CHAPTER 11

The Thoracic Ring Approach™
A Whole Person Framework to Assess and Treat the Thoracic Spine and Rib Cage

LINDA-JOY (LJ) LEE*

INTRODUCTION: THE NEED FOR A BROADER VIEW OF THE THORAX

The thoracic spine is the largest region of the vertebral column and trunk, comprising approximately 20% of overall body length, compared with 12% for the lumbar spine and 8% for the cervical spine.[1] The complex arrangement of thoracic vertebrae, intervertebral discs, ribs, cartilage, sternum, and manubrium, together with the internal cavity created by the skeletal frame, defines what is called the thorax.[1] Clinicians have long recognized that the thoracic spine can be the silent but underlying cause, or **driver**, for problems elsewhere in the body. Most commonly, the hypothesis is that a stiff thorax creates excessive forces and pain in adjacent areas such as the lumbar spine, neck, and shoulder girdle.[2–4] The thoracic structures can also be a source of referred pain in neighboring regions.[5,6]

A challenge for clinicians is how to determine when treatment to the thorax will resolve symptoms either locally or distally. Research on the benefits of thoracic spine treatment is limited and provides conflicting insight into when treatment will improve outcomes. For example, although some patients with neck pain have experienced positive outcomes with thoracic spine manipulation or mobilization treatment, approximately one third of patients in both groups experienced adverse responses, including aggravation of symptoms, muscle spasm, and headache.[3] These data are consistent with clinical experiences. That is, although some patients benefit from treatment to the thorax, others do not. Furthermore, treatment of the thorax may aggravate symptoms or cause other adverse experiences such as nausea and sympathetic nervous system symptoms. It is therefore proposed that to make wise clinical decisions regarding when and how to treat the thoracic spine and ribs, a broader lens is needed.

Broadening our view of the thorax is required on multiple levels. First, the thoracic spine, ribs and their associated articulations need to be assessed and treated within the context of the three-dimensional "thoracic ring" wherever there are anterior attachments.[7–10] Second, it is necessary to consider other types of dysfunction in the thorax beyond the problems of stiffness and referred pain. Evidence supports that the thorax is inherently flexible,[9,11–14] and the presentation of decreased mobility reflects a loss of optimal neuromuscular control and imbalanced muscular forces around and between the thoracic rings.[9,15–19] A broader view of dysfunction in the thorax provides insight into the role of the thorax in whole body function and how the thorax can be the driver for more varied and distal problems, including incontinence, pelvic organ prolapse, groin pain, knee pain, Achilles tendinopathy, headaches, and sympathetic system sensitization.[15–19] Thus the thoracic rings need to be assessed within the context of the

*The author, editors, and publisher wish to acknowledge Diane Lee for her contributions on this topic in the previous edition.

whole person and whole body function. That is, to determine whether treatment of the thorax will positively affect a patient's problem, it is necessary to understand and assess the connections between the thorax and the rest of the body and to recognize the potential role of emotional and psychosocial features. Finally, treatment of the thorax needs to expand beyond techniques that aim to increase mobility to incorporate training optimal neuromuscular control and muscle balance around and between the thoracic rings for optimal movement, load transfer, and respiration.

It has been more than a decade since the original proposals about the importance of neuromuscular control in the thorax were made.[7,20] Since that time, there has been extensive development of the clinical ideas, techniques, and clinical reasoning approach to assess and treat the thorax. There has also been greater research interest around the thorax, which has informed and refined the developing clinical ideas. The Thoracic Ring Approach™[17,18] incorporates the most current research and extensive clinical experiences, providing a range of assessment and treatment techniques for the thoracic rings, along with a clinical reasoning framework to determine whether the dysfunctional thorax, whether painful or pain free, is the true underlying cause or driver of the patient's problems. Even if the thorax is painful, if it is not the driver, then treatment applied to the thorax will not provide optimal clinical outcomes and may exacerbate symptoms. With thorax-driven problems, whether it be pain anywhere in the body, disability, or decreased performance, treatment to the thorax will be the most efficient and effective way to address the patient's nonoptimal experience of his or her body and restore optimal function and performance in a meaningful way. The aim of this chapter is to introduce key concepts and the assessment framework to determine whether the thorax is a driver and then discuss principles and techniques to effectively treat thoracic ring drivers.

CONNECTING THE THORACIC SPINE AND RIB CAGE: EVIDENCE FOR "THORACIC RINGS"

In both the research and clinical realms, the thoracic spine is commonly considered in isolation from the ribs and rib cage, with separate assessment and treatment techniques for each.[21–24] However, anatomical[1] and recent biomechanical data[25,26] support that it is most accurate to view the thoracic spine and rib cage as an integrated complex rather than as separate. Multiple articulations and strong ligaments connect the ribs to their related thoracic spinal segment.[1] In cadaveric studies, if these connections are disrupted by removing the ribs or preserving only posterior stubs of the ribs, the axis of rotation of the thoracic vertebral segment is significantly displaced anteriorly to a location in front of the vertebral body or in the anterior portion of the vertebral body, respectively. Both of these locations would cause shear and endanger the integrity of the spinal cord. Therefore, data from thoracic specimens without an intact rib cage slice should be considered inaccurate.[25] Measurement of the integrated thoracic ring in vivo is challenging, but recent data support that during functional movements, the thoracic spine and ribs move as an integrated three-dimensional complex. For example, small changes in thoracic spine alignment in the sagittal plane (i.e., flexion/extension) create three-dimensional changes in the shape of the rib cage at multiple levels.[26]

Thus, the evidence supports that wherever anterior attachments are present, it is most accurate to define the functional spinal unit (FSU) of the thorax as a **thoracic ring**.[7–10,15,16,25,26] For example, the fifth thoracic ring is comprised of the right and left fifth ribs, their anterior attachments to the sternum, the T4 and T5 thoracic vertebrae, and the T4-T5 intervertebral disc.[7–10,18] The thorax is thus composed of a "stack" of 10 thoracic rings (rings 1-10) and the thoracolumbar region (made up of T11 and T12 vertebrae and the 11th and 12th ribs). The thoracolumbar region is functionally more similar to the lumbar spine and thus will not be covered in this chapter. For the rest of the thorax, given the integrated nature of the thoracic spine and rib cage, there is a need for manual assessment and treatment techniques for the entire thoracic ring.

Manual Techniques to Assess and Treat the Thoracic Rings

Thoracic Ring Approach[17,18] techniques use palpation points and forces applied around the anterior, lateral, and posterior rib cage to assess and treat the three-dimensional thoracic rings (Figure 11-1).[7,8,10,16–18] Because of the strong anatomical connections, motion detected at the lateral ribs reflects vertebral motion, and forces applied to the side of the ring affect the vertebral segment as well as the ribs (i.e., the entire ring).[27] Thoracic "ring palpation"[7,8,10,16–18] is applied farthest from the axis of rotation of the thoracic segment and where greater amplitude of motion can be detected compared with palpation points centrally at the vertebra. There is also less muscle bulk over the sides of the rings compared with the posterior aspect of the ring (and over the transverse processes of the vertebrae), providing less confounding input from changes in muscle activity when analyzing ring motion during functional tasks. Thoracic ring techniques facilitate assessment of inter-ring (i.e., segmental) position, motion and control during functional tasks, as well as analysis of multiple rings and inter-regional relationships simultaneously. For example, palpation at the lateral aspect of rings 3, 4, and 5 reflects motion of the T2 to T5 vertebral segments and their related ribs (right and left third, fourth, and fifth ribs). Treatment can be applied

Figure 11-1 **A**, Hand position illustrating technique for Thoracic Ring Assessment and Correction of the upper thoracic rings (from the Thoracic Ring Approach). Because of differences in anatomy, ring palpation techniques change when moving from the upper thoracic rings to the lower thoracic rings. **B**, Lower thoracic ring correction technique during resisted arm flexion (*vertical arrow*) to determine whether restoring optimal biomechanics and neuromuscular control to the thoracic ring will result in positive change for the meaningful task and support a hypothesis that the thoracic ring is the driver for the patient's shoulder problem. Note the change in orientation of the correcting left hand to match the angle of the lower rings (*lower arrow*). (Copyright LJ Lee Physiotherapist Corp.)

to several sequential thoracic rings at once, so that dysfunction at several vertebral segments and ribs can be addressed simultaneously (Figure 11-2).

It is a well-accepted principle in manual therapy that findings from articular accessory glides should be interpreted in reference to the starting position of the segment. For example, if the C5 segment is in a position of right side bending/right rotation, this affects findings for the amplitude of motion found on examination of both the right and left zygapophyseal joint glides. It is proposed that similarly, the position of the three-dimensional thoracic ring must be considered when interpreting the findings from established articular mobility assessment techniques of the thoracic spine and rib articulations. Without consideration of the thoracic ring positions, articular mobility may be evaluated as restricted, but when thoracic ring position is aligned into a neutral position, articular mobility is restored as symmetrical and equal to levels above and below. If treatment techniques for the thorax are chosen based on articular findings without incorporating findings from the thoracic ring assessment, the potential for less effective treatment choices is greater.

In relation to the challenging question of when treating the thorax will positively improve a patient's problem or not, a significant benefit of thoracic ring palpation and "thoracic ring correction" techniques[7,8,16–18] is that they provide a method of evaluating the connections between a dysfunctional thoracic ring and whole body function across postural and movement tasks.[8,16,18,28] In this way, the clinician can evaluate the effect of temporarily providing optimal thoracic ring function on the rest of the body and on other painful structures, which forms a key part of the clinical reasoning process to decide whether or not the thorax is the true underlying driver for the patient's problem.

However, before the assessment framework to determine whether the thorax is the driver is discussed, it is necessary to broaden one's understanding of the role of the thorax in whole body function and what the most common underlying impairments in the thorax are.

OPTIMAL FUNCTION OF THE THORACIC RINGS: STIFF AND STABLE, OR NEEDING FINE CONTROL?

The thoracic spine has long been characterized as an inherently stiff and stable structure because of the rib cage.[4,29,30] However, minimal data support this belief. Although the rib cage does increase the stiffness of the thoracic spine and increases the critical buckling load sustainable by the osseoligamentous thoracolumbar spine by a factor of 3 or 4, these loads are still well below those

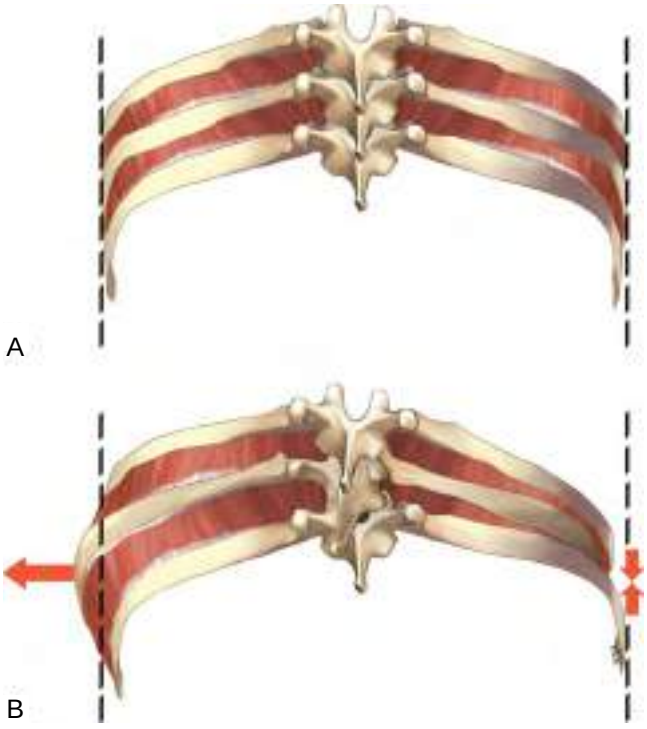

Figure 11-2 **A,** "Stacked" thoracic rings. When neuromuscular forces are balanced around and between the thoracic rings, optimal alignment is supported and provides a base from which to initiate movement. There is sufficient space between the thoracic rings. Although not all depicted here, optimal alignment of the thoracic rings is supported by balance between the deep and superficial muscles attaching to the rings. Note that the top vertebra is missing from the superior thoracic ring. If this figure depicts rings 3, 4, and 5, the related vertebral segments include T2 to T5. Less muscle bulk over the sides of the rings compared with the posterior aspect of the ring facilitates more accurate analysis of ring motion during functional tasks. **B**, "Unstacked" thoracic rings. When force vectors around the thoracic rings are unbalanced, there are multiple patterns of thoracic ring dysfunction that can occur. This figure depicts one potential pattern of nonoptimal inter-ring relationships. Compression between the upper and lower rings on the right creates left translation of the middle ring, which is coupled with right rotation. Compression of the rings also creates side bending, which is coupled with rotation. These inter-ring relationships can be assessed simultaneously using thoracic ring palpation techniques. Findings from manual assessment of the posterior joints of the thoracic spine and rib cage need to be interpreted in reference to the position and behavior of the related thoracic ring. (Copyright LJ Lee Physiotherapist Corp.)

that the spine is exposed to in normal function.[31] Support from neuromuscular forces is essential. Biomechanical data show that the intact thorax is mobile in all planes.[11–13] In contrast to the limited rotation of lumbar spine segments, the primary movement of the thorax is rotation (transverse plane motion), followed by lateral bending (coronal plane motion), with significantly less flexion and extension range of motion.[11–14] Thus the evidence supports that the thorax is inherently *flexible*.

Each typical thoracic ring has 13 articulations,[1] and in total, the 136 joints of the thorax provide significant mobility. The capacity for movement within and between the segments of the thorax, along with the requirements for control of upright posture and respiration, requires complex coordination of muscle activity by the central nervous system (CNS) to meet the demands of stability and movement. For example, during tasks that create perturbations to the thorax in the sagittal plane (flexion/extension), the deep multifidus and superficial longissimus muscles are similarly recruited to control challenges to stability. In contrast, when challenges to stability occur in the transverse plane, the CNS controls the deep multifidus and superficial longissimus muscles differentially. Differential control of these two layers of thoracic paraspinal muscles is apparent only in the plane in which the thorax has the greatest movement, in the transverse plane, for control of opposite rotational perturbations.[32–34]

These data are consistent with clinical proposals that the most common direction for poor control in the thorax is related to control of rotational forces.[4,7,15–17,28] Because of the coupling of lateral translation with rotation,[11,12] functionally, a loss of rotational control can also be manifested as poor control of lateral translation forces.[7,8] Similarly, loss of rotational control can be coupled with loss of lateral bending control (i.e., control of coronal plane motion).

Shifting from the paradigm that the thorax is stiff and requiring mobilization to one where the thorax is flexible and requiring optimal neuromuscular control provides greater insight into why the thorax can drive distal problems. This is because the paradigm moves away from conceptualizing the thorax as a static, stiff box to being a **dynamic stack of 10 rings**, much like a Slinky or a shock-absorbing spring. When there is loss of optimal sequencing, force modulation, and synergy between the muscles around the thoracic ring, between the 10 thoracic rings, and between the rings and other regions of the body, there are many possible consequences throughout the whole body. These consequences can result in nonoptimal loading of multiple different structures and regions of the body that can drive conditions as diverse as hip osteoarthritis, impingement and groin pain, pelvic girdle and low back pain, incontinence and prolapse, patellofemoral pain, Achilles tendinopathy, lack of "core stability," headaches, and shoulder impingement. Furthermore, because of the anatomical relationships to the sympathetic chain and innervation of the viscera, the dysfunction of the thoracic rings can drive other nonoptimal experiences such as sensitization of the sympathetic nervous system and gastrointestinal symptoms.

Clinical Example: Potential Mechanisms by Which Nonoptimal Neuromuscular Function of Thoracic Rings Can Drive Distal Problems

Suppose one considers the possible effect when there is nonoptimal neuromuscular control and altered muscle balance related to the fourth thoracic ring during a squat, resulting in left translation and right rotation of the

fourth ring (upper thorax) upon initiation of the squat motion. This movement of the fourth thoracic ring creates both a lateral and rotational perturbation to the trunk. To counter this perturbation, activity in the right external oblique and left internal oblique muscles may increase, resulting in asymmetrical abdominal wall activation and potentially an opposite rotation in the lower thorax. Commonly, the pelvis and hips counter-rotate to compensate for the rotation of the upper thorax, so the pelvis rotates to the left and the right hip moves forward. The twist in the thorax alters all muscle relationships around the thorax, affecting scapular, neck, and head neuromuscular control and position. Because all abdominal muscles are innervated from the lower thorax (T7 to L1/L2), the twist of the thorax may further contribute to abdominal wall dys-synergies via neural mechanisms. Excessive and asymmetrical contraction of the superficial muscles such as the external obliques (EO), changes in diaphragm activity (attaches to the lower six thoracic rings), and depression of the scapulae restrict mobility and compress the thorax, affecting the balance between intrathoracic and intra-abdominal pressure, and create increased pressure in the lower abdomen (a "pressure belly"). In response to the increase in intra-abdominal pressure, the pelvic floor muscles can become hypertonic, contributing to pain syndromes and/or stress urinary incontinence (SUI). Interestingly, the EO attaches as high as the fifth thoracic ring, and increased resting activity of the EO and pelvic floor muscles occurs in subgroups of women with SUI.[35]

Left lateral translation of the fourth thoracic ring also results in a left translation of the upper thorax and affects the position of the center of mass over the feet, which, in turn, affects control of postural equilibrium and alters medial-lateral forces all the way down the kinetic chain to the feet, altering muscle activation and loading patterns. For example, left translation of the trunk often correlates with decreased right gluteus medius and maximus muscle activity as a result of decreased weight bearing on the right leg. When combined with compensatory pelvis rotation, this creates an altered axis of movement and control of the right hip, providing a biologically plausible mechanism to explain thoracic driven hip impingement and groin pain. In these subgroups the hip symptoms do not resolve without treatment to change neuromuscular control of the driving thoracic rings. Figures 11-1, 11-3, 11-4, and 11-5 show clinical examples of thorax driven shoulder pain, abdominal wall dysfunction, low back pain, and foot pain.

The previous example is simplified to illustrate the effect of nonoptimal muscle synergies around the fourth thoracic ring. It is also common to find patterns of excessive compression between the thoracic rings and hypertonicity of the intercostals at different points around the 3-dimensional ring that create a loss of the ability to dissociate movement of each ring relative to the other rings, creating **"glued ring complexes"**. The nonoptimal muscle patterns around two to three rings (or more) creates an "unstacked" multiring complex that is unable to behave optimally across a variety of tasks. The rings may be held as a unit in various patterns of rotation/lateral translation/ side bending and/or compression (see Figure 11-2). These patterns of nonoptimal muscle

Figure 11-3 The thoracic rings are a common underlying cause for dys-synergies of the abdominal wall, inability to recruit transversus abdominis (TrA) and/or pelvic floor muscles, asymmetry of transversus abdominis muscle and pelvic floor contraction, and/or hypertonicity and asymmetry of the superficial and deep layers of the abdominal wall and/or the pelvic floor. **A**, With verbal cues designed to elicit a bilateral (symmetrical) contraction of transversus abdominis muscle, there is a response from the left transversus abdominis (not shown) but no response on the right. Note inset ultrasound image and arrow indicating transversus abdominis layer; with cues there is no change in the architecture of the transversus abdominis muscle. Changing cues and effort and paying more attention to the right side do not change the ability to recruit the right transversus abdominis muscle. **B**, When the driving thoracic rings are corrected (third/fourth), the same cues result in immediate recruitment of the right transversus abdominis muscle in a symmetrical manner with the left transversus abdominis—symmetry of recruitment is restored. Inset shows response of right transversus abdominis; note the increase in width of the TrA layer and the lateral slide of the muscle (indicated by arrows). In thoracic driven abdominal wall dysfunction, transversus abdominis muscle contraction occurs in response to a cue directed to control of the thoracic rings, *not* in response to abdominal wall cues. Figure 11-4 Assessment of thoracic ring control during the plank task. Patient reported an inability to do plank exercises because of difficulty breathing and low back pain during this task. **A**, With correction of upper thoracic rings (3 and 4), there was no low back pain and the patient was able to breathe and feel her abdominal and pelvic floor muscles contract. **B**, The change in thoracic and lumbar spine position is shown once the correction to the upper thoracic rings is released. The upper rings translate to the left and rotate right (*horizontal arrow*). This imparts a rotation, extension, and anterior translation load to the lumbar spine (*vertical arrow*). This patient also reported an inability to feel a pelvic floor muscle contraction without thoracic ring correction that was fully restored with the correction. (Copyright LJ Lee Physiotherapist Corp.)

activity and hypertonicity create a significant loss of variability in available options for movement of the thoracic rings, and the more rings that are held together and function as one unit, the greater the loss of options and the greater impact on mobility of the thoracic rings. These glued ring complexes are common, and therefore it is advisable that the clinician always palpate and determine thoracic ring behavior relative to the ring above and the ring below in order to implement treatment that will restore optimal relationships between the thoracic rings. When intercostal hypertonicity is present, assessment and treatment of the two related sequential thoracic rings is essential (these complexes are annotated as "Ring 4/3 correction," indicating that the fourth ring is relatively left translated and the third ring relatively right translated).

ASSESSMENT: DETERMINING WHETHER THE THORAX IS THE DRIVER FOR THE PATIENT'S PROBLEM

The previous section illustrates that a patient with a dysfunctional thorax can present with a wide variety of symptoms and functional problems. Location of pain or tissue changes do not always correlate to the primary underlying cause of the problem. Thoracic pain can be driven from dysfunction in the thorax or from elsewhere in the body, such as the foot or pelvis. Similarly, the presence of dysfunction in the thorax is insufficient to make a clinical decision to treat the thoracic rings. In every patient, there are multiple different impairments that can be identified throughout the body. Therefore a whole body assessment paradigm is required to determine how a dysfunctional thorax relates to the presenting problem.

Meaningful Task Analysis (MTA) was initially proposed as an assessment framework to determine whether dysfunction in the thorax was the *underlying cause*, or *driver,* of the patient's problem[28] and is thus the assessment framework to find thoracic drivers within the Thoracic Ring Approach.[17,18] The principles of MTA are also part of the Integrated Systems Model for Disability and Pain (ISM)[36] and have been further developed in the ConnectTherapy™ Model.[37,38]

MTA incorporates not only the biomechanical features of a task but also the emotional, cognitive, social, and contextual features related to a specific problematic or goal-related movement. Meaningful tasks are determined from the patient's story and direct the choice of screening tasks analyzed in the objective assessment. A **"meaningful task"** is one in which symptoms such as pain or other nonoptimal sensorial experiences, such as decreased power, decreased ease of movement, altered breathing, or incontinence, occur.

Many meaningful tasks are complex, multiplanar, multijoint movements. The purpose behind **"meaningful screening tasks"** is to use related simple movements that enable accurate manual assessment of joint and muscle function throughout the body during functional movements. To determine whether the thorax is the driver, thoracic ring function is assessed and manual thoracic ring corrections are applied to evaluate their impact on task performance and patient experience. Ideally, the screening tasks chosen closely resemble the meaningful task from multiple aspects, including biomechanical, emotional, and contextual features. The complexity of the screening task used depends on practitioner skill; more skilled practitioners can use more complex movements as screening tasks. In the early stages of thoracic ring skill acquisition,

Figure 11-5 Meaningful Task Analysis (MTA).[28] To find the driver for the patient's foot pain related to push-off during running, a step forward task is used as a meaningful screening task. Multiple areas of nonoptimal alignment, biomechanics, and/or control (nonoptimal load transfer [NOLT]) are identified during the task. **A**, During left step forward, the right foot demonstrates lateral weight bearing on push-off, with varus forces at the ankle. At initiation of the step forward, the fourth thoracic ring is felt to translate left, creating a segmental right rotation. Optimally, the upper thorax should rotate left, and therefore the movement of the fourth thoracic ring is nonoptimal. The resultant left shift of the thorax over the base of support requires the compensatory varus at the ankle to neutralize the center of mass over the base of support. On loading of the left leg, the left side of the pelvis loses segmental control and "unlocks" (palpation not shown; the innominate anteriorly rotates relative to the sacrum, a less optimal position to transfer loads in the pelvis). Inset shows a close up of the impact of the early left translation of the fourth thoracic ring on the right foot. **B**, Correction of the fourth thoracic ring during the left step forward task results in optimal weight bearing through the right ankle and foot during push-off and reduction of the patient's symptoms. The left side of the pelvis no longer loses segmental control (palpation not shown). The starting position of the thoracic rings needs to be corrected by stacking them into optimal inter-ring relationships in standing posture; then optimal movement and control are manually facilitated during the task. The thorax can drive distal problems in the hip, knee, ankle, and foot because of rotational mechanisms and the effect that lateral translation of the thorax has on the center of mass relative to the base of support. Inset shows close-up of the right foot at push-off in response to the fourth thoracic ring correction. Note the significantly improved position. Application of thoracic ring correction techniques during functional movement analysis allows evaluation of the potential impact that treating specific levels of the thorax will have on symptoms, task performance, and other problematic areas in the kinetic chain. **C**, The impact of corrections to other areas of NOLT is assessed and compared with the impact of the thoracic ring correction. Upper panel demonstrates correction of pelvis alignment with bilateral anterior compression, and lower panel demonstrates a correction of the right ankle/foot. The thoracic ring correction resulted in the best change in task performance, the most positive change on all areas of NOLT, and optimized load transfer through the right foot (area of symptoms) and pelvis. (Copyright LJ Lee Physiotherapist Corp.)

simpler, "building block" or component movements of the meaningful task are used to rule in or rule out a thoracic ring driver. Correction of the hypothesized driver can then be performed in the more complex meaningful task to provide further confirmation. In some situations, the meaningful task is simple enough to be used itself (Figure 11-6).

For any task that is chosen for assessment, the clinician uses observation and palpation skills to determine whether the current strategy being used is optimal or nonoptimal, considering task requirements and individual characteristics of the patient. The ability to function optimally across the diverse spectrum of human activity requires that one can access and choose multiple strategies. The CNS needs to have the ability to match the strategy to the specific demands of the task whether that task is sitting at a desk or running a marathon. Clinically, it is common for patients to lose movement options and variability. That is, they have fewer strategies to choose from, or they "get stuck" in one or two strategies that they apply across multiple tasks. In some cases, the strategy is appropriate for the task, but in other tasks, the same strategy causes pain or other nonoptimal sensorial experiences, along with disability or loss of performance.

Figure 11-6 Meaningful Task Analysis (MTA)—overhead squat with dowel. In this case the meaningful task (MT) is simple enough relative to the clinician's skills to be able to use the MT to assess for nonoptimal load transfer (NOLT) of the thoracic rings and perform corrections to find the driver. The panels from left to right show therapist hand and body position to assess rings 4/3 during the MT. (Copyright LJ Lee Physiotherapist Corp.)

When the CNS is successful at planning an optimal strategy for matching task demands:

1. Motion of all joint complexes is controlled with optimal axes of rotation, while allowing the necessary range of motion required for the task, without rigidity.
2. Spinal posture and orientation are controlled both within and between regions and appropriate for the demands of the task.
3. Postural equilibrium is maintained.
4. Respiration, continence, and other systems are supported and not compromised (e.g., vascular system is not compromised by musculoskeletal structures during movement).
5. Intra-abdominal and intrathoracic pressure are sufficient and balanced.
6. Desired qualitative and quantitative features are present.

In addition, there is enough movement (i.e., give) in the system to dampen and control multiple predictable and unpredictable challenges such as internal or external perturbations, varying loads, and risk in potentially changing environments.[39–41] Therefore, the clinician can determine whether a strategy is optimal based on the ability of the patient to demonstrate these features during any task. Failure to maintain any of these features is an indication that the patient is using a **nonoptimal strategy** for the task. The clinician must determine how the nonoptimal strategy and the nonoptimal sensorial experience are connected. Correction of the "primary driver" will result in positive changes in all nonoptimal features identified during task performance and a positive sensorial experience.

Signs of Optimal Strategies for Meaningful Task Analysis

Optimal strategies for function and performance support optimal function of multiple systems (Figure 11-7) and will do the following:

- Balance mobility and control of all joints in the body. Joint motion will be controlled without rigidity and optimal axis of motion maintained. This equates to optimal load transfer (OLT).
- Control spinal posture and orientation and maintain postural equilibrium under varying loads.
- Maintain sufficient intra-abdominal pressure (IAP) that is balanced with intrathoracic pressure ("pressure belly" is a sign of an imbalance, excessive IAP).
- Allow the rib cage to expand for optimal respiration.
- Support other systems such as vascular function and continence.
- Allow sufficient mobility to dampen and react to perturbation forces. This is the "give" in the system.
- Create desired qualitative and quantitative features related to function and performance goals, "beautiful movement."
- Support positive experiences of the body (e.g., Center Circle, the Patient Experience).

Nonoptimal strategies affect multiple systems; therefore there are multiple possible signs of nonoptimal strategies. When the driver is corrected, all these signs should show positive change.

In some cases, patients may be choosing a nonoptimal strategy related to performance or one that causes nonoptimal loading of some structures but offloads other structures that are the priority for the nervous system to support. For example, a nonoptimal strategy may be appropriate when there is tissue injury and the state of healing is currently associated with inflammation (e.g., acute ankle sprain, muscle tear or strain, inflamed nerve or organ). In these cases, the nonoptimal strategy is appropriate or adaptive in the short term but would be in inappropriate in the long term. Therefore, a clinical reasoning process that considers all influences on the patient's current strategy for posture and movement and his or her current experience allows the clinician to decide appropriate treatment intervention for each individual at different stages of the rehabilitation process (see Figure 11-7).

As noted previously, dysfunction in any region or system can be the underlying cause for the whole body nonoptimal strategy and patient experience. Thus, any positive findings for dysfunction in a region may be a sign indicating that the region is a driver or that it is a "victim," a consequence rather than the cause. To determine whether an area is a driver, the relationship of regional dysfunction

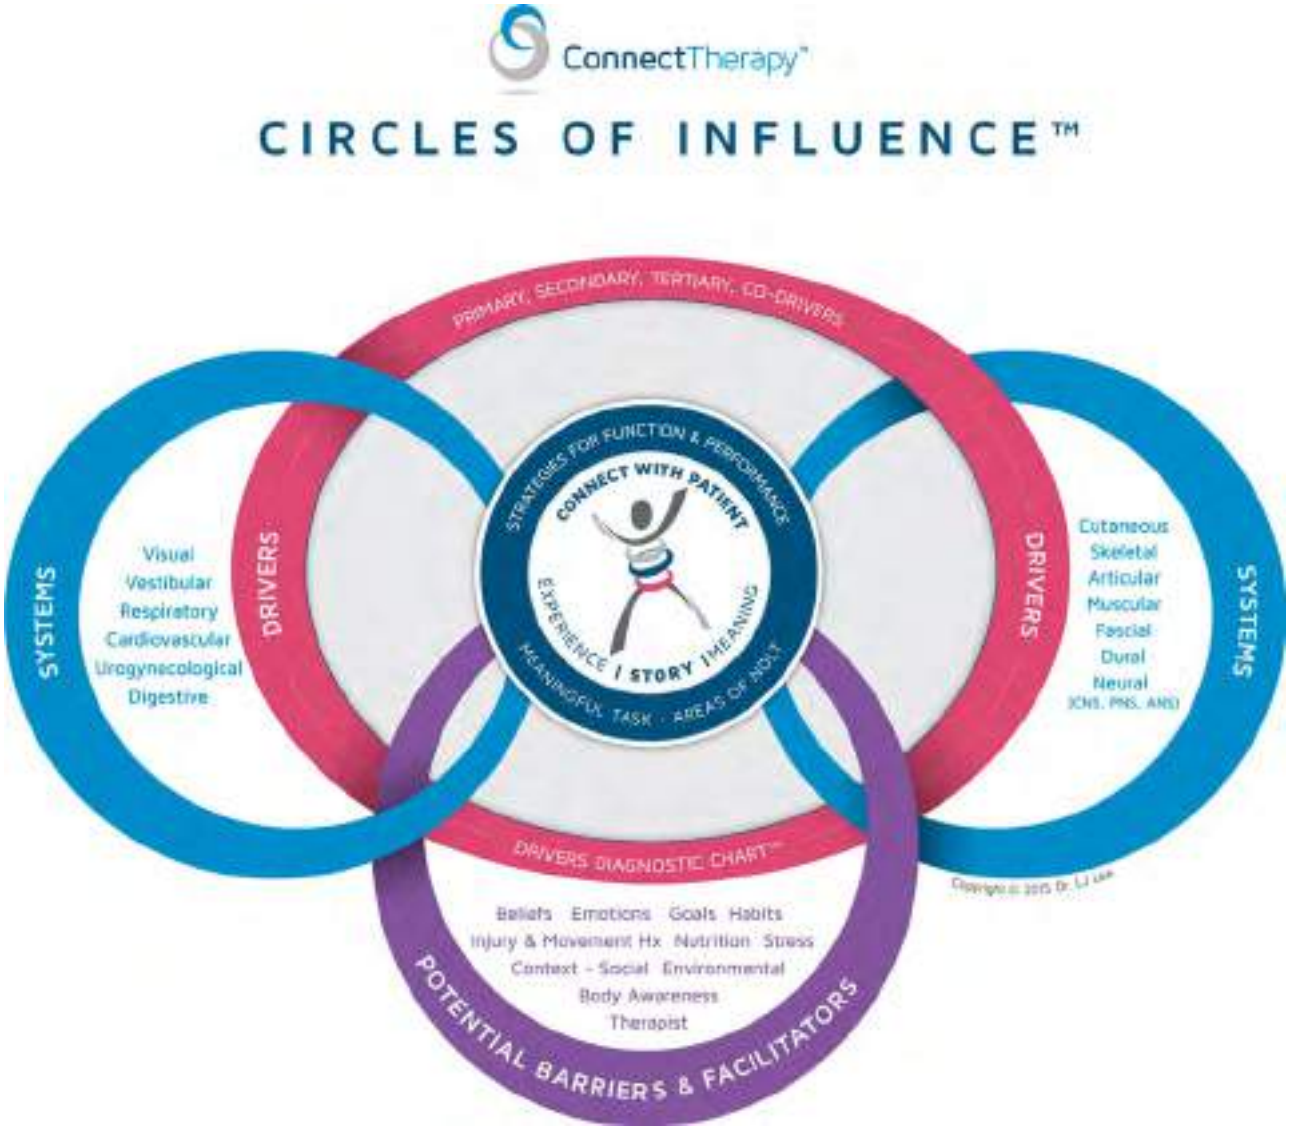

Figure 11-7 The ConnectTherapy Circles of Influence™ is a tool to facilitate organization of knowledge and information from multiple domains and determine the most relevant influencers on the patient's current (1) experience of his or her body and (2) strategies for function and performance. The circles represent influences both intrinsic and extrinsic to the patient; the amount of overlap and linking between the different circles can change over time and help the clinician adjust priorities and choose appropriate interventions. The Circles of Influence illustrate the construct of connectedness that is central to ConnectTherapy. *Hx*, History; *CNS*, central nervous system; *PNS*, peripheral nervous system; *ANS*, autonomic nervous system. (Copyright LJ Lee Physiotherapist Corp.)

to whole body function and patient experience needs to be assessed and determined. This is accomplished by implementing a series of clinical tests governed by a robust clinical reasoning process. The ConnectTherapy Drivers Diagnostics Chart™[37,38] for MTA and provides a clinical reasoning algorithm that facilitates an understanding of the connections between all dysfunctional regions of the body and is used to determine which areas are the underlying problems, or drivers, for the patient's problem. In complex or chronic problems, there is often more than a single **"primary driver"**, with several areas contributing to the problem, either as a **"secondary driver"** or **"tertiary driver"** or two dysfunctional areas equally contributing as co-drivers. It is beyond the scope of this chapter to cover the full depth of this diagnostic process; however, the process to rule in or rule out the thoracic rings as a primary driver is described here to illustrate the basic clinical reasoning principles involved.

In summary, the clinical decision as to whether the thorax should be treated, and which specific thoracic rings to treat, is determined by assessing and manually modifying thoracic ring behavior during meaningful screening tasks. For example, for a runner who experiences lateral foot pain on the push-off phase of gait, a relevant screening task is a step forward task (see Figure 11-5). If nonoptimal alignment, biomechanics, movement, or control of any thoracic rings occurs during the task, a thoracic ring correction is performed, whereby optimal thoracic ring alignment, biomechanics, movement, and control are provided through gentle but specific manual facilitation at the specific ring level.[7,8,17,18,28] Ring correction involves different hand position and direction of force input depending on whether the upper or lower rings are being corrected.[7,17,18] The reference for what is optimal behavior for the thoracic rings is based on the task requirements and the patient's individual architectural features. If the thoracic ring correction (1) positively changes the ease of task performance, (2) positively changes the meaningful experience/symptoms during task performance, and (3) optimizes transfer of loads and neuromuscular function in other areas of the body, then there is support for the hypothesis of a thoracic ring driver. To further strengthen the hypothesis, manual corrections are also applied to other areas of **nonoptimal load transfer (NOLT)** identified and their impact compared with the thoracic ring correction. In the case of a primary thoracic ring driver, corrections to other areas either have a negative effect or not as positive an effect as the thoracic ring correction.[7,8,16–18,28] If manual correction to a different area of the body results in a greater improvement in task performance and patient experience and automatically fully restores optimal behavior of the thoracic rings, then the thorax is *not* the primary driver for the patient's problem, and even if there is dysfunction in the thorax present, it should not be treated.

Clinical Findings That Support the Hypothesis of a Thoracic Ring Driver Underlying the Patient's Problem

- Specific thoracic rings demonstrate nonoptimal Alignment, Biomechanics/movement, and/or motor Control (ABCs) = nonoptimal load transfer (NOLT) *early* during the meaningful task (MT) or meaningful screening task; often starts in nonoptimal alignment before movement.
- Manual correction of the specific thoracic rings (to provide optimal ABCs) creates a significant positive change in the following:
  - Performance of the task, both subjectively and objectively (i.e., range of motion, strength, ease of movement increase)
  - The patient's experience of his or her body during the task
  - The meaningful complaint
  - Automatic improvement or full correction of multiple other areas of NOLT identified during the MT
- Manual correction of other areas of NOLT in the body (e.g., pelvis, foot, hip, neck) do not create as positive a change, make the specific thoracic rings' function worse, or make the task performance and experience worse.
- Manual correction of the specific thoracic rings results in positive changes in other signs of nonoptimal strategies (e.g., improves ease of breathing, decreases pressure belly, improves pelvic floor muscle contraction, etc.).

Analysis of Thoracic Ring Function in Common Screening Tasks

Optimal function of the thoracic rings supports optimal function of multiple systems and structures for optimal health of the whole person across a wide variety of postures and functional tasks. It is therefore important to understand what optimal thoracic ring behavior is across different functional tasks as a reference point in the assessment process. This section describes thoracic ring function and assessment across several screening tasks relevant to common meaningful tasks for patients, but many other tasks can be used based on the clinical context (see Figures 11-1, 11-4, 11-5, and 11-6). The aim is to provide reference principles that can then be applied to more complex and diverse meaningful tasks based on what is known from research and clinical experience. The clinical reasoning process described earlier to determine whether the thorax is the primary driver for the patient's problem applies to all of the tasks described next.

Standing Posture

The way patients hold themselves in space can provide insight on many levels, including habitual patterns, the degree of pain, and the patient's emotional status. For some patients, standing is their *meaningful task;* that is, they experience their symptoms when they are standing, especially during prolonged standing. For these patients, more time is spent analyzing standing posture and performing manual corrections to different body regions, including the thoracic rings, in order to find the

driver for the problem. If standing is not the patient's meaningful task, the findings in standing serve as a reference and starting point for movement into the screening task/meaningful task. In this case, the impact of corrections on standing posture is less important than the impact these corrections have during performance of the screening task. It is also important to recognize that asymmetry in postural findings is common and not always relevant to the problem the patient experiences during his or her meaningful task.

If the individual identifies particular postures as painful or aggravating to his or her symptoms, those specific postures are assessed and the findings compared with standing posture. It is most relevant to assess how a patient habitually assumes his or her posture, rather than changing foot position or giving cues before the initial evaluation of the habitual posture is completed. In patients who have ongoing or recurrent pain, the posture assumed often puts excessive forces through structures that are painful, perpetuating the generation of nociceptive input. In other cases, the alignment assumed may be ideal in terms of the position of the bones, but the muscle strategy (i.e., *how* the patient attained the ideal alignment) is not optimal, resulting in excessive compression, repetitive microtrauma, and pain. Conversely, in acute pain states, the posture the patient chooses often is one that results in the most relief and unloading of the painful structure or structures.

Nonoptimal alignment of the thorax is a sign of a nonoptimal strategy for the task of standing and will be linked to asymmetrical and nonoptimal patterns of muscle activity (i.e., resting tone) throughout the body. Several questions should be considered when analyzing posture. How is the thorax aligned? What muscles are being used? How does the muscle activity relate to the resultant posture? Why are those muscles being used? What is the impact of the resultant forces (e.g., line of gravity, compression from muscle activity) on the joints as a result of the combination of alignment and muscle patterns? How does this relate to the pain-generating structure?

In assessing alignment of the thorax, the relationship of the thorax relative to other regions (i.e., inter-regional relationships) is determined first, and these findings are correlated with intrathoracic findings (inter-ring alignment) as determined by thoracic ring palpation techniques (Figure 11-8). Optimal strategies support the thoracic rings in a centered position in all planes related to one another, and as a whole, the thorax is centered under the head, over the pelvis and in relation to the base of support (i.e., the feet). In the sagittal plane, the manubriosternal (MS) junction will be vertically aligned over the pubic symphysis (PS) for neutral anteroposterior (AP) alignment of the thorax over the pelvis.

Optimal postural strategies place the joints in a neutral position, where compression forces are best distributed; however, the ability to maintain this position relies on complex feedback and feedforward mechanisms to modulate and maintain muscle activity at multiple levels.

Multiple patterns of nonoptimal alignment are possible, creating various presentations in altered multisegmental curves of the thoracic spine, which correlate to the sum of all segmental alterations in rotation, side bending, and translation (i.e., lateral, anterior, posterior) of the 10 thoracic rings (see Figure 11-2). In volume 1 of this series *(Orthopedic Physical Assessment),* several categories of deviation from optimal alignment are described.[42] Excessive thoracic kyphosis and loss of kyphosis (lordosis) are two common presentations. Commonly, these patterns are perceived to be solely related to thoracic spine alignment, with segments excessively flexed (kyphosis) or extended (lordosis). This belief is in conflict with the evidence that there is minimal flexion and extension of the thoracic vertebrae. In contrast, the greatest neutral zone exists for rotation and side bending.[11–14] Data support that increased kyphosis or lordosis of the thoracic spine is more related to the degree of posterior and anterior translation of the thorax relative to the pelvis.[43] Furthermore, although the altered position is most obvious in the sagittal plane, there are actually three-dimensional, multiplanar alterations in the alignment of the thoracic rings, which is more consistent with the large available motion in the neutral zone related to the transverse and coronal planes. It is the author's clinical experience that a combination of lateral translation, rotation, side bending, and compression, along with posterior translation (kyphosis) or anterior translation (lordosis) of the thoracic rings relative to the pelvis and/or feet, underlies the observed, seemingly sagittal plane altered alignment. Therefore these postures are best corrected by addressing the lateral translation/rotational/side bending components first using thoracic ring correction techniques, which then frees up motion in the neutral zone to allow correction of the AP translation relative to neighboring regions. Thoracic ring correction techniques are used to determine whether specific levels in the thorax are the driver for the inability of the patient to correct the AP thoracopelvic translational relationship. If corrections to specific thoracic rings creates optimal alignment and loading of all other areas in the thorax and in the rest of the body, then those specific thoracic rings are the driver for the patient's problem in the meaningful task of standing.

Seated Trunk Rotation

In contrast to the limited rotation of lumbar spine segments,[44] the primary movement of the thorax is rotation, and control of rotational forces is essential for functional activities. It, therefore, is an important movement to assess in patients with thoracic pain or dysfunction and is a key screening task related to any meaningful activity that requires trunk rotation. Furthermore, because of the relatively large amplitude of motion of the rings and marked change in trunk rotation range of motion when the "driving" thoracic ring(s) are corrected in this activity, trunk rotation

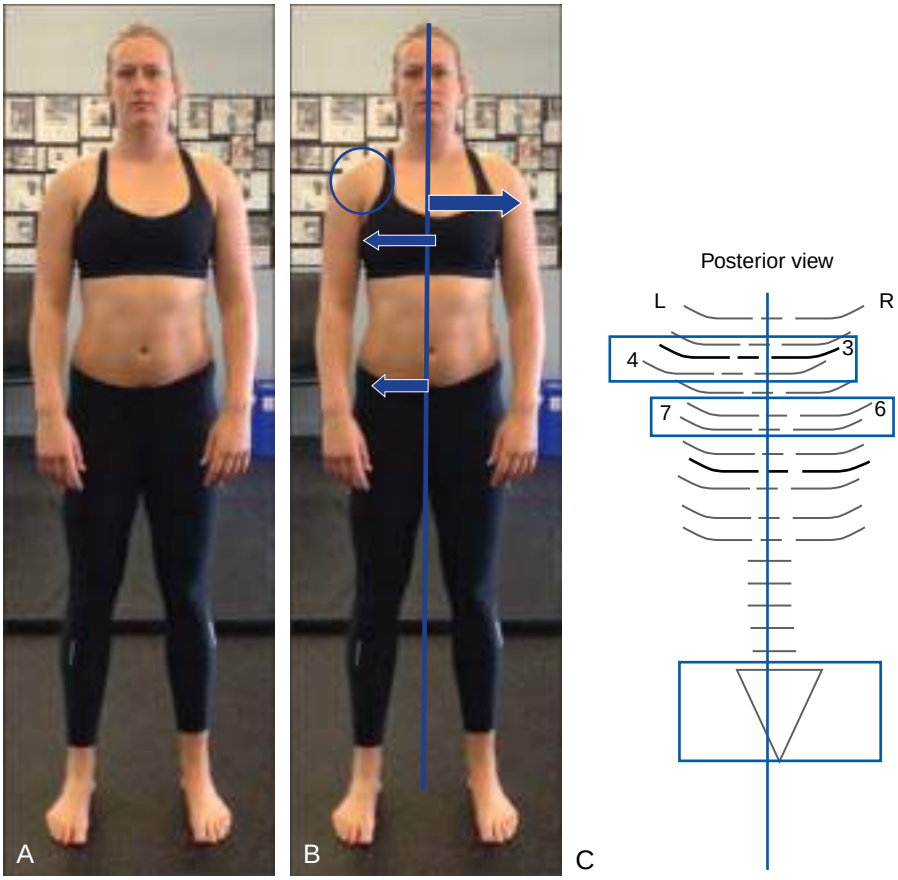

Figure 11-8 Analysis of strategy for standing posture. **A** and **B**, Inter-regional relationships are sometimes more obvious when viewed from the anterior aspect. Note that if a line is drawn vertically from a midpoint between the feet (the base of support), the thorax is left translated relative to the pelvis and relative to the base of support. Note also the asymmetry in the abdominal wall resting tone and infrasternal angle. Visually there is an appearance that the upper thorax is left rotated, but palpation reveals right rotation and left translation of the upper thoracic rings. The visual impression of left rotation comes from the right shoulder position being anterior, which is related to the shoulder girdle being in a left intrashoulder girdle torsion. **C**, Manual palpation of the rings provides more detail about inter-ring relationships and position of the rings relative to the base of support. This schematic represents ring alignment from the *posterior* aspect of the same patient. The vertical blue line represents the midline relative to the base of support. As indicated by the blue rectangular boxes, there are several rings translated left/rotated right relative to midline in the upper thorax (rings 2, 3, 4), with the fourth ring translation amplitude the greatest. Ring 3 and ring 5 are therefore right translated relative to the fourth ring when considering inter-ring relationships. The lower rings (7, 6) are slightly translated right relative to midline but significantly right translated relative to the upper rings, and they could be hypothesized as the body's attempt to compensate for the upper ring left translation. However, without performing ring corrections to determine the primary driver in the thorax, it is not possible to confirm this hypothesis. The pelvis is also slightly translated right of midline. Ring corrections are performed based on the inter-ring relationships. In this patient, if standing was the meaningful task, the impact of several different ring corrections would be compared with each other: correction of rings 4/3, correction of rings 4/5, correction of rings 5/6, and correction of rings 7/6. If the meaningful task was not standing, ring corrections would not be performed until assessment of ring nonoptimal load transfer (NOLT) during a relevant screening task was performed. The rings identified as showing NOLT on the dynamic task would then direct which rings to correct. (Copyright LJ Lee Physiotherapist Corp.)

provides the clinician with good opportunity to acquire and hone his or her thoracic ring palpation and correction skills.

During trunk rotation, motion of each thoracic ring contributes to the total range of motion, with somewhat greater contributions from the upper thoracic rings.[14] With right rotation of the trunk, the osteokinematics of the typical thoracic ring (between the third to seventh thoracic ring) have been described as follows: for the fifth thoracic ring, the T4 vertebra rotates and side flexes to the right and translates to the left relative to T5; the right fifth rib posteriorly rotates and translates anteromedially relative to the T5 transverse process; and the left fifth rib anteriorly rotates and translates posterolaterally relative to the T5 transverse process.[45] These movements are osteokinematic (i.e., movements of the bones) and require concurrent accessory movements at all joints (i.e., arthrokinematics) of the functional thoracic ring. In addition, a contralateral translation (i.e., left translation) of the entire ring complex occurs that is palpable as inter-ring motion (Figure 11-9).[7,8,10,17,18] However, there should not be a large shift of the entire thorax to the left or right relative to the pelvis base. These same biomechanics occur in the lower thoracic rings (Figure 11-10), but the direction of coupled side flexion can be ipsilateral or contralateral given the increased flexibility from greater cartilaginous attachments anteriorly and a decrease in size of the rib head articulation with the superior vertebra.[45] Furthermore, because of the more planar articulations of the costotransverse joints,

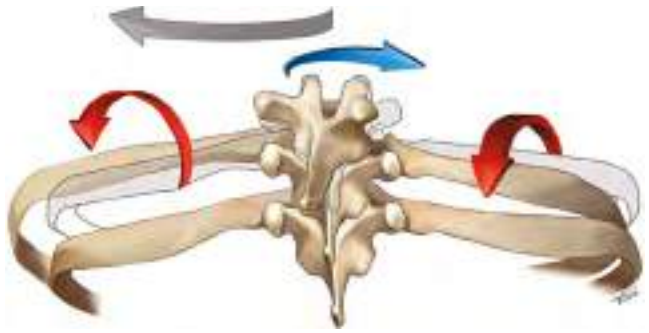

Figure 11-9 Two "thoracic rings," with the upper thoracic ring depicting the osteokinematics that occur with right rotation. During right rotation, the vertebra rotates right, the right rib posteriorly rotates, and the left rib anteriorly rotates,[45] and there is a left (i.e., contralateral) translation of the thoracic ring that can be palpated at the lateral aspect of the ring.[7,8] (Copyright LJ Lee Physiotherapist Corp.)

there is greater change in lateral diameter of the rings associated with anterior/posterior rotation of the ribs.

It is important to note that these biomechanics require intact passive integrity of the ring articulations and optimal neuromuscular control and muscle patterning to occur. If trauma disrupts the passive structures (e.g., vertebral body, disc, ligaments, cartilaginous or synovial joints) anteriorly, posteriorly, or both, the body's ability to produce these physiological movements is affected. Most commonly, altered patterns of muscle activation around and between the thoracic rings changes the osteokinematic movements and therefore the arthrokinematic movements produced during trunk rotation also changes.

In addition to assessing overall range of rotation motion in each direction, the examiner should note whether asymmetry of range is present. If rotation is restricted bilaterally, it is often easiest to find the best ring correction that changes the most restricted direction of rotation and then confirm that the same ring correction also improves the other direction of rotation. The examiner uses thoracic ring palpation and spans two to three rings concurrently (i.e., anterolaterally and laterally along the sides of the rings from rings 2-10) to identify any rings that NOLT during trunk rotation. The upper rings can also be palpated anteriorly, just lateral to the costochondral joints. NOLT is generally defined for any region of the body with nonoptimal alignment, biomechanics, and/or control relative to what is optimal for performance of a task or activity. Therefore, for the task of right trunk rotation, several possibilities of NOLT for the thoracic rings can occur:

1. An unstacked complex of two or more rings maintain their nonoptimal inter-ring relationships (see Figure 11-2) and are unable to dissociate to create optimal ring osteokinematics. They may remain in their nonoptimal alignment and not move, or as a complex, they may translate to the left or right.
2. One or more rings do not move in synchrony with the rings above and below, which can be palpated as a loss of contralateral inter-ring translation and the associated intraring biomechanics.
3. One or more rings move in the opposite pattern of translation and rotation (e.g., the ring displays left rotation biomechanics during right trunk rotation), palpated as prominence of the ring on the ipsilateral side of rotation (i.e., right side in example).
4. One or more rings move excessively into the optimal direction of translation but out of synchrony in relation to the rings above and below.
5. Excessive compression between two or more thoracic rings at different points around the three-dimensional ring.

The examiner notes all rings that display NOLT during the task and then systematically performs thoracic ring corrections at those levels. Two sequential rings are first "stacked" or aligned in neutral and then gentle manual facilitation of optimal ring biomechanics is performed while the patient repeats the difficult rotation movement. The examiner assesses the impact of the ring correction on the following:

1. Rotation range of motion (It should markedly increase if the driving rings are being corrected; see Figure 11-10.)
2. Ease of movement and any symptoms
3. NOLT of other rings (These should significantly improve or fully correct when the primary driving rings are corrected.)
4. NOLT of other areas of the body (e.g., pelvis, hip, shoulder girdle, neck) (These should significantly improve or fully correct when the primary driving thoracic rings are corrected.)

The impact of ring corrections at all levels displaying NOLT during the task are compared, and the correction with most positive changes is then compared with corrections of other regions of the body (e.g., cervical spine, scapula, glenohumeral joint, pelvis, and foot as described later). If the specific thoracic ring correction provides the most positive changes compared with all other corrections, it indicates the specific thoracic ring levels that are the primary drivers for the task of trunk rotation. If the patient's meaningful task is a more complex task requiring rotation, the examiner then applies the same ring correction during the more complex task to confirm that similar positive changes in task performance, patient experience, and other areas of NOLT occur.

Further tests of the driving thoracic ring(s) are then performed to determine the treatment techniques and progressive exercise plan required (see Treatment section later in this chapter), but the clinician has confirmed which specific ring(s) need to be addressed to restore full functional trunk rotation. Note that if motion of the ring can be fully restored with gentle manual correction, joint fixations and articular fibrosis are ruled out.

Single-Arm Lift

The **single-arm lift (SAL) test** has previously been described as the "sitting arm lift"[7,8,10]; The name has now been changed because it is useful to perform in standing, sitting, and other postures related to the patient's meaningful task (Figures 11-11 and 11-12). The **prone arm lift (PAL)**

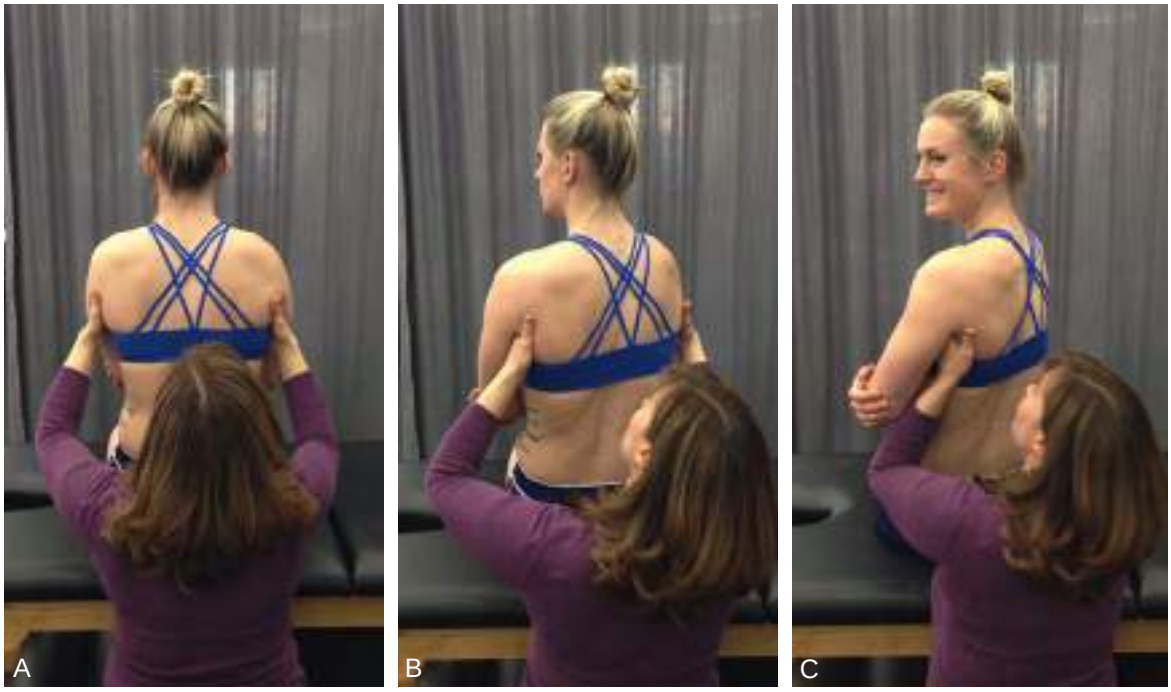

Figure 11-10 Seated trunk rotation with thoracic ring palpation and correction. **A,** Clinician's hand position for palpation of the third and fourth thoracic rings. The palpation is performed along the distal end of flat fingers; there is no pressure posteriorly from the heel of the hand or palm. **B,** The patient left rotates; the clinician notes the range of motion and any nonoptimal load transfer (NOLT) of the upper thoracic rings during the movement. The patient then returns to neutral. **C,** Left rotation with correction of the fourth thoracic ring on the left and the third thoracic ring on the right and facilitation of optimal biomechanics for the task. Note the increased range of motion and positive patient experience resulting from this ring correction. (Copyright LJ Lee Physiotherapist Corp.)

Figure 11-11 Single-arm lift (SAL) in sitting. Palpation for areas of nonoptimal load transfer (NOLT) in the upper quadrant. Optimal load transfer for each region for the task is the reference for determining whether NOLT is occurring. **A**, Palpation of several upper thoracic rings for any loss of neutral ring alignment. There should be no translations of any ring along any axis and no rotation or side bending occurring until the end range of movement. **B**, Palpation of the glenohumeral joint. The humeral head is palpated anteriorly and posteriorly just inferior to the acromion process. The position of the humeral head is noted at rest and during the SAL. The humeral head should remain centered in the glenoid fossa; note any anterior or superior translations during the task. **C**, Bilateral palpation of the articular pillars of the cervical spine is performed to monitor loss of neutral lordosis and any lateral translation or rotation of the cervical segments. As with the thorax, a small amount of extension, rotation, or lateral bending occurs at the very end of arm elevation, but this should be shared throughout the midcervical spine rather than occur excessively at one level. **D**, The clinician performs a correction at C0-C1 with one hand while monitoring the impact of the correction on left translation (NOLT) of the upper thoracic rings with the other hand. (Copyright LJ Lee Physiotherapist Corp.)

and the SAL were originally developed as tests for segmental control in the thorax[8,20] based on the principles of the **active straight-leg raise (ASLR) test,**[46–48] a validated test of failed load transfer in the pelvic girdle in pregnancy-related pelvic girdle pain. As arm function is also supported by optimal load transfer through multiple regions in the upper quadrant, the SAL and PAL tests were soon further developed to include evaluation and manual corrections of NOLT (previously described as "failed load transfer") in other regions of the upper quadrant, including the

cervical spine, scapula, and glenohumeral joint to guide the clinician in determining where to focus treatment in patients with upper quadrant symptoms.[8,10] This clinical reasoning process formed the basis for finding the driver in MTA, which recognizes that any task is a whole body task and that the driver for the patient's problem could be in any region, both locally or distally to the problem site. For example, although the ASLR has been researched as a test for patients with pelvic girdle pain, if there is loss of optimal strategies for control of the thoracic rings, thoracic dysfunction could be the driver of a positive ASLR test, "unlocking" of the sacroiliac joints during one leg loading, and pelvic girdle pain.[16]

Because any unilateral limb movement creates a rotational or lateral translation perturbation to the thorax, a single-arm or single-leg lift can highlight the presence of poor strategies for rotational control of the thoracic rings, indicated by the presence of lateral translation or rotation of the ring(s) on loading. When optimal strategies are used, during the SAL, all the thoracic rings will be aligned and stacked in a neutral position relative to the pelvis and the feet, with sufficient space between the rings. There will be no translations (i.e., anterior, posterior, or lateral), rotations, side bending, or increased vertical compression between the rings. During the last stage of full arm elevation, all levels of the thorax should move into extension, ipsilateral rotation, and side bending, with more movement in the upper thorax than in the lower portion. These movements should not occur through range.

The clinician instructs the patient to lift one arm (usually the pain-free side first if ipsilateral symptoms are present), with the arm straight, into elevation through shoulder flexion and then to lower the arm. Next, the patient is instructed to lift the other arm and lower it. The patient then is asked, "Does one arm feel heavier to lift than the other or different to lift than the other?" The clinician notes whether symptoms are produced and also observes which arm looks as if it requires more effort to lift. With regard to effort, the key part of the range to note is from the initiation of movement to the first 70° to 90° of flexion. If one arm is heavier or requires more effort to lift, *finding the driver analysis* is performed using the positive (i.e., the heavy) arm. The assessment and clinical reasoning process to find the driver for the positive SAL is the same as that described earlier for trunk rotation and follows the principles previously outlined. Figures 11-11 and 11-12 illustrate corrections of other regions that can be compared with thoracic ring corrections when ruling in or ruling out a thoracic ring driver for this task.

Figure 11-12 Single-arm lift (SAL) performed in standing. This position may be more relevant to the patient's meaningful task and is also an easier position to evaluate the impact of distal areas of nonoptimal load transfer (NOLT) on the ability to perform the task. In relation to testing the hypothesis of a thoracic ring driver for the SAL task, the impact of each of these distal corrections is compared with the impact of the best thoracic ring correction. **A**, The right hip is corrected by applying gentle posterosuperior distraction to the ischial tuberosity to create space to glide the femoral head posteriorly and center the femoral head. The correction is maintained while the SAL is repeated and the impact of the hip correction is compared with other corrections. **B**, The right ankle and foot are corrected by neutralizing perpendicular compression forces across the joints of the foot and creating a more optimal foot "pyramid" by aligning the bones of the foot. When in an optimal pyramid, there will be equal weight bearing on the medial and lateral columns of the foot. The foot correction is maintained while the SAL task is performed and the impact noted. Neurodynamic Tests and The Thoracic Rings

Because of connections between the nervous system and the thorax, thoracic ring dysfunction can play a role in distal symptoms in the legs or arms. To assess the impact of the thoracic rings on distal symptoms, thoracic ring assessment and correction techniques are applied to neurodynamic tests such as the slump and upper limb neurodynamic tests.[49,50]

Slump Test. The slump test is described in *Orthopedic Physical Asssessment*[42] and by Butler.[49,50] Using thoracic ring palpation, the clinician assesses the thorax and identifies any rings that demonstrate NOLT (i.e., excessive or asymmetrical compression, lateral translation or rotation, side flexion) as the patient moves into the slump position while extending the knee and then dorsiflexing the ankle (Figure 11-13). The side of knee extension and ankle dorsiflexion that reproduce the patient's symptoms is noted, along with any asymmetry or restriction of range of leg movement. The thoracic rings should be in neutral alignment with respect to translation/rotation/side bending and remain stacked throughout the slump test, while moving into flexion and posterior translation. If any thoracic rings demonstrate NOLT during any component of the slump test, the patient is asked to return to the neutral starting position. The clinician then performs thoracic ring corrections and maintains optimal alignment of the ring(s) as the patient repeats the slump test and lower extremity movements that reproduced the symptoms. If

Figure 11-13 Neurodynamics and thoracic ring function: the slump test. The clinician spans several rings with his or her hands to determine whether nonoptimal load transfer (NOLT) occurs as the patient performs the slump test. The overall range of motion of the slump test (i.e., the amount of leg extension and ankle dorsiflexion) is noted, and all thoracic rings are palpated to identify any levels displaying nonoptimal alignment, biomechanics, or control during the task (NOLT). Timing of NOLT relative to initiation of the slump movement is noted, and the rings displaying NOLT the earliest are corrected first while the slump test is repeated. The impact of the correction on leg extension range of motion and on the patient's symptoms are then noted. (Copyright LJ Lee Physiotherapist Corp.)

correction of any of the identified thoracic rings reduces the symptoms and increases the range of motion of the lower extremity movements, the ring or ring complex should be considered a driver for altered neurodynamic function. These findings are compared with the drivers found in MTA; if the same thoracic rings are found to be the driver in MTA, it indicates that treatment to the thoracic rings will address the patient's problem and restore altered neurodynamic function.

Upper Limb Neurodynamic Test. The upper thorax is often involved when the upper limb neurodynamic test result is positive, although all rings should be assessed. The upper limb neurodynamic test as described by Butler[49,50] and in *Orthopedic Physical Assessment*[42] is performed. The clinician then repeats the positive variation of the test (ULNT1 [median], ULNT2 [median], ULNT2 [radial], ULNT3 [ulnar]) while palpating the lateral border of the rings to feel for any lateral translation or other NOLT (Figure 11-14). The ideal response is neutral alignment of all the thoracic rings (until very end range movement) and, specifically, no movement or loss of alignment at one level compared with the rest of the rib cage. The arm is returned to the starting position, and the clinician corrects the ring of interest while the neurodynamic test is repeated. If correction of the thoracic ring reduces the symptoms and increases the

Figure 11-14 Neurodynamics and thoracic ring function: upper limb neurodynamic test. The clinician performs the variations of the upper limb neurodynamic test to determine which variation is positive for symptom reproduction and restricted motion compared with the other side. **A**, Several thoracic rings are then palpated laterally while the positive test is repeated. **B**, If lateral translation or other types of nonoptimal load transfer are palpated of one or more thoracic rings during the test, the clinician returns to the start position and performs a thoracic ring correction and maintains optimal ring alignment while the test is repeated. A significant increase in range of motion and/or decrease in symptoms supports that the thoracic ring(s) may be a driver for the restriction in the neurodynamic test. (Copyright LJ Lee Physiotherapist Corp.)

range of motion of the arm movements, treatment of the thoracic ring should be included to alleviate the distal arm symptoms. These findings are compared with the drivers found in MTA; if the same thoracic rings are found to be the driver in MTA, it indicates that treatment to the thoracic rings will address the patient's problem and restore altered neurodynamic function.

