrophy in the thenar and hypothenar eminence, and decreased joint mobility in the carpal and MCP joints and all finger joints.

UNIT

7

CASE STUDY NO. 1

Cody is a 17-year-old high school student who complains of right (R) hip pain. He describes onset of hip pain after playing soccer that began with summer training. Pain has gradually worsened over the season to the point that he is unable to practice or play without pain lasting several days. The pain is located at the lateral hip and groin region. One it is aggravated, pain is present in sitting as well. He is able to walk with minimal pain, but cutting and kicking seem to aggravate it the most.

EXAMINATION

Pain: 4/10 in sitting, constant in nature: 2/10 with weight-bearing, 6/10 with passive hip flexion/IR/adduction.

Gait: Excessive pelvic rotation versus hip flexion with swing, + Trendelenburg pattern with excessive hip IR during stance.

Active Range of Motion: 90 degrees hip flexion before onset of lumbar flexion, excessive pelvic rotation with hip ER in prone, limited hip IR to 20 degrees. Hip abduction limited to 15 degrees before onset of lateral pelvic tilt, hip adduction 20 degrees.

Passive Range of Motion: Hip flexion 95 degrees with pain end range, hip ER 20 degrees, hip IR 20 degrees prone, 5 degrees at 90 degrees hip flexion, hip abduction 20 degrees, hip adduction WNL

Accessory Motion: Limited posterior glide R femoral head

Special Tests: + hip impingement, limited hip IR and hip flexion/cluster sign for cam impingement

Palpation: Tenderness middle third of groin region and over greater trochanter

Strength Testing: Gluteus medius 3–/5; adductor 3+/5; gluteus maximus 3+/5; Iliopsoas 3–/5; Hip lateral rotators 3–/5; hip internal rotators 3+/5; quadriceps 4/5; hamstrings 4–/5

Pelvic Alignment: Intrapelvic torsion with R innominate (inlet) extension, IR, adduction; L innominate (inlet) flexion, ER, abduction

Balance: Failed load transfer onto R limb with slight pelvic drop, femur MR, and foot pronation

Additional Tests: Imaging reveals sizable cam impingement

Functional Outcome Score: Lower Extremity Functional Scale (LEFS): (range 0 to 80) 45—moderate activity limitation (MCID = 9) (Accessed February 2015, from http://www.mccreadyfoundation.org/documents/LEFS.pdf)

EVALUATION: Painful hip in positions of impingement or in high loads or ROM demands in WB

Impairment

- Limited and painful hip ROM
- Decreased strength to iliopsoas, gluteus medius, hip lateral rotators
- Intrapelvic torsion favoring femoral movement patterns into IR, adduction, and extension
- Hip adduction, IR patterns during stance phase of gait
- Decreased static and dynamic standing balance

Activity Limitation

- Painful motions of the pelvis over the femur when changing directions
- Poor muscle performance for optimal gait and running mechanics
- Acetabular and femoral incongruence causing pain in WB and sitting activity
- Faulty biomechanics in gait

Participation Restriction

- Unable to cut in soccer or sit in class
- Unable to run or kick in soccer

DIAGNOSIS: Cam deformity with clinical findings of limited and painful hip flexion, adduction, IR

PROGNOSIS

Short-Term Goals (7 to 10 days)

1. Walk 3 miles with optimal mechanics and without hip pain
2. Sit for 60 minutes without hip pain
3. Improve LEFS score to 61 (mild limitation)

Long-Term Goals (3 to 4 weeks)

1. Kick soccer ball during drills for 10 minutes without hip pain
2. Run and cut at full speed during game without hip pain
3. Improve LEFS score to 76 (no limitation)

CASE STUDY NO. 2

Sarah is a 69-year-old, retired college professor with a medical diagnosis of osteoarthritis in both knees. She is widowed and living alone in a third-floor apartment with elevator access. Yesterday, Sarah underwent elective surgery for bilateral (B) total-knee arthroplasties. Her medical history includes emphysema, myocardial infarct 2 years ago, moderate obesity, and hypertension. She lives independently. Prior to surgery, she had a maximum walking tolerance of one-half block when using a cane for support.

EXAMINATION

Arousal/Cognition: Alert and oriented; follows complex commands; motivated to get out of bed

Cardiovascular: Pale with complaints of nausea; short of breath with exertion; diaphoretic in sitting; vital signs: pulse 96 supine, 108 sitting; blood pressure 144/66 mm Hg supine, 126/64 mm Hg sitting

Wounds: Dressed with gauze and clear tape, moderately soaked with bloody drainage; periwound regions warm to touch, hypererythemic, and swollen

Pain: 3/10 at rest, 8/10 with movement

Active Range of Motion: R knee extension/flexion 20 to 47 degrees (pain elicited); L knee extension/flexion 15 to 52 degrees (pain elicited)

Endurance: Maximum sitting tolerance 15 minutes; maximum standing tolerance 20 seconds

Strength Testing: Iliopsoas (B) 2+/5; gluteus maximus (B) 4/5; gluteus medius (B) 2+/5; quadriceps (R) 2/5, (L) 3–/5; hamstrings (R) 2+/5, (L) 3–/5

Resisted Testing: Shoulder girdle extension and depression, elbow extension all strong and pain free

Posture: Semiflexed both knees, with L > R valgus knee deformity

Gait: Wide base of support, stiff knees, flexed trunk, maximum upper extremity support on walker

EVALUATION: Acute, postoperative pain, inflammation, muscle weakness, and decreased active motion of both knees

Impairment

- Bilateral decreased knee active range of motion
- Bilateral weak quadriceps and hamstrings
- Postoperative pain and inflammatory response
- Markedly limited activity tolerance

Activity Limitation

- Required moderate assistance for bed mobility and basic sit to stand transfer
- Unable to sit >15 minutes
- Unable to stand >20 seconds
- Unable to walk

Participation Restriction

- Unable to resume independent basic and instrumental activities of daily living
- Unable to walk household distances
- Unable to resume teaching and writing interests
- Unable to access family, church, and clubs for social interaction

DIAGNOSIS: Postopera.tive day 1 after bilateral total knee arthroplasties

PROGNOSIS

Short-Term Goals (7 to 10 days)

1. Independent bed mobility and basic transfer with walker
2. Independent ambulation 30 m with walker
3. Active knee range of motion >10 to 70 degrees to enable up/downstairs
4. Out of bed and up in chair >5 hours per day

Long-Term Goals (12 weeks)

1. Ambulation >100 m, rest breaks as needed, allowing for baseline compromised cardiopulmonary status
2. Return to independent driving for community access
3. Return to preoperative vocational routine

CASE STUDY NO. 3

Cathy is a 61-year-old journalist with a number of complaints, including trunk weakness, leg weakness, and generalized fatigue. She has a history of osteoporosis, osteoarthritis, and a recent 2-week bout with diarrhea caused by her medication. Previously, Cathy worked a 40- to 50-hour work week. In the past 6 months, the pain and fatigue have limited her work to no more than 30 hours per week in a good week. Pain is primarily in her low back, hips, and knees. She has been managed by a Pain Clinic, resulting in a change to her medications and she was referred to a physical therapist. She has no history of regular exercise nor any home exercise equipment. Her maximum walking tolerance is reportedly one block, limited by shortness of breath, general fatigue, and hip discomfort.

EXAMINATION

Posture/Alignment: Long kyphosis with posterior displacement of the upper trunk and a forward head. Lumbar spine is flattened. Posterior pelvic tilt. B hips extended and internally rotated. B knees in recurvatum; tibial external rotation; scapulae abducted and elevated

Muscle Length: Hamstrings—passive straight-leg raise to 50 degrees (B)

Strength Testing: Trunk curl 3−/5; leg lowering 2−/5; iliopsoas (R) 3/5 degrees, (L) 3−/5; gluteus medius (R) 3/5, (L) 2+/5; gluteus maximus (B) 3+/5; quadriceps (R) 4/5, (L) 4−/5; hamstrings (R) 4−/5, (L) 3+/5; rhomboids (B) 3+/5; lower trapezius (B) 3/5

Active and Passive Range of Motion:

Thoracolumbar spine: Forward bend thoracic > lumbar flexion with lumbar spine remaining in neutral; back bend with excessive extension at thoracolumbar junction; patient reports stiffness with all movements.

Hip: Internal rotation (R) 0 to 20 degrees, (L) 0 to 15 degrees, external rotation (R) 0 to 35 degrees, (L) 0 to 33 degrees, flexion (bent knee) 0 to 85 degrees, extension 0 to 5 degrees

Shoulder: Flexion in scapular plane 0 to 140 degrees when lifting bilaterally, with early upward rotation of scapulae and lacking thoracic extension and complaining of mid-back pain at end range. Single arm flexion results in an additional 10 degrees of elevation.

Functional Outcome Score: Standardized 12-minute walk test completed with subjective complaints of shortness of breath and lower extremity muscle fatigue; distance, 900 m; standing rest required at 10 minutes, peak heart rate of 132, blood pressure of 153/88 mm Hg

WOMAC: 46%

EVALUATION: Generalized deconditioning with gradual onset of faulty alignment because of changes in joint mobility and muscle strength and length, compounded by recent illness

Impairment

- Muscle weakness pelvic girdle
- Faulty spinal, pelvic, and lower extremity alignment
- Muscle shortening of hamstrings, rectus abdominis, and pectoralis major and minor bilaterally
- Decreased cardiorespiratory endurance
- Decreased lower extremity muscle endurance
- Restrictions at thoracolumbar spine intervertebral and thoracic spine costovertebral joints
- Faulty shoulder girdle movement patterns
- Impaired muscle performance of axioscapular upward rotators
- Hip joint restrictions

Activity Limitation

- Unable to walk >10 minutes without shortness of breath and fatigue
- Stairs require rail support
- Difficulty getting up from low chairs
- Rest breaks required during AM and PM self-care routine

Participation Restriction

- Unable to tolerate exertion of more than 30 hours per week of work
- Unable to complete basic and instrumental activities of daily living in a timely manner
- Avoidance of social activities because of fatigue and pain

DIAGNOSIS: Generalized deconditioning superimposed on baseline medical diagnoses of osteoporosis, osteoarthritis, and chronic pain involving primarily low back and lower quarter.

PROGNOSIS

Short-Term Goals (2 weeks)

1. Demonstration of energy conservation and pacing techniques to maximize activity tolerance at work and home

Long-Term Goals (4 to 6 months)

1. Increase in musculoskeletal and cardiovascular endurance to allow resumption of full duties at work and home

CASE STUDY NO. 4

Jack is a 58-year-old retired banker who presented with complaints of right (R) shoulder pain that was most noticeable when reaching overhead or behind. His pain occasionally wakes him at night. Jack's medical history is significant for a nonspecific R shoulder injury sustained playing tennis 2 years ago. This went untreated, and the symptoms resolved. Jack has been refurbishing his 35-feet wooden sailboat and noticed the onset of shoulder pain after sanding the deck. He is R-hand dominant. He is currently limited in recreational activities, but not limited in his ability to perform work duties.

EXAMINATION

Posture/Alignment: Forward head with upper cervical extension, head tilt (R), cervical-thoracic junction flexion, and flattened thoracolumbar spine; scapulae elevated, abducted, and downwardly rotated R > L; R humerus anteriorly and superiorly displaced in the glenohumeral joint

Active Range of Motion: R shoulder flexion 0 to 90 degrees, extension 0 to 30 degrees, abduction 0 to 100 degrees, external rotation 0 to 25 degrees, internal rotation 0 to 50 degrees; pain elicited end range all directions; neck rotation limited by 50% to the right (pain R shoulder end range) and 25% to the left (pain R shoulder end range), neck flexion limited by 50% (pain R shoulder end range), neck extension limited by 50% (pain R shoulder end range)

Passive Range of Motion: R shoulder flexion 0 to 110 degrees, extension 0 to 33 degrees, abduction 0 to 110 degrees, external rotation 0 to 25 degrees, internal rotation 0 to 55 degrees; end range pain elicited in all directions; neck ROM similar to active range with pain elicited in R shoulder at end range in all directions

Neural Tension Testing: + ULTT for median and radial nerves (R)

Accessory Motion Testing:

Glenohumeral: Diffusely hypomobile, especially posterior and inferior glides

Scapulothoracic: Hypomobile medial glide and upward rotation; hypermobile lateral/cephalic glides

Upper thoracic: Hypomobile segmental anterior/posterior glides T2–T8

Strength Testing: Upper trapezius/levator scapula (R) 5/5, (L) 5/5; middle trapezius (R) 3/5, (L) 3/5; lower trapezius (R) 3/5, (L) 3/5; rhomboids (R) 3/5, (L) 4/5; serratus anterior (R) 2+/5, (L) 5/5; GH LR (R) 3–/5, (L) 4/5; GH MR (R) 3–/5, (L) 4/5; Bicep (R) 3–/5, (L) 4+/5; Tricep (B) 4/5; thumb abduction (R) 3–/5, (L) 4/5

Resisted Testing (neutral position): Weak and painless R shoulder flexion, extension, internal rotation, abduction and adduction; external rotation

Quality of Movement: Glenohumeral flexion/abduction achieved through 30 degrees of glenohumeral motion, followed by 1:1 scapulohumeral rhythm to roughly 90 degrees; remaining motion achieved through shoulder girdle elevation

Additional Tests: Imaging reveals HNP at C5/C6 encroaching on R nerve root

Functional Outcome Score: Quick Dash (Gummesson C, Ward MM, Atroshi I. The shortened disabilities of the arm, shoulder and hand questionnaire (Quick DASH): validity and reliability based on responses within the full-length DASH. BMC Musculoskelet Disord 2006;7(44):1–7): range 0 to 100; Quick Dash: 59 (moderate activity limitation); Quick Dash Work Module: 15 (no activity limitation); Quick Dash Sports Module: 65 (severe activity limitation) Minimal Clinical Important Difference (MCID) 8% (Accessed February 3, 2015, from http://www.physio-pedia.com/DASH_Outcome_Measure#cite_note-Gummesson-3)

EVALUATION: Decreased osteokinematic and arthrokinematic motion of R shoulder girdle and cervical-thoracic spine, resulting in faulty movement patterns and pain with end range shoulder function; neural tension and weakness pattern suggestive of C5/C6 level disc pathology

Impairment
- Decreased physiologic and accessory motion
- Faulty scapulothoracic, glenohumeral, and cervical-thoracic spine alignment
- Faulty shoulder girdle movement patterns
- Pain with end range shoulder girdle motion, especially forward flexion
- Limited neck mobility
- + ULTT

Activity Limitation
- Unable to reach overhead or behind back, lift, or pull overhead
- Disturbed sleep

Participation Restriction
- Difficulty retrieving wallet from back pocket
- Difficulty unlocking car passenger door from driver's seat
- Unable to complete moderate- or heavy-duty boat refurbishing tasks

(*continued*)

CASE STUDY NO. 4 (*continued*)

DIAGNOSIS: Subacute R shoulder adhesive capsulitis secondary to cervical disc pathology

PROGNOSIS

Short-Term Goals (3 weeks)

1. Decrease night pain by 50%
2. Light weight lifting and reaching activities up to shoulder height without pain
3. Improve Quick Dash Sport Module to 36 (moderate activity limitation)

Long-Term Goals (3 to 4 months)

1. No night pain
2. Ability to tolerate resisted motion at end range of shoulder motion; thus able to complete heavy-duty jobs on boat
3. Improve Quick Dash Sport Module to 15 (no activity limitation)

CASE STUDY NO. 5

Irene is an 85-year-old woman who fell at home, resulting in acute low back pain and right more than left (R > L) lower extremity radiculopathy and necessitating bed rest for more than 2 weeks. She is weak, deconditioned, unsteady on her feet, and fearful of falling. She now uses a walker for ambulation. Her back still gives her pain, although she no longer suffers lower extremity symptoms. Irene lives in her own apartment in an assisted-living environment. Before the fall, she independently handled her basic activities of daily living and was socially active with fellow residents.