When doing both the slump test and the upper limb neurodynamic tests, thoracic ring correction may only partially improve findings, which indicates that there are neural system vectors connected to the thoracic ring and related to specific ranges of the neurodynamic test. Treatment, in this instance, involves performing "sliders" or other nerve gliding techniques while maintaining the thoracic rings corrected and stacked.

TREATMENT: SUPPORTING OPTIMAL HEALTH | CHANGE STRATEGIES FOR WHOLE BODY FUNCTION AND PERFORMANCE TO CREATE POSITIVE EXPERIENCES OF THE BODY

General Principles

Regardless of where the patient's symptoms present, the indication to treat the thorax, and specific levels of the thorax, is that specific thoracic ring(s) are shown to be a "driver" for the patient's problem in MTA. This provides a clinical rationale that treatment to the thoracic rings will result in positive clinical outcomes for whole body function and will create positive change in the patient's experience of their body. Changing the patient's experience of his or her body during MTA illustrates for the patient how dysfunction of the driver is connected to the problem and is the starting point for educating the patient on how treatment to the driver will resolve the symptoms. When patients experience significant change in symptoms and ease of movement during MTA, new synaptic connections and neural pathways are created.[51] This creates change at multiple levels, not only physically, but emotionally and cognitively, and sets up the potential for training new brain maps. A new sensorial experience during MTA opens the patient's mind to the possibilities and potential that he or she has for a more positive experience of his or her body, better movement, and optimized performance.

If one takes the broader view that "pain is an opinion on the organism's state of health rather than a mere reflexive response to injury,"[52] one needs to alter his or her focus and consider what it means to be "in health" and not only what it means to be "in pain." The World Health Assembly has defined *health* as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity."[53] Restoring health is about more than removing disease; similarly, creating optimal strategies for function and performance is about more than removing pain.

What it means to be "in health" is individually defined. Therefore, changing one's focus from removing pain to restoring optimal health and optimal strategies for function and performance is intrinsically linked to the patient's values and goals. The role of the clinician is to best facilitate and empower patients on their journey to achieve their personal optimal health and function. To do this effectively, one needs to understand not only the patient's pain but also the patient as a person. Jones and Rivett[54] refer to this as "understanding both the problem and the person."

This paradigm requires clinicians to broaden their perspectives and skill sets, and also opens up a wider range of potential and possibility for effecting change.

Ultimately, the goal of treatment is to facilitate the patient's journey toward a more optimal state of health. Changing the way the patient lives and moves in his or her body supports this overarching goal. Any type of treatment intervention should, therefore, support these two interconnected aims:

1. *To teach and train more optimal strategies for posture, movement, and performance.* This requires establishing new brain maps and consolidating new whole body movement patterns into unconscious and automatic behaviors. Training optimal strategies creates maximum efficiency and synergy within and between systems in the body so that the patient experiences ease of movement, confidence in his or her body, and a sense of grace and power during movement. Optimal strategies create beautiful, fluid movement. Athletes will often describe the feeling of "being in the zone" or "in the flow" that comes when a state of relaxed, but intense, movement is attained during periods of high performance.
2. *To change the way the patient experiences his or her body from negative to positive experiences.* Negative experiences include pain and discomfort, as well as other nonpainful but undesired symptoms such as the following:
   - Stiffness
   - Loss of ease of movement
   - Incontinence
   - Feeling of heaviness or pressure
   - Sensation of one side of the body "feeling wrong" or "feeling twisted" compared with the other side
   - Difficulty breathing in certain positions or tasks
   - Other systems disturbances, such as bloating or gastrointestinal upset, hyperhidrosis, altered temperature regulation, paresthesias, altered balance

Research from the pain sciences has established that pain is an output based on multiple different inputs, and the same can be said of other undesirable, negative sensorial experiences of the body. How the clinician focuses the patient's attention can have a significant effect on these experiences. This may be as simple as changing the patient's focus to positive constructs, such as a newly found ease of movement and lighter limbs when walking up stairs.

So how does one facilitate change? How much change is possible? There are many factors that influence the answers to these questions, and they are individually determined. Letting go of old postural and movement strategies and replacing them with new ones requires a multidimensional treatment approach that has an impact on emotional, social, environmental, and cognitive dimensions along with physical factors. The ConnectTherapy Circles of Influence™[55] (see Figure 11-7) is a tool that provides a broad framework to organize knowledge from multiple domains and determine the most relevant influencers, both intrinsic and extrinsic, on the patient's current (1) experience of his or her body and (2) strategies for function and performance. The Circles of Influence represent both intrinsic and extrinsic influences to the patient; the amount of overlap and linking between the different circles can change over time and help the clinician adjust priorities and choose appropriate interventions. Impairments related to the underlying drivers are a strong influencer, and it is proposed that the "Primary Driver" is the "way in" to making change in the nervous system, because it has not only physical but also emotional and cognitive impact as a result of use of MTA. Therefore, a key construct of ConnectTherapy and the Thoracic Ring Approach is that if the patient has a primary thoracic ring driver for his or her loss of function and current problem, then treating the thoracic ring driver is the most efficient and effective pathway to reach the goal of restoring optimal health.

TREATING THE THORACIC RING DRIVER

To effectively treat the thoracic rings, the underlying impairments specific to the driving ring(s) must be determined. Although it is widely held that the most common impairment in the thorax is stiffness, resulting from the presence of the rib cage,[4,29,30] minimal data support this belief. As highlighted in previous sections of this chapter, taken as a whole, the evidence supports that the thorax is inherently flexible in nature.[9,11–13] Clinically, multiple patterns of nonoptimal sequencing, force modulation, and synergy between the muscles around the thoracic ring(s), between the 10 thoracic rings, and between the rings and other regions of the body have been observed.[7,16–18] These nonoptimal neuromuscular forces create the appearance of stiffness that is not related to true articular restriction. This proposal is consistent with studies that demonstrate that mobilization and manipulation techniques effect change via neurophysiological mechanisms that alter muscle tone and activity.[56]

Therefore, it is essential that treatment of the thoracic ring driver support the overall goal of creating more optimal patterns of muscle recruitment and muscle balance related to the thoracic rings during function. This is addressed through a multimodal treatment program, ensuring that any cognitive or emotional components are addressed along with physical impairments. In general terms, treatment interventions can be categorized into two objectives (Figure 11-15):

1. *Down-train the existing nonoptimal strategy and create options to set the stage for learning new strategies for posture and movement.* This is accomplished by treating underlying impairments related to the thoracic ring driver and addressing any barriers such as cognitive or emotional factors (see *Potential Barriers & Facilitators* circle within Circles of Influence - Figure 11-7).
2. *Support, teach, and train a new, more optimal strategy for posture and movement.* Exercises are designed

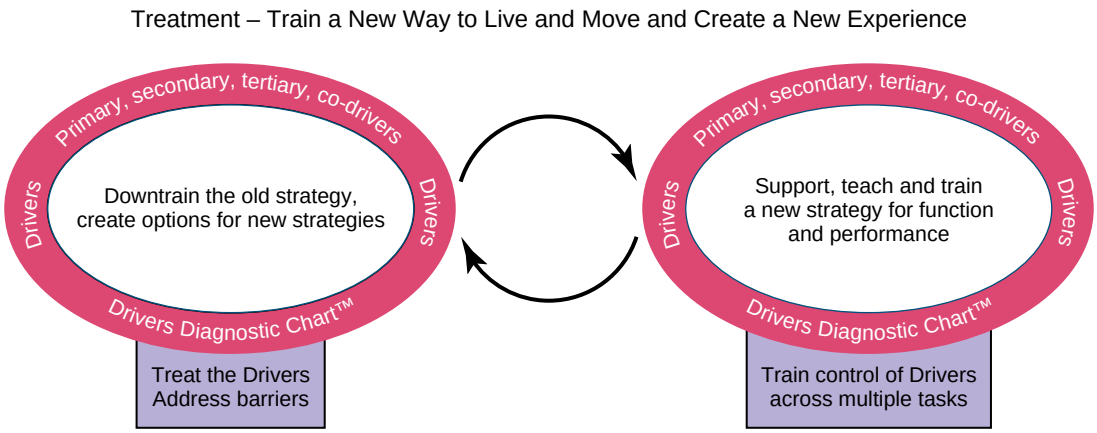

Figure 11-15 Treatment principles for the Thoracic Ring Approach and ConnectTherapy. Treatment interventions for the thoracic ring driver fall into two interconnected objectives that positively influence outcomes in the other. Down-training nonoptimal strategies is best achieved by treating system impairments related to the Primary Driver (see Circles of Influence [see Figure 11-7] where the *Drivers* circle and *Systems* circle intersect). Addressing current barriers, both extrinsic and intrinsic to the patient, will facilitate the rehabilitation process (see *Potential Barriers and Facilitators* circle). New, more optimal strategies are taught by focusing exercise and movement training to the primary driver across a variety of tasks. (Copyright LJ Lee Physiotherapist Corp.)

to train new patterns of neuromuscular activity, balance muscular synergies, and build capacity (strength, endurance) for more optimal control and movement of the driving thoracic ring(s) across a wide variety of movements and loading contexts. To enhance retention of new brain maps, it is important to train control of the thoracic ring driver across multiple tasks and movement patterns to support increased movement variability. The patient's goals and meaningful task also guide exercise prescription, along with the multitude of different movements required for daily function.

These two objectives are not linear; they are interconnected such that success in one domain positively influences outcomes in the other. The treatment program can be conceptualized into three phases that are really part of a continuum of progressive input and reevaluation to move the patient from early rehabilitation to discharge. As the patient progresses from phase 1 to phase 3, there is less reliance on hands-on treatment from the clinician and more active mechanisms for the patient to be self-sufficient in self-treating his or her thoracic ring driver.

Down-Train the Nonoptimal Strategy and Create Options to Train a New Strategy for Posture and Movement

Barriers to training new strategies for movement and control of the driving thoracic rings can originate in multiple different systems. It is common to find impairments that create nonoptimal force vectors around the thoracic rings that reduce mobility and/or reduce options for movement between the rings and between the rings and other regions. Loss of integrity in different systems may present as excessive movement or restricted movement depending on how the neuromuscular system compensates for the loss of integrity.

Therefore, to design the most effective treatment program, further assessment of the specific driving thoracic ring needs to be performed. This section describes tests to determine what impairments are causing dysfunction of the thoracic rings and outlines specific thoracic ring treatment techniques to address those impairments.

Tests for Vectors That Limit Dissociation between Thoracic Rings, Reduce Movement Options, and Reduce Mobility

Nonoptimal force vectors related to the thoracic rings can arise from multiple structures attaching externally or internally anywhere around the three-dimensional ring. Vectors have both direction and magnitude, and the sum of all force vectors acting on the thoracic ring at any point in time determines postural alignment of the ring(s) and behavior of the rings during movement. Most common vectors are related to hypertonic muscles, whereby increased resting tone in muscles attaching to the thoracic ring(s) prevents optimal ring movement (i.e., osteokinematics), dissociation between thoracic rings, and loss of optimal coordination between the thoracic rings and other regions of the body during function. Hypertonicity in muscles reflects altered neural drive and is therefore an impairment of the neural system and is most effectively addressed using techniques that effect change via neurophysiological mechanisms. Other types of neural system impairments, for example, those related to nerve injury, are possible but less common than neuromuscular vectors.

Impairments in other systems can also create nonoptimal vectors on the thoracic rings, such as adhesions or fibrosis related to the visceral system, muscular system, fascial system (including superficial and deep fascia), dural system, cutaneous system, and articular system (see *Systems Circles* in the Circles of Influence - Figure 11-7).

"Thoracic ring vector analysis"[57] assesses the location and type of system vectors. This technique can be performed in any position and also more statically or through movement ("dynamic vector analysis"). The driving rings (usually two sequential thoracic rings) are manually corrected and stacked into optimal alignment in all planes and dimensions, and the location and quality of the resistance to the correction are evaluated. Different system impairments have characteristic qualities of resistance. Combined with anatomical knowledge, a hypothesis can be made about the type of impairment affecting the thoracic ring, which is confirmed by palpation of the relevant structure while changing the degree of thoracic ring correction and noting if changes in tension in the palpated structure correlate with changes in the degree of thoracic ring correction performed.

Assessment of System Impairments: Thoracic Ring Vector Analysis

- Manually correct and stack the driving thoracic rings in a position related to the meaningful task, and note the following:
  - Quality of the resistance
  - Location of the resistance (relate to anatomy)
  - Point in the neutral zone where the resistance occurs (i.e., beginning, middle, or end feel of the thoracic ring correction)
- As the first resistance to the ring correction is encountered, consider the anatomy of different structures attaching to the thoracic ring and make a hypothesis of what structure could be creating the resistance given the characteristics of the resistance. The most common vectors are neural in origin, presenting as hypertonicity in muscles attaching to the driving thoracic ring(s); these have an elastic quality to the resistance. Palpate for hypertonic fascicles or fascial restriction in muscles that match the location and line of pull that is felt.
- Confirm neuromuscular and myofascial vectors. Increase and decrease the amount of correction on the thoracic rings while monitoring for change in tone/tension in the muscle hypothesized to be creating the vector. If the muscle is a relevant vector to treat, tone/resistance in the muscle should increase and decrease as the degree of thoracic ring correction is increased and decreased.
- Confirm articular vectors with passive accessory vertebral movements (PAVMs), and relate findings to the starting position of the thoracic ring. If PAVM findings change with correction of the ring, it is unlikely to be a true articular impairment; rather, the decreased movement is related to altered neuromuscular forces changing the joint glide findings.

- Neuromuscular vectors (neural impairment creating hypertonicity or excessive activity in muscles attaching to the driving thoracic rings) have an elastic quality to their resistance and typically occur at the beginning and throughout the neutral zone. The line of pull of the resistance is related to the angle and location of the muscle attachment. As vectors are released, the resistance is felt at a later point in the neutral zone.
- Visceral vectors create a resistance from deep inside the thoracic rings, are less linear in quality, and can feel like a broader fullness inside the ring preventing motion anywhere around the inner cavity of the chest. Different viscera create characteristic qualities dependent on their structure; programs such as the visceral curriculum with the Barral Institute (www.barralinstitute.com) provide the practitioner with more specific assessment and treatment skills for visceral system vectors.
- Myofascial vectors resulting from adhesions or lack of sliding of muscle and/or fascial interfaces can occur in any part of the neutral zone and are more easily detected once neuromuscular vectors are released. Myofascial vectors have a fibrotic, scar tissue–like quality and can have a sheet-like dimension to the resistance felt. Similar to neuromuscular vectors, their location is dependent on orientation and direction of specific muscle attachments and fascial planes.
- Articular vectors can result from capsular fibrosis (as consequence of a joint effusion) or joint ankylosis (related to a pathological condition such as ankylosing spondylitis) of the costotransverse and/or zygapophyseal joints. The location of articular vectors is therefore at the most posterior aspect of the thoracic rings and are best assessed after neuromuscular, visceral, and myofascial vectors are released. Articular vectors reduce the size of the neutral zone, but they do not affect the quality of the neutral zone until the end; that is, articular vectors create resistance late in the neutral zone with a firm end feel. They are confirmed with passive accessory joint glides (see volume 1 of this series, *Orthopedic Physical Assessment*[42]).

Treat the Underlying Impairments Related to the Thoracic Ring Driver

Specific treatment to the structures identified as creating the resistance can then be applied. Tools such as specific myofascial and neuromuscular release, dry needling (Figure 11-16), muscle energy, **Release with Awareness (RWA),**[10,58,59] mobilization, and manipulation can be successful in addressing these impairments (Table 11-1). However, multiple vectors are usually present concurrently, and accurate identification of vectors around the thoracic ring requires a more advanced level of skill. A novel treatment technique, the thoracic ring stack and breathe technique,[57] provides a method to simultaneously release multiple different vectors around and between the thoracic rings. Given the anatomical complexity of possible vectors attaching to the thoracic rings, the stack and breathe technique provides an efficient and effective route of addressing multiple vectors on the rings and can be progressed to dynamic contexts to combine release and neuromuscular training (Figure 11-17).[57]

Figure 11-16 Dry needling can be a useful adjunct to release neuromuscular vectors related to the thoracic rings. In cases of long-standing altered alignment and movement patterns in the thoracic rings, muscle adaptation, asymmetries, and imbalances are often present in neighboring regions. For example, in upper thoracic ring drivers, it is common to also find nonoptimal vectors in the shoulder girdle muscles that create vertical compression forces on the rings. To determine the most relevant shoulder girdle muscles to release, the driving thoracic rings are first stacked (**A**) and then the patient positioned such that shoulder range of motion is increased to engage vectors related to the shoulder girdle and the rings. Manual palpation while maintaining the stacked rings identifies hypertonic fascicles in the most relevant muscles (**B**). Once identified, specific neuromuscular release techniques can be applied to the muscle, in this case dry needling to specific fascicles of the left latissimus dorsi (**C**). (Copyright LJ Lee Physiotherapist Corp.)

TABLE **11-1**

Potential System Vectors and Treatment to Restore Mobility of the Thoracic Ring

Type of Vector/System	Location of Resistance around Ring	Quality of Resistance	Point in Neutral Zone Related to Ring Correction	Treatment Techniques
Neuromuscular (neural)	Anywhere around the three-dimensional ring related to anatomical muscular attachments Muscles like the diaphragm create vectors from inside the ring	Elastic resistance that can be modulated with speed of correction force application; has a linear line of pull that is consistent with anatomy of hypertonic muscle fascicle orientation	Present throughout the neutral zone, commonly early and felt at initiation of ring correction Onset of resistance becomes later during ring correction as more vectors are released Resistance from vectors can change dependent on task and position of body/orientation of thoracic rings relative to upper and lower extremities, lumbopelvic region	• Stack and breathe[57] • Stack and breathe combined with specific muscle release • Release with Awareness (RWA)[10] to specific muscles • Breath work (focused, vary positions to address different vectors) • Manipulation • Oscillatory mobilization • Dry needling • Acupuncture • Muscle energy
Visceral	Resistance felt within the rings, at any point around the three-dimensional ring depending on anatomical attachments of related viscera	Less linear, more general fullness deep inside the ring	Throughout the neutral zone, can be felt at any point during ring correction Can change dependent on task and position of body	• Stack and breathe[57] • Visceral techniques • Breath work (use inversion postures to change relationship of viscera to gravity and the diaphragm)
Myofascial	Anywhere around the three-dimensional ring related to anatomical muscular and fascial attachments	Fibrous quality that can be linear or sheet-like and does not change with speed of application of ring correction	Can be felt at any point in the ring correction/neutral zone; often present later in the neutral zone and easiest to discern quality once neuromuscular and/or visceral vectors are released Can change dependent on task and position of body/orientation of thoracic rings relative to upper and lower extremities, lumbopelvic region	• Stack and release[57] • Specific fascial or myofascial release techniques
Articular	Farthest posterior aspect of rings, close to midline (related to anatomical location of zygapophyseal and costotransverse joints)	Firm end feel; rapid increase in resistance to movement that does not change with speed	Occurs at end of neutral zone/ring correction and easiest to identify once other types of vectors are released Presence of vector does not change relative to body position or task	• Specific end range sustained joint mobilization

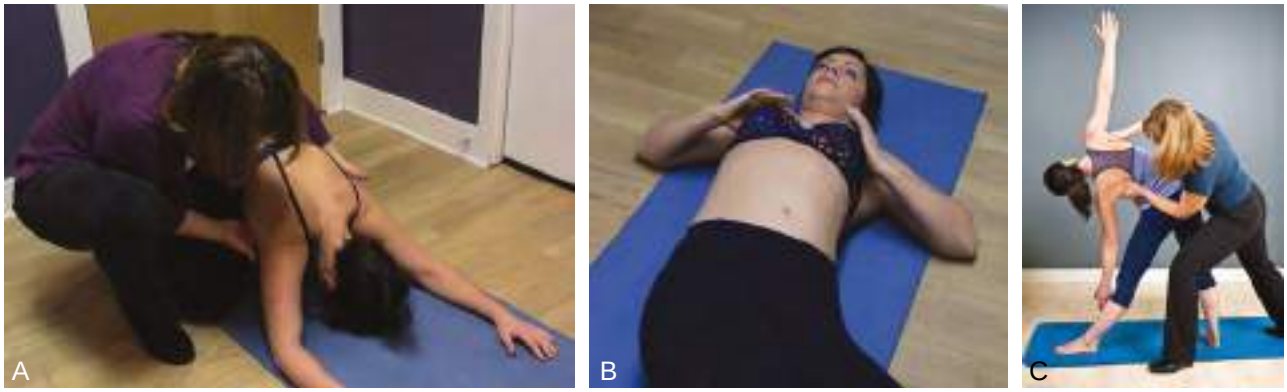

Figure 11-17 Thoracic ring stack and breathe.[57] This technique can be performed by the therapist in combination with specific muscle releases (e.g., the serratus anterior) or taught to patients as a self-release technique. The driving thoracic rings are corrected and manually controlled while different breathing patterns and movements of the trunk and extremities are used to tension different vectors acting on the rings. Over multiple cycles of deep breaths and through movement, the relevant vectors are released, creating a platform to train new muscle recruitment patterns. **A**, Thoracic ring stack and breathe of rings 3/4 while moving through child's pose to release vectors between the shoulder girdle/arms and the driving thoracic rings. **B**, Self-stack and breathe of rings 3/4. The patient self-corrects two sequential thoracic rings on opposite sides and uses a bent knee lift or head lift to check that he or she has corrected the desired rings (i.e., the effort to lift the leg or the head should be easier with the driving ring corrected). Over several breath cycles, the patient maintains the ring correction and moves the pelvis/hips into rotation to release vectors between the driving thoracic rings and the lumbopelvic–hip region. **C**, Dynamic thoracic ring stack and breathe. The driving thoracic rings are corrected while the patient moves into a functional task and breathes in different patterns. The clinician can modify this to become a training exercise for thoracic ring control by modulating the degree of support and correction provided, giving primarily sensory input and less manual correction support so that the patient actively controls the thoracic rings during movement. (Copyright LJ Lee Physiotherapist Corp.)

Clinical Reasoning to Decide Which Neuromuscular Vectors are Relevant to Treat

- Patients presents with many hypertonic and overactive muscles in the trunk. The most clinically relevant muscles to release are the following:
  - Those who display increased tone at rest and further *increase* in tone when correction of the thoracic ring driver is performed
  - Those who display early or dominant activity during meaningful screening task analysis and the timing of muscle activation correlates to nonoptimal load transfer (NOLT) of the driving thoracic ring
- Muscles that exhibit *reduced* tone or activity when the driving thoracic rings are corrected are muscles that are active to counter the forces created by the driving ring and do not need to be treated. Treating these muscles have the potential to make the driver worse. For example, in the case of a fourth thoracic ring driver translating left and rotating right, activity in the lower right external oblique (EO) muscle increases to counter the right rotation and can be the source of a runner's "stitch." Releasing the right EO muscle will enhance the right rotation force generated from the fourth thoracic ring driver and will not effectively treat the problem.

Benefits of Thoracic Ring Stack and Breathe Treatment Technique

- It simultaneously releases multiple vectors three-dimensionally around the driving thoracic rings.
- Clinician can control and maintain optimal relationships between two sequential rings (i.e., three vertebrae) and release vectors between "glued" rings, thereby preventing inadvertently making one ring more nonoptimal while correcting a ring above or below that is held by intercostal tone
- Treatment efficacy is not dependent on accurate identification of location and type of vector.
- It can be combined with specific neuromuscular release and myofascial release (ring stack and release).
- It indirectly releases visceral vectors (i.e., diaphragmatic movement creates movement of the viscera).
- It can be used in any position and dynamically with multiple movement variations (see Figure 11-17) to release vectors between the thoracic rings and other regions to combine release and exercise training for integrated treatment.

Thoracic Ring Stack and Breathe: Basic Technique

Patient Position. Multiple positions and postures are used related to different aims. In irritable, sensitized systems, supine is chosen. Supine also provides a position of greater mechanical advantage to release stronger vectors around the rings, but different vectors may be present in upright postures such as sitting or standing. It is usually necessary as treatment progresses to use postures and movements of the trunk and extremities in order to release longer vectors between the thoracic rings and the lumbopelvic–hip region, the upper extremities, and the lower extremities. Determine a loading task that is relatively heavy or has decreased ease compared with the other side (e.g., bent knee lift, SAL, head lift).

Technique. The two sequential thoracic rings identified as the primary driver are fully corrected and aligned in three dimensions, stacking them so that the intraring and inter-ring rotation/sidebending/translation are neutralized and the center of each ring is aligned with the midline of the body. This is done by gently introducing a vector of correction

and adjusting the next input for correction based on the response felt in the rings. Verbal cues are used to facilitate relaxation and "letting go" of specific muscles to facilitate correction of the rings. Once the clinician has stacked the rings, accuracy of the ring correction should be checked by ensuring it improves a loading task such as limb movement, a squat, a head lift, or a bent knee lift. The position of the rings is then maintained while deep breaths are cued into different patterns (i.e., lateral costal, apical, belly breath, breath between the scapulae). The pattern of breathing that creates the greatest pull and resistance to maintaining the ring correction is identified. The breath pattern is repeated over three to four deep breaths while the ring correction is maintained throughout. As the muscles release around the rings, the resistance to correction will decrease. The correction pressure is gently released and ring alignment, inter-ring neutral zone glide, and control of the ring are reassessed during the screening task or meaningful task.

Multiple variations of the stack and breathe technique can be used depending on the phase of treatment (see "Support, Teach, and Train a New Strategy" later in this chapter), the specific vectors affecting the rings, the need to release longer vectors between the driving rings and other regions, and treatment aims (see Figure 11-17). These include the following:

1. "Releasing of the vectors" between the rings and other regions: upper extremities, lower extremities, lumbopelvic–hip complex, head and neck. Movement of the limbs or trunk is induced to engage new vectors, that is, until the point where increased resistance to the thoracic ring correction is felt. Movement is then paused, and stack and breathe is performed in the new position until the vectors release and then greater range of movement is performed to engage the next vectors. Movements are chosen related to goals for exercise training and functional tasks; releases are graded to allow for training new strategies for control as new range of motion is gained.

Variations of Thoracic Ring Stack and Breathe Technique to Release Longer Vectors and Visceral Vectors

- Supine, knees move to right or left to induce rotation of the lumbopelvic–hip complex relative to the rings, repeat to the other side for balance (see Figure 11-17, *B*)
- Sitting with head rotation; both right and left rotation
- Supine knees bent to legs straight
- On decline dench or inversion table to alter relationship of viscera to diaphragm motion
- High kneeling → 4 point → child's pose (see Figure 11-17, *A*)
- Hands on wall → increase arm elevation range of motion with sequential releases, change shoulder abduction/adduction, use internal/external rotation to engage different vectors
- Forward fold
- Downward dog in yoga, starting with table dog (Figure 11-18) and progressing to modified downward dog (Figure 11-19), then to weight bearing on bent elbows instead of hands (dolphin pose in yoga, Figure 11-20)
- Unilateral high kneeling lunge ± trunk rotation
- Through any meaningful task (dynamic ring stack and breathe) (see Figure 11-17, *C*)

Figure 11-18 "Table dog" exercise, a phase 2 exercise to train control of the thoracic rings in neutral while dissociating and integrating with shoulder girdle control in closed-chain positions. The thoracic ring stack and breathe technique can be performed by stacking the driving rings in standing and maintaining their position while the patient moves into the position. As resistance to ring correction is noted, the movement is paused and breathing and manual release are used to release specific vectors before moving into range requiring greater shoulder elevation. Once vectors are released, the patient is able to train control of the rings in this exercise. (Copyright LJ Lee Physiotherapist Corp.)

Figure 11-19 Three-point modified downward dog. To increase the challenge to thoracic ring control, one leg is extended from the downward dog position. This is a closed-chain phase 2 inversion exercise. (Copyright LJ Lee Physiotherapist Corp.)

Figure 11-20 Dolphin pose. This position requires greater release of vectors between the thoracic rings and the upper extremities. The thoracic ring stack and breathe technique can be used to release vectors with the forearms in a similar position on the wall before progressing the release and then training into this position. (Copyright LJ Lee Physiotherapist Corp.)

2. "Self-stack and breathe." Patients are taught in supine how to self-correct their driving rings and use trunk rotation and lower extremity movements to self-release vectors as part of their self-management strategies and in preparation for training exercises.
3. "Stack and breathe combined with manual release." The stack and breathe technique can be combined with the manual release of specific vectors using trigger point pressure and patient cues for muscles such as the intercostals, serratus anterior, pectoralis minor, external oblique, and shoulder girdle muscles affected by altered ring function and position. The rings are maintained in their stacked position while hypertonic bands are palpated. The patient is made aware of holding patterns and is taught how to decrease activity in these hypertonic muscles; in this way the patient learns how to down-train the key muscles that are part of the old strategy. Myofascial release can also be added as the hypertonic fascicles decrease in tone (stack and release).
4. "Dynamic stack and breathe." This combines release and training of new strategies simultaneously, as partial or full correction of thoracic rings is maintained during dynamic movement. This can also facilitate strength and endurance training in superficial muscles that have deficits from long-standing altered ring function, which then facilitates recruitment of segmental ring control muscles.

Specific Neuromuscular Vector Releases

The thoracic ring stack and breathe technique and its variations are very effective at releasing vectors around the thoracic rings. However, after treating a patient with the stack and breathe technique, there may be one or two more dominant vectors related to specific muscles. As long as intercostal hypertonicity and glued rings have been released to dissociate the driving rings, then specific muscle releases can be performed. Techniques can include dry needling, Release with Awareness,[10,58,59] manipulation, mobilization, and other types of release techniques that create a change in muscle tone via neurophysiological mechanisms.

Release with Awareness

The principles of the Release with Awareness technique,[10,58,59] as they are applied to the thorax and scapula, are as follows:

1. The driving thoracic rings are manually stacked to identify the most relevant muscles to release. The area of increased tone (i.e., hypertonic fascicle or trigger point) is palpated with gentle pressure.
2. To release the erector spinae muscles, the driving ring is positioned so as to shorten the origin and insertion of the specific fascicle of the erector spinae muscle that is hypertonic (e.g., spinalis, longissimus, iliocostalis). For scapular release, the scapula is moved to shorten the origin and insertion of the hypertonic muscle. As the clinician passively shortens the muscle, the afferent input from the primary annulospiral ending in the intrafusal muscle spindle decreases, and the spinal cord responds by decreasing the efferent output to the extrafusal muscle fiber. This is felt as a "softening of tone" in the trigger point. The clinician waits for this to occur (up to 30-45 seconds).
3. The clinician cues the patient to "release," or soften, the muscle with verbal and manual cues to "let go." This step is critical to the awareness training, and it is the point where learning occurs.
4. The scapula or thoracic ring is moved in various combinations to maximally release the muscle as the clinician cues the patient (with words and touch) to be aware of the softening and release. The key is to use words that encourage the patient to let go and stop holding rather than to "do something." As greater release occurs, the clinician can increase the amount of correction of the driving thoracic rings, and new vectors will be engaged.

   If there is a specific muscle that creates recurring vectors on a driving thoracic ring, home exercises for self-release with awareness can be designed and prescribed for specific muscles around the thoracic ring, such as the pectoralis minor, the intercostals, latissimus dorsi, and serratus anterior muscles.
5. The patients' homework is to recreate this sensation of letting go. As they practice at home, they quickly remember and learn how to stop bracing. They also learn that they can control and reduce the pain when the bracing is decreased. This is positive reinforcement for changing their nonoptimal strategy.

Manipulation and the Thorax

Manipulation, or high-velocity low-amplitude thrust (HVLAT) techniques, are often used in the thorax. Notably, the thorax has been reported to be the most commonly manipulated area of the spine,[60] and there is increasing research interest in the effectiveness of thoracic

manipulation in the treatment of pain in neighboring regions, such as for patients with neck pain[3] and shoulder pain.[2] Manipulation to the thoracic spine is perceived to be significantly safer than manipulation to the cervical spine, and as such, it is being considered as an alternative treatment for neck pain in place of cervical spine thrust manipulation. However, serious adverse effects from thoracic manipulation, including herniation of thoracic discs,[61] epidural bruising,[62] and esophageal rupture,[63] have been reported in the literature. It is the author's clinical experience that adverse responses to thoracic manipulation occur when excessive posterior translation is used as a manipulation vector. Instead, the primary vector for thoracic spine facet joint manipulation should be in a cranial direction, with a slight posterior vector to gap the joint. Posterior translation in the thoracic spine has no bony barrier and therefore excessive amplitude or force combined with posterior translation is likely to injure the thoracic disc.

In terms of the clinical decision as to *when* to manipulate the thorax and *what levels* to manipulate, the clinical reasoning approach of the Thoracic Ring Approach supports that the thoracic joints should be manipulated only if the thorax is the driver for the patient's problem as assessed with MTA. Thoracic manipulation affects change in muscle tone (i.e., neuromuscular vectors) via neurophysiological mechanisms and, therefore, will most likely result in changes in muscles innervated by the thoracic segment being manipulated. As discussed earlier, there are many nonoptimal vectors that can affect the driving thoracic ring, but not all of these muscles receive their innervation from the thorax. These muscles include the thoracic erector spinae (T1-T12), the intercostals (T1-T12), and the abdominal muscles (T7-L1). Many patients have experienced the significant change in trunk rotation range of motion when the large thoracic longissimus and the abdominal muscles decrease in resting tone after a manipulation. However, if thoracic ring vector analysis indicates that the strongest vectors around the ring are around the lateral and anterior aspect of the ring(s), then release of the posterior erector spinae vectors via upper thoracic spine manipulation has the potential to relatively enhance the effect of lateral and anterior vectors, thereby making the thoracic rings functionally worse and increasing symptoms. Furthermore, in terms of intercostal tone, because of their complex neural drive related to breathing, manipulation of the related vertebral segment may or may not change intercostal tone around the entire thoracic ring. Vector analysis of the two sequential rings is required to determine whether the manipulation produced the desired release effect. If thoracic ring vector analysis is used consistently as a premanipulation and postmanipulation test, over time, the skilled practitioner will acquire a library of "characteristic vector resistance patterns" that are effectively released by manipulation and those that are not. In this way, the chance of adverse reactions will be decreased, and more effective treatment choices can be made based on a collection of clinical tests and a clinical reasoning process.

Tests for Integrity of Systems Related to the Thoracic Ring

If the patient's story and injury history suggest that there may be loss of integrity in any system, specific tests for integrity need to be performed. The nature and degree of loss of integrity will inform expectations about rate of recovery, grading, and progressing treatment, and potential for future recurrences and thus is important to establish early on in the process.

Passive Integrity of the Articular System

Tests for integrity of the articular system are also known as passive stability tests. In the presence of underlying loss of passive integrity, different patterns of neuromuscular compensation are possible. Depending on how the nervous system modulates resting muscle tone and alters recruitment patterns to support deficiency in articular structures, patients may present with either increased or decreased mobility when doing active range of motion tests and/or passive articular mobility tests. In cases in which neuromuscular vectors are present, these must first be released before performing stability tests in order to get a valid test result. Hypertonic muscles can result in a false-negative finding (e.g., consider the case of hamstring spasm with an underlying third degree anterior cruciate ligament [ACL] tear).

Once hypertonic muscles are released or relaxed, several signs are consistent with a loss of passive integrity of the anterior or posterior articulations of the thoracic ring:

- Marked altered positional findings (nonoptimal alignment) of the thoracic ring or specific bones of the thoracic ring relative to the ring above and below, especially in translational components (posterior, anterior, or lateral translation)
- Excessive movement of the ring or bones of the ring on active and passive mobility tests

However, it is important to recognize that significant loss of optimal neuromuscular control and decreased muscular capacity in the segmental muscles around the ring can also be consistent with the aforementioned findings. If the patient's story is not consistent with injury to the articular structures, then the likely underlying impairment is one of neuromuscular control and/or muscle capacity (e.g., cross-sectional area, endurance, and/or strength).

To rule in or rule out a loss of passive integrity, specific articular integrity tests are performed; these have been described elsewhere.[22,64] These are tests of multiple articular structures to resist translation in nonphysiological

planes. An analysis of the amplitude and quality of both the neutral and elastic zones of motion is performed with the joints and rings initially in a neutral position (i.e., not rotated, flexed or extended). An increase in the size of the neutral zone combined with a soft end feel are characteristic of a segment with a loss of integrity in the passive system (see volume 2 of this series, *Scientific Foundations and Principles of Practice in Musculoskeletal Rehabilitation,* Chapters 19 and 24). The specific structures affected depend on the direction of the translation applied. If an increased neutral zone and soft end feel are noted with the joint in a neutral position, a loss of passive integrity in structures related to the directional restraints is supported. The tests can be repeated with the facet joints in the close packed position (i.e., full extension) or under full posterior ligamentous tension (i.e., full flexion), in which the size of the neutral zone should be markedly reduced and the end feel firm. The presence of an increased neutral zone and soft end feel in full extension or flexion confirms that more significant laxity exists in the articular (and connecting fascial) support system (i.e., a loss of passive integrity).

Data from resection studies indicate the importance of the thoracic disc as a key restraint for passive stability, along with the costovertebral joints.[9,30,65] Notably, at the segmental level, loss of rib articulations does not affect mobility until the disc is also resected.[66] These findings have implications for treatment decisions involving interventions such as prolotherapy to the facet joints and costotransverse joints (discussed later). A specific adaptation of the initially proposed lateral translation stability test[22,64] assesses lateral integrity of the posterior structures of the thoracic ring and is designed to bias forces through the head of the rib into the thoracic intervertebral disc (Figure 11-21).

A dynamic component can be added to any of the passive articular integrity tests in several ways. In the sitting position, the patient can be asked to lift the arms against the clinician's resistance. The stability test is repeated while the muscles are active. If the segmental deep and multisegmental superficial muscles are working synergistically, the results of the stability test will be negative (i.e., translation is controlled). If the deep segmental muscles of the ring are not working appropriately, even with contraction of the superficial muscles, the result of the stability test is positive (i.e., translation is not controlled). Once the patient has been taught how to recruit the deep segmental stabilizing muscles, the stability test can be repeated with a precontraction of the segmental muscles in any position. With a low-force contraction of the local stabilizing muscles (i.e., 10%-20% of the maximum voluntary contraction), the neutral zone should be reduced to zero and produce a solid resistance to the translation applied in the stability test. This resistance to translation suggests a good prognosis for recovery of dynamic control of the thoracic ring even in the presence of decreased passive integrity. A progressive training program for thoracic ring control across a variety of movement tasks and contexts is essential for successful return to activities (see later discussion). However, given the presence of the underlying loss of passive integrity, this subgroup of patients is more likely to experience recurrent episodes of pain and dysfunction, depending on their activities and postures, and intermittent treatment may be necessary to settle flare-ups.

Figure 11-21 Intraring integrity with a focus on posterior articular structures: lateral translation. Patient position: Compare findings in both sitting and prone. Clinician position and palpation: At the ring of interest, the left hand translates the left half of the ring (i.e., left rib) medially into the rib–vertebrae–disc interface at the spinal segment and stabilizes the segment (*left arrow*). The other hand translates the right half of the ring (i.e., right rib) medially into the rib–vertebrae–disc interface (left translation) (*right arrow*) and notes any increase in amplitude of the neutral zone or soft end feel. The test is repeated with the right hand stabilizing the right half of the ring segment and the left hand testing the amplitude and quality of the end feel to right translation. (Copyright LJ Lee Physiotherapist Corp.)

Treatment of Thoracic Ring Driver with an Underlying Loss of Passive Articular Integrity

DOWN-TRAIN THE OLD STRATEGY, CREATE OPTIONS FOR NEW STRATEGIES, ADDRESS BARRIERS

- Systems Circle—Neural
  - Release hypertonic muscles around the thoracic ring creating excessive compression on articular structures.
- Systems Circle—Articular
  - Perform specific articular integrity tests.
  - Teach recruitment of deep segmental ring muscles and determine their ability to control positive articular integrity tests.

SUPPORT, TEACH, AND TRAIN A NEW STRATEGY FOR FUNCTION AND PERFORMANCE

- Tape the driving rings.
- Systems Circle—Neural and Muscular
  - Train control of the thoracic ring across multiple tasks and in diverse contexts (Table 11-2).
- Circles of Influence—Potential Barriers and Facilitators
  - Educate about potential activities and postures that could overload patient's capacity to control the underlying loss of integrity.
  - Provide self-management strategies, including self-release and reset exercises; self-check movements help determine whether and when they need to seek treatment.

If the neutral zone does not change with segmental muscle contraction, the clinician has several scenarios to consider. First, the patient may not be sufficiently recruiting the segmental muscles. Second, the segmental muscles (e.g., multifidus and intercostals) may have insufficient bulk to produce a sufficient increase in tension in the fascial system to change the resistance to translation. Change in fascial tension is one mechanism by which the muscle system changes compression across joints.[67–69] In this case, a palpable decrease in the bulk and resting tone of the segmental muscles will be noted. Again, a well-designed and prescribed training program is an essential component for successful treatment. As the exercise rehabilitation program is progressed and muscle bulk increases, the resultant increased fascial tension may increase passive support sufficiently to produce a negative result on the stability test.

Prolotherapy has been proposed to be a tool for remediation of significant passive articular deficiencies. One *note of caution* in these cases is to consider that of the posterior articulations, the thoracic intervertebral disc, and the costovertebral articulations provide the most significant contribution to passive stability.[30,65,66] If prolotherapy is performed to the zygapophyseal and costotransverse joints

TABLE **11-2**

Exercise Categories for Thoracic Ring Exercise Progressions and Program Design

Exercise Category	Description and Exercise Examples
Segmental control *Intraring and inter-ring*	Deep muscles; optimal recruitment evidenced by change in ring position and control in response to verbal cues and without superficial muscle activity (establish in *Phase 1*).
Inter-regional control *Thoracic rings—head/neck*	*Phase 2:* Maintain neutral thoracic ring stacking and dissociate from head movements (e.g., seated head rotation, side flexion) *Phase 3:* Concurrent movement of thoracic rings and head into ipsilateral and contralateral rotation patterns; more complex loading between thoracic rings and head in rotation (e.g., triangle pose in yoga)
Inter-regional control *Thoracic rings—shoulder girdle: open kinetic chain*	*Phase 2:* Maintain neutral thoracic ring stacking and dissociate from shoulder girdle movement (e.g., supine horizontal shoulder abduction, triceps extensions, bilateral elevation) *Phase 3:* Dissociate thoracic ring control from shoulder girdle in rotation/side flexion/lateral translation patterns; both congruent and incongruent from other region (e.g., bow and arrow with pulley, lateral medicine ball throws)
Inter-regional control *Thoracic rings—shoulder girdle: closed kinetic chain*	*Phase 2:* Maintain neutral thoracic ring stacking with upper extremity weight bearing: wall lands, wall ball roll-outs (Figure 11-24) wall push-ups, bench push-ups; include movements that require movement of neutral thoracic rings through fixed weight-bearing arm (e.g., 4-point kneeling transition to modified downward dog in yoga (Figure 11-22), then moving in and out of plank—dynamic) *Phase 3:* Dissociate thoracic ring control from shoulder girdle in rotation/side flexion/lateral translation patterns (e.g., wall "plank" open into unilateral wall side "plank") Inversion postures are key to train vertical loading capacity in the thorax (e.g., downward dog modified with knees bent → wall handstands → handstand push-ups on wall)
Inter-regional control *Thoracic rings-lumbopelvic–hip (trunk control)*	*Phase 2:* Maintain neutral trunk position during lower extremity challenges (e.g., squats, split squats, forward-backward lunges → progress to deep lateral lunges, diagonal lunges, star lunges) → progress to combined upper/lower extremity challenges (e.g., pulley reach patterns, unilateral pulley resistance to forward lunges, front medicine ball throws) *Phase 3:* Dissociate thoracic ring control in rotation/side flexion patterns—both congruent and incongruent from other region (e.g., walking lunges with contralateral trunk rotation, rotational pulley patterns [e.g., wood chop])
Postural equilibrium *Thoracic rings—feet (base of support)*	Use challenges to postural equilibrium and trunk control in coronal plane (i.e., lateral perturbations) while ensuring optimal thoracic ring alignment and control (e.g., asymmetrical resistance with tubing or pulley applied to the trunk/ upper extremity/ lower extremity during sagittal plane movements like forward lunges, deep lateral lunges, star lunges, lateral hops)
Thoracic spring	Ensure thoracic ring control while maintaining vertical space and without bracing or rigidity: jump squats, front-back hops, lateral hops, skipping

when the disc is the most significant underlying impairment, the existing loss of disc integrity will be functionally amplified as a result of the relative increase in passive support to the other structures. In this case, symptoms will be exacerbated and functional ability diminished. Therefore, careful consideration of the structures involved is needed before implementation of tools such as prolotherapy.

Surgical intervention in the thorax is indicated only in extreme and severe cases when cord compromise is a risk.

Articular Fixation of the Costotransverse or Zygapophyseal Joints

When a force is applied to the joints of the thorax sufficient to stretch or tear the articular ligaments, the muscles respond to prevent dislocation and further trauma to the joint. The resulting spasm may fix the joint in an abnormal resting position, and marked asymmetry may be present. This type of articular "fixation"[70] can occur in any movement direction. It is common with trauma involving excessive rotation of the unrestrained thorax or when rotation of the thorax is forced against a fixed rib cage (e.g., seat belt injury). Another common scenario is an impact force to a specific rib, such as can occur in contact sports. This results in a fixation of the costotransverse joint.

The degree of underlying loss of integrity of the articular structures is variable and can be minimal or significant, but the consistent presenting feature is excessive compression from neuromuscular vectors, and the clinician will note marked altered positional findings and joint restriction. Resistance on thoracic ring vector analysis depends on whether the zygapophyseal (facet) or costotransverse joint is fixated. If the facet joint is fixated, the clinician can initiate ring correction via motion of the rib, but as the vertebral component is engaged, there will be a rapid increase in resistance from the farthest posteromedial aspect of the ring on one side of the ring. If the costotransverse joint is fixated, there will be early and rapid increase in resistance to ring correction on one half of the ring, again coming from the posterior aspect of the ring on one side. On passive mobility testing, the neutral zone of movement cannot be felt, and a hard, nonbony end feel is present.

Initial treatment must include techniques to release the neuromuscular vectors and restore articular mobility; high-velocity low-amplitude manipulation (grade 5 mobilization) treatment (HVLAT)[22] techniques to gap the specific fixated joint can provide an effective neurophysiological release. Treatment for this patient that focuses on exercise without first addressing the fixation of the joint tends to be ineffective and commonly increases symptoms. Conversely, if treatment includes only manual therapy (i.e., joint mobilization, manipulation, or muscle energy techniques), relief tends to be temporary, and dependence on the health care practitioner to provide the manual correction is common. This impairment requires a multimodal therapeutic approach to management that includes manual therapy to decompress and align the thoracic rings. It is essential that release techniques be followed by assessment of articular integrity, taping to support the thoracic ring, and training for neuromuscular control and capacity (i.e., endurance and strength) across a variety of functional tasks (see later discussion).

Anterior Joints of the Thoracic Ring

Anteriorly, the costochondral and sternochondral joints can become excessively loaded and a source of localized anterior chest pain. Consider the impact on these joints when there are asymmetrical rotational and compressive loads related to nonoptimal function of the three-dimensional thoracic ring. Altered forces between the rings and the shoulder girdle can also medially compress the anterior joints, and the combination of medial compression and rotational torque through the ring can exhaust the adaptive potential of these structures under loads and create an acutely painful articulation. Treatment of these cases involves the approach as outlined earlier, that is, a clinical reasoning process to determine where the underlying driver is and then treatment to the driver to restore more optimal loading through the anterior articulations. It is important to note that the driving thoracic rings may be one or more levels above or below the painful level; thus the function of the entire thorax needs to be considered in the context of the meaningful task in order to determine which thoracic rings to treat.

The anterior articulations can also be damaged by blunt force injury, creating a loss of passive integrity. Acute management of these injuries is essential to prevent a chronic passive integrity problem. These joints may be fixated or subluxed as a result of the trauma, but they are not treated with manipulation. Instead, thoracic ring vector analysis and the ring stack and breathe technique are used to release neuromuscular vectors around the three-dimensional ring and restore optimal relationships between the ring and the rings above and below. Balancing forces around the ring creates an optimal position for the injured anterior structures to heal. Tape is used to support the anterior joints and thoracic ring in optimal alignment to reduce stress on the injured structures and optimize formation of a functional scar.

SUPPORT, TEACH, AND TRAIN A NEW STRATEGY FOR MOVEMENT AND CONTROL OF THE THORACIC RINGS ACROSS MULTIPLE TASKS

Evaluation of neuromuscular strategies for the thorax needs to include segmental control (i.e., intraring and inter-ring), inter-regional control, and control of postural equilibrium.[9,39] As patients learn how to release and down-train specific muscles around the thoracic rings, skills needed to recruit new muscles are taught concurrently. Exercise prescription is based on control impairments found on assessment. Based on anatomical attachments and research from other areas of the spine, it has been proposed that the deep segmental muscles such

as thoracic multifidus/rotatores and the intercostals are architecturally suited to control intraring and inter-ring motion.[71] These clinical proposals are consistent with studies showing that the CNS exhibits differential control of the deep and superficial thoracic paraspinal muscles for control of opposite rotational perturbations.[32–34] Imagery, visualization, and sensory cues combined with specific thoracic ring taping (Figure 11-23) are used to decrease activity in hypertonic, overactive muscles around the thoracic ring, and facilitate recruitment of the deep ring control muscles. This new strategy for thoracic ring control is progressively integrated across a variety of movement patterns and relevant loads to increase capacity and robustness, and to train synergistic patterns with superficial, multisegmental muscles connecting the thoracic rings to other regions.[7,10,17,18,20,28]

Movement patterns and exercises for the thoracic rings can be organized into different categories (see Table 11-2). As the rehabilitation program is progressed, the clinician should ensure that multiple categories of exercises are incorporated to ensure there is diversity in challenges to thoracic ring loading and control. Task variability enhances retention and consolidation of new brain maps.

Training new strategies for thoracic ring control and movement is organized into three phases of treatment progression. Each phase has different features and aims as outlined here.

Phase 1: Establish A New Strategy to Control the Driving Thoracic Rings - Optimize Recruitment Between Deep and Superficial Thoracic Ring Muscles

Principle: Train a new strategy for control of the driver by creating awareness of previous non-optimal neuromuscular patterns and teaching new recruitment patterns around the driver. Find the best "ring stack" cue or combination of cues that changes control of the rings during the initiation of simple, low load tasks so that the patient can compare the impact of the old strategy to the new strategy. Best positions are those where the thorax is symmetrical (e.g., supine lying). Side lying is too challenging for early progressions due to lateral translation forces on the rings.

- Phase 1 should last approximately the first 1 to 2 weeks.
- Release nonoptimal vectors on the driving rings.
- Establish whether any underlying loss of passive integrity is present.
- Address other barriers (e.g., sympathetic system sensitization can be treated with acupuncture and breathing exercises to increase parasympathetic system activity).
- Teach self-release techniques (e.g., self-stack and breathe, specific muscle release techniques).
- Establish best "ring stack" cue. This best "driver cue" results in a more optimal balance of deep and superficial muscle activity around the driving thoracic rings. Determine best position to practice the "ring stack" cue for intraring and inter-ring control in simple tasks that will act as a "Cue Check" for the patient (discussed later). (SAL, squat, one leg standing, supine bent knee fall-outs, supine arm abduction). This cue may need to be modified over the first few sessions as the patient learns and adapts.
- Train awareness and confidence in ability to release vectors and activate deep ring muscles to change the patient's subjective effort in simple task performance; use sensory feedback and mirrors.
- Train endurance of the new ring control strategy (best "Driver Cue") (aim for 3 sets of 10-15 repetitions, practice twice a day).

Figure 11-22 Examples of phase 2 exercises to train control of the thoracic rings in neutral while dissociating and integrating with shoulder girdle control in closed-chain and inversion postures. Inversion postures are essential to increase the ability to sustain vertical loading in the thorax. Note that the thoracic ring stack and breathe technique can be performed by the therapist in any of these positions by maintaining full correction of the driving rings and pausing to perform release and breathing at points through range when new or stronger vectors are felt on the rings. **A**, The patient provides sensory input to facilitate the best phase 1 "ring stack" cue before starting the movement; this cue is maintained throughout the exercise. **B**, Four-point kneeling provides a starting position to transition into the modified downward dog pose. **C**, Controlling neutral alignment of the thoracic rings is facilitated by thinking of "space" and "length" between the sides of the driving rings while the rings move in relation to the fixed hands. This requires coordination of ring control and shoulder girdle control. **D**, Modified downward dog. The knees are flexed and the femoral heads seated. The patient thinks of pushing their rings away from the hands in a line toward the hips (*blue arrow*); the thorax is not allowed to drop into anterior translation or extension. (Copyright LJ Lee Physiotherapist Corp.)

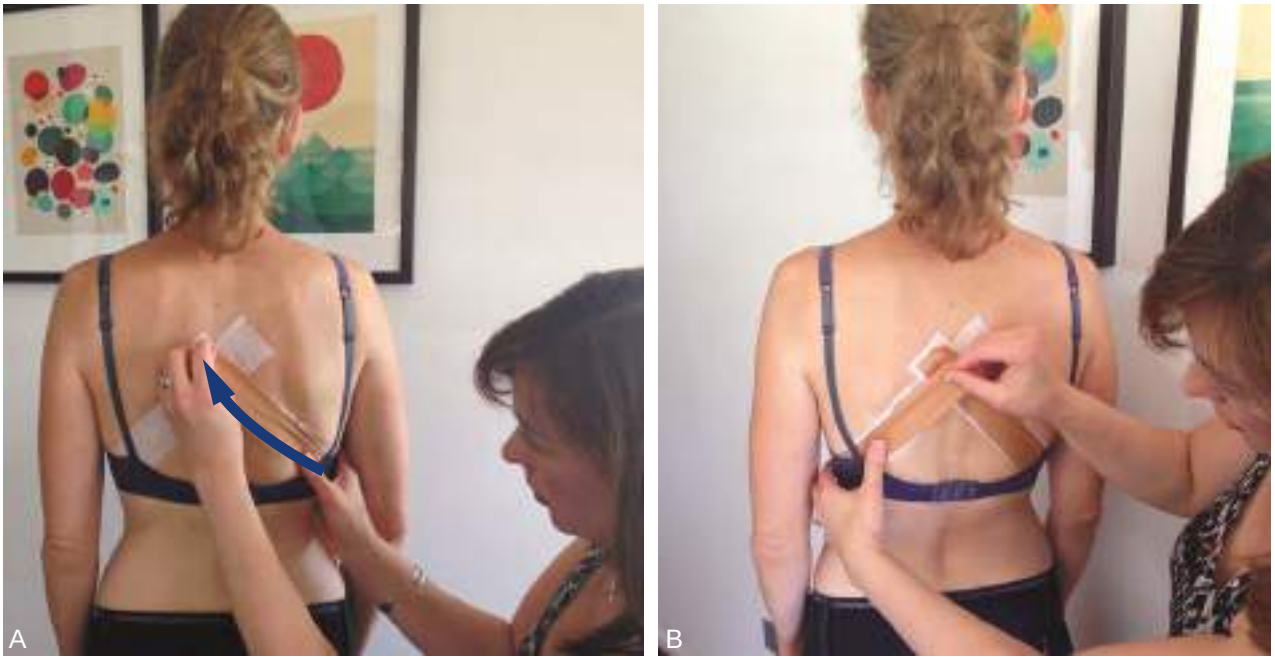

Figure 11-23 Lower thoracic ring taping. Supportive tape can be applied in a variety of directions to provide both proprioceptive input and mechanical support to the driving ring(s). Here, the eighth ring is corrected from a right lateral translation/left rotated position via the right eighth rib while the ninth ring is corrected from a relative left lateral translation/right rotated position via the left ninth rib. **A**, White COVER-ROLL® tape is applied along the line of both rings to ensure appropriate placement of the leukotape and to guide the direction of the force application. The clinician's right hand provides a gentle force to craniomedially translate the ring to the left along the line of the rib to facilitate optimal biomechanics of the ring *(blue arrow)* as LEUKOTAPE® is applied to support the ring in this position. The entire ring can be corrected in this way only in the absence of a significant loss of integrity in the passive system in one of the articulations of the ring. **B**, The process is repeated for the left ninth ring. It is essential that nonoptimal vectors around the ring and related to the 9/8 ring complex be released before the tape is applied. Otherwise, taping may make symptoms worse. The relevant screening task should be repeated after the tape is applied to ensure that the correct level has been taped and that sufficient support has been provided (i.e., the task movement should be easier after application of the tape). (Copyright LJ Lee Physiotherapist Corp.)

- Support with ring taping. Scapula taping in addition to ring taping is helpful when large shoulder girdle muscle bulk creates excessive compression on the rings.
- Integrate best "ring stack" (driver) cues into daily activities (e.g., walking), and integrate postural education cues.

Phase 1 Cueing. After releasing vectors around the driving thoracic rings, reassess for NOLT during a simple loading task (SAL, squat, one leg standing). Determine how many repetitions can be performed without NOLT. If NOLT of the driver (thoracic rings) still occurs after release of vectors (e.g., within 0-20 repetitions), this indicates that the patient needs to be taught a new neuromuscular strategy for ring control. NOLT may recur due to insufficient recruitment of the deep segmental ring muscles, or due to a return of the non-optimal patterns of excessive superficial muscle activity.

Provide sensory/proprioceptive input into the lateral aspect of the rings with gentle vertical decompression of the rings, or sink deep into the segmental multifidus muscle posteriorly next to the spinous process and provide a cranial pressure. Try different *verbal cues or images,* and assess the response of the thoracic rings to the cues:

- "Imagine a hook attaching to your vertebra and a string gently lifting the vertebra 1 mm off the rest of the spine."
- "Think of the sides of the rings floating up and apart—space between the rings right where you feel my fingers."
- "Keep the sides of the body long, like you are opening space between the slinky of your rib cage from my fingers."
- "Imagine balloons inflating in your armpits to float your shoulder girdle."
- "Imagine space opening between the back of your rings and your shoulder blades."

The clinician palpates the driving rings and monitors the response to different cues. The key indicator that there is a more optimal recruitment pattern between the deep and superficial muscles around the thoracic ring(s) is that the thoracic rings of interest correct and stack with the cue without bracing or superficial muscle recruitment, and without breath holding.

Patient Instructions. The patient is usually unsure of "doing anything," so his or her attention is instead focused on the change in ease of task performance during a simple task such as a SAL or squat. The patient performs the task with no cue and then with the cue and notes the change in the lightness or ease of movement, especially at initiation of the movement. (If the task effort has not improved, then the patient finesses his or her cue). This provides feedback that the cue is being effective, and the task is called a "Cue Check." The goal is to become proficient at using the cue to stack the rings as a base for exercise progressions. The patient is advised to practice 10 to 30 repetitions of this "ring stack" cue and to try to sustain the cue for multiple breaths with each repetition (up to 10 seconds). A minimum of two sessions of practice a day are advised in order to consolidate the skill in 7 to 14 days.

Phase 2: Control of Neutral Thoracic Ring Stacking across Multiple Tasks

As the patient moves from phase 1 to phase 2 of the treatment process, together, the manual release of vectors, supportive taping, education, and home exercise practice for better thoracic ring control create positive change in both symptoms and function. However, progression of the exercise program is essential to ensure sufficient capacity for thoracic ring control and loading across multiple tasks.

If dysfunction of the thoracic rings has been present for any significant period of time, alterations in strength and synergies of muscles between the driving thoracic rings and connected regions will be present. For example, if the upper thoracic rings have functioned in left translation/right rotation, muscles on both sides of the shoulder girdle will have adapted. As old nonoptimal patterns are removed, weakness in specific shoulder girdle muscles will become evident and need to be addressed. Exercises that train maintenance of thoracic ring control with shoulder girdle dissociation, both in open- and closed-chain progressions, provide an intermediate step to more complex movements. These types of building block movements are characteristic of phase 2 treatment progression.

Furthermore, the clinician needs to be mindful that the changes being made to thoracic ring alignment and control change loading throughout the kinetic chain, and many other structures are being loaded in a new way. These structures require a graded training program for positive adaptation to occur. Consider, for example, the loads through the Achilles tendon pre– and post–thoracic ring treatment in the scenario in Figure 11-5, where medial-lateral forces through the lower limb are significantly altered by changes in the thorax. Therefore, an understanding of the connections between thoracic ring function and the rest of the body inform the clinician's advice to patients about how to progress training loads and return to activities.

In phase 2, the focus is on training control of neutral thoracic ring alignment with upper and lower extremity dissociation and perturbation patterns, progressing from simple to complex movement patterns and from sagittal plane movements to movements outside the sagittal plane. For thoracic ring drivers, lateral perturbation forces will create the greatest challenge to rotational control. As patients progress through phase 2, there should be increasing variability in movement patterns and challenges to thoracic ring control to include all categories of exercises (see Table 11-2 and Figures 11-18, 11-19, 11-20, 11-22, and 11-24). Timing and speed of progression to phase 3 levels of exercise may vary for different categories of exercise (e.g., open kinetic chain versus closed kinetic chain), but the aim is to progress all categories to more three-dimensional, whole body movement patterns that require thoracic ring control during trunk rotation patterns relative to other regions (Figure 11-25). Several examples are provided in Table 11-2.

Principles for Phase 2 Exercise Prescription.

- Focus is on inter-regional control and establishing ability to control stacked thoracic rings (in neutral) during movements that require dissociation from other regions.
- Initially, the clinician decides whether the patient can perform higher repetitions with upper or lower extremity dissociation challenges (e.g., squat versus bilateral arm elevation in supine) and trains these patterns separately to build endurance in thoracic ring control and new superficial muscle movement patterns.
- Establish "*self-check*" movements. These are simple movements that the patient can perform to check the current status of their driver. The self-check task provides the patient with a way to self-evaluate the impact of any exercise or activity on their driver, as well as determine when he or she needs to do self-release of vectors on his or her driver. A reduction in ease of motion or range of motion of the self-check movement indicates a return of nonoptimal strategies and related vectors on the driving thoracic rings. Self-checks are any movement or task that the patient can feel a difference pre– and post–thoracic ring release and are used throughout phase 2 and phase 3 whenever new, more challenging exercises are added. Self-check tasks must be sensitive to changes in the status of the driver and this change must be detectable by the patient. Some options include the following:
  - Head rotation (in cases when the thoracic rings are the driver for neck function)
  - Forward arm reach with shoulder protraction (note ease of scapular glide and feel for "sticky shoulder blade")
  - Trunk rotation (with or without a deep breath at end range)
  - Right versus left SAL
- Once the first phase 2 exercise progression is trained to the point where the patient finds it easy

Figure 11-24 Examples of phase 2 exercises: training control of neutral alignment of the thoracic rings. **A**, Unweighted triceps extensions are a very early phase 2 exercise to train dissociation of the shoulder girdle with neutral thoracic ring stacking. The clinician monitors control of the driving ring(s) and provides sensory input, cues and partial corrections to facilitate optimal control during the exercise. **B**, The patient is self-palpating and cueing her thoracic ring control while balancing on a rocker board set to create sagittal plane challenges. This can be progressed to performing squats on the rocker board. **C**, Swiss ball roll-outs on the wall are an example of an intermediate phase 2 exercise for inter-regional control between the thoracic rings and the shoulder girdle in a closed-chain loading. The rings are kept stacked while the shoulders are flexed and extended to roll the ball up and down the wall (*double arrow*). This exercise prevents scapular muscle bracing as closed-chain loads are added. (Copyright LJ Lee Physiotherapist Corp.)

to perform 3 sets of 15 repetitions with good thoracic ring control, this exercise is a likely candidate to become the first "reset" exercise that will be used during the next progressions. A *reset exercise* is an exercise in which the patient demonstrates the ability to use the new, more optimal neuromuscular strategy for control of the driver, with ease and with a high number of repetitions. The active use of the new strategy creates an automatic release of nonoptimal vectors. Reset exercises are performed interspersed with other exercises when new progressions are added to the exercise program as the patient learns to implement the new strategy for ring control in the new exercises. If there is a negative change to the self-check after performing a new exercise, the patient can perform the reset exercise to release the nonoptimal vectors or strategies that have returned during the preceding exercise. After a reset exercise is performed, the clinician will find the thoracic rings more stacked and fewer nonoptimal vectors on ring vector analysis, and the patient will feel a positive effect on the self-check.

Figure 11-25 "Bow and arrow" is an example of a phase 3 exercise because it requires optimal control of rotation through the thoracic rings and the shoulder girdle with dissociation of the shoulder girdle from the thoracic rings. Patients may progress from phase 2 to phase 3 exercises at different rates for the different categories. For example, open kinetic chain shoulder girdle–thoracic ring exercises can commonly be progressed faster than closed kinetic chain exercises. Therefore this bow and arrow exercise is often added before the equivalent phase 3 closed-chain exercise is added. Many patients find the bow and arrow exercise a good reset exercise when in later stages of rehabilitation and progressing to higher loads in other exercises. (Copyright LJ Lee Physiotherapist Corp.)

Reset Exercise Criteria

- Any exercise where the patient demonstrates the ability to use the new, optimal strategies for ring control with ease and minimal concentration.
- Patient must be able to perform high repetitions with optimal strategy (3 sets of 10-15 repetitions).
- If self-check movement becomes restricted, performing one set of 10 repetitions of the reset exercise decreases nonoptimal vectors on the thoracic rings and improves the ease and range of motion of the self-check movement.

Reset exercises create an automatic release of vectors because the new, more optimal strategy for thoracic ring control is being used. They empower patients to self-release, self-monitor, and explore exercise progressions with confidence. Reset exercises should be progressed in complexity as the patient progresses through phases 2 and 3 (i.e., as the patient masters using the optimal strategy for thoracic ring control in more challenging exercises, those exercises become options to be used as reset exercises).

- A variety of Phase 2 exercise progression options are listed in Table 11-2.
- Unstable surfaces can be used to progress any exercise and "thoracic spring" category of exercises should be added in phase 2.
- Manual release techniques are progressed from static positions to *dynamic ring vector analysis and release*, where the ring stack and breathe technique is performed in the midst of training exercises to release through relevant ranges and integrate release and training simultaneously (see Figure 11-17, C).
- The clinician can provide partial ring corrections during movement to train more optimal superficial muscle patterning/recruitment, which will conversely support better segmental ring control.
- Continue to support with taping.

Phase 3: Control Thoracic Ring Stacking and Movement Through Rotation and Side Bending Range of Motion; Under High Compression Loads; In Multiplanar Perturbation Challenges

Phase 3 exercise progressions include any movement or task that requires control of intraring and inter-ring motion during trunk rotation or side bending range of motion (moving out of neutral). Phase 3 also includes closed chain tasks through the upper extremity that require dissociation of the shoulder girdle in a rotation movement (e.g. rotation of the trunk away from a fixed arm). Higher loads, especially vertical compression loads with overhead weight (such as overhead squats) are also a Phase 3 exercise. For inversion exercises, handstands and handstand push-ups are considered Phase 3 exercises. Principles for Phase 3 exercise progression include:

- Use multijoint, multiplanar movements that challenge thoracic ring control during rotational movements between regions (i.e., inter-regional control of rotation).
- Add lateral challenges to postural equilibrium and thoracic spring exercises.
- Add more complex whole body movement patterns and training specific to the meaningful task or sport activity.
- Continue to use dynamic ring vector analysis and release and taping, and progress reset exercises to more complex movement patterns in which the patient can still maintain optimal control of the driving thoracic rings.

OUTCOME MEASURES AND THE THORACIC RING APPROACH

Because dysfunction of the thoracic rings can be the underlying driver for a diverse range of symptoms and problems, the choice of outcome measures is based on what tools are available and shown to be best suited to measure change in the meaningful complaint and impairment. For example, when treating a patient with thoracic driven neck pain the Neck Disability Index (NDI)[72] can be used. When treating a patient with thoracic driven adductor tendinopathy, adductor squeeze pressure measures with a blood pressure cuff (mm Hg) can track change. For all

patients, a meaningful measure is provided by the Patient-Specific Functional Scale (PSFS),[73] whereby the patient ranks his or her ability to perform the desired meaningful task on a scale of 0 to 10 (0 = no ability to perform the meaningful task; 10 = full return to meaningful task/activity).

SUMMARY

Shifting from the paradigm that the thorax is stiff and requires mobilization to one where the thorax is flexible and requires optimal neuromuscular control provides greater insight into why the thorax can drive distal problems. This paradigm shift moves away from conceptualizing the thorax as a static, stiff box to being a dynamic stack of 10 rings, much like a Slinky or a shock-absorbing spring. When there is loss of optimal sequencing, force modulation, and synergy between the muscles around the thoracic ring; between the 10 thoracic rings; and between the rings and other regions of the body, there are many possible consequences throughout the whole body.

The Thoracic Ring Approach[17,18] incorporates current research on the thorax and provides innovative clinical assessment and treatment skills for the thorax, as well as a clinical reasoning framework that considers the multiple connections between the thorax and other regions of the body. Patients present with nonoptimal strategies for their meaningful task that are linked to nonoptimal experiences of their body. In thorax-driven cases, treating the thoracic ring(s) in the context of a biopsychosocial model that recognizes both intrinsic and extrinsic influences on the patient provides the pathway to change these nonoptimal strategies and create a positive experience of movement, reconceptualize pain, and support optimal strategies for function and performance for the whole person.

CHAPTER 12

Low Back Pain
Disability and Diagnostic Issues

MARK D. BISHOP, TREVOR A. LENTZ, STEVEN Z. GEORGE

INTRODUCTION

This chapter presents a current and practical approach to the diagnosis of low back pain (LBP). It discusses the etiology, epidemiology, course, and societal impact of LBP so as to give the clinician a context for understanding the importance of effective LBP management. The chapter also presents a model for management of LBP that emphasizes a psychologically informed classification approach. This approach involves the identification of red flags, screening for yellow flags, as well as specific subgroups of patients with LBP.

RISK AND ETIOLOGY OF INCIDENT LOW BACK PAIN

Definitive causes of LBP represent a "holy grail" for clinicians and researchers working in spine care. Evidence indicates that identifiable causes exist for specific lumbar conditions. Most notable is the line of research involving intervertebral disc degeneration. However, evidence also suggests that single, definite causes of clinical LBP remain elusive. This point was illustrated in a meta-analysis investigating incident LBP rates and risk factors associated with these rates.[1] The literature search in this meta-analysis was limited to 41 prospective studies that investigated reports of first-time LBP or LBP after a pain-free state. Results were similar for occupational or community-based samples and indicated that the pooled incident rate was approximately 25%. There was wide variation in the physical and psychosocial factors that were predictive of incident LBP but little consistency in these predictors. In fact, the only consistent finding was that a prior episode of LBP was predictive of LBP after a pain-free state.

In an attempt to provide additional guidance on causes and risk factors for LBP in this chapter, the authors have limited their narrative review to factors that have a theoretically plausible link to the development of LBP. Furthermore, the authors have emphasized results from two commonly implemented study designs that are used to investigate causes of LBP: epidemiological and monozygotic twin studies. In epidemiological studies,[2] cause can be inferred if the proposed causative factor meets all five criteria presented in Table 12-1. If the proposed causative factor does not meet all five criteria, it is not likely to cause LBP.

Monozygotic twin studies can also be used to infer causes of LBP because they control for potential confounding factors by matching participants on gender, age, genotype, and childhood environments.[3] Using this methodology, groups of twins who have discordance on the factor of interest are recruited and statistically compared for differences in the prevalence of LBP. For example, in this study design, LBP prevalence would be compared in monozygotic twins who differed in smoking status to determine whether smoking was a likely cause of LBP.[4]

Genetics

When genetic causes of LBP are considered, research has focused on allele (i.e., certain inherited characteristics) variations that adversely affect the quality of the intervertebral discs. A direct pathway involves polymorphisms that affect intervertebral disc composition, resulting in an increased probability of disc degeneration. Polymorphisms in the collagen IX,[5,6] aggrecan,[7] vitamin D receptor,[8,9] and matrix metalloproteinase-3[10] genes all have been associated with the development of intervertebral disc degeneration in humans. For example, one case-control study found that a specific variation in one of three collagen IX genes was present in 12.2% of patients with intervertebral disc degeneration but in only 4.7% of control patients. This difference was statistically significant ($p<0.001$) and suggested that a polymorphism in one of the collagen IX genes increased the risk of disc degeneration by approximately 3 times.[6] Another study demonstrated that patients with a specific polymorphism in the vitamin D receptor gene were more likely to experience annular tears.[8]

TABLE **12-1**

Determining the Cause of Low Back Pain from Epidemiological Studies

Criteria	Definition
Theoretically plausible	The factor of interest has a reasonable biological, anatomical, biomechanical, or physiological causal link with low back pain
Significant and meaningful association	The factor of interest has a consistent, statistically significant, and strong association (i.e., odds or relative risk ratios greater than 2) with low back pain as reported across several studies
Monotonic dose-response relationship	Low back pain increases in prevalence as the factor of interest increases in magnitude
Temporality	The factor of interest is present before the onset of low back pain
Reversibility	Low back pain decreases in prevalence when the factor of interest is stopped or is no longer present

Data from Leboeuf-Yde C: Body weight and low back pain: a systematic literature review of 56 journal articles reporting on 65 epidemiologic studies, *Spine* 25:226-237, 2000.

An indirect pathway for a genetic cause of LBP involves polymorphisms that adversely affect the inflammatory cascade by creating excessive amounts of proinflammatory cytokines (i.e., interleukin-1, interleukin-6, interleukin-8, and tumor necrosis factor-α), and/or creating limited amounts of cytokines that mediate the inflammatory response (i.e., interleukin receptor antagonists). Proinflammatory cytokines are produced when intervertebral discs are damaged,[11,12] and these substances can irritate nerve roots without concurrent mechanical compression.[13,14] Therefore it has been hypothesized that polymorphisms in genes that produce proinflammatory or inflammation-mediating cytokines have the potential to cause intervertebral disc degeneration, LBP, and/or sciatica.[15–17] Research supports this hypothesis because a cluster polymorphism in the interleukin-1 gene locus has been associated with increased odds of disc degeneration.[16] Specifically, patients who were heterozygous (odds ratio [OR], 2.2; 95% confidence interval [CI], 1.1 to 4.5) or homozygous (OR, 3.5; 95% CI, 1.0 to 11.9) for the interleukin-1αT^{889} allele were more likely to have a specific sign of degeneration (i.e., disc bulge) when compared with those homozygous for the interleukin-1αC^{889} allele.[16] Monozygotic twin studies corroborate these findings by investigating the broad role that heredity plays, without investigating the effect of specific genes. It has been estimated that heredity for lumbar disc degeneration is approximately 74% (95% CI, 64% to 81%).[18] In a study by Battie et al.,[19] heredity explained the largest amount of variance in disc degeneration in a multivariate model also containing age and physical loading. When predicting variance in disc degeneration from monozygotic twins at levels T12 to L4, the addition of physical loading explained 7% of the variance, age explained 9% of the variance, and familial aggregation explained 61%, and a similar pattern was noticed for levels L4 to S1.[19] A systematic review of studies of LBP based on twin studies concluded that these effects of genetics were higher for chronic LBP compared with acute LBP.[20]

Collectively the studies suggest genetic factors play an important role in the development of lumbar disc degeneration. However, the clinician must interpret these studies with caution because the presence of lumbar disc degeneration does not automatically preclude clinical presentation of LBP.[3] In fact, a monozygotic twin study published in 1989 suggested that the overall genetic influence on clinical LBP may be low.[21] In this study, the heredity estimates for LBP were low: 20.8% for sciatica and 10.6% for hospitalizations due to disc herniation.[21] Studies linking specific genetic factors to LBP have recently been reported in the literature, and cluster polymorphisms in the aforementioned interleukin-1 gene locus were associated with increased prevalence of LBP in the past year, increased number of days experiencing LBP, and increased pain intensity with LBP.[17] Another study involving a single polymorphism of the interleukin-6 gene locus demonstrated that a specific genotype was more likely to be associated with sciatica (OR, 5.4; 95% CI, 1.5 to 19.2).[15] These studies demonstrate a promising start on confirming a genetic link to clinical presentation of LBP, but these results should be viewed with caution because they conflict with what was reported in the better controlled twin study[21] and they involved small sample sizes with imprecise estimates of the influence genetic factors had on LBP.

Genetic factors seem to play an important role in the development of disc degeneration, but their role in the cause of clinical LBP is not as clear (Table 12-2). This is an area of current interest in the scientific literature, and there are likely to be many advances made in the next few years. The clinician should realize that genetic factors do not appear to play a purely Mendelian role in the development of LBP. In fact, there is already some evidence in the literature that indicates how complex the relationship may be between genetic factors, nongenetic factors, and clinical LBP. A monozygotic twin study modeled the influence of genes and the environment to predict what was the strongest component in the development of LBP.[22] The results suggested that shared environment was the

TABLE 12-2

Summary of Possible Causative Factors in Low Back Pain

Reversibility	?	N	N	N	N	N

?, Preliminary or inconsistent evidence supporting this factor; *N*, Consistent evidence against this factor; Y, Consistent evidence supporting this factor.

strongest component until age 15, and after 15, the effect of non-shared environment increased, as did nonadditive genetic effects. The authors of this study estimated the age-adjusted heredity for LBP to be 44% (95% CI, 37% to 50%) for males and 40% (95% CI, 34% to 46%) for females and concluded, "As people grow older, the effect of the non-shared environment increases and non-additive genetic effects become more evident, indicating an increasing degree of genetic interaction as age increases."[22] Another study demonstrated that a polymorphism in the collagen IX gene was more likely to be associated with lumbar disc degeneration for obese subjects.[23] Clearly, more research is needed to elucidate the relationships between genetic factors, nongenetic factors, and their role in the development of LBP.

Physical Loading

In the peer-reviewed literature, relations between physical loading factors, intervertebral disc degeneration, and LBP have been extensively investigated. Common examples of physical loading factors that have been studied include materials handling, postural loading, vehicular vibration, and type and/or amount of exercise. The common way these factors are theorized to cause LBP is that excessive or repeated loads cause macro or micro tissue damage, respectively, to spinal structures. This tissue damage then accelerates degenerative changes to spinal structures, eventually causing LBP. For example, basic studies have suggested that intervertebral disc degeneration results from increased intradiscal pressure and/or ligamentous creep following physical loading.[24–28]

The clinical evidence presented on physical loading factors and lumbar disc degeneration is paradoxical because some studies have demonstrated a positive association between the two factors[29–33] and other studies have not.[34–36] In these studies, many potential confounding factors were not adequately controlled, which limits their comparison and interpretability. As a result, this review is focused on studies of monozygotic twins that differed in amounts of physical loading. In a study of monozygotic twins that differed in occupational and leisure time activities, Battie et al.[19] found that physical loading explained only small amounts of variance in disc degeneration: 7% (occupational physical loading) and 2% (leisure time physical loading) for the upper and lower lumbar spine, respectively. In other monozygotic twin studies, there was no difference in lumbar disc degeneration for twins who differed on resistance or endurance training.[32] However, it should be noted that the same study did find evidence for increased disc degeneration in the lower thoracic (T6 to T12) spine for twins participating in resistance training.[32] Twins who differed in whole-body vibration through lifetime exposure to motorized vehicles did not have measurable differences in lumbar disc degeneration.[29] Therefore it appears that physical loading has a minimal effect on lumbar disc degeneration when these better controlled clinical studies are considered.[3]

In contrast to the association for disc degeneration, the evidence presented on physical loading factors and the clinical presentation of LBP suggests a positive association between the two.[37–43] However, it is not clear if this is a causal relationship. For example, a study in a machinery manufacturing plant compared LBP prevalence between 69 workers involved with manual handling and 51 involved in machinery operation.[43] The workers involved with manual handling were more likely to have experienced LBP in the past year (63.8% versus 37.3%, $p<0.01$).[43] However, it is not possible to determine if the jobs caused the differences in the LBP because the study was cross sectional and lacked the necessary temporal requirement for inferring cause. Other examples in the literature that meet the temporal requirement for causality appear to have inconsistent results. A 3-year study of LBP incidence and prevalence in a cohort of 288 scaffolders found that none of the physical loading factors (i.e., high manual handling of materials, high strenuous arm movements, and high awkward back postures) were associated with onset of LBP.[38] In contrast, a study found policemen wearing body armor (weighing approximately 8.5 kg [18.7 lb]) were more likely to have LBP when compared with those not wearing body armor.[37] A likely reason for the inconsistency in the literature is that these studies often did not adequately control for confounding factors with the potential to influence associations between physical factors and LBP. Another likely reason for the inconsistency is that many different occupations have been studied, and standard definitions for job demands are not universally applied. Therefore it appears that more

rigorous studies are necessary before it can be determined if physical factors definitively cause LBP (see Table 12-2) or if the causality of physical factors is occupation specific.

Smoking

Smoking has been hypothesized to be a causative factor in LBP, and one theory suggests that smoking adversely affects the blood supply to the lumbar spine (i.e., abdominal aorta, lumbar artery, and middle sacral artery) through functional vasoconstriction (immediate effect) and cardiovascular disease (long-term effect).[44,45] It has been suggested that either of these mechanisms could cause LBP. For example, functional vasoconstriction could cause LBP through ischemia, and cardiovascular disease could cause LBP by limiting the blood supply to lumbar structures, accelerating degeneration of the lumbar intervertebral disc and/or spinal structures. The importance of an oxygen gradient for the intervertebral disc was confirmed in a statistical model,[46] and an acute smoking test has been shown to adversely affect the diffusion of nutrients into the disc in an animal model.[47] Another way smoking has been linked to lumbar disc degeneration is through nicotine exposure. In basic studies, direct nicotine exposure to intervertebral discs caused morphological changes (i.e., disruptions in cell proliferation and architecture) that were indicative of early degenerative changes.[48,49]

Support for a link between the effects of smoking, disc degeneration, and LBP is consistently found in smaller-scale studies ($n<200$) involving postmortem examinations of patients.[50–52] In one study, atherosclerosis of the abdominal aorta and stenosis of the ostia of the lumbar and middle sacral arteries were significantly associated with lumbar disc degeneration, which was independent of the age of the subject.[51] In addition, lumbar and middle sacral arteries were significantly more likely to be missing or occluded in patients who had reported a history of low back symptoms during their lifetime.[52] Occluded lumbar and middle sacral arteries were more common in those having had a history of LBP that lasted 3 months or more, with an OR of 8.5 (95% CI, 2.9 to 24.0), adjusted for age and sex.[50]

Support for a link between effects of smoking, disc degeneration, and LBP can also be found in population-based studies. For example, a prospective cohort of 606 subjects was followed, and those who developed calcifications in the posterior wall of the abdominal aorta were twice as likely to develop intervertebral disc degeneration (OR, 2.0; 95% CI, 1.2 to 3.5).[52] In the same study, subjects with grade 3 (severe) posterior aortic calcification were more likely to report LBP during adult life (OR, 1.6; 95% CI, 1.1 to 2.2).[53] In a different population-based study of 29,244 subjects, habitual smokers (defined as at least one cigarette/day) reported 57% prevalence of LBP in the past year, whereas only 40% of nonsmokers (defined as those that had never smoked) reported LBP in the past year (OR, 2.0; 95% CI, 1.9 to 2.1).[45] Habitual smoking was also associated with a longer duration of LBP, with an OR of 1.4 (95% CI, 1.3 to 1.6) for 1 to 7 days of LBP and increasing to an OR of 3.0 (95% CI, 2.8 to 3.3) for more than 30 days of LBP.[45]

However, support for a smoking link to LBP diminishes when studies of monozygotic twins are considered. Differences in LBP were either minimal or not observed when monozygotic twins who smoked and did not smoke were compared.[4,19,45] In one specific twin study, 53% of smokers reported LBP and 52% of the nonsmokers reported LBP, a difference that was not statistically significant.[45] Further evidence against smoking as a cause of LBP was demonstrated in this same study, which reported no clear dose-response association between smoking and LBP for number of cigarettes smoked or number of years smoked; smoking cessation was not associated with lower prevalence of LBP, and there were no differences in LBP for smokers based on body mass index (BMI).[45] Additional work in 2006 indicated that in a longitudinal cohort of twins discordant for back pain, there were only very weak, nonsignificant effects related to smoking.[54] A 1999 systematic literature review of 47 epidemiological studies had similar conclusions, finding statistically significant associations between LBP and smoking in only 51% of the studies, and rate ratios reported were generally below 2.0 (indication of a noncausal association).[44] In addition, the systematic literature review found no clear evidence of a dose-response association between smoking and LBP, and no true data supporting temporality or reversibility of smoking and LBP.[44] Thus there does not appear to be substantive evidence to support smoking as a definitive cause of LBP (see Table 12-2).

Obesity

People who are obese do have more LBP. For example, the results of a meta-analysis that pooled the results of 35 studies indicated that compared with people with normal BMI, overweight and obese people had an increased prevalence of LBP in the past 12 months (OR, 1.3; 95% CI, 1.1 to 1.5), seeking care for LBP (OR, 1.6; 95% CI, 1.5 to 1.7), and chronic LBP (OR, 1.4; 95% CI, 1.3 to 1.6).[55] However, the studies included in that particular analysis were cross sectional and as such were unable to identify obesity as a cause of LBP. When cohort studies were analyzed, there was a small increase in the incidence of LBP in the past 12 months (OR, 1.5; 95% CI, 1.2 to 1.9).[55] Obesity has been hypothesized to be a cause of LBP by increasing the mechanical demands (i.e., via compressive or shear forces) on lumbar anatomy.[2,56] Obesity is also hypothesized to be an indirect cause of LBP because it may represent a proxy measure for another more difficult to measure factor (i.e., lifestyle) that is actually the "true cause" of LBP (Figure 12-1).[2,56] There is evidence to suggest that biochemical and metabolic changes related to increased adiposity might also play a role.[57]

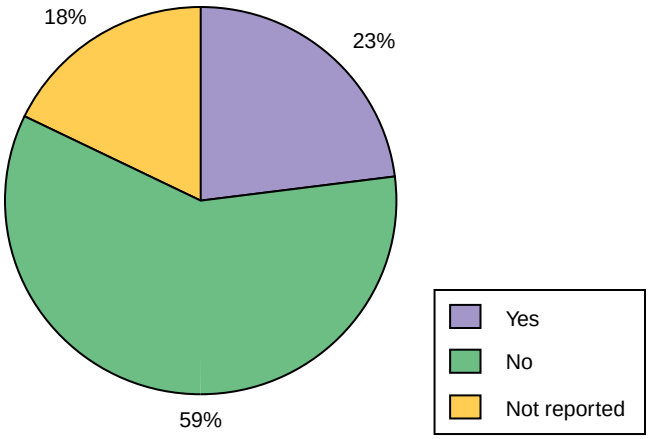

Figure 12-1 Statistically significant associations reported in the literature between body weight measures and variables related to low back pain. (Adapted from Leboeuf-Yde C: Body weight and low back pain: a systematic literature review of 56 journal articles reporting on 65 epidemiologic studies, *Spine* 25:226-237, 2000.)

Evidence against obesity as a cause of LBP is demonstrated in a study that investigated monozygotic twins who differed in BMI. In that study, there was no association between obesity and LBP in the past year with the OR for LBP being 0.9 (95% CI, 0.7 to 1.2) for an underweight category, 1.1 (95% CI, 0.8 to 1.5) for an overweight category, and 1.1 (95% CI, 0.5 to 2.0) for a heavy overweight category.[56] The lack of a consistent dose-response curve is another indication that obesity is not a cause of LBP. Positive monotonic dose-response curves (i.e., higher weight associated with more LBP) have been reported in the literature[58,59]; however, other shaped dose-response curves have also been reported.[56,60] Furthermore, there are no studies reported in the literature to suggest that temporality or reversibility exists with regard to obesity and LBP.[2] Collectively the peer-review literature does not appear to support obesity as a definitive cause of LBP (see Table 12-2).

Obesity does not appear to be causative of LBP (see Table 12-2), but there is some evidence that suggests obesity is associated with longer duration of LBP. In one study, LBP lasting greater than 30 days was consistently associated with BMI categories, for example, the OR for the underweight category was 0.7, the OR for the overweight category was 1.6, and the OR for the heavy overweight category was 1.7.[56] The authors did not report the 95% CI for the ORs in the text, but they did indicate that there were significant differences between the underweight and heavy overweight categories.[56] In a separate study in an occupational setting, obesity was a significant prognostic factor (OR, 1.68; 95% CI, 1.01 to 2.81) in a multivariate model for determining patients receiving compensation 3 months following a low back injury.[61] This evidence is preliminary, but it suggests although *obesity may not cause LBP*, it may have a *meaningful impact on how long LBP persists.*

Psychological and Psychosocial Factors

Psychological and/or psychosocial distress are thought to be causative of LBP through two pathways.[62] The first pathway involves the notion that psychological distress can lead to a situation in which the nervous system is "sensitized," making it more likely to receive a nonnoxious peripheral stimuli as painful. The second pathway relates to the notion that patients with psychological distress also have a tendency to somatize their symptoms.[63] Therefore certain patients who are distressed may express their psychological symptoms as LBP. Here, evidence is presented from prospective studies that considered whether psychological and/or psychosocial factors were associated with or causative of LBP.

In a U.K. study of 1638 adults who were not currently experiencing LBP, a validated measure of psychological distress (i.e., the General Health Questionnaire, which primarily focuses on symptoms of anxiety and depression) was predictive of new episodes of LBP during the next 12 months.[62] Specifically the OR for those with higher psychological distress (i.e., patients in upper third of General Health Questionnaire versus those in the lower third) was 1.8 (95% CI, 1.4 to 2.4).[62] This factor remained predictive even when potential confounders, such as poor physical health, history of LBP, employment status, age, sex, and social status, were considered.[62] A prospective study of 403 volunteers with no prior history of "serious" LBP demonstrated that psychological distress (i.e., a combination of somatic perception and depressive symptoms) was significantly predictive of a "serious" first-time episode of LBP, whereas only somatic perception was predictive of "any" first-time episode of LBP.[64]

In another U.K. study of 1412 workers not currently experiencing LBP, psychosocial factors related to the workplace were predictive of new episodes of LBP.[65] Patients who were slightly dissatisfied (OR, 1.7; 95% CI, 1.2 to 2.4) or severely dissatisfied (OR, 2.0; 95% CI, 1.2 to 3.3) with their job were more likely to experience an episode of LBP in the 12-month study period. Patients who perceived their income to be severely inadequate were also more likely (OR, 3.6; 95% CI, 1.8 to 7.2) to experience an episode of LBP during the 12-month study period.[65] The psychosocial factors remained predictive, even after controlling for the potential confounder of general psychological distress.[65] Further evidence suggesting psychological factors precede LBP can be found in an intriguing study that reported that discography

in asymptomatic patients with psychological distress resulted in reports of significant back pain for at least 1 year after injection, whereas subjects with normal psychometric test results reported no long-term back pain after discography.[66]

This smaller body of literature suggests that psychological and psychosocial factors are associated with new episodes of LBP.[62,64–66] The influence of these factors has been estimated to account for approximately 16% of new episodes of LBP in the general population[62] and up to 25% of new episodes in the working population.[65] However, these factors still cannot be seen as causative of LBP due to the fact that the number of prospective cohort reports remains relatively small, the magnitude of the reported associations is not consistently higher than 2.0, a clear monotonic dose-response curve has not been reported, and studies of reversibility have not been reported (see Table 12-2).

Therefore, psychological and psychosocial factors may not cause LBP, but like obesity, they do appear to have a meaningful effect on the duration of LBP. Several prospective studies have documented that psychological and/or psychosocial distress during acute LBP episodes significantly increased the probability of experiencing chronic LBP.[67,68] The OR for high levels of psychological distress predicting chronic LBP was 3.3 (95% CI, 1.5 to 7.2) in a group of 180 patients followed for a year in the United Kingdom.[68] The identification of psychological and/or psychosocial distress factors (i.e., "yellow flags") is an *important part of the differential diagnosis of LBP because of their strong link to development of chronic LBP*. A specific strategy for identifying specific psychological factors will be discussed later in this chapter.

Alcohol

Alcohol has been hypothesized to contribute to LBP by a direct route, involving uncoordinated movements that damage spinal structures, or by indirect routes, involving the development of co-morbidities that cause LBP.[69] Alcohol has not been thoroughly investigated as a cause of LBP in the peer-reviewed literature. For example, a systematic review identified only nine potential studies that focused on alcohol and LBP, and none of them were prospective in nature.[69] When these studies were reviewed collectively, none reported statistically significant associations between increased alcohol consumption and LBP.[69] For example, one study found similar LBP rates between moderate (OR, 0.88; 95% CI, 0.79 to 0.99) and excessive (OR, 0.72; 95% CI, 0.62 to 0.85) alcohol consumption.[59] Because of the limited number of reports and concerns with the methodology of the studies that were reported in the literature, the author of the systematic review concluded that alcohol did not appear to be a cause of LBP (see Table 12-2).[69]

EPIDEMIOLOGY OF LOW BACK PAIN

Expert opinion has likened the frequency of LBP experienced by modern society to an "epidemic,"[70] and reports in the literature consistently support this view. In the United States, data from the Centers for Disease Control and Prevention suggest that 28.1% of adults 18 and older reported LBP in the past 3 months, making this the most frequent pain complaint reported.[71] This trend is worldwide. A postal questionnaire study demonstrated that LBP was the most prevalent form of musculoskeletal pain reported by adults 25 years of age and older.[72] Specifically the point prevalence of LBP in the study was 26.9% (95% CI, 25.5 to 28.3), which was significantly higher than the point prevalence of the next two most common categories: shoulder pain at 20.9% (95% CI, 19.6 to 22.2) and neck pain at 20.6% (95% CI, 19.3 to 21.9).[72] Although it is clear that individuals in all strata of society commonly experience LBP, its prevalence does appear to vary based on factors such as sex, age, occupation, and socioeconomic status.

Women tend to have a higher prevalence of LBP than men, although the differences reported vary in magnitude.[72–76] For example, in the previously mentioned Dutch study, the point prevalence for women was 28.1% (95% CI, 26.1 to 30.1) and for men it was 25.6% (95% CI, 23.5 to 27.7). In a study involving Arabic subjects, the difference in overall prevalence was larger, reported as 56.1% for males and 73.8% in females. An increase in age is also associated with higher prevalence of LBP. In a Greek population-based study, the odds of experiencing any LBP in the past month were significantly higher for those aged 46 to 65 (OR, 1.82; 95% CI, 1.38 to 2.38) and 66+ (OR, 2.7; 95% CI, 1.85 to 3.93) years, when compared with those 45 years old and younger.[77] In a Danish study of 12- to 41-year-olds, the prevalence of LBP in the past year increased from 7% for 12-year-olds to 56% for 41-year-olds.[74] A separate epidemiological review suggests that this trend in increasing prevalence of LBP continues past 41 and peaks in the sixth decade of life.[78] After the sixth decade, the prevalence of LBP appears to level and eventually decline in the later decades (Figure 12-2).[72]

Occupational differences in LBP prevalence are demonstrated in a study of Chinese workers. A 50% annual prevalence rate of LBP (defined as lasting 24 hours or more) was reported, but this rate was significantly higher for garment workers than teachers (74% versus 40%).[39] In a study involving 1562 Canadian utility workers, lifetime and point prevalence of LBP were 60% and 11%, respectively.[41] In this same sample, LBP prevalence was significantly higher in workers who had jobs that were physically demanding or involved heavy lifting.[41] In a group of 288 scaffolders who were followed for 3 years, 60% experienced LBP in the past year and the prevalence was significantly associated with high material handling

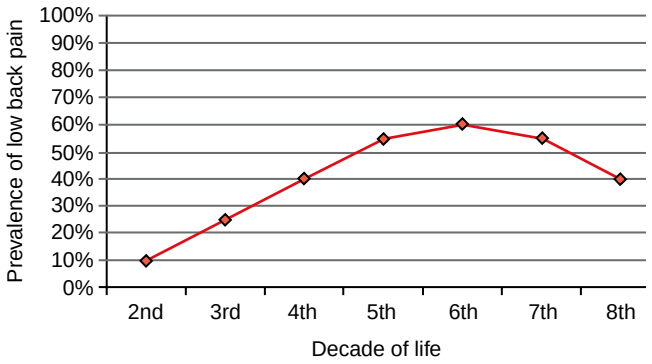

Figure 12-2 Qualitative composite of 1-year LBP prevalence through the second to eighth decades of life.[72,74,78]

or job demand.[38] It is interesting to note that although differences exist between different occupational groups, similar LBP prevalence rates have been reported between working and nonworking groups.[75] Results of a global study of occupational LBP in 187 countries indicated that the relative risk of LBP was highest for workers in agriculture, forestry, and fishing (OR, 3.7; 95% CI, 2.6, 5.3) compared with clerical workers.[79]

Specific socioeconomic factors appear to be associated with the prevalence of LBP. In the previously mentioned Greek study, being married resulted in an OR of 1.53 (95% CI, 1.15 to 2.03) for experiencing LBP in the past month,[77] and a study of Canadian utility workers found a similar association between LBP and marriage.[41] In addition, lower educational levels have been linked with higher prevalence of LBP,[72,73] and social classes involving unskilled occupations have been weakly linked with a higher prevalence of LBP.[65]

The differences in reported LBP prevalence rates for specific factors (i.e., sex and age) can be confusing to interpret. It is important for the clinician to realize that these prevalence estimates vary in a large part because of methodological differences between studies.[70] For example, it is common for epidemiological studies to differ on sampling methods, populations sampled, response rates, definitions of LBP, and measurement techniques. All of these factors have the potential to influence the prevalence estimate reported in a study. This fact is best demonstrated when systematic reviews of prevalence studies are attempted. One systematic review of LBP prevalence found only 30 of 56 identified studies were homogeneous and methodologically sound enough for pooling. Once pooled, the prevalence estimates continued to have wide intervals, for example, LBP point prevalence was estimated at 12% to 33%, 1-year prevalence was estimated at 22% to 65%, and lifetime LBP prevalence was estimated at 11% to 84%.[80] Although LBP clearly is a common experience, improving the precision of prevalence estimates is a goal of future epidemiological research.

Given its overall prevalence, it is not surprising that LBP is a common reason to seek health care. In a Finnish study, pain was the primary reason for visiting a physician in 40% of reviewed cases, and LBP was the most common source of pain.[81] In the United States, LBP is the second most common reason to visit a physician, behind the common cold.[82] Patients commonly seek health care from traditional medical providers, such as general practice (i.e., primary care) physicians, orthopedic physicians, and physical therapists.[82–84] LBP is also one of the most common reasons to seek health care from complementary and alternative medical (CAM) providers.[85] The 2007 National Health Interview Survey indicated that 38% of adults in the United States sought interventions from a CAM provider and that LBP was the most common disorder for which intervention was sought.[86]

The clinician should be aware that a patient with LBP could be using some form of CAM treatment during the episode of care. This issue is relevant because evidence suggests that only 38.5% of patients discussed their CAM treatment with their traditional medical provider and 46.0% used a CAM treatment for a principal medical condition without input from either type of provider.[85] The clinician managing the patient with LBP should determine what type of CAM treatments are currently being used because this will allow appropriate coordination of the patient's subsequent therapy.

Clinicians must also recognize that not all who experience LBP seek health care. In fact, several studies involving general practice and occupational settings reported that only 25% to 50% of individuals who experience LBP actually sought health care.[72,83,87] These studies found that high amounts of disability and pain were the primary differences between patients seeking health care and those not seeking health care.[72,83,87,88] Specifically women and men with high disability were more likely to seek health care for LBP compared with individuals of the same sex with low disability, with the ORs being 7.4 (95% CI, 5.0 to 11.0) and 4.9 (95% CI, 3.3 to 7.1), respectively.[88] Women and men with high pain intensity were also more likely to seek health care for LBP, compared with individuals of the same sex with low pain intensity, with the OR being 3.7 (95% CI, 2.2 to 6.0) and 1.7 (95% CI, 1.1 to 2.8), respectively.[88] Another study suggested that patients from unskilled, manual occupations (OR, 4.8; 95% CI, 2.0 to 11.5) were more likely to seek health care for LBP, as were those who perceived their income to be inadequate (OR, 3.6; 95% CI, 1.8 to 7.2).[65]

COURSE OF LOW BACK PAIN

The course of LBP has been described as consisting of acute, subacute, and chronic phases, with temporal definitions typically associated with each phase. Different operational definitions have been reported in the literature, but a commonly accepted definition for the acute phase is between 0 and 1 month since the episode of LBP, the subacute phase is between 2 and 3 months since episode

of LBP, and the chronic phase is greater than 3 months since episode of LBP. The prognosis of LBP appears to be favorable, predictable, and static when these temporal definitions are used (Figure 12-3, *A*). For example, up to 90% of patients with LBP are expected to be pain free or show dramatic improvement during the acute phase, and only approximately 10% of patients are expected to report LBP that continues into the chronic phase.

Because LBP is often recurrent in nature, exclusive use of temporal definitions to describe its course has been challenged in the literature.[89,90] The primary argument is that when LBP is recurrent, the time to improvement from a single episode does not accurately describe its outcome. This issue is perhaps best summarized by Von Korff et al.[90]: "*For example, a person experiencing recurrent episodes of back pain on half the days in a year might appear to have a favorable outcome of each episode, but an unfavorable outcome across episodes. For this reason, the outcome of a recurrent pain condition is more appropriately assessed by the total time with pain across episodes and the characteristic severity of those episodes than by the duration of a single episode*" (p. 855).

This is not purely an academic issue because the prognosis of LBP changes when the influence of recurrence is considered. Of patients with acute LBP who were followed for 1 year, 65% reported one or more additional episodes.[91] In that same study, 2 months was the median time to another episode of LBP and 60 days was the median time to experience LBP in the year. Other studies have reported lower, but still substantial, recurrence rates ranging from 20% to 35% (6 and 22 months)[92] to 45% (4 years). Von Korff[89] has suggested operational definitions to standardize the description of the course of LBP for clinicians and researchers (Table 12-3). Although these definitions have not been universally adopted, preliminary evidence exists to support their construct validity because patients classified with chronic LBP had higher pain scores and social disability and were more likely to use medication to treat LBP.[93]

When these other factors are considered, the prognosis for LBP becomes less favorable and more variable (Figure 12-3, *B*). At 1-year follow-up of primary care back patients, 69% of patients with recent onset (i.e., within the past 6 months) of LBP reported having pain in the last month.[90] Only 21% of these patients were pain free at 1 year, with 55% reporting low disability and pain intensity, 10% reporting low disability and high pain intensity, and 14% reporting high disability with varying amounts of pain intensity.[90] Similar trends were noted for the 82% of patients with prevalent (i.e., onset longer than the past 6 months) LBP that reported having pain in the last month.[90] At 1-year follow-up, only 12% were pain free, with 52% reporting low disability and pain intensity, 16% reporting low disability and high

TABLE **12-3**

Standard Definitions for Manifestations of Low Back Pain

Descriptor	Operational Definition for an Episode of Low Back Pain
Transient back pain	Present for no more than 90 consecutive days and does not recur over a 12-month period
Recurrent back pain	Present for fewer than half the days in a 12-month period and occurs in multiple episodes over the year
Chronic back pain	Present for at least half the days in a 12-month period in single or multiple episodes
Acute back pain	Recent and sudden in onset and does not meet the previously defined criteria for recurrent or chronic pain
First onset	First occurrence in the patient's lifetime
Flare-up	Distinct phase of pain (with definable beginning and end points) superimposed on a chronic or recurrent course; a period when the pain is markedly more severe than is usual for the patient

Data from Von Korff M: Studying the natural history of back pain, *Spine* 19:2041S-2046S, 1994.

pain intensity, and 20% reporting high disability with varying amounts of pain intensity.[90] These results are further supported by a systematic review that pooled results from 11 longitudinal studies of the course of LBP. The pooled estimates for the proportion of patients with ongoing pain were 80% at 1 month, 67% at 3 months, and 57% at 6 months, and 65% of patients continue to experience pain at 1 year.[94]

This line of research suggests that the clinician obtaining a history from a patient with LBP must ask the patient to describe the course of the back pain in more than just temporal terms associated with the most recent episode that led to the present episode of health care. Other pertinent historical factors include number of previous episodes, the severity of the present episode, the number of days with LBP in the past year, and the amount of interference with daily activities.[89,95]

Important Historical Questions Related to the Course of Low Back Pain[89,95]

- How long has the present episode of low back pain bothered you?
- How many previous episodes of low back pain have you experienced?
- How many days have you had low back pain in the past year?
- How severe is your present episode of low back pain?
- How much does low back pain interfere with your daily activities?

SOCIETAL IMPACT OF LOW BACK PAIN

Given that LBP is a common experience and can be chronic or recurrent in nature, it is not surprising that it is a significant cause of disability and cost to society, and this cost seems to be increasing exponentially over the past three decades.[70,96–99] In the general population, 53% of adults had experienced some disability from LBP during a 6-month period.[99] Chronic LBP substantially influences the capacity to work and has been associated with the inability to obtain or maintain employment[97] and to reduced productivity at work.[98]

LBP is included in a top 10 list for most costly physical ailments.[78] LBP related to occupational settings appears to have made an especially large impact on society. It has been estimated that at least 33% of all health care and indemnity costs under workers' compensation are accounted for by LBP.[100] The cost of lost work productivity due to the most common chronic pain conditions (including LBP, headache, arthritis, and an "other" category) has been estimated at $61.2 billion per year.[98] Of specific pain categories studied, chronic LBP accounted for the most lost productivity time (5.2 hours/wk).[98]

Other estimates of annual health care expenditure for chronic LBP are excessive, especially when compared with other chronic pain conditions. For example, the 1993 direct health care cost estimates were $1 billion dollars for headache[101] and $33 billion for LBP.[102] Indirect cost estimates demonstrated a similar discrepancy, with estimates exceeding $13 billion for headache[101] and $50 billion for LBP.[102] Interestingly the excessive costs associated with disability from LBP did not appear to be evenly distributed.[103] For example, Williams et al.[104] found that health care costs were disproportionate, with 20% of the claimants disabled for 16 weeks or more accounting for 60% of the health care costs. Other authors have reported similar disproportionate patient-cost associations in LBP.[105–107] From 1997 to 2006, health care expenditures for the management of spine conditions increased from 82% to $85 billion.[108]

Therefore, the excessive and increasing societal cost of LBP does not appear to be due to an increase in the condition because a study that used consistent methodology showed similar prevalence rates over different time periods.[109] Instead, the increased cost seems to be associated with the way LBP has traditionally been managed.[70] Clinicians working in progressive environments must be aware that a priority of their treatment is the effective reduction of LBP for the minority of individuals who eventually experience chronic symptoms and accrue exorbitant health care costs.[110–115]

BIOPSYCHOSOCIAL MODEL OF LOW BACK PAIN

Currently there is very little evidence to support a single "magic bullet" cause of LBP (see Table 12-2). The conceptualization of LBP as a distinct and specific disease may be the most direct explanation for difficulty identifying causative factors of LBP.[113] Instead of a specific disease, LBP may be best conceptualized as an illness, one which is characterized and influenced by input from different factors across multiple domains.[113] This realization has led to the implementation of a comprehensive model that describes the development of LBP.

In 1987, Gordon Waddell first proposed a model that considered the simultaneous influence of physical, psychological, and social factors in the development of LBP.[113] The exact parameters of this "biopsychosocial" model have been modified over time, but it remains the currently accepted model of LBP for research and clinical practice (Figure 12-4). The advantage of using this model in clinical practice is that it accounts for all the previously described considerations relating to etiology, epidemiology, course, and societal impact of LBP. Quite simply, a biopsychosocial model regards LBP as an illness, which is a more accurate representation of the clinical presentation. In addition, a task force charged in part to develop diagnostic criteria for LBP by the National Institutes of Health reported that developing pathoanatomic diagnostic criteria for LBP was unfeasible at present.[116] Therefore a biopsychosocial model of LBP is this chapter's framework for discussing the management of LBP.

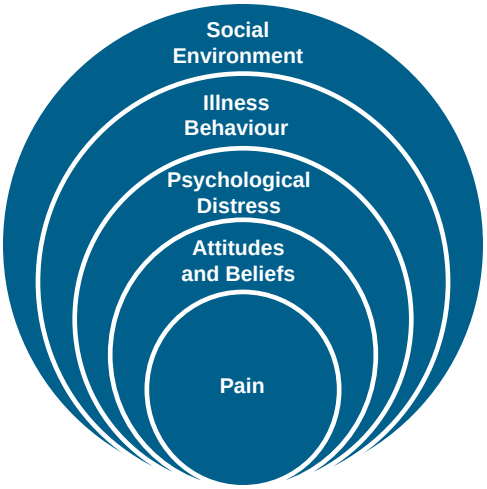

Figure 12-4 Biopsychosocial model of low back pain. (From Waddell G: 1987 Volvo Award in Clinical Sciences: a new clinical model for the treatment of low-back pain, *Spine*, 12:632-644, 1987.)

DIFFERENTIAL DIAGNOSIS OF LOW BACK PAIN

The tasks of the clinician are straightforward when a biopsychosocial model is used for differential diagnosis and classification of patients with LBP. The specific tasks are described in detail, after a brief review of anatomical causes of LBP and imaging of the lumbar spine.

POTENTIAL PAIN GENERATORS IN THE LUMBAR SPINE

Any innervated structure in the lumbar spine can cause symptoms of LBP and referred pain into the extremity or extremities. For example, Kuslich et al.[117] present data from 193 consecutive patients with back pain who were progressively anesthetized and the structures of the lumbar spine stimulated by either blunt mechanical force from a surgical tool or low-power cautery. Only stimulation of the posterior dura and nerve roots by mechanical or thermal stimuli gave patients the sensation of leg pain in this investigation (Table 12-4). In comparison, after Kellgren[118] injected the intraspinous ligaments with saline, subjects reported aching pain in the buttock and leg from a variety of segmental levels, implying that somatic musculoskeletal structures could also refer pain into the extremity (Figure 12-5).

Potential Generators of Low Back Pain[117–119]

- Muscles
- Ligaments
- Dura mater
- Nerve roots
- Zygapophyseal joints
- Annulus fibrosus
- Thoracolumbar fascia
- Vertebrae

TABLE **12-4**

Percentage of Patients Reporting Pain and Pain Location after Stimulation of Different Lumbar Tissues

Anatomical Structure	Number Tested	Percentage Reporting Pain (%)	Pain Location
Lumbar fascia	193	17	Back
Paravertebral muscle	193	41	Back
Supraspinous ligament	193	25	Back
Lamina	193	10	Back
Facet capsule	192	30	Back, buttock
Ligamentum flavum	167	0	—
Posterior dura	92	23	Buttock, leg
Compressed nerve root	167	99	Buttock, leg, foot
Normal nerve root	55	11	Buttock, leg
Central annulus	183	74	Back
Lateral annulus	144	71	Back
Nucleus	176	0	—
Vertebral end plate	109	61	Back

Data from Kuslich SD, Ulstrom CL, Michael CJ: The tissue origin of low back pain and sciatica: a report of pain response to tissue stimulation during operations on the lumbar spine using local anesthesia, *Orthop Clin North Am* 22:181-187, 1991.

The quality of pain reported by the patient may help to differentiate whether the source of the pain is related to a somatic musculoskeletal structure or if the pain is radicular in origin. *Radicular pain* is a sharp, shooting pain in the leg in a defined band less than 4 cm wide[120] either superficial or "deep in the leg,"[120,121] whereas *somatic pain* is poorly localized and reported as aching. However, it is unlikely that compression of the nerve root is the primary causative mechanism. Compression of nerve root tissue causes radiculopathy; that is, radiating paresthesia, numbness, weakness, or a combination of symptoms but not pain.[120] It is only when a previously damaged nerve root is compressed[117,120] that the characteristic pain is elicited. Consequently, a patient may not always present with radiculopathy *and* radicular pain.

Radicular Pain, Radiculopathy, and Somatic Pain

- *Radicular pain:* Sharp, shooting, superficial, or deep pain into the leg in a defined band less than 4 cm (1.6 inches) wide
- *Radiculopathy:* Radiating paresthesia, numbness in a dermatome, weakness (myotome), or a combination of these; however, the patient does not experience pain
- *Somatic pain:* Poorly localized, aching pain

Inflammation of the dural sleeve and nerve root is implicated in the genesis of the initial radicular symptoms. Although the source of the inflammation is not obvious,

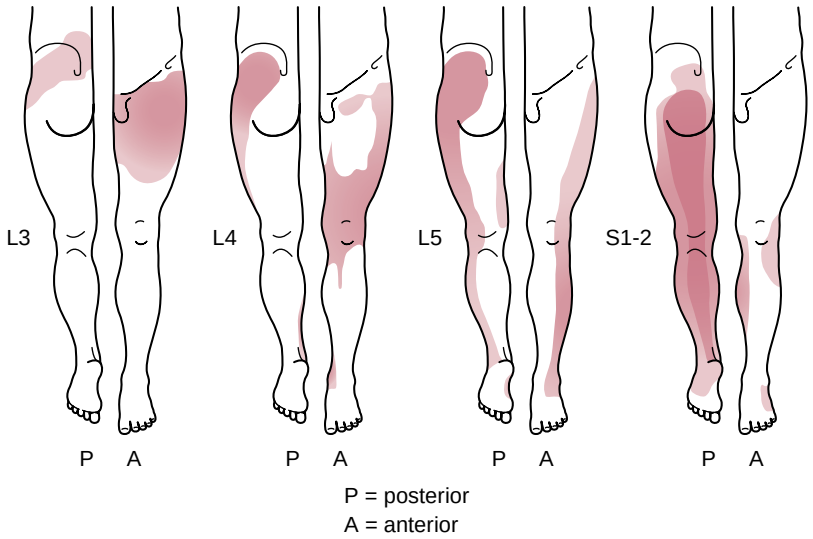

Figure 12-5 Distribution of pain from the interspinous ligament, which has been injected with saline. (From Kellgren J: On the distribution of pain arising from deep somatic structures with charts of the segmental areas, *Clin Sci* 4:35-46, 1939.)

exposure to nuclear material of the intervertebral disc may cause a chemical inflammatory response in the dural and nerve root tissue and eventual fibrosis of the perineural tissues.[120,122] Subsequent compression of the damaged neural tissue will generate radicular symptoms. For example, Kuslich et al.[117] demonstrated that mechanical deformation of perineural scar tissue evoked no pain response, but stimulation of the nerve root at the point of compression produced radicular symptoms.

In the absence of extrusion of nucleus pulposis material into the spinal canal, a precursor inflammatory response may result from traumatic compression.[123] Animal models also suggest that compression of the nerve root tissue eventually generates local edema and ischemia of the nerve root and ganglion.[124,125] Therefore any of the pathologies that cause prolonged nerve root compression may eventually result in damage to the nerve root or ganglion. After this damage occurs, further compression may then result in complaints of radicular pain.

SPECIFIC SOMATIC PAIN GENERATORS

Contractile Tissue

Available literature suggests that paraspinal muscles of patients with LBP are dysfunctional. Studies have demonstrated muscle atrophy,[126–128] reduced activity during trunk movements,[129,130] decreased muscle strength,[131,132] and increased trunk muscular fatigability[133,134] in patients with LBP. The studies that demonstrate decreased muscle performance associated with LBP support a model of muscle deficiency in lumbar dysfunction, rather than a muscle spasm model.[135] Atrophy of the paraspinal muscles has been documented in those patients with short duration[128] and chronic[126] LBP. The atrophy appears specific to multifidus muscle, suggesting a mechanism other than disuse to explain the atrophy noted.[135] Hides et al.[128] have suggested that reflex inhibition is a likely cause of atrophy in lumbar paraspinal muscles. Experimental support for this theoretical construct is offered in a porcine model in which rapid inhibition of the deep paraspinal muscles occurs after distention of the zygapophyseal joints by injection with saline solution.[136] However, this theory has been challenged given the lack of association between paraspinal muscle asymmetry with LBP severity, disability, or frequency of episodes.[137]

Characteristics of Paraspinal and Trunk Muscles in Patients with Low Back Pain

- Atrophy
- Reduced activity during trunk movements
- Decreased muscle strength
- Increased fatigability
- Change in percentage of fiber types

In addition to deep muscle atrophy, patients with LBP have a significantly higher proportion of type IIB (i.e., fast-twitch glycolytic) fibers than the slow-twitch type I fibers[134] in the posterior trunk muscles. Duration of LBP symptoms has been shown to be significantly associated with a higher proportion of type II fibers, such that the longer the duration of pain, the more glycolytic the paraspinal fiber composition.[134] This finding may provide some explanation for the increase in fatigability noted in patients with LBP. These muscular performance changes may contribute to LBP by decreasing the muscular support of the lumbar spine, placing increased stress on the noncontractile structures.

The disorders that affect predominantly the musculature of the lumbar spine include muscle strain injury,

spasm or guarding, and myofascial complaints, such as trigger points. Muscles of the lumbar spine have been demonstrated to act as primary sources of back and buttock pain in experiments using saline distention of a muscle[119] and mechanical stimulation.[117,118] However, consistent with studies of noncontractile tissues, the magnitude of muscle damage does not match well with ratings of pain intensity. In an experimental study using eccentric exercise to induce muscle damage, pain intensity had very weak, nonsignificant correlations with the area of muscle damage determined using magnetic resonance imaging (MRI).[138]

Evidence that increased muscle activity occurs in the muscles in response to pain has been shown in patients with temporomandibular dysfunction,[139] healthy subjects chewing gum,[140] and patients with cervical dysfunction.[141,142] Subjects with pain and a history of cervical soft-tissue injury have lower blood flow in the muscles on the painful side relative to the nonpainful side, when compared with control subjects.[143] The differences in blood flow were pronounced at low-level muscle contractions. The impaired circulation probably contributes to muscle pain by causing an accumulation of metabolites producing pain and a further disturbance of the circulation in a vicious circle.[144] Although this phenomenon has not been demonstrated in the lumbar spine, it is conceivable that similar increases in muscle activity and changes in circulation might occur.

Noncontractile Tissue

Kellgren[118,119] demonstrated that noncontractile tissue, such as fascia, ligaments, and the periostium, are viable sources of LBP. Research by Kuslich et al.[117] supports these early observations and provides additional insight into components of the intervertebral disc as direct sources of pain (see Table 12-4).

Discogenic Pain

Mechanical stimulation of the outer annulus fibrosis causes central back pain, not leg pain,[117,120] and the innervation of the outer annulus fibrosis has been well documented. Therefore the intervertebral disc should be considered a cause of back pain. In addition, changes in the intervertebral disc contribute to other conditions that subsequently result in somatic or radicular pain.

Only the outer third of the annulus is innervated. Torsional injury is thought to occur to the outer annulus fibrosis particularly when the torsion is coupled with lumbar flexion.[145,146] Bogduk[147] has suggested that this mechanism be considered similar to a ligamentous sprain injury because fibers of the outer annulus might be traumatized.

Alternatively, pain response from outer annulus fibrosis may be elicited with exposure of nociceptive endings in the annulus fibrosis to material from the nucleus pulposis or breakdown products from nuclear degradation. The specific mechanism of degeneration is not well understood but may be related to genetic factors (see 'Genetics' in the section "Risk and etiology of incident low back pain"). In vitro evidence suggests that changes in compressive stress on the disc (such as occurs with disruption of the annulus or minor vertebral body damage) within the nucleus will disrupt cellular metabolism throughout the disc, progressively deteriorating the matrix.[148] Radial fissures developing in the inner two thirds of the annulus will eventually reach the innervated outer third.[146,149,150] As the innervated outer third of the annulus becomes disrupted, comes in contact with nuclear material, or both, the patient will complain of backache but is not likely to have radicular pain or signs of radiculopathy because there is no prolapse or herniation of disc material.

Disc prolapse can occur gradually when discs are subjected to repetitive compression and flexion loading,[148] but radial fissuring in the annulus must precede disc prolapse.[151] Milette et al.[152] report that disc bulges and disc protrusions do not differ significantly in internal architecture, based on the findings of discography. A bulge in the disc that occurs as the annulus weakens may impinge on neural structures within the spinal canal. Eventually herniation of disc material will occur, that is, when radial fissures reach the periphery of the disc and nuclear material may be herniated into the spinal canal.[148,149] The chemical irritation of the nerve root or ganglion will lead to subsequent radicular pain. However, not only nuclear material is herniated. Lebkowski and Dzieciol[153] examined specimens of herniated disc material from 187 patients and reported that in 29% of the cases, the herniation was primarily annular material. This finding may explain the lack of radicular symptoms in some cases of disc herniation (i.e., the nerve root is predominantly exposed to annular not nuclear material).

Ligament and Fascia

Kuslich et al.[117] demonstrated that both the supraspinous and interspinous ligaments might be a source of central LBP, whereas Kellgren[118] reported back and leg pain in subjects in whom the interspinous ligament had been injected. However, the prevalence of specific sprain injury to the interspinous ligament is likely to be very low. The common tendon of the longissimus thoracis muscle[154,155] and the long dorsal sacroiliac ligament[156] are also ligamentous sources of pain, particularly pain to palpation around the posterior iliac spine. In addition, the thoracolumbar fascia might be a source of pain. Little data have been identified regarding diagnosis of ligamentous or fascial injury in the low back; however, one might speculate that sprain injuries to these structures would have a similar mechanism of injury in the trunk as in the extremities. Alternatively, pain might arise after prolonged stress on ligamentous tissue related to postural changes or movement impairments.[157]

Zygapophysial Joints (Facet Joint Syndrome)

The prevalence of zygapophysial involvement in the genesis of LBP may be as high as 25%.[158] The zygapophysial joints have been identified as a source of back and leg pain by generating pain in healthy subjects,[159] reproducing pain in patients,[117] and by relieving pain with injection in certain patients.[160]

El-Bohy et al.[161] demonstrated the potential for capsular sprain injury of the zygapophysial joint, and fractures, capsular tears, and damage to the articular cartilage have been documented on postmortem studies.[162] Degenerative arthritis of the zygaphophysial joints is another possible cause of pain. However, not all arthritis is painful because radiographic changes of osteoarthritis are equally common in patients with and without LBP.[163] Other theories regarding the genesis of lumbar pain from the zygapophysial joint include meniscoid entrapment,[164] synovial impingement,[160,164] and mechanical injury to the joint's capsule.[165] Unfortunately, there is no definitive way to identify the zygapophysial joint as the source of LBP and lower extremity pain from history or clinical findings.[160,166,167] For example, Marks[168] reported that pain radiating to the buttock or trochanteric region occurred mostly from the L4 and L5 levels and that groin pain was produced from L2 to L5, but no consistent pain pattern has been identified related to the joints. This work is supported by that of O'Neill et al., who also identified referral of pain from zygapophysial joints into the groin and anterior thigh.[169] Diagnosis of the zygapophysial joint as the source of LBP is based on controlled diagnostic blocks of the joint or its nerve supply.[160,166,167]

Vertebrae

The vertebral body is involved in several painful conditions, such as Paget's disease,[170] primary or secondary tumors,[170,171] and fracture. The posterior elements of the vertebrae can be affected similarly to the vertebral body; however, several lesions are peculiar to the posterior elements. Increased lumbar lordosis or hyperextension trauma may result in impact of the spinous process or lamina of articulating vertebrae. This may result in periostitis of the spinous process or lamina or inflammation of the interspinous ligament.

Spondylolysis is a defect of the pars articularis often related to fatigue fracture,[172] although there may be some predisposition to development of the condition related to weakness in the pars interarticularis.[173] The location of a pars defect is related to activities in which the patient is involved. For example, fast bowling in cricket is associated with unilateral defects, whereas soccer players develop more bilateral defects.[172] Likewise, the incidence of spondylolysis is related to activity. In gymnastics the incidence of a pars defect is 11% in females,[174] whereas the incidence in university-aged athletes playing American football may be as high as 15%.

The prevalence of spondylolysis in asymptomatic adult subjects ranges from 6%[175] to 9.7%.[176] Libson et al.[176] compared 938 asymptomatic individuals to 662 subjects with LBP and determined the overall incidence of spondylolysis to be equivalent (9.7%) for both groups. However, these authors did indicate that a bilateral defect is more likely to be associated with a complaint of pain. These data suggest that a pars defect itself may not be the source of pain. Rather the defect compromises the arthokinematics of intervertebral motion such that increased stress is placed on other structures of the posterior vertebral arch, such as the ligaments or paraspinal muscles.

Spondylolisthesis is anterior displacement of one vertebra over another.[177] Spondylolisthesis usually results from spondylolysis after the normal resistance to forward displacement of the vertebra is disrupted because of fracture or elongation of the pars interarticularis.[178] Narrowing of the spinal canal will occur if posterior elements also slide forward. Szyprt et al.[179] demonstrated that a pars defect was associated with a prevalence of disc degeneration greater than that seen in a normal aging population.

With enough anterior slippage, the central spinal canal and the structures within may become compromised. However, slips present in juvenile or adolescent patients may autofuse or ankylose once the patient reaches skeletal maturity and remain asymptomatic throughout life.[180] Frennered et al.[181] performed follow-up with juvenile patients with spondylolisthesis after a mean time of 7 years. Thirty percent of the patients had surgery after 3.7 years, whereas 83% of the nonoperatively treated patients were rated excellent or good. These authors were unable to predict progression of slip or need for future operative treatment from findings at the initial consultation.[181] Beutler et al.[182] followed juvenile patients who had lesions of the pars identified using radiography, for 45 years. Patients with unilateral defects never experienced slippage over the course of the study, with 30% of the defects healing. Of the patients with bilateral defects, 81% progressed to spondylolisthesis. Progression of spondylolisthesis was greatest in the first decade after identification (i.e., in the teens) with subsequent slowing with each subsequent decade. There was no association of slip progression and LBP.[182]

Other vertebral anomalies, such as transitional lumbar vertebrae (TLV) or spina bifida occulta (SBO), have been associated with increased severity of LBP,[183] but the overall evidence for such an association is equivocal.[184] In a series of 4000 individuals, Tini et al.[185] demonstrated no association between LBP and the presence of a TLV. Peterson et al.[186] found similar results—352 patients with LBP had no difference in self-report of pain or disability based on TLV status.

Other reports indicated that TLV increased nerve root symptoms, whereas SBO did not.[183] Patients with nerve root symptoms and a TLV have a greater incidence of disc prolapse than those without a TLV for the

vertebral level directly above the TLV.[187] In addition, spinal stenosis in the absence of spondylolisthesis is more likely to occur at the level above a TLV.[187] However, it is important to note that radiographic evidence of a vertebral anomaly does not necessarily indicate a greater likelihood of LBP.

LUMBAR SPINE IMAGING

The advent of stronger magnets used in MRI has resulted in finer resolution of subsequent image reconstructions of the target tissue. For example, researchers at the University of Florida have successfully obtained MR images and spectra from single neurons.[188] One might expect that improving the resolution of imaging technology increased the likelihood of detecting a link between pathology and pain in the lumbar spine. Realistically, the determination of a pathoanatomic origin of LBP is made difficult by the rate of false-positive findings on imaging studies (i.e., subjects without LBP showing abnormal findings).

The reported rates of these false-positive findings appear to vary. For example, Stadnik et al.[189] report that 81% of asymptomatic patients had evidence of a disc bulge and that radial annular tears might be found in 56% of asymptomatic patients, whereas Jensen et al.[190] reported in their study that 52% of subjects without pain had a bulge at one level, and 27% showed disc protrusion, and 14% had evidence of disruption of the outer annulus. Evidence of herniation of disc material is shown on computerized tomography (CT) scan,[163] MRI,[191] and myelography,[192] in 20% to 76% of persons with no sciatica.

Nondisc pathology is also often identified in patients without back pain. Some 13%[192,193] to 19%[190] of asymptomatic patients have evidence of Schmorl's nodes. SBO (26%) and osteophyte formation (47%) may be present in individuals without the symptoms of back pain,[193] as is stenotic change.[194] In addition, the prevalence of all identified conditions increases with age. Autopsy studies on a large number of subjects have found disc degeneration, facet joint osteoarthritis, or osteophytes in 90% to 100% of subjects over age 64.[195] Using MRI, researchers have identified central stenosis in as many as 21% of asymptomatic subjects over age 60 and 80% of subjects over age 70.[194] Likewise the prevalence of disc bulges increases but not that of protrusions.[190] Other vertebral anomalies, such as SBO and TLV, also occur in people without pain. For example, 12% of high school- and college-aged males without LBP have evidence of SBO without LBP,[196] and the incidence of TLV may be as high as 30%, regardless of whether the person has LBP.[197]

Thus, the association between clinical complaints and concurrent "pathological" radiological findings must be considered cautiously. This association also appears to apply to the predictive ability of imaging. Savage et al.[36] reported that 32% of asymptomatic subjects had "abnormal" lumbar spines (i.e., evidence of disc degeneration, disc bulging or protrusion, facet hypertrophy, or nerve root compression). To obfuscate matters, only 47% of subjects who were experiencing LBP had an abnormality identified.[36] When those subjects without LBP but with abnormal findings on imaging were followed for 12 months, 13 subjects experienced LBP for the first time; however, there were no changes in the MRI appearances of their lumbar spines that these authors could identify that accounted for the onset of LBP.[36] Therefore pain developed in the absence of any associated change in the radiographic appearance of the spine.

In contrast, Elffering[198] reported that over the course of 5 years, identified disc herniations progressed to degenerative disc disease while the patients remained asymptomatic, indicating that pathology progressed in the absence of any associated pain response. In addition, Boos et al.[199] also followed asymptomatic patients with a disc herniation for 5 years and determined that physical job characteristics and psychological aspects of work were more powerful than MRI-identified disc abnormalities in predicting the need for medical consultation related to LBP.

Multiple potential pathoanatomical pain generators have been identified in the lumbar spine by diagnostic imaging. However, the reality is that the ability of the clinician to identify specific anatomical lesions causing the pain is limited, even with the best available imaging studies. In fact, it has been estimated that the specific anatomical lesion causing LBP is unidentifiable 80% to 85% of the time.[200] On top of this, reviews and editorials have indicated that unnecessary imaging is associated with higher rates of spinal surgery, contributes to additional harm from radiation exposure, and does not improve outcomes in patients without serious pathology.[201]

However, the utility of imaging of the lumbar spine does increase when the clinician is suspicious of a serious pathology or nerve root compression. For example, radiography is indicated when the clinician suspects a compression fracture or neoplasm. Likewise, ultrasound of the abdomen is the currently accepted gold standard for identification of abdominal aneurysm.[202] Imaging studies may also be appropriate if the patient fails to improve with conservative therapy or shows progression of neurological involvement. These assertions of focused imaging in the diagnostic process of LBP are supported by a longitudinal study that found limited accuracy of "common" MRI findings (i.e., disc desiccation, bulges, loss of height) but improved accuracy when less common MRI findings (i.e., central stenosis and nerve root compression) were considered.[203]

MANAGEMENT OF LOW BACK PAIN

Figure 12-6 summarizes the specific management process presented in this chapter. The primary task of the

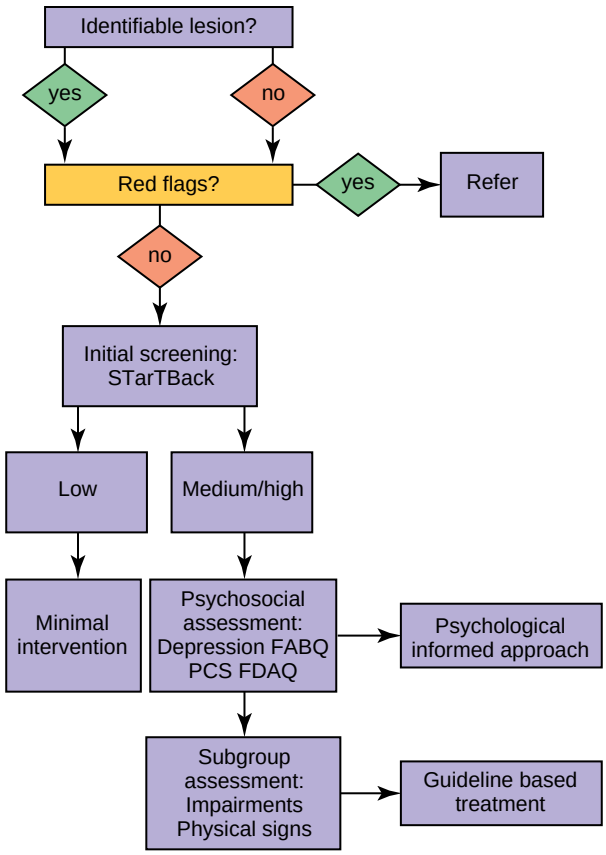

Figure 12-6 Proposed conceptual model for the diagnosis and management of low back pain. *FABQ*, Fear-Avoidance Beliefs Questionnaire; *PCS*, Pain Catastrophizing Scale; *FDAQ*, Fear of Daily Activities Questionnaire.

clinician is to identify red flags that may indicate a serious pathology, mimicking the symptoms of LBP, that should be referred to a specialist. Red flag identification is accomplished through the patient history or appropriate laboratory studies. Once systemic pathology has been eliminated as a potential source of LBP, the secondary task is to identify yellow flags that are predictive of the development of chronic LBP. Once factors that affect the prognosis have been identified, the tertiary task is to recognize the subgroup classification associated with the optimum treatment outcome.

Identification of Red Flags

The clinician must first determine whether the LBP symptoms arise from a serious pathology of another source (Table 12-5). This procedure should take little time for most patients, and a high number of "positive" findings is not expected. However, the clinician must remain diligent in performing this part of the diagnostic process because the consequences of failing to identify serious pathology are potentially severe for the patient.