EXAMINATION

Posture: Kyphotic/lordotic thoracolumbar alignment; anterior pelvic tilt; hips slightly flexed

Strength Testing: Leg lowering 2/5; gluteus maximus (R) 2+/5, (L) 3+/5; gluteus medius (R) 2/5, (L) 3/5; iliopsoas (R) 3/5, (L) 4–/5; quadriceps (R) 4/5, (L) 4+/5; hamstrings (R) 3–/5, (L) 3+/5

Muscle Length: Moderate shortening of quads > iliopsoas, R > L; (B) hamstrings unremarkable

Functional Movement Testing: Pain with standing or walking (4/10). Pain relief with sitting or sidelying. Standing forward bend at 20 degrees; standing backward bend trace with reproduction of symptoms

Gait: Positive Trendelenburg with stance R > L; wide base of support; flexed at hips with forward displaced trunk over pelvis; markedly diminished lumbopelvic rhythm

Balance: Standardized stand reach test of 6 inches; provoked balance response demonstrates delayed step response with hip > ankle strategies

Reflexes: Knee jerk (B) 2+; ankle jerk (R) 1+, (L) 2+

Sensory: Light touch intact, mildly decreased proprioception, R > L

Functional Outcome Score: Berg Balance Score (0 to 56) (Accessed January 17, 2017 from https://www.physio-pedia.com/images/b/bd/Berg_balance_scale_with_instructions.pdf)—36 (high fall risk); Oswestry Disability Index Score (0-100) (Accessed January 17, 2017 from http://www.physio-pedia.com/Oswestry_Disability_Index): 35 (severe activity limitation)

EVALUATION: Fixed kyphosis and lordosis malalignment, with corresponding muscle length and tension changes; painful with active or passive extension, affecting static and dynamic standing balance, and standing tolerance

Impairment

- Fixed kyphotic-lordotic alignment of thoracolumbar spine
- Muscle weakness, especially trunk and proximal lower extremity
- Shortened iliopsoas and quadriceps, R > L
- Decreased static and dynamic standing balance (Berg Balance Score 36)
- Fear of falling
- Pain with lumbar extension

Activity Limitation

- Assistance required to get out of bed or up from a chair
- Inability to stand >2 minutes
- Inability to walk >10 m
- Mobility avoidance

Participation Restriction

- Loss of independence performing basic activities of daily living
- Loss of independence with ambulation
- Unable to walk to dining room
- Reluctant to participate in usual social activities (bridge, films, out for dinner with family)

DIAGNOSIS: Signs and symptoms consistent with lumbar stenosis exacerbated by fall.

PROGNOSIS

Short-Term Goals (2 weeks)

1. Independent ambulation with walker, 25 m
2. Independent transfer out of bed
3. Independent stand for 10 minutes for morning self-care routine
4. Improve Berg Balance score to 45 (moderate fall risk)
5. Improve Oswestry score to 30 (moderate activity limitation)

Long-Term Goals (8 weeks)

1. Independent ambulation within building complex; no assistive device
2. Resume all previous social activities with friends and family
3. Improve Berg Balance Score to 56 (functional balance)
4. Improve Oswestry Score to 15 (mild activity limitation)

CASE STUDY NO. 6

Megan, a 12-year-old female tennis and volleyball player, presented 2 weeks after right (R) anterior cruciate ligament injury which occurred during volleyball. MRI showed no meniscal damage. At this point, she does not wish to have surgery and would rather wait to see if her knee is unstable before considering reconstruction. She does not wish to give up either her tennis or volleyball.

EXAMINATION

Gait: Toe-touch pattern with use of axillary crutches; knee held semiflexed

Active Range of Motion: Knee extension/flexion 15 to 90 degrees with subjective sensation of "tightness" at both extremes

Passive Range of Motion: Knee extension/flexion full extension to 100 degrees with end range flexion limited by muscle guarding

Palpation: Moderate suprapatellar swelling; posterior capsule distention; girth (3 cm proximal to superior patellar pole) R = 44 cm, L = 38 cm; 1+ joint effusion; joint lines nontender

Strength Testing: Resisted testing contraindicated; patient unable to perform a quadriceps set; able to perform straight leg raise in hip flexion, abduction, and extension

Accessory Motion: Normal patellar glides

Special Testing: Varus and valgus stress testing at 0 and 30 degrees flexion: negative; Lachman's 2+; Instrumented laxity testing: 4 mm greater anterior displacement on the R compared with the L

Functional Outcome Score: KOOS QoL = 5; KOOS Sports & Recreation = 0; KOOS ADL = 33

EVALUATION: R knee joint effusion, pain, decreased range of motion, and altered muscle recruitment patterns

Impairment

- Localized swelling in suprapatellar and posterior capsule regions
- Subacute pain rated at 4/10
- Impaired quadriceps recruitment
- Loss of R lower extremity coordination

Activity Limitation

- Unable to tolerate foot flat stance on R with a step through pattern
- Ambulates with flexed knee gait pattern
- Crutches required secondary to above gait problems
- Stair negotiation slow
- Unable to squat with knee control

Participation Restriction

- Unable to participate in usual sports

DIAGNOSIS: R knee dysfunction from primary structural injury

PROGNOSIS

Short-Term Goals (2 to 4 weeks)

1. Ambulate without assistive device
2. Return to modified school routine without assistive device

Long-Term Goals (6 to 12 months)

3. Return to volleyball and tennis
4. Adopt appropriate movement patterns to prevent further knee injury and avoid surgery

CASE STUDY NO. 7

Mary is a 36-year-old wife and mother of two young children. She has a 6-month history of chronic back, R hip, and R ankle pain, recently diagnosed with psoriatic arthritis. She is not working, although she is trained as a research laboratory technician. Mary reports she's having a hard time keeping up with her husband and children and increasing difficulty managing her home. Even minor activities such as lifting or carrying her children can result in profound pain, fatigue, or weakness just a few hours later. She once was very active and now is skeptical but hopeful that she can return to a regular exercise program. Ultimately, she would like to return to part-time work. She is scheduled for a follow-up with her rheumatologist to discuss treatment with biologic drugs. She has been referred to physical therapy to help with managing painful regions and getting back to a fitness program.

EXAMINATION

Posture and Observation: Medium build; stands in ankle plantar flexion, knee recurvatum (R > L), anterior pelvic tilt, lumbar lordosis, thoracic kyphosis. R iliac crest is elevated, R femur adduction and IR, R > L midfoot pronation. Resting muscle tension apparent in lumbar erector spinae. Upper chest breathing pattern.

Active Range of Motion: Thoracolumbar: flexion to floor with thoracic and hip motion relatively greater than lumbar motion, pain elicited at onset of forward bend and upon return to extension; faulty lumbopelvic rhythm. Extension, rotation, and sidebending all moderately decreased with guarding; squatting limited by 50% due to R hip and R ankle pain. Ankle ROM limited to 5 degrees (R), 8 degrees (L) DF. R hip mildly limited in abduction, ER, and flexion compared to L; L limited in adduction, IR, and extension compared to R.

Passive Range of Motion: Painful before onset tissue resistance with R hip flexion, abduction, ER (7/10) (hyperalgesia). Painful at end range of tissue resistance ankle DF (4/10).

Accessory Joint Mobility: Limitation with PA pressure thoracic spine T1–T10. Limitation transverse PA pressure L4–L5, S1 on R.

Muscle Length: Shortened hamstrings (L); shortened gastroc/soleus (R); shortened two joint hip flexors, adductors (R).

Strength Testing: Trunk curl 3–/5; leg lowering 2/5; gluteus maximus (B) 3+/5; gluteus medius (R) 3–/5, (L) 3/5; iliopsoas (B) 3+/5; quads 4–/5 B; hamstrings (R) 4+/5, (L) 4–/5; gastrocsoleus 10 heel raises before fatigue on R, 20 on L. L4, L5 LM on R abnormal muscle contraction with multifidus lift test (Hebert et al., 2013).*

Movement Testing: Active movement testing revealed lumbar extension/rotation patterns with limb motions. R hip adduction and IR patterns with closed chain testing. R > L ankle PF and pronation patterns with closed chain testing.

Surface Electromyography: Elevated resting muscle tension prevalent lumbar paraspinals; lacking flexion relaxation response at end range forward bending.

Palpation: Painful (7/10) to light pressure in lumbar paraspinal lateral hip and groin, and along posterior tibialis insertion (allodynia), joint position; intrapelvic torsion with sacral rotation to R and R innominate in extension, adduction, IR; L innominate flexion, abduction, ER.

Functional Outcome Score: Fear Avoidance Behavior Questionnaire—Physical Activity (FABQpa) (0 to 24) (Accessed February 3, 2015 http://www.physio-pedia.com/images/2/29/FABQ.pdf): 12 (moderate fear avoidance); Oswestry Disability Index Score: 40 (moderate activity limitation); LEFS Score: 42 (moderate activity limitation)

EVALUATION: Low back pain with movement impairment of extension/rotation syndrome; hip pain with movement impairment of hip adduction with IR; foot pronation syndrome. Soft tissue pain in posterior tibialis. All painful conditions aggravated with activity.

Impairment

- Low back, R hip, R ankle regional pain, aggravated with activity
- Movement impairment patterns present in the low back, hip, and ankle
- Abnormal static and dynamic muscle tension and recruitment patterns, B lumbar erector spinae elevated and R LM reduced
- Mild diffuse loss of active physiologic range of motion, affecting spine, hips, and ankles

Activity Limitation

- Unable to sit >10 minutes
- Unable to stand >15 minutes
- Unable to walk >1/2 mile
- Unable to lift >10 lb from floor height

Participation Restriction

- Unable to play on the floor with children
- Unable to tolerate sexual intercourse
- Unable to return to work as laboratory technician
- Unable to resume fitness activities

* Hebert JJ, Koppenhaver SL, Teyhen DS, et al. The evaluation of lumbar multifidus muscle function via palpation: reliability and validity of a new clinical test. Spine J 2015;15: 1196–1202.

(continued)

CASE STUDY NO. 7 (*continued*)

DIAGNOSIS: Regional chronic pain with comorbidity of psoriatic arthritis and elevated FABQ score with findings of weakness, fatigue, loss of motion, and abnormal motor recruitment.

PROGNOSIS

Short-Term Goals (6 to 8 weeks)

1. Ambulate 15 minutes twice per day without residual symptoms
2. Lift 20 lb from floor height
3. Carry 15 lb for 3 minutes
4. Squat to thigh parallel to ground x 10 repetitions without residual symptoms
5. Improve FABQ score to 9 (mild fear avoidance)
6. Improve LEFS score to 61 (mild activity limitation)
7. Improve Oswestry score to 15 (mild activity limitation)

Long-Term Goals (1 year)

1. Return to work part time
2. Continuous ambulation for 30 to 40 minutes without residual pain or fatigue
3. Resume variety of fitness activities including weight lifting, yoga, Pilates
4. Improve FABQ score to 4 (minimal to no fear avoidance)
5. Improve LEFS score to 76 (no activity limitation)
6. Improve Oswestry score to 4 (no activity limitation)

CASE STUDY NO. 8

George is a 35-year-old computer data entry specialist with a 9-month history of multiple complaints, including interscapular pain, head, jaw, and neck pain with associated headaches, and right (R) lateral forearm pain. No specific traumatic event preceded these symptoms, although they have progressively worsened over the last couple of months such that they now interfere with his ability to work. He does report clenching his jaw when under stressful deadlines and wears a night guard. His employer completed a workstation assessment several months ago and provided state-of-the-art office equipment, but this has provided no significant relief of George's symptoms. Typically, he can spend several uninterrupted hours on the computer without awareness of time passed. A typical work week is 60 hours. George is moderately obese and admits to a sedentary lifestyle. He is currently moderately limited in his ability to work related to UQ symptoms.

EXAMINATION

Posture/Alignment: Forward head, elevated shoulders L > R, excessive lumbar lordosis with anterior pelvic tilt. Scapulae excessively abducted and downwardly rotated L > R. Cubital fossa oriented medially bilaterally. Laterally rotated femurs with hyperextended knees in postural knock-knees

Active Range of Motion:

Cervical: Flexion 0 to 25 degrees; extension 0 to 60 degrees, pain elicited; rotation (R) 0 to 55 degrees, (L) 0 to 60 degrees; sidebend (R) 0 to 35 degrees, (L) 0 to 45 degrees

TMJ: Jaw opening to 45 mm with lasting deviation to the R

Shoulder: Forward flexion (R) 0 to 120 degrees, (L) 0 to 140 degrees; extension (R) 0 to 30 degrees, (L) 0 to 45 degrees; external rotation (R) 0 to 35 degrees, (L) 0 to 50 degrees

Hip: Hip external rotation (B) 0 to 45 degrees, internal rotation (B) 0 to 10 degrees

Muscle Length: Shortened latissimus dorsi; lengthened rhomboids and mid-lower trapezius; shortened pectoralis major

Strength Testing: Serratus anterior 3/5; rhomboid major 4/5; upper trapezius 5/5; middle and lower trapezius 1 to 2/5; infraspinatus/teres minor 4/5; anterior/middle deltoid 5/5; biceps (R) 4–/5, (L) 5/5; triceps (B) 5/5; flexor carpi radialis/ulnaris (R) 4/5, (L) 5/5; extensor carpi radialis longus brevis (R) 3+/5, pain elicited, (L) 5/5; pronator teres/supinator (R) 4–/5, (L) 5/5; trunk curl 3/5; leg lowering 2/5; iliopsoas (R) 3+/5, (L) 4/5

Accessory Motion Testing: Cervical—L > R hypomobile posterior/anterior and rotation segmental testing at C1/2 and C2/3; decreased R TMJ in all directions; shoulder girdle: decreased anterior/inferior glenohumeral glides; decreased scapulothoracic inferior glide and downward rotation; excessive scapulothoracic lateral glide and upward rotation

Palpation: Suboccipital region moderately tender; tender R masseter, pterygoids, and temporalis; diffusely tender interscapular L > R; tender R lateral epicondyle

Deep Tendon Reflexes: Biceps (R) 1+, (L) 2+; triceps 2+ and symmetric

Sensation: Diminished light touch R lateral forearm and thumb

Functional Outcome Score: Neck Disability Index Score (NDI) (0 to 50) (Accessed February 3, 2015, from http://academic.regis.edu/clinicaleducation/pdf%27s/NDI_with_scoring.pdf): 23 (moderate activity limitation); Quick Dash: 37 (moderate activity limitation); Quick Dash Work Module: 63 (moderate activity limitation)

EVALUATION: Chronic postural malalignment resulting in multifocal postural and movement dysfunction most evident in overstretched and weakened scapular stabilizers and upper cervical and TMJ segmental hypomobility; subsequent musculoskeletal pain and headaches; subacute overuse injury to R wrist extensor group

Impairment

- Upper cervical, asymmetric facet joint motion dysfunction
- Asymmetric TMJ joint motion with overall reduced opening
- Painful and shortened deep suboccipital extensors and R TMJ closing musculature
- Faulty shoulder girdle alignment

Activity Limitation

- Unable to sit >30 minutes
- Daily headaches, limiting concentration
- Difficulty with wide mouth opening
- Difficulty keying with R hand because of forearm pain

Participation Restriction

- Unable to complete job requirements
- Loss of job satisfaction
- Unable to open mouth wide to eat large size food such as a burger or apple

(continued)

CASE STUDY NO. 8 (*continued*)

Impairment

- Overstretched and weakened shoulder girdle adductors, upward rotators, and depressors
- Postural muscle weakness and fatigue
- Pain and inflammation R extensor carpi radialis longus

Activity Limitation

Participation Restriction

DIAGNOSIS: Chronic grade 1 muscle strain of middle and lower trapezius; upper cervical facet joint movement dysfunction and possible fixed deformity; R TMJ joint hypomobility; R extensor carpi radialis longus tendinitis

PROGNOSIS

Short-Term Goals (2 to 4 weeks)

1. Reduce headache frequency and intensity by 50%
2. Increase sitting tolerance to 60 minutes, incorporating postural adjustments and short breaks
3. Open mouth to 50 mm
4. Improve NDI score to 15 (mild activity limitation)
5. Improve Quick Dash Work score to 35 (mild activity limitation)

Long-Term Goals (6 months)

1. Reduce headache frequency and intensity by 75% to 100%
2. Return to baseline work level
3. Open mouth wide enough to eat apples and burgers
4. Improve NDI score to 3 (mild activity limitation)
5. Improve Quick Dash Work score to 10 (no activity limitation)

CASE STUDY NO. 9

Janet is a 47-year-old nurse with primary complaints of posterolateral right (R) thigh pain. The pain is worse with weight-bearing first thing in the morning, gets better with limited activity, but worsens by the end of the day—especially if she has been on her feet quite a bit during the day. Secondary complaints include intermittent, dull low back pain and occasional bouts of sharp pain in the arch of her R foot. She is a regular walker, walking in the country on the road facing traffic, approximately 3 miles per day, 5 days per week. She has had to stop this activity due to lateral R knee pain.