Deyo et al.[204] have suggested a set of historical questions that can be used in screening for serious pathology in patients with LBP. These cover topics such as a history of cancer, unexplained weight loss, failure of rest to relieve pain, and a history of fevers or chills, intravenous drug use, and/or recent urinary tract infection.[204] Additional screening questions should be specific for urinary retention and saddle anesthesia, osteoporosis, and/or history of compression fracture.[204] If necessary, a review of pertinent medical history in first-order relatives may give insight into possible spondyloarthropathies, if these are suspected in a particular patient.

Red Flags for Low Back Pain

- Abdominal aortic aneurysm
- Kidney disease
- Liver disease
- Duodenal ulcers
- Pancreatitis
- Endometriosis
- Cancer
- Cauda equina syndrome
- Spondyloarthropathies
- Fractures
- Infection

Abdominal Aortic Aneurysm

An abdominal aortic aneurysm (AAA) is a pathological dilatation of the abdominal aorta below the renal arteries to a diameter greater than 3.0 cm (1.2 inches). AAAs are found in 4% to 8% of older men and 0.5% to 1.5% of older women.[205–208] Feilding et al.[209] reported that the most common symptoms reported by patients on the first presentation with AAA are abdominal pain and backache. Age, smoking, sex, and family history are the most significant AAA risk factors. In fact, Lederle et al.[207] indicated that the excess prevalence associated with smoking (i.e., 100 cigarettes lifetime) accounted for 75% of all AAAs of 4.0 cm or larger. Table 12-5 lists the ORs associated with these individual risk factors for AAA.

Fielding et al.[209] indicated that diagnosis could be made by careful routine palpation. Deep and careful palpation should be performed to the left of the midline, keeping the hands steady in one position until the aortic pulse is felt, and then carefully evaluating the lateral extent of the pulse with the pads of the fingers.[210] Physical findings may include a tender, palpable, pulsatile abdominal mass.[209] However, the reported sensitivity and specificity of palpation vary dramatically.[211] For example, detection of AAA by palpation improves in thinner patients[210] and in the presence of recognizable risk factors.[202,210]

Despite the support for palpation, abdominal ultrasound remains the gold standard for identification of AAA.[202] Specifically, the clinician should consider the possibility of rupture of an AAA in a male patient over the age of 60 years who smokes and presents with sudden onset of back and/or loin pain.[212]

TABLE 12-5

Red Flag Pathology and Associated Likelihood and Odds Ratios Indicative of Serious Disease

Condition	Findings	LR	OR (95% CI)
Cancer[171]	Previous history of cancer	14.7	
	Age >50	2.7	
	Failure to respond to conservative intervention	3.0	
	ESR ≥20 mm/h	2.4	
	ESR ≥50 mm/h	19.2	
	ESR ≥100 mm/h	55.5	
Aneurysm (≥4 cm [1.6 inches])[205]	Smoking (100 cigarettes lifetime)		5.07 (4.13-6.21)
	Female		0.18 (0.07-0.48)
	Non-Caucasian		1.02 (0.77-1.35)
	Age		1.71 (1.61-1.82)
	Family history		1.94 (1.63-2.32)
Aneurysm[209]	Positive palpation examination: Abdominal girth ≤100 cm (39.4 inches) Each 1 cm (0.5 inches) increase in AAA diameter	3.2	1.95 (1.06-3.58)
Compression fracture[171,237]	Age >70	11.2	
	Female	—	
	Corticosteroid use	48.5	
	Trauma (significant in young, minor in elderly)	10.0	
	2 of 4	15.5	
	3 of 4	218.3	
Spinal infection[171,222,239]	Fever: tuberculous osteomyelitis	13.5	
	Fever: pyogenic osteomyelitis	25.0	
	Fever: spinal epidural abscess	41.5	
General red flag history[240]	Sleep problems (wakes from sleep, uses medication, cannot sleep)	3.8	
	Unable to urinate	3.0	
	Unable to hold urine	1.4	
	Current smoker	3.3

Back pain is a common historical complaint in a variety of conditions affecting the kidney. LBP (71.3%) was the most common discomfort reported by patients with polycystic kidney disease (PKD) during the course of their disease, with abdominal pain the second most common. These complaints were recorded by 42% of patients before diagnosis of PKD.[213] In addition, 26% of patients with PKD in a study by Bajwa et al.[213] reported back pain radiating to the hips or legs. Central back and flank pain has been described by patients in renal failure[214] and with viral infection.[215]

Massive liver cysts may also result in LBP from the effect of changes in posture as cysts grow, enlarging the abdomen.[213] Duodenal ulcers[216] may refer pain into the upper lumbar spine, and abdominal pain and LBP are the primary historical complaints of patients with pancreatitis[217] and endometriosis.[218]

Cancer

Although spinal cord compression is a complication of malignancy that affects the quality of life of an estimated 12,700 new patients each year,[219] the prevalence of cancer related to back pain is likely to be low in primary care settings. Deyo and Diehl[171] reported a prevalence of cancer-related back pain in primary care patients of 0.66%. This is similar to the prevalence reported for academic multidisciplinary spine centers (0.69%) and higher than that noted (0.12%) in private practice multidisciplinary spine centers.[220] Deyo and Diehl[171] have presented several historical and laboratory findings associated with cancer-related back pain. These authors outline a strategy whereby key historical findings (i.e., age over 50, previous history of cancer, unexplained weight loss, and failure to respond to conservative intervention) are supported by key laboratory tests (erythrocyte sedimentation rate [ESR]).[171] Subsequent investigation has supported the key historical findings of night pain, aching character of symptom manifestation, and unexplained weight loss originally reported.[220] Cancers of the skin may also be implicated in local tenderness over the tissues of the lumbar spine. Ogboli et al.[221] reported that six different types of common skin tumors may present as areas that are tender when palpated.

The positive likelihood ratios for cancer screening using selected historical and laboratory findings are presented in Table 12-5. It has been suggested that prompt spinal imaging might be indicated for those patients having two or more historical findings and an ESR ≥20 mm/h.[171] It should also be noted that Hollingworth et al.[222] indicated that the benefits of using MR imaging for screening rather than x-ray did not justify the increased costs.

Cauda Equina Syndrome

Compression of the cauda equina of any cause (e.g., trauma, central disc protrusion, hemorrhage, or tumor) requires immediate surgical referral.[204] Fortunately the incidence and prevalence of this condition are very low. Johnsson et al.[223] report the population incidence of the syndrome to be 0.03% in Denmark and 0.005% in Sweden.[224,225]

The most consistent findings in cauda equina syndrome are urinary retention and sensory changes on the buttocks, thighs, and peritoneum "saddle anaesthesia."[226] Loss of anal sphincter tone is present in 60% to 80% of cases.[227] Urinary retention is also common in simple nerve root compression syndromes with no relation to true cauda equina syndrome.[227]

Spondyloarthropathies

The prevalence of spondyloarthropathies is estimated to be 1% to 2% of the population. Spondyloarthropathies are related inflammatory spinal arthropathies characterized by sacroiliac involvement and a relationship to HLA-B27 but distinct from rheumatoid arthritis. This group of conditions includes ankylosing spondylitis (AS), reactive arthritis (including Reiter's syndrome), psoriatic arthritis, arthritis associated with bowel disease (i.e., enteropathic arthritis), juvenile spondyloarthropathy, and a set of unspecified spondyloarthropathies. The diagnostic criteria recommended by the Assessment of Spondyloarthritis International Society are listed in Box 12-1.[228]

AS is considered the most common of the spondyloarthropathies. Connective tissue changes occur as subchondral tissue thickens and eventually is replaced by fibrocartilage and finally bone. AS affects men more than women, beginning with complaints of back pain and stiffness in early adulthood. The final diagnosis often is not made until the patient is older because the earlier symptoms are minimal. Neck pain and stiffness are associated with advanced disease. Historical findings include reports of insidious onset back pain that is worse with inactivity and improves with exercise. These complaints are not particularly specific; however, association with a family history of spondyloarthropathy, acute anterior uveitis (iritis), and impaired trunk mobility or chest expansion strengthens the clinical picture. Clinical diagnosis is further supported by radiographic evidence of sacroiliitis, which is considered the hallmark of AS. MRI can be helpful in detecting early change in the spine, but the increased cost may limit its routine use.

BOX 12-1

Assessment of Spondyloarthritis International Society Classification Criteria

AXIAL SPONDYLOARTHRITIS

Criterion: In patients with >3 months' back pain and age <45 years
Sacroiliitis on imaging
AND 1 or more features
OR HLA-B27 AND 2 or more features

Features of Spondyloarthropathies:

- Inflammatory back pain
- Arthritis
- Enthesitis (heel) (inflammation where tendons insert)
- Uveitis (inflammation of the uvea in the eye)
- Dactylitis (inflammation of an entire finger or toe)
- Psoriasis
- Crohn's disease and colitis
- Good response to NSAIDs
- Family history of spondyloarthritis
- HLA-B27
- Elevated C-reactive protein

HLA-B27, human leukocyte antigen-B27; NSAIDs, non-steroidal anti-inflammatory drugs.

Data from Mease P: Psoriatic arthritis and spondyloarthritis assessment and management update, *Curr Opin Rheumatology* 25(3):287-296, 2013.

Reactive arthritis is an episode of aseptic, acute, asymmetric peripheral arthritis occurring within 1 month of a primary infection elsewhere in the body. It is frequently associated with one or more extra-articular features, such as conjunctivitis or acute iritis, enthesitis at the Achilles tendon or plantar fascia, mucocutaneous lesions, urethritis, and carditis.[229] The combination of arthritis, conjunctivitis, and urethritis has been called Reiter's syndrome, but most patients with reactive arthritis do not present with this triad.[229]

Psoriasis is a common skin disease (1% to 3% prevalence)[230,231] in Caucasian adults that affects men and women equally. The disease is less common in other ethnic groups, such as Native Americans (0.3%).[230] Approximately 10%[230] to 30%[232,233] of patients with psoriasis have associated inflammatory arthritis. Skin lesions usually appear before the arthritis in approximately 50% of patients with psoriatic arthritis. The arthritis usually begins between 30 and 50 years of age, but it can also begin in childhood. When searching for psoriasis, the skin check should not be limited to the extremities but should also include the scalp, ears, umbilicus, pelvic area, perineum, natal cleft, palms, soles, and nails. Nail involvement is often a useful clue in diagnosis of psoriatic arthritis.[231] Gladman[234] suggests that psoriatic arthritis may be distinguished from the other spondyloarthropathies by the presence of asymmetrical, peripheral arthritis, asymmetrical spinal involvement, and lower level of pain.

Enteropathic arthritis refers to inflammatory arthritic conditions associated with bowel disorders, such as

Crohn's disease and ulcerative colitis. de Vlam et al.[235] reported that 39% of consecutive patients with ulcerative colitis or Crohn's disease had enteropathic arthritis and 90% met the criteria for spondyloarthropathy. Peripheral arthritis tends to be more frequent in enteropathic arthritis than AS.[235]

Fractures

Compression fractures usually occur in osteoporotic bone, most frequently at T8, T12, L1, and L5.[236] Historical findings that increase the probability of compression fracture are reported in Table 12-5. The patient is often older without a history of specific spinal trauma but with other clinical features of osteoporosis, such as kyphosis or a previous history of wrist and hip fractures.[236] The patient will often report pain after a seemingly simple maneuver, such as a cough or opening a window. In addition, some compression fractures occur spontaneously while the patient is lying in bed.[236] Deyo et al.[204] recommend that a patient on long-term corticosteroid therapy who is complaining of spine pain should be considered to have a fracture until proven otherwise because this historical finding greatly affects the probability of compression fracture. This observation has been supported in a primary care study in which Henschke et al.[237] investigated a combination of four red flags (i.e., age >70 years, female, corticosteroid use, and history of trauma). Two positive of four red flags resulted in an increase in the suspicion of fracture (likelihood ratio [LR]+15.5; 95% CI, 8.5 to 28.4). Three red flags of four yielded a large LR+ (LR+ 218.3; 95% CI, 45.6 to 953.8), but the authors encouraged caution when interpreting this result because of the extremely large CI (see Table 12-5).

Spinal Infections

Fever of unknown origin is defined as a temperature higher than 38.3°C (101°F).[238] Urinary tract infections, indwelling urinary catheters, skin infections, and injection sites for intravenous drugs have been identified as potential sites from which a spinal infection develops in approximately 40% of patients with osteomyelitis.[239] Fewer than 2% of patients with back pain attending a primary care clinic presented with fever,[171] indicating that there are very few false positives when associating fever to infection in patients with LBP (see Table 12-5).

Red Flag Summary

Roach et al.[240] collected demographic and clinical information from 174 patients with LBP to examine the sensitivity and specificity of historical questions to identify patients with serious pathology in the lumbar spine. These authors classified serious pathology to include osteoporotic fracture, tumor, infection, and surgical management of spinal stenosis or disc herniation. The historical questions with the best positive LRs were related to the inability to urinate or hold urine, sleep disturbances, and current smoking history (see Table 12-5).[240] It should be noted that although these questions had very high specificity (i.e., high true negative), they also had a very low true positive rate. The implication of this relationship is that many of the patients with serious pathology (as defined by Roach et al.[240]) did not answer "yes" to the historical questions.

Identification of Yellow Flags

Once red flags have been considered, the clinician may decide that referral to another specialist is necessary before conservative rehabilitation is deemed appropriate. This outcome must always be considered, but it is not a frequent outcome for most practice areas. More often the clinician proceeds to screen for yellow flags, the second step of the differential diagnosis and classification approach.

Yellow Flags for Low Back Pain

- Depression
- Fear-avoidance beliefs
- Pain catastrophizing

Yellow flags represent psychological constructs with documented influences on pain, treatment participation, and outcomes.[241] In general terms, the identification of yellow flags allows the clinician to determine the potential for a psychological influence on a patient's clinical presentation of LBP. The rationale for considering yellow flags in the differential diagnosis and classification of LBP is summarized in the *New Zealand Acute Low Back Pain Guide*[242]: "The goal of identifying yellow flags is to find factors that can be influenced positively to facilitate recovery and prevent or reduce long-term disability and work loss. This includes identifying both the frequent unintentional learning or emotional barriers and the less common intentional barriers to improvement."

Waddell et al.[243,244] first described signs believed to be associated with aspects of distress and abnormal illness behavior that could lead to increasing amounts of disability. These signs were described as nonorganic and have been investigated in prospective studies predicting return to work status. Several studies have demonstrated that the presence of nonorganic signs were predictive of a delayed return to work,[245–248] whereas other studies have reported that nonorganic signs were not predictive of return to work.[249,250] Fritz et al.[251] investigated nonorganic signs as a screening tool for predicting return to work and presented strong evidence indicating high false-positive rates are a consistent problem with nonorganic signs (Table 12-6). For example, even under the best condition reported in the literature (–LR, 0.48), the posttest probability only decreases from 50% to 32% for predicting

TABLE 12-6

Lack of Evidence for Use of Nonorganic Signs to Screen for Return to Work

Author	Sample Description	Nonorganic Signs for Positive Finding	Outcome Determination	Negative LR
Bradish et al.[249]	Work-related LBP	Three or more	Return to at least part-time work	0.60
Werneke et al.[250]	Nonworking or partly disabled patients with LBP	One or more	Return to work or improved work status	0.59
Kummel[247]	Work-related LBP	Three or more	Return to at least part-time work	0.48
Karas et al.[246]	Work-related LBP	Three or more	Return to at least part-time work	0.77
Fritz et al.[251]	Work-related LBP	Two or more	Return to full-time work	0.75

LBP, Low back pain; *LR*, likelihood ratio.

Data from Fritz JM, Wainner RS, Hicks GE: The use of nonorganic signs and symptoms as a screening tool for return-to-work in patients with acute low back pain, *Spine* 25:1925-1931, 2000.

inability to return to work based on two or fewer nonorganic signs. Collectively, this evidence suggests clinicians should consider methods other than nonorganic signs when screening for psychological influence.

Screening for Yellow Flags

Screening tools have been developed in an effort to better identify patients at risk for poor outcomes due to psychological distress following an episode of LBP. Some tools are designed to identify patient subgroups for the purposes of treatment allocation,[252–254] whereas others are used to identify those at risk for poor functional or pain-related outcomes.[255–258] Two common multifactorial screening tools for the assessment of yellow flags in patients with LBP are the Örebro Musculoskeletal Pain Screening Questionnaire (ÖMPSQ) and the Subgroups for Targeted Treatment (STarT) Back Tool, or SBT.

The ÖMPSQ is a 25-item yellow flag screening tool that predicts long-term disability and the inability to return to work.[257] Originally developed to predict sick leave outcomes in occupational LBP, the ÖMPSQ has been adopted as a subgrouping tool in clinical practice. High-risk cutoff scores have been reported in the literature for a variety of patient populations.[259–264] A systematic review concluded the ÖMPSQ had a moderate ability to predict long-term pain, disability, and sick leave outcomes.[265] A short-form of the ÖMPSQ was developed in a primary care sample with good correlation to information obtained from the original questionnaire. A cutoff of 50 on the short form identified 83% of patients accumulating more than 14 days of sick leave.[258]

In contrast to the ÖMPSQ, which was originally developed as a prognostic tool, the SBT was designed as a subgrouping tool to identify treatment-modifiable indicators associated with low, medium, and high risk of poor functional outcomes. The SBT is a brief, nine-item questionnaire consisting of physical and psychosocial subscales appropriate for use across the spectrum of patients with nonspecific LBP.[266] The psychosocial subscale comprises individual items from single-construct questionnaires representing modifiable psychosocial factors shown to predict poor functional or pain-related outcomes. Physical and psychosocial subscales are combined to provide an overall risk assessment. In a randomized, clinical trial, Hill et al.[254] demonstrated superior improvements in disability, generic health benefits, and cost savings with stratified care as the result of SBT screening. Studies using the SBT in outpatient physical therapy support its validity for identifying patients at risk of poor outcomes.[267,268] The SBT provides comparable measurement properties to the ÖMPSQ, yet offers the advantages of being shorter and easier to score.[269]

Figure 12-6 outlines the integration of the SBT into a clinical decision-making algorithm. Overall scores of ≤3 indicate a low-risk category. Overall scores >3 but <4 on the psychosocial subscale indicate medium risk. Psychosocial subscale scores ≥4 indicate high risk.[266] Because prognosis for patients in the low-risk group is generally favorable, minimal intervention is suggested. For patients in the medium- or high-risk categories, a more thorough assessment of psychological factors is suggested before initiation of treatment. This assessment allows the clinician to more thoroughly evaluate specific psychological constructs involved in the development and maintenance of chronic LBP. Furthermore, this assessment provides direction for psychologically informed interventions that may improve outcomes for patients in medium- or high-risk categories.[254] A comprehensive review of specific psychological constructs is beyond the scope of this chapter; however, interested readers are referred to reviews by Pincus.[270,271]

Assessment of Yellow Flags

Typically, self-report questionnaires are used to more thoroughly assess common psychological influences involved with LBP that are general (depression) or specific (fear-avoidance beliefs, activity-specific fear, pain catastrophizing) in nature.

Depression

Depression is a commonly experienced illness or mood state, with a wide variety of symptoms ranging from loss of appetite to suicidal thoughts.[272] Depression is commonly

experienced in the general population, but it appears to be more commonly experienced in conjunction with chronic LBP.[273–275] A Canadian population-based study estimated the general rate of major depression to be 5.9% for pain-free individuals and 19.8% for individuals with chronic LBP.[274] Other studies have reported depression prevalence rates of up to 32% for individuals with chronic LBP.[276,277] Based on this epidemiological information, the authors felt that routine screening for depression should be part of the clinical diagnosis of LBP.

Studies have linked depressive symptoms with increased pain intensity, disability, medication use, satisfaction with care, and unemployment in patients seeking care for LBP.[264,278,279] Depression is also predictive of poor functional and pain-related outcomes. For example, Melloh et al.[280] found that depression and maladaptive cognitions predicted the development of persistent pain following an acute episode of LBP. In a study of patients undergoing physical therapy, George et al.[281] found depressive symptoms were the strongest contributors to baseline pain and function and were predictive of pain intensity ratings and functional status at discharge. They also found patients with higher levels of depression had a longer duration of treatment and more clinic visits compared with patients with normal depressive symptoms.

Despite this evidence of its deleterious influence on LBP, depression does not appear to be adequately screened for in practice settings that commonly examine patients with LBP. For example, depressive symptoms were not identified in 35% to 75% of patients seeking treatment from primary care physicians,[272,282] 63% of spine surgeons indicated that they only occasionally or never screen use psychological tests,[283] and surveys of physical therapy practice do not mention psychological screening as part of normal practice patterns.[284–286]

Effective screening for depression involves more than just generating a clinical impression that the patient is depressed. Separate studies involving spine surgeons[283] and physical therapists[275] have demonstrated that clinical impressions are not sensitive enough to detect depression in patients with LBP. Instead, it appears to be more effective to use self-report questionnaires (e.g., Zung Self-Rating Depression Scale, Beck's Depression Inventory, or the Depression Anxiety Stress Scales) to screen for depression. However, these questionnaires often contain more than 20 items, which may place a burden on the patient and clinician.

Any dialogue between mental health and spine clinicians should determine whether depressed patients should be treated concurrently. In our opinion, examples of **inappropriate treatment** of a depressed patient by a spine clinician include (1) a patient in whom low back symptoms represent only somatic complaints, without associated physical impairment, and (2) a patient whose depressive symptoms are severe or extreme and include suicidal thoughts.

Evidence suggests that using two specific questions from the **Primary Care Evaluation of Mental Disorders** patient questionnaire can effectively screen for depression in primary care settings.[287] The questions are (1) "During the past month, have you often been bothered by feeling down, depressed, or hopeless?" and (2) "During the past month, have you often been bothered by little interest or pleasure in doing things?" The patient responds to the questions with "yes" or "no," and the number of yes items are totaled, giving a potential range of 0 to 2. A study involving LBP suggests that these two questions also accurately identified depression in patients seeking physical therapy treatment for LBP (Table 12-7).[275] Studies indicate a single question from the **Subjective Health Complaints (SHC) Inventory** (*"To what extent have you been affected by depression/low mood during the last month?"*) has sufficient sensitivity (0.79 to 0.95) and negative predictive value (89% to 99%) to screen for depressive symptoms.[288,289]

Fear-Avoidance Beliefs

Fear-avoidance beliefs are a measure of patients' beliefs and attitudes toward LBP.[290] Specifically, fear-avoidance

TABLE **12-7**

Accuracy of Screening for Depression Using Two Questions from the Primary Care Evaluation of Mental Disorders Patient Questionnaire

	Mild Depression	Moderate Depression	Severe Depression	Extreme Depression
One Question Result				
Positive LR	3.40 (2.40, 4.82)	2.76 (2.10, 3.62)	2.44 (1.91, 3.12)	2.25 (1.71, 2.96)
Negative LR	0.37 (0.26, 0.51)	0.29 (0.18, 0.49)	0.25 (0.11, 0.55)	0.23 (0.06, 0.84)
Two Questions Result				
Positive LR	5.40 (3.10, 9.42)	4.61 (3.0, 7.0)	4.32 (3.0, 6.1)	3.89 (2.80, 5.40)
Negative LR	0.55 (0.44, 0.67)	0.43 (0.30, 0.60)	0.28 (0.14, 0.53)	0.18 (0.05, 0.66)

LR, Likelihood ratio.

Modified from Haggman S, Maher CG, Refshauge KM: Screening for symptoms of depression by physical therapists managing low back pain, *Phys Ther* 84:1157-1166, 2004; and Whooley MA, Avins AL, Miranda J et al: Case-finding instruments for depression: two questions are as good as many, *J Gen Intern Med* 12:439-445, 1997.

beliefs are a composite measure of the patient's fear related to LBP, how physical activity and work affect LBP, and how LBP should be managed.[290–292] Theoretically, patients with elevated fear-avoidance beliefs are more likely to use an avoidance response to their LBP, resulting in the development of an exaggerated pain perception and chronic disability.[290] Prospective studies have supported the validity of fear-avoidance beliefs because they are predictive of the development of chronic LBP,[293–296] poor work-related outcomes,[297,298] reduced function,[299,300] and higher health care use.[301]

As a result of this evidence, identification of elevated fear-avoidance beliefs has been suggested as an important component in the diagnosis of LBP. The **Fear-Avoidance Beliefs Questionnaire (FABQ)** is commonly used to assess fear-avoidance beliefs in patients with LBP.[292] The FABQ has 16 items that are scored on a scale ranging from 0 (strongly disagree) to 6 (strongly agree). The individual items are then summed to generate an estimate of fear-avoidance beliefs, and higher numbers on the FABQ indicate increased levels of fear-avoidance beliefs. Two subscales are contained within the FABQ: a seven-item (items 6, 7, 9-12, and 15) work subscale (FABQ-W; score range 0 to 42) for fear-avoidance beliefs about work and a four-item (items 2-5) physical activity subscale (FABQ-PA; score range 0 to 24) for fear-avoidance beliefs about physical activity. Several studies indicate that the FABQ is a reliable, valid, and/or responsive measure,[292,302–304] suggesting it is appropriate for use in clinical settings.

Evidence suggests the FABQ-W can be used effectively in occupational LBP.[305] A study of patients with acute, work-related LBP who were evaluated for demographic, physical, and psychosocial factors found that the FABQ-W was the strongest predictor for return to work at 4 weeks.[293] Patients who scored greater than 34 on the FABQ-W were less likely to return to work by 4 weeks (+LR, 3.33; 95% CI, 1.65 to 6.77). In contrast, patients who scored less than 29 on the FABQ-W were less likely to return to work (–LR, 0.08; 95% CI, 0.01 to 0.54). In another study of work-related musculoskeletal disorders, Holden et al.[306] showed an FABQ-W score of ≤27.5 had maximum sensitivity (100%), whereas an FABQ-W score of >39.5 had maximum specificity (81.9%) for identifying patients at risk for poor return to work outcomes. Although the FABQ-W may be most effective in predicting functional and work-related outcomes in patients with occupational LBP, a study by George et al.[307] suggests the FABQ-W may also be useful for identifying patients at risk for higher disability as the result of nonoccupational LBP in physical therapy settings. This study found patients scoring above a previously established cutoff score (>29) on the FABQ-W had higher disability scores and were less likely to show improvements in disability at 6 months. Further analysis in this cohort found FABQ-W scores <5 might be useful in identifying patients most likely to show improvements in disability at 6 months. Conversely, FABQ-W scores >20 were associated with the highest positive likelihood ratios (2.3 to 5.1) for showing no improvements in disability at 6 months.[307] Unfortunately, similar cutoff scores have not been reported for the FABQ-PA, making assessment of fear-avoidance beliefs related to physical activity difficult. It has been suggested that a score higher than 14 indicates an elevated FABQ-PA,[292,308] but studies have not supported the predictive utility of this cutoff for identifying patients likely to experience poor functional outcomes.[293,307]

Activity-Specific Fear

Many studies have examined the relationship between fear-avoidance beliefs and actual physical capacity in patients with chronic LBP with variable results.[309–314] One potential explanation for this variability is the differential demands of individual tasks used in each study to measure physical capacity. For instance, pain-related fear may influence tasks that require maximum effort more significantly than tasks that require submaximal effort.[315] As a result, general fear-avoidance belief measures (e.g., FABQ) may not be sensitive enough to predict fear-related functional limitations equally across tasks. In these cases, activity-specific fear may be a stronger predictor of clinical outcomes.

Beneciuk et al.[316] provide empirical support for assessing general and activity-specific fear separately. In a study of patients with LBP seeking physical therapy, they found patients with high specific fear and patients with high general fear and high catastrophizing comprised two distinct groups. Interestingly, patients reporting elevated levels of specific activity-related fear did not demonstrate elevated levels of general pain-related fear beliefs or catastrophizing, supporting the differential assessment of general and activity-specific fear. Furthermore, the authors found a subgroup by time interaction, suggesting different types of fear may be differentially associated with clinical outcomes. Further evidence to support consideration of activity-specific fear is provided by Demoulin et al.,[315] who found poor associations between general and activity-specific measures of pain-related fear. These findings suggest general and activity-specific fear measures may be evaluating distinct fear-related constructs.[315]

Activity-specific fear measures have been proposed (1) to more adequately assess the influence of fear on function and (2) to direct in vivo graded exposure paradigms.[317] The **Photograph Series of Daily Activities (PHODA)** is an assessment tool for activity-specific fear commonly used in the development of graded exposure paradigms. It includes 100 photographs of common activities patients may encounter in their daily life, from household chores to physical exercise. Patients report concern for harming their back when engaging in each activity from 0

(not harmful) to 100 (extremely harmful). An electronic, 40-question version of the PHODA (PHODA-SeV) has demonstrated good construct validity, with overall PHODA-SeV scores moderately correlated with self-reported pain severity and fear of movement/(re)injury.[318] Leeuw et al. also reported that patients who received graded exposure in vivo aimed at reducing the perceived harmfulness of activities had significantly lower PHODA-SeV scores after treatment than patients receiving graded activity that did not address these assumptions.[318]

The **Fear of Daily Activities Questionnaire (FDAQ)** is another activity-specific fear assessment tool designed for use in clinical practice.[319] The FDAQ lists 10 activities that patients commonly report fear of performing due to LBP. Patients can also list two additional open-ended responses and rate their fear for performing those activities. Patients rate each FDAQ item on a numeric rating scale from 0 (no fear) to 100 (maximal fear). The FDAQ is scored by totaling the Numerical Rating Scale (NRS) ratings for the 10 standard activities and divided by 10. Like the PHODA, the FDAQ was primarily designed to guide physical therapy interventions supplemented with graded exposure. Currently, there is limited support for the predictive validity of the FDAQ for pain-related outcomes; however, strong associations with concurrent disability suggest fear of specific activities may contribute to the disablement process in LBP. Furthermore, changes in fear of specific activities were shown to predict change in disability after 4 weeks of physical therapy.[319] These findings provide empirical support for the incorporation of both general beliefs about pain-related fear and beliefs about specific activities in the assessment of LBP.[319,320]

Pain Catastrophizing

Pain catastrophizing is a negative cognition related to the belief that the experienced pain will inevitably result in the worst possible outcome.[321] Pain catastrophizing is believed to be a multidimensional construct comprising rumination, helplessness, and pessimism.[321] A practical example might help to illustrate the concept of pain catastrophizing. A patient with elevated pain catastrophizing would expect to have severe pain for the rest of his or her life, even if his LBP were mild in severity and was being treated appropriately.

Pain catastrophizing has also been linked to the development and maintenance of chronic pain. Most of the literature documenting the unique influence of pain catastrophizing on chronic pain is cross sectional,[322–325] but there are some prospective studies that provide supporting evidence. For example, frequent pain catastrophizing during acute LBP was predictive of self-reported disability 6 months[67] and 1 year later,[326] even after considering select historical and clinical predictors. In a systematic review, pain catastrophizing at baseline predicted disability at follow-up in four studies and pain at follow-up in two studies.[327] Three studies found no predictive effect of catastrophizing. In another systematic review, 66% ($n=8$) of studies that investigated self-reported outcome measures found catastrophizing to be associated with pain and disability at follow-up in acute, subacute, and chronic LBP patients.[328] In studies that applied cutoff values, 83% ($n=5$) found that patients with high levels of pain catastrophizing experienced worse clinical outcomes compared with patients with low levels of pain catastrophizing.[327]

Pain catastrophizing can be measured by the **Pain Catastrophizing Scale (PCS)**, which is a 13-item scale that assesses the degree of catastrophic cognitions a patient experiences while in pain.[329] The scale ranges from 1 (not at all) to 4 (always), and an example of an item is, "I worry all the time about whether the pain will end." In clinical settings, the PCS is commonly reported as a whole number by summing all 13 items (range, 0 to 52). Psychometric studies suggest acceptable levels of reliability and validity.[322,329] Factor analysis suggests a hierarchical factor structure, with three individual subscales of the PCS (i.e., rumination, magnification, and pessimism) contributing to an overall factor of pain catastrophizing.[322,329] Accordingly, the PCS offers multidimensional measurement of catastrophizing, whereas other common measures of catastrophizing (e.g., **Pain-Related Self-Statement Scale [PRSS]** or **Coping Strategies Questionnaire [CSQ]**) assess the construct unidimensionally.[327] Prediction of pain and disability with PCS is supported analytically[327,328]; however, few cutoffs have been reported in the peer-reviewed literature for use of the PCS to predict the clinical outcome of LBP. Of the cutoffs reported, many of the values are based on normative distributions.[330–332] For example, Linton et al.[331] established a cutoff of >23 for high versus low catastrophizing based on a quartile split and found higher disability in patients with a combination of high depression and high catastrophizing. Franklin et al.[330] found higher opioid use with elevated levels on a PCS; however, they used cutoffs based on a shortened version of the PCS.

Yellow Flag Summary

The consideration of yellow flags is an important part of the diagnostic process of LBP because it alerts the clinician to patients (1) who may be appropriate for referral because of depression or (2) who need treatment modifications to decrease risk of experiencing chronic disability. Specific education and exercise philosophies, more commonly referred to as psychologically informed practice approaches, have been proposed to address elevated psychosocial factors.[291] These approaches may be especially warranted for patients who score high on individual psychosocial or yellow flag screening measures. A detailed discussion of these approaches is beyond the scope of this

chapter; however, they have been described in the literature, for example, synthesized in a 2011 Special Issue of *Physical Therapy*,[333,334] and results from randomized trials demonstrating efficacy of psychologically informed practice.[254,308,335]

SUMMARY

In 2014, the National Institutes of Health Pain Consortium convened a taskforce that was charged to develop research standards for LBP.[116] As part of that process, the group concluded that a pathophysiological diagnosis of LBP was unfeasible. Therefore, the primary way for the clinician to proceed is to first rule out "red flags," then screen for "yellow flags" and assess yellow flags in greater detail if indicated by the screening. After this, the next task is to determine the appropriate patient treatment strategy. Treatment strategies may include psychologically informed approaches when appropriate and/or assignment to a treatment subgroup classification (i.e., the subgroup that maximizes the probability of a favorable outcome). A review of treatment strategies and classification systems is beyond the scope of this chapter. Readers are referred to clinical practice guidelines for the treatment of LBP established by the Orthopedic Section of the American Physical Therapy Association.[336]

CASE EXAMPLES FOR DIAGNOSING LOW BACK PAIN

Case Example 1

A 62-year-old patient presents with complaints of nonspecific central LBP. He is unable to describe a mechanism of injury but relates that the pain has gradually worsened over several months. Furthermore, he describes his current pain as a constant, deep ache. During the history, the patient indicates that he has a previous history of cancer.

Cancer is a potential cause of LBP for this patient. The LRs from Table 12-5 are used to estimate the probability that this patient has cancer. In general, a 0.66% probability exists that cancer is a source of back pain (this estimate is based on a previously reported prevalence study[171]). The+LR that a patient over age 50 has cancer as a source of LBP is 2.7. Figure 12-7 shows a graphic method used to estimate the effect the patient's age has on the probability that cancer is a source of LBP. The Y-axis on the left side of the graph is the pretest probability in percentage. The line begins at 0.66%, crosses the central Y-axis (representing the LR) at 2.7, and as a result, intersects the right axis at approximately 2% (see Figure 12-7, *A*). Two percent is the new (post-test) probability that the patient has cancer

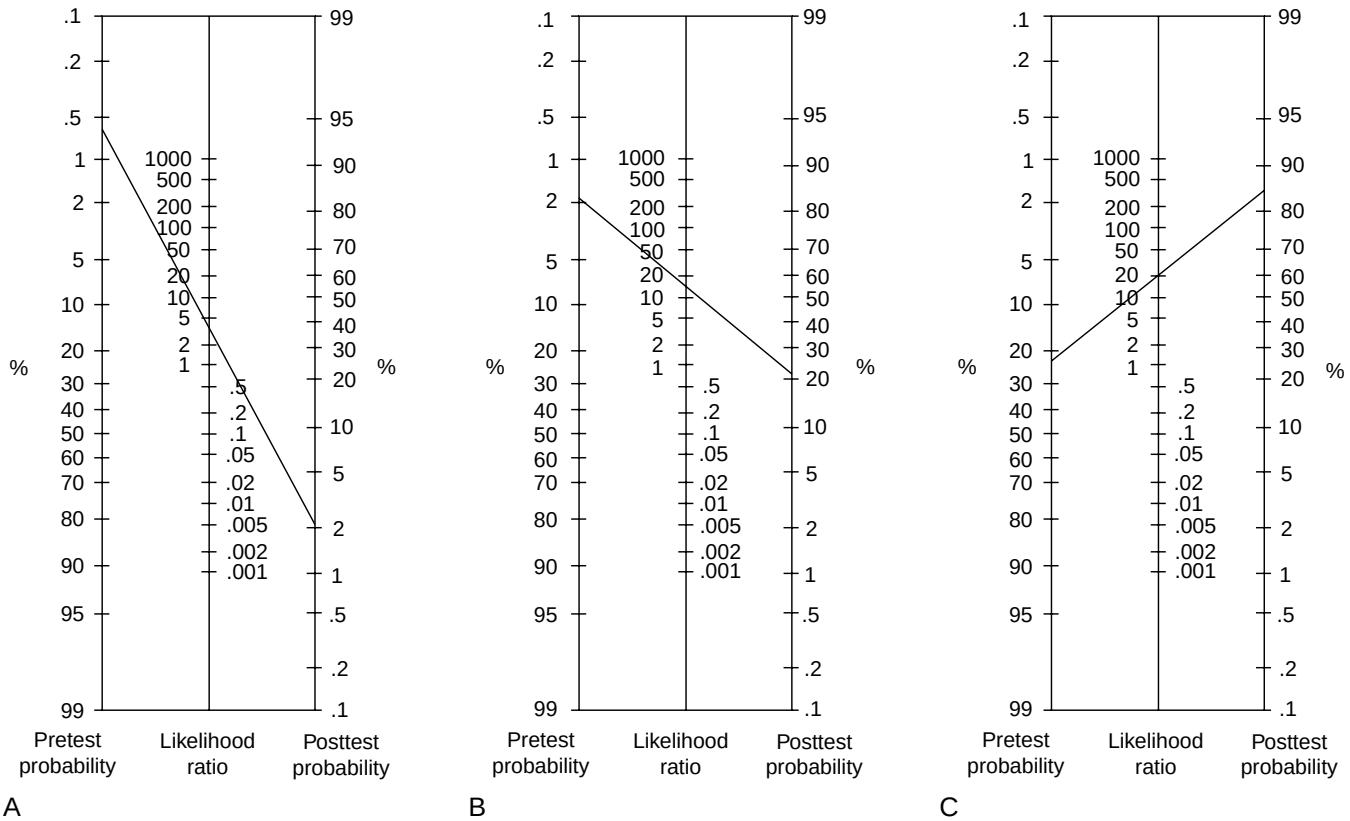

Figure 12-7 **A,** The probability of cancer for this patient increases from 0.66% to approximately 2% because he is over 50 years of age. **B,** The probability of cancer for this patient increases from 2% to approximately 22% because he has a previous history of cancer. **C,** The probability of cancer for this patient increases from 22% to greater than 80% based on erythrocyte sedimentation rate results.

(the actual calculated value is 1.8%). The previous history of cancer (+LR, 14.7) is considered in Figure 12-7, *B* and the resultant posttest probability of cancer has increased to 22%. Blood work is ordered for this patient, and it shows an ESR of 60 mm/h (+LR, 19.2) (see Figure 12-7, *C*); the resultant posttest probability of cancer has increased to greater than 80%. At this point, the most appropriate course of action for this patient is referral to an oncologist.

This example also provides specific detail on how to estimate the influence of examination findings on pretext to posttest probabilities using likelihood ratios.

Case Example 2

A 45-year-old patient presents to a clinic with complaints of LBP. Patients examined in this clinic are routinely screened for depression with the two previously described questions from the Primary Care Evaluation of Mental Disorders patient questionnaire.

The LRs from Table 12-7 were used to estimate the probability that this patient has severe depression. In general, approximately a 20% probability exists that patients with back pain also have major depression (this estimate is based on a previously reported prevalence study[274]).

The –LR that a patient with one negative response has severe depression is 0.29. Figure 12-8 shows a graphic method used to estimate the effect that one negative response has on the probability of having severe depression. The Y-axis on the left side of the graph is the pretest probability in percentage. The line begins at 20%, crosses the central Y-axis (representing the LR) at 0.29, and as a result, intersects the right axis at approximately 5% (see Figure 12-8, *A*). Five percent is the new (posttest) probability that the patient has severe depression (the actual calculated value is 5.8%). The most appropriate course of action in this scenario would be to continue the examination of this patient, with lowered suspicion of severe depression.

In contrast, the+LR that a patient with two positive responses has severe depression is 4.32 (see Table 12-5). Figure 12-8, *B* demonstrates that two positive responses raise the posttest probability of having severe depression from 20% to approximately 50% (the actual calculated value is 51.9%). The most appropriate course of action in this scenario would be to consider the patient for referral or further workup for depression, depending on the expertise of the clinician.

Case Example 3

A 34-year-old patient injured his back at work and is examined 7 days after the injury. As part of the examination process, the clinician has the patient complete the FABQ.

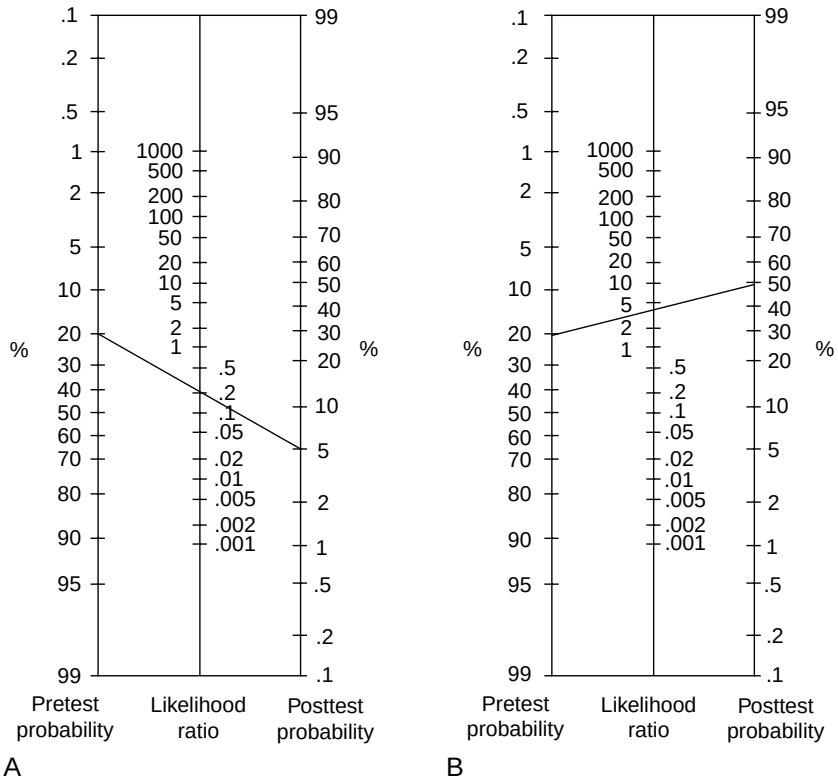

Figure 12-8 **A,** The probability of severe depression decreases from 20% to approximately 5% with one negative response to the two-question depression screening instrument. **B,** The probability of severe depression increases from 20% to approximately 50% with two positive responses to the two-question depression screening instrument.

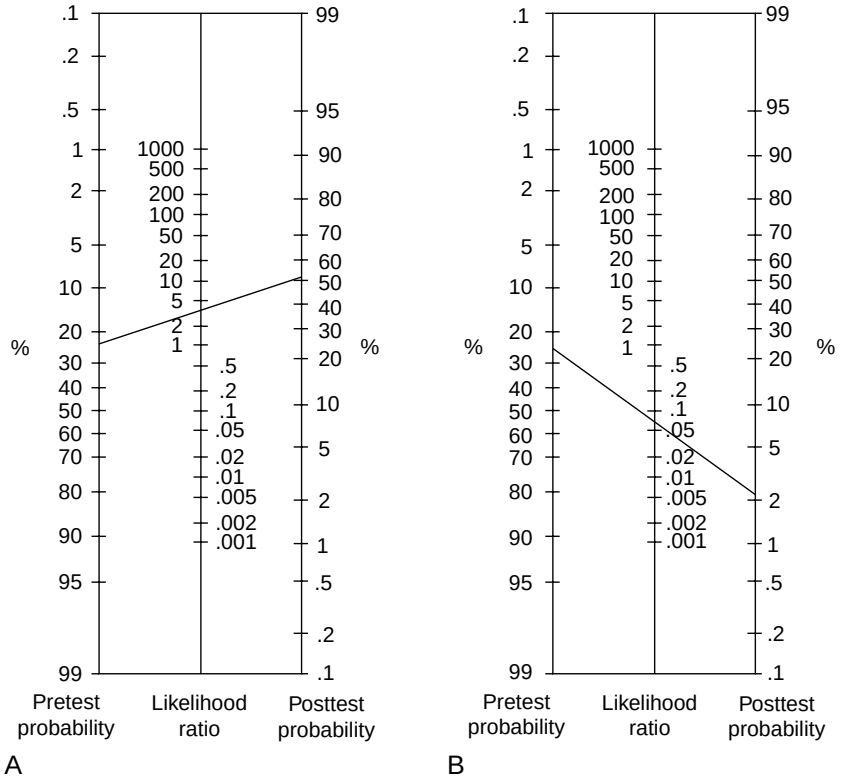

Figure 12-9 **A,** The probability of not returning to work increases from 25% to approximately 52% with a positive FABQ-W. **B,** The probability of not returning to work decreases from 25% to approximately 2.5% with a negative FABQ-W.

Then, estimates of whether the patient will return to work in 4 weeks can be generated. The LRs from the study[293] cited in the text were used to estimate the probability that this patient would *not* return to work. The clinician estimates that a 25% probability exists that patients with back pain will not return to work (this estimate is based on a clinic's database).

In the first scenario, the patient has an FABW-W score of 38, and the associated+LR is 3.33. Figure 12-9 shows a graphic method used to estimate the effect this FABQ score has on the probability of not returning to work in 4 weeks. The Y-axis on the left side of the graph is the pretest probability in percentage. The line begins at 25%, crosses the central Y-axis (representing the LR) at 3.33, and as a result, intersects the right axis at approximately 52% (see Figure 12-9, *A*). Fifty-two percent is the new (post-test) probability that the patient will not return to work in 4 weeks (the actual calculated value is 52.6%). The most appropriate course of action in this scenario would be a management strategy that optimized the likelihood of returning to work. For example, interventions that addressed elevated fear-avoidance beliefs and/or early involvement of case management might be considered.

In the second scenario of this case, the patient has an FABQ-W score of 17, and the associated−LR is 0.08. Figure 12-9, *B* shows that the posttest probability of not returning to work has decreased from 25% to approximately 2.5% (the actual calculated value is 2.6%). The most appropriate course of action in this scenario would be to continue the examination process in anticipation of a favorable outcome.

CHAPTER 13

Lumbar Spine
Treatment of Hypomobility and Disc Conditions

JIM MEADOWS, DAVID J. MAGEE

INTRODUCTION

Manual therapy techniques (i.e., spinal mobilization and spinal manipulation) play a major role in the treatment of low back pain. This chapter discusses the use of manual therapy, particularly specific and indirect segmental techniques for lumbopelvic pain. In the context of this chapter, **mobilization** is defined as a series of rhythmical or nonrhythmical movements of the joints' articular surfaces that are applied by the clinician but are within the patient's control to stop (through muscle contraction). Similarly, **manipulation** is defined as a single, high-velocity, low-amplitude thrust technique that is intended to abolish the barrier to movement and is not within the patient's control (i.e., it happens too quickly for the patient to react).

Characteristics of Hypomobility Dysfunction

- Altered patterns of movement
- Decreased range of motion
- Tissue or joint swelling
- Altered joint play
- Abnormal end feel
- Tight, short muscles
- Inhibition of antagonists

For the most part, the manual therapy techniques applied in the treatment of lumbar hypomobility are used to reduce pain and increase range of movement. They also may be used to reduce reflex inhibition of the musculature that supports the spine. The exact mechanism of these effects is presently unknown. However, two primary models are used to explain the effects of spinal mobilization and manipulation: the neurophysiological model and pathomechanical model.

Neurophysiological Model

According to the neurophysiological model, segmental hypomobility occurs as a result of a neurophysiological processing problem in the control system; this processing problem is caused by pain, which produces protective muscle spasm and instability. In this context, the term *control system* refers to the concept set forth by Panjabi[1–3] and involves neural control (through the central and peripheral nervous systems) as well as the passive structures around the joints (i.e., ligaments, capsules, and discs) and active components (i.e., muscles). It also refers to control of the arthrokinematic movements (e.g., spin, slide, roll).[4–6] Inadequate control of the joint leads to changes in muscle tone which, in turn, result in more pain and reduced range of motion, a somewhat circuitous model.

Manual therapy techniques, such as mobilization and manipulation, in the neurophysiological model, provide a sensory stimulus that affects one or more of the joint mechanoreceptors, muscle spindle systems, or Golgi tendon organs, resulting in reduced muscle tone, increased range of motion, and decreased pain.[6] These changes are produced through neurophysiological pain and mechanoreceptor modulation at the spinal cord level (summation or gating) and/or by activating descending pathways.

Pathomechanical Model

The pathomechanical model is based on the premise that the primary dysfunction is essentially the result of a structural breakdown of one or more spinal segments, which allows the articulations to jam, fixate, lock, or sublux. In this context, a *spinal segment* is the trijoint complex (i.e., two vertebrae, the zygapophyseal joints, and the disc). The result of the structural breakdown is a pathomechanical hypomobility that limits movement in one or more

directions. Pain is caused by mechanical stress; this stress can occur to the affected joint, or it may occur at another location as a result of excess stress on some other, remote tissue, possibly resulting in hypermobility of the remote tissue because of the pathomechanical hypomobility of the specific segment in question. In the pathomechanical model, manual treatment mechanically mobilizes the hypomobile joint to relieve the stress on the painful structure while protecting the hypermobile structures.[7]

Both the neurophysiological and pathomechanical models are able to explain clinical observations (i.e., pain, restricted or excessive movement), and each of the two models can be used in isolation. However, they are more useful to clinicians if they are combined.

Manual therapy techniques have been shown to produce both neurophysiological and mechanical effects on the segmental tissues.[4,8–15] In acute pain states, particularly with spasm or nonreflexive muscle guarding, overly aggressive manual therapy techniques (e.g., Maitland grade 3+ and grade 4+) can, and usually do, aggravate the condition by exacerbating existing inflammation (see Volume 2 in this series, *Scientific Foundations and Principles of Practice in Musculoskeletal Rehabilitation,* Chapter 24). In these cases, more gentle manual therapy techniques (e.g., Maitland grade 1 and grade 2) are used to reduce the pain through neurophysiological modulation.[16] These gentle techniques do not (or should not) directly engage the pathological or anatomical barrier (i.e., end of range of motion) or cause any discomfort. They can be considered *pain-dominant* techniques. If pain is not the predominant clinical feature and if its onset follows the clinician's perception of the pathological barrier to passive movement (*restriction-dominant* condition), a technique that directly stresses the pathological barrier (e.g., Maitland grade 3+ and grade 4+ and minithrusts) is the treatment of choice. For pathomechanical or pericapsular hypomobility (i.e., stiff, inextensible articular tissues), manipulation and mobilization, respectively, may be more efficient and effective.

For the purposes of manual therapy, pathological barriers can be divided into muscle, collagen, or inert tissue related, as well as neurological barriers. Muscle barriers occur as a result of injury to contract out tissue (i.e., muscle), or they are the result of protective muscle spasm. Examples of a muscle barrier include hypertonicity of a muscle, muscle spasm, and adaptive shortening of the muscle.[17] In these cases, the end feel is muscle spasm or, as Cyriax described it, a "vibrant twang" or "mushy" tissue stretch (i.e., a tight muscle).[18–21] Collagen and inert tissue barriers occur as a result of injury to inert tissue (e.g., the capsule and ligaments) and other collagen in or adjacent to the joint, including scar tissue. In these cases, the end feel is capsular (e.g., a capsular pattern), soft capsular (e.g., synovitis or soft tissue edema), springy block (e.g., meniscus), or bone to bone (e.g., osteophyte formation). Inert tissue barriers may be articular or periarticular. Neurological barriers are primarily the result of pain causing an empty end feel or one with neurological signs (e.g., tingling, numbness, "pins and needles", painless weakness).

MANUAL THERAPY FOR LUMBAR INTERVERTEBRAL DISC HERNIATION

In addition to addressing pain and segmental pathomechanics, manual therapy techniques (especially manipulation) may be used as an intervention for lumbar intervertebral disc herniation. Probably the greatest proponent of manipulative therapy for the treatment of disc herniation was James Cyriax.[18–21] However, his advocacy of this approach was not based so much on existing pathology but on the clinical model he proposed. This model essentially held that facet joint syndrome (and other, similar pathomechanical conditions) and sacroiliac joint dysfunction were extremely rare and that most low back pain was caused by varying degrees of disc pathology (i.e., protrusion, prolapse, extrusion, or sequestration).

Currently spinal manipulation in the treatment of disc herniation is used primarily by chiropractors and it tends to be avoided by the medical, osteopathic, and physical therapy professions. The contention that manipulative techniques affect the intervertebral disc is not controversial; what is open to question is whether the effect is beneficial or harmful. In a cadaveric study, Sheng et al.[22] found that rotation manipulation combined with compression increased intradiscal pressure and rotation manipulation combined with traction reduced it. Two magnetic resonance imaging (MRI) and clinical outcome studies of patients with lumbar disc herniation found that spinal manipulation combined with traction, physical therapy (undefined), and exercises[23] or spinal manipulation alone[24] resulted in a significant improvement in clinical symptoms, function, and MRI findings.

Most of the evidence for the efficacy of manipulation in the treatment of disc herniation is anecdotal or comes from case reports[25]; however, the use of spinal manipulation for lumbar disc herniation appears to have some degree of effectiveness.[26,27] Chiropractic reports provide examples of cases of lumbosacral disc herniations that were more lateral, causing back and leg pain with sensory deficit (confirmed by MRI), and that were treated successfully by manipulation.[28–30] Some case reports even indicate the successful use of manipulation in patients with established cauda equina lesions, a condition most clinicians consider an absolute contraindication to manual therapy.[31–34]

Many other reports show harmful effects from spinal manipulation with a disc herniation. According to Assendelft,[35] disc herniation, aggravation of disc herniation, and cauda equina syndrome (CES) are the most common serious complications of lumbar spinal manipulation, accounting for more than 20% of all serious complications of manipulation in all spinal regions, making

possible disc herniation the second most serious complication after neurovascular injury subsequent to manipulation of the cervical spine.

A literature review by Haldeman and Rubinstein[36] that covered the years 1911 to 1989 found only 10 cases of CES after spinal manipulative therapy (SMT). Their review also reported on three new cases that were related at least temporally to SMT. In the three new cases, neither the treating clinician nor the emergency department physician recognized the onset of the problem.[36] A number of other cases of CES have been reported since 1989. In an unusual case, the disc fragment did not fragment but bulged onto the artery that supplied the conus (i.e., caudal narrowing area of the spinal canal).[37] Li[38] reported five cases of CES or conus medullaris syndrome (CMS), all of which occurred after spinal manipulation, some of them immediately after the manipulation. Powell et al.[39] listed six risk factors for spinal manipulation, one of which was the presence of a herniated nucleus pulposus.

Therefore, it cannot be argued that SMT does not result in CES or CMS syndrome in some cases; however, the incidence of these syndromes as adverse effects of SMT is believed to be very low, somewhere in the range of 0.5 to 1 per 1 million manipulations.[34,40]

For most clinicians, the risk (however low) of very serious complications, unproven efficacy, and inexperience in the use of manipulation for disc herniation are factors that cause them to avoid using these techniques. Most clinicians also have the advantage of working in a system that encourages referral of difficult cases for further investigation and the availability of other treatment methods that do not carry the same degree of risk. Consequently, for the most part, clinicians tend to view the presence of an established disc herniation as a contraindication to most forms of manual therapy.

TRACTION FOR DISC HERNIATIONS (VERTEBRAL AXIAL DECOMPRESSION THERAPY)

In contrast to manipulation, spinal traction is used quite frequently in the treatment of disc herniation. Since the age of Hippocrates, practitioners have known about the application of longitudinal force to the axis of the spine to provide facet joint distraction, reduction of disc protrusion, soft tissue elongation, muscle relaxation, and patient mobilization. Spinal traction has been heavily explored as a therapeutic option in musculoskeletal medicine since the late 18th century. It enjoyed a renewed popularity in the 1950s and 1960s based on James Cyriax's findings on the efficacy of spinal traction for the treatment of discogenic back and leg pain.[19] Saunders[41] further popularized the use of intermittent spinal traction in the 1980s and 1990s through the development of improved stabilization belts and split table technology. In the 2000s, as a result of improved pneumatic instrumentation, an enhanced form of vertebral axial spinal decompression (VAX-D) is being widely used in the management of disc conditions. Advances in imaging and microinstrumentation have fueled a growing body of clinical evidence that spinal decompression and/or traction should be considered a front-line intervention for these conditions.[42–44]

Vertebral axial decompression therapy uses a computer-driven table to apply traction to the lumbar spine. It is postulated that this traction technique may effect decompression of the disc. Experimental results have been encouraging,[45,46] but the lack of scientific evidence based on well-designed studies has led several groups to question its effectiveness.[45–49]

SELECTION OF A LUMBAR SPINE MANUAL THERAPY TECHNIQUE

The primary use of manual therapy is in the treatment of segmental dysfunction or hypomobility. In this context, "segmental dysfunction" means injury or abnormal movement in the trijoint complex, which consists of the two zygapophyseal joints and the disc. The technique selected must be specific to the pathological barrier associated with the dysfunction. If pain, spasm, or hypertonicity (or all three) is the principal problem, a neurophysiological technique is indicated; however, if inextensibility of pericapsular tissues or pathomechanical hypomobility is the chief problem, a restriction-dominant technique is the preferred choice. If the joint must be stretched or if it is fixed (jammed or subluxed) and the hypomobility is pathomechanical, the joint needs to be manipulated with a sudden, low-amplitude force. The following information is based on the clinical experience of the chapter's first author, Jim Meadows.

A number of factors must be considered in the selection of a manual technique. Two of these have already been discussed: the level of pain (i.e., pain dominant or restriction dominant) and the condition itself (i.e., disc herniation, pericapsular restriction, pathomechanical hypomobility). In addition, the dose of the treatment, which is actually a subset of the previous considerations, must be selected.

Causes of Hypomobility

MYOFASCIAL CAUSES
- Adaptive shortening or hypertonicity of muscles
- Posttraumatic adhesions
- Scarring

PERICAPSULAR CAUSES
- Damage to capsule or ligament
- Adhesions
- Scarring
- Arthritis or arthrosis
- Fibrosis
- Tissue adaptation

PATHOMECHANICAL CAUSES (JOINT TRAUMA)
- Macrotrauma
- Microtrauma

Causes of a Pathological (Restrictive) Barrier

- Trauma (macrotrauma or microtrauma)
- Inflammatory response
- Muscle spasm
- Edema
- Pain
- Tissue alterations (e.g., adaptive shortening)

Important Factors in the Mobilization Process

- Presenting condition or tissue disorder (contractile?, inert [collagen]?, neurological?)
- Quality of the movement present
- Resistance felt (i.e., type of barrier, end feel)
- Pathological state of the tissues (i.e., acute, subacute, chronic; stage of healing)
- Symptoms elicited before, during, and after treatment (i.e., pain dominant or restriction dominant pattern)
- Indications for treatment (i.e., pain-dominant or restriction dominant pattern)
- Treatment parameters (e.g., grade of technique, positioning of patient)
- Cautions and contraindications to use of certain techniques
- Patient's use of any medications (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs]) that may affect treatment
- Methods of testing for instability and vascular insufficiency
- Need for adjunctive treatment (e.g., exercise, electrophysical agent)
- Need to reassess

Probably the most common method used to discuss doses of manual treatment is the Maitland grading system.[16,50,51] This system has undergone many refinements over the years; however, for the purposes of this chapter, the grades can be divided into two categories: those that have mainly a neurophysiological effect and those that have a mechanical effect on the pathological barrier. Figure 13-1 depicts the simplest interpretation of this system. Purists may take issue with this interpretation, but it presents all that is required to discuss grading techniques for the purposes of this chapter.

As Figure 13-1 shows, grade 1 and grade 2 techniques are unquestionably neurophysiological in effect because they do not approach the end of the available range of movement, and they should not produce pain or discomfort. Technically, grade 3 and grade 4 techniques are also subbarrier because they should reach the end of range but not stress the tissues at end range. Minithrusts and grade 5 (manipulation) techniques would be applied at the barrier. If pain is experienced before or at the same time tissue resistance is encountered, a subbarrier technique is indicated. If any attempt at reaching the pathological barrier produces or increases pain, the condition is in a subacute stage or almost certainly in the acute phase. However, in clinical practice, clinicians commonly tend to push into the barrier; when this happens, these techniques more properly should be labeled grade 3+ and grade 4+ techniques. Regardless of

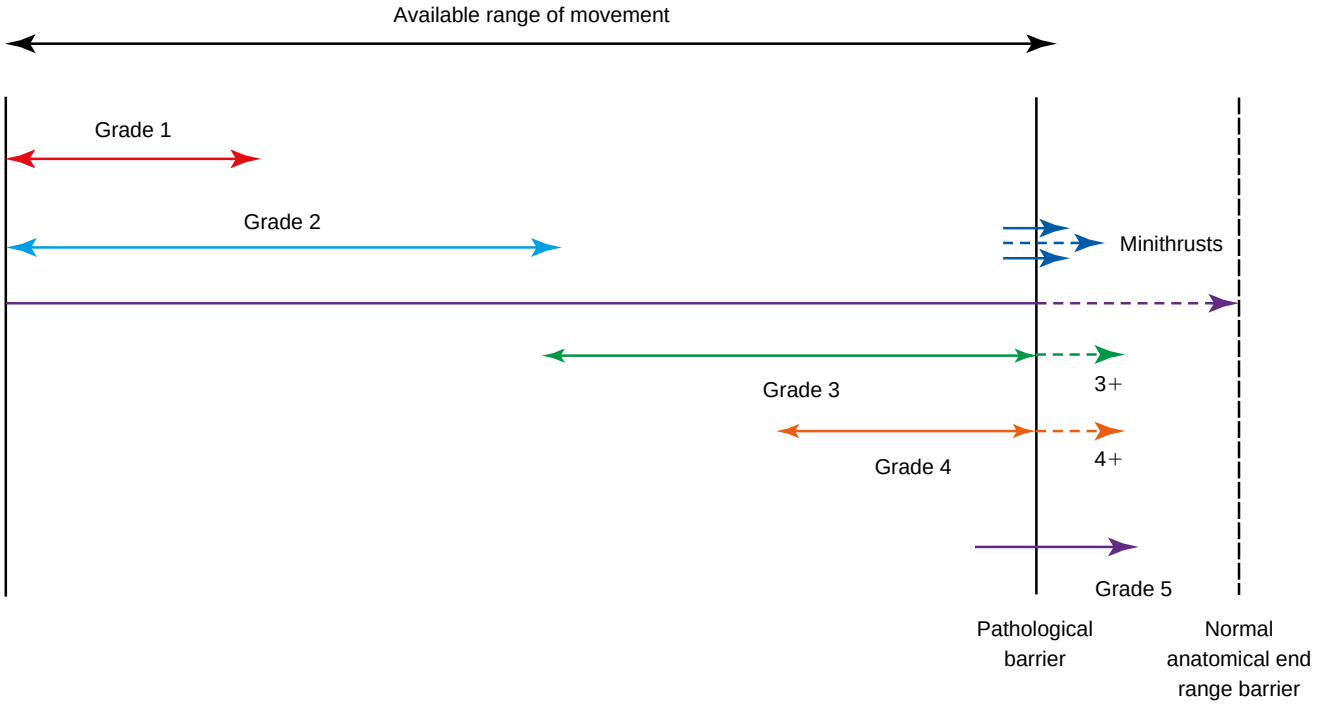

Figure 13-1 Maitland grades of movement used in lumbar mobilization techniques. As the diagram shows, grade 1 and grade 2 techniques are definitely neurophysiological because they do not approach the end of the available range of movement, and they should not produce pain or discomfort. Technically, grade 3 and grade 4 techniques are also subbarrier because they should reach the end of the available range but not stress it. However, in clinical practice, clinicians commonly tend to push into the barrier. When this happens, these techniques are more properly labeled grade 3+ and grade 4+. Regardless of the grade of the technique, all mobilizations have an oscillatory component. Oscillation prevents neurophysiological accommodation to the input, which would attenuate the pain-reduction effect of the technique. (Data from Maitland GD: *Vertebral manipulation,* London, 1986, Butterworth.)

the grade of technique used, all mobilizations include an oscillatory component, which prevents neurophysiological accommodation to the input from attenuating the pain-reduction effect of the technique.

Clinicians commonly use terms such as *acute, subacute,* and *nonacute* in nontemporal terms to depict how painful and irritable (i.e., acute) the condition is. Semantics, definitions, and communication, as well as a common level of understanding, are critical among clinicians, and this is often a problem in manual therapy. Terms must be standardized, and associating the onset of pain with the onset of the symptoms can do this. Table 13-1 is an attempt to "quasi-quantify" the relationship of pain to the end feel to enable the clinician to determine whether the problem is pain dominant or restriction dominant.

True constant pain must be considered to possibly indicate visceral or certain types of bone pathology that are not usually amenable to manual therapy techniques. Pain that is unrelieved by rest and generally considered an indication of inflammation should actually be called *variable pain* because it is affected by varying mechanical stresses and therefore variable rather than constant. In actuality this is high-level, continuous pain that may be treated by manual therapy techniques (see Table 13-1).

To summarize, the choice of manual therapy techniques depends on the dominant tissue type barrier. In addition, whether pain or restriction predominates or whether the problem is pericapsular or pathomechanical, the clinician must consider whether the patient's personal attributes (e.g., emotional liability, psychological well-being) might be affecting the condition. Ultimately, all of these factors must be assessed to optimize the use of manual therapy techniques. Patient selection is a critical concern for therapeutic success. In addition, the clinician must ensure that informed consent is obtained before any treatment is provided.

Informed Consent Process

- Discuss the proposed technique and reason it is deemed the best choice
- Discuss possible alternatives
- Discuss both the benefits and risks of the technique
- Have information sheets available for the patient, or note how the information was given; include the time and date it was provided (i.e., documentation)
- Allow the patient to ask questions (if necessary, prompt the person)
- Obtain the patient's written consent

Patient Selection

Not all patients are suited for manual therapy. The list of patients who fall into this category is longer for some professions than for others. For example, physical therapists generally lack enthusiasm for manual treatment of a disc herniation, whereas chiropractors frequently use manipulation for this condition. For most physical therapists, the patients suited for manual therapy are those suffering from a biomechanical segmental dysfunction (or its peripheral equivalent). For the purposes of this chapter, manual therapy as described is used for a very specific type of mechanical low back pain.

TABLE 13-1

Relationship of Pain to End Feel, Presumptive Pathology, and Treatment

Pain and Tissue Resistance (End Feel)	Acuteness or "Irritability" Level	Presumptive Pathology	Treatment	Dominance
All pain, no resistance	Hyperacute	Almost always serious pathology	Refer to physician	Pain dominant
Constant pain*	Hyperacute	Significant inflammation or serious pathology	No manual treatment	Pain dominant
Pain before resistance	Acute	Inflammation, very irritable	Low-dose subbarrier techniques (grade 1)	Pain dominant
Pain simultaneous with resistance	Subacute	Moderate or mild inflammation, moderately irritable	Higher-dose subbarrier techniques (grade 2)	
Pain after resistance	Nonacute	Mechanical pathology; may be slightly irritable	Barrier techniques (grade 3/3+ or grade 4/4+), either mobilization or manipulation, depending on end feel	Restriction dominant
No pain, all resistance	Stiff or jammed	Mechanical pathology with no irritability	Barrier techniques (grade 3/3+ or grade 4/4+), either mobilization or manipulation grades, depending on end feel	Restriction dominant

*Constant pain implies pain that is always present and does not change with movement or weight bearing.

Mechanical Low Back Pain: Two Theoretical Models

The term *mechanical low back pain* is a way of saying that the problem encountered does not lend itself to a true medical diagnosis. Although the average clinical presentation of a patient with this condition is fairly easy to recognize, the explanations given for the underlying pathology are controversial and contentious. In general, a patient with pathomechanical segmental dysfunction (i.e., caused by hypomobility) displays the clinical findings listed in Table 13-2.[51–53]

The clinical findings in Table 13-2 are the criteria used to diagnose pathomechanical segmental dysfunction (i.e., hypomobility), which can be addressed with mobilization techniques. In contrast, neurophysiological segmental dysfunction (i.e., instability), which often accompanies or results from hypomobility, is not amenable to mobilization therapy because it involves excessive motion, not reduced motion. However, conditions involving excessive motion are amenable to stabilization training (see Chapter 14 and Volume 2 of this series, *Scientific Foundation and Principles of Practice in Musculoskeletal Rehabilitation*, Chapter 19).

Two primary theories have been proposed for this apparent dichotomy. One theory holds that in patients with the clinical profile previously described, two distinct dysfunctions are present at different joints or different segments, one being hypomobile and the other unstable. According to the other theory, only one dysfunction is present, but its characteristics change from time to time, with painful episodes interrupting longer periods of pain-free function. The affected segment undergoes a form of phase transition. A *phase transition* can be defined as a clinical episode in which a profound change occurs in symptom behavior and manifestation with little change in the physical composition of the segment. Regardless of which theory is preferred, it must be understood that a theory or explanation is not required to be the "truth"; rather, its function is to offer a conceptualization of what is happening so that the user of the model can visualize events. Theories are used, consciously or unconsciously, all of the time. The following model of phase transition fits the observations concerning the presentation of biomechanical back pain and its response to various treatments at least as well if not better than most other models, but it is not necessarily true.

As mentioned, a phase transition is considered to have occurred when a radical change in the behavioral characteristics of a substance or system occurs without a similar change in the composition of the substance or system. This concept has been taken from physics. It describes a major change in the thermodynamics of a system in which essentially the same substance has completely different behavioral characteristics. For example, consider the change from water to ice—ice cannot put out fire until it changes to water; ice is extremely slippery, water considerably less so. Although in the strictest sense the term *phase transition* is used to describe fundamental property changes in a thermodynamic system, it might be used to good effect to describe a model of biomechanical dysfunction of the lumbar spine.

If the patient is experiencing a "phase" that may best be described as a lack of spinal stability and control, this phase is relatively painless and mobile, and it leaves the patient fully functional but with symptoms indicating that the patient cannot control the movement. Assessment during this unstable phase reveals abnormally pliable tissue compliance (i.e., instability) and hypermobility. If a phase transition occurs, passive physiological mobility tests will demonstrate hypomobility and will be painful; however, all of the characteristics of subluxation-fixation and the stability test results will be negative. In effect, the segment goes from the matrix of instability to hyperstability and from a painless state to a painful state. It undergoes transition from one phase to another and back again as effective forces are applied. Therefore, using the phase transition model for segmental dysfunction, an unstable segment oscillates between a pain-free phase, which is its unstable ground state, and a painful phase, in which its instability allows the joint to fix at one end of its range and either become painful itself or cause pain at another joint that is stressed by the hypomobility. Therefore treatment focuses on the phase in which patients find themselves at the time of treatment. If the painful, hypomobile phase is encountered, manual therapy to move the joint and relieve the pain is required. If the unstable phase is to be treated, stability therapy and movement reeducation can be used.

To determine the motion state dysfunction at the segment, the clinician must perform a detailed biomechanical

TABLE 13-2

Signs and Symptoms of Segmental Dysfunction

Neurophysiological Segmental Dysfunction (Hypermobility and Instability)	Pathomechanical Segmental Dysfunction (Hypomobility)
• Asynchronous movement • Increased range of motion • Joint swelling • Altered joint play • Late muscle spasm • Abnormal end feel • Pain localized to back • Seldom pain referral • Painful episode related to load, speed of movements, muscle fatigue • No incapacitation deformity • Possible instability jog (muscle twitch)	• Altered patterns of movement • Decreased range of motion when joint is painful • Tissue or joint swelling • Altered joint play • Abnormal end feel • Tight (hypertonic) muscles (postural) • Inhibition of antagonists • Moderate nonneuropathic pain • Possibly referral of pain to buttock • Minor or unknown trigger to painful episodes

examination. This examination must determine four important factors:

1. Is a movement dysfunction present?
2. If a movement dysfunction is present, is it one of hypomobility, hypermobility, or instability?
3. If the dysfunction is a hypomobility dysfunction, is it articular or extraarticular in origin?
4. If the hypomobility dysfunction is articular in origin, is it pericapsular or pathomechanical?

Only after these determinations have been made, can a specific treatment be applied to a specific segment in a specific direction. Some schools of thought hold that it is unnecessary to be specific about the segment to be mobilized. The intervention discussion in this chapter focuses on specific treatments. However, some discussion of the nonspecific approach is needed, because it is rapidly becoming *the* method of treatment, especially in the United States.

The use of nonspecific manual treatment by physical therapists was first popularized by Cyriax in the 1950s, and this approach still has its adherents.[19] A disc herniation model was used, and it was thought that large-amplitude regional techniques using strong traction would have a beneficial effect on the disc lesion. The differential diagnostic examination afforded limited specificity as to the segment requiring treatment, and absolutely no attempt was made to make the treatment technique specific. In 2002 Flynn et al.[54] resurrected this idea, using clinical prediction rules to determine which patients would benefit from manipulative therapy of the lumbar spine. The study came up with a five-point clinical prediction rule that gave a likelihood of success of 45% to 90% if four out of five points were evident.

Flynn's Clinical Prediction Rules[54]

- Recent onset of symptoms (<16 days)
- No fear-avoidance beliefs (i.e., Fear-Avoidance Beliefs Questionnaire [FABQ] score < 19)
- Lumbar hypomobility in at least one segment
- Good medial rotation range of motion in at least one hip (>35°)
- No symptoms distal to the knee

The manipulation used in the study was not only nonspecific to any segment, but it also had been used previously to manipulate the sacroiliac joint. Flynn et al.[54] further made the point that segmental specificity was not necessary for a technique to be effective (a point borne out by the longevity of the Cyriax techniques and other studies).[19–21] However, clinical reasons exist for making both the thought processes involved in the determination of treatment and the technique itself more specific. The previous discussion is entirely about effectiveness. It does not address other issues, such as safety and ways to treat patients who do not meet four of the five criteria described by Flynn et al.[54]

Nonspecific techniques do not pretend to safeguard segments that may not be able to withstand the forces involved in manual treatment if they are not specifically locked. For example, in the cervical spine, the vertebral artery is at risk unless the technique's effect is minimized throughout the neck, especially if rotational techniques are used. Although the clinical prediction rule may help to include patients in the manipulation group, it does not do much about excluding those who are marginal or who should not be manipulated because of unrelated but significant pathologies. This oversimplification of a very complex system (i.e., the patient) allows newcomers to manual therapy to assume that all that is required is that the patient match a few points on a list. As much as Flynn et al.[54] speak out against an algorithmic approach, it is the way clinicians tend to think, and it provides a stronger rationale for doing what clinicians do than simply following a clinical prediction rule.

Biomechanical Segmental Assessment

To determine whether a specific manual treatment should be performed for pathomechanical dysfunction, the clinician must perform a passive biomechanical segmental assessment that uses passive physiological intervertebral movements (PPIVMs), followed by passive arthrokinematic (accessory) intervertebral movements (PAIVMs). Figure 13-2 presents a simple algorithm of the examination.

Using PPIVMs and PAIVMs, the clinician can determine a number of findings that will guide the use of manual therapy techniques for the hypomobile joint or segment. A pericapsular restriction is indicated by restriction on PPIVM tests associated with restriction on PAIVM tests, with both types of movements showing the hard capsular end feel of stiffness. A pathomechanical hypomobility may be determined by the PPIVM tests associated with restriction on the PAIVM tests, with both showing a pathomechanical end feel. For a hypermobile joint or segment, using the phase transition model, the presence of an instability requires treatment of the instability because this is the phase the back condition exhibits.

Before the definitive technique can be applied, the clinician may and probably will encounter one or more pathological barriers between the initial hands-on end feel once the patient has been positioned for treatment. The end feel will vary, depending on the pathological barrier encountered. To briefly review barrier end feels, an inextensibility of the pericapsular tissues produces a predominantly hard capsular end feel, and a subluxation produces a hard, jammed end feel. Increased muscle tone can produce a variety of end feels, depending on the degree of hypertonicity and its effect. A minor degree of hypertonicity may produce only an increased drag on the way to the definitive end feel, whereas a greater amount of hypertonicity can cause an almost capsular end feel but

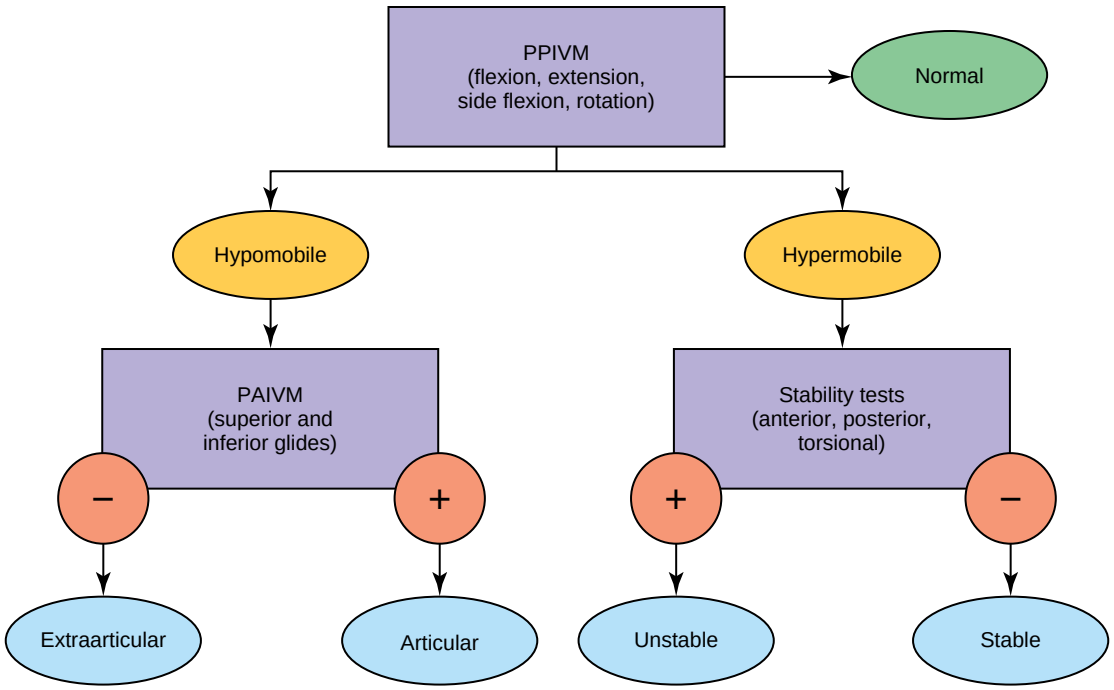

Figure 13-2 Algorithm for the passive biomechanical segmental assessment.

with a "lively resilience" (Cyriax's "vibrant twang").[19] If the hypertonus alters the biomechanics of the segment by acting as an "abnormal ligament," it can cause the joint to jam, resulting in a pathomechanical end feel similar to that of a subluxed joint. In all cases, light hold-relax, contract-relax, or muscle energy techniques can reduce the hypertonus and drastically alter the end feel.

Another pathological barrier is soreness, which often is first encountered once the segment is positioned near its abnormal end of range. The patient may complain of soreness, or the clinician may feel the patient's reaction to the position (this is not acute pain, and certainly no spasm accompanies the pain).

For manual therapy techniques to succeed, each of these pathological barriers must be addressed as it is met. Mild degrees of soreness can be reduced or eliminated with grade 3 or grade 4 oscillatory techniques that do not produce pain; hypertonus can be addressed with muscle relaxation techniques, including hold-relax, contract-relax, and muscle energy and active release techniques; pericapsular restrictions are best treated with a grade 3+ or grade 4+ mobilization; and subluxations are treated with manipulation or with minithrusts, if manipulation is not chosen. Usually multiple pathological barriers are met at each treatment. The positioning causes some minor soreness, which is relieved by a grade 3 or grade 4 mobilization, and muscle tone (normal or high) may then be encountered and reduced. Finally the definitive pathological barrier is met and treated with a grade 3+ or 4+ mobilization or manipulation (minithrusts if manipulation is not an option). This approach is more effective because it eliminates the inappropriate use of manual therapy techniques, such as ballistic stretching of muscle (which occurs if grade 4+ techniques are used on hypertonic muscles) and incorrect manipulative methods for extensive capsular tightening.

Positioning and Treatment

When deciding how to position the patient for the most effective use of manual therapy techniques, the clinician first must consider whether the hypomobility occurs into flexion or extension and whether it is at the right or the left zygapophyseal joint. If side flexion is considered in terms of flexion or extension of the zygapophyseal joint, rather than the segment's movement as a whole, right side flexion is seen by most authors as causing the right joint to extend and the left to flex. If rotation is considered instead of side flexion, the issue of which joint flexes and which extends becomes much more problematic; considerable controversy exists about the coupling that occurs with rotation, and there is almost no agreement on which direction of side flexion couples with a specific direction of rotation (Table 13-3). A study using live subjects found that coupling depended not only on whether it occurred at the lumbar spine but also at which specific level[55–57]; a cadaveric study found that at L5-S1, the coupling changed, depending on whether it was initiated by rotation or by side flexion.[50]

In addition to the lack of consensus among experts and research studies on this point, the indisputable fact is that patients do not have normal or even optimum biomechanics; therefore a discussion of normal movement may be irrelevant. The most useful course is to ignore rotation

TABLE 13-3

Coupled Movements (Side Flexion and Rotation) Believed to Occur in the Spine in Different Positions*

and use side flexion as the coupling model because side flexion does not interfere with the way the joint moves; it moves down with ipsilateral (same) side flexion and up with contralateral (opposite) side flexion (Table 13-4).

If the clinical requirement for treating the patient is to increase flexion of the right zygapophyseal joint, the whole segment could be mobilized into left side flexion. However, this carries the risk that the mobilization will "hypermobilize" the left joint. The clinician must also consider that if this joint has been overstressed by its hypomobile partner, it should be protected from the force of the technique. To reduce the stresses on the opposite joint, an asymmetrical technique is chosen if an asymmetrical dysfunction exists (this is determined by asymmetrical movement restriction). Therefore flexion of the right zygapophyseal joint (where the hypomobility dysfunction exists) must be combined with either rotation or side flexion to the pathological barrier of the target joint (i.e., the right zygapophyseal joint), and the opposite joint must be moved away from the end of range so that the unaffected side (i.e., the left zygapophyseal joint) is not stressed. The usual method is to select rotation as the discriminative component of the technique, but as has already been discussed, considerable controversy exists as to how rotation "couples." Consequently, side flexion is the preferred method for positioning the joint at its restrictive barrier. Therefore, to increase flexion of the right zygapophyseal joint, the segment is flexed and left side flexed with the direction of the mobilization being one that increases left side flexion. To gain right zygapophyseal joint extension, the segment is extended and right side flexed, and the technique is into right side flexion. The hypomobility can be treated with the patient lying on either the right or left side.

TABLE 13-4

Positioning for Flexion and Extension of the Zygapophyseal (Facet) Joints

Position	Flexion or Extension Side	Extremity of Position
Flexion	Bilateral flexion	Moderate
Extension	Bilateral extension	Moderate

Flexion and left side flexion	Right flexion	End range
Extension and right side flexion	Right extension	End range
Extension and left side flexion	Left extension	End range

"Barriering" (Locking)

If acute pain is not a factor, standard positioning can be used to mobilize a stiff or subluxed joint. When standard positioning is used, the spine is not locked specifically above and below the target segment to keep it in neutral because there is no point in doing so. This is analogous to mobilizing the elbow to regain the last 10° of extension from the biomechanically neutral position. The effort of moving through 60° would be wasted to get to the point where treatment was needed.

If standard positioning is not used, the spine is positioned so that the target joint is moved as close to the end of its reduced physiological (or osteokinematic) range of motion as possible from above and below. This is more properly called "*barriering*," rather than locking, because the latter implies moving nontarget segments to block their motion while retaining the neutral position of the target segment. After the spine has been put in its end range of the movement to be recovered, the segments that will be levered through are "unbarriered" by passively moving them away from the end of range so that they are protected to some degree from the force of the mobilization.

Another variation in positioning is locking down to the affected segment (i.e., locking all the segments above the target joint), leaving the target joint in neutral to "barrier" it against the abnormal restriction. This positioning technique (Figure 13-3) is used when pain is to be treated with subbarrier or pain-dominant techniques (i.e., grade

Figure 13-3 Positioning for a target segment. The clinician's right hand is pulling the pelvis forward while fingers of the clinician's left hand are palpating the spinal segment being mobilized.

1 and grade 2) or when very specific positioning is required to protect an irritable or vulnerable segment above or below the segment.

Mobilization Using the "Pelvis Upward" or "Pelvis Downward" Technique

The mobilization or thrust force is generated through the pelvis. Clinicians can achieve this either by using the strength of their arm (if the patient is relatively small and light) or, more usually, by exploiting gravity through the use of controlled body weight. The force is directed through the uppermost innominate, rocking the pelvic girdle on its opposite trochanter and causing side flexion of the lumbar spine. Imagine the patient lying on the left side. If the pelvis is rocked down toward the feet, left side flexion of the spine results (Figure 13-4, *A*). If the pelvis is tipped up toward the head, right side flexion occurs (Figure 13-4, *B*).

Rocking the "pelvis upward" requires positioning by arm strength and is a somewhat more complicated technique. However, it is generally a more specific technique, and the lead author's experience is that most clinicians are more comfortable using it to deliver the sudden, sharp thrust demanded for manipulation. The "pelvis downward" technique allows the clinician to use body weight; therefore it is easier to maintain for longer periods and is better used for mobilizations.

In the following treatment descriptions, the L3-4 segment is used as an example; however, these techniques may be used throughout the lumbar spine and even into the lower thoracic region.

Left Flexion Hypomobility: "Pelvis Downward" Technique

The patient lies on the right side. The patient's hips are flexed while the target segment (e.g., L3-4) is palpated to ensure that the flexion movement goes at least through this segment (Figure 13-5, *A*). The segment is bilaterally flexed at this point. The patient's lower leg can then be extended so that the patient's thighs are not parallel to each other; this allows rotation of the patient's pelvis when rotation locking is required for the segments below L3-4 (Figure 13-5, *B*).

The segment is now flexed and right side flexed from above; the patient's upper arm is allowed to lie forward in front of the body (this allows the side flexion to be induced into flexion), and the patient's lower arm is pulled caudally and parallel to the bed while the clinician palpates the L3-4 segment to ensure that the side flexion or flexion movement is carried through this segment (Figure 13-5, *C*). The clinician need not be concerned if the segments below are also moving because these will be unflexed later.

The patient's upper arm can now be moved back onto the patient's side without fear of extending the spine, provided the movement is produced at the patient's shoulder and not at the trunk. The patient's lower thigh is pushed backward so that the segments below L3-4 are extended while the clinician palpates L3-4 to ensure that this segment remains in flexion (Figure 13-5, *D*). At this point, the lower segments are in side flexion but away from their

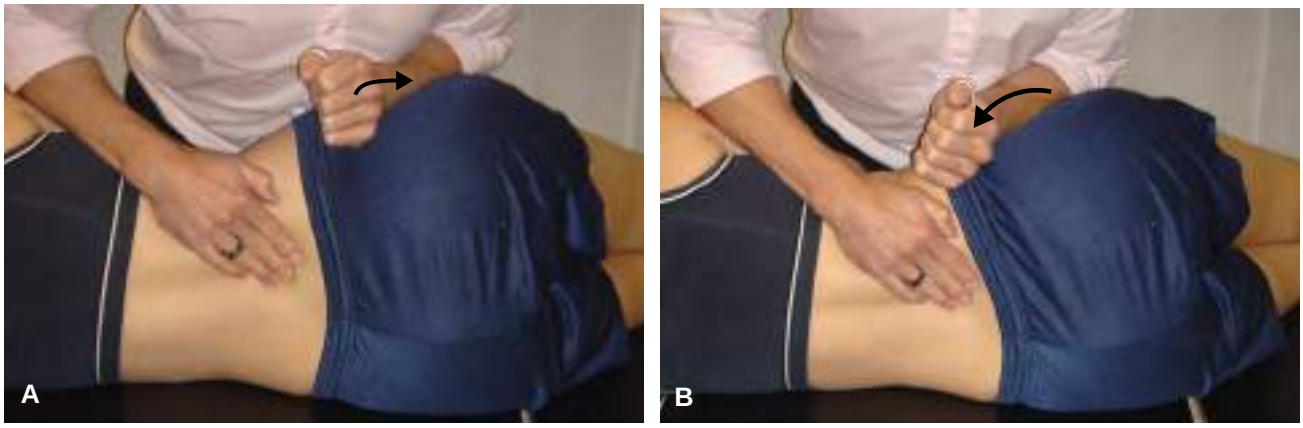

Figure 13-4 **A,** "Pelvis downward" technique. **B,** "Pelvis upward" technique. Note: The fingers of the clinician's right hand are palpating for movement at the spinal segment.

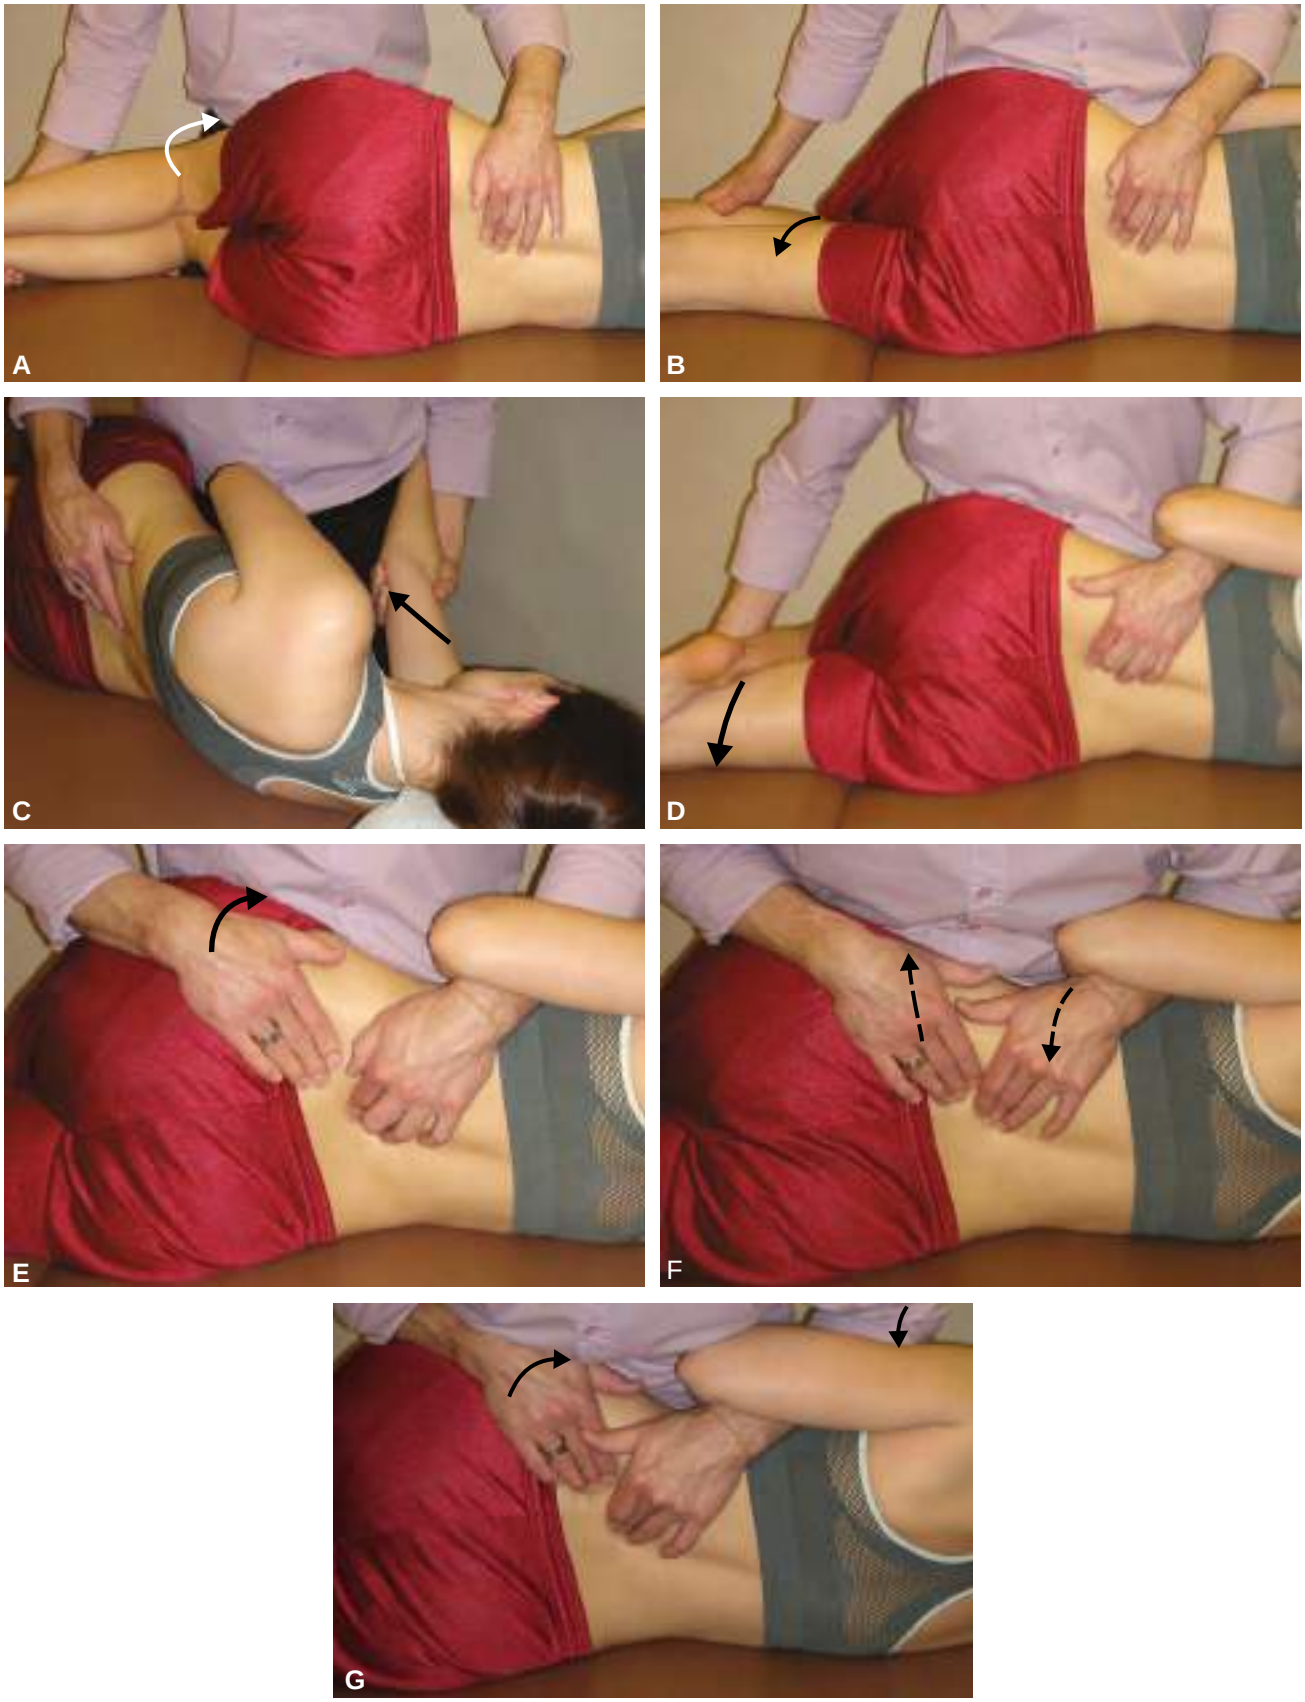

Figure 13-5 Left flexion hypomobility: "pelvis downward" technique. **A,** Bilateral flexion. **B,** Lower leg extension. **C,** Arm is pulled caudally, causing trunk flexion, left side flexion. **D,** Extension of segments below target segment. **E,** Locking of lower segments. **F,** Mobilization of L3-4. **G,** Locking of segments above and below the target segment. Note: The clinician's fingers on the spine are palpating for movement at the spinal segment.

flexion barrier, whereas the target segment is fully flexed and right side flexed, meaning that the left zygapophyseal joint is fully flexed, at least as far as its restriction allows. In essence it is at its abnormal pathological barrier and ready to be mobilized or manipulated.

To safeguard the patient's lower segments a little more, the patient's lower segments are rotated to lock them. This is accomplished by rotating the patient's pelvis forward toward the clinician while L3-4 is palpated to ensure that the rotation does not go through this segment (Figure 13-5, *E*). If rotation in the segment occurs, coupled side flexion will alter the position and perhaps undo the previously induced side flexion, depending on the direction of coupling at this segment. The rotation should be as pure (i.e., axial) as possible to minimize the coupled side flexion, although this must occur to some degree, if not at this point, then when the treatment technique is applied.

The segments below the target segment are now locked away from a flexion or extension pathological barrier (at least as much as the clinician is able to do), the segments above the target are locked in flexion and right side flexion (however, because the mobilization force going through the segments is subsequent to that going through the target segment, it should be minimal if the appropriate force is applied), and the target segment's left zygapophyseal joint is at its flexion barrier and ready to be mobilized (Figure 13-5, *F*).

The clinician "snuggles" against the patient's abdomen, linking the clinician's cranial arm with the patient's upper arm, and palpates the target segment while pulling the patient toward the clinician. The flexor aspect of the clinician's caudal forearm makes contact with the soft part of the patient's innominate between the trochanter and the crest, approximately over the piriformis muscle belly, and pulls the patient's pelvis forward. The patient now is logrolled into the clinician and is stable (Figure 13-5, *G*). The patient's pelvis then is independently rotated forward, which sequentially rotates each spinal segment to the left (i.e., the lower vertebra is rotating to the right, of course, but the segment is rotating to the left), until slight movement is felt at the target segment. This is then undone by reversing the pelvic rotation, leaving the target segment unrotated.

The clinician's chest is then lowered onto the forearm, which rests on the patient's pelvis, and the clinician applies body weight onto the arm by gently lunging from the left leg. The final direction of the technique is against the worst end feel but is roughly in a sagittal plane. Whether a single thrust, multiple minithrusts, or prolonged grade 3+ or grade 4+ techniques are used depends entirely on the pathological barrier to be mobilized and the clinician's decision whether to manipulate, taking into account cautions and contraindications.

Left Flexion Hypomobility: "Pelvis Upward" Technique

The same hypomobility can be mobilized with the patient lying on the left side. One side may be chosen over the other because of the clinician's preference or the patient's requirements. For example, if a left rotatory instability is present at L5-S1 or L4-5 (or any segment below the target segment), the patient's pelvis cannot be pulled forward if the patient is lying on the left side because this would produce right rotation; because of the right rotatory instability, locking could not be achieved. Similarly, if attempts at locking the lower segments with rotation produce discomfort to the point where the patient will not tolerate the attempt, an alternative position must be used.

With the patient in the left side lying position, the lumbar spine is flexed from below by flexing the patient's hips (Figure 13-6, *A*) and the patient's legs are taken from the parallel orientation by extending the lower leg in the same manner as for the previous technique. However, another method now must be used to produce flexion and right side flexion from above. The patient's upper arm is allowed to hang forward to bias the trunk to flexion in the same manner as before, but now the patient's lower arm is pulled cranially and parallel to the bed to produce right side flexion and flexion (Figure 13-6, *B*).

The clinician brings the patient's lower arm back onto the patient's side. The clinician's cranial arm is linked through and the clinician palpates the segment in the same manner as in Figure 13-5 as the patient's lower thigh is extended until the segments below the target segment are moved out of flexion and then rotated to lock them.

The patient is logrolled into the clinician in the same manner as in the previous technique, but the clinician now pulls the patient's pelvis upward, away from the table, rocking it onto the cranial side of the patient's trochanter and thereby producing side flexion to the right (Figure 13-6, *C*). The clinician holds the pelvis in that position by applying controlled body weight through the forearm. The mobilization or thrust is achieved using graded amounts of body weight to the patient's pelvis. Because the pelvis is already prerocked, the clinician's "drops" (i.e., the controlled body weight through the clinician's forearm to the patient's pelvis) do not have to deliberately produce side flexion but can be more or less straight downward, which is far easier.

Left Extension Hypomobility: "Pelvis Downward" Technique

The patient lies on the left side with the hips extended as the clinician palpates the target segment (L3-4 in this case) to ensure that the extension movement runs through the segment (Figure 13-7, *A*). The patient's hip is then flexed to allow pelvic rotation, and the clinician makes sure that the target segment does not flex to take the legs out of their parallel orientation.

The patient's upper arm then is positioned behind the patient so that the side flexion is induced into extension (Figure 13-7, *B*). The patient's lower arm is pulled caudally but away from the bed to right side flex and extend the spine (Figure 13-7, *C*).

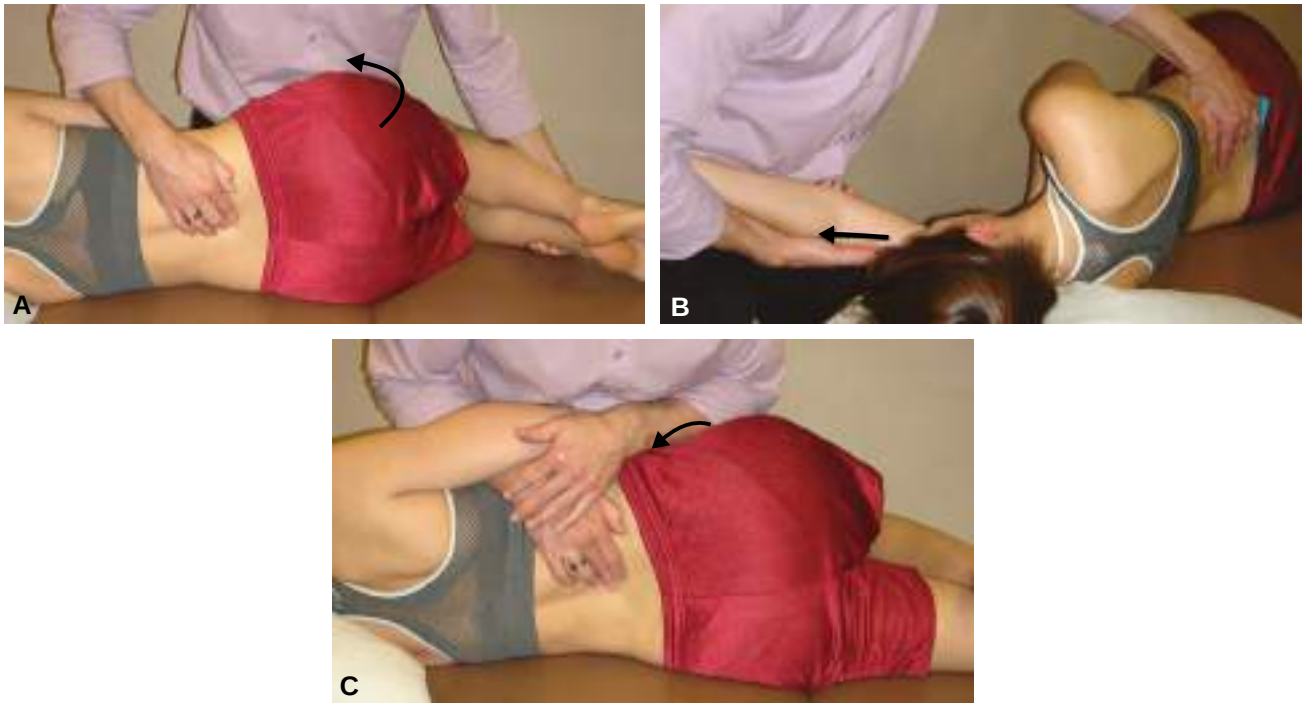

Figure 13-6 Left flexion hypomobility: "pelvis upward" technique. **A,** Flexing the lumbar spine. **B,** Lower arm is pulled cranially. **C,** Rocking the pelvis upward. Note: The fingers of the clinician's right hand are palpating for movement at the spinal segment.

The patient's upper arm is now moved back onto the patient's side, and the patient's lower thigh is pulled forward to flex the segments below L3-4 while the clinician palpates L3-4 to make sure this segment remains in extension (Figure 13-7, *D*). At this point, the lower segments are away from their extension barrier but in side flexion, whereas the target segment is fully extended and left side flexed, meaning that the left zygapophyseal joint is fully extended at least as far as its restriction allows. The L3-4 left zygapophyseal joint is now at its abnormal pathological barrier and ready to be mobilized or manipulated.

The patient is now logrolled toward the clinician, locking the lower segments with axial rotation (Figure 13-7, *E*), and the clinician applies a caudal force to the patient's innominate, with the forearm resting on the innominate, to rock the pelvis downward over the trochanter.

Right Extension Hypomobility: "Pelvis Upward" Technique

As in the previous description, the target segment needs to be extended and right side flexed; however, the patient now is lying on the left side. Again, the clinician's preference or the patient's requirements determine which side lying position is used. For example, if a left rotatory instability is present at L5-S1 or L4-5 (or any segment below the target segment), the patient's pelvis cannot be pulled forward if the patient is lying on the right side because this would produce left rotation; because of the left rotatory instability, locking could not be achieved. Similarly, if attempts at locking the lower segments with left rotation produce discomfort to the point where the patient will not tolerate the attempt, an alternative position must be used.

With the patient in the right side lying position, the patient's lumbar spine is extended from below by extending the patient's hips, and the legs are taken from their parallel orientation by flexing the patient's lower leg in the same manner as for the previous technique (see Figure 13-7, *A* which shows the opposite side). However, now another method must be used to produce extension and right side flexion from above. The patient's upper arm is positioned behind the patient to bias the trunk to extension in the same manner as before, but now the patient's lower arm is pulled cranially and upward toward the ceiling, away from the bed, to produce right side flexion (Figure 13-8, *A*).

The clinician brings the patient's lower arm back to the patient's side. The clinician's cranial arm is linked through the patient's upper arm and the clinician palpates the target segment as the patient's lower thigh is flexed until the segments below the target segment are moved out of extension. These segments are then rotated forward (i.e., right rotation) to lock them (Figure 13-8, *B*). The patient is logrolled into the clinician in the same manner as in the previous technique, but now the clinician pulls the patient's pelvis upward, away from the table, rocking it onto the cranial side of the trochanter, thereby producing side flexion to the right. The clinician holds the patient's pelvis in this position by applying controlled body weight through the forearm (Figure 13-8, *C*). The mobilization or thrust is achieved using graded amounts of the clinician's body weight to the patient's pelvis; because the patient's pelvis is already prerocked, the clinician's "drops" do not have to deliberately produce side flexion but can be more or less straight downward, which is far easier.

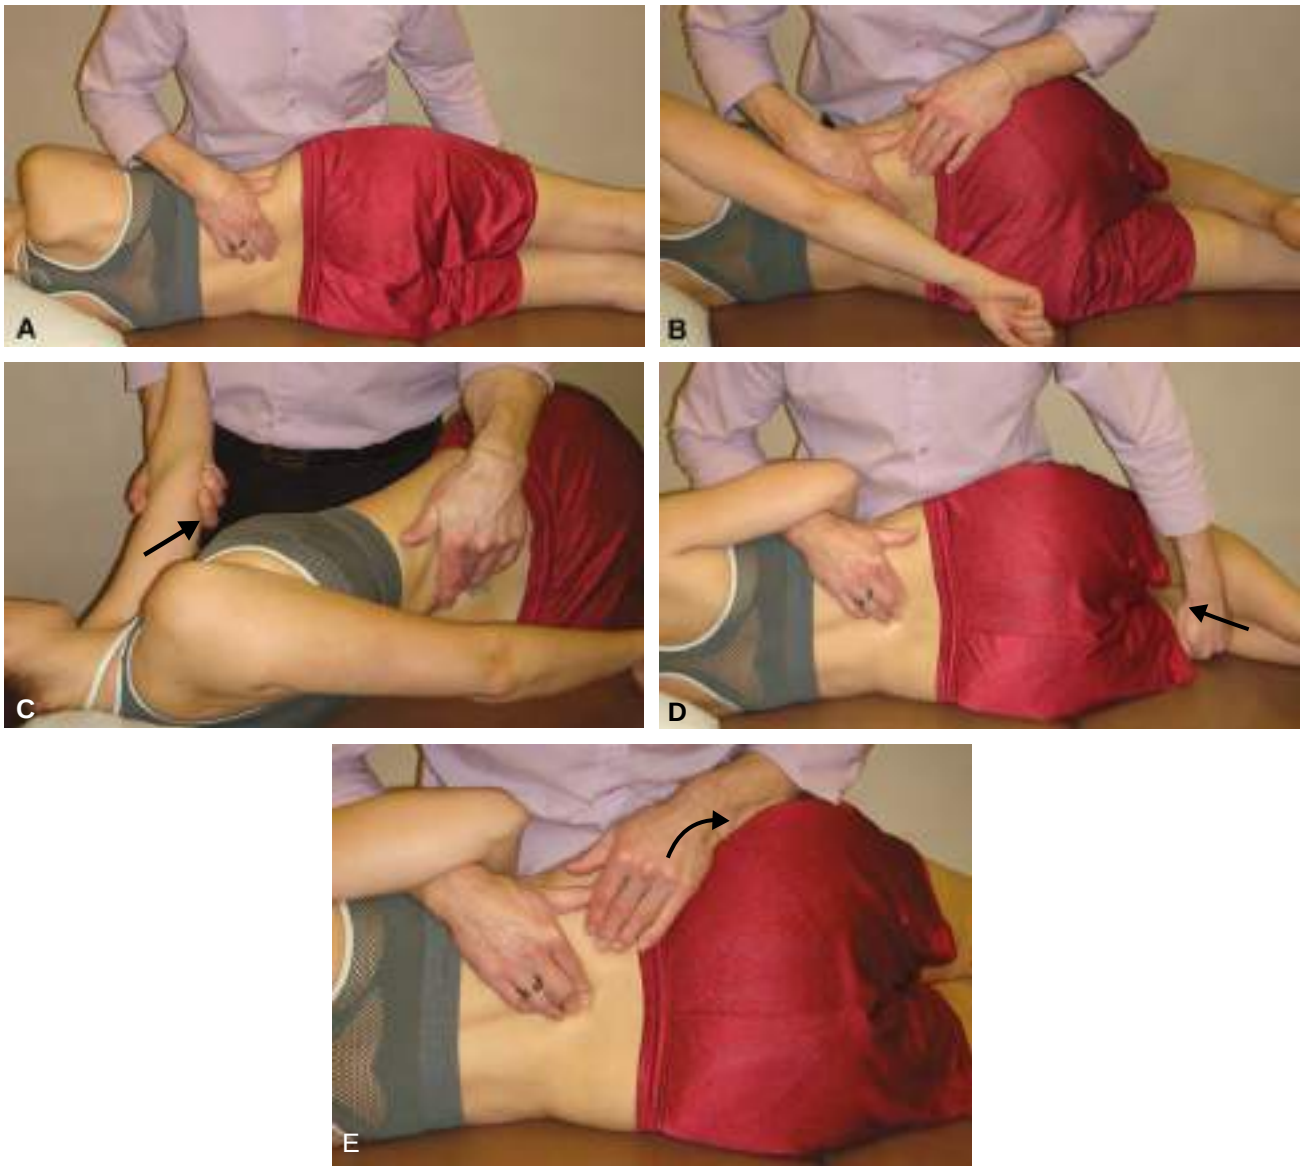

Figure 13-7 Right extension hypomobility: "pelvis downward" technique. **A,** Extension of L3-4. **B,** Patient's arm is drawn behind to encourage extension. **C,** Lower arm is pulled caudally. **D,** Flexing segments below L3-4. **E,** Extension mobilization, pelvis down technique. Note: The fingers of the clinician's right hand are palpating for movement at the appropriate spinal segment.

Superior Vertebrae Hypomobility: "Rotation Lock"

If a problem above the target segment must be treated (e.g., instability or discomfort with side flexion barriering such that either side flexion or the flexion or extension pathological barriers cannot be achieved), the vertebrae may be locked by means of rotation, provided the rotation does not enter the target segment. This technique is also useful when a considerable size discrepancy exists between the clinician and the patient because rotation is easier to achieve. Side flexion requires more clinician upper body strength than does rotation, and it is not as easy to use specifically. However, care must be taken to avoid rotating through the segment (if the clinician wants to avoid issues with the coupling theory). The rotation may be combined with either flexion or extension, and the choice depends on the condition of the segments to be locked. For example, if a painful extension hypermobility exists, it can be avoided by locking the segments with rotation and flexion; because the lock does not enter the target segment, it does not matter whether flexion, extension, or right or left rotation is used.

For the lock with rotation technique, the patient lies on one side. The clinician then barriers the target segment from below through flexion or extension, as required by the dysfunction, in the manner already described. The patient's lower arm is now pulled anteriorly, away from the body, which rotates the patient's trunk around the vertical axis of the body (Figure 13-9, *A*). *If the patient is lying on the left side, right rotation occurs; if the patient is lying on the right side, left rotation occurs.*

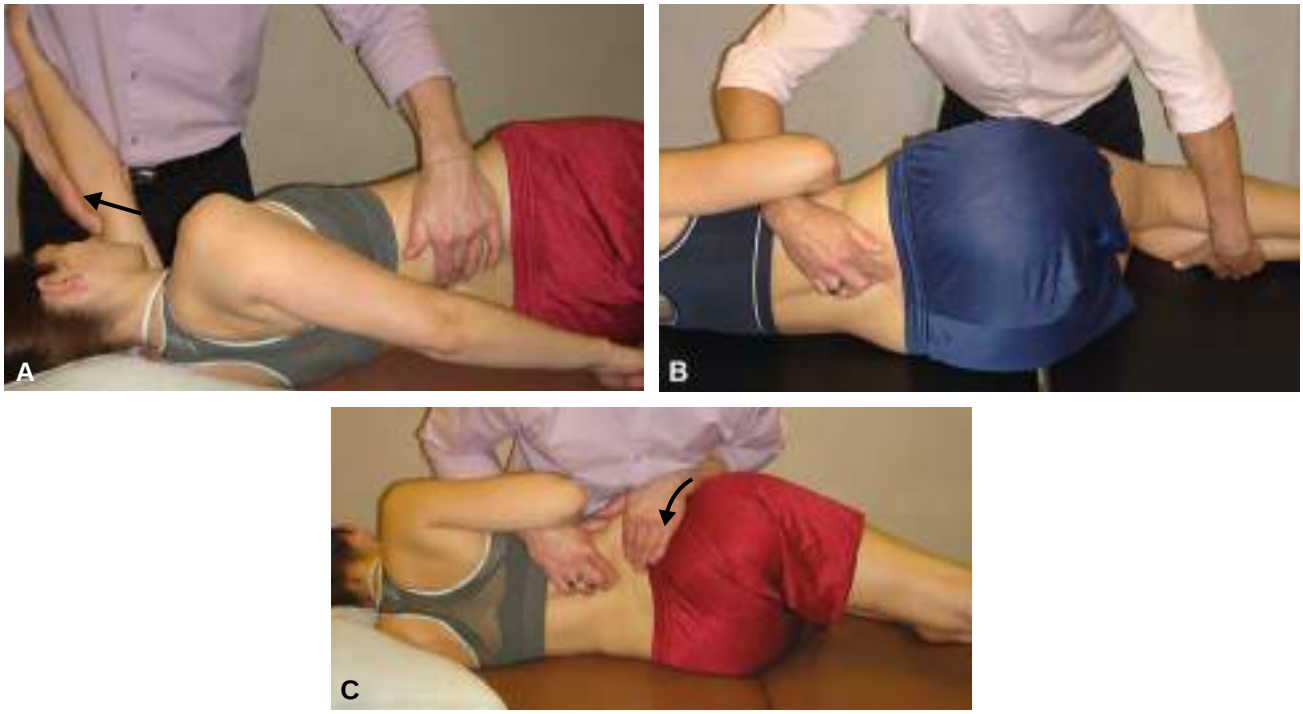

Figure 13-8 Right extension hypomobility: "pelvis upward"" technique. **A,** Arm is pulled cranially and upward. **B,** Patient's lower thigh is flexed. **C,** Right side flexion, pelvis up technique. Note: The clinician's fingers on the spine are palpating for movement at the appropriate segment and when it stops.

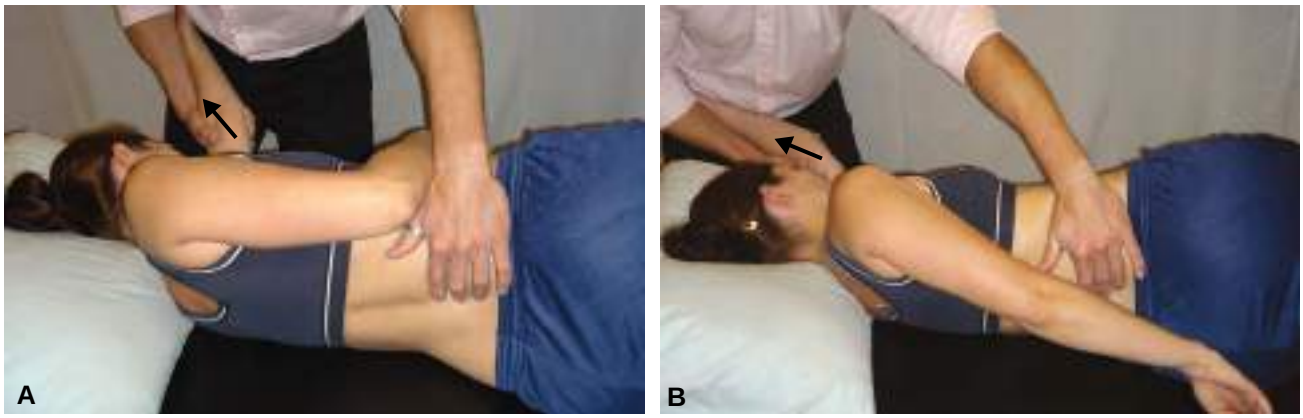

Figure 13-9 Superior vertebrae hypomobility: "rotation lock." **A,** Patient's lower arm is pulled anteriorly, causing right rotation. **B,** Extension rotation. Note: The fingers of the clinician's left hand are palpating for movement at the appropriate segment and when it stops.

To bias the rotation to flexion, the patient's upper arm is allowed to hang forward in front of the body, and the patient's lower arm is pulled parallel to the bed. If extension rotation is required, the patient's upper arm is positioned behind the patient, and the patient's lower arm is pulled away from the body but toward the ceiling (Figure 13-9, *B*).

CAUTIONS (YELLOW FLAGS) AND CONTRAINDICATIONS (RED FLAGS) TO MANUAL THERAPY

The risk of serious adverse effects from manipulative therapy (and presumably mobilization) to the lumber spine is considered very low.[34,58–64] However, the actual risk is not well understood. In a review of the literature, Assendelft et al.[35] found 61 cases of either cauda equine syndrome or lumbar disc herniation after manipulation, approximately 21% of all serious complications in this review. Another review of the literature for the years 1911 to 1989 found only 10 cases of CES related to manipulative treatment.[36]

Some clinicians may believe that only one contraindication exists to manual treatment of the spine, intolerance to the technique, and that all other considerations are "detail." However, the detail is important. Presumably, manipulation carries a higher threat to the patient in that the force is sudden and not under the patient's control;

therefore any unfortunate effect occurs without warning if the detail has not been recognized before the technique is applied. This is not to say that mobilization does not carry some degree of risk. Indeed, any treatment that is completely without risk is almost certainly without benefit. Any adverse effects from mobilization are likely to be less drastic (i.e., are less likely to cause fracture and bleeding) than manipulative techniques, especially in the lumbar spine, where injuries to the arterial system seem not to occur unless a predisposition exists. Therefore all general contraindications to manipulation and mobilization must be considered as either absolute or relative contraindications.

Absolute contraindications are those that scream "don't touch me," and this demand must be obeyed by all clinicians who care anything about the patient's and their own well-being, at least until adequate objective diagnostic imaging and other medical tests have ruled out any risk. For example, multiple sclerosis produces spinal cord signs and symptoms, but it is not necessarily a contraindication to manual therapy. Examples of absolute contraindications include instability, fractures, acute pain, severe osteoporosis, bleeding disorders, acute CES, spinal cord compromise, severe rheumatoid arthritis, a suggestion of cancer or visceral disease, and a truly disoriented or psychotic patient.

Relative contraindications are those that are contraindications for some clinicians, usually the newcomer to manual therapy, but not for the more experienced manual therapist; however, even these require extreme caution. Relative contraindications include pregnancy, spinal stenosis, spondylolisthesis in a nontarget segment, a patient with a history of cancer who has had a recent clear screening test, equivocating signs of disc herniation, atypical patterns, neurological signs and symptoms, collagenous disease, and a history of poor response to manual techniques.

The main risks are misdiagnosis of cancer (especially prostatic or metastatic) and enlargement of a disc herniation with or without cauda equina compression, but other conditions must be considered. Table 13-5 lists contraindications and the possible problems that may arise if these risks are realized.

Clinical Note

Clinicians must understand that mere lists are not the same as being faced with problematic conditions, and the clinician must be more adept at recognizing presentations that preclude manual therapy than at performing manual therapy.

For the newcomer to manual therapy, the wise course is to develop a clear understanding of the indications for manipulation and to avoid treating any patient who does not fall within these strict parameters, at least until the clinician becomes more experienced and confident with both examination and treatment techniques. The profile of the patient with mechanical back pain has been described numerous times, even in this chapter. Flynn et al.[54] looked at factors that would determine which patients would have a greater chance of a successful outcome from manipulation, and Fritz et al.[49] investigated factors that would reduce that chance. Between the two studies, a shorter duration of symptoms, minimum referred pain, restricted range of motion in the lumbar spine, and normal hip rotation range of motion indicated a better chance of a successful outcome, particularly when these factors were clustered in the individual patient. In effect, these criteria suggest the standard patient with mechanical low back pain who does not have more complex problems or contraindicating signs or symptoms. It is reasonable to suppose that these factors similarly would point to a successful outcome for mobilization and that they would also indicate patients with a greater likelihood of responding well to manual treatment in general.

High-Risk Indicators in Spinal Mobilization

General indicators of high risk in the mobilization of the lumbar spine, especially manipulation, include suggestions of disc herniation and cauda equina syndrome:

- Radicular pain, especially bilateral
- Paresthesia, especially bilateral
- Severe somatic sciatica, especially bilateral
- Motor paresis, especially multisegmental and bilateral
- Sensory paresis, especially multisegmental and bilateral
- Saddle paresthesia
- Saddle anesthesia
- Segmental or multisegmental hyporeflexia or areflexia
- High frequency, low-volume bladder
- Bladder incontinence
- Lack of rectal expulsive power
- L1 or L2 palsy
- Exacerbations related to diet
- Hematuria
- Severe leg pain without straight leg raising (SLR) limitation
- Severe limitation of range of motion
- Deviation with radicular pain

Signs of an Enlarging Disc Herniation

- Peripheralization of symptoms
- Bilateral symptoms
- Appearance of radicular pain
- Appearance of neurological signs
- Numbness that replaces paresthesia
- Increase in the severity of the articular signs
- Appearance of urinary retention or incontinence signs
- Decrease in the straight leg raise or prone knee bending

TABLE 13-5

Contraindications and Cautions to Lumbar Manipulation and Mobilization

Cautions and Contraindications	Characteristics and Potential Problems
Neoplastic disease	Medical diagnosis: possibility of fracture
Cauda equina signs and symptoms	Bilateral, multisegmental lower motor neuron signs and symptoms, including bladder dysfunction: possibility of serious compression damage and permanent palsy
Spinal cord signs and symptoms	Multisegmental upper motor neuron signs and symptoms: possibility of serious compression damage and permanent deficit
Nonmechanical causes	Minimal musculoskeletal signs and symptoms: wasted effort and delay in getting appropriate care
Trilevel segmental signs	Disc compression (can affect a maximum of two levels of the nerve root): possibility of neoplastic disease, spondylolisthesis, or cauda equina compression
Neuropathic pain	Nerve root damage or severe inflammation
Sign of the buttock	Empty end feel on hip flexion; painful weakness of hip extension; limited straight leg raising, trunk flexion, and hip flexion; noncapsular pattern of hip restriction; swollen buttock: Possible serious disease (e.g., sacral fracture, neoplasm, infection)
Various serious pathologies	Empty end feel and severe multidirectional spasm
Adverse joint environment	Spasm: acute inflammation, fracture
Acute fracture or dislocation	Immediate onset of posttraumatic pain and loss of function
Bone disease	Deep pain and relatively minimal musculoskeletal signs: wasted effort and possibility of a fracture
Acute rheumatoid arthritis episode	Medical diagnosis: possibility of increased tissue damage and severe exacerbation
Infective arthritis	Severe inflammation and reddening: delay in getting appropriate medical care
Emotionally dependent patient	Seeks manipulation: long-term dependency without much hope of benefit
Chronic pain or fibromyalgia-type syndromes	Inadequate signs to explain the patient's widespread symptoms: long-term dependency without much hope of benefit
Rheumatoid arthritis	Medical diagnosis: possibility of increased tissue damage and severe exacerbation
Osteoporosis	Medical diagnosis: fracture
Spinal nerve (root) compression	Segmental neurological signs: probable wasted effort and possibility of increasing the compression
Spondylolisthesis	Radiographic evidence: exacerbation of signs and symptoms
Hypermobility	Clinical finding: increased hypermobility and pain
Acute pain states	Onset of pain before or simultaneous with tissue resistance: possibility of severe exacerbation
Pregnancy	Risk of ligamentous damage as a result of relaxing effect and risk of coincident miscarriage
Repeated steroid injections	Tearing of collagen tissue
Long-term systemic steroid use	Tearing of collagen tissue and fracture
History of neoplastic disease	Risk of recurrence
Distal pain on movement	Acute root compression or severe joint inflammation
Nuclear prolapse or meniscoid entrapment	Springy end feel
Central or lateral stenosis	Paresthesia that dominates pain

SUMMARY

Manual therapy for mechanical low back pain, particularly lumbar hypomobility, is reasonably well established, both from a research perspective and as a standard of care for clinical treatment. The risk is low and the benefits, at least over the short term, are great, as long as appropriate inclusion and exclusion criteria are met. This means that before applying any technique, clinicians must have exercised competent diagnostic skills to rule out medical conditions that would contraindicate a particular type of manual treatment.

CHAPTER 14

Lumbar Spine: Treatment of Motor Control Disorders

PAUL W. HODGES, PAULO H. FERREIRA, MANUELA L. FERREIRA

INTRODUCTION

Interventions that aim to modify the manner in which patients with low back pain (LBP) control their spine and pelvis have become popular over the past few decades. These interventions are based on the premise that a patient's pain is related to loading of spine and pelvis tissues and the potential role of suboptimal posture and postural alignment, muscle activation and movement in this loading. These motor control features may either be a precursor to the onset of pain or injury (e.g., repetitive suboptimal loading of tissues) or a consequence of pain or injury (e.g., adaptation of motor control to protect an injured structure or poor control linked to some "inhibitory" process). There is substantial evidence for the efficacy of these approaches,[1] but the application of each approach has important considerations. Although some approaches have advocated relatively straightforward application of exercise, the prevailing view is that exercise must be tailored to the individual patient.[2]

Although, historically, there had been an assumption that pain is related to "instability,"[3] it is increasingly clear that patients can present across a spectrum from too little to too much control, and the focus on "instability" is too narrow and poorly defined. Instead, the focus has shifted to dynamic control of the spine and pelvis.[4] With this in mind, it is clear that exercise interventions aimed at rehabilitation and prevention of low back and pelvic pain should not simply maximize stiffness but instead must optimize the balance between movement and stiffness as appropriate for specific functions. Many exercise interventions have been proposed to improve control of the spine and pelvis, and much has been written about the goals of training and how this can be achieved.[5] The approach outlined in this chapter assumes that features of the manner in which an individual controls his or her spine and pelvis may suboptimally load the tissues, and through careful consideration of muscle activation, posture and postural alignment, movement, sensation (both proprioception and kinesthesia as well as other sensory inputs) and the multiple functions of the trunk muscles, within a biopsychosocial view of a patient, this approach aims to restore optimal loading. This may involve targets as diverse as increased or decreased muscle activation, modification of spinal alignment, optimized load sharing between adjacent body segments, coordination of postural and respiratory functions of the trunk, and exposure to threat. This diverse approach requires careful assessment and precise application of training strategies. The purpose of this chapter is to consider the requirements for optimal motor control of the spine and pelvis, review the changes in this system in the presence of low back and pelvic pain, provide an overview of clinical assessment of the patient with pain, introduce strategies to train or restore optimal motor control of the spine and pelvis, and review the evidence for the efficacy of interventions that aim to improve the motor control of the spine and pelvis.

DYNAMIC CONTROL OF THE LUMBAR SPINE AND PELVIS

Requirements for Dynamic Motor Control of the Lumbar Spine and Pelvis

For function the spine and pelvis must be controlled dynamically. The requirements for dynamic control can be described in terms of a range of interdependent goals that ultimately must be integrated to meet the objectives of stiffness and movement. The term *stability* is generally defined as the property of a structure that allows it to return to equilibrium if perturbed.[5] This applies to both a position and a trajectory of movement: to maintain or return to a specific alignment or to a path of movement. Thus, by definition, stability is achieved by a balance between movement and stiffness, depending on the task (e.g., high stiffness may be required when lifting a weight from the floor; whereas motion is required during walking to transfer and dampen forces, and minimize energy

expenditure). This contrasts the simple assumption that is commonly applied in clinical interventions that implies the spine must be stiffened. Rather than describing poor spine control in terms of "more" or "less" stability (i.e., "instability"), it has been argued that control of the spine is best described in terms of "robustness."[6] A robust system is one in which control of position or movement can be maintained despite various challenges, whereas a system with low robustness fails even in the presence of minor challenges. This robust system is maintained by a combination of movement and stiffness, depending on the task. For instance, if the stiffness of the spine is high in quiet standing, balance is compromised even with minor disturbances,[7] yet if the spine moves and is controlled dynamically, the robustness of maintenance of spine control is enhanced and the body can respond effectively to more challenging disturbances.

Clinical Note

A robust spine is one in which control of a static position or a dynamic movement is maintained despite different challenges being applied to the spine.

Whether the objective is to move or stiffen the spine, the moving or stiffening depends on the contribution of muscles. In vitro experiments have shown that the lumbar spine without muscle buckles when loaded with as little as 9 kg (~90 N).[8] Buckling of the spine (i.e., lack of stability of individual segments) can involve any combination of the six degrees of freedom that must be controlled at each intervertebral segment (i.e., three rotations and three translations) and at the sacroiliac joints (Figure 14-1). It is the static control of rotation buckling that is the primary consideration in most contemporary models of spine stability.[5,8,9]

Stiffening the muscles and their tendons can stabilize the spine. In this sense, it may be assumed that the stiffer the spine, the better. If the spine is stiffened by muscle contraction, then greater force is required to perturb it. Stiffness control by co-contraction of the trunk muscles is one of the mechanisms used by the nervous system to meet the demands for stability and to control buckling of the spine. However, stiffening the spine is not the only option available, and many functions do not involve simple co-contraction but instead use carefully orchestrated patterns of muscle activity using movement to absorb and dissipate forces, transfer loads, minimize energy expenditure, and enable coordination of spine control demands with the other functions of the trunk muscles (e.g., breathing). Although co-contraction and stiffening are used in some functional situations, they are not the only solution, because many functions involve dynamic control of the movement.

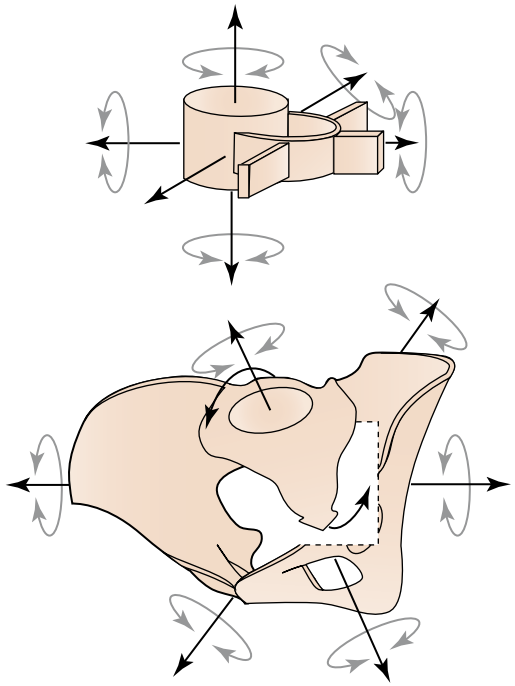

Figure 14-1 Six degrees of freedom, including rotation about and translation along each of the three orthogonal axes, must be controlled to maintain healthy spinal and pelvic function.