EXAMINATION

Posture and Alignment: Thoracic kyphosis, lumbar lordosis, posterior pelvic tilt with anterior displacement of pelvis over base of support; elevated iliac crest R > L; medially rotated femurs R > L; laterally rotated tibias R > L; foot pronation R > L; leg length measures: R leg $^3/_8$-inch longer than the L

Active Range of Motion: Hip internal rotation 0 to 55 degrees, external rotation 0 to 30 degrees; thoracolumbar flexion full and pain free with reversal of lumbar lordosis

Muscle Length: Shortened tensor fascia lata/iliotibial band (TFL/ITB) with end range stretch pain; shortened hamstrings (medial > lateral); shortened gastroc/soleus on the R

Strength Testing: Leg lowering 2/5; trunk curl 4/5; gluteus medius (R) 2+/5, (L) 3/5; gluteus maximus (R) 3/5, (L) 3+/5; TFL (R) 3+/5 (pain elicited), (L) 4/5; iliopsoas (R) 2+/5, (L) 3/5; quadriceps (R) 4–/5, (L) 4+/5; hamstrings (R) 4+/5, (L) 4+/5; posterior tibialis (B) 5/5 (R > L muscle fatigue)

Accessory Motion Testing: Hypermobile posterior/anterior glides T10–L2 with relative hypomobility of lower lumbar segments; hypomobile dorsal glide great toe R > L

Movement Testing: Single-leg stance (R) with pain and excessive medial rotation of femur; decreased pain when femur held in lateral rotation

Gait: Positive Trendelenburg (R), medial rotation of femur midstance (R), excessive foot pronation early and late stance R > L

Palpation: Tender along R ITB, particularly at distal lateral knee; slight tenderness to deep palpation of plantar fascia at calcaneus origin

Functional Outcome Score: KOOS Symptom Scale = 75; KOOS Pain = 61; KOOS QoL = 50

EVALUATION: Acute, easily irritable pain arising from R ITB resulting from compensatory TFL patterns associated with weakness and length–tension imbalance of TFL synergists; intermittent bouts of foot pain arising from plantar fascia, excessive pronation, and great toe hypomobility

Impairment

- Postural alignment fault of posterior pelvic tilt, medially rotated femur, and foot pronation; leg length difference
- Muscle weakness of TFL synergists, including gluteus medius, iliopsoas, and quadriceps
- Shortened iliotibial band
- Lengthened gluteus medius
- Faulty movement patterns during gait

Activity Limitation

- Unable to walk 20 minutes without onset of R leg pain

Participation Restriction

- Unable to perform all job requirements for full 8-hour shift
- Unable to walk for fitness
- Difficulty performing household tasks because of leg pain

DIAGNOSIS: ITB fasciitis and intermittent plantar fasciitis

PROGNOSIS

Short-Term Goals (4 to 6 weeks)

1. Perform light duty work 40 hours per week
2. Walk 1.5 miles per day, paced at 20 minutes per mile, without leg or foot pain
3. Perform housework without leg pain if paced at 30- to 40-minute work intervals

Long-Term Goals (12 to 16 weeks)

1. Resume full duty work at 40 hours per week
2. Walk 3 miles per day, paced at 20 minutes per mile, without leg or foot pain
3. Perform all housework without limitations
4. Improve KOOS score by 50%

CASE STUDY NO. 10

Pete is a 38-year-old man with complaints of right (R) shoulder and hip pain. He fell onto his R shoulder 6 months ago. He complains of clicking and instability, particularly during movements of hand behind back. He also has impingement pain at the middle to end range of arm elevation. He is an avid runner (30 to 40 miles per week) and has posterior, superior, and medial hip pain after about 2 miles of running. The hip pain resolves about 45 to 60 minutes after the run. His occupation requires prolonged sitting at a computer, and he has increased hip pain after 45 to 60 minutes of sitting. His shoulder also begins to ache after approximately the same time period. He was also planning on beginning swimming to train for a triathlon when he fell. He has not been able to make any progress on his swimming skills.

EXAMINATION

Alignment: Slight forward head and head tilt to left (L); R head of humerus slightly anterior displaced; R scapula in moderate depression, tilt, downward rotation, adduction; R iliac crest elevated relative to L; R femur adducted and in slight medial rotation relative to L; R tibia slightly laterally rotated; R foot in slight abduction and pronation. Total body posture is a classic swayback. Sitting alignment is with pelvis in posterior tilt and R trunk sidebending with R scapula depressed, downwardly rotated, and tilted

Gait: At load response, the trunk is in R sidebend with R scapula depressed, downwardly rotated, and adducted; throughout R stance phase, the pelvis demonstrates a compensated Trendelenburg on the R; throughout swing phase on the L, the pelvis moves in excessive R forward rotation (clockwise approximately 12 degrees); foot mechanics appear unremarkable with the exception of slight excessive supination at terminal stance

Lumbar and Cervical Scan Examinations: Negative for reproduction of symptoms or neurologic signs

Range of Motion:

R shoulder: Flexion 0 to 150 degrees, scaption 0 to 150 degrees, lateral rotation/medial rotation (with arm abducted 90 degrees) 90 to 40 degrees

R hip: Flexion/extension 95 to 10 degrees, abduction/adduction 30 to 5 degrees, lateral/medial rotation (prone) 50 to 20 degrees

Thoracic rotation: 25% limitation R rotation

Scapulohumeral Rhythm: During arm elevation, scapula is slow to upwardly rotate; most of the rotation occurs in the last phase of arm elevation; reduced overall scapulothoracic (ST) upward rotation on R relative to L; scapular winging on return from elevation

Muscle Length: Moderate shortness in R medial hamstrings, R tensor fascia lata/iliotibial band (TFL/ITB), excessive length of R iliopsoas, moderate shortness in R rhomboid, significant shortness in infraspinatus/teres minor (R), excessive length in R lower trapezius and serratus anterior

Strength Testing (short-range positional strength): Gluteus medius (R) 3+/5, (L) 4+/5; gluteus maximus (R) 4–/5, (L) 4+5; iliopsoas (R) 3/5, (L) 4/5; medial hamstrings (R) 4–/5 (pain elicited), (L) 5/5; adductors (R) 4–/5 (pain elicited), (L) 5/5; hip lateral rotators (R) 3+/5, (L) 4+/5; subscapularis (R) 3+/5, (L) 4+/5; infraspinatus/teres minor (R)/(L) 5/5; upper trapezius (R) 4–/5, (L) 5/5; middle trapezius (R) 3+/5, (L) 4/5; lower trapezius (R) 3+/5, (L) 4/5; serratus anterior (R) 3–/5, (L) 4/5; trunk curl 5/5; leg lowering 3/5

Joint Mobility: Moderate restriction in glenohumeral (GH) posterior and inferior glide (capsular end-feel, pain after resistance), moderate excessive mobility in GH anterior glide (capsular end-feel); moderate restriction in ST upward rotation (muscular end-feel), and acromioclavicular joint anterior glide (capsular end-feel); moderate restriction in hip posterior and inferior glide (capsular end-feel, pain after resistance)

Resisted Tests: Weak and painful R medial hamstrings, hip adductors, and supraspinatus and subscapularis

Special Tests: Positive apprehension and relocation signs for R shoulder, positive anterior impingement sign for R shoulder, positive slump test for R lower extremity (pain reproduced in posterior, superior, and medial hip)

Palpation: Tenderness over subscapularis and supraspinatus insertions; tenderness in the region of medial ischial tuberosity and inferior pubic ramus

Functional Tests: Pain and apprehension with reaching R hand behind back; painful arc with touching R hand to head; during hand behind back maneuver, R scapula fails to adduct, and humeral head translates excessively anteriorly when compared with L. Step-ups illustrate hip hike with hip flexion phase on R and compensated R Trendelenburg with R stance limb; squats reveal asymmetrical hip flexion with R hip hike at end range

CASE STUDY NO. 10 (*continued*)

Functional Outcome Measures: Quick Dash: 39

EVALUATION: Chronic strain to R hamstring and adductor muscles; chronic strain to R subscapularis and supraspinatus; impingement R shoulder; questionable R shoulder instability

Impairment

- Localized pain R anterior and superior shoulder and R hip
- Hypermobility/instability(?) of R shoulder
- Capsular restriction R hip
- Short ST downward rotators, GH lateral rotators, medial hamstrings, TFL/ITB, R adductors
- Long ST upward rotators, subscapularis, iliopsoas
- Thoracic spine, GH, ST, hip joint restrictions
- Weakness in R shoulder upward rotators, subscapularis, gluteus medius, gluteus maximus, iliopsoas, hip lateral rotators

Activity Limitation

- Unable to reach R hand behind back or overhead without discomfort or unstable feeling
- Unable to sit, climb more than five flights of stairs, or run 2 miles without R hip discomfort

Participation Restriction

- Unable to sit at computer for more than 45 to 60 minutes at a time at work
- Unable to participate in recreational activity of running at desired level

DIAGNOSIS: R shoulder impingement and functional instability; R subscapularis strain and supraspinatus tendinopathy; R medial hamstrings and adductor magnus strain with secondary sciatic nerve injury or entrapment. Need to rule out R glenoid labrum tear and long thoracic nerve injury, which may have occurred during the fall.

PROGNOSIS

Short-Term Goals (2 to 3 months)

1. Elevate R arm through full range of motion and reach behind back and overhead without pain or instability
2. Sit 45 minutes without R hip pain
3. Climb 5 flights of stairs without R hip pain
4. Run 15 miles per week without increased R hip pain
5. Participate in a swimming program of mixed strokes up to 500 yards TIW

Long-Term Goals (6 to 8 months)

1. Unlimited use of R arm without pain or instability
2. Sit unlimited periods (in good alignment) without R hip pain
3. Climb up to 10 flights of stairs without R hip pain
4. Run 30 miles per week without R hip pain
5. Swim 1.0 mile without pain or instability
6. Improve Quick Dash to at least 75

COMPLETE INTERVENTION

A complete intervention for this case study follows on the next few pages—Complete Intervention: Lower Quadrant and Complete Intervention: Upper Quadrant.

COMPLETE INTERVENTION—LOWER QUADRANT
For Case Study No. 10

The following is a comprehensive exercise program for lower quadrant intervention for Pete. It is prescribed in the first week.

AT WEEK 1

ACTIVITY: Hand-knee rocking (see Self-Management 19-7 in Chapter 19).

PURPOSE: To improve the flexibility of the hips, stretch the posterior hip muscles, and train independent movement between the hips, pelvis, and spine.

RISK FACTORS: Watch for symmetry when rocking backward.

SUBSYSTEM OF MOVEMENT SYSTEM EMPHASIZED: Passive subsystem.

STAGE OF MOTOR CONTROL: Mobility.

MODE: Passive movement exclusively of the hips.

POSTURE: Hands and knees with hips directly over the knees and shoulders directly over the hands. Hip joints should be at a 90-degree angle. Knees and ankles are hip-width apart with feet pointing straight back. Hands shoulder-width apart with hands pointing straight forward. Keep a slight extension curve in the low back.

MOVEMENT: First activate intrinsic spinal muscles (see Patient-Related Instruction 17-1 in Chapter 17). The patient is instructed to rock backward at the hip joint only, stopping before the onset of back movement.

SPECIAL CONSIDERATIONS: Motion at the hips should be independent from the lumbopelvic region.

DOSAGE

Special Considerations

Anatomic: Hip joints, not the lumbopelvic region

Physiologic: Asymmetric hip stiffness at end range hip flexion

Learning Capability: Ingrained movement pattern of hip hiking with functional activities; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: 30 repetitions, 1 set

Frequency: 7 days per week

Sequence: Begin with this exercise, followed by the open kinetic chain strengthening exercises.

Speed: Slowly to monitor accessory lumbopelvic movements

Environment: At home on a flat, firm surface, initially, in front of a mirror

Feedback: Initially in the clinic with clinician providing tactile and verbal feedback and a mirror providing visual feedback. Begin with knowledge of performance for every repetition, then taper every three to four repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Ascending stairs, gait, and running without asymmetric pattern.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve hip flexion mobility resulting from reduced extensibility in the capsule, ligament, muscle, or myofascial stiffness. For Pete to have a symmetric walking, stair-climbing, and running pattern, hip mobility needs to be WNL bilaterally. It is assumed that the stiffness in his R hip contributes to the hip hiking pattern and that this pattern contributes to the upper quarter asymmetry as well. To recover from both lower and upper quarter conditions, hip mobility impairment should be resolved.

ACTIVITY: Iliopsoas strengthening (see Self-Management 19-5, Level I, in Chapter 19).

PURPOSE: Iliopsoas neuromuscular education to promote recruitment in the shortened range with hip flexion.

RISK FACTORS: Ensure use of iliopsoas and not TFL or RF recruitment. Watch for hip hiking on the R.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Active and neural subsystems

STAGE OF MOTOR CONTROL: Mobility.

MODE: Isometric iliopsoas contraction.

POSTURE: Seated with unilateral hip flexion and slight hip lateral rotation.

MOVEMENT: First set intrinsic spinal muscles. The patient passively flexes the hip into end range flexion with slight lateral rotation. Avoidance of hip hike or lumbar flexion is critical. The patient simply holds the limb without any resistance provided.

SPECIAL CONSIDERATIONS: Hip medial rotation will recruit the dominant hip flexor muscle, TFL, over the iliopsoas contributing to further shortening of the IT band. Hip hiking will contribute to lateral pelvic tilt versus hip flexion and should be avoided.

DOSAGE

Special Considerations

Anatomic: R iliopsoas, R hip joint

Physiologic: Length-associated changes in strength; stronger in the lengthened range than the shortened range

Learning Capability: Very ingrained movement pattern from a long history of high-mileage running; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: To form fatigue, pain, or 20 to 30 repetitions, up to three sets

Frequency: 6 to 7 days per week

Sequence: After quadruped rocking

Speed: Hold for 10 seconds

Environment: At home on a firm surface

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every three to four repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Ascending stairs, gait, and running.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve muscle performance and motor control strategies of hip flexor muscles. Hip flexion without contributing to IT band shortening or hip hiking patterns depends on proper recruitment of the iliopsoas muscle in the shortened range. This method of neuromuscular reeducation is necessary before translating to dynamic activity and function.

ACTIVITY: Stomach lying gluteus medius strengthening (see Self-Management 19-4, Level I, in Chapter 19).

PURPOSE: Gluteus medius muscle strengthening in the shortened range.

RISK FACTORS: Medial hamstring and adductor magnus strain.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Active subsystem

STAGE OF MOTOR CONTROL: Mobility.

MODE: Concentric and eccentric gluteus medius contractions.

POSTURE: Stomach lying with a pillow under the pelvis if indicated by the physical therapist. Legs should be in line with hips and slightly rotated outward.

MOVEMENT: First set intrinsic spinal muscles. Next perform an isometric contraction of the gluteus maximus. Slightly lift the leg into extension and abduction until lateral tilt is seen. Stop just short of lateral tilt of the pelvis. Hold at end range. Ensure the knee remains slightly rotated laterally.

SPECIAL CONSIDERATIONS: Keep the lumbopelvic region stable using the intrinsic spinal muscles. Hold slight hip lateral rotation throughout the range to avoid TFL muscle recruitment. Recruit the gluteus maximus and relax the hamstring muscles.

DOSAGE

Special Considerations

Anatomic: R gluteus medius, R hip joint

Physiologic: Length-associated changes in strength; stronger in the lengthened range than the shortened range

Learning Capability: May be difficult secondary to capsular restrictions. Ingrained muscle recruitment pattern of the TFL muscle and lateral trunk muscles from a long history of high-mileage running; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: To form fatigue, pain, or 20 to 30 repetitions

Frequency: 6 to 7 days per week

Sequence: After quadruped rocking

Speed: Slowly

Environment: At home on a firm surface

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every couple repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Ascending stairs, gait, and running.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve motor control strategies and strength of gluteus medius, and gluteus maximus muscles. Lumbopelvic stability and IT band extensibility depends on proper recruitment of the gluteus medius muscle throughout the range. This method of neuromuscular reeducation and strengthening is necessary before returning to functional activities.

AT 3 WEEKS

ACTIVITY: Iliopsoas strengthening (see Self-Management 19-5, Level 2, in Chapter 19).

PURPOSE: Iliopsoas strengthening to improve muscle balance of hip flexor muscles.

RISK FACTORS: Watch for TFL substitution or lateral pelvic tilt.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Active subsystem

STAGE OF MOTOR CONTROL: Mobility.

MODE: Resistive isometric iliopsoas contraction.

POSTURE: Sitting with unilateral hip flexion and slight hip lateral rotation.

MOVEMENT: First set intrinsic spinal muscles. The patient passively flexes the hip as far as possible while maintaining neutral lumbopelvic position. Next, the patient holds the position and provides gentle resistance to the hip in the direction of extension and slight lateral rotation. The contraction should be isometric.

SPECIAL CONSIDERATIONS: Hip medial rotation will recruit the dominant hip flexor muscle, TFL, over the iliopsoas contributing to further shortening of the IT band.

(continued)

DOSAGE

Special Considerations

Anatomic: R iliopsoas, R hip joint

Physiologic: Length-associated changes in strength; stronger in the lengthened range than the shortened range

Learning Capability: Very ingrained recruitment pattern from a long history of high-mileage running; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: To form fatigue, pain, or 15 repetitions, up to three sets

Frequency: 3 to 4 days per week

Sequence: After quadruped rocking

Speed: Hold for 10 seconds

Environment: At home on a firm surface

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every three to four repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Ascending stairs, gait, and running.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve strength of iliopsoas muscle. This is the progression from isometric hold without resistance. Hip flexion without contributing to IT band shortening depends on proper recruitment of the iliopsoas muscle in the shortened range. Iliopsoas strengthening decreases TFL muscle dominance during dynamic activity and function.

ACTIVITY: Sidelying gluteus medius strengthening (see Self-Management 19-4, Level 4, in Chapter 19).

PURPOSE: Gluteus medius muscle strengthening in the shortened range.

RISK FACTORS: Medial hamstring and adductor magnus strain.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Active

STAGE OF MOTOR CONTROL: Mobility/stability.

MODE: Concentric and eccentric gluteus medius contractions.

POSTURE: Sidelying against a wall with a small towel roll behind the superior gluteal. The towel roll ensures the hip slides up the wall in slight extension. Superior hip should be slightly laterally rotated.

MOVEMENT: First set intrinsic spinal muscles. Slide the leg up the wall, keeping the heel in contact with the wall to ensure hip extension, to end range. Stop before lateral pelvic tilt. Hold at end range. Be sure the hip stays laterally rotated.

SPECIAL CONSIDERATIONS: Keep the lumbopelvic region stable using the intrinsic spinal muscles to prevent lateral pelvic tilt. Hold slight hip lateral rotation and extension throughout the range to avoid TFL muscle recruitment.

DOSAGE

Special Considerations

Anatomic: R gluteus medius, R hip joint

Physiologic: Length-associated changes in strength; stronger in the lengthened range than the shortened range

Learning Capability: May be difficult secondary to capsular restrictions. Ingrained muscle recruitment pattern of the TFL muscle from a long history of high-mileage running; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: To form fatigue, pain, or six to eight repetitions

Frequency: 3 to 4 days per week

Sequence: After iliopsoas strengthening

Speed: Slowly

Environment: At home on a firm surface

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every couple repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Ascending stairs, gait, and running.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve strength of the gluteus medius muscle. Lumbopelvic stability and IT band extensibility depends on proper recruitment of the gluteus medius muscle throughout the range. Open kinetic chain gluteus medius strengthening is necessary before transferring to dynamic activity and function.

ACTIVITY: Squats (see Self-Management 19-9 in Chapter 19).

PURPOSE: Strengthen hip girdle muscles and train independent movement between hips and spine in a functional context.

RISK FACTORS: Watch for symmetric loading between extremities.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Active and neural subsystems

STAGE OF MOTOR CONTROL: Controlled mobility.

MODE: Concentric and eccentric hip girdle muscle contractions.

POSTURE: Standing with weight equally distributed between both feet, and pelvis and spine in neutral in front of a full-length mirror.

MOVEMENT: First set intrinsic spinal muscles. Slowly bend your hips and knees. Return to the start position by using quadriceps and gluteals.

SPECIAL CONSIDERATIONS: Knees should not flex beyond the length of the feet or medial to the second toes.

More emphasis should be placed on gluteal muscles versus hamstring muscles. Keep the lumbopelvic region stable and bend through the hips with equal loading and avoidance of lateral pelvic tilt.

DOSAGE

Special Considerations

Anatomic: Bilateral hip girdle muscles, bilateral hip joints

Physiologic: Length-associated changes in eccentric and concentric strength and asymmetric mobility in hips

Learning Capability: Very ingrained movement pattern from a long history of high-mileage running; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: To form fatigue, pain, or 20 to 30 repetitions

Frequency: 6 to 7 days per week

Sequence: After gluteus medius strengthening

Speed: Slowly

Environment: At home with or without a chair, depending on strength

Feedback: Initially in clinic with clinician providing tactile and verbal feedback and mirror providing visual feedback. Taper to continued use of mirror, with knowledge of results of verbal feedback after every three to four repetitions. Withdraw mirror and verbally provide knowledge of results every three to four repetitions.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Ascending stairs, sit to stand, walking, and running.

RATIONALE FOR EXERCISE CHOICE: This functional exercise was chosen to improve strength of hip girdle muscles and hip joint mobility. Improved hip joint mobility and force-generating capability of the gluteus maximus enables increased hip flexion and decreased knee flexion during squatting activities. Squats with shared forces at the hip and knee decrease excessive forces at the low back and knee.

ACTIVITY: Step-ups (see Self-Management 19-3 in Chapter 19)

PURPOSE: Incorporate proper total-body movements in a functional context.

RISK FACTORS: Avoid hip hike patterns and hamstring dominance.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Active and neural subsystems

STAGE OF MOTOR CONTROL: Controlled mobility.

MODE: Concentric and eccentric hip girdle muscle contractions.

POSTURE: Standing in front of a 6-in step in front of a mirror.

MOVEMENT: First set intrinsic spinal muscles. Lift the R leg onto the step. Step up.

SPECIAL CONSIDERATIONS: Be sure the patient does not hike his R hip during the hip flexion phase or perform a Trendelenburg pattern during hip extension phase. The pelvis must remain level and stable throughout the entire exercise to adequately recruit iliopsoas during hip flexion and prepare to use gluteus maximus and gluteus medius muscles in their proper length–tension properties during hip extension.

DOSAGE

Special Considerations

Anatomic: R hamstring and adductor

Physiologic: Chronic moderate strain

Learning Capability: Very ingrained movement pattern from a long history of high-mileage running; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: To form fatigue as evidenced by hip hike, pain, or 20 to 30 repetitions, up to three sets

Frequency: 6 to 7 days per week

Sequence: Perform after specific exercises for psoas and gluteus medius muscle performance and squats.

Speed: Slow progressed to functional speed

Environment: At home in front of a mirror

Feedback: Initially in clinic with clinician providing tactile and verbal feedback and mirror providing visual feedback. Taper to continued use of mirror, with knowledge of results of verbal feedback after every three to four repetitions. Withdraw mirror and verbally provide knowledge of results every three to four repetitions. Progress toward skill.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Ascending stairs, walking, running.

RATIONALE FOR EXERCISE CHOICE: This functional exercise was chosen to replace the faulty movement with one that is correct. Faulty hip hiking does not emphasize hip flexion and efficient recruitment of the gluteus maximus and medius muscles. Trendelenburg pattern does not emphasize lumbopelvic stability. Correct step-up pattern encourages gluteus maximus and quadriceps recruitment over hamstring and gluteus medius recruitment over TFL or adductors.

COMPLETE INTERVENTION—UPPER QUADRANT

For Case Study No. 10

The following is a comprehensive exercise program for upper quadrant intervention for Peter. It is prescribed in week 3 post initial evaluation.

AT WEEK 3

ACTIVITY: Sidelying lateral rotator and posterior capsule stretch (see Self-Management 25-4 in Chapter 25)

PURPOSE: To lengthen lateral rotators of the shoulder.

RISK FACTORS: Ensure sufficient posterior glide of the humerus on the glenoid to prevent overstretching anterior capsule; i.e., verify normal accessory motion prior to self-stretching

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Passive subsystem

STAGE OF MOTOR CONTROL: Mobility.

MODE: Contract-relax of the shoulder lateral rotators.

POSTURE: Sidelying with bottom arm elevated to 90 degrees and elbow flexed to 90 degrees and the shoulder starting in neutral rotation.

MOVEMENT: Shoulder joint should internally rotate allowing your forearm to move toward your feet and the floor. At that point, lightly press up into the resistance of the other hand and hold for 6 to 10 seconds. Relax and gently push the bottom forearm further toward your feet and the floor. Repeat three to four times.

SPECIAL CONSIDERATIONS: Scapula should be entirely on your back rather than under your body to target the lateral rotators. If the scapula slips under your body, scapular adductors will stretch instead. Avoid anterior shoulder pain.

DOSAGE

Special Considerations

Anatomic: R shoulder lateral rotators.

Physiologic: Short shoulder lateral rotators. Length-associated changes in strength; stronger in the shortened range than the lengthened range.

Learning Capability: Good with specific verbal and visual instructions.

Repetitions/Sets: Three to four repetitions; two sets

Frequency: Three to five times per day, 7 days per week

Sequence: Begin with this stretch followed by the rest of the exercises.

Speed: Hold for 6 to 10 seconds

Environment: At home on a firm surface

Feedback: Initially in clinic with clinician providing verbal, visual, and tactile feedback. Begin with knowledge of performance for every repetition, then taper every other repetition with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Reaching overhead without discomfort or unstable feeling.

RATIONALE FOR EXERCISE CHOICE: This stretch was chosen to improve the length of the shoulder lateral rotators. Sufficient shoulder medial rotation is needed for optimal GH congruency and to prevent anterior displacement of the humeral head.

ACTIVITY: Supine GH lateral and medial rotation.

PURPOSE: Develop motor control strategy of the rotator cuff muscles for ideal path of instant center of rotation (PICR) of the GH joint.

RISK FACTORS: Chronic subscapularis strain and supraspinatus tendinopathy.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: neural and passive subsystems

STAGE OF MOTOR CONTROL: Mobility.

MODE: Concentric and eccentric rotator cuff contractions.

POSTURE: Lying supine with arm abducted to 90 degrees and elbow flexed to 90 degrees on an even, stable surface. R scapular spine should lie at the level of the second vertebra.

MOVEMENT: Slowly rotate arm so that your forearm moves back toward your head, then in the opposite direction so the forearm moves forward.

SPECIAL CONSIDERATIONS: The arm should move independently from the scapula spinning in its socket. The scapula should not displace forward or depress nor should the humeral head displace forward from the socket.

DOSAGE

Special Considerations

Anatomic: R medial and lateral rotator cuff muscles, right GH joint

Physiologic: Chronic moderate strain and tendinitis, questionable instability of the right GH joint

Learning Capability: Existing motor programs may accentuate instability; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: To form fatigue, pain, or 20 to 30 repetitions, up to three sets

Frequency: 6 to 7 days per week

Sequence: Begin with this exercise followed by the wall slide with subscapularis bias and muscle performance exercise of the serratus anterior.

Speed: Slowly for good-quality movement.

Environment: At home on the floor or firm bed.

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every three to four repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Reaching behind the back without discomfort or unstable feeling.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve motor control strategies of shoulder medial and lateral rotators. Independent movement of the GH joint with ideal PICR is the goal rather than faulty compensatory scapulothoracic movement.

ACTIVITY: R arm wall slide with medial rotation bias (see Fig. 25-4B in Chapter 25)

PURPOSE: Develop motor control strategy to encourage rotator cuff activation, specifically the subscapularis, as opposed to pectoralis major, latissimus dorsi, and teres major muscles for ideal PICR of the GH joint.

RISK FACTORS: Chronic subscapularis strain.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Neural and active subsystems

STAGE OF MOTOR CONTROL: Controlled mobility.

MODE: Isometric rotator cuff activation with subscapularis bias.

POSTURE: Standing with palm of the hand against the door frame. R scapular spine should lie at the level of the second vertebra.

MOVEMENT: Slide the hand upward and downward while maintaining mild pressure into medial rotation against the door frame.

SPECIAL CONSIDERATIONS: More than mild pressure applied into medial rotation against the door frame will recruit pectoralis major, latissimus dorsi, and teres major muscles instead of subscapularis causing anterior translation of the humeral head.

DOSAGE

Special Considerations

Anatomic: R subscapularis, right GH joint

Physiologic: Chronic moderate strain and tendinitis, questionable instability of the right GH joint

Learning Capability: Very ingrained movement pattern from a long history of high-mileage running; may require high repetitions and significant feedback in early stages of learning

Repetitions/Sets: To form fatigue, pain, or 20 to 30 repetitions, up to three sets

Frequency: 6 to 7 days per week

Sequence: After GH rotation but before muscle performance exercise of the serratus anterior.

Speed: Slowly for good-quality movement.

Environment: At home in a door frame.

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every three to four repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Reaching overhead and behind the back without discomfort or unstable feeling.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve motor control strategies of shoulder medial rotators. Proper recruitment of the subscapularis muscle over other medial rotators provides dynamic anterior stability of the GH joint during dynamic activity. It is important that the subscapularis muscle is trained because of its anterior insertion close to the axis of rotation.