An illustration of the role of movement in the control of robust stability of the spine comes from the postural adjustment associated with arm movement. Studies of arm movement show that when a limb is moved, the nervous system does not simply stiffen the trunk to support the movement, but instead, the spine and pelvis are moved in the direction opposite to the perturbation in advance of the perturbation.[10,11] This is achieved by alternating activity of the trunk flexor and extensor muscles rather than co-contraction. Such movement will act to dampen the force impact on the spine, and limit the effect of the perturbation. People who stiffen their spines have an ability to allow greater perturbation to the spine[12] and to maintain balance.[13] Thus, although coordinated movement of the spine requires more complex control strategies than simple stiffening (and hence a more complicated controller), it is likely to be more ideal in the long term.

A final consideration is that, if one looks beyond the demand to control buckling of the spine and motion, it is obvious that the stability of other functions needs to be considered. For instance, the spine contributes to respiration. This is not only as a result of the direct contribution of spinal movement to expansion of the thorax during inspiration[14] but also because small-amplitude motions of the spine are required to compensate for the disturbance to balance caused by breathing.[15,16] If spine stability was maintained simply by stiffening, respiratory efficiency would be compromised because of the reduced contribution of spinal movement. Similarly, balance control requires a contribution from movement of the hips and trunk. Two basic balance strategies have been described:

the **"ankle" strategy** and the **"hip" strategy**.[17] Although postural equilibrium can be maintained in quiet stance and with minor perturbations by movements about the ankle with the body acting as an inverted pendulum (i.e., ankle strategy), when the perturbations are increased, torque at the ankle is insufficient to maintain balance and movement of the hip and trunk is required (i.e., hip strategy). Thus the ability of the spine to move in a manner that is essential to maintain balance. If movement is restricted, balance is compromised.[18] Finally, movement is required to minimize energy expenditure. For instance, rotation of the spine and pelvis around each axis during gait reduces the displacement of the center of mass and the associated energy requirement to achieve the movement.[19]

In summary, healthy function of the spine requires maintenance of balance between movement and stiffness. As such, simple attempts to stiffen the spine through muscle co-contraction, although appropriate under some circumstances, are unlikely to be ideal in many tasks. Thus dynamic control of the spine requires complex control of flexible strategies to meet the multiple demands placed on it to function effectively.

Guiding Principles for a Healthy Functioning Spine

- Static models are unlikely to be able to predict the ideal strategies for motor control.
- Optimal stability is not simply achieved by maximal stiffness.
- Spine requires movement for ideal function.

Guiding Principles: Requirements for Spinal Control

STATIC MAINTENANCE OF POSITION

- Control of postural alignment
- Control of segment translation/rotation

DYNAMIC CONTROL OF MOVEMENT

- Movement for function
- Movement for shock absorption and braking action
- Movement for force/load transfer
- Movement to minimize energy expenditure
- Movement for other functions, such as:
  - Respiration
  - Balance control

Neural Mechanisms for Dynamic Control of the Lumbar Spine and Pelvis

To meet the demands placed on the spine, Panjabi[1] recognized that lumbopelvic stability depends not only on the contribution of the passive elements (including the intervertebral discs, ligaments, joint capsules and facet joints) but also on the active elements (i.e., muscles) and the controller (i.e., the nervous system). When the spine is considered in a static sense, only one muscle activation strategy is required to meet the demands of stability: co-contraction of the large superficial trunk muscles to increase spinal stiffness. Observations from a number of tasks such as lifting are consistent with this proposal.[20] Although control of buckling is critical for the maintenance of healthy spinal function, as mentioned in the previous section, this control fails to consider how *movement* of the spine is controlled or how *stability* of the movement trajectory is maintained. Furthermore, the contribution of trunk muscles to other homeostatic functions such as balance and breathing and continence further complicates the task for the nervous system in controlling the spine and pelvis. Strategies other than simple co-contraction are available and are necessary to control the spine and pelvis in a dynamic sense. It is unlikely one will be able to predict the ideal strategies for lumbopelvic control or the ideal exercise interventions for back pain from basic static models of stability.

The task for the nervous system to control the spine and pelvis is immense. It must detect the current status of the stability of the spine utilizing input from the range of mechanoreceptors in the muscles and passive structures of the spine/pelvis, in addition to input from the visual and vestibular systems regarding the status of the body with respect to the world. It must consider the demands of the intended action by consideration of the dynamics of the body using an internal model of body dynamics built up over a lifetime of movement experiences, and select an appropriate strategy of muscle activity to meet the demands of movement and stability to accomplish the desired task. It must initiate a muscle activation strategy, then determine the outcome, and make any appropriate adjustments to ensure success. The complexity of this control and the level of the nervous system involvement are primarily determined by temporal demands. When the nervous system responds to an unexpected disturbance such as a trip or a slip, the time delay must be short, the complexity is limited, and the strategy involves a combination of reflex and triggered (i.e., multisegmental responses that are faster than voluntary movement but more flexible than reflexes) components. This type of control is mediated by feedback (i.e., *feedback adjustment*). When the task is predictable (e.g., voluntarily initiated tasks such as lifting a mass or catching a ball), there can be sufficient time to plan and optimize the control. In this situation the postural adjustment precedes the movement and is referred to as a *feedforward or preparatory adjustment*.[11] Although the simplest strategy to meet the demands for control might appear to be stiffening the trunk by co-contraction, in view of the necessity to maintain mobility, more complex strategies are involved. A third type of control involves the *maintenance of low level tonic activation* of muscle.[21] The basis of this strategy is that, because reflexes involve

a delay and not all challenges can be predicted, low-level tonic ongoing activity provides a first line of defense to control the segment in cases in which the spine is unexpectedly challenged. Feedforward and feedback strategies can add to this control as able or required. Trunk muscles are known to act in this manner. For example, gentle activity of a few percent of maximum voluntary contraction is maintained in quiet upright postures.[5]

Guiding Principles: Strategies Available for Optimal Spine Control

- *Reactive control*: feedback-mediated strategies in response to sensory input from unexpected challenges
- *Anticipatory control*: feedforward strategies initiated in advance of a predictable challenge
- *Ongoing tonic muscle activation*: first line of defense to provide control before reflexes can be initiated

A critical element in this system is accurate sensory information from the spine and pelvis. Afferent input from the mechanoreceptors in the intervertebral disc, joint capsules, ligaments, and muscles all contribute to the awareness of spinal position and movement. Muscle proprioceptors are particularly dense in the deep muscles,[22] providing the potential to detect small intervertebral motion. Furthermore, electrical stimulation of the mechanoreceptors in the intervertebral disc[23] and joint capsule of the sacroiliac joint[24] lead to short latency responses of the paraspinal and pelvic muscles. This provides evidence of basic spinal mechanisms to maintain spinal control. Of note, deficits in sensory function are commonly reported in LBP,[25,26] which may underlie changes in the accuracy of movement control.

One way to view movement control strategies is to consider a spectrum from static/stiffening control at one end and dynamic strategies involving movement at the other (Figure 14-2). Tasks that involve high load, poor predictability, and the necessity to maintain the alignment of the spine are likely to involve co-contraction strategies, as this is likely to provide the greatest amount of stiffness. In contrast, tasks that involve low load and greater predictability or tasks that require greater movement are likely to involve a more complex dynamic strategy. This simple conceptual model considers just a few of the large number of factors considered by the nervous system when selecting an appropriate response but can help us understand the decisions that are made and the muscle activation patterns that are initiated to meet the movement demands. The nervous system has a large number of muscles available to contribute to these control strategies. Although all muscles are likely to contribute to some extent, anatomical features are likely to influence the decision to recruit specific muscles for a particular function.

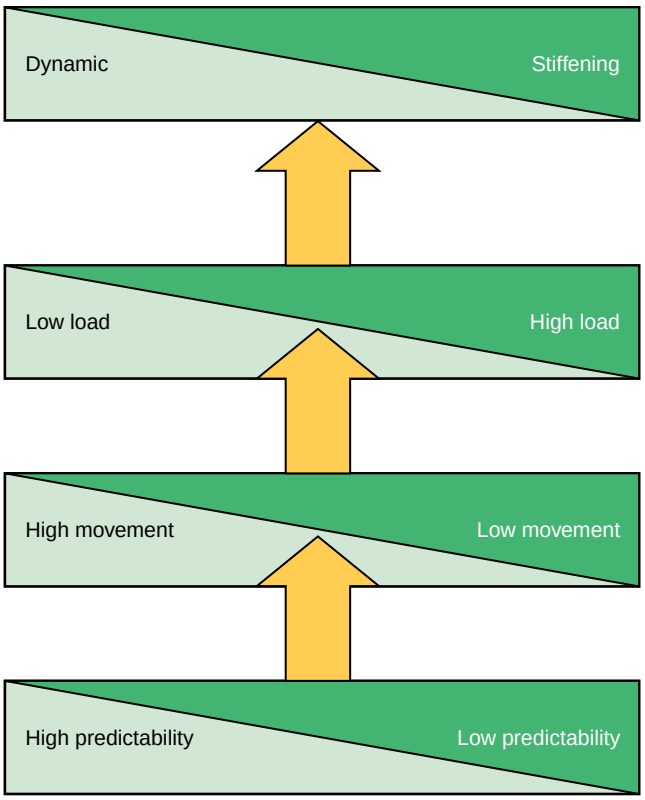

Figure 14-2 A spectrum of control strategies, ranging from dynamic control to static stiffening, is available to the nervous system, depending on task demands. The strategy used is influenced by a range of factors, including the load, movement requirement, and predictability.

Muscular Mechanisms for Control of the Spine and Pelvis

Large superficial muscles of the lumbar spine and pelvis are required for optimal control of the spine. Bergmark[27] defined the superficial muscles that cross from the pelvis to the rib cage as **global muscles**. Contraction of these muscles generates torque to oppose external forces and move the spine, pelvis, and whole body. Co-contraction of these muscles on either side of the trunk provide an ideal strategy to increase trunk stiffness and is common during tasks such as lifting.[20] However, during many functional activities, rather than simple co-contraction to increase trunk stiffness, activity of these muscles is carefully timed to perfectly match the movement and stability demands. For instance, the superficial trunk muscles such as obliquus externus abdominis and the lumbar erector spinae are active in alternating bursts in association with arm movements to oppose the reactive forces using a dynamic strategy of trunk movement rather than simple trunk stiffening.[10,12,28] Furthermore, during gait, global muscles co-contract at heel strike (the time of maximal impact to the spine) but have specific phasic bursts associated with forward propulsion of the body, displacement of the center of mass, and changes in direction of pelvic motion.[29]

Many studies have attempted to identify the global muscles with the "greatest" potential to maintain stability of the spine.[9] Although muscles such as obliquus externus abdominis and the thoracic erector spinae are often highlighted as providing a large contribution,[9] the selection of muscles for a specific function depends on a range of factors, including the direction of force. In general, it must be acknowledged that the specific pattern of global or superficial muscle activity is task specific.

In addition to the essential contribution of the large superficial muscles to control of the lumbar spine and pelvis, the central nervous system (CNS) also relies on the contribution of the deep muscles of the trunk. Bergmark[27] defined these muscles as **local muscles**, which have direct attachments to the lumbar vertebrae. Data from a range of biomechanical and in vitro or in vivo studies have confirmed the essential contribution of these muscles to spinal control. For instance, data from experiments involving biomechanical models,[30] animals,[31] in vitro human tissue,[32] and in vivo human participants[33] indicate that activity of the lumbar multifidus (MF) contributes to control of intervertebral motion. Likewise, animal studies[34] and in vitro[35] and in vivo human[10,11] studies indicate that activity of transversus abdominis, the deepest abdominal muscle, contributes to control of intervertebral[11,36] and sacroiliac[37] motion, particularly translation. These muscles, along with other deep muscles with segmental attachments (e.g., psoas major[38]), are often activated either early or tonically in a range of tasks and often in a manner that is not specific to the direction of forces acting on the spine.

If these muscles are inaccurately considered as flexors and extensors of the trunk (transversus abdominis has a minimal ability to act as a flexor as its fiber angle is only up to 12° from horizontal, and the short deep fibers of MF are close to the center of rotation of the lumbar joints with a trivial moment arm for extension), these muscles would be erroneously concluded to contribute little to spinal control. However, via contributions to intra-abdominal pressure, tensioning of the thoracolumbar fascia and the direct effects of contraction on the intervertebral segments, these muscles provide an additional contribution to intervertebral control.[34,35] In fact, as a result of the limited contribution to generation of torque at the trunk, these muscles provide a major advantage to the nervous system—the ability to influence intervertebral control during movement, without restricting range of motion[31] and without requiring control of other torques generated by muscle contraction. A major control issue for the more superficial global muscles is that these muscles also generate torque. This means that whenever they are recruited to provide control to the spine and pelvis, additional muscles must contract to control the complex torques generated by contraction of the superficial global muscles. Thus the deep muscles provide a possible solution to simplify control of the spine and, potentially, an ideal solution for maintenance of dynamic control by allowing control during movement, in conjunction with the activation of the global muscles to generate and control the torques. It is critical to note that most functional tasks require coordinated activity of both the deep and superficial muscles to meet the demands for control and movement. The balance between the deep and superficial muscles is likely to be guided by the principles outlined in Figure 14-2. In Figure 14-2 tasks that lie to the right involve greater co-contraction of the superficial muscles, with underlying activation of deep muscles. Tasks to the left are likely to have a greater contribution from deep muscles and the fine-tuned activation of the superficial muscles in a dynamic manner matched to the direction of force.

As intra-abdominal pressure and fascial tension are important for the control of intervertebral motion, other muscles that surround the abdominal cavity provide an additional contribution. This includes the diaphragm and pelvic floor muscles. Data from in vitro[39] and in vivo studies[40] confirm that activity of these muscles contributes to the control of the lumbar spine (Figure 14-3) and sacroiliac joints (Figure 14-4). Because of the dual role of these muscles in controlling stiffness and movement of the spine, as well as respiration and continence, additional complexity is introduced to the nervous system.

Guiding Principles: Selection of Muscle Activation Strategy

- Superficial global muscles co-contract to stiffen the trunk during tasks with high load, poor predictability
- Phasic bursts of superficial global muscles activity are matched to the demands of task to overcome external and internal forces
- Deep local muscles are generally active early and tonically, in a manner that is less dependent on the direction of force

The Challenge to Coordinate the Multiple Functions of the Trunk Muscles

In addition to the control of movement and stiffness of the spine and pelvis, trunk muscles also have important respiratory and continence functions. Breathing involves movement of the spine and pelvis. The diaphragm is the principal muscle of inspiration, depressing the central tendon and elevating the lower ribs to increase the vertical and lateral dimensions of the thorax. Other muscles, such as the erector spinae and latissimus dorsi, extend the spine to assist inspiration and oppose deflationary forces transmitted to the vertebral column by the rib cage articulations.[41] During strong expiratory efforts, activity of the paraspinal muscles is also likely to be required to counteract the flexion moment from activity of the expiratory abdominal muscles.

The abdominal muscles deflate the rib cage and elevate the diaphragm to assist expiration (Figure 14-5).[42] Although the abdominal muscles are active during quiet

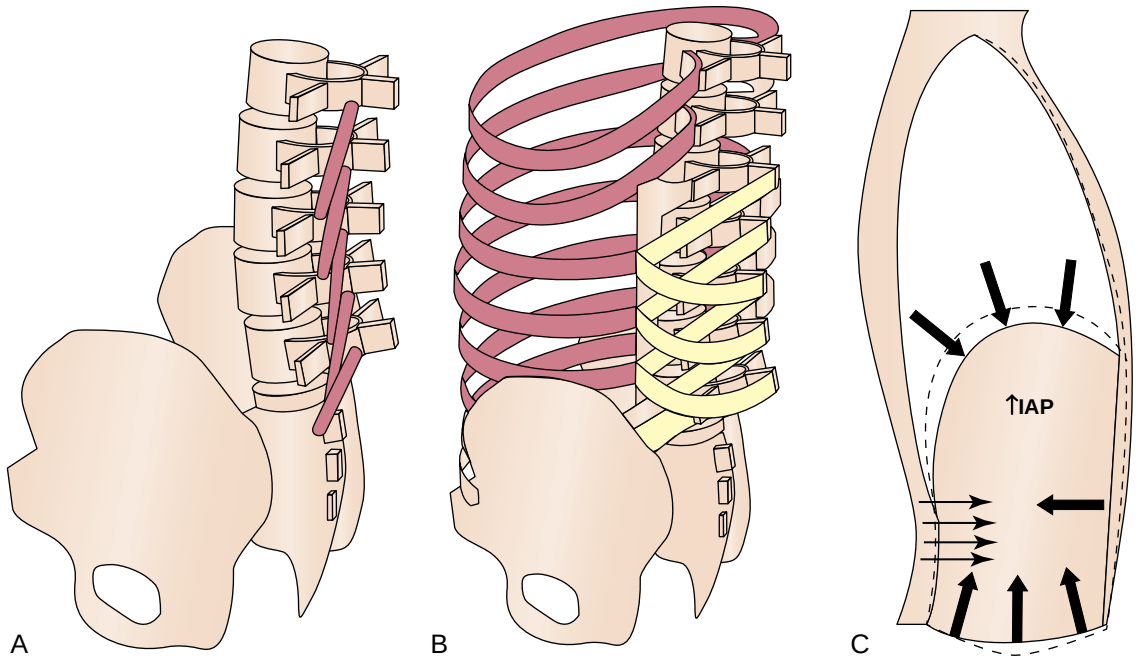

Figure 14-3 Deep muscles of the trunk contribute to control of the lumbar spine. **A**, Multifidus contributes to control of intervertebral motion by means of gentle compression between segments and control of posteroanterior translation. **B**, Transversus abdominis contributes to control of intervertebral motion by means of increased intra-abdominal pressure (IAP) and tension in the thoracolumbar fascia. **C**, These effects depend on co-contraction of the diaphragm and pelvic floor muscles.

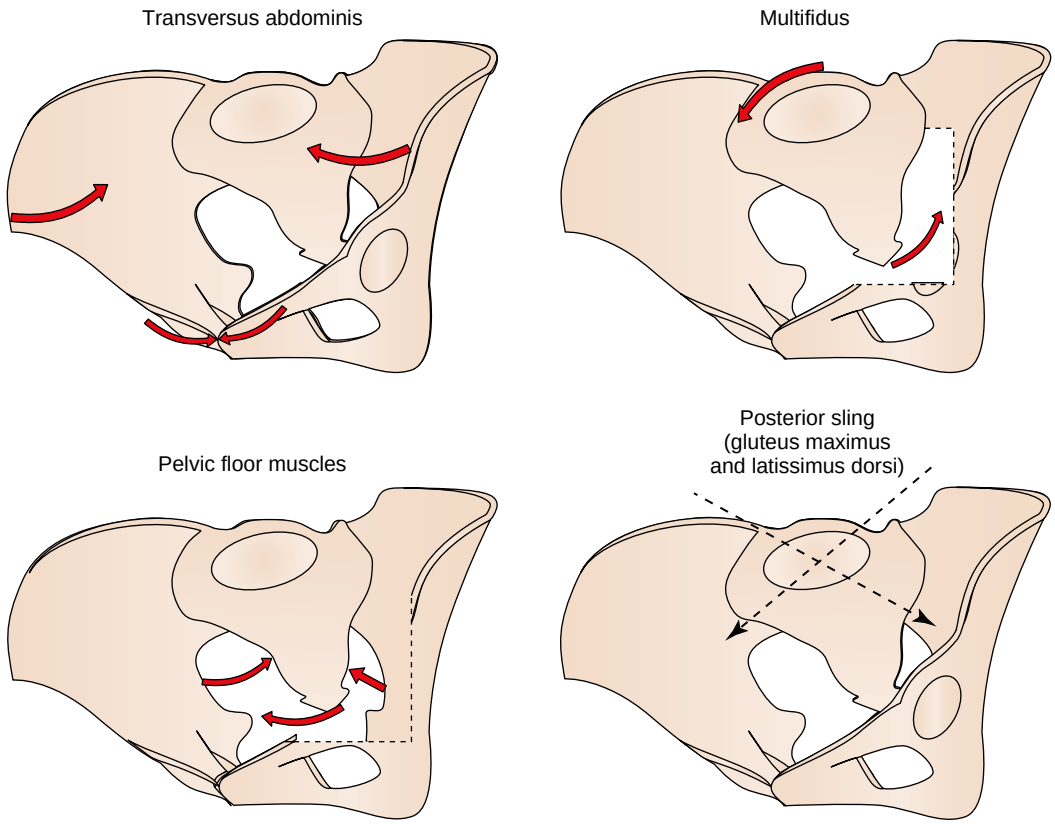

Figure 14-4 Deep muscles of the trunk contribute to the control of sacroiliac (SI) joint stability. Contraction of the transversus abdominis and the pelvic floor muscles provides compression to the SI joint. Although contraction of the pelvic floor muscles counternutates the sacrum (i.e., rotates the sacrum posteriorly relative to the ilia), which places the joint in a less stable position, this can be counteracted by activity of the multifidus and potentially the posterior sling muscles (i.e., gluteus maximus and latissimus dorsi) that attach to the thoracolumbar fascia.

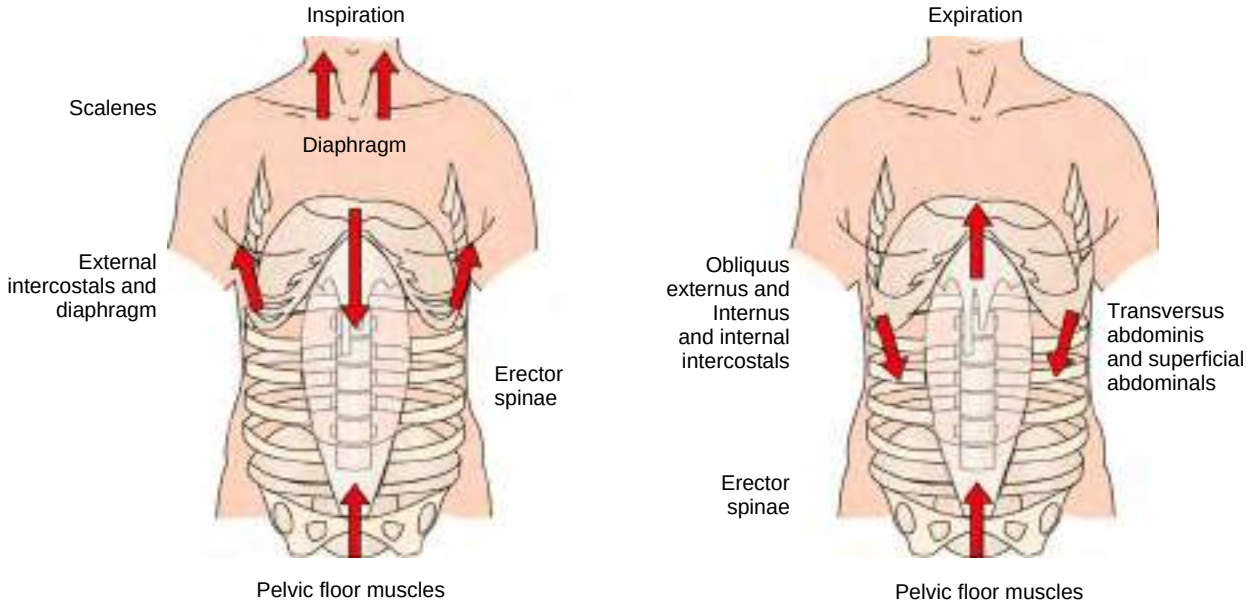

Figure 14-5 Contribution of the trunk muscles to inspiration and expiration.

breathing in supine with expiration produced by elastic recoil of the ribcage and lungs, when the trunk is upright, the abdominal muscles are recruited with quiet breathing. Furthermore, activity of the pelvic floor muscles is required during breathing to support the abdominal contents and control continence in association[43] with variation in intra-abdominal pressure during respiration (see Figure 14-5).[44] This is necessary during both inspiration and expiration; the pelvic floor muscles contract eccentrically during inspiration (gentle lengthening), and concentrically (shortening) during expiration.[43]

The respiratory functions of the trunk muscles must be coordinated with the demands for these muscles to contribute to spinal control. It is well established that respiratory muscles contribute to the strategies used by the nervous system to control the trunk. Activity of the diaphragm and transversus abdominis muscle are initiated prior to rapid limb movements[11] and are maintained tonically during repetitive movements of the arm[45,46] and walking.[47] Furthermore, intercostal muscles are active during trunk rotation.[48] The challenge for the nervous system is to coordinate the postural and respiratory functions. Under normal conditions these functions can be coordinated. During repetitive arm movement, the diaphragm is tonically active, which is consistent with the demand to control spinal stability, but this activity phasically modulates in conjunction with breathing to maintain airflow.[45] Similar responses of the abdominal muscles have been identified in walking.[47]

Under certain conditions the coordination of this breathing and spinal control is compromised. During lifting most individuals either hold their breath or expire.[49,50] Activity of the trunk muscles in association with spinal stability may be compromised when respiratory demand is increased. For instance, a potential conflict exists for contribution of abdominal muscles to spine control when ventilation is challenged during lifting[51] or other tasks such as repetitive arm movements, which repetitively challenges spinal stability.[52] Postural activity of the diaphragm is reduced during repetitive arm movement when respiratory demand is increased by breathing with increased dead-space to induce hypercapnea[52] and in patients with chronic airway disease.[53] In each of these situations, the reduced activation of specific trunk muscles during certain respiratory phases (i.e., reduced activation of diaphragm during expiration) may compromise spinal stability, and conversely, greater activation of muscles during certain respiratory phases (e.g., increased activation of obliquus externus abdominis during expiration) may excessively load the spine.[51]

In addition to the contribution of trunk muscles to airflow, these muscles also move the spine and pelvis in a manner that counteracts the body sway that is caused by breathing movements of the chest wall. Movement of the spine and pelvis, along with activity of lumbopelvic muscles, is time locked to the respiratory movement of the rib cage and abdomen[15,16] and matches the displacement on the center of mass induced by breathing. This motion is reduced in patients with LBP (this is consistent with the finding that stiffness of the spine is increased in this population [see section "Changes in Muscle Control in Lumbopelvic Pain"]) with subsequent disturbance to balance during breathing (augmented motion of the center of pressure).[54,55]

Continence is maintained when pressure in the urethra exceeds that in the bladder. Activity of the pelvic floor muscles contributes to the former, but abdominal and diaphragm muscle activation increases the latter.

For maintenance of lumbopelvic stability, activity of the pelvic floor muscles is necessary for elevation of intra-abdominal pressure, providing an indirect contribution to spinal control via the elevation of abdominal pressure and tension in the thoracolumbar fascia (which depends on pressure in the abdominal cavity to maintain geometry of the abdominal wall[56]).[40] In addition, tension in the pelvic floor muscles might also increase the stiffness of the sacroiliac joints in women.[39]

The demand for pelvic floor muscle activity to contribute to continence is generally consistent with the demands of lumbopelvic control, unless activation is excessive (as has been proposed in some conditions[57]). Consistent with this proposal, pelvic floor muscles contribute to the postural adjustment associated with perturbations to the spine from arm movement in women and men.[40,58] However, activity of the other muscles surrounding the abdominal cavity (e.g., diaphragm and abdominal muscles) to increased intra-abdominal pressure for spine control places additional demand on the pelvic floor muscles. In stress urinary incontinence, pelvic floor muscle activity may be compromised, and recent data suggest that women with this condition often have increased activity of the obliquus externus abdominis.[59,60] Together, these changes may be associated with a combination of incontinence and poor dynamic control of the spine and pelvis.

Static models of spinal control do not take into account the interaction between spinal control, breathing and continence. This is important because, although activation of a muscle such as obliquus externus abdominis may stiffen the spine when co-contracting with the paraspinal muscles, this may restrict the ability of the individual to expand the rib cage to breathe in. Static strategies for spinal stability that stiffen the spine and prevent spinal and rib cage movement are unlikely to be sustainable for anything other than brief efforts because of their effect on the essential demands of breathing. Without consideration of effects such as this, it is unlikely that static models will adequately explain the strategies used by the CNS to control spinal movement. From another perspective, it is important to consider that deficits in respiration and continence may lead to compromised spinal control. Epidemiological studies suggest that continence and respiration are associated with increased risk for LBP.[61,62]

Guiding Principles for a Dynamic Spine

- Trunk muscles contribute to a range of functions in addition to their role in controlling movement and stability of the spine
- Trunk muscles play major competing roles in breathing, continence, and balance
- Incontinence and breathing disorders are associated with an increased risk of developing low back pain

CHANGES IN DYNAMIC CONTROL WITH LUMBOPELVIC PAIN

Dynamic Control of the Spine in Low Back and Pelvic Pain

There is considerable variability regarding changes in control of the lumbopelvic stability in low back and pelvic pain. Increased,[63] decreased,[64] and no change[65,66] in muscle activity have been reported. Inconsistent and incomplete understanding of the motor adaptations in low back and pelvic pain has led to a major controversy in clinical practice. Although physiological/biomechanical studies suggest that spine stability is augmented in LBP as a result of adaptation in the activity of the trunk muscles,[67,68] paradoxically, much of the clinical literature argues that exercise should aim to increase stability to compensate for "spinal instability."[3] Variable trunk muscle activity in back pain and the narrow view that stability is synonymous with stiffness has led to confusion. Yet, there has been an explosion of exercise programs to enhance stability, despite lack of evidence that such programs reduce back pain. In contrast, strategies to restore muscle coordination improve outcomes.[69,70] Understanding the pathophysiology of trunk control changes in low back and pelvic pain is critical when considering the most effective preventative and rehabilitation strategies.

Changes in Posture and Postural Alignment in Lumbopelvic Pain

There is no definitive link between a single posture and pain. For every aspect of posture that is considered suboptimal, there will always be examples of individuals who frequently use the posture, without reporting symptoms. Although this has been used as evidence of lack of relevance of postural deviations to pain, it is important to consider that the relevance of a posture (i.e., a strategy for loading the spine) for development of pain depends not only on the amplitude of the load but also on the exposure (i.e., frequency with which the loading strategy is adopted)[71] and the tissue properties of the individual. Thus a specific posture (related to suboptimal loading strategy) may lead to pain only if there is sufficient exposure to exceed tolerance, and different patients will likely present with different postures. Recent work has indicated that patients with LBP commonly adopt postures that are more flexed or extended than pain-free individuals,[72] and this depends on their patient subgroup (see section "Patient Subgrouping"). Postural deviations may result from pain or be a precursor for future pain.

Changes in Muscle Control in Lumbopelvic Pain

Lumbopelvic pain is associated with vast array of changes in activity of the trunk muscles. Many of these changes

are likely to affect the movement and stiffness of the spine and pelvis, but the nature of these changes is complicated; some changes suggest less stiffness whereas others suggest increased stiffness, both of which may underlie less robust stability. For instance, increased co-contraction of flexor and extensor muscles has been reported when a load is released from the trunk,[73] activity of erector spinae muscles is increased during gait[63] and during a sit-up,[74] and "bracing" of the abdominal muscles is increased during an active straight leg raise[75] in patients with chronic low back and/or pelvic pain. Furthermore, activity of the obliquus externus abdominis muscle is increased during shoulder movements during experimentally induced pain[76] or when pain is anticipated.[77] When healthy individuals are given experimental pain, most adapt muscle activity to increase stiffness and protection, but no two individuals achieve this with the same combination of muscle changes.[67] Consistent with this observation, inspection of the data presented by Radebold et al.[73] reveals increased activity of at least one superficial trunk muscle in all participants in a postural task but the specific muscles involved varied between individuals. Together these findings suggest that an increase in the protection of the spine and pelvis is common in LBP. This is supported by findings of reduced motion of the spine in patients with back pain; patients with LBP less commonly prepare the spine by movement in advance of rapid arm movements,[78] intervertebral motion is decreased during trunk flexion,[79] and counter-rotation of the shoulders and pelvis is reduced during locomotion.[80]

In contrast, other data tend to indicate that the control of the spine is compromised in the presence of pain. For instance, activity of transversus abdominis[81] and MF[82] muscles is delayed during arm movements, and tonic activity of transversus abdominis is reduced during walking[83] and with repetitive arm movements during experimentally induced back pain,[76] and amplitude of activity is reduced during leg movements.[84] There is also evidence for decreased cross-sectional area,[85] increased fatiguability,[86] and structural changes such as increased intramuscular fat [87,88] of the paraspinal muscles, particularly the lumbar MF. These measures, although not directly indicating changes in the ability to control movement, do suggest functional changes in specific trunk muscles. Findings of impaired structure and behavior of the deep trunk muscles have been interpreted to suggest that control of the spine and pelvis is impaired in many individuals with low back and pelvic pain. Although no studies have directly measured stability when activity of the deep muscles is removed, this hypothesis is based on the in vivo and in vitro evidence for a contribution of these muscles in spinal control.[31,34,36,89] Other data from specific back pain populations have provided direct evidence of impaired intervertebral control. For instance, intervertebral translation is abnormal in patients with spondylolisthesis,[90] and buckling has been observed with fluoroscopy in a single subject during a weight-lifting effort.[91]

In summary, patients can present with a complex mix of reduced and increased control. Although some may present at the extreme of a net excess or insufficiency of control, many will present with elements of both (e.g., excessive recruitment of long paraspinal muscles, with compromised control of MF). Identification of the relevance of individual variation in muscle activation can be simplified by consideration of patient subgroups (see section "Patient Subgrouping"). The substantial variability in the adaptation of the trunk muscles in patients with lumbopelvic pain is often interpreted to suggest that there is no consistent adaptation of muscle control during pain. But there may be a common goal that underpins the adaptation to pain in many patients. Despite the variability, the CNS may adapt to pain or injury by increasing spinal stiffness to increase the *safety margin*—that is, to protect the part from pain and/or (re)injury. In this case the nervous system may adopt a strategy to increase stiffness of the spine by increasing the co-contraction of trunk muscles. Thus, rather than selecting a strategy of coordination of deep and superficial muscle activation that is specific to a task, the nervous system may simplify control by stiffening the spine with reduced flexibility of movement choices. This may be specific to a direction of movement. With this strategy, the nervous system would decrease the potential for error, limit the impact of unanticipated disturbances to the spine, and limit the potential for further injury. In effect, rather than selecting a strategy from a spectrum of dynamic possibilities that are perfectly matched to the demands of the task, the nervous system may select a simple solution that provides reasonable (but perhaps not optimal) quality of movement control that satisfies the demands of a range of conditions. However, because many muscles can achieve the same goal (that is, the system is "redundant" as there are multiple solutions to the same problem), different individuals may select different combinations of muscle activity to achieve this goal and the strategy may differ between different tasks.

To test the idea that a range of different strategies of muscle activation achieve a similar outcome for the spine, van Dieen et al.[68] undertook a modeling experiment in which they simulated a range of strategies adopted by patients with back pain in a biomechanical model of stability. The outcome was that stability was increased by each alternative pattern of increased muscle activation, whether the strategy involved increased co-contraction of flexors and extensors, increased activity of the flexors alone or increased activity of the extensors alone. Consistent with this modeling study, recent data from a study of experimental pain suggest that, when pain is induced in healthy individuals, most subjects adopt a pattern of increased activity, but again the pattern varied between individuals.[67] Of note, these individuals also presented with impaired activity of the deep muscles. Thus an individual may present with changes in the deep muscles that would be consistent with compromised control, yet activity of

the superficial muscles may be increased, which is consistent with increased stiffening of the spine. Despite the increased activity, the control of intervertebral motion may be compromised as a result of reduced or impaired activity of the deep muscles. Whether the poor control of the deep muscles leads to compensation by the more superficial muscles or whether overactivity of the superficial muscles supersedes the activity of the deep muscles is discussed in section "Mechanisms for Changes in Motor Control in Lumbopelvic Pain."

In summary, available data suggest that individuals with low back/pelvic pain present with a spectrum of changes that range from insufficient control to excessive control, and some present with elements of both underactivity and overactivity of muscles. Within this large variation, there is likely to be subgroups, which may be characterized by features of motor control that are provocative or relieving, and this may relate to specific patterns of muscle activation.

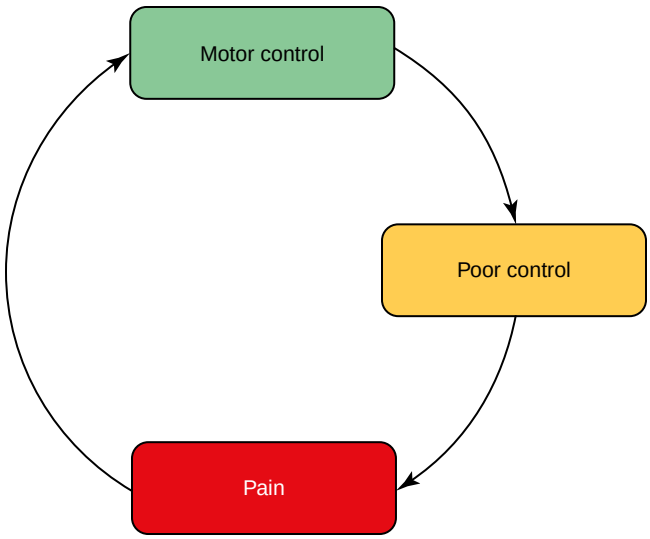

Figure 14-6 Vicious cycle of pain and motor control deficits. Although motor control deficits may lead to pain as a result of compromised control of the spine and pelvis, pain can also lead to changes in motor control. A patient who presents with pain has already entered the cycle; where the person entered it is less important.

CHANGES IN MOVEMENT IN LUMBOPELVIC PAIN

As for the other dimensions of motor control, there is large diversity in the manner in which changes in movement present in patients with low back and pelvic pain. Movement may be considered as motion of the spine in space (e.g., flexion/extension of the entire spine), specific motion of a region of the spine (e.g., lordosis/kyphosis of the lumbar spine), relative motion of adjacent regions (e.g., lumbar spine relative to thoracolumbar junction, or hip relative to lumbar spine), or motion of intervertebral segments (e.g., translation at a segment or range of motion at a specific segment acting like a "hinge"). Evidence is variable. In general, studies that show modified motion has been derived from specific patient subgroups including modified control at a segmental level in patients with spondylolisthesis,[90] poor control of spine during hip movement in subgroups into an "extension-rotation" subgroup,[92–95] and reduced counter-rotation of the trunk in gait.[80] Thus modification to movement is common and may range from strategies that reduce motion to enhance protection to strategies that lead to excessive motion. That is, a spectrum of changes from too much to too little control. This underscores the necessity to consider patients individually to determine the relevance of motor control for their pain presentation.

Mechanisms for Changes in Motor Control in Lumbopelvic Pain

Why is control of the spine modified in patients with low back and pelvic pain? There are a number of questions to consider. One is whether the pain precedes the motor control changes or motor control changes precede pain (Figure 14-6). There is evidence for both. Several authors argue that changes in motor control can lead to the development of pain. Cholewicki et al.[96] reported an association between delayed offset of activity of the superficial abdominal muscles and subsequent development of episodes of acute back pain in athletes. Early work by Janda[97] argued that children with "soft" neurological signs were at risk of developing back pain as adults. Sahrmann[92] argued that repeated movement with poor control (e.g., motion of the spine instead of the hip) was a precursor to pain. If true, there must be factors that "motivate" the adoption of the suboptimal control strategy prior to pain onset. Issues as diverse as habitual postures or movement patterns[92] and secondary consequence of breathing disorders or incontinence[61] have been implicated.

Conversely, it is also argued that pain and injury lead to changes in control and structure of the trunk muscles. For instance, experimental pain can cause changes in trunk muscle activity during gait[63] and other tasks such as arm movements[76]; experimental injury in animals leads to rapid muscle atrophy[98] and changes in muscle structure (i.e., muscle fiber types, connective tissue and fat[99]) in the MF muscle; and these changes are similar in many respects to those identified in patients with clinical pain.[81,85]

If pain and injury lead to changes in structure and behavior of the trunk muscles, what is the mechanism? Pain can affect control at multiple levels of the nervous system (Figure 14-7). In reality, when an individual presents with pain, whether the pain caused the changes or whether the changes caused the pain is to some extent irrelevant as the patient will already be in a cycle in which pain and injury have the potential to increase or perpetuate the changes in motor control. Motor control may be modified by mechanisms involving both the sensory and motor mechanisms at multiple levels of the nervous system. These mechanisms could be complementary, additive, or competitive.

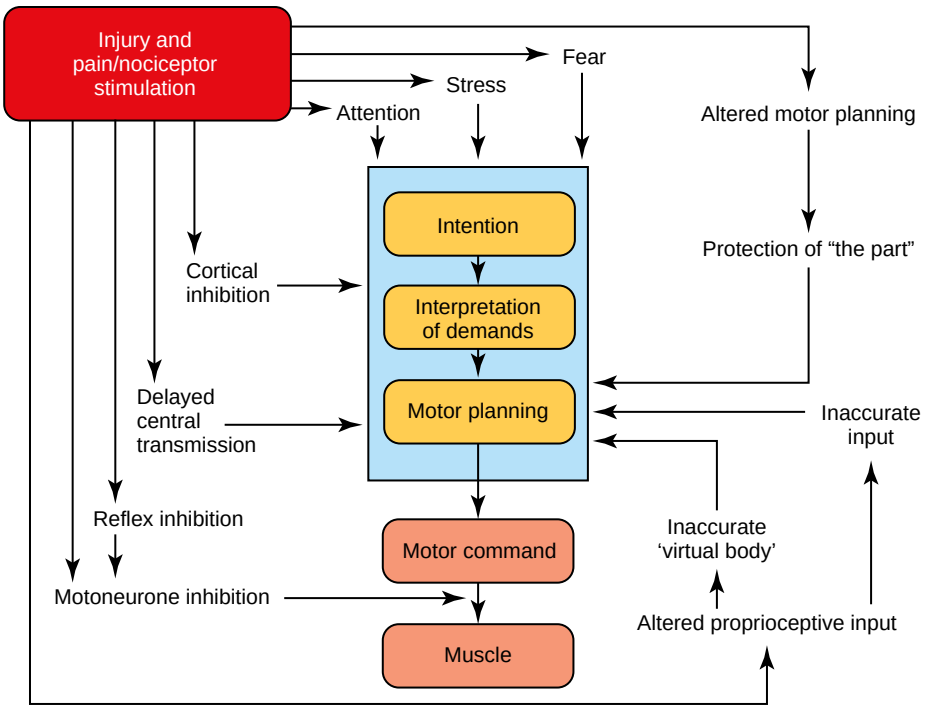

Figure 14-7 Possible mechanisms of pain that can affect the planning of movement and activation of trunk muscles.

Guiding Principles of Motor Control

- Changes in motor control may lead to pain and injury
- Pain and injury can change motor control
- Motor control may adapt by increasing the stability of the spine and pelvis
- There is substantial individual variation that must be considered when attempting to understand the relationship between pain and motor control

Sensory System Mechanisms

Deficits in the detection, transmission, integration, utilization, and perception of sensory information could modify motor control. Errors in the detection or interpretation of position or movement of the body would render optimal control of the lumbar spine and pelvis impossible. Proprioceptive deficits (e.g., detection or perception of position and movement) are commonly reported in LBP. These changes manifest as reduced ability to reposition the spine or pelvis to a target posture or alignment and decreasing sensitivity for detection movement.[25] Such changes will influence the quality of control of back motion and have several potential mechanisms:

1. Afferent input will be compromised by injury to mechanoreceptors (e.g. muscle spindles or mechanoreceptors in the intervertebral disc) or the tissues in which they reside.[100]
2. Processing of sensory information may be "ignored" by the nervous system, as a result of sensory "reweighting," which refers to the capacity of the nervous system to rely on information from multiple sources and reduce or increase reliance on a specific source. Despite the availability of afferent input from the injured part the nervous system may elect not to use it (e.g., decreased responsiveness to back muscle proprioception and increased responsiveness to ankle input,[101] or increased dependence on vision[102]).
3. The representation of the body region at the primary sensory cortex may be distorted[103] or the body schema altered.[104] Reorganization of the primary sensory cortex in chronic spinal pain involves enlargement and medial shift of the representation of the low back relative to that identified in pain-free individuals, and these changes are correlated with pain duration.[103] Sensory cortex activity measured from somatosensory evoked potentials indicate increased N80 component, which relates to the sensory-discriminative pain processing at the primary sensory cortex, and no change in the N150 component, which indicates processing in secondary sensory cortex.[105] Together, these data highlight the potential for reorganization (and possible sensitization) to the primary sensory cortex, which may contribute to modified motor control.[103]

Any of these changes in sensory function could underpin compromised control. Each would have different implications for management. For instance, injury to a mechanoreceptor may have limited potential for recovery, but reweighting and sensory cortex reorganization may be amenable to training.

Motor System Mechanisms

Many regions of the nervous system are involved in the planning and generation of movement, and changes at

any site, including the motor cortex, subcortical, spinal, and peripheral sites, may contribute to motor control changes due to pain.

A key site of recent investigation has been the primary motor cortex. Studies in chronic LBP have revealed reorganization of the cortical territory with projections to trunk muscles. Similar to the changes in the primary sensory cortex,[103] recurrent nonspecific LBP involves more diffuse and posterolaterally shifted cortical representation of the deep trunk muscle, transversus abdominis, relative to pain-free individuals.[106] This change appears to have a behavioral relevance, as the cortical reorganization is correlated with changes in motor behavior (i.e., muscle activation during arm movements), which implies a potential role in the mechanism of the adapted behavior.[106] There is also reorganization of the representation of the paraspinal muscles. Transcranial magnetic stimulation and selective muscle recordings from deep fascicles of MF and the superficial longissimus with fine-wire electromyography demonstrate reduced excitability and a convergence (i.e., "smudging") of the cortical representations of each muscle group in chronic LBP.[107] Similar to other cortical changes, the magnitude of convergence of cortical areas appears related to the severity or location of pain and preliminary evidence implies convergence of discrete motor cortical representation is linked with the transition from acute to chronic back pain.[108]

The loss of discrete motor cortical representation for the paraspinal muscles helps explain features of motor dysfunction in chronic spinal pain. Evidence from other conditions implies that the presence of discrete cortical representation of individual muscles may have relevance for independent control of the different muscle layers. In another painful condition, focal hand dystonia, there is similar blurring and overlap of the cortical representation of individual fingers, which is associated with loss of independent finger movement and impaired hand function.[109] In a similar manner and unlike pain-free individuals who maintain separate control of individual back muscles, patients with LBP co-activate the deep and superficial back and abdominal muscles during arm movements[81,110] and with changes in sitting posture.[111] It is hypothesized that the reorganization of the motor cortex underpins adoption of new motor strategies that prioritizes protection of the spine with a simplified strategy of co-activation of the trunk muscles providing a greater safety margin, rather than the finely tuned coordination between multiple muscles, that although it may be more optimal, the finely tuned coordination has greater potential for error.[112] Indirect support of this hypothesis comes from other data, which show that when challenged by acute experimental pain, the excitability of the corticomotor pathway for the transversus abdominis muscle is reduced and that for obliquus externus abdominis muscle is increased,[107] again suggesting a shift in strategy from fine-tuned control to a simplified more protective solution. Several authors have argued that the CNS adopts this strategy to compensate for reduced osseoligamentous stability of the spine (Figure 14-8).[3,68] However, similar changes in motor control may be replicated when pain is induced experimentally by injection of hypertonic saline,[76] that is, when osseoligamentous stability has not changed. Furthermore, similar changes may occur even when pain is anticipated but not present.[77] For example, if painful electrical shocks to the back are provided every

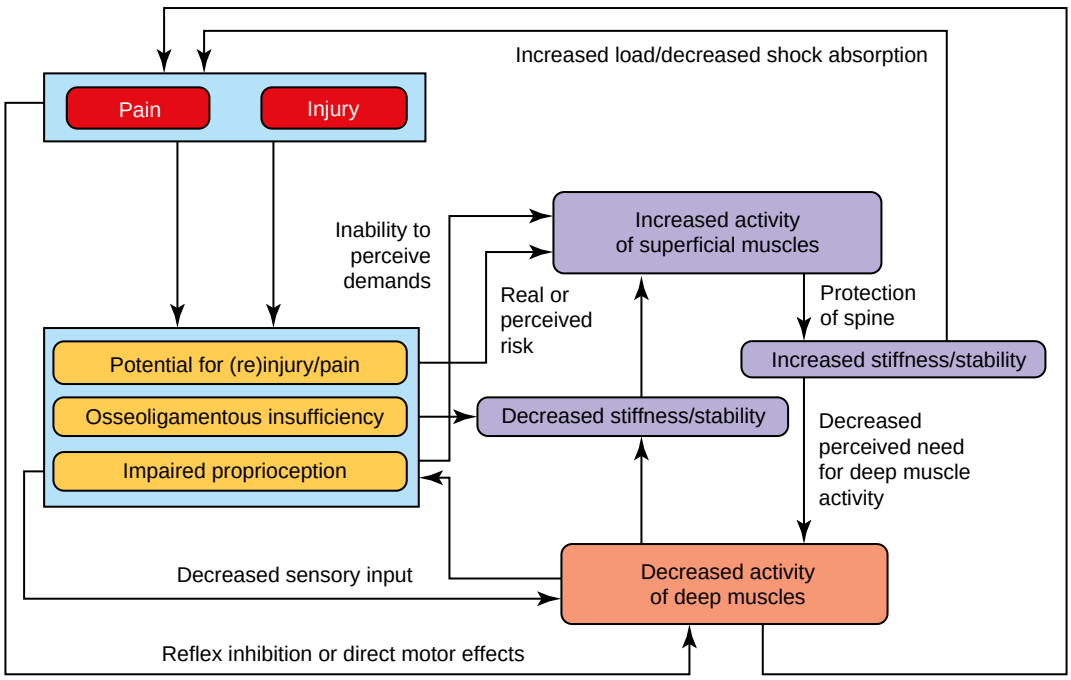

Figure 14-8 Possible factors that may explain the relationship between impaired activity of the deep muscles and increased activity of the superficial muscles. Pain and injury may lead to opposite changes in the deep and superficial muscles.

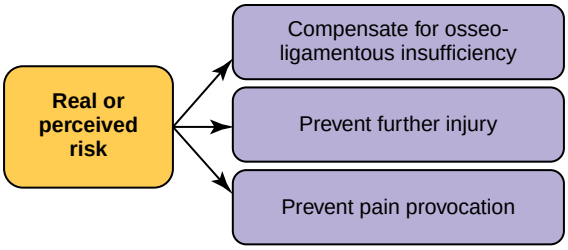

Figure 14-9 Motor control may change because of real or perceived risk to the spine as a result of instability and the risk of pain and injury or reinjury.

time an arm is moved, the response of the obliquus externus abdominis muscle is augmented and occurs earlier in association with arm movement, and this is maintained after the painful stimulation is no longer linked to the arm movement.[113] Thus adaptation may occur in a number of situations when the real or perceived control of the spine is decreased leading to a real or perceived risk of further injury or pain (Figure 14-9).

When dynamic control of the spine is considered, muscle activity is precisely matched to the demands to maintain stability of the trajectory and all other components of spinal control. However, this dynamic strategy has potential for error, if the timing or amplitude or muscle activation does not match the actual demand. In a healthy system, where there is tolerance for small errors, this is not problematic. However, if the tolerance for errors is reduced (e.g., as a result of osseoligamentous insufficiency, pain, or poor proprioception), the CNS may adopt a simplified more protective static strategy to increase spinal stiffness. Thus, rather than using a range of control alternatives, the preferred strategy adopted by the CNS may be a simplified solution, but the presentation of this adaptation will vary among individuals.

In addition to changes in descending control from the higher centers of the nervous system, there is also evidence that mechanisms at the spinal cord may underpin changes in sensorimotor control. Reflex inhibition, caused by altered afferent input from an injured joint, leads to reduced activity of extensor muscles and facilitation of flexors muscles in the limbs. This mechanism, which involves interneurons at a single spinal segment, can account for the rapid atrophy of the MF muscle after the onset of acute back pain.[85] This is supported by reduced responsiveness of MF to intervertebral disc stimulation following experimental infusion of a facet joint in pigs[23] and reduced response of MF to electrical stimulation of the descending motor tracts following intervertebral disc lesion in pigs.[114] This latter observation was coupled with evidence of increased excitability at the cortex, which implies competing effects at the cortex and spinal cord. One interpretation of this observation is that although the motor control strategy planned by the higher centers aims to augment activation of the deeper muscles, this was counteracted by inhibition at the spinal cord.

The ability to control posture/alignment and movement will be affected by changes in structural changes in muscles. These changes may include atrophy, muscle fiber changes, and fatty and connective tissue changes. LBP or injury are characterized by increased fatigability of back extensor muscles is increased,[86] atrophy of back muscles in the acute and chronic period (but not subacute period, thus highlighting the potential for different mechanisms at different time points),[85,98,115] fatty infiltration,[115] and transformation from type 1 (fatigue resistant) to type 2 (nonfatigue resistant) muscle fibers[99,116] of MF. Recent work suggests a role for pro-inflammatory cytokines in this structural remodeling of muscle,[112,117] which highlights the potential for complex neurobiological processes associated with injury and pain.

Changes in coordination of firing of motor units within muscles have been studied extensively for simple limb tasks. Voluntary contraction of limb muscles in pain involves redistribution of motor unit activity within and between muscles[118] rather than uniform inhibition of motoneuron discharge as was predicted by earlier theories.[119] Whether similar changes affect trunk muscles requires further investigation. As the motoneuron and muscle fibers are the final common pathways of the motor system, all these changes will have an impact on the output of the sensorimotor system.

Summary

In summary, multiple factors have the potential to change control of the muscle activity, posture/alignment, and movement before and after pain and injury. In most cases, it is likely that a range of factors is involved, and one issue for management is to consider the importance of each factor. The presence of changes at multiple levels of the nervous system should be seen as an opportunity rather than a negative, because it broadens the range of clinical techniques that may be applied. For instance, a combination of techniques to influence spinal cord excitability may be beneficial in conjunction with motor learning strategies to modify planning of movement.

Consequences of Changes in Dynamic Control

A fundamental issue related to changes in structure and behavior of the trunk muscles, posture/alignment and movement is whether the adaptations are beneficial or detrimental, in the short and long term. Changes in strategy that lead to increased and decreased stability may have consequences for the spine. This is significant because motor control changes commonly do not resolve when pain recovers.[81,120]

From one point of view, a strategy to increase stiffness and protection of the spine and pelvis may be positive because it increases the safety margin to prevent pain and reinjury.[3,121] Although this may provide benefit in the short term, if the adaptation is maintained for a long period,

it is likely to have negative consequences for the spine and pelvis secondary to increased loading,[122,123] restriction of movement,[78] reduced variation, and inadequate fine-tuning of trunk movement (see Figure 14-8).

Loading on the spine is increased as a result of muscle co-contraction. This has been confirmed in studies of patients with back pain during lifting.[123] Although there is debate whether increased loading is detrimental to the spine, it is argued that high cumulative loads may lead to mechanical and physiological changes.[124,125] These changes may accelerate degeneration[126] and potentially increase the long-term risk of LBP recurrence.

A consequence of spinal stiffening and muscle co-contraction is the reduced availability of movement as a mechanism to absorb and dissipate force. As described earlier, movement presents a range of advantages to the control of forces at the spine. Some data show that patients with LBP are less likely to use movement as a component of the strategy to control the spine, which is associated with a greater perturbation to the trunk[78] and a greater time to recover balance after a perturbation.[13] Both of these issues are likely to have consequences in the long term. In addition, if spine movement is reduced, the contribution of spinal motion to respiration and balance control would be compromised. Consistent with this proposal, it has been reported that patients with LBP sway more with breathing[54,55] and have increased vertical motion of the rib cage with breathing.[127] This latter finding suggests restricted ability to use anteroposterior and lateral motion of the abdominal wall and rib cage secondary to increased activity of the superficial abdominal muscles. In terms of balance, increased spinal stiffness may limit the contribution of spinal movement to control postural equilibrium. Patients with LBP are less able to use a hip strategy to maintain balance when standing on a short support base,[18] and when lumbar motion is restricted by the application of a brace, balance quality is reduced.[7] Another important consideration is that if the nervous system adopts a control strategy that relies on spinal stiffening rather than movement, it may limit the ability of the CNS to perform some tasks. Although the stiffening strategy may be suitable for tasks where movement can be restricted (i.e., movement is not required, can be compensated elsewhere, or can be reduced without preventing the task from being completed), when movement is obligatory, an appropriate strategy may not be available. For instance, when standing on one leg, it is essential to shift the center of mass over the stance leg. Inappropriate control of the spine in this context through trunk stiffening makes the aforementioned task difficult to execute.[128]

Optimal control of any body segment depends on some variation. Although excessive variation is problematic, so is too little variation.[129] Variation is necessary to share the load around tissues such that no single muscle, ligament, or area of joint surface is loaded for every repetition of a task. Variation is also necessary for learning, to be exposed to new movement solutions. One possible consequence of adaptation in motor control is reduced variation when patients adopt a more stereotypical movement pattern. This can be problematic in the long term. For instance, lower limb kinematics of runners with lower limb problems are characterized by less variation.[129]

Finally, impaired activity of the deep muscles, in conjunction with increased activity of the superficial muscles, is likely to have consequences for the control of movement and stability at the intervertebral level. As mentioned earlier, it is well accepted from a number of experimental models that deep muscle function is important for spinal control (see section "Muscular Mechanisms for Control of the Spine and Pelvis"). The contribution of the deep muscles in controlling the lumbar spine and pelvis is unlikely to be completely compensated for, or replicated by, activity of the larger, more superficial muscles, especially in dynamic situations. The models of Bergmark[27] and Crisco and Panjabi[130] predict that, without activity of the deeper muscles, the integrity of the spine cannot be maintained. Thus impaired function of these muscles is likely to render the entire spinal system, and its control, vulnerable, thus leading to compromised quality of control. Although this may not be a problem in the short term, as the increased activity of the superficial muscles is likely to stiffen and protect the spine, in the long term, this has the potential to be problematic.

For the reasons outlined above it could be argued that the muscle co-contraction strategy with its short-term benefit may lead to increased risk of back pain recurrence if the almost obligatory use of this strategy does not resolve after the resolution of pain. It is well accepted that previous back pain is a strong predictor of future back injury.[131] The failure of changes in trunk muscle control to resolve may be a mechanism underlying this finding. Data from numerous studies of individuals with a history of pain, but no pain at the time of testing, indicate that changes in motor control persist after the resolution of symptoms.[81,110] This implies that motor strategies do not resolve spontaneously after cessation of pain, at least in some individuals. The possibility that abnormal muscle activation leads to future LBP is supported by recent data that suggest delayed offset of activity of the abdominal muscles predicts LBP.[96] This feature of muscle activation was a predictor both for those with a history of LBP and for those with no history of pain. This indicates that factors other than pain could be responsible for the preexisting modifications in motor control. In another example, reduced cross-sectional area of the MF muscle that is not restored by specific training was associated with increased risk of back pain recurrence relative to individuals who did receive such training.[70] A key issue to consider is why some individuals go on to have back pain recurrence whereas others do not. Further work is required to determine possible factors that may contribute to back pain recurrence. Some data suggest that the failure of

resolution of the motor adaptation may be linked to unhelpful attitudes and beliefs about pain.[132] As persistence or recurrence of LBP[133,134] and pain-related attitudes are associated with changes in motor strategy,[135] this may provide a link between physiological and psychological factors and back pain recurrence.

Guiding Principles: Adapted Motor Patterns in Low Back Pain May Have Negative Long-Term Consequences as a Result of:

- Increased loading as secondary to enhanced muscle co-contraction, or suboptimal movement and/or posture and postural alignment
- Increased stiffness and reduced shock absorption
- Decreased movement variation to share load and learn
- Decreased control quality of intervertebral motion

Interpretation of Motor Changes for Exercise Planning

The potential negative long-term effects of an adaptation that increases the stiffness of the spine challenges the view that exercise to enhance spinal stability is universally appropriate for management of LBP. In the management of a patient with low back and/or pelvic pain, an important consideration is whether the adaptation is beneficial or detrimental, that is, whether the adaptation should be encouraged or discouraged. On one hand, it may be necessary to maintain some element of adaptation to compensate for reduced osseoligamentous control (e.g., requirement for thigh muscle activation to compensate for reduced passive restraint of the knee in knee osteoarthritis), limited ability of the tissues to tolerate load and movement, poor awareness of position and/or movement, or sensitization of the tissues. This point of view has been argued by different authors[3,121] and forms the basis of a range of intervention strategies that aim to increase the stiffness and stability of the spine.[122]

The alternative point of view is that training a strategy that solely aims to increase stiffness of the spine may have negative consequences for the spine and contribute to maintenance or recurrence of back pain and injury for some individuals. The alternative view is that rehabilitation should aim to optimize control, and this involves training a balance between movement and stiffness, which involves training and refinement of the coordination between the deep and superficial muscles to restore an optimal dynamic strategy for control of the spine.[2] This highlights the need for comprehensive assessment of the patient to determine the relationship between motor control (i.e., posture and postural alignment, muscle activation and movement) and the presenting symptoms to identify which elements of the motor control system require enhancement and which elements should be reduced.

Guiding Principles of Motor Control Treatment

- Some elements of motor control require enhancement
- Some elements of motor control should be reduced
- Development of treatment goals can be achieved only through careful assessment and evaluation of the response to change

Summary

Optimal control of the spine and pelvis requires a carefully controlled dynamic system with a balance between movement and stiffness. Application of motor control principles to the management of low back and pelvic pain has evolved from a relatively straightforward approach that aimed to enhance stiffness, to an individualized approach where exercise is tailored to the individual to match the presentation in terms of the patient's unique presentation of posture and postural alignment, muscle activation and movement and their functional demands. Treatment planning relies on careful assessment and tailoring of exercises to meet the individual patient's needs. The following sections summarize key elements of this approach.

CLINICAL APPROACH TO MOTOR CONTROL TRAINING

Principles of Clinical Approach to Motor Control Training for Low Back and Pelvic Pain

Motor control training for low back and pelvic pain aims to restore optimal control of the spine and pelvis, with consideration of posture/postural alignment, muscle activation and movement. Sensation and the multiple functions of the trunk muscles (e.g., respiratory, continence, balance) are also key considerations. The objective of this approach is to optimize load on the structures of the spine and pelvis (that may be a source of ongoing nociceptor discharge), in a manner that is matched to the changes in motor control that are specific to the individual and matched to his or her functional demands. This requires consideration of the role of biology (e.g., role of ongoing nociceptor discharge in the maintenance of pain and/or the role of exposure to healthy movement to recovery) within the biopsychosocial presentation of the patient.

Although motor control training is unlikely to be appropriate for all patients with low back and pelvic pain, for those who retain a component of their condition related to loading of the spinal tissues, motor control training appears to be relevant. Motor control training requires careful assessment of each element of motor control, and the guiding principal is to use a clinical reasoning approach to apply specific tests to identify features of motor control that are relevant for the patient's symptoms. At the completion of the assessment, the clinician has a clear picture of whether or not motor control is altered in the patient,

how it relates to pain provocation or relief and tissue loading, and a prioritized list of features of motor control to address with treatment. The intervention is specifically targeted to the presentation of the patient.

Motor Learning

Rehabilitation involves a motor learning approach.[2] Motor learning involves the acquisition and refinement of movement and coordination that leads to a permanent change in movement performance.[136] This can be achieved by drawing on the principles of motor training for skill learning. Different researchers have defined either two or three phases of motor learning. Fitts and Posner[137] proposed three phases. The **cognitive phase** focuses on cognitively based problems, and all components of the task are organized cognitively with attention to feedback, movement sequence, and quality of performance. The **associative phase** commences once the patient has acquired the fundamentals of the movement and the focus shifts to emphasize the consistency of performance and the cognitive demands are reduced. In the **automatic phase**, which is achieved after considerable practice, the demand for conscious intervention is reduced and the focus shift to transferring the task between environments. Gentile[138] proposes two phases, which parallel those of Fitts and Posner. In phase 1, the patient "gets the idea"; in phase 2, the emphasis is on fixation and diversification of the skill.

Motor learning principles provide guidance for a range of strategies for optimal training of motor function. Motor learning of complex movements can be facilitated by *practice of parts* of the movement (i.e., segmentation) before practicing the whole movement. Learning can be facilitated by *simplification* of the task by modification of elements such as reducing the load, speed, or changing the body position to make it easier for the patient to correctly perform the task. Feedback is critical to ensure learning. Feedback of both the quality of performances and the results of the task can be provided.

Training of motor control of the trunk in the framework of motor learning involves training of the components of function that are found to be relevant for a patient's symptoms in the detailed assessment of posture and postural alignment, muscle activation and movement. The sequence of phases is outlined in Figure 14-10. The process involves progressive phases that increase the complexity of training to enable a patient to regain optimal motor control from the initial attempts to address the specific deficits in motor control through to high-level functional training. In addition to this basic sequence, there are other issues that may require consideration for specific individuals. For instance, it is critical to regain breathing during the early stages of training and throughout program progression, and this may be a specific problem for some individuals. The following sections outline the key aspects related to the methods used to guide the clinical reasoning approach based on subgrouping and important considerations for treatment planning based on the mechanisms of pain and the interaction between the biological, psychological, and social aspects of pain.

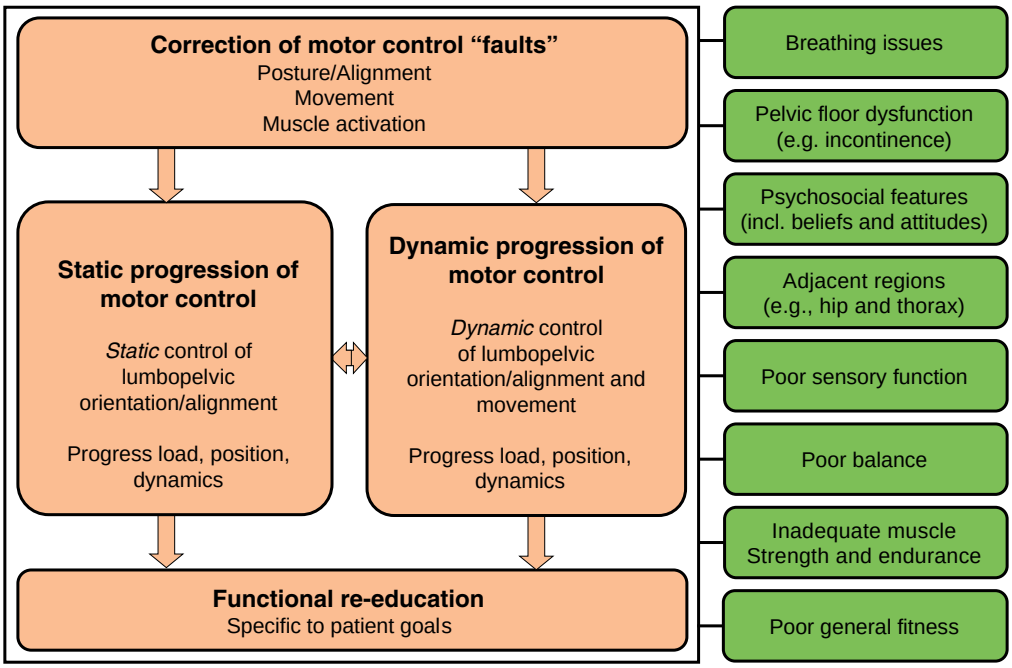

Figure 14-10 Progression of motor control training for dynamic control of the spine and pelvis. Items to the left-hand side indicate the basic progression of exercise from initial identification and retraining of specific features of sensorimotor control that are related to the patient's symptoms. Once skills are learned to correct motor control "faults," this is progressed through integration of control of these features in more demanding contexts via static and dynamic progressions. The final phase involves integration into functional tasks identified by the patient. Items to the right-hand side are features that may present as barriers to recovery of optimal motor control that should be screened for and included in the intervention as necessary for an individual patient.