ACTIVITY: Supine serratus anterior isometric (see Self-Management 25-3, Level I in Chapter 25)

PURPOSE: Serratus anterior neuromuscular education to promote recruitment in the shortened range with scapular upward rotation.

RISK FACTORS: Impingement of rotator cuff tendons.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Neural and active subsystems

STAGE OF MOTOR CONTROL: Mobility.

MODE: Isometric serratus anterior contraction.

POSTURE: Supine with arm elevated resting on pillows placed above your head.

MOVEMENT: Lightly press thumb into pillows engaging the serratus anterior muscle.

SPECIAL CONSIDERATIONS: More than mild pressure applied into the pillows will recruit muscles of the GH joint over the serratus anterior causing anterior translation of the humeral head.

DOSAGE

Special Considerations

Anatomic: R serratus anterior, R scapulothoracic joint

Physiologic: Length-associated changes in strength; stronger in the lengthened range than the shortened range

Learning Capability: May be difficult secondary to painful arc. May require a less than desirable starting point in the range

Repetitions/Sets: To form fatigue, pain, or 20 to 30 repetitions, up to three sets

Frequency: 6 to 7 days per week

(continued)

Sequence: After wall slides and GH rotation

Speed: Hold for 10 seconds

Environment: At home on a firm surface

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every three to four repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Reaching overhead without discomfort or unstable feeling.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve motor control strategies of shoulder elevator muscles. Sufficient scapular upward rotation depends on proper recruitment of the serratus anterior muscle in the shortened range with arm elevation. This method of neuromuscular reeducation is necessary before translating to dynamic activity and function.

AT 3 WEEKS

ACTIVITY: Stomach lying middle and lower trapezius isometric

PURPOSE: Middle and lower trapezius neuromuscular education to hold the scapula in a position of upward rotation

RISK FACTORS: Impingement of rotator cuff tendons and anterior displacement of the humeral head

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Neural subsystem

STAGE OF MOTOR CONTROL: Stability.

MODE: Isometric middle and lower trapezius contraction (see Self-Management 25-2, Level I in Chapter 25)

POSTURE: Stomach lying with both hands resting on the head. Good cervical and scapular alignment.

MOVEMENT: Barely lift your elbows keeping neck and upper trapezius muscles relaxed. Contract middle and lower trapezius muscles.

SPECIAL CONSIDERATIONS: Lifting elbows excessively will recruit posterior muscles of the GH joint and rhomboids causing anterior translation of the humeral head and scapular adduction, respectively.

DOSAGE

Special Considerations

Anatomic: Bilaterally middle and lower trapezius muscles, scapulothoracic joint

Physiologic: Weak middle and lower trapezius muscles, dominant rhomboids

Learning Capability: May be difficult secondary to painful arc.

Repetitions/Sets: To form fatigue, pain, or 20 to 30 repetitions, up to three sets

Frequency: 6 to 7 days per week

Sequence: Begin with this exercise followed by stomach lying shoulder rotation and sidelying serratus anterior exercises.

Speed: Hold for 10 seconds

Environment: At home on a firm surface

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every three to four repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Reaching overhead without discomfort or unstable feeling.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve motor control strategies of scapular stabilizing muscles. Scapular upward rotation about a stable PICR depends on recruitment of the middle and lower trapezius muscles with arm elevation. This method of neuromuscular reeducation is necessary before translating to dynamic activity and function.

ACTIVITY: Prone GH lateral and medial rotation with 1-lb weight (see Self-Management 25-1 in Chapter 25)

PURPOSE: Develop motor control strategy of the rotator cuff muscles and scapulothoracic muscles for ideal PICR of the GH joint and scapula.

RISK FACTORS: Chronic subscapularis strain and tendinitis.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Neural and active subsystems

STAGE OF MOTOR CONTROL: Controlled mobility

MODE: Concentric and eccentric rotator cuff contractions. Isometric contractions of the middle and lower trapezius muscles.

POSTURE: Lying prone with arm abducted to 90 degrees and elbow flexed to 90 degrees on an even, stable surface. A towel roll should be placed under the anterior shoulder joint.

MOVEMENT: Slowly rotate arm so that your forearm moves up toward your head, then in the opposite direction so the forearm moves back toward your feet.

SPECIAL CONSIDERATIONS: The arm should move independent from the scapula spinning in its socket. The scapula should not displace forward nor should the humeral head displace forward from the socket.

DOSAGE

Special Considerations

Anatomic: R medial and lateral rotator cuff muscles, right GH joint, R middle and lower trapezius muscles, R scapula.

Physiologic: Chronic moderate strain and tendinitis, questionable instability of the right GH joint

Learning Capability: Very ingrained movement pattern from a long history of high-mileage running; may require high repetitions

Repetitions/Sets: To form fatigue, pain, or six to eight repetitions with fatigue

Frequency: 3 to 4 days per week

Sequence: Begin with this exercise followed by the wall slide with subscapularis bias and muscle performance exercise of the serratus anterior.

Speed: Slowly for good-quality movement.

Environment: At home on the floor or firm bed.

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every couple of repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Reaching behind the back without discomfort or unstable feeling.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve motor control strategies of scapular stabilizers and shoulder medial and lateral rotators. Independent movement of the GH joint with ideal PICR and a stable scapula are the goals.

ACTIVITY: Sidelying serratus anterior dynamic contractions with resistive band (see Self-Management 25-3, Level II in Chapter 25)

PURPOSE: Serratus anterior muscle strengthening throughout the range with scapular upward rotation.

RISK FACTORS: Impingement of rotator cuff tendons.

SUBSYSTEM OF THE MOVEMENT SYSTEM EMPHASIZED: Neural and active subsystems

STAGE OF MOTOR CONTROL: Controlled mobility.

MODE: Concentric and eccentric serratus anterior contractions.

POSTURE: Sidelying with arm rested on pillows placed in front of your head and shoulders. Resistive band is attached on the upper foot and the other end grasped in the resting hand.

MOVEMENT: Slide your arm upward toward your head, keeping it in contact with the pillows. On the return, slowly lower the arm back down to the starting position against the resistance of the band.

SPECIAL CONSIDERATIONS: Keep the scapula on your back upwardly rotating about a stable PICR.

DOSAGE

Special Considerations

Anatomic: R serratus anterior, R scapulothoracic joint.

Physiologic: Faulty eccentric motor control of serratus anterior muscle.

Learning Capability: May be difficult secondary to painful arc. May require a less than desirable starting point in the range.

Repetitions/Sets: To form fatigue, pain, or six to eight repetitions.

Frequency: 3 to 4 days per week.

Sequence: After wall slides and GH rotation.

Speed: Slowly.

Environment: At home on a firm surface.

Feedback: Initially in clinic with clinician providing tactile and verbal feedback. Begin with knowledge of performance for every repetition, then taper every couple of repetitions with knowledge of results.

FUNCTIONAL MOVEMENT PATTERN TO REINFORCE GOAL OF EXERCISE: Reaching overhead and behind the back without discomfort or unstable feeling.

RATIONALE FOR EXERCISE CHOICE: This exercise was chosen to improve motor control strategies and strength of shoulder elevator muscles. Sufficient scapular upward rotation depends on proper recruitment of the serratus anterior muscle throughout the range with arm elevation. This method of neuromuscular reeducation and strengthening is necessary before returning to functional activities.

CASE STUDY NO. 11

Mr. Lawn, a 67-year-old man, had a right (R) total hip replacement (THR) 4 years ago. He also has left (L) hip degenerative joint disease (DJD). For the last 4 months he has been noticing increasing L hip pain and is beginning to have pain in the R hip as well if he attempts to play more than nine holes of golf. He states that 18 holes is usual, and he pulls his own cart. Recent muddy conditions seem to have made symptoms worse. His main concern is that R low back pain will be triggered by R hip pain, as it has been in the past. During the last episode of low back pain, he had to sleep sitting up in his chair, because it was the only place he could get comfortable. Mr. Lawn lives with his wife, who is in the early stages of Alzheimer disease, and his golf games are his main social contact with friends. He is otherwise healthy and does all the driving, shopping, and housework.

EXAMINATION

Pain: L hip at rest 2/10, after 18 holes of golf 7/10; R hip at rest 1/10, after golf 3/10; R low back at rest 0/10, after golf 1/10

Posture: In standing: bilateral (B) supinated feet; marked B tibial bowing; B femoral internal rotation; high L iliac crest; anterior tilted pelvis; mild hip flexion; supine apparent short R leg; R iliac crest and ischial tuberosity high compared with L

Gait: Marked B trunk sidebend to side of stance leg, decreased hip and knee flexion; slight circumduction B; decreased pronation B feet; R stance time decreased compared with L

Active Range of Motion (open chain):

	R hip	L hip
Extension/flexion	5 to 110 degrees	5 to 115 degrees (pain)
Internal/external rotation	20 to 25 degrees	20 to 15 degrees (pain)
Abduction	30 degrees	20 degrees
Knee flexion/extension	2 to 125 B degrees	
Lumbar flexion	Hands 4 in below knees	
Lumbar extension	25% normal range (pain)	

Accessory Motion: L Hip—hypomobile in distal glide, capsular tightness in internal and external passive rotation. Lumbar spine—extension and R sidebend with overpressure restricted and painful compared with L

Palpation: B rectus femoris, iliopsoas, hip adductors, and R quadratus lumborum dense/tender

Strength Testing: Rectus femoris (B) 5/5; iliopsoas (R) 4−/5, (L) 5/5; gluteus maximus (R) 4−/5, (L) 4/5; gluteus medius (R) 4−/5, (L) 3+/5; quadriceps (B) 5/5; gastroc/soleus (B) 5/5; abdominals 4−/5 by leg lowering test

Balance: R single-leg stance time: 5 seconds; L single-leg stance time: 12 seconds

Neurologic Signs: Normal for L3–S1 light touch, deep tendon reflexes, and key muscle strength.

Active Movement Testing (open chain): Pain is elicited with L hip flexion. Internal rotation and abduction at end of available range in each motion. Standing lumbar sidebend and R rotation is painful. Single-leg stance (R) causes R hip pain, and closed chain testing was deferred because of initial apprehension and balance deficits.

Functional Outcome Score: Hip Harris score (0 to 100) (Accessed February 3, 2015, from http://www.orthopaedicscore.com/scorepages/harris_hip_score.html): 70 (moderate activity limitation), Modified Oswestry Back Index score: 30 (moderate activity limitation); Mini- BESTest (0 to 28) 25 (low fall risk)

EVALUATION: DJD-related hip muscle strength and range deficits leading to gait and pelvic asymmetry and hip joint pain and to R L5/S1 compression and irritation.

Impairment

- B hip range of motion restriction
- B hip joint muscle weakness
- Abdominal muscle overstretch
- Frontal plane pelvic asymmetry
- Sagittal plane lumbopelvic asymmetry
- Decreased standing balance
- Gait abnormality
- Unable to maintain neutral pelvis

Activity Limitation

- Pain limits walk endurance

Participation Restriction

- Unable to play golf
- Unable to socialize and restore self mentally and emotionally for wife's care

CASE STUDY NO. 11 (*continued*)

DIAGNOSIS: Condition after R hip THR; L hip DJD with muscle imbalance leading to probable R L5–S1 facet compression irritation

PROGNOSIS

Short-Term Goals (14 to 21 days)

1. Regain sagittal and frontal plane alignment in standing and walking
2. Regain at least 4/5 strength in all hip and abdominal muscle groups
3. Equalize L hip range of motion to that of R hip
4. Able to balance 30 seconds in single-leg stance (B)
5. Improve Hip Harris Score to 80 (mild activity limitation)
6. Improve Oswestry Score to 20 (mild activity limitation)

Long-Term Goals (4 to 6 weeks)

1. Ambulate with normal gait pattern
2. Walk 18 holes of golf, pulling cart, without pain in hips or low back
3. Improve Hip Harris Score to 90 (no activity limitation)
4. Improve Oswestry Score to 5 (no activity limitation)

CASE STUDY NO. 12

Harriet is a retired 70-year-old female who presented with burning at her perineum and some mixed urge and urinary incontinence in the last 1.5 to 2 years. She has a long history of mid-back pain since a motor vehicle accident 4 years ago. Since the accident, she wears a brace for prolonged sitting that puts her in a flexed position. Her primary complaint is that she has constant burning pain at her perineum, worsened with direct contact over the region, limiting ability to wear underwear, wear pants, and sit for >30 minutes. She has managed by lying on her back and wearing skirts without underwear. She enjoys primarily sedentary tasks such as reading and knitting. She volunteers weekly as a tutor and travels to visit her grandchildren about every other weekend (2-hour car ride) which flares up symptoms.

EXAMINATION

Observation: Forward head, moderate to severely rounded shoulders, moderate kyphosis of thoracic spine

Gait: Pelvis demonstrates a mild bilateral Trendelenburg, mild hip ER on R, mild hip flexion and forward head with scapular protraction, moderate. Foot mechanics appear unremarkable.

Range of Motion:

Cervical Spine: Flexion 25, extension 45, rotation 45 to R and L; Thoracic Spine: seated rotation 45 R and 60 L, pain at mid-back at end range

Shoulder AROM: Flexion 0 to 135 R, 0 to 150 L, abduction 0 to 150 R and 0 to 160 L

Hip flexion: Full range noted, extension limited to −10 bilaterally, internal rotation: 25 R, 35 L, external rotation: 65 R, 55 L

Neurologic screen: Negative for lower and upper extremity normal myotome, dermatome, and reflexes

Upper Limb Neural Tension: + ulnar and median nerve bilaterally

Functional and Special Tests

Pelvis: No obvious asymmetry in alignment and sacroiliac joint screening negative for hyper and hypomobility

Scour: Negative bilaterally

Sacroiliac Joint Shearing: Negative bilaterally

Sacroiliac Joint Compression: Negative bilaterally

Muscle Length: Hamstrings 0 to 80 degrees bilaterally from 90/90 test position, Gluteus maximus, quadriceps all negative bilaterally; lengthened rhomboids and mid-lower trapezius; shortened pectoralis major

Pelvic Floor Examination:

Palpation: External, nontender, constant burning at vulvar region, moderate activity of pelvic floor superficial muscles

Reflexes: Intact for bulbocavernosus and anal wink

Sharp/dull discrimination: Intact

Internal Pelvic Examination:

Internal exam: Performed vaginally, unable to assess rectally due to external anal sphincter very tight, tender

Tissue quality: Increased tension with right perineal muscles

Palpation: Tender at deep pelvic floor layer R > L, also triggers mid-back pain

MMT: Gluteus medius: 3+/5 R and 4−/5, gluteus maximus 4/5 bilaterally

Performance Score of Pelvic Floor Musculature Using the "PERF" Scale

Power: 2/5 (0 = no contraction; 1 = trace flicker; 2 = poor, contraction with no lift; 3 = fair, palpable contraction and lift from posterior to anterior; 4 = good, strong contraction and lift with compression from ant, post, and side walls; 5 = strong, stronger lift and compression with inferior deflection from finger)

Endurance: Patient able to hold pelvic floor contraction for 5 seconds (10 seconds = strong performance; 2 seconds = fair performance)

CASE STUDY NO. 12 (*continued*)

Repetitions: She completes four repetitions of 5-second holds prior to fatigue

Fast Twitch: Able to perform three quick flick repetitions in 10 seconds, incomplete relaxation

Additional Findings Related to Pelvic Floor

Elevation: Absent

Cocontraction of abdominals: Present, excessive

Timing: Absent

Abdominal, adductor and gluteal muscle substitution pattern is evident.

Cystocele is present; Rectocele is absent.

Pelvic floor descent, Valsalva: unable

Paradoxical relaxation: Present

EVALUATION: Chronic pelvic pain possibly related to chronic postural dysfunction and sympathetic nervous system from a hypomobility of the thoracic spine.

Impairment

- Hypomobility of thoracic spine
- Hypersensitivity of perineum, reduced tolerance to contact
- Faulty postural mechanics: tight pecs, lengthened mid-back muscles

Activity Limitations

- Unable to wear underwear or pants
- Unable to sit for longer periods of time

Participation Restriction

- Unable to tolerate internal exam for gynecologic health maintenance
- Unable to sit in waiting room for >30 minutes for medical appointments
- Unable to drive or ride in car for 2 hours which would take to visit family members
- Unable to sit for volunteer work as tutor

DIAGNOSIS: Vulvodynia and thoracic back pain

PROGNOSIS

Short-Term Goals (2 to 3 months)

1. Management of urge/stress incontinence
2. Improve pelvic floor coordination

Long-Term Goals (4 to 6 months)

1. Reduced pelvic pain to be able to wear pants and underwear
2. Reduced pelvic pain to be able to tolerate sitting 1 hour for tutoring sessions
3. Management of back pain to be able to put away dishes
4. Management of back pain to tolerate prolonged sitting 2 hours to be able to visit her family

APPENDIX 1

Red Flags: Recognizing Signs and Symptoms

DAVID MUSNICK* • CARRIE M. HALL

Because therapists often have consistent daily or weekly contact with patients, they may be the health professionals to recognize serious neuromusculoskeletal pathology or systemic disease requiring medical referral. A thorough history, carefully conducted interview, systems review, and screening examinations must be completed during the initial evaluation. Any red flags—signs or symptoms that signal pathologic conditions—may indicate serious somatic or visceral disease or disorders that are beyond the scope of physical therapy intervention. The information outlined in this appendix delineates signs and symptoms of somatic and visceral origin.

Physical therapists often perform interventions, such as therapeutic exercise, to alleviate pain. The physical therapist must be sure that the pain is of neuromusculoskeletal origin and is within the scope of physical therapy practice. A patient with pain that may be caused by serious pathology or referred from a visceral source should be immediately referred to a medical physician for further testing.

Visceral structures can be a source of referred pain to musculoskeletal regions, particularly to the shoulder, back, chest, hip, or groin. The mechanism by which visceral structures refer pain to musculoskeletal regions is twofold:

1. Visceral afferents that supply internal organs transmit impulses to the dorsal horn in which somatic and visceral pain fibers share second-order neurons. Impulses from visceral nerve endings arrive at similar interneuron pools as impulses from somatic origin. Visceral pain may then be felt in somatic segments and skin areas with which it shares neurons in the dorsal horn. This pattern is called referred visceral sensation. Broader pain referral from visceral structures can occur with multiple-segment overlap. Referred visceral sensation may coexist with reflex muscle spasm and vasomotor changes.
2. Visceral structures in the thoracic and abdominal cavities have free nerve endings in loose connective tissue in epithelial and serous linings and in blood vessels. Neural afferent information is transmitted along small, unmyelinated, type C nerve fibers within sympathetic and parasympathetic nerves of the autonomic nervous system. The pain is usually not well localized by the patient and is usually described as vague, deep, and aching.

Signs and symptoms associated with referred visceral pain are the most common red flags signaling the need for further evaluation. The cause of this pain is related to the pathologic function of the primary visceral structure involved. Viscera may refer pain caused by tissue ischemia, obstruction, mechanical distention, or inflammation. **Tables A-1** and **A-2** describe the sources and characteristics of somatic and visceral pain. **Tables A-3** and **A-4** review the signs and symptoms associated with referred visceral pain. Whenever a patient reports symptoms described in Tables A-3 and A-4, screening for systemic disease is appropriate. The decision to screen for systemic disease may be even more critical if the patient is older than 45 years of age and the symptoms have an insidious onset.

Table A-5 describes systemic, visceral, or nonmechanical causes of regional musculoskeletal pain. The physical therapist should be aware of constant, severe pain with increases in intensity, nonmechanical patterns, or the symptoms or signs described in Table A-4 in association with regional musculoskeletal pain. Referral of the patient to a physician is indicated when pain in a musculoskeletal region is accompanied by symptoms and signs indicating systemic or nonmechanical disease. Some types of referred visceral pain are made worse with mechanical stress. Mechanical exacerbation on examination is not 100% specific and cannot alone be used for diagnosing mechanical problems.

Female patients, persons older than 50 years of age, and children may present with symptoms about which the practitioner should be aware:

- Female patients with new-onset thoracolumbar, lumbosacral, or sacroiliac pain should be screened through a renal and reproductive history and lumbar scanning examination. Prompt medical screening is indicated if the person has fever, costovertebral angle tenderness, urinary symptoms, pelvic or suprapubic pain or tenderness, tachycardia, orthostatic changes, or an unclear diagnosis. Renal and reproductive organ disease can cause significant morbidity if not treated quickly.
- Malignant disease should be suspected in patients older than 50 years of age who have constant back pain that is increased with recumbency, history of primary tumor, pathologic fractures, night pain, or multiple painful areas in the spine. The axial skeleton is involved more commonly than the appendicular

*David Musnick, MD, is an internal medicine/sports medicine physician in Seattle and Bellevue, Washington. He conducts seminars in differential diagnosis to physical therapists. He has taken numerous courses in exercise and manual therapy topics taught by physical therapists. He has written a book on functional exercise, Conditioning for Outdoor Fitness, published by Mountaineers Books in Seattle.

TABLE A-1

Sources and Characteristics of Somatic and Visceral Pain

Somatic Sources

Superficial Somatic Cutaneous Pain

- Localized but may refer within 6–12 inches
- Aching
- Burning
- Throbbing (e.g., abscesses)
- Neck, hip, or elbow pain with reactive lymph nodes
- Reactive lymph glands are aggravated by pressure or stretching

Deep Somatic Pain[a]

Muscles

- Localized or may be in referred patterns
- Increases with direct pressure on a tender area or site of lesion, locally or in a referral pattern

Joints

- Deep aching that is vague within the area (more common with peripheral joints) and a referred pattern that is felt more distally from the area (especially spinal joints)
- May decrease with rest or when stressful action has stopped
- May increase with activity
- Increases with stress testing or palpation

Ligaments

- Deep aching in the region of the ligament but may also be perceived distally
- Increases with stress testing or palpation

Neurologic Pain

- Characteristic pain referral patterns based on the site of the lesion
- May be associated with bone pain if the origin of neurologic compression is bone

Bone Pain

- Perceived close to the bone (see Table A-2)
- Constant and not relieved by rest
- May be worse with walking, jumping, or other impact
- If a tumor is growing in a bone the pain will be gradually increasing and may be worse at night when the patient is trying to sleep

Visceral Sources

- Vague pain
- Deep pain
- Aching pain
- Boring pain
- Tearing pain
- If a hollow organ is involved, pain may be more colicky (i.e., crescendo and decrescendo)

[a]Pain may originate in muscles, ligaments, joints, periosteum, vessels, dura, and fascia.

skeleton, with the lumbar and thoracic spine affected similarly (incidence of approximately 45% to 50%). Cord compression signs require immediate referral to a physician.

- Back pain is rare in patients younger than 16 years of age, especially in nongymnasts and in patients without trauma. Pediatric patients with low back pain and without history of trauma or overuse should be screened by a medical practitioner.
- Pediatric patients with hip pathology may complain of knee or hip pain or a vague pain with walking. Any pediatric patient seen for recent onset, undiagnosed limping should be evaluated with a medical history and scan of the lumbar spine, hip, knee, and lower extremity (including temperature). Patients with these complaints should be seen promptly by a medical practitioner and have an x-ray examination to evaluate the hip, if indicated.

TABLE A-2

Causes of Bone Pain and Associated Signs and Symptoms

CAUSES	ASSOCIATED CONDITIONS AND SYMPTOMS
Stress and compression fractures	Overuse Osteoporosis Evaluate for menstrual and eating disorders in young females
Avascular necrosis (wrist, femoral head, shoulders, feet)	Corticosteroid use Trauma
Osteomyelitis	Fever or other source of infection
Hematologic disorders of the bone marrow	Fatigue Multiple areas of bone pain, especially in the spine and pelvis
Paget disease	Cranial neuropathies Leg deformities Warm bones on examination
Benign tumor	Scoliosis if in the spine, especially in a child
Cancer (primary or metastatic)	Symptoms of primary cancer Fatigue Pain of bone origin in more than one spine site; a spine site combined with a rib or long bone site may be metastatic cancer and should be referred for evaluation

TABLE A-3

Characteristics of Systemic Symptoms

DATA OBTAINED FROM THE HISTORY	CONSTITUTIONAL SYMPTOMS
■ Insidious onset or no known cause (or both)	■ Fever
■ Pattern of presentation: gradual, progressive, cyclical	■ Chills
■ Constant	■ Malaise
■ Intense	■ Fatigue
■ Bilateral	■ Night sweats
■ Unrelieved by rest or change of position	■ Gastrointestinal symptoms
■ Night pain	■ Skin rash
■ History of infection	■ Weight loss
■ Migratory arthralgias	■ Dyspnea (i.e., shortness of breath)
	■ Diaphoresis at rest or with minimal exertion

TABLE A-4

Visceral Symptoms and Signs Categorized by Origin

Infection
- Fever
- Chills
- Malaise
- Fatigue
- Night sweats
- Red rash
- Swelling
- Purulence
- Constant pain
- Painful, enlarged lymph nodes
- Superficial palpation or percussion tenderness
- Root or cord compression by space-occupying lesion in spine

Pulmonary
- Cough
- Sputum
- Wheezing
- Shortness of breath
- Chest pain
- Pain worsened by deep inspiration
- Hemoptysis (i.e., coughing up blood)
- Decreased aerobic exercise capacity

Cardiac
- Arrhythmia (fast >120, slow <40)
- Pauses
- Irregular pulse
- Chest, jaw, scapular, or left arm pain
- High or low blood pressure (>180 or <85)
- Dizziness
- Syncope (i.e., fainting)
- Bilateral leg and foot swelling
- Shortness of breath

Vascular
- Low-amplitude pulse
- Coldness
- Paleness
- Swelling
- Constant pain
- Tearing or boring pain
- Color change

Gastrointestinal
- Nausea
- Vomiting
- Bloating
- Weight loss
- Loss of appetite
- Change in stools
- Bloody stools
- Diarrhea
- Absence of bowel movement
- Abdominal pain
- Yellow eyes or skin
- Food may help or aggravate

Renal
- Costovertebral angle tenderness
- Hematuria (i.e., red urine)
- Painful or frequent urination

Endocrine
- Energy or temperature changes
- Urinary volume change
- Possible bone pain

Neoplastic
- Constant or night pain
- Age >45 y
- Myelopathy signs (e.g., spinal cord compression)
- Previous primary tumor
- Pathologic fracture
- Generalized weakness
- Pain in multiple bony locations

Gynecologic
- Pelvic or low back pain
- Menstrual abnormalities
- Pelvic mass

Rheumatologic
- Peripheral joint swelling
- Deformity
- Redness or pain
- Rash

TABLE A-5

Systemic Disease or Visceral Pain Referred from the Musculoskeletal Region

Headache
- Intracranial tumor (U)
- Meningitis (U)
- Subarachnoid hemorrhage (U)
- Sinus infection
- Temporal arteritis; refer patients with visual problems immediately to prevent blindness (U)

Cervical Spine Region Pain
Visceral Referred Pain
Thoracic Origin
- Cardiac ischemia or infarction (U)
- Pneumomediastinum (U)
- Pericarditis (U)
- Aortic arch dissection (U)
- Pancoast tumor
- Pleuritis

Infectious Origin
- Meningitis (U)
- Epidural abscess (U)
- Osteomyelitis (U)
- Disk space infection (U)
- Transverse myelitis (U)
- Lyme disease

Neoplastic Causes
- Metastatic tumor
- Intramedullary or extramedullary tumor
- Epidural hematoma (U)

Vascular Origin
- Subarachnoid hemorrhage (U)
- Vertebral artery dissection (U)
- Carotid artery thrombosis (U)

Other Visceral Referred Pain
- Sphenoid sinusitis
- Thyroiditis
- Parotitis
- Cervical lymphadenitis (from a throat or skin source)
- Pharyngeal space infection (P) (U)
- Cysts (P)

Nonviscerogenic Referred Pain
Rheumatologic Disease
- Fibromyalgia
- Polymyalgia rheumatica
- Rheumatoid arthritis
- Ankylosing spondylitis
- Gout or other crystal-induced inflammation

Shoulder Pain
Visceral Referred Pain
Neoplastic Causes
- Metastatic lesions
- Breast
- Prostate
- Kidney
- Lung
- Thyroid
- Cervical cord or root compression
- Pancoast tumor
- Lung cancer

Cardiac Origin (Left Shoulder)
- Angina or myocardial infarction (U)
- Pericarditis (U)
- Aortic aneurysm (U)

Pulmonary Origin
- Empyema and lung abscess
- Pulmonary tuberculosis
- Spontaneous pneumothorax (U)
- Lung cancer

Breast Origin
- Mastodynia
- Primary or secondary cancer

Abdominal Origin
- Liver disease
- Ruptured spleen (U)
- Gallbladder disease
- Subphrenic abscess

Systemic Disease
- Collagen vascular disease
- Gout
- Syphilis, gonorrhea
- Sickle cell anemia
- Hemophilia
- Rheumatic disease

Thoracic-Scapular Region Pain
Visceral Referred Pain
Cardiac Origin
- Myocardial ischemia or infarction (U)
- Dissecting aortic aneurysm (U)

Pulmonary Origin
- Pneumonia (U)
- Pleuritis
- Pulmonary embolism (U)
- Pneumothorax (U)
- Empyema (U)

Neoplastic Causes
- Mediastinal tumors
- Pancreatic carcinoma

Neck Origin
- Esophagitis
- Abdominal Origin
- Liver disease (e.g., hepatitis, cirrhosis, metastatic tumors)
- Gallbladder disease

Anterior or Lateral Chest Pain
Serious Causes (U)
Pulmonary Origin
- Pulmonary embolism
- Pneumothorax
- Pneumomediastinum
- Pneumopericardium
- Mediastinal tumor
- Asthma
- Pneumonia (if respiratory rate >20 and short of breath)

Cardiac Origin
- Pericarditis
- Dissecting coronary artery or aorta (e.g., Marfan syndrome)
- Cardiac hypertrophy
- Primary pulmonary hypertension
- Myocarditis
- Tachycardia (heart rate >140–160 at rest)
- Suspected myocardial infarction (may occur in younger patient using cocaine)

Less Serious Causes
Infectious Origin
- Herpes zoster infection
- Pneumonia (if no respiratory compromise)
- Pleurisy
- Bronchitis

Gastrointestinal Origin
- Esophageal tear
- Spasm
- Reflux

Thoracolumbar Spine and Sacroiliac Region Pain
Visceral Referred Pain
Neoplastic Causes
- Malignant tumors of the spinal cord or meninges (neurologic deficit)
- Lymphoma (night sweats, weight loss, lymphadenopathy)
- Multiple myeloma (>40 y of age, moderately severe bone pain, multiple osteopenic spine lesions, kidney disease, fatigue from excessive calcium)
- Metastatic tumors (e.g., prostate, breast, lung, kidney, thyroid, colon)
- Pediatric malignancies (e.g., Ewing sarcoma, osteosarcoma, lymphoma, leukemia, skeletal metastasis from Wilms tumor, neuroblastoma, rhabdomyosarcoma) (P)