Patient Subgrouping

Subgrouping of patients involves identification of features of a patient's presentation that can identify more homogeneous groups from within the heterogeneous population with low back and pelvic pain. Several approaches can be used, including those that allocate patients on the basis of their responsiveness to interventions (e.g., treatment based classification[139]), pathoanatomical diagnosis of the pain source,[140] a combination of both,[141] or on the basis of features of motor control that provide guidance for the prioritization of the features of posture or postural alignment, muscle activation, and movement that should be addressed with the treatment.[92,142] These latter approaches integrate well with the motor control approach outlined in this chapter. One of the features that characterize skilled clinical practice is recognition of patterns that can simplify and guide the selection of treatments. Subgrouping of a patient according to a cluster of features of pain provocation/relief (i.e., movements or positions that provoke or relieve pain) and motor control strategies (e.g., poor control of lumbar lordosis, relative flexibility of hip and spine) follows this philosophy and aims to facilitate the process for the clinician to identify the cluster of relevant features of the patients presentation and plan targeted treatment. The ultimate test of subgrouping will be to show, with clinical trials, that the outcomes are improved when intervention is based on the subgrouping. There is encouraging evidence from a recent study.[143] It is also necessary to consider the patient's pain presentation and the probable relevance of neurobiological processes and the psychological and social elements of a pain presentation, which are considered to varying amounts by different subgrouping strategies.[144] The following sections consider how these elements can be considered in a patient's presentation.

Neurobiology of Pain

A critical consideration for application of motor control training in low back and pelvic pain is the potential role of tissue loading in perpetuation of a patient's pain presentation. There is considerable debate regarding the involvement of ongoing nociceptive input in the presence of persistent pain. Although some ongoing pain states may be mediated by central sensitization mechanisms (i.e., amplification of neural signaling within the CNS that elicits pain hypersensitivity[145]) or neuropathic pain (i.e., pain attributable to a lesion or dysfunction in the nervous system[146]), patients may also maintain a contribution from nociceptive input from the periphery, although this is likely to be sensitized. Nociceptive pain is assumed to be predominantly maintained by activation of peripheral nociceptive sensory neurons.[147] Theoretically, it is individuals whose symptoms retain a contribution from activation of nociceptors who are likely to benefit from intervention that addresses suboptimal loading of tissues. Typical features of a nociceptive pain presentation are that the pain is localized to the area of injury or dysfunction; has a clear, proportionate mechanical or anatomical nature that responds predictably to aggravating and easing factors; is usually intermittent; may be manifested as sharp pain with movement or mechanical provocation; and may also present as a constant dull ache or throb at rest.[148] A recent study reported that, in a nonspecific LBP group, motor control training was more effective for individuals who scored higher on a questionnaire based on a consensus opinion of features that characterized lumbar "instability."[149] An issue for consideration is that the questionnaire is largely focused on features reflective of nociceptive type pain, and a plausible interpretation of the study was that the responsiveness of treatment was not based on the presence of "instability" but instead on the presence of nociceptive features to pain.

Pain related to central sensitization is characterized by a disproportionate, nonmechanical, and unpredictable pattern of pain in response to multiple or nonspecific aggravating or easing factors; an intensity that is disproportionate to the nature and extent of injury or pathology; a strong association with maladaptive psychosocial factors; and diffuse or nonanatomical areas of pain or tenderness on palpation.[150] Patients with this presentation may still benefit from exposure to "healthy" movement, but the attention to the detail of movement may be unnecessary or unhelpful if it focuses too much attention on protection of the tissues. Neuropathic pain, by definition, includes trauma to peripheral nerves and could benefit from modification of movement to alter the mechanical interface of the nerve with surrounding tissues.

Biopsychosocial Model of Pain

There is no question that LBP and pelvic pain include biological, psychological, and social aspects, with varying degrees depending on the individual. The biological domain includes the mechanical loading of the tissues/structures of the spine and pelvis, and the neurobiological processes related to sensitization, immune response and its interaction with nociceptive processing. This, of course, interacts with psychological and social features. Although psychological and social factors are unlikely to cause pain in the first instance, they can moderate the pain and influence the long-term outcome. The relevance of psychological and social issues in back pain is clear, and a range of factors have been found to be associated with transition of back pain from acute to chronic pain.[134] It is clear that these factors must be considered in the assessment and management of back pain. An important consideration is that a person's report of pain is not linearly related to the amplitude of input from the nociceptive afferents in the periphery but is influenced and molded by many issues including the individual's experience and other psychological and social issues.[151]

Pain catastrophizing, fear, and poor pain coping skills can influence neurobiology of pain, drive sensitization processes, and influence the manner in which the motor

system adapts, often leading to motor adaptation that is *greater* than what is necessary, maintained *beyond* when it is necessary, or completely *inappropriate* for the health of the tissues.[112] It is increasingly recognized that motor control can be changed by psychological factors, which include, but are not limited to, stress and fear of pain and (re)injury. It has been reported that control of the trunk is changed during lifting under "stressful" conditions.[152] Furthermore, when a person anticipates back pain, changes in motor control are similar to those identified in clinical pain; for instance, the onset of activity in the deep abdominal muscles is delayed during arm movements[77] and activity of the superficial muscles occurs earlier.[113] Notably, these motor control features do not appear to recover rapidly in all individuals after the removal of the threat of pain. The failure of these changes to resolve on the resolution of symptoms has been linked with unhelpful attitudes about back pain.[132] In summary, biological (including features of motor control) and psychological changes are likely to be interdependent and require co-intervention in many cases. Effective management of the whole patient must include consideration of all aspects as each may present as a barrier to clinical improvement.

Summary

Optimal control of the spine and pelvis requires a carefully controlled dynamic system. In such a system, the nervous system matches the strategy of activation of the trunk muscles, control of posture and postural alignment, and movement to the multiple tasks that must be coordinated to achieve optimal control of the spine. On balance, data from patients with low back pain indicate that deficits are present in the ability of the nervous system to select the appropriate control strategy, and this may present across a spectrum from simple strategies that involve co-contraction to protect the spine and increase the safety margin to inadequate control of a movement/region/segment. Underlying these different movement presentations is a combination of suboptimal posture and postural alignment, muscle activation (i.e., variable presentation of decreased and increased activation of deep and superficial muscles), movement, sensory function, modification of control of the multiple functions of the trunk muscles and structural changes in muscle (i.e., atrophy, fatty infiltration, muscle stiffness/length changes). In view of the individual-specific nature of these changes, comprehensive rehabilitation will require comprehensive assessment (potentially guided by patient subgrouping), and a tailored motor learning approach to restore control. The following sections provide an overview of the assessment, training goals, and treatment options as well as guidelines for progression of exercise.

Practical Application of Clinical Approach to Motor Control Training

The purpose of the following sections is to provide an overview of the basis and application of motor control training to the management of patients with lumbopelvic pain and dysfunction. Optimization of motor control requires careful assessment and treatment planning. There is no single intervention that works for all patients, and a treatment can be planned only once the clinician has identified the features of control that require modification. This must be nested in a biopsychosocial framework to ensure that all aspects of the presentation and the interaction among them have been addressed. Many approaches to motor control training have been proposed, and the following information is an amalgamation of elements of many of these approaches. The combination of approaches enhances a clinician's toolbox from which to draw flexibility to match a package of intervention to the needs and preferences of the patient. Although clinical trials provide evidence of the efficacy of the approach, there are many elements that require further development. For instance, most assessments rely on the skilled observation of the clinician and have not been subjected to assessment of clinometric properties. Furthermore, the basis for the clinical decision making is based on clinical reasoning, rather than simplified algorithms because of the diversity of presentations. Although subgrouping can simplify the process of targeting treatment by aiding the identification of patterns, clinical skill is required to prioritize treatment targets and identify effective solutions.

Clinical Approach to Motor Control Training of Posture and Postural Alignment

Principles. At a basic level, the application of a motor control approach to posture and postural alignment aims to identify features of the manner in which the patient's posture deviates from "ideal" and how different postures either provoke or relieve pain. Although population studies generally indicate an unclear link between posture and pain,[153] major limitations of that work is the lack of recognition that there will not be a single posture related to pain, that the relationship between posture and pain will depend on exposure to the posture, and the failure to consider the unique manner in which a posture may relate to pain for an individual patient. A clear relationship is not always easily revealed, but for many patients, there are specific features that modify their pain in a predictable and repeatable manner. The challenge clinically is to identify the relevant features and find a strategy to induce a change in the postural behavior.

Assessment of posture and postural alignment of a patient with low back and pelvic pain involves identification of aspects that might be related to pain presentation. Three features can help determine potentially relevant features: (1) features that deviate from a predicted "ideal" posture, (2) elements of posture that provoke or relieve pain (e.g., curvature), and (3) muscle activation required to maintain the position (e.g., excessive activity [i.e., excessive loading of the posterior elements when sitting in excessive lumbar extension] or insufficient activity [i.e., excessive flexion loading of the spine in slump sitting]). What is *ideal*

posture? A range of postures has been defined as "ideal" or "neutral" in the clinical literature (for review, see reference[154]). A postural alignment that is founded on several sources of evidence and appears clinically relevant is one that involves optimal sagittal balance (i.e., C7 over the sacrum), gentle curvature (i.e., cervical lordosis, thoracic kyphosis, a smooth transition to a gentle lumbar lordosis), and a pelvis that is level or slightly anteriorly tilted and symmetrical in the frontal and transverse planes. This posture is considered ideal because it (1) provides optimal sharing of loading between spinal structures[155]; (2) is midrange and thus avoids "creep" of viscoelastic tissues into flexion, extension, lateral flexion or rotation; (3) is associated with minimal activity of large, more superficial trunk muscles such as those required to overcome gravity if the center of mass of the trunk is biased anteriorly or posteriorly relative to the pelvis[156,157]; (4) is thought to encourage greater activity of the deeper muscles of the trunk,[156] including the pelvic floor muscles[158]; and (5) involves a more efficient breathing pattern.[159] Postural alignment is strongly associated with muscle activation; activation of the MF muscle and the lower regions of transversus abdominis and obliquus internus abdominis muscles is greatest when sitting with a lumbar lordosis associated with a smooth transition to kyphosis at the thoracolumbar junction, whereas thoracic erector spinae and obliquus externus abdominis muscle activity is greatest when the thoracolumbar region is extended; and activity of the extensor muscles is minimal in slumped sitting.[156,160] Swayback postures involve a tendency to "hang" on the obliquus externus abdominis muscle as a result of the more posterior alignment of the upper trunk relative to the pelvis.

Although this proposed "ideal" postural alignment is unlikely to be ideal for all individuals (for reasons such as pathology [e.g., spinal stenosis], spinal segmental mobility, function, habitual postures and movements, anthropometric features [e.g., lumbosacral angle], and other issues), it serves as a starting point for identification of features that can be evaluated for relevance to pain. In a way, it is the basic blueprint for postural alignment that acts as a starting point for assessment, but this needs to be molded by the specific presentation of the patient to identify the postural alignment that is ideal for their unique individual situation. If a feature of postural alignment is identified that deviates from ideal, it can be modified to assess the relationship to pain/muscle activation. If correction changes symptoms and/or reduces overactivity of muscle, then the feature is likely to be relevant to consider in planning of the motor control training program.

The key to application of motor control training for correction of posture or postural alignment is careful assessment to identify the features that are relevant to the patient's symptoms, and the evaluation of the outcome for his or her symptoms when specific features are modified. Clinicians have a host of techniques available to them to assist the patient in "correcting" the suboptimal features of motor control and a trial and error approach to find the best solution is advocated.

Assessment and Treatment Goal Planning. Assessment of posture and postural alignment is undertaken in a range of positions. In addition to the specific posture that a patient indicates is problematic, it is common to assess posture in sitting and standing. There is a broad range of features that are considered (Table 14-1). The relevance of a specific feature of postural alignment for the patient's presentation can be supported if successful modification of the features makes a positive change in symptoms and/or reduces muscle overactivity/hyperactivity. In many patients, it will be possible to identify a predictable mechanical response to changes in posture and postural alignment, but this is not always the case. Considering the fact that pain has a nonlinear relationship to nociceptive input (see section "Neurobiology of Pain"), it is not surprising that for some patients there is no clear mechanical presentation to their symptoms, and a precise relationship between posture and pain may not be forthcoming. Furthermore, in some cases pain may be provoked only by prolonged posture. In these cases it may be more helpful to consider the optimization of muscle activity as an indicator of the target alignment.

At the conclusion of the assessment, the clinician records a list of key features that have been identified as having a relationship to the patient's symptoms. This list should be ranked in order of importance and highlighted for reference throughout the progression of rehabilitation of the patient. The optimization of posture and postural alignment can achieve a number of interconnected goals, which are outlined in Table 14-2.

Training. Training of posture and postural alignment involves identification of a strategy to modify the features that were identified to be relevant for the patient's presentation in the assessment and prioritized in treatment planning. Many possible training strategies are available, and once trialed, the strategy's outcome must be assessed. It is acceptable for the new posture to feel "odd" or "awkward," but it should not be painful or difficult to hold (i.e., it should not require substantial muscle activity to maintain the posture). This requires consideration of pathology if known (e.g., in advanced spinal stenosis, it is likely that pain will be provoked by trying to adopt a lordotic lumbar curve) and the individual patient's presentation. According to the principles of motor learning, the patient should be given a strategy to cognitively correct the posture with a feedback method to ensure he or she has performed the correct modification (e.g., feedback with mirror, manual cues). Once identified, training may commence with a few sessions throughout the day as a home program to learn to change posture. This should be progressed to frequent adoption of the posture at regular intervals throughout the day as required by the functions being performed. Table 14-3 presents a range of strategies that may be helpful to modify posture.

TABLE 14-1

Assessment of Posture and Postural Alignment: Features Assessed for Deviation Relative to "Ideal" Posture and Relevance for Symptoms

Sagittal alignment/sagittal balance	• Alignment of C7 over sacrum; or manubriosternal junction over symphysis pubis ○ Sway (thorax posterior to pelvis), kyphotic/slump (thorax forward of the pelvis)
Spinal curves	• Start and finish of sagittal spinal curves, depth of curves ○ Lumbar lordosis ○ Thoracic kyphosis ○ Transition from thoracic kyphosis and lumbar lordosis (i.e., flat, flexed, or extended at the thoracolumbar junction) ○ Cervical lordosis and level head position • Segmental changes, such as segmental lordosis, segmental lumbar kyphosis (i.e., flexion at lumbosacral junction) • Pelvic position ○ Anterior/posterior tilt; look at relation of anterior superior iliac spines to posterior superior iliac spines
Frontal plane (front/back)	• Lateral shift/list upper trunk • Pelvis lateral tilt/rotation • Right/left weight bearing • Scoliosis: structural versus functional • Infrasternal angle symmetry
Muscle activity	• Assessed with observation, palpation, electromyography, ultrasound imaging ○ Hypertrophy/atrophy ○ Hyperactivity/hypoactivity ○ Asymmetry
Posture/postural alignment of adjacent segments	• Lower limb, including the feet ○ Hip: flexed, neutral, extended, adducted, rotated ○ Knee: flexed, neutral, (hyper)extended, medial (internal)/lateral (external) rotation of tibia and/or femur ○ Foot/ankle: pronated/supinated • Shoulder girdle: scapular position and stability • Neck/thorax

TABLE 14-2

Training Goals of Posture and Postural Alignment

Optimize lumbopelvic loading	• Avoid postures that do the following: ○ Provoke pain ○ Are difficult to maintain • Encourage postures that do the following: ○ Relieve pain ○ Correct asymmetry ○ Minimize activity of hyperactive muscles (often superficial/global muscles) ○ Enhance activity of hypoactive muscles (often deep/local muscles, but not limited to these muscles) • Avoid prolonged postures. • Encourage flexible use of posture/posture change.
Optimize respiratory pattern	• Change in posture will influence breathing pattern[159]
Optimize control of pelvic floor muscles	• Change in posture will influence pelvic floor muscle activity[158]

Clinical Approach to Motor Control Training of Muscle Activation

Principles. Activation of muscles of the lumbopelvic region influences the control of posture and postural alignment, and movement. Depending on the individual patient, modification of muscle activation may be the initial target for treatment. Alternatively, it may be easier to change muscle activation by modifying posture and postural alignment, or easier to modify posture and postural alignment, or movement by first changing muscle activation. Data from clinical trials highlight the value of detailed consideration of muscle activation. Motor control

TABLE **14-3**

Example Techniques for Correction of Posture and Postural Alignment

Instructions	• Verbal instructions are to guide the patient to modify the target feature of posture. • Examples: ○ "Roll forward on your tailbone" to improve anterior tilt and lordosis of the lumbar spine; "breathe into base of ribs" to remove excessive extension of the thoracolumbar junction ○ "Grow tall" ○ "Position (or lift) ischial tuberosities while sitting, avoiding flexion at the lumbosacral junction" ○ "Check that the shoulder girdle is relaxed"
Imagery (visual and proprioceptive)	• A "mental image" is selected that aids the patient to gain the understanding of the change that is required. • Example: ○ "Lengthening" of the spine may help reduce thoracic kyphosis
Manual guidance	• The clinician's or patient's hands may be placed on the patient's body to guide motion toward the corrected position. • Examples: ○ Hand on sacrum to provide guidance of anterior rotation of the pelvis ○ Hand on the thoracolumbar junction to provide guidance to relax into flattening in this region
Manual cues	• The patient places his or her hands on key landmarks of the body as a reference to monitor position/alignment. • Example: ○ Little finger and thumb of one hand on the xiphoid and navel to monitor the distance between these two landmarks as indirect feedback of changes in the angle of the thoracolumbar junction (i.e., distance reduces and increases with thoracolumbar flexion and extension)
"Dissociation" tasks	• Guidance is provided to change the relative motion of adjacent body regions. • Examples: ○ "Waiter's bow" exercise to teach a patient to flex at the hips rather than flex the lumbar spine ○ Attention to control of thoracolumbar junction curvature while rotating the pelvis and lower lumbar spine
Muscle activation	• Techniques are used to either increase or decrease activity of muscle(s) to aid movement to a specific posture. • Examples: ○ Augmented feedback of muscle activity to aid in increasing or decreasing activity (by palpation, observation, electromyography, ultrasound imaging or biofeedback) ○ Application of techniques to directly or indirectly change activity such as manual therapies (articular mobilization; connective tissue massage) ○ Use of serratus anterior activation (reversed origin insertion) to facilitate a thoracic kyphosis
Cues/reminders	• Tape is applied to remind the patient to adjust posture if it is no longer maintained. • Examples: ○ Application of therapeutic tape to the spine when positioned in lordosis to provide feedback by stretch sensation if curvature flattens; a software program that flashes a reminder on the computer screen at predetermined intervals ○ Photos taken to show patient his or her posture in different positions; sticky dots placed over the tragus, middle of the shoulder (anteroposterior), middle of the hip, middle of the knee and anterior to the lateral malleolus to demonstrate the appropriate line of gravity

training approaches can successfully change muscle activation.[161,162] Furthermore, several studies have shown that a patient's ability to activate muscles at baseline predicts his or her response to motor control training,[163,164] and the degree of improvement of muscle activation is related to clinical improvement.[163–165] In a general sense, muscle activation may be either too much or too little, and these extremes of muscle activation may both present for different muscles in the same patient. Muscles may also present with inadequate strength and endurance. Furthermore, muscles may be atrophied or have undergone a process of structural remodeling with increased fat and connective tissue. There is considerable interindividual variation with respect to the muscles that are involved and the manner in which the muscle activation is changed. Clinical strategies to subgroup patients based on their motor control presentation can aid identification of common patterns of modified muscle activation, and can facilitate the clinical reasoning required for treatment selection. A rule of thumb is that a first step should be to correct the pattern of activation before adding a load to induce change in strength, endurance, and structure.[166]

Clinical Note

The pattern of muscle activation should be corrected *before* adding load to induce change in strength, endurance, and/or structure.

There is no uniform strategy for training muscle activation and no single muscle that requires training in all patients. Instead, the strategy of motor control training depends on detailed assessment to identify suboptimal features of the muscle activation strategy. Ideally an assessment might involve detailed assessment of muscle activation used in multiple functions against known standards of muscle activation. Although clear in principle, this is difficult in reality because it would necessitate assessment of muscle activation with invasive procedures and detailed understanding of each task. In lieu of this complexity, specialized tests have been developed to provide insight into the features of the pattern of muscle activity that require training for an individual patient. The outcome of these tests is combined with insight gained from evaluation of the muscle activation patterns the patient uses in different postures and movements. Once the feature(s) of muscle activation that require attention have been identified, the challenge is then to find a technique that will encourage change in muscle recruitment and then transfer of the improved muscle activation pattern to function through progression of exercise.

Assessment and Treatment Goal Planning. Assessment of muscle activation strategy is complicated by difficulty associated with accurate assessment of muscle function in clinical practice in the absence of invasive recording methods. Although it may be relatively straightforward to assess the strength of a limb muscle by investigation of developed torque, when the target of assessment is to evaluate the quality of motor control, it is important to consider the subtle control of timing and amplitude of activity during the performance of a movement, and that requires consideration of muscles that are superficial and easily accessed plus deep muscles that cannot be easily assessed. Every time a patient moves and every posture he or she adopts will provide some information of muscle activation strategies, although methods to quantify activation are not readily available. As an alternative, assessments can be performed that evaluate a patient's ability to activate specific muscles. Table 14-4 presents details of the tests used to assess the potential impairment of activation of the deeper muscles of the trunk and any individual specific pattern of over activation of the more superficial muscles. The results of these tests have been shown to relate to the manner in which the muscles are functionally activated[167] and clinical rating scales (Table 14-5) are available to quantify the performance. These scales are repeatable and can discriminate between individuals with and without LBP.[168]

TABLE **14-4**

Assessment of Muscle Activation: Test of Independent Activation of Deep Trunk Muscles to Determine the Ability of Patient to Activate the Deep Trunk Muscles and Any Strategy for Overactivity of the Superficial Trunk Muscles

Test principle	• Evaluate ability to activate short/deep muscles independently from long/superficial muscles; outcome is related to quality of control of the muscle during function.[167]
Task	• Ability to cognitively perform the motor skill of contraction of the transversus abdominis or multifidus muscle independently from the other superficial trunk muscles. Assessments have also been devised along similar principles for psoas and pelvic floor muscles, to name a few.

Measure	• Precision
	  ○ Which muscles?
	  – By observation, palpation, electromyography, ultrasound imaging
	  – Aim for independent activation of deep muscle(s) without activation of the superficial muscles
	  ○ What sequence?
	  ○ What quality?
	  – Smooth, symmetrical, slow
	• Ideal response
	  ○ Palpable slow gentle increase in tension of deep muscle
	  ○ Co-contraction with other deep muscles
	  ○ No or little activity of superficial muscles
	  ○ Symmetrical contraction
	  ○ Smooth and sustained (not jerky) contraction
	  ○ Normal breathing
	  ○ Repeat multiple contractions (up to 10×10 seconds)

Interpretation	• Ability to activate specific deep muscles equals well-controlled activation during function with relevance for predicting treatment efficacy.[163] • Strategy of hyperactivity of superficial trunk muscles. This generally forms the foundation (in addition to information gleaned from assessment of posture and movement) of identification of the muscles that may require reduction in activity to optimize load on the spine/pelvis.

TABLE 14-5

Clinical Rating Scale to Assess Quality of Muscle Contraction and Interaction between Deep and Superficial Muscles

Criteria	Score
Quality of Contraction	
No contraction	0
Rapid superficial contraction	1
Just perceptible contraction	2
Good quality gentle slow contraction	3
Substitution	
Resting substitution	0
Moderate to strong substitution	1
Subtle perceptible substitution	2
No substitution	3
Symmetry	
Unilateral contraction	0
Bilateral but asymmetrical contraction	1
Symmetrical contraction	2
Breathing	
Inability or difficulty with breathing during contraction	0
Able to hold contraction while maintaining breathing	1
Holding	
Hold <10 seconds	0
Hold ≥10 seconds	1

Training muscle activation aims to encourage a strategy of muscle activation that maintains optimal load on the spine and pelvis, by a combination of increasing and decreasing muscle activity as indicated by assessment of the individual patient. The outcome of the test will indicate whether deep muscles require training and, if so, which specific muscles are involved. The test will also identify which of the more superficial muscles is potentially overactive or hyperactive and require "downtraining." As with posture and postural alignment correction, training of muscle activation may achieve several goals (Table 14-6).

Training. Every attempt to modify motor control, including those that target posture and postural alignment, and movement will influence muscle activation. Although in some cases simply addressing posture and movement may be sufficient, for many, attention must also be placed on changing muscle activation patterns directly. Many techniques have been described in clinical practice to explicitly target changing muscle activation in order to modify the load on the tissues of the spine and pelvis; either by enhancing muscle activation to improve control of aberrant movement or reducing muscle activation to decrease overload. Some of these techniques are presented in Table 14-7.

As a basic principle it is necessary to identify (1) a strategy that works best for the patient to modify his or her pattern of muscle activation, which will generally include components that achieve the best contraction of underactive/hypoactive components and reduce overactive/hyperactive components; (2) a feedback technique so that the patient can be sure that he or she is practicing the correct exercise at home; and (3) the number of contractions and duration of holding that the patient can perform

TABLE 14-6

Training Goals of Muscle Activation

Optimize lumbopelvic loading	• Avoid muscle activity that does the following:
	  ○ Provokes pain by overloading tissues
	  ○ Prevents an ideal posture or motion path
	• Encourage muscle activity that does the following:
	  ○ Relieves pain
	  ○ Improves control by reducing aberrant motion or enables a more ideal loading strategy of posture or movement
	  ○ Corrects asymmetry
	  ○ Minimizes activity of overactive/hyperactive muscles (often superficial/global muscles)
	  ○ Enhances activity of underactive/hypoactive muscles (often deep/local muscles, but not limited to these muscles)
	• Avoid prolonged postures
	• Encourage variation in muscle activation strategy to "share the load"
	• Encourage functional use of improved muscle activation patterns in postures and movements

Optimize breathing pattern	
Optimize control of pelvic floor muscles	
Aim to increase endurance in muscles which control spinal posture	

TABLE **14-7**

Example Techniques to Train Muscle Activation

Techniques to reduce activity of overactive/hyperactive lumbopelvic muscles	• Whole body posture (in general, more activity requires more support to encourage reduction) • Spinal posture (in general, "neutral" spinal alignment involves less activity of superficial muscles) • Instruction • Breathing techniques • Feedback (e.g., electromyography, palpation) • Decreased effort • Connective tissue techniques, trigger point, dry needling • Inhibitory taping • Imagery
Techniques to increase activity of underactive/hypoactive lumbopelvic muscles	• Whole body posture (stretch on muscle) • Spinal posture (greater activity in neutral) • Instruction • Co-contraction with other muscles to facilitate contraction (e.g., pelvic floor muscles can be used to encourage improved contraction of transversus abdominis[169]) • Manual facilitation • Imagery • Feedback (i.e., observation, palpation, ultrasound imaging) • Taping

while maintaining the contraction quality. With this information, it is possible to design an effective home program for the patient to practice for two to three sessions per day initially. Progression involves increased hold time/repetition and decreased feedback. The aim is for a "confident" correction of the muscle activation strategy that can be performed independently, cognitively, with minimal feedback, minimal effort, held for at least 10 seconds, and all while the patient breathes normally.

Clinical Approach to Motor Control Training of Movement

Principles. As for the other components of the approach, motor control training that addresses movement aims to change features that are identified in the assessment as having relevance for a patient's symptoms. Features of movements may be relevant because they load the tissues through motion into a provocative position, they involve provocative muscle activation, or they may load the tissues inappropriately as a result of too much or too little control. There are many potential underlying mechanisms. For instance, movement may excessively load the spine secondary to poor interaction between adjacent body regions (e.g., movement of the spine instead of the hip), suboptimal postures, or suboptimal muscle activation. The principles for training are similar to those outlined for posture and postural alignment, with the exception that the goal of training is the control of a trajectory of dynamic movement rather than a specific position. As for the other elements of motor control, there is not a single feature that requires training in all individuals, and treatment must be targeted to the individual presentation after careful and detailed assessment. The clinician's goal is to find a clinical tool or technique to aid the patient to change his or her movement strategy. The key to successful correction of movement is the accuracy of the assessment of the relevance of motor control for the patient's presentation (i.e., is the movement feature relevant to symptoms?) and the assessment of the outcome of the application of a treatment technique (has the technique made a difference to movement?). As outlined in section "Patient Subgrouping," a major focus in the recent clinical literature has been the identification of clinical subgroups; clusters of features that characterize a specific patient presentation. Subgrouping methods that include careful analysis of movement include those described by Sahrmann,[92] O'Sullivan,[142] and McKenzie.[141] The objective is to simplify the clinical reasoning approach by aiding the identification of patterns that can help the clinician select an appropriate course of treatment. Movement presentation forms a key element of many subgrouping approaches.[144] As always, careful assessment is critical.

Assessment and Treatment Goal Planning. For guidance of motor control training, movement assessment focuses on identification of features of movement that are related to symptoms and include feature(s) that suboptimally load the tissues in a manner that could be responsible for the development, provocation, or maintenance of symptoms. Identification of relevant features is guided by the pain response, comparison of the movement strategy against the expected optimal strategy for the task, and/or the muscle response. In addition to the observation of the movement, it is critical to consider the starting posture or position, as this will make an impact on the ensuing movement (e.g., motion of the lumbar spine during a function will differ depending on whether the lumbar region starts in a position of flexion or extension). Movement strategy can be assessed in several ways: (1) physiological movements (e.g., flexion in standing), (2) specific functional tasks (e.g., sit-to-stand),

(3) formal movement tests (e.g., assessment of dissociation of hip rotation from motion of the spine in prone), and (4) the functional task(s) that the patient indicates is problematic. In each case, the movement is observed in detail. Table 14-8 summarizes key principles of assessment of movement.

Similar to posture correction, strategies to change movement have many goals; these include, but are not limited to, changing movement to avoid provocative movements. Again, the key distinction is that, for movement correction, the objective is to change aspects that

TABLE **14-8**

Elements of Assessment of Movement Control Incorporating Tests from Multiple Subgrouping Paradigms

Features of Movement Evaluated	
Evaluation of changes in sagittal/frontal/transverse alignment during movement	• Timing • Amplitude • Sequence
Evaluation of muscle activity	• For example, palpation, observation, electromyography, ultrasound imaging
Evaluation of posture/movement of adjacent segments and ability to dissociate movement of lumbopelvic region from adjacent segments	• Lumbar versus hip • Lumbar versus thoracolumbar junction • Lower limb and feet • Shoulder girdle • Neck/thorax
Specific Movement Tests	

Basic physiological movements	• Flexion in standing
	  ○ Observe for loss of motion, increased lumbar flexion/lateral shift, increased lumbar extension, increased thoracolumbar extension, increased posterior/anterior pelvic tilt, relationship between hip and lumbar motion
	• Return from flexion in standing
	  ○ Observe for relationship between hip and lumbar motion, increased thoracolumbar extension, anterior pelvic sway, increased or decreased extension, anterior pelvic rotation
	• Extension
	• Side bending (lateral flexion)
	• Side "glide"
	• Rotation
	• Response to axial loading

Standardized functional movement	• Sit-to-stand
	  ○ Stand after placing spine in neutral
	  ○ Observe ability to maintain lumbar lordosis; observe where the movement is initiated, increased lumbar flexion, decreased lumbar extension, increased thoracolumbar extension, increased posterior pelvic tilt, anterior pelvic sway, medial hip rotation, relationship between hip, and lumbar motion
	• Squat
	  ○ Observe ability to maintain lumbar lordosis; observe for increased lumbar flexion, decreased lumbar extension, increased thoracolumbar extension, increased posterior pelvic tilt, medial hip rotation, relationship between hip and lumbar motion
	  ○ Include single leg squat and minisquat
	• Single leg stance
	  ○ Observe ability to control pelvic/trunk movement during single leg stance; observe for Trendelenburg sign (i.e., drop of pelvis on side of lifted leg), lateral shift of thorax/lateral flexion, medial hip rotation, pelvic sway
	  ○ Pelvic rotation
	  ○ Weight through heels not toes
	• Rolling
	  ○ Observe rotation of trunk and effect of control of rotation of trunk
	• Gait
	  ○ Observe for symmetry between sides, decreased motion, excessive pelvic rotation, relationship between hip and lumbar motion, increased lumbar flexion/lateral shift, increased thoracolumbar extension, increased anterior/posterior pelvic rotation, lack of thoracic rotation, limping

(*Continued*)

TABLE **14-8**

Elements of Assessment of Movement Control Incorporating Tests from Multiple Subgrouping Paradigms—cont'd

Specific Movement Tests	

Specific movement tests	• Slump/rock backward in sitting
	• Sit upright/erect in sitting
	  ○ Observe for inability to move lumbar spine and pelvis independently from thoracolumbar regions
	• Neutral repositioning test in sitting
	  ○ Place in neutral, fully slump and return
	  – Observe for flexion at symptomatic segment
	  ○ Bend forward while maintaining neutral position
	  – Observe for flexion at symptomatic segment
	• Knee extension with ankle dorsiflexion
	  ○ Observe for inability to dissociate hip from spine
	• Hip abduction/lateral rotation with hips and knees flexed in supine
	  ○ Observe for ability to move hip independently of lumbar spine and pelvis, asymmetry
	• Knee flexion (active and passive) in prone
	  ○ Observe for pelvic rotation, anterior pelvic tilt
	• Hip rotation medial and lateral (active and passive) in prone
	  ○ Observe for pelvic rotation
	• Hip and knee extension in prone
	  ○ Observe for excessive lumbar extension or segmental extension, absence of gluteal muscle activation, excessive trunk rotation
	• Hip abduction/lateral rotation in side lying with heels together
	  ○ Observe for pelvic rotation
	• Hip and knee flexion in supine
	  ○ Observe for lumbar flexion, pelvic rotation with lumbar extension
	• Anterior pelvic rotation in supine
	  ○ Observe for ability to rotate pelvis and extend lumbar spine independent of thoracolumbar junction
	• Posterior pelvic rotation in supine
	  ○ Observe for ability to rotate pelvis and extend lumbar spine independent of hip
	• Lateral pelvic rotation in supine
	  ○ Observe for ability to rotate pelvis independent of thoracolumbar junction and hip
	• Four point kneeling
	  ○ Rock back and forward
	  – Observe for relative motion of hips and lumbar spine, hip motion independent of thoracolumbar junction, lateral deviation of pelvis, lumbar rotation
	  ○ Arm lift
	  – Observe for lumbar rotation
	  ○ Anterior and posterior pelvic tilt
	  – Observe for relative motion of lumbar spine and thoracolumbar junction, lateral deviation

Muscle length/stiffness tests	• Tensor fasciae latae, rectus femoris, psoas (Thomas test) • Hamstrings in supine • Paraspinal muscles • Tensor fasciae latae/iliotibial band in side-lying (Ober's test)

load the tissues suboptimally in a dynamic sense as the spine and pelvis move through a trajectory. Table 14-9 includes a summary of the multiple goals that may be targeted with correction of movement, each with varying relevance for individual patients.

Training. Training movement control aims to find a clinical technique to change movement such that it is performed in a manner that more optimally loads the tissues. A range of training techniques is available to encourage a change in movement strategy. After each technique is trialed, it is critical to identify whether the desired modification of movement has been achieved. It is acceptable for the new movement to feel "odd" or "unusual," but it should not be painful or difficult to maintain (i.e., muscle activity required to control the movement should not be excessive). As for posture or postural alignment correction, the target movement needs to be considered with respect to pathology (if it is known) and the individual patient's motor control presentation. The objective is to find an optimal method to modify the target feature(s) of

TABLE **14-9**

Training Goals for Movement Correction

Optimize lumbopelvic loading	• Avoid movements that do the following: ○ Provoke pain ○ Are difficult to maintain because of high muscular effort • Encourage movements that do the following: ○ Relieve pain ○ Correct asymmetry ○ Correct specific movement faults – Dissociation between regions – Poor control at a specific segment/region – Maintain spinal alignment (e.g., lumbar lordosis, thoracic kyphosis and cervical lordosis) ○ Minimize activity of overactive/hyperactive muscles (often superficial/global muscles) ○ Enhance activity of underactive/hypoactive muscles (often deep/local muscles, but not limited to these muscles) • Avoid prolonged postures. • Encourage flexible use of posture and postural change
Optimize respiratory pattern	
Optimize control of pelvic floor muscles	

movement and identify a feedback technique (e.g., palpation, visual feedback with mirror) that the patient can use to confirm the correct performance. The home program commences with practice of the skill during a few sessions throughout the day and adoption of the corrected movement pattern as able during function.

Techniques to Correct Individual Specific Movement Faults

- Instructions (e.g., maintain lordosis when bending)
- Imagery (e.g., visual and proprioceptive)
- Manual guidance (e.g., hand on sacrum to facilitate anterior rotation of pelvis)
- Manual cues (e.g., finger on xiphoid and navel to control thoracolumbar junction)
- Dissociation tasks (e.g., separate lumbar from thoracolumbar junction motion, "waiter's bow")
- Muscle activation (e.g., palpation, observation, EMG biofeedback)
- Cues/reminders (e.g., taping)

Clinical Approach to Progression of Motor Control Training

Once a patient has mastered the skills to control posture and postural alignment, muscle activation, and movement, the next step is to challenge patients through a range of progressions to consolidate the improved motor control strategies and to challenge the patient for readiness for more challenging and more functional contexts. The program presented in Figure 14-10 shows a sequence through static and dynamic progressions, ultimately leading to function. The program also considers factors that may need to be included if they present as barriers for an individual patient. The following sections provide an overview of the principles applied in each progression.

Progression of Motor Control of the Spine and Pelvis with Static Training. Many clinical programs are available to progressively add load to progress training of control of static alignment of the spine and pelvis. In this phase, the patient is encouraged to maintain specific alignment of the spine and pelvis while load is applied to the trunk either directly or via limb movement or loading. Although many approaches begin training with this type of exercise from the outset, the alternative view promoted in this chapter is that the patient should first be trained to correct the relevant features of posture and postural alignment, muscle activation, and movement, and then train the control under load as a progression once he or she is confident with the correction. The basic sequence involves (1) correction of spine and pelvic alignment, (2) enhancement of contraction of the deep muscles, and (3) application of load or resistance to encourage activation of the more superficial muscles. The key feature that is monitored in the static phase of training is the ability to maintain the alignment of the spine and pelvis. If alignment cannot be maintained, then the load needs to be reduced to the point at which the control is challenged but not overcome. It is important to assess the threshold load that can be tolerated before control of alignment is lost; and any asymmetries in the control of alignment (such as lower threshold for loss of control of alignment in one direction when load is applied into rotation). The goals of static training are presented in Tables 14-10 and 14-11, which provide an overview of some common approaches to target this aspect of training.

Dynamic Control of the Spine and Pelvis and Motor Control Training. Training of dynamic control of the spine and pelvis follows the same overall principle as static progression (i.e., to monitor the patient's ability to control features of motor control while the spine is challenged). Although the goal in static progression is straight forward (i.e., to monitor and control of alignment of the spine and pelvis), the goal in dynamic progression is more complex. Every different movement has a different "ideal" against which the patient's performance is being judged. The clinician must have an understanding of the ideal performance of the task and a clear understanding of the patient's individual suboptimal features from the

TABLE **14-10**

Training Goals of Static Progression

Correct relevant features of motor control while the system is loaded	• Train integration of correct muscle activation • Train integration of correct posture and postural alignment • Train integration of correct movement (e.g., dissociation of hip from spine)
Focus on improving static control of lumbopelvic orientation/alignment	• Increase threshold load amplitude before loss of control of alignment • Target specific deficits in muscle system (e.g., asymmetries in load tolerance) • Target the functional needs of the patient • Train endurance • Progress by the following: o Load – ↑ Lever length – ↑ Load/resistance o Position – Supported – Unsupported o Dynamic – ↑ Speed of movement – ↑ Instability

TABLE **14-11**

Example Clinical Options for Static Progression

Strategy	Principles	Example Exercises
Leg loading	In crook lying, load is applied in a progressive manner by moving the legs in different planes of motion. The patient is instructed to maintain the position of the spine and pelvis.	Bent knee fall-outs: leg is slowly lowered to the side while maintaining the position of the pelvis and spine. The position of the spine and pelvis can be monitored with a pressure biofeedback unit. Specific directions of greater and lesser control can be identified by directions of movement that are associated with loss of control of alignment.
Rhythmic stabilizations (proprioceptive neuromuscular facilitation)	The patient maintains a neutral position as force is applied to the body. Force is normally low (~30%), and the direction slowly alternates.	In sitting with neutral alignment, a rotary force can be applied to the shoulders in alternating directions. During the change in direction, the activation of the superficial muscles alternates over the top of the tonically maintained activation of the deeper muscles.
Limb loading	The neutral position of the spine is maintained in any body position as load is applied first through short levers (i.e., bent limbs) and then through longer levers with the limbs straight.	In a quadruped position, the position of the spine is maintained in neutral as either the arm or leg or both are moved to the side or in the sagittal plane. Postural preparations are required to ensure the center of mass is placed over the new base of support.
Pilates	Load is applied though the use of limb load, springs, and other equipment as the spine is maintained in a neutral position.	On a Pilates Reformer Bed® (sliding bed with springs adjusted to resist the motion of the bed), the patient precontracts the deep muscles and maintains the neutral position as the sliding surface is translated by extension and flexion of the bed. Although this technique often involves movement on expiration, it may be more ideal to train movement with both phases of breathing.
Large exercise balls	The neutral position of the spine is maintained while the body is partly or completely supported on a ball. Load can be added by addition of limb load.	Patients can sit in neutral on a large ball with the hips above 90°. Load can be applied by reduction of the base of support (e.g., lifting a leg) or by increasing the load (e.g., by movement of the arms or legs).

assessment of movement. Progression of training through dynamic control requires an individualized approach and requires greater skill of assessment and training to be able to ensure that the patient is successful and that he or she is sufficiently challenged.

The goals of dynamic training are presented in Table 14-12. Two common approaches to dynamic progression are (1) exercises that challenge control of the spine as it moves and (2) exercises that challenge control of the spine during dynamic balance control (e.g., unstable surfaces). In both of these situations the aim is to challenge the spine by increasing the requirement to move, and the patient aims to control the features of movement that were identified on the initial assessment to be problematic (e.g., feedback to maintain lumbar lordosis and not move into lumbar flexion while standing on a balance board). Care must be taken to ensure progression occurs at a rate the patient can control, and not too fast. Table 14-13 presents common treatment approaches that may be applied in this phase of training.

Functional Retraining of Control of the Spine and Pelvis and Motor Control Training. A critical element of progression of exercise to function is that the best transfer to function is achieved the closer an exercise is to the function being targeted. The static and dynamic progressions discussed in preceding sections should ideally be linked to the functional needs of the patient, and the functional retraining phase of a motor control approach should be merely an extension of these earlier phases to ensure that the functional tasks that the patient highlighted in the initial assessment, or those that the patient continues to experience problems with are addressed.

The goal of functional retraining in the context of motor control training is to ensure that the correction

TABLE **14-12**

Training Goals of Dynamic Progression

Correct relevant features of motor control while the system is loaded dynamically	• Train integration of correct muscle activation • Train integration of correct posture and postural alignment • Train integration of correct movement (e.g., dissociation of hip from spine)

Focus on improved dynamic control of lumbopelvic movement	• Train control during changes in lumbopelvic position
	• Train incorporation of lumbopelvic movement into simple dynamic functions
	• Increase threshold load amplitude before loss of control of alignment
	• Target specific deficits in muscle system (e.g., asymmetries in load tolerance)
	• Target the functional needs of the patient
	• Train endurance
	• Progress by the following:
	  ○ Load
	  – ↑ Lever length
	  – ↑ Load/resistance
	  ○ Position
	  – Supported
	  – Unsupported
	  ○ Dynamic
	  – ↑ Speed of movement
	  – ↑ Instability

TABLE **14-13**

Example Clinical Options for Dynamic Progression

Strategy	Principles	Example Exercises
Unstable surfaces	The patient aims to maintain balance and alignment of the trunk when placed on an unstable surface. To maintain balance, movement of the spine is necessary, because it is impossible to maintain balance simply by control at the ankle. Careful attention is made to the features of muscle activity, alignment and/or movement that were identified to be poorly controlled in the assessment.	Balance boards Therapy balls
Function-specific tasks	Specific movements that are required for function are trained. The movement is segmented, simplified, and performed with reduced speed and reduced load.	Walking (progressing from side-side weight shift), trunk rotation

of motor control issues is integrated into function. Assessment of function relies on the principles described for dynamic and static progression and requires careful evaluation of the individual patient's key features of motor control (posture and postural alignment, muscle activation and movement) during the performance of the functional task. The target functions are assessed to determine which features are related to their symptoms. Those features are then modified using the skills the patients have learned in the early phase of correction and have reinforced through the phases of static and dynamic progression. It is necessary to draw on the principles of motor learning (i.e., segmentation, simplification and feedback) to optimize correction of performance of the function. Patients are challenged with increasing demand up to the intensity required for their natural performance.

Clinical Application of Strategies to Manage Barriers to Recovery. In addition to attention to correction of the basic elements of motor control, comprehensive management of a patient's symptoms may require consideration of other issues that can commonly present as barriers to recovery for an individual patient. Although the effect of many of these issues may only be minor for many, in some patients, these issues require careful attention in exercise prescription to achieve clinical change. The challenge for the clinician is to determine the importance of a potential barrier and to determine the amount of time and effort to devote to assessment and management. Table 14-14 presents a range of common barriers that may require consideration.

EVIDENCE FOR EFFICACY OF MOTOR CONTROL EXERCISES FOR SPINAL AND PELVIC PAIN

As described in the previous sections, rehabilitation of dynamic control of the spine and pelvis involves a motor learning approach targeted at all aspects of motor control. The intervention therefore involves more than a set of simple exercises targeted at specific muscles. Instead, the approach requires the clinician's attention to assessment of movement, posture and postural alignment, muscle activation (including detecting signs of overactivity and underactivity of specific muscle groups), in combination with consideration of other features including breathing, continence, balance, sensory function, and beliefs and attitudes about pain. Few clinical trials have investigated a comprehensive intervention. Most studies have been

TABLE **14-14**

Common Barriers to Training

Beliefs and attitudes	• Unhealthy attitudes and beliefs about back pain may compromise the attainment of motor control goals (e.g., fear of pain may encourage protective strategies). • Assessment and management of fear, catastrophizing, and pain coping skills may be required.
Breathing	• Because trunk muscles are involved in breathing and trunk control, modification of breathing pattern may challenge the control of the spine. • Careful assessment of the interaction of these functions and the effect of increased respiratory demand may be required.
Pelvic floor muscle function	• Issues of continence, pelvic organ support, and pelvic pain can all involve modified activation of the pelvic floor and abdominal muscles, which may interfere with progression of training for lumbopelvic control. • Specific assessment of the pelvic floor muscle dysfunction may be required.
Adjacent body regions	• Poor control of adjacent regions of the body will affect lumbopelvic control. • Biomechanical and neuromuscular interactions between the lower limbs and lumbopelvic region (e.g., pronation of the feet can lead to internal [medial] rotation of the femurs and anterior pelvic tilt), and between neck-thorax-shoulder require assessment and management if relevant.
Balance	• Patients with lumbopelvic pain often present with balance problems either secondary to reduced spinal motion (which is necessary for balance control) or poor sensory function of the spine.
Sensory function	• Training of posture and postural alignment, muscle activation, and movement includes a major sensory component associated with perception of incorrect and correct control of each element. • In some patients, additional attention to sensation may be required if it presents as a major factor.
Strength and endurance	• Although a major focus of motor control training is coordination of muscle activity, it is also necessary to address muscle strength and endurance if these features are compromised. • This may be particularly relevant in a more chronic context where structural remodeling of muscle (i.e., increased fat and connective tissue) is present. • Loading should not be commenced until muscle activity, alignment and/or movement can be controlled adequately.
Fitness	• Many patients with chronic pain are deconditioned and require general fitness training. • This should be commenced once the patient can control movement.

limited to investigation of the training of activation of the deep trunk muscles (i.e., transversus abdominis and MF) in isolation from the more superficial muscles. In some trials this is progressed to control of the muscles during static control of the trunk while adding load to the trunk via movement of the extremities. Furthermore, in most cases the intervention is applied in a generic manner, without individualization and to a participant group of nonspecific LBP. Unfortunately, most clinical studies include a limited description of the exercise intervention. If the description of the intervention is unclear, judging whether the study should be used to assess the efficacy of the intervention becomes difficult.

Several systematic reviews have been published that review the available literature and include meta-analysis of the outcomes.[1,170,171] These reviews conclude that motor control training is efficacious for reducing pain and/or disability in low back and pelvic pain. However, the comparison with other treatments remains unclear. A major limitation of the previous systematic reviews is the limited consideration of the content of the clinical program or the study population. This section provides an overview of evidence of efficacy of motor control training for spinal and pelvic pain with specific attention to these two aspects. The evidence discussed is restricted to studies that are conducted as randomized, controlled studies. A typical randomized, controlled study involves patients with a specific condition who are randomly allocated to a controlled group or to a group receiving the treatment of interest. To assess the efficacy of motor control exercises, only information provided by good quality studies is used. Good quality studies usually have a score of at least 3 on the 0-10 PEDro scale. The PEDro scale assesses the quality of randomized, controlled trials based on criteria such as allocation of patients and eligibility criteria.[172]

Randomized, controlled trials that included at least one exercise intervention that could be considered to involve elements of the motor control approach were identified. The comparison group could include no intervention, other exercise interventions, and other interventions, such as manual therapy techniques. Motor control training could be delivered in isolation or in combination with other treatments. Table 14-15 summarizes the study population, content of the motor control training program, comparison group, PEDro score, and outcome.

Can Motor Control Training Help in the Treatment of Acute Low Back Pain?

Can Motor Control Training Reduce Pain or Disability in Patients with Acute Low Back Pain?

One trial by Hides et al.[120] has addressed the issue of the efficacy of motor control exercises (involving training of MF in combination with transversus abdominis with a range of techniques and progressed into functional positions) in the treatment of pain and disability associated with acute first episode unilateral LBP. This trial compared motor control training plus medical management to medical management alone for acute LBP. The majority of participants in both groups recovered, and the effect of motor control exercise on the short-term outcome of pain was small and not significant. Motor control training showed no effect on disability in the short term. However, the size of the MF was restored only in individuals who received the motor control intervention, and this was predicted to have a potential relevance for long-term outcome (see next section).

Can Motor Control Training Reduce Recurrence after an Acute Episode of Low Back Pain?

Hides et al. published a follow-up study examining the ability of motor control training to reduce the recurrence of episodes after acute unilateral LBP.[70] Motor control training plus medical management was substantially more effective than medical management alone for reducing recurrence at the 1- and 3-year follow-up. Individuals who did not receive the motor control intervention were 12.4 times more likely to suffer a subsequent episode of LBP.

Can Motor Control Training Help in the Treatment of

Clinical Point

Motor control training does not appear to offer substantial short-term benefit in reducing pain or disability in patients suffering from low back pain (LBP) of less than 3 months' duration. However, research has shown that acute LBP changes the pattern of muscle recruitment, possibly leading to further back pain; therefore this approach appears to be useful in reducing the number of future episodes of LBP. Patients should be advised that the *purpose of the intervention is to reduce the recurrence of back pain episodes* and that the intervention is unlikely to affect pain or disability dramatically in the short term.

Chronic Nonspecific Low Back Pain?

Is Motor Control Training More Helpful in Reducing Pain or Disability Than Usual Care, No/Minimal Interventions, or Placebo in Patients with Chronic Low Back Pain?

Six trials have examined the effects of motor control training compared with no treatment,[173] educational booklet,[174] placebo,[175] or usual care by a physical therapist[176] or general practitioner.[177,178] Most of these studies used an intervention limited to activation of the deep muscles with progression into functional postures. Only the study of Costa et al.[175] included consideration of posture and movement, and this was limited in scope. Three trials combined other treatments with the motor control interventions.[176–178] In general, the studies reported that motor control was efficacious for pain and/or disability in the short and long term, with better outcomes than the comparison group. However, this was not universal. Although motor control training was effective, one

Randomized Clinical Trials of Motor Control Training

Author	Participants	Motor Control Program	Comparison	PEDro Score	Outcome
Acute LBP					
Hides et al.[120] Hides et al.[70]	Acute first episode unilateral LBP (<3 weeks)	Co-contraction of MF with TrA, feedback with ultrasound imaging, postural correction in standing + Medical management	Medical management (advice+medication)	7[120] 6[70]	Equal improvement in pain and disability at 4 weeks; symmetry of cross-sectional area of multifidus restored only for motor control group; decrease recurrence for motor control (1 year: 30% versus 84%, 3 years: 35% versus 75%)
Chronic Nonspecific LBP: Comparison with No/Minimal Intervention, Usual Care, or Placebo					
Costa et al.[175]	Chronic nonspecific LBP (>12 weeks)	Individualized exercise based on participant's presentation with aim to improve function of TrA and MF, progressed to basic correction of posture and movement	Placebo (detuned ultrasound therapy+detuned short-wave therapy)	9	Greater reduction in pain at 12 months, but not 2 or 6 months; significantly greater improvement in activity and global perceived effect for motor control at all time points
Niemisto et al.[178]	Chronic nonspecific LBP (>3 months)	Activation of TrA in prone, progressed to more functional positions and daily activities + Manual therapy and muscle energy	Usual general practitioner care (education booklet)	8	Greater improvement in pain and disability at 5 and 12 months
Cairns et al.[176]	Recurrent nonspecific LBP	Endurance training for TrA and MF muscles + Manual therapy	Conventional treatment	7	Equal improvement in pain and disability at treatment at 12 months
Moseley[177]	Chronic nonspecific LBP (>2 months)	Motor control exercises according to Richardson and Jull[179] (activation of TrA and MF in nonfunctional postures, progressed to static training with limb movements and muscle activation in functional positions)+manual therapy+education of neurophysiology of pain	Usual general practitioner care	6	Greater improvement in pain and disability for motor control at 1 and 12 months
Shaughnessy et al.[173]	Chronic nonspecific LBP (>12 weeks)	Activation of TrA and MF in nonfunctional postures, progressed to static training with limb movements	No intervention	5	Greater improvement in disability for motor control group
Goldby et al.[174]	Chronic nonspecific LBP (>12 weeks)	Training of co-contraction of TrA and MF, progressed to function	Education booklet	4	Equal improvement in pain and disability
Chronic Nonspecific LBP: Comparison with Manual Therapy					
Ferreira et al.[182]	Chronic nonspecific LBP (>3 months)	Training of co-contraction of TrA and MF with real-time ultrasound feedback Progressed to activation in functional positions and training the coordination of all trunk muscles during functional tasks	Spinal manipulative therapy	8	Equal improvements in pain and function at 8 weeks, 6 months, and 12 months

TABLE **14-15**

Randomized Clinical Trials of Motor Control Training—cont'd

Author	Participants	Motor Control Program	Comparison	PEDro Score	Outcome
Critchley et al.[181]	Chronic non-specific LBP (>12 weeks)	Training of co-contraction of TrA and MF, progressed to group exercises that challenged stability	Manual therapy+home exercises pain management program	7	Equal improvements in pain and disability at 18 months
Rasmussen-Barr 2003[180]	Chronic nonspecific LBP (>12 weeks)	Training of co-contraction of TrA and MF, progressed to activation with limb loading, activation in functional task and in situations that provoke pain	Manual therapy	5	Greater reduction in disability after treatment and 12 months
Goldby et al.[174]	Chronic nonspecific LBP (>12 weeks)	Training of co-contraction of TrA and MF, progressed to function	Manual therapy	4	Greater reduction in pain and quality of life at 6 months
Chronic Nonspecific LBP: Comparison with Other Exercise					
Macedo et al.[183,184]	Chronic nonspecific LBP (>12 weeks)	Individualized exercise based on participant's presentation with aim to improve function of TrA and MF, progressed to basic correction of posture and movement	Graded physical activity	8	Equal improvements in outcome at 2, 6, and 12 months; greater reduction in pain with motor for patients with high score on lumbar instability questionnaire
Ferreira et al.[182]	Chronic nonspecific LBP (>3 months)	Real-time ultrasound Progression by incorporating more functional positions and training the coordination of all trunk muscles during those functional tasks	General exercise (strengthening, stretching, and cardiovascular exercise)	8	Better function and global perceived effect for motor control at 8 weeks; outcome not different between groups at 6 and 12 months
França et al.[187]	Chronic nonspecific LBP (>3 months)	Exercises focused on the TrA and MF muscles progressed to upright postures	Muscle stretching exercise	8	Greater improvement in pain and disability with motor control at 6 weeks
Unsgaard-Tøndel[189]	Chronic nonspecific LBP	Training of co-contraction of TrA and MF with ultrasound imaging, progressed to activation in function	High load sling exercise or general exercise	7	Equal improvement in pain and disability at treatment conclusion and 1 year
França et al.[188]	Chronic nonspecific LBP (>3 months)	Training of co-contraction of TrA and MF progressed to upright postures	Strength training of global muscles	7	Greater improvement in pain and disability with motor control at 6 weeks
Koumantakis et al.[186]	Chronic nonspecific LBP (>6 months)	Training of co-contraction of TrA and MF in nonfunctional positions, progressed by incorporation into functional task and heavier load exercise tasks performed by comparison group	Higher load exercise for extensor and flexor muscles	7	Equal improvements in pain and disability at 2 and 5 months
Kladny et al.[190]	Chronic nonspecific LBP	Training of co-contraction of TrA and MF motor control exercises + General exercises	General exercises+manual therapy	5	Greater reduction in disability for motor control at end of treatment

Author	Participants	Motor Control Program	Comparison	PEDro Score	Outcome
Miller et al.[185]	Chronic nonspecific LBP (>7 weeks)	Activation of TrA (with MF), progressed to maintenance of activation while movement of extremities in multiple positions and functional tasks	McKenzie approach	5	Equal improvements in pain for both groups at 6 weeks
Stevens et al.[191]	Chronic nonspecific LBP	Training of co-contraction of TrA and MF progressed to contraction in different contexts + Manual therapy (10%)	General exercises of trunk muscle function and coordination	2	Greater improvement in pain for motor control in short term, then no difference
Chronic Nonspecific LBP: Comparison with Surgery					
Brox et al.[193] Forholdt et al.[194]	Chronic LBP (>12 months) with spine degeneration or spondylosis	Training of co-contraction of TrA and MF+exercise for endurance and coordination+cognitive intervention	Lumbar fusion surgery	8	Equal improvement in disability at 1 and 9 years; greater improvement in fear avoidance for motor control group
Chronic LBP with Specific Diagnosis					
Stuge et al.[195,196]	Pelvic girdle pain	Training of co-contraction of TrA and MF, progressed to global muscles with increased loading+manual therapy	Usual physical therapy	7	Greater improvement in pain and disability for motor control group at 20 weeks, 1 year, and 2 years
O'Sullivan et al.[69]	Chronic LBP with radiological diagnosis of spondylolysis or spondylolisthesis	Training of co-contraction of TrA and MF, progressed to activation with limb loading, activation in functional tasks and aggravating static postures	Usual general practitioner care	7	Greater reduction in pain and disability for motor control at 3, 6, and 30 months

MF, Multifidus; *TrA*, transversus abdominis; *LBP*, low back pain.

study showed that it was not more effective than a comprehensive physical therapy intervention for patients with recurrent LBP.[176] Notably, motor control training led to greater improvement in activity and had a greater global perceived effect than placebo at 12 months.

Is Motor Control Training More Helpful in Reducing Pain or Disability Than Manual Therapy in Patients with Chronic Low Back Pain?

Four trials have examined the effect of motor control training compared with manual therapy (i.e., spinal manipulative therapy).[174,180–182] In each trial, motor control training was limited to activation the deep trunk muscles with progression to functional positions and motor control training improved pain or disability. The effects were generally similar to those achieved with manual therapy in the short and long term, with the exception of outcomes favoring motor control training for reduction of disability at 12 months in one study[180] and pain and quality of life at 6 months in another.[174]

Clinical Point

Motor control training offers more benefits to patients with chronic LBP than does no provision of treatment or common traditional interventions such as educational booklets or treatment at the discretion of a medical practitioner. Patients with chronic LBP have altered patterns of muscle recruitment and a high level of disability. The effects of motor control training in reducing pain and disability appear to be similar to those seen with manual therapy treatment. Although some studies have attempted to identify subgroups of patients with LBP features that characterize patients who respond better to a particular intervention is still not known. Patients who benefit from motor control exercises show clinical patterns that have been suggested to indicate "spinal instability" (although the interpretation of this remains unclear as the scale used to assess "instability" may in fact provide information regarding pain characteristics [e.g., nociceptive versus central bias to symptoms] rather than "spinal instability"), probably more critically, signs of altered motor control. Although this issue has not been investigated extensively, *the authors recommend that clinicians assess patterns of movement and muscle recruitment to gain clinical insight into whether a patient would respond better to a motor control exercise approach or to treatment that focuses on mobilization of spinal joints.* Although the idea of treating patients with chronic LBP with a combination of motor control exercises and manual therapy seems appealing, this clinical question has not yet been investigated.

Is Motor Control Training More Helpful in Reducing Pain or Disability Than Other Forms of Exercises in Patients with Chronic Nonspecific Low Back Pain?

Nine trials have compared motor control exercises to other forms of exercises in nonspecific LBP.[182–191] The comparison exercise programs have included general exercises for muscle strength/endurance/flexibility,[182] graded physical activity using behavioral principles,[183,184] or other specific exercise approaches, including McKenzie exercises (i.e., end range repetitive spine motion)[185] and high load training for global trunk muscles.[186–189] Motor control training has generally been limited to activation of deep muscles with progression to functional positions with or without static training with loading applied by movement of the extremities. One study involved some element of individualization of training with consideration of muscle activation and some consideration of posture and movement.[183,184] In general, for these studies of nonspecific LBP, motor control training targeted at activation of deep muscles was equally efficacious for improvements in either disability or pain at 12 months. Three studies found greater effect of motor control training than general exercises for pain and/or disability on short-term outcomes (3 months,[191] 6 weeks[187,188]) and another found greater global perceived effect at 8 weeks (the primary outcome measure of the study).[182] Macedo et al.[183,184] found that motor control training was more efficacious than a graded activity program for patients who had higher scores on a questionnaire based on the clinical consensus opinion of features that relate to lumbar spine instability.[192] This preliminary observation requires validation in a new study, and it remains to be determined whether these features are indicative of "instability" or simply reflect characteristics of nociceptive pain.

What Is the Efficacy of Motor Control Training Compared with Surgery for Patients with Chronic Low Back Pain?

One trial (quality score of 8[193] on the PEDro scale) examined the effect of motor control training and education compared to surgery and physical therapy treatment (advice and exercises). The two groups produced similar reductions in pain and disability at 12 months and 9 years.[194]

Clinical Point

Motor control training is effective when applied as part of a treatment package that usually includes sessions of manual therapy and education. Currently, it appears that when applied in a non-specific manner to patients with "non-specific" low back pain, motor control exercises offer similar effects in terms of pain and disability compared with other forms of exercises, although in the short term, motor control exercises appear to be more beneficial than general exercises, and there is preliminary evidence that baseline features of an individual's presentation may aid identification of patients who are likely to respond best to this treatment. Treatment packages that include motor control training produce reductions in pain and disability similar to those seen with surgical procedures, such as spinal fusion. Clinicians should keep this in mind when recommending exercises for chronic LBP, especially given the high cost and risks associated with surgical procedures.

Is Motor Control Training Helpful in the Treatment of Patients with Specific Back Pain Characteristics?

One study investigated the effect of motor control training for management of pelvic girdle pain.[195] In this trial, motor control training involved activation of deep muscles progressing to higher load exercises applied using

a sling. The intervention included manual therapy and ergonomic advice and was compared to a conventional physical therapy program. When added to a conventional physical therapy program, motor control training was more effective than conventional physical therapy alone for all outcomes at 20 weeks and 1 year, and this was maintained at 2 years.[196]

One study investigated motor control training (i.e., co-contraction of transverse abdominus [TrA] and MF muscles, progressing to activation with limb loading and activation in functional tasks and aggravating static postures) for patients with chronic LBP associated with radiological diagnosis of spondylolysis or spondylolisthesis compared to usual care by a general practitioner.[69] Outcomes for pain and disability were superior for motor control training at all time points including 30-month follow-up.

An additional recent study (2013) evaluated a comprehensive motor control training program that addressed maladaptive movement/posture behaviors with integration into function (i.e., positive cognitive and lifestyle behaviors) for patients with chronic LBP that presented with a mechanical behavior (i.e., movement clearly associated with pain).[197] The treatment produced a greater improvement in pain and disability at 3 and 12 months than the comparison intervention. However, interpretation is complicated as both treatments addressed features of motor control; the comparison intervention combined manual therapy with simple nontargeted isolation of deep muscle activation, without consideration of progression or other elements of motor control.

Clinical Point

Approximately 50% of pregnant women experience lumbopelvic pain during pregnancy. It is known that specific deep abdominal and pelvic muscles maintain pelvic stability.[75] Pelvic pain has been associated with compromised control of the pelvic joints. The finding that motor control training is helpful in reducing pain and disability in patients with pregnancy-related pelvic pain[198] is important, both because of the prevalence of this condition and because of the lack of evidence of efficacy of other physical therapy interventions in its treatment.

Can Motor Control Training Change the Control of Muscle Activation, Posture, and Movement, and Is This Related to Outcome?