Abdominal Origin
- Abdominal aortic aneurysm (U)
- Peptic ulcer
- Pancreatic disorders
- Pyelonephritis (U)
- Nephrolithiasis (renal stone) (U)
- Hydronephrosis
- Renal tumor
- Renal infarction (U)

Pelvic Origin
- Urinary bladder retention
- Crohn disease of the rectum
- Chronic prostatitis
- Uterine masses
- Retroverted or prolapsed uterus
- Endometriosis
- Pelvic inflammatory disease (fever, nausea, pelvic pain) (U)
- Ectopic pregnancy (missed menstrual cycle, pelvic pain) (U)
- Benign ovarian tumor
- Colon diverticulitis
- Retroperitoneal fibrosis

Rheumatologic Causes
- Ankylosing spondylitis
- Reiter syndrome
- Psoriatic arthritis

(continued)

TABLE A-5

Systemic Disease or Visceral Pain Referred from the Musculoskeletal Region (*continued*)

Infectious Origin (U)
- Osteomyelitis
- Disk space infection
- Epidural abscess
- Pyogenic sacroiliitis

Endocrine and Metabolic Causes
- Osteoporosis with compression fracture

Hip, Groin, and Thigh Pain
Visceral Referred Pain

Neoplastic Causes
- Bone tumors
- Spinal metastasis

Abdominal Origin
- Inguinal or femoral hernia
- Appendicitis (U)
- Crohn disease
- Ureteral colic

Pelvic Origin

Systemic disease
- Pelvic inflammatory disease (P)
- Thrombosis Syndromes (U)
- Deep venous thrombosis (DVT) with proximal extension to femoral vein and/or pelvic veins (calf pain and swelling)
- Greater saphenous vein phlebitis (superficial, may progress to DVT)

Arthritis
- Osteoarthritis
- Gout, pseudogout
- Rheumatoid arthritis
- Ankylosing spondylitis (degenerative joint disease of hip in a younger male)
- Reiter syndrome

Pediatric Hip Disease (P)
- Legg–Calvé–Perthes (proximal femoral epiphyseal blood flow interruption and necrosis; collapse of femoral head; hip pain, limp, adductor and iliopsoas spasm, possible Trendelenburg sign; child 4–8 y old)
- Slipped capital femoral epiphysis (hip, thigh, or knee pain; hip hypomobility especially in medial rotation; older child or adolescent)
- Transient synovitis (hip, thigh, or knee pain; difficulty walking and possible fever, 2–12 y of age with peak incidence at 6–7 y)

Infectious Origin
- Lymphadenitis caused by cellulitis distally or abdominal wall, perineum, or genital areas or other infections, including sexually transmitted diseases (U)
- Iliopsoas abscess (retroperitoneal infection or inflammation) (U)

P, pediatric; U, urgent.

APPENDIX 2

Red Flags: Potentially Serious Symptoms and Signs in Exercising Patients

SCOTT TAUFERNER • CARRIE M. HALL

Certain symptoms occurring during exercise may indicate significant medical problems and may be the reason for referral. **Display A-1** lists the symptoms associated with medical conditions and the tests that should be performed to exclude a medical emergency. **Display A-2** lists signs indicating medical problems that necessitate medical referral.

During supervised exercise, a patient may develop serious signs and symptoms. **Display A-3** describes the signs and symptoms related to exercise and the appropriate course of action with respect to various comorbidities:

- Asthma or other pulmonary disease
- Cough
- Cardiovascular disorders
- Syncope
- Hypoglycemia
- Allergic reactions
- Deep vein thrombosis (DVT)
- Pulmonary embolus (PE)
- Spinal cord compression from metastatic disease

DISPLAY A-1

Symptoms Associated with Medical Conditions

CONDITION	SYMPTOMS	TESTS
Asthma, pulmonary disease	■ Wheezing ■ Pleuritic pain (chest pain increased by a deep breath) ■ Cough ■ Significant shortness of breath	■ Pulse ■ Respiratory rate ■ Blood pressure ■ Peak flow
Coronary artery, heart valve, myocardial infarction	■ Tightness or pain in the left chest, jaw, scapula, or left arm ■ Light-headedness ■ Nausea	■ Pulse ■ Blood pressure in both arms to determine differential
Cardiac rhythm disturbance	■ Light-headedness ■ Fainting ■ Bradycardia (heart rate <50) ■ Pauses between beats, especially if associated with light-headedness	■ Postural pulse ■ Blood pressure ■ Neurologic screen
Chronic fatigue or fibromyalgia	■ Flare-up of fatigue after exercise ■ Intolerance to aerobic or strength training	■ Screen for tender points
Cervical or intracerebral pathologies Neurogenic, vascular claudication, or DVT	■ Exercise-induced headaches ■ Calf pain with exercise	■ Complete neurologic and cervical screen ■ Peripheral pulses ■ Straight-leg raise ■ Neurologic screen ■ Homans test ■ Calf circumference

DISPLAY A-2

Signs Associated with Medical Conditions

SIGNS	CONDITION
Heart Rate	
Less than 50 beats per minute (unless very aerobically fit individual) Pauses >3 seconds between beats (especially if associated with light-headedness) Moderately elevated heart rates during and after cessation of exercise	▪ Bradycardia ▪ Diseased sinus node ▪ Serious bradycardia ▪ Chronic pulmonary or cardiac disease ▪ Arrhythmia
Elevated heart rate before exercise	▪ Fever ▪ Pulmonary compromise ▪ Hyperthyroidism ▪ Volume depletion (from bleeding or other fluid loss)
Heart rate elevation >120 beats per minute, 5 minutes after exercise; if heart rate is >140 beats per minute and accompanied by chest pain, considered a medical emergency	▪ Possible myocardial infarction ▪ Fever ▪ Hyperthyroidism ▪ Arrhythmia (tachycardia) ▪ Volume depletion
Blood Pressure	
Systolic blood pressure <85 mm Hg (exercise is contraindicated) Systolic blood pressure >140 (exercise not contraindicated until systolic reaches 170; isometric exercise contraindicated)	▪ Hypotension ▪ Hypertension
Respiratory Rate	
Greater than 20 (exercise contraindicated unless there is a known chronic lung condition)	▪ Asthma ▪ Pulmonary infections ▪ Chronic lung conditions ▪ Acute pain ▪ Fever

DISPLAY A-3

Common Medical Conditions That May Produce Serious Signs and Symptoms During Exercise

Asthma, Pulmonary Diseases, and Shortness of Breath

If a patient has a history of asthma, chronic pulmonary disease, or recent upper respiratory tract infection with any of the symptoms listed below during or after exercise, he or she may have an asthma flare, temporary bronchospasm, or another pulmonary problem (e.g., bronchitis, pneumonia). Any patient with active asthma should be managed by a physician and encouraged to bring his or her asthma inhaler and peak flow meter to the therapy department.

Symptoms and Signs

- Coughing
- Wheezing
- Substernal chest tightness
- Mild shortness of breath at rest or precipitated by exercise or cold weather
- Use of accessory muscles of respiration (e.g., scalenes, pectoralis minor, intercostals)
- Elevated respiratory rate (>18 breaths per minute) 5 minutes after cessation of exercise
- Low peak flow level for age, sex, and height

Clinical Actions

- Administer the patient's bronchospasm inhaler. A second inhalation should be administered after 1 to 2 minutes. Recheck signs and symptoms within 5 to 10 minutes.
- Peak flow of <80% of predicted indicates asthma or chronic obstructive pulmonary disease, indicating referral for a medical evaluation.
- Peak flow of <250 indicates severe airway obstruction and is reason for referral to the emergency room.
- Respiratory rate >24, resting heart rate >100, and a peak flow of <200 to 250 are signs of pulmonary compromise or a severe exacerbation and poor clinical response to the medication. If the patient does not show improvements significantly after the inhalation of medication, the patient's physician should be called immediately. If the patient appears to be in respiratory distress, he or she should be transferred to an emergency room.
- Exercise can be continued if the patient responds well to the medication. The physician should be called regarding management of the medications to prevent future exacerbations.

DISPLAY A-3

Common Medical Conditions That May Produce Serious Signs and Symptoms During Exercise (*continued*)

Cough

Associated Conditions

- Pulmonary infection (accompanied by colored sputum, fever, chills)
- Medication side effect
- Serious lung disorder
- Asthma
- Reactive airway disease
- Congestive heart failure
- Mild respiratory tract infection

Increased intraabdominal and intrathoracic pressure induced by coughing can greatly exacerbate spine pain conditions of a mechanical nature. Patients with spinal disorders should be advised to suppress cough with over-the-counter medications and consult their physician to determine the cause and receive definitive treatment. Patients with a persistent cough should be referred to a physician.

Cardiovascular Disorders

Symptoms

- Chest, substernal, left arm, anterior neck, jaw, and periscapular pain
- Headache, blurred vision, exacerbation of neck pain (symptoms of severe hypertension)
- Uncontrolled hypertension that exacerbates headache and neck pain
- Chest pain, light-headedness, fainting, and perceptions of strong beats or irregularity (symptoms of heart rhythm abnormalities)

Clinical Actions

- If heart rate is <45 or >150 beats per minute after cessation of exercise for more than 5 minutes, refer the patient immediately or call 911.
- If the patient has a heart rate >150 and is younger than 50 years old, an attempt to decrease the heart rate by putting slight pressure on the carotid body can be made by massaging the carotid pulse just inferior to the angle of the jaw. The radial pulse can be monitored with another hand, and if it begins to slow, pressure can be taken off the carotid body. If there is no effect within 10 to 15 seconds, this procedure should be stopped.
- If the patient has angina symptoms (i.e., severe, constricting chest pain) with known coronary disease, administer his or her own nitroglycerin while sitting or lying down. You may repeat this after 5 minutes. If no relief occurs after a total of three doses in 15 minutes, call 911.
- If systolic blood pressure is >180 or diastolic pressure is >110, the therapy appointment should be terminated and the patient referred to his physician.
- If the systolic blood pressure is >220 and the diastolic pressure is >130, the patient should go to the emergency room, and the referring physician should be called.
- High blood pressure, midline thoracic pain, and between-arm blood pressure differences of 10 mm Hg should be referred immediately.
- A patient with a history of coronary disease should be referred immediately if he or she is experiencing arrhythmia and has chest pain.
- If the patient is unconscious, call 911 and begin cardiopulmonary resuscitation.

Syncope

Syncope is defined as a sudden and reversible loss of consciousness and decrease or loss of postural muscle tone. It can be caused by transient cerebral ischemia (a total loss of cerebral flow for 10 seconds leads to a blood pressure <70) or altered chemical composition of blood flow to the brain (brain cells depend on a constant level of glucose for energy).

Symptoms

- Changes in vision
- Nausea
- Sweating
- Feeling of dizziness
- Feeling of leg or trunk postural weakness
- Palpitations or chest pain if tachycardia
- Calf or chest pain if pulmonary embolism

To determine if the syncope is caused by postural changes, the blood pressure and heart rate are taken in three positions: supine, sitting, and standing. The blood pressure is assessed in each position. If the systolic pressure lowers by more than 20 points or the heart rate elevates by more than 20 points with each positional change, the patient can be determined to have posturally related syncope.

Clinical Actions

- The patient should be positioned in supine with legs elevated for at least 3 minutes to increase venous return of blood.
- A patient with posturally related syncope and a history of vomiting or diarrhea is usually dehydrated and requires significant rehydration with more than 2 L of fluid. The patient should have arrangements made for transportation to a physician's office or a medical facility. It may be possible for the patient to take in enough fluid orally. Rehydration may be started in the therapy department, but it should not be completed in the therapy department.
- Syncope that occurs more than one time requires termination of the therapy appointment and transportation to the emergency room (unless it is clearly a vasovagal faint). A vasovagal faint is one in which there is no ongoing pathology and the blood pressure and pulse become normal after 3 to 5 minutes in all positions. Patients who faint more than one time should not be allowed to transport themselves to a medical facility.

Hypoglycemic Episodes

Hypoglycemic episodes most commonly occur in patients with diabetes. The causes vary, including improper timing of meals or snacks, excessive insulin or improper dosing or timing of insulin, and excessive or unplanned exercise coupled with inadequate food intake.

Symptoms and Signs

- Shakiness
- Weakness
- Sweaty
- Blurred vision
- Excessive anxiety
- Irritability
- Light-headedness
- Confusion
- Decreased cognitive abilities
- Unconsciousness
- Blood sugar levels <50 to 60

(continued)

DISPLAY A-3

Common Medical Conditions That May Produce Serious Signs and Symptoms During Exercise (*continued*)

All diabetes patients should be asked to bring their meters with strips to every therapy visit in case of a hypoglycemic episode. Any of the above symptoms should prompt blood sugar assessment.

Clinical Actions

- If the glucose level is <60, and the patient is awake, give a carbohydrate snack of three glucose tablets, a tube of Insta-Glucose gel, *or* 1/2 to 1 cup of juice. Ask the patient to take a snack including carbohydrate and protein or fat.
- Do not begin any aerobic exercise.
- Recheck the serum glucose level in 30 minutes. If the patient feels significantly better, he or she can resume exercise.
- If the patient is unconscious, administer glucagon immediately. Mix the liquid in the syringe with the powder in the bottle, and then inject the whole clear solution that is in the syringe into the deltoid muscle or the quadriceps muscle. Place the patient in a sidelying position to protect the airway. When the patient awakens and is fully conscious, give a glucose snack and protein, refer the patient to the emergency room, and call the primary physician.

Instructions for Diabetic Patients Before Exercise

- If the glucose level is 100 to 180, administer 15 g of carbohydrate.
- If the glucose level is 180 to 250, it is not necessary to increase food intake.
- If the glucose level is more than 250, do not start aerobic exercise.

Allergic Reactions

Patients may develop allergic reactions to exercise that can occur for the first time in the therapy department:

- Exercise-related hives (i.e., itchy, raised skin areas filled with fluid)
- Angioedema (i.e., swelling in the subcutaneous tissues around the eyes, lips, hands, and feet, and possibly in the tongue and posterior pharynx and airway)
- Anaphylactic shock (i.e., associated with decreased blood pressure, increased pulse, sweatiness, pallor, angioedema, and asthma symptoms)

Anaphylactic shock may occur as a reaction to a medication such as antibiotics, angiotensin-converting enzyme inhibitors, aspirin, or nonsteroidal anti-inflammatory drugs. Exercise-induced anaphylaxis may occur with vigorous aerobic exercise as the only precipitating factor. Any patient with a history of exercise-induced shock should always exercise with another person and should always carry an epinephrine kit.

A patient may also develop any of these reactions in response to latex gloves or another allergen that he or she is severely allergic to that may be used in the therapy department. A patient may also react to medications.

Clinical Actions

- Hives usually do not cause emergent problems unless this condition progresses to other, more serious problems. Stop exercise, and consider having the patient take an antihistamine such as Benadryl. Call the patient's primary physician.
- Angioedema is an emergency if it involves swelling of the tongue and airway. If the patient displays difficulty controlling saliva or breathing, the treatment of choice is to administer one dose of epinephrine (0.3 mL of 1:1,000 solution) in the deltoid area. If a qualified person is not on the premises to administer this treatment, call 911.
- Anaphylactic shock is a **severe, life-threatening emergency**. Blood pressure and pulse should be taken, although blood pressure may be difficult to detect. The patient should lie down with legs elevated. A dose of epinephrine should be administered immediately and 911 called.

Deep Vein Thrombosis

Individuals at risk of DVT include those who have sustained local trauma to a vessel, have a hypercoagulable disorder, or have been immobilized by bed rest or casts. The most common locations of DVT include the calf, thigh, arms, and pelvis.

Symptoms and Signs

- Pain in the calf or thigh
- Swelling of the calf (circumferential tape measurements are indicated to verify swelling)
- Pain in the calf with walking
- Tenderness with palpation of the deep calf along the midline
- Complete the Well's scale for DVT

Any patient complaining of calf pain or swelling should be evaluated for DVT.

Clinical Actions

- Suspicion of DVT warrants referral to a physician or emergency room within the next few hours.
- The patient should walk minimally, because there is a danger of the clot breaking off from the vessel.

Pulmonary Embolus

PE is an **urgent condition** in which an area of lung is infarcted as a result of a thrombus occluding a pulmonary artery. The thrombus usually originates in a deep vein of the leg and travels through the venous return circulation into the right side of the heart and out through the pulmonary circulation to occlude a pulmonary artery. Small thrombi may progress to the periphery of the lung and infarct the peripheral lung tissue, with resultant inflammation and pleuritic pain. Large thrombi may occlude the pulmonary circulation and lead to severe cardiac compromise.

Symptoms and Signs

- Pleuritic pain with referred areas of pain
- Shortness of breath
- Fast respiratory rate
- Coughing up blood
- Rapid pulse rate

Suspicion of PE requires immediate referral to the emergency room. If not on the hospital premises, call 911.

Spinal Cord Compression and Metastatic Disease

Patients with metastatic spine lesions can develop cord compression that is manifested by sensory, motor, or bladder symptoms. For a patient with multisite bone pain and new-onset neurologic symptoms, a complete neurologic examination is indicated. If you suspect a cord compression syndrome, check for upper motor neuron (UMN) signs on examination (e.g., clonus, Babinski, Hoffman's, hypertonicity). If UMN signs and motor, sensory, or bladder symptoms are present, refer the patient immediately.

APPENDIX 3

2016 PAR-Q +: The Physical Activity Readiness Questionnaire for Everyone

Source: Physical Activity Readiness Questionnaire (PAR-Q). © 2016. Reprinted from the Canadian Society for Exercise Physiology. Available at: http:/www.csep.ca/forms.asp. Accessed December 28, 2015, with permission.

2016 PAR-Q+

The Physical Activity Readiness Questionnaire for Everyone

The health benefits of regular physical activity are clear; more people should engage in physical activity every day of the week. Participating in physical activity is very safe for MOST people. This questionnaire will tell you whether it is necessary for you to seek further advice from your doctor OR a qualified exercise professional before becoming more physically active.

GENERAL HEALTH QUESTIONS

Please read the 7 questions below carefully and answer each one honestly: check YES or NO.	**YES**	**NO**
1) Has your doctor ever said that you have a heart condition ☐ OR high blood pressure ☐?	☐	☐
2) Do you feel pain in your chest at rest, during your daily activities of living, **OR** when you do physical activity?	☐	☐
3) Do you lose balance because of dizziness **OR** have you lost consciousness in the last 12 months? Please answer **NO** if your dizziness was associated with over-breathing (including during vigorous exercise).	☐	☐
4) Have you ever been diagnosed with another chronic medical condition (other than heart disease or high blood pressure)? **PLEASE LIST CONDITION(S) HERE:** ______	☐	☐
5) Are you currently taking prescribed medications for a chronic medical condition? **PLEASE LIST CONDITION(S) AND MEDICATIONS HERE:** ______	☐	☐
6) Do you currently have (or have had within the past 12 months) a bone, joint, or soft tissue (muscle, ligament, or tendon) problem that could be made worse by becoming more physically active? Please answer **NO** if you had a problem in the past, but it ***does not limit your current ability*** to be physically active. **PLEASE LIST CONDITION(S) HERE:** ______	☐	☐
7) Has your doctor ever said that you should only do medically supervised physical activity?	☐	☐

If you answered NO to all of the questions above, you are cleared for physical activity.
Go to Page 4 to sign the PARTICIPANT DECLARATION. You do not need to complete Pages 2 and 3.

- Start becoming much more physically active—start slowly and build up gradually.
- Follow International Physical Activity Guidelines for your age (www.who.int/dietphysicalactivity/en/).
- You may take part in a health and fitness appraisal.
- If you are over the age of 45 yr and **NOT** accustomed to regular vigorous to maximal effort exercise, consult a qualified exercise professional before engaging in this intensity of exercise.
- If you have any further questions, contact a qualified exercise professional.

If you answered YES to one or more of the questions above, COMPLETE PAGES 2 AND 3.

Delay becoming more active if:

- You have a temporary illness such as a cold or fever; it is best to wait until you feel better.
- You are pregnant—talk to your health care practitioner, your physician, a qualified exercise professional, and/or complete the ePARmed-X+ at **www.eparmedx.com** before becoming more physically active.
- Your health changes—answer the questions on Pages 2 and 3 of this document and/or talk to your doctor or a qualified exercise professional before continuing with any physical activity program.

2016 PAR-Q+

FOLLOW-UP QUESTIONS ABOUT YOUR MEDICAL CONDITION(S)

1. Do you have Arthritis, Osteoporosis, or Back Problems?

If the above condition(s) is/are present, answer questions 1a–1c   If **NO** ☐ go to question 2

1a. Do you have difficulty controlling your condition with medications or other physician-prescribed therapies? (Answer **NO** if you are not currently taking medications or other treatments) YES ☐ NO ☐

1b. Do you have joint problems causing pain, a recent fracture or fracture caused by osteoporosis or cancer, displaced vertebra (e.g., spondylolisthesis), and/or spondylolysis/pars defect (a crack in the bony ring on the back of the spinal column)? YES ☐ NO ☐

1c. Have you had steroid injections or taken steroid tablets regularly for more than 3 months? YES ☐ NO ☐

2. Do you currently have Cancer of any kind?

If the above condition(s) is/are present, answer questions 2a–2b   If **NO** ☐ go to question 3

2a. Does your cancer diagnosis include any of the following types: lung/bronchogenic, multiple myeloma (cancer of plasma cells), head, and/or neck? YES ☐ NO ☐

2b. Are you currently receiving cancer therapy (such as chemotheraphy or radiotherapy)? YES ☐ NO ☐

3. Do you have a Heart or Cardiovascular Condition? *This includes Coronary Artery Disease, Heart Failure, Diagnosed Abnormality of Heart Rhythm*

If the above condition(s) is/are present, answer questions 3a–3d   If **NO** ☐ go to question 4

3a. Do you have difficulty controlling your condition with medications or other physician-prescribed therapies? (Answer **NO** if you are not currently taking medications or other treatments) YES ☐ NO ☐

3b. Do you have an irregular heart beat that requires medical management? (e.g., atrial fibrillation, premature ventricular contraction) YES ☐ NO ☐

3c. Do you have chronic heart failure? YES ☐ NO ☐

3d. Do you have diagnosed coronary artery (cardiovascular) disease and have not participated in regular physical activity in the last 2 months? YES ☐ NO ☐

4. Do you have High Blood Pressure?

If the above condition(s) is/are present, answer questions 4a–4b   If **NO** ☐ go to question 5

4a. Do you have difficulty controlling your condition with medications or other physician-prescribed therapies? (Answer **NO** if you are not currently taking medications or other treatments) YES ☐ NO ☐

4b. Do you have a resting blood pressure equal to or greater than 160/90 mm Hg with or without medication? (Answer **YES** if you do not know your resting blood pressure) YES ☐ NO ☐

5. Do you have any Metabolic Conditions? *This includes Type 1 Diabetes, Type 2 Diabetes, Pre-Diabetes*

If the above condition(s) is/are present, answer questions 5a–5e   If **NO** ☐ go to question 6

5a. Do you often have difficulty controlling your blood sugar levels with foods, medications, or other physician-prescribed therapies? YES ☐ NO ☐

5b. Do you often suffer from signs and symptoms of low blood sugar (hypoglycemia) following exercise and/or during activities of daily living? Signs of hypoglycemia may include shakiness, nervousness, unusual irritability, abnormal sweating, dizziness or light-headedness, mental confusion, difficulty speaking, weakness, or sleepiness. YES ☐ NO ☐

5c. Do you have any signs or symptoms of diabetes complications such as heart or vascular disease and/or complications affecting your eyes, kidneys, **OR** the sensation in your toes and feet? YES ☐ NO ☐

5d. Do you have other metabolic conditions (such as current pregnancy-related diabetes, chronic kidney disease, or liver problems)? YES ☐ NO ☐

5e. Are you planning to engage in what for you is unusually high (or vigorous) intensity exercise in the near future? YES ☐ NO ☐

2016 PAR-Q+

6. Do you have any Mental Health Problems or Learning Difficulties? *This includes Alzheimer's, Dementia, Depression, Anxiety Disorder, Eating Disorder, Psychotic Disorder, Intellectual Disability, Down Syndrome*

If the above condition(s) is/are present, answer questions 6a–6b — If **NO** ☐ go to question 7

6a.	Do you have difficulty controlling your condition with medications or other physician-prescribed therapies? (Answer **NO** if you are not currently taking medications or other treatments)	YES ☐ NO ☐
6b.	Do you have Down Syndrome **AND** back problems affecting nerves or muscles?	YES ☐ NO ☐

7. Do you have a Respiratory Disease? *This includes Chronic Obstructive Pulmonary Disease, Asthma, Pulmonary High Blood Pressure*

If the above condition(s) is/are present, answer questions 7a–7d — If **NO** ☐ go to question 8

7a.	Do you have difficulty controlling your condition with medications or other physician-prescribed therapies? (Answer **NO** if you are not currently taking medications or other treatments)	YES ☐ NO ☐
7b.	Has your doctor ever said your blood oxygen level is low at rest or during exercise and/or that you require supplemental oxygen therapy?	YES ☐ NO ☐
7c.	If asthmatic, do you currently have symptoms of chest tightness, wheezing, laboured breathing, consistent cough (more than 2 days/week), or have you used your rescue medication more than twice in the last week?	YES ☐ NO ☐
7d.	Has your doctor ever said you have high blood pressure in the blood vessels of your lungs?	YES ☐ NO ☐

8. Do you have a Spinal Cord Injury? *This includes Tetraplegia and Paraplegia*

If the above condition(s) is/are present, answer questions 8a–8c — If **NO** ☐ go to question 9

8a.	Do you have difficulty controlling your condition with medications or other physician-prescribed therapies? (Answer **NO** if you are not currently taking medications or other treatments)	YES ☐ NO ☐
8b.	Do you commonly exhibit low resting blood pressure significant enough to cause dizziness, light-headedness, and/or fainting?	YES ☐ NO ☐
8c.	Has your physician indicated that you exhibit sudden bouts of high blood pressure (known as Autonomic Dysreflexia)?	YES ☐ NO ☐

9. Have you had a Stroke? *This includes Transient Ischemic Attack (TIA) or Cerebrovascular Event*

If the above condition(s) is/are present, answer questions 9a–9c — If **NO** ☐ go to question 10

9a.	Do you have difficulty controlling your condition with medications or other physician-prescribed therapies? (Answer **NO** if you are not currently taking medications or other treatments)	YES ☐ NO ☐
9b.	Do you have any impairment in walking or mobility?	YES ☐ NO ☐
9c.	Have you experienced a stroke or impairment in nerves or muscles in the past 6 months?	YES ☐ NO ☐

10. Do you have any other medical condition not listed above or do you have two or more medical conditions?

If you have other medical conditions, answer questions 10a–10c — If **NO** ☐ read the Page 4 recommendations

10a.	Have you experienced a blackout, fainted, or lost consciousness as a result of a head injury within the last 12 months **OR** have you had a diagnosed concussion within the last 12 months?	YES ☐ NO ☐
10b.	Do you have a medical condition that is not listed (such as epilepsy, neurological conditions, kidney problems)?	YES ☐ NO ☐
10c.	Do you currently live with two or more medical conditions?	YES ☐ NO ☐

PLEASE LIST YOUR MEDICAL CONDITION(S) AND ANY RELATED MEDICATIONS HERE: ____________________

GO to Page 4 for recommendations about your current medical condition(s) and sign the PARTICIPANT DECLARATION.

OSHF Ontario Society for Health and Fitness

2016 PAR-Q+

If you answered NO to all of the follow-up questions about your medical condition, you are ready to become more physically active—sign the PARTICIPANT DECLARATION below:

- It is advised that you consult a qualified exercise professional to help you develop a safe and effective physical activity plan to meet your health needs.
- You are encouraged to start slowly and build up gradually—20 to 60 minutes of low to moderate intensity exercise, 3 to 5 days per week including aerobic and muscle strengthening exercises.
- As you progress, you should aim to accumulate 150 minutes or more of moderate intensity physical activity per week.
- If you are over the age of 45 yr and **NOT** accustomed to regular vigorous to maximal effort exercise, consult a qualified exercise professional before engaging in this intensity of exercise.

If you answered **YES** to **one or more of the follow-up questions** about your medical condition:

You should seek further information before becoming more physically active or engaging in a fitness appraisal. You should complete the specially designed online screening and exercise recommendations program—the **ePARmed-X+ at www.eparmedx.com** and/or visit a qualified exercise professional to work through the ePARmed-X+ and for further information.

Delay becoming more active if:

- You have a temporary illness such as a cold or fever; it is best to wait until you feel better.
- You are pregnant—talk to your health care practitioner, your physician, a qualified exercise professional, and/or complete the ePARmed-X+ **at www.eparmedx.com** before becoming more physically active.
- Your health changes—talk to your doctor or qualified exercise professional before continuing with any physical activity program.

- You are encouraged to photocopy the PAR-Q+. You must use the entire questionnaire and NO changes are permitted.
- The authors, the PAR-Q+ Collaboration, partner organizations, and their agents assume no liability for persons who undertake physical activity and/or make use of the PAR-Q+ or ePARmed-X+. If in doubt after completing the questionnaire, consult your doctor prior to physical activity.

PARTICIPANT DECLARATION

- All persons who have completed the PAR-Q+ please read and sign the declaration below.
- If you are less than the legal age required for consent or require the assent of a care provider, your parent, guardian, or care provider must also sign this form.

I, the undersigned, have read, understood to my full satisfaction and completed this questionnaire. I acknowledge that this physical activity clearance is valid for a maximum of 12 months from the date it is completed and becomes invalid if my condition changes. I also acknowledge that a Trustee (such as my employer, community/fitness centre, health care provider, or other designate) may retain a copy of this form for their records. In these instances, the Trustee will be required to adhere to local, national, and international guidelines regarding the storage of personal health information ensuring that the Trustee maintains the privacy of the information and does not misuse or wrongfully disclose such information.

THERAPEUTIC EXERCISE

MOVING TOWARD FUNCTION

4th EDITION

Lori Thein Brody, PT, PhD, SCS, ATC
Carrie M. Hall, PT, MHS

Succeed in your course and your future career with this proven resource

This practical book does more than provide a listing of exercises—it helps you develop the clinical reasoning skills you'll need in practice by focusing on the rationale behind exercise selections and progressions. Now in striking full color and more accessible than ever, this edition emphasizes return to function, aligns with the most recent ICF framework, and reflects the latest strategies in physical therapy.

Key Features:

- **Exercises with detailed steps** make learning the toolbox of exercises easier.
- **Case Studies** in every chapter help you think through and apply what you've learned to specific scenarios.
- **Building Blocks** pose scenarios to help you critically synthesize chapter material.
- **Online Video Clips** illustrate exercise techniques in a memorable way.
- **How-to information,** organized by region, helps you decide what exercises to teach, how to teach them, and how to evaluate the prescribed program for the desired functional outcome.