If motor control training is effective, it is important to consider whether the intervention can actually change the features of motor control it aims to address and, if so, whether improvements in motor control are associated with improvements in clinical outcomes. In terms of muscle activation, cognitive training of motor control of the deep muscles can change the timing of activation of the transversus abdominis muscle toward that identified for pain-free individuals,[199] the improvements in control persist when tested at 6 months after the intervention,[200] and the improvement in timing is related to restoration of the organization of the representation of the muscle at the motor cortex.[201] Timing of activation of the transversus abdominis muscle was not restored by other exercise that activates TrA but without any cognitive attention to contraction of the muscle or modification of its activity (e.g., a sit-up[200] or during abdominal bracing maneuvers[202]). Other studies report greater thickening of the TrA on ultrasound imaging during leg movement (consistent with improved muscle activation) after a motor control intervention but not after a general exercise program or a course of manual therapy.[203] In terms of muscle structure, Hides et al.[120] reported that the cross-sectional area of the MF can be restored with low-intensity activation in patients with acute first-episode LBP. In contrast, Danneels et al.[115] reported that this approach could not restore MF cross-sectional area in chronic LBP and high-level training to overload the muscle was required.

In terms of correction of posture, one study of patients with neck pain has reported that a program of cognitive correction of spinal alignment can improve spontaneous posture.[204] Likewise, features of movement presentation can be corrected with cognitive training.[205] Further work is required to study the effect of training on transfer of modified strategies for control of movement and posture to functional activities.

The association between changes in motor control and clinical improvement has also been studied, but to date this has been limited to investigation of the relationship between changes in activation of transversus abdominis and clinical trial outcomes.[165,203] Two studies have investigated changes in recruitment of the TrA with ultrasound, after the application of motor control training. In one study, which compared motor control training to general exercise and manual therapy, a subset of 34 participants with chronic LBP were assessed for ability to recruit the TrA by means of ultrasound measurement during a leg movement task and this was compared with clinical outcomes of function, disability, and pain. Patients with chronic LBP who received motor control training showed greater increase in thickness of TrA than patients who received general and spinal manipulative therapy. A moderate but significant correlation was found between changes in recruitment of the TrA and changes in the clinical outcomes of global perceived effect and disability (Figure 14-11).[203] The other study showed a relationship between increased thickening of TrA on ultrasound imaging (and decreased thickening of obliquus internus abdominis on ultrasound imaging) during voluntary TrA activation and pain reduction after training. Of note, this relationship between improvement in activation of TrA was achieved with each of the exercise interventions included in the study and not limited to the group that received motor control training.

A final issue is whether activation of the deep muscles, before treatment, can be used to predict the potential effect of motor control training for the individual. Data from a study by Ferreira[203] suggest that patients with poorer activation of the TrA before treatment have a greater response.

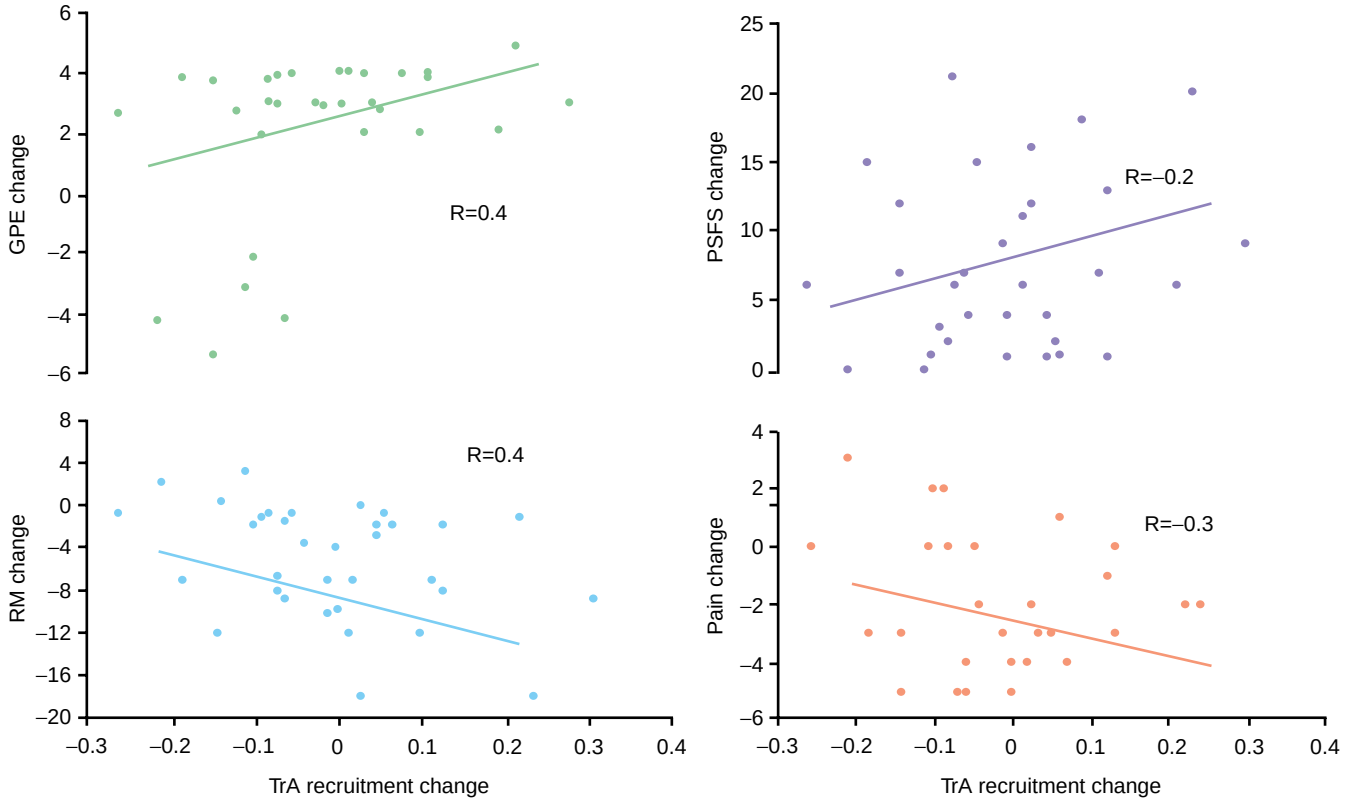

Figure 14-11 Correlation between changes in recruitment of the transversus abdominis measured with ultrasonography and changes in clinical outcomes. Lines represent R squared best of fit. *GPE*, Global perceived effect; *PSFS*, patient-specific functional scale; *RM*, Roland Morris.

In another study, individuals who improved the shortening/lateral slide of TrA observed on ultrasound imaging, after training, had higher odds for a clinically significant improvement at 12 months after an intervention.[164]

SUMMARY AND DIRECTIONS FOR THE FUTURE

Although existing studies are promising, further research is needed to further clarify the efficacy of motor control training in LBP. Critical issues that need to be addressed include the identification of subgroups that assist in the selection of the most appropriate treatment strategies and evaluation of the most appropriate clinical path for progression of exercise. Motor control training likely has a place in the management of many patients with low back and pelvic pain, but the relative contribution of the intervention to clinical outcomes will vary from individual to individual.

CHAPTER 15

Spinal Pathology
Nonsurgical Intervention

OMAR EL ABD, DANIEL CAMARGO PIMENTEL, JOAO EDUARDO DAUD AMADERA

INTRODUCTION

Painful spinal conditions are very common in the general population. The lifetime prevalence of back pain can be higher than 80%.[1] In 2011, episodes of back pain were responsible for more than 3.4 million visits to outpatients departments[2] and 3.9 million visits to emergency departments,[3] being the fourth leading symptom prompting patients to seek evaluation by a physician.[4] These conditions are responsible for much pain and physical suffering for patients and for social and financial pressures in the community. Interventional spinal techniques are a new and evolving field that combines different aspects of the medical field to manage patients with painful spinal conditions. These interventions combine various aspects of physical medicine and rehabilitation, orthopedics, pain management, radiology, rheumatology, neurology, and physical therapy. The objectives of these interventional techniques are to diagnose and efficiently treat painful spinal conditions and to minimize the persistence or recurrence of pain using minimally invasive procedures. These procedures are often faster, safer, and less costly than standard surgical techniques and produce successful outcomes when well indicated.

This chapter discusses painful spinal conditions and their management through interventional techniques. It provides an overview of the clinical presentations of different pathologies and, focusing on interventional spinal procedures, discusses appropriate imaging studies, indications, techniques, side effects, and complications.

EPIDEMIOLOGY

The incidence and prevalence of back pain have been the subjects of multiple epidemiological studies. The *incidence* is the rate at which healthy subjects report a new symptom or disease within a certain period. The *prevalence* is the number of subjects reporting certain symptoms or a certain disease at a particular period. Waterman et al.[5] estimated a back pain incidence of 139/100,000 person-years with a bimodal distribution among age groups. Two peaks were found: between 25 and 29 years of age (258/100,000 person-years) and 95 and 99 years of age (147/100,000 person-years). Lawrence et al.[6] reported a prevalence of 59.1 million U.S. adults who have had back pain within the past 3 months. According to the American National Center for Health Statistics 2012 report,[7] 28.9% of all those living in the United States older than 18 years have had low back pain and 15.8% have had neck pain within the past 3 months. As reported by Balagué et al.,[1] the lifetime prevalence of back pain can be as high as 84%, and the prevalence of chronic back pain is approximately 23% with up to 12% of the population being disabled by this condition. Back pain also represents a heavy economic burden for industrialized countries. Annual direct costs related to back pain range from $22.7 to $82.6 billion, and the total cost can be as high as $238.1 billion a year.[8]

With regard to the location of pain, the prevalence of radiculopathy (9.9% to 25%)[9] is reported to be much lower than the prevalence of axial back pain (11% to 84%).[10] The percentage of patients who report an acute episode of back pain and later develop chronic pain (lasting 3 to 6 months or longer) is the subject of controversy. Several studies suggested that 75% to 90% of patients with an acute episode of back pain recover within 4 to 6 weeks.[11] However, studies have shown a higher incidence of recurrence and persistence of pain after the initial acute episode.[12] Although the findings of studies vary, clinicians encounter a number of patients who convert from acute to chronic pain.

ANATOMY AND PAIN-PRODUCING STRUCTURES

The human spine normally consists of 7 cervical, 12 thoracic, and 5 lumbar vertebral bodies, as well as 5 fused sacral vertebrae and 5 fused coccygeal vertebrae, although anomalies can sometimes occur. The spinal cord runs in the central canal and commonly ends at the L1-2 level.

Nerve roots emerge from the neural foramina. There are seven cervical intervertebral discs and eight cervical nerve roots. In the cervical region, the nerve roots emerge cephalad to their corresponding vertebral bodies except for the C8 nerve root, which emerges caudal to the C7 vertebral body. In the thoracic, lumbar, sacral, and coccygeal regions, nerve roots continue to emerge from the neural foramina just caudal to the corresponding vertebral bodies. The cauda equina develops at the L1-2 level; it is formed by an aggregation of lumbar, sacral, and coccygeal nerve roots. These nerve roots are present in the central canal and emerge at their corresponding neural foramina. Multiple ligaments and muscles support the spine. A spinal segment (Figure 15-1) consists of two vertebral bodies: an intervertebral disc and a set of two facets on each side (zygapophyseal joints). Pain can occur as a result of pathology involving a single element, multiple elements of a particular segment, or multiple segments.

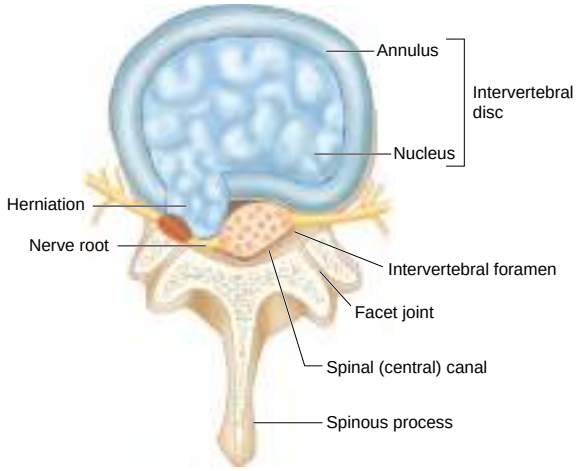

Figure 15-2 A lateral disc herniation compressing the exiting nerve root. (From Jandial R, Garfin SR: *Best evidence for spine surgery: 20 cardinal cases*, Philadelphia, 2012, Saunders.)

Radicular Pain

Involvement of nerve roots causes radicular pain. Nerve roots are affected secondary to mechanical pressure, inflammation, or both. Mechanical pressure usually occurs secondary to disc protrusion (herniation) or spinal stenosis. In the case of disc herniation, the nucleus pulposus protrudes through the annulus fibrosus and causes mechanical compression of the nerve root either in the central canal or in the intervertebral foramen (Figure 15-2). Acute disc herniations are accompanied by multiple inflammatory products (listed later in this chapter), which play an important role in the production of pain. Disc herniations occur in all age groups but are predominant in the young and middle aged. In contrast, spinal stenosis most often affects the elderly. This condition is a combination of disc degeneration, ligamentum hypertrophy and facet joint arthropathy, and/or spondylolisthesis, resulting in stenosis of the central spinal canal in the cervical and lumbar spine (Figure 15-3). Spinal stenosis causes pressure on and possibly dysfunction of the spinal cord (myelopathy) when it involves the central canal in the cervical and thoracic spine. In the lumbar spine, the cauda equina roots are involved, which causes neurogenic claudication.

With radiculopathy, symptoms are present along a nerve root distribution. This causes pain in the upper and lower extremities. It is worth mentioning that pain in the periscapular, pericostal, and buttock area can be radicular in origin. Sensory symptoms include pain, numbness, and

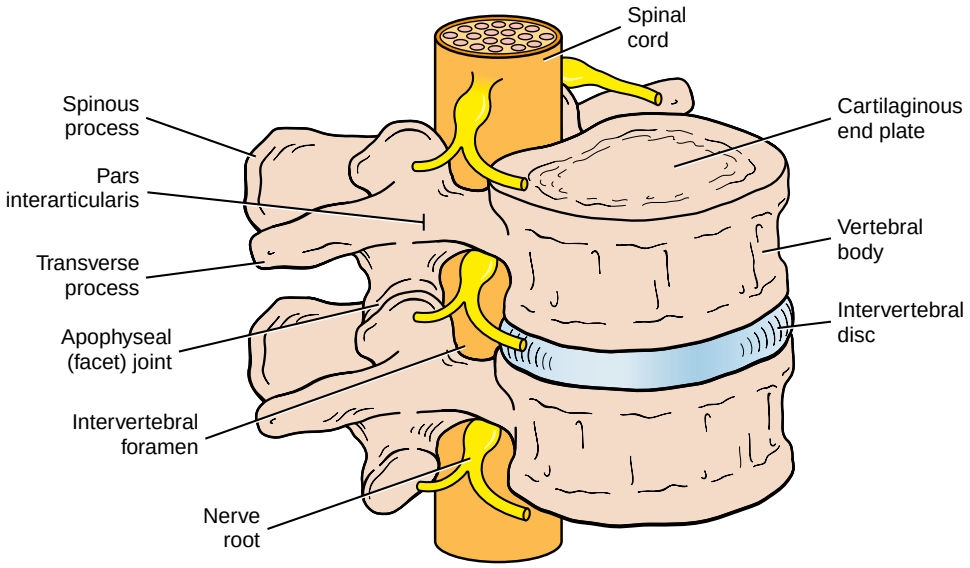

Figure 15-1 Spinal segment.

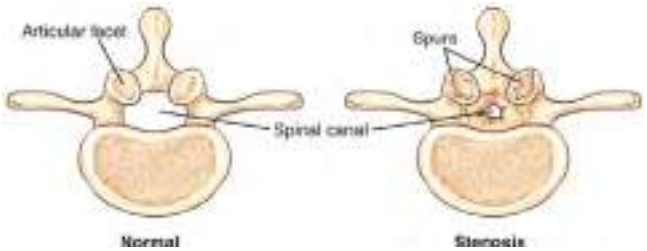

Figure 15-3 Axial cuts through vertebra showing a normal spinal canal (*left*), spinal stenosis (*right*). (From Lundy-Ekman L: *Neuroscience: Fundamentals for rehabilitation*, ed 3, St. Louis, 2007, Saunders.)

tingling that follow the distribution of a particular nerve root (see Figure 15-5 later in the chapter). The symptoms may be accompanied by motor weakness in a myotomal distribution.

Axial Pain

Axial pain occurs predominantly in the paraspinal areas and along the spinous processes. It also may be associated with pain in the extremities; however, by definition, paraspinal (axial) pain is more severe than the pain in the extremities.

Intervertebral Disc

Degenerative disc disease (spondylosis) is an important cause of axial pain. The pain from the intervertebral discs is located axially near the degenerated disc. The human disc is shaped like a donut and is formed of three distinct parts: the nucleus pulposus, the annulus fibrosus, and the cartilaginous end plates, which are adjacent to the vertebral bodies above and below. The nucleus pulposus is a semifluid mass of mucoid material composed of collagen fibers and proteoglycans. Water constitutes approximately 80% to 90% of the nucleus. As the disc ages, it loses its water content, which is replaced by fibrocartilage. The end plates function as the nutrient pathways for the disc. They are composed of hyaline cartilage, which is located toward the vertebral body surface, and fibrocartilage, which is concentrated toward the nucleus pulposus. Degeneration of the annulus predisposes the nucleus to herniation, which occurs most often at the annulus' weakest part, its posterolateral aspect. Good evidence indicates that, in addition to the pain caused by mechanical irritation of the sensory nociceptive fibers in the damaged intervertebral disc, discogenic pain occurs secondary to chemical irritation. Multiple inflammatory products are found in the painful disc tissue. These include phospholipase A2 (present in high levels), prostaglandin E, histamine-like substances, potassium ions, lactic acid, and substance P, as well as calcitonin gene-related peptide, vasoactive intestinal peptide, and other polypeptide amines, which can increase the excitability of the sensory neurons.[13,14]

The mechanism of pain referral is complex. Healthy lumbar intervertebral discs receive sensory supply into the annulus fibrosus, whereas diseased discs, according to one report, have an in-growth of nerve fibers that express substance P into their nuclei.[15] Two extensively interconnected nerve plexuses, the anterior and posterior plexuses, serve as the source of nerve endings within the lumbar intervertebral discs. The anterior plexus is formed from branches of both sympathetic trunks: the proximal ends of the gray ramii communicantes and the perivascular nerve plexuses of the segmental arteries. Therefore the anterior part of the disc is innervated solely by sympathetic fibers.[16,17]

The sinuvertebral nerves constitute the vast majority of the posterior plexus. Although some consider these nerves recurrent branches of the spinal nerves, others regard them as branches of spinal nerves with a sympathetic component. Luschka first described the sinuvertebral nerve as reentering the canal and providing innervation to the posterior longitudinal ligament and annulus fibrosus.[18] It now is widely accepted that the sinuvertebral nerve is the main nerve supply to all structures in the spinal canal. It enters the spinal canal through the intervertebral foramen. Once inside, it gives off multiple ascending and descending branches, which eventually combine to form a plexus along the posterior longitudinal ligament.[19,20] This plexus receives branches from the ipsilateral caudal and cephalic segments of the sinuvertebral nerve and as suggested the contralateral side as well.[21] Because of the interaction with the sympathetic system, as well as the segmental anastomosis, somatic pain referral is extremely common; that is, pain occurs in areas that commonly feel pain, such as the skin and underlying muscles.

Facet Joint

The facet (zygapophyseal) joints can be another source of axial pain. Pain is attributed to facet joint pathology in approximately 15% to 32% of patients who describe axial pain.[22] The facets are paired synovial joints located adjacent to the neural arches. They are formed by the superior articular process of the vertebra below and the inferior articular process of the vertebra above.

Pain is located predominantly in the paraspinal area. Pain originating from the facet joints can be either unilateral or bilateral. The results of multiple studies have led to the development of specific pain referral maps for the cervical facet joints. The facet joints receive their innervations from the medial branch of the dorsal ramii, with each medial branch innervating two joints.[23] Each joint is innervated by the medial branches rostral and caudal to that joint.[23] In the cervical spine, cervical facet pain can be accompanied by headaches in arthropathies of the atlantooccipital, atlantoaxial (C1-2 facet joint),

C2-3, and C3-4 facet joints. This is especially observed in patients with a history of whiplash events.[24,25] The third occipital nerve, which is the superficial medial branch of the C3 dorsal ramus, predominantly innervates the C2-3 joint, along with articular branches from the C2 dorsal ramus. At times, a small, inconsistent contribution arises from a communicating branch of the great occipital nerve.[26,27] The C1-2 lateral joints are innervated by the anterior ramii of C1 and C2.[28] Upon entering the spinal cord, the C1, C2, and C3 nerves converge with trigeminal nerve afferents on cells in the dorsal gray column of C1 to C3. This results in the communication between both afferents known as *trigeminal volleys.* The trigeminal nerve provides superficial sensations to most of the face and anterior scalp. Therefore pain is referred in the trigeminal nerve distribution.

Compression Fractures

Acute vertebral compression fractures are becoming an increasingly common cause of axial back pain. This increase in incidence is probably due to the aging population and the prevalence of osteoporosis. The pain usually is very severe and localized, and it usually occurs in the area overlying the involved vertebral body. Vertebral osteoporotic compression fractures most often occur in the thoracolumbar junction area. The occurrence of these fractures increases with age, and its prevalence is estimated to be 10% to 26% among women and men older than 50 years.[29] The pain usually is precipitated by trauma, although it has been reported to follow minor events, such as coughing. It also can occur spontaneously in patients with severe osteoporosis because osteoporotic vertebral bodies are unable to withstand stress. In addition, compression fractures may be caused by malignancies involving the spine.

Sacroiliac Joint

Sacroiliac (SI) joint arthropathy also can be a cause of axial back pain that affects 15% to 30% of individuals with chronic nonradicular pain.[30] The pain is located in the lumbosacral-buttock junction with referral to the lower extremities and to the groin area. Painful conditions of the SI joint can result from spondyloarthropathies, infection, malignancies, pregnancies, and trauma, or they can even occur spontaneously.

Referred Pain

Musculoskeletal structures and organs near the spine are potential sources of pain, from which the pain can be referred to the spine and the paraspinal area. A careful, detailed physical examination is needed to assess these conditions because various shoulder and hip conditions can mimic radiculopathies. Pelvic conditions and malignancies involving the supraclavicular area or the axilla should be considered if symptoms persist despite the absence of identifiable lesions on imaging studies, especially if the patient has constitutional symptoms (e.g., fever, chills, weight loss) or bowel and bladder changes.

PATIENT EVALUATION

Careful history taking and a thorough physical examination are the most important aspects of the evaluation of patients with a painful spinal condition. This process is necessary so that the clinician can interpret the imaging studies accurately in context and formulate the treatment plan.

History Taking

As in any clinical encounter, the clinician inquires about the history of the painful condition, including its location, onset, character, radiation, exacerbating and mitigating factors, and accompanying symptoms. It is crucial to establish which area is the most painful; this allows the clinician to formulate the preliminary differential diagnosis and to determine whether the pain is axial, radicular, or referred from other structures. Discogenic pain originating from painful disc conditions usually is difficult to localize. On questioning, patients frequently point to a general area of pain. This pain usually is exacerbated by sitting and mitigated by a change in position. Pain may be characterized but not limited to aching or a sharp sensation. In the cervical spine, upper cervical discs refer pain to the occipital area, causing headaches.[27] In the lumbar spine, pain may be referred to the abdominal and inguinal areas.[21]

Cervical facet joint pain is usually but not explicitly exacerbated by neck extension or lateral bending. In the lumbar region, pain from facet joints usually is exacerbated by standing and walking and mitigated by sitting; however, pain from lumbar facet joints can occur on forward flexion as well. Pain from facet joints usually overlies the facet joints in the paraspinal area and is more localized than discogenic pain. Pain can be referred ipsilaterally or bilaterally.

Specific diagrams are available that show the referral patterns for cervical facet joint pain (Figure 15-4). The referral pattern for cervical facet joint pain has been studied and established.[31] To map the pain referral patterns for the cervical facet joints, researchers stimulated the joints in healthy subjects and noted the painful locations.[26,32,33] Different studies produced essentially very similar pain referral maps in the cervical spine. However, the authors of the chapter are not aware of studies that consistently reproduced pain referral maps from the lumbar facet joints.

Patients with radicular symptoms usually describe pain predominantly in the extremities. The pain may start as axial pain (in the case of disc herniations), which is followed by the onset of limb pain as the axial pain improves. It is important to note that the buttocks and periscapular regions are considered part of the limbs. Pain predominantly in these locations is considered radicular pain rather than

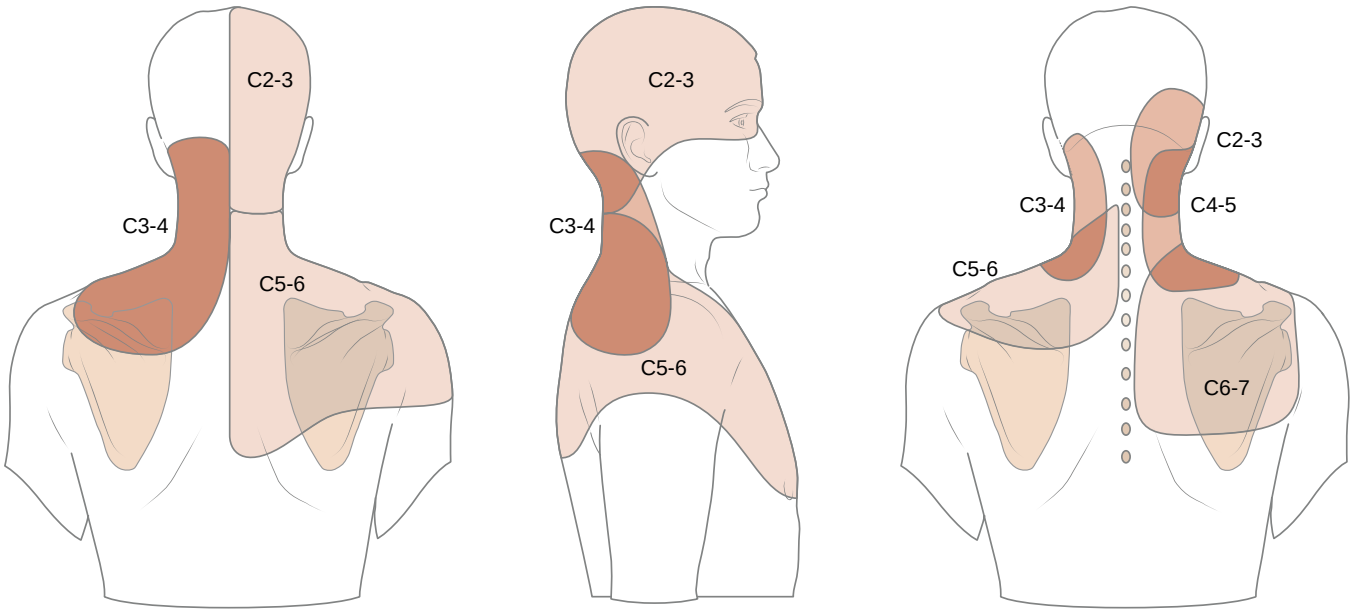

Figure 15-4 Referral patterns of cervical facet joint pain. *Dark brown* indicates overlap. In figure on the left, note that dermatomes overlap and different dermatomes are shown on each side. (From Slipman C, Derby R, Simeone F et al: *Interventional spine: an algorithmic approach*, p 614, Philadelphia, 2008, Saunders.)

axial pain. The pain often is described as shooting, stabbing, sharp, or burning, and patients often are able to localize the painful area accurately. The pain usually follows a specific nerve root distribution, with some variability.[34] Cervical radicular pain is exacerbated by cervical extension and lateral bending. The pain may be relieved by overhead elevation of the ipsilateral upper extremity because this maneuver reduces tension on the lower nerve roots (shoulder abduction relief sign).[35] Dermatome maps are available that outline the spinal nerve root distribution (Figure 15-5). It is important to note that these maps are not 100% accurate as nerve root distribution varies from individual to individual.

Clinical Note

Dermatome patterns can vary from individual to individual.

In cases of disc herniation and foraminal stenosis, lumbar radicular pain is often exacerbated by sitting and mitigated by walking. In cases of spinal stenosis, pain is generally exacerbated by walking (spinal extension) and mitigated by sitting (neurogenic claudication). Differentiating neurogenic claudication from vascular claudication, which occurs secondary to vascular insufficiency, is important because both conditions affect the same (elderly) population. Patients with vascular claudication feel relief from pain when they stop walking or when they stand rather than sit. Patients with neurogenic claudication have more pain when walking downhill (because of spinal extension) and less pain when walking with a walker or a shopping cart (because of spinal flexion). Pain from neurogenic claudication follows a nerve root distribution, whereas pain from vascular claudication is present globally in the location supplied by specific arteries.

Pain referred from the SI joint should be suspected in patients who describe pain in the low back, predominantly in the sacral sulcus area, with or without radiation to the lower extremity and the groin area. Pain occurs secondary to systemic conditions (e.g., spondyloarthropathies, repetitive shear events) and after trauma, or it can occur spontaneously.[36]

Physical Examination

A focused physical examination based on the information acquired in the patient's history establishes a working differential diagnosis. Some elements of the general physical examination are essential in the evaluation of patients with painful spinal conditions. These elements are detailed in Table 15-1.

Spinal Physical Examination Maneuvers

Specific maneuvers are used to evaluate a variety of conditions and anatomical areas that may cause a patient pain. These maneuvers are outlined in Table 15-2. Discogenic provocative maneuvers provoke pain reproduction in patients with lumbar discogenic pain. Root tension signs in the upper and lower extremities reproduce radicular pain. SI provocative maneuvers are used to reproduce pain in patients with SI joint syndrome. These tests are neither specific nor sensitive. (More information on these tests and others can be found in Volume 1 of this series, *Orthopedic Physical Assessment*.)

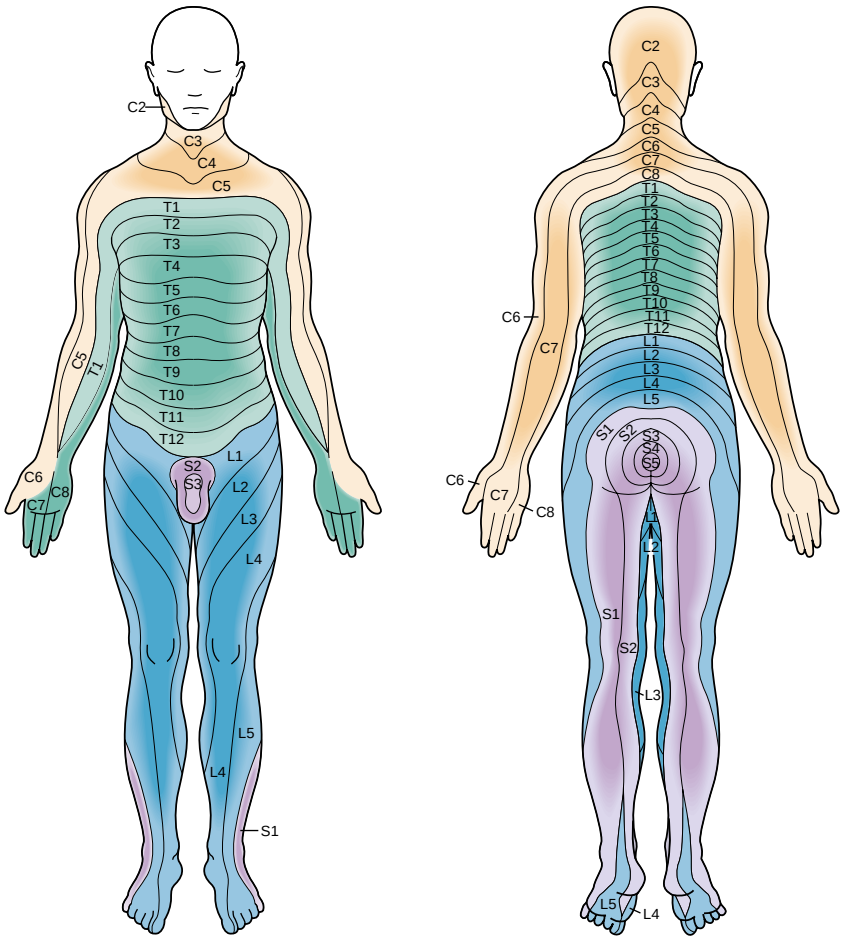

Figure 15-5 Dermatome maps. (From Marx J, Hockberger R, Walls, R: *Rosen's emergency medicine: concepts and clinical practice*, ed 8, Philadelphia, 2014, Saunders.)

TABLE **15-1**

General Physical Examination Elements that May Have Bearing on a Spinal Condition

Evaluation	Description	Rationale
Height and weight	Measurement	Height-weight ratio assessment, exercise and diet recommendations; unusual loss of weight requires medical workup
Deformity	Scoliosis, kyphosis, reduced lordosis (cervical or lumbar)	Sign of spinal pathology, postural changes, and possible causes of musculoskeletal imbalances
Muscle wasting	Inspection of the peripheral muscles	Sign of radiculopathy or other neurological disorder
Leg length discrepancy	Measurement	Postural changes and musculoskeletal imbalances
Examination of pulses	Arterial pulses in the upper and lower extremities	Peripheral vascular disease may result in painful conditions that mimic radiculopathy
Palpation of lymph nodes	Presence of lymph nodes in the neck, axilla, and inguinal area	Possible sign of occult malignancy resulting in metastasis to the spine
Palpation of tenderness	Over the spinous processes and facet and SI joints	Spine pathology, such as compression fractures and facet joint and SI joint arthropathy
Peripheral joint examination	Range of motion and specific joint maneuvers	Extraspinal source of pain with referral to the spine
Gait examination	Assessment of gait, heel walking, toe walking, and tandem walking	Good screening tool for evaluation of weakness and neurological disorders

SI, sacroiliac.

TABLE **15-2**

Spinal Physical Examination Maneuvers

Maneuver	Technique	Result
Pelvic rock	With the patient supine, flex the hips until the flexed knees approximate to the chest; then rotate the lower extremities from one side to the other	Provokes lumbar discogenic pain
Sustained hip flexion	With the patient supine, raise the extended lower extremities to approximately 60°. Ask the patient to hold the lower extremities in that position and release. The test result is positive with reproduction of low lumbar and/or buttock pain. Next, lower the extremities successively approximately 15° and at each point note the reproduction and intensity of pain	Provokes lumbar discogenic pain
Upper extremity: root tension signs	Perform contralateral neck lateral bending and abduction of the ipsilateral upper extremity	Reproduces cervical radicular pain in the periscapular area or in the upper extremity
Spurling's maneuver	Passively perform cervical extension, lateral bending toward the side of symptoms, and axial compression	Reproduces cervical radicular pain in the periscapular area or in the upper extremity
Straight leg raise	With the patient supine, the involved lower extremity is passively flexed to 30° with the knee in full extension	Reproduces pain in the buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Reverse straight leg raise	With the patient prone, the involved lower extremity is passively extended, the knee flexed	Reproduces pain in the buttock and anterior thigh in conditions with high lumbar (e.g., L3 and L4) radicular pain
Crossed straight leg raise	With the patient supine, the contralateral lower extremity is passively flexed to 30° with the knee in full extension	Reproduces pain in the ipsilateral buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Sitting root	With the patient sitting, the involved lower extremity is passively flexed with the knee extended	Reproduces pain in the buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Lasegue's test	With the patient supine, the involved lower extremity is passively flexed to 90°	Reproduces pain in the buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Bragard's maneuver	With the patient supine, the involved lower extremity is passively flexed to 30°, with dorsiflexion of the foot	Reproduces pain in the buttock, posterior thigh, and posterior calf in conditions with S1 radicular pain
Gaenslen's maneuver	Position the patient supine with the affected side flush with the edge of the examination table. The hip and knee on the unaffected side are flexed, and the patient clasps the flexed knee to the chest. The examiner then applies pressure against the clasped knee, extends the lower extremity on the ipsilateral side, and brings it under the surface of the examination table	Reproduces pain in patients with SI joint syndrome
SI joint compression	With the patient side lying, apply compression to the joint	Reproduces pain in patients with SI joint syndrome
Pressure at the sacral sulcus	With the patient in a prone position, apply pressure on the posterior superior iliac spine (PSIS) (dimple)	Reproduces pain in patients with SI joint syndrome
Patrick's test or FABER test	With the patient supine, the knee and hip are flexed. The hip is abducted and externally rotated	Reproduces pain in patients with SI joint syndrome, facet joint arthropathy (pain is reproduced in the low back), and degenerative joint disease of the hip (pain is reproduced in the groin)
Yeoman's test	With the patient prone, the hip is extended and the ilium is externally rotated	Reproduces pain in patients with SI joint syndrome
Iliac gapping test	Distraction to the anterior SI ligaments can be performed by applying pressure to the anterosuperior iliac spine	Reproduces pain in patients with SI joint syndrome

SI, sacroiliac.

The best diagnostic method for evaluating pain that emanates from the SI joint is a fluoroscopically guided, intra-articular diagnostic injection with a local anesthetic.[37]

Sensory Examination

Pinprick, light touch, position, and vibration sensation are examined, with particular emphasis on the limb with radicular pain. The sensations of vibration and position are diminished in severe spinal stenosis, especially in the cervical spine with central canal involvement. In radiculopathy, reduced pinprick and light touch sensations are noted in specific dermatomal distribution.

Spinal Sensory Changes with Pathology

- Spinal stenosis: sensations of vibration and position are affected
- Radiculopathy: sensations of pinprick and light touch are affected in specific dermatomes

Deep Tendon Reflexes

Examination of the deep tendon reflexes is helpful in the diagnosis of radiculopathies, especially if asymmetrical reflexes are present (Table 15-3). Deep tendon reflexes may be diminished secondary to multiple neurological conditions or as a result of age. In contrast, deep tendon reflexes may remain unaffected in radiculopathies or may even be hyperactive in radiculopathies accompanied by upper motor neuron lesions.

Manual Muscle Testing

Manual muscle testing is performed on the four extremities to determine whether a myotomic weakness is present. To detect myotomic weakness, two different muscles supplied by the same nerve root and two different peripheral nerves usually are tested. For example, to examine the L5 nerve root for muscle weakness, the extensor hallucis longus (L5, deep peroneal nerve) and gluteus medius and minimus (L5, superior gluteal nerve) are tested. This testing rules out different neurological conditions that cause weakness, such as myopathies, peripheral nerve injuries, and plexopathies.

TABLE **15-3**

Deep Tendon Reflexes

Deep Tendon Reflex	Nerve Root Affected
Biceps	C6
Triceps	C7
Quadriceps	L4
Medial hamstring (not commonly elicited)	L5
Gastrocsoleus	S1

Spinal Range of Motion

Range of motion usually is restricted in patients with spinal pain because of degenerative spinal conditions and muscle guarding around the painful structure.

IMAGING STUDIES

Imaging studies are essential to confirm a suspected diagnosis. Furthermore, imaging must be done before spinal intervention procedures are performed. With the advances in imaging technology, a high number of false-positive findings may be encountered. Imaging of the spine solely identifies anatomical changes but not biochemical or physiological changes that cause pain. It is important to correlate the imaging findings with the clinical picture. For example, anatomical changes, which are visualized through various radiologic and imaging studies, can be attributable to the aging process. However, these changes may not cause symptoms. Ordering unnecessary imaging studies without a clear management plan is not beneficial. Sorting out the positive findings is really the clinician's task. When the imaging studies are properly correlated with the clinical picture and other investigations, the accuracy of the diagnosis, and therefore management, is optimized.

Clinical Note

The clinician must always correlate the findings from diagnostic imaging with the clinical findings for the diagnostic imaging findings to have clinical significance related to the patient's problems.

Radiographic Imaging

Traditionally, radiographic imaging is the first step in the evaluation of painful spinal disorders. Although x-ray films cannot be used to evaluate soft tissues, such as the intervertebral discs, nerves, ligaments, or spinal cord, they are useful for screening for fractures, bone changes, and anatomical deformities. Radiographic studies can be used to evaluate the alignment of the spine and the integrity and architecture of the radiopaque structures. Dynamic x-ray images, such as flexion and extension views, can be used to evaluate spinal instability.

Plain x-ray film anteroposterior, oblique, and lateral views constitute a routine examination. These views provide information about intervertebral disc heights, spondylotic changes, foraminal size variability, deformities, and bony alignment. X-ray films can be useful for identifying malignancy and destructive, metabolic, and rheumatological diseases. The usefulness of ordering x-ray films for acute low back pain is the subject of debate in the literature. Because the pain from this condition improves in a short time, radiographic results usually are not significant and do not affect management. X-ray films should be requested in atypical presentations. Deyo and Diehl[38] suggested criteria for ordering x-ray films to

TABLE **15-4**

Criteria for Use of X-Ray Imaging in Acute Low Back Pain

Criteria	Rationale
Age >50 years	Higher risk of osteoporotic fractures
Significant trauma	Risk of fractures
Neurological deficit	Sign of radiculopathy
Unexplained weight loss	Occult spinal lesion (e.g., malignancy)
Suspicion of ankylosing spondylitis	Spine and sacroiliac joint x-ray films are diagnostic for this condition
History of alcohol or drug abuse	Risk of infection (e.g., osteomyelitis)
History of cancer	Possible spinal metastasis
Corticosteroid use	Osteoporotic fractures
Fever	Possible osteomyelitis
Pain that persists longer than 1 month	Pain is becoming chronic, and further management is recommended
Litigation	To further establish the cause of pain

Data from Deyo RA, Diehl AK: Lumbar spine films in primary care: current use and effects of selective ordering criteria, *J Gen Intern Med* 1:20-25, 1986.

evaluate painful conditions of the lumbar spine. The purpose is mainly to exclude other significant conditions that can manifest as low back pain. These criteria and their rationales are summarized in Table 15-4.

Common Spinal Pathology X-ray Series

- Anteroposterior view
- Oblique view
- Lateral view

Computed Tomography

Computed tomography (CT) scans use two x-ray beams focused on a particular plane of an object. Multiple images are taken, and composite axial images are created using a computer and a rotating x-ray beam. With advances in digital reformatting of the axial images, coronal and sagittal images can be obtained as well as a digital three-dimensional image reconstruction.

A CT scan of the spine provides superior quality imaging of the bone structures. With a CT scan, the clinician can identify subtle fractures that are not identifiable on plain x-ray films. CT scans also provide information about destructive bone pathologies (e.g., infection and malignancy) and on bony union after surgery. Using myelography in conjunction with CT scans enhances imaging for painful spinal disorders. Myelography involves injection of a contrast material into the spinal canal, after which the CT scan is performed. (Before the use of CT scans, myelography was performed with plain x-ray films.) CT scan myelography provides information about the status of the spinal canal in addition to the spinal bony elements. CT scans and CT myelograms are important in the postoperative workup of painful spinal conditions involving implanted ferromagnetic hardware and in patients unable to have magnetic resonance imaging (MRI) because of implanted devices.

Bone Scan

Bone scanning (also called *bone scintigraphy*) allows the clinician to assess both the anatomy and the physiological activity of tissues. It is an effective screening modality for evaluating systemic pathologies because it covers the whole body. Before and as part of the bone scan, the patient is given an intravenous injection of nuclear tracers that emit small amounts of γ- radiation proportional to the uptake from a specific tissue. Imaging of the radiation produced in tissues allows evaluation of the location of tissue metabolic pathologies. Technetium-99 m is used in the evaluation of bone pathologies, and gallium-67 is used in the evaluation of infections. Healthy bones are in a constant state of normal turnover of bone breakdown (osteoclast activity) and bone rebuilding (osteoblast activity). An increased concentration of the technetium-99 tracer suggests increased bone turnover, which can occur in pathologies such as osteoblastic malignant lesions and acute fractures. Lack of radioactive tracer activity indicates cessation of bone activity (cold defect), which can occur with osteonecrosis. Imaging of the radiotracer traditionally is performed in a uniplanar anteroposterior fashion. Single photon emission CT (SPECT) now allows tomographic images to be obtained, which improves the sensitivity and specificity of this modality.

Bone scanning is particularly useful for evaluating for occult lesions and suspected infections and as a screening tool for metastases. Because most metastatic spinal lesions are osteoblastic in origin, bone scans detect high bone turnover activity with these lesions. A minority of malignancies involving the spine (e.g., multiple myeloma) may involve osteoclastic activity; in these cases, a bone scan result is negative. If a bone scan result is positive, further imaging of the involved area(s) is performed using other modalities, such as CT scanning and MRI studies, which provide anatomical details.

Magnetic Resonance Imaging

MRI was first used in the late 1970s and had gained popularity by the mid-1980s. MRI has become the imaging modality of choice for evaluating painful spinal conditions. It provides a detailed anatomical picture that surpasses the results of other modalities, allowing the clinician to better visualize and evaluate structures, such as the nerve roots, spinal cord, paraspinal area, and soft tissues

(e.g., intervertebral discs). MRI is sensitive to bone marrow abnormalities found in malignancy, infection, and disc degeneration. With the use of intravenous contrast (gadolinium), MRI provides optimum information on spinal cord lesions, demyelination, infections, fractures, and tumors. In the evaluation of postoperative spinal pain recurrence, comparison of the MRI images before and after intravenous administration of gadolinium contrast helps to differentiate new disc herniations, recurrence, and postoperative scarring.

MRI technology does not involve the use of ionizing radiation. Instead it uses magnetic fields and pulsed radiofrequency through which computer-generated sagittal, axial, and coronal images are produced. An external magnet polarizes the hydrogen protons in water molecules, and a specific radiofrequency is pulsed into the body. Images are generated according to the tissues' mobile intrinsic hydrogen ions.

Two frequency spin sequences are used for MRI imaging: T1-weighted imaging (the longitudinal relaxation time) and T2-weighted imaging (the transverse relaxation time). On T1-weighted images, fat-rich tissues have a bright signal. On T2-weighted images, extracellular free water has a bright signal.

The most common terminology used by clinicians to describe MRI spinal findings is presented in Table 15-5, and findings are shown in Figures 15-6 to 15-13.

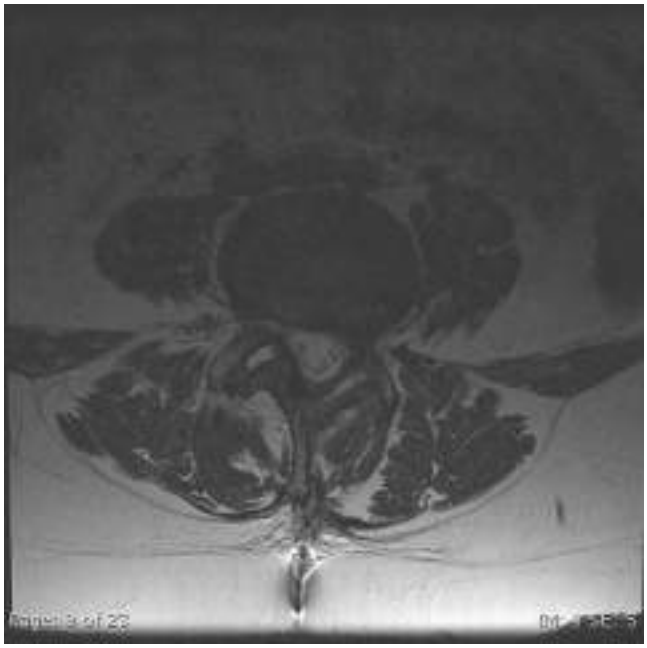

Figure 15-6 Axial T2-weighted image demonstrating fluid in the right L4-5 facet joint after left L4 laminectomy and facetectomy, indicating stress on the right L4-5 facet joint with possible pain.

TABLE **15-5**

Common Magnetic Resonance Imaging Terminology and Descriptions

Term	Description
Disc desiccation	Reduction of the bright nuclear signal on the sagittal T2-weighted images; this finding signifies disc degeneration and reduction of the water content of the nucleus
Disc bulge	Circumferential, broad-based extension of the annulus beyond the vertebral end plate
Disc herniation	General term used to describe the displacement of the nucleus pulposus beyond the disc itself
Focal disc protrusion	More specific term describing disc displacement. The nuclear material protrudes into the annulus without disrupting its outer wall; this results in a change in the contour of the annulus (see Figures 15-6 to 15-12)
Disc extrusion	Nuclear material protrudes through the outer wall of the annulus. The protruded material can remain contained by the posterior longitudinal ligament (subligamentous extrusion) or may extend beyond it (transligamentous extrusion)
Sequestered disc	Nuclear material is detached from the disc and migrates in the spinal canal cranially or caudally
High-intensity zone	An area of high intensity on T2-weighted images in the annulus;[39] it occurs secondary to an area of vascularized granulation tissue in the outer region of the annulus
Foraminal stenosis	Narrowing of the neural foramen; this commonly occurs secondary to a lateral disc herniation, bone spurs, or spondylolisthesis
Central stenosis	Narrowing of the central canal; this commonly occurs secondary to a combination of disc herniation and/or ligamentum hypertrophy, facet joint hypertrophy, and spondylolisthesis
Myelomalacia	T2-weighted signal changes in the spinal cord commonly present in severe central stenosis
End plate changes (Modic changes[40])	Changes in the end plates associated with degenerative disc disease at the level of involvement, first described by Modic et al.[40] Type 1 changes decrease signal intensity on T1-weighted images and increase signal intensity on T2-weighted images. Type 2 changes increase signal intensity on T1-weighted images and isointense or slightly increase signal intensity on T2-weighted images; type 3 changes show a decreased signal intensity on both T1- and T2-weighted images. These changes in signal intensity appear to reflect a spectrum of vertebral body marrow changes associated with degenerative disc disease

SPINAL INTERVENTION PROCEDURES

The two main types of spinal intervention procedures are diagnostic interventions and therapeutic interventions.

Diagnostic Intervention Procedures

The purpose of diagnostic spinal interventions is to establish and confirm a suspected diagnosis. In many cases the physical examination, imaging techniques, and electrodiagnostic studies fail to provide an accurate assessment of spinal pathologies. This often is due to multiple-level imaging findings or a lack of imaging or electrodiagnostic evidence of a painful spinal disorder. Through the use of local anesthetics, diagnostic interventions attempt either to "block" the painful structure and eliminate or reduce the pain or to provoke pain to allow an accurate assessment of the location of the pathology based on the patient's response.

Pharmacological Intervention Procedures

Local Steroid Injections

Therapeutic interventions are widely used to treat painful spinal conditions. These can include local steroid injections or other devices and procedures, such as

Figure 15-11 Sagittal T2-weighted image with a large focal protrusion at the L5-S1 disc level.

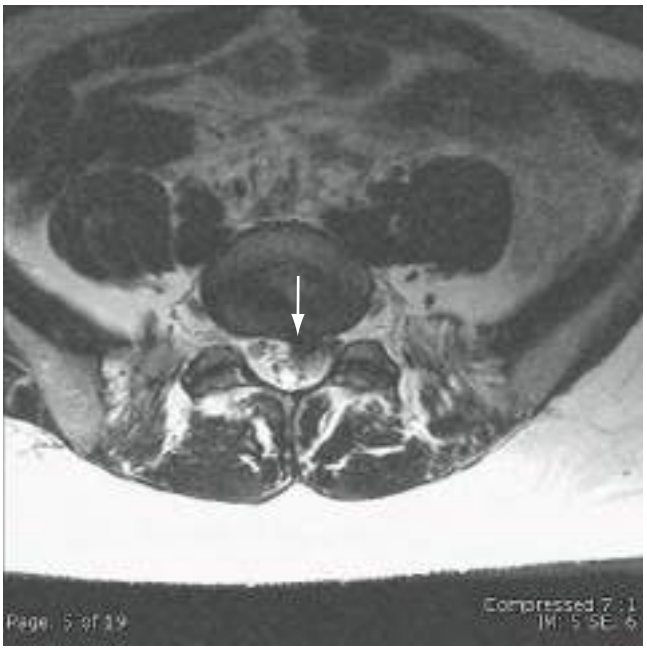

Figure 15-12 Axial T2-weighted image showing a large, left focal protrusion at the L5-S1 disc level compressing the left S1 nerve.

radiofrequency and percutaneous disc decompression. Administration of a local steroid injection in or around the painful structure is considered an efficient way to use steroids in small amounts without systemic side effects.

Steroids are a potent anti-inflammatory medication. They reduce inflammation around the intervertebral discs, spinal nerves, and facet joints. At the cellular level, steroids inhibit the action of phospholipase A2, preventing the formation of arachidonic acid and inflammatory mediators.

Figure 15-13 Axial T1-weighted image showing a large, left focal protrusion at the L5-S1 disc level compressing the left S1 nerve.

They also act as membrane stabilizers, blocking the conduction of nociceptive C fibers that carry pain signals. Steroids diminish the sensitization of the dorsal horn cells by reducing prostaglandins. After the inflammation has been reduced, edema around the nerve roots subsides and microcirculation is improved, reducing nerve ischemia. The steroids most often used in spinal interventions are listed in Table 15-6.

Interlaminar and Caudal Epidural Injections

Interlaminar epidural injections are the traditional and most frequently used spinal therapeutic intervention in the management of axial discogenic pain and radicular pain. Dogliotti[41] first introduced epidural injections in 1933. The injections were first used in the management of lumbosacral pain in 1952.[42] Currently the use of interlaminar and caudal epidural injections versus transforaminal epidural injections is the subject of debate, although the literature is increasingly showing more benefit of transforaminal epidural injection for the treatment of certain spine conditions as compared with other injections.[43] Interlaminar and caudal epidural injections are considered nontarget specific compared with transforaminal injections. Steroids are injected into the posterior epidural space but do not reach the anterior space because of the presence of ligaments. In a randomized, double-blind trial, Carette et al.[44] administered up to three interlaminar epidural injections of methylprednisolone acetate or isotonic saline to 158 patients with sciatica caused by a herniated nucleus pulposus (HNP). No significant differences in outcomes were seen in the short or long term (1 year). These researchers concluded that interlaminar epidural injections offered no significant functional

TABLE **15-6**

Common Medications Used for Spinal Intervention Procedures

	Hydrocortisone	Methylprednisolone (Depo-Medrol)	Triamcinolone Acetonide (Kenalog)	Betamethasone Sodium Phosphate and Acetate (Celestone, Soluspan)	Dexamethasone Sodium Phosphate (Decadron Phosphate)

benefit, nor did they reduce the need for surgery. The major flaw in this study was that fluoroscopic guidance was not used. Needle positioning was not confirmed either with fluoroscopy or by adding local anesthetic, and transient sensory and motor deficits were not monitored after the epidural injection.

Koes et al.[45] reviewed data from 12 randomized studies and reported that the efficacy of interlaminar epidural steroid injections was not established. The benefits of epidural steroid injections, if any, were of short duration only. Watts and Silagy[46] reviewed 11 randomized studies involving a total of 907 patients and reported no long-term adverse outcomes. They also provided quantitative evidence from meta-analysis that epidural administration of corticosteroids is effective in the management of lumbosacral radicular pain. In a retrospective study of 75 patients, Manchikanti et al.[47] compared pain relief after blind interlaminar epidural injections, caudal epidural injections, and transforaminal epidural injections. The response was most favorable with transforaminal injections, followed by caudal injections, which surpassed the outcome for blind interlaminar injections.

Indications for Interlaminar and Caudal Epidural Injections

- Overall, studies have shown better outcomes for interlaminar and caudal epidural injections in acute rather than chronic pain, with a longer duration of improvement for radicular pain.
- Interlaminar epidural injections are declining in popularity among interventionalists, whereas transforaminal epidural injections are growing in popularity because of their better outcomes.

Interlaminar epidural injections are performed blindly or with fluoroscopic guidance. In a prospective study that included 316 patients undergoing blind epidural injections, needle positions were evaluated using fluoroscopy.[48] Renfrew et al.[48] reported that, even in experienced hands, blind placement of the injection needle was optimal in only 60% of cases. They recommended fluoroscopic control and contrast administration to ensure correct needle placement and to prevent inadvertent vascular injections.

Technique for Interlaminar Epidural Injections. With fluoroscopic guidance, the level of the injection can be accurately assessed and the epidural location can be accurately confirmed using contrast. This reduces the patient's discomfort. Using contrast helps reduce the incidence of intravascular injections; such an injection can be readily identified because the contrast has a quick runoff (i.e., fast flow of contrast under fluoroscopy when the medium is injected into a blood vessel). The use of fluoroscopy and contrast is highly recommended in postoperative patients because it readily identifies the surgical level and confirms needle positioning.

The patient is placed in the prone position on the fluoroscopy table. A pillow is placed under the abdomen to open up the interlaminar space. Conscious sedation can be used but is not recommended; avoiding its use provides extra protection from accidental neural trauma. Light sedation is suggested if the patient is very anxious or has a history of vasovagal events. The blood pressure, pulse, and pulse oxymetry are monitored. The skin is prepped with iodine and draped with sterile drapes. The interlaminar space is properly identified under fluoroscopy by adjusting the end plates and aligning the spinous processes. A midline interspinous or slightly paraspinal entry point is identified. Using a 25-gauge, 4-cm (1.5-inch) needle, the clinician injects 0.5 cc of lidocaine 1% subcutaneously, forming a skin wheal. This injection is used to numb the skin, and it also provides the clinician with a needle introduction site.

For the intralaminar injection, 17- to 22-gauge Tuohy needles are used. These are special needles with curved tips designed to reduce the incidence of dural punctures. In most cases 9-cm (3.5-inch) needles are used, but 13-cm (5-inch) needles occasionally are needed for obese

patients. Pencil point tip (Whitacre and Sprotte), sharp tip (Quincke), and blunt tip needles are also used.

The needle is introduced through the skin and advanced into the midline of the interlaminar space. The needle stylet is removed, and a loss of resistance syringe is applied. A "loss of resistance" syringe is a special syringe made of plastic or glass. The clinician introduces the needle, under fluoroscopic guidance, while applying continuous pressure on the syringe plunger. Once the needle passes through the thick ligamentum flavum, the clinician feels a sense of give and encounters a loss of resistance on the syringe plunger. Aspiration is performed to ensure that there is no leakage of cerebrospinal fluid. Contrast is injected to confirm the needle's position. When the epidural flow is confirmed, steroids and local anesthetics are injected. The needle is then removed. If the vital signs are stable, the patient is transferred by stretcher or wheelchair to the waiting area for monitoring for approximately 15 minutes. As soon as the lower extremities regain their full strength, the patient is discharged.

Evidence of Vasovagal Events (Vasovagal Attack)

- Lightheadedness (dizziness)
- Paleness
- Sweating
- Nausea
- Decreased blood pressure
- Decreased heart rate
- Loss of consciousness

The cervical spine is a narrower space; however, the same technique is used. Cervical interlaminar epidural injections are performed at the C6-7 or C7-T1 level because of the relative increase in spinal canal diameter at those levels. Performing the injections at these levels is relatively safer because the wider central canal reduces the chances of spinal cord injury and provides a better space for introducing catheters. A needle and catheter technique frequently is used to perform cervical interlaminar epidural injections. An epidural catheter is inserted through an epidural needle placed at the C6-7 or the C7-T1 level. The epidural needle is introduced with the loss of resistance technique. Once the positioning is confirmed with fluoroscopy, a 20-gauge catheter is introduced and driven cephalad in the epidural space near the level of the pathology. Contrast is used to confirm the catheter's presence in the epidural space before medications are injected. This technique has the advantage of introducing the medication near the pathology while accessing the epidural space in the lower cervical spine.

Lumbosacral or caudal epidural steroid injections are performed blindly or with fluoroscopic guidance. In the blind technique, the patient is placed in the prone position, and the sacral hiatus is palpated. The skin is prepped and draped in the usual sterile manner. A spinal needle is introduced at 45°. A pop is felt as the needle passes through the sacrococcygeal ligament. The angle of the needle is reduced, and the needle is advanced superiorly. The "loss of resistance technique" is used to confirm the needle's position. Once the epidural positioning has been confirmed, a mixture of steroids and local anesthetics is injected. With the "fluoroscopically guided technique," the sacral hiatus is identified, the needle is inserted in a similar fashion to above but the needle is guided using a fluoroscope and its position is confirmed with contrast.

Transforaminal Epidural Injections

Transforaminal epidural injections are administered only under fluoroscopic guidance. This injection aims for the disc and spinal nerve interface. The needle is introduced into a triangular space within the anterosuperior third of the neural foramen; this space, known as the "safe triangle" (Figure 15-14), is bounded by the pedicle superiorly, exiting nerve inferomedially, and lateral margin of the neural foramen laterally. The needle is lodged at the 6 o'clock position, just inferior to the pedicle. If the needle is introduced farther medially, such that the safe triangle is violated, a dural puncture may result. Once the needle is in position, the medication can be efficiently injected into the lateral epidural space or around the emerging nerve root, depending on the needle position and the bevel (slanted) orientation.

This approach is commonly used in the treatment of radicular pain,[16] and it also is used in the management of axial discogenic pain. In experienced hands, the transforaminal technique is safe and produces a good outcome.

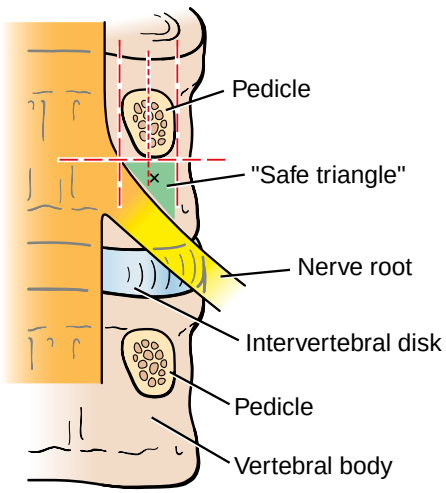

Figure 15-14 The safe triangle.

Transforaminal epidural steroid injection is gaining popularity over the interlaminar approach because it is more effective at administering the medication at the spinal nerve-disc interface in the lateral epidural space rather than in the dorsal epidural space, which is separated from the lateral epidural space by the ligamentum flavum. Fluoroscopic guidance is essential for this procedure, and administration of steroids at the level of the pathology is crucial to effectiveness.

Transforaminal epidural injections have both diagnostic and therapeutic value. If the pathology is unclear or if multiple pathologies are present, administration of local anesthetic (without a steroid) has diagnostic value if pain is relieved immediately after the injection is given. For therapeutic purposes, steroids are injected with the goal of pain relief 2 or 3 days after the injection. The effectiveness of therapeutic transforaminal epidural injections has been the subject of a number of studies. In a prospective study, Lutz and Wisneski[18] evaluated the outcomes of therapeutic transforaminal epidural steroid injections in 69 patients for a mean period of 80 weeks. They found that 75% of their patients reported improvement of pain intensity of at least 50% and near return to functional activities after 1.8 injections.

In a prospectively randomized study, Riew et al.[49] evaluated 55 patients with lumbar radicular pain with radiographic confirmation of nerve root compression. All of their patients had requested operative intervention and were considered surgical candidates. Instead the patients were randomized and underwent a selective nerve root injection with either bupivacaine alone or bupivacaine with betamethasone. The treating physicians and the patients were blinded to the medication. Twenty-nine patients did not have surgery during a follow-up period of 13 to 28 months. Of the 27 patients who had received bupivacaine alone, nine did not have surgery. Of the 28 patients who had received bupivacaine and betamethasone, 20 decided not to have surgery.

A study by Vad et al.[50] prospectively included 50 patients with lumbar radicular pain that had lasted longer than 6 weeks. All of the patients had MRI evidence of an HNP with less than 50% narrowing of the neural foramen, along with radicular pain corresponding to the MRI positive level of pathology. The patients were randomized into two groups. The treatment group received fluoroscopically guided transforaminal epidural injections, and the control group received trigger point injections. Forty-eight patients completed the study, and the average follow-up was 16 months. Outcome measures were the Roland Morris Questionnaire, a visual analogue scale, and the finger to floor test. An 84% improvement was seen in the study group, and only a 24% improvement in the control group.

In a prospective study, Botwin et al.[51] included 34 patients with unilateral radicular pain, caused by degenerative spinal stenosis, who were not responding to conservative management. Their patients received an average of 1.9 fluoroscopically guided transforaminal epidural injections on the symptomatic side. A visual analogue scale score, the Roland 5-point pain scale, standing and walking tolerance, and a patient satisfaction scale were assessed 2 and 12 months after the injections. The results showed that 75% of the patients reported a pain score reduction of greater than 50% after the injection therapy; in addition, 64% had improved walking tolerance and 57% had improved standing tolerance at 12 months.

Slipman et al.[16] retrospectively evaluated 20 patients who had had cervical radicular pain for longer than 5 months. Their patients received an average of 2.2 cervical transforaminal epidural injections in addition to physical therapy. The patients were followed for 21 months. Their pain scores, medication use, work status, and satisfaction were assessed. Sixty percent of the patients reported excellent or good outcomes, and 30% underwent surgery.

Huston et al.[17] prospectively studied the side effects and complications of transforaminal epidural injections. An analysis of 350 consecutive cervical and lumbar transforaminal injections identified no instance in which dural punctures occurred. Lutz and Wisneski[18] found no epidural punctures or other major complications in 50 patients who received lumbar transforaminal epidural injections. Botwin et al.[19] reviewed complications in 322 transforaminal lumbar epidural injections performed on 207 patients. They reported a complete absence of postdural puncture headache (PDHD). The most common complication found in their study was headache, which occurred in 3.1% of patients. These headaches were transient and resolved after 24 hours. These patients' epidurograms were reviewed, and no intrathecal pattern was noted.

Spinal cord injury has been reported after lumbosacral nerve root block with steroid injections.[52] This is postulated to occur secondary to an injury or to injection of particulate steroids in patients with an aberrant artery of Adamkiewicz. Another possibility is occlusion of the anterior spinal artery, with resultant spinal cord infarction, after inadvertent injection into a feeder artery in the neural foramen. A hypothesis for this occurrence is the use of Depo-Medrol and Kenalog preparations for the procedure; these preparations form large particulate granules, which can occlude the anterior spinal artery unless a meticulous technique is followed. El Abd et al.[53] demonstrated that the use of digital subtraction angiography (DSA) is capable of detecting intravascular needle placements that were missed by contrast injection under live fluoroscopy, thus adding a safety step before

medication injection. In addition, the use of nonparticulate steroids, such as dexamethasone, is preferred as another safety measure to avoid vascular occlusion during transforaminal epidural injections.

Technique for Cervical Transforaminal Epidural Injections. The patient is placed in the supine position on the fluoroscopy table. A bolster is placed under the contralateral shoulder. The blood pressure, pulse, and pulse oxymetry are monitored. The fluoroscopy beam is rotated to visualize the neural foramen in a perpendicular plane to the radiographic imager. Once the neural foramen has been properly visualized, a 25-gauge needle is introduced through the skin. The needle is advanced until it abuts the superior articular process of the corresponding neural foramen. The needle then is slightly advanced into the foramen. Contrast (0.3 cc of Omnipaque 300) is used to confirm the needle's position. When contrast clearly outlines the exiting nerve root, 0.5 cc of lidocaine 1% is given and the patient is asked about unusual taste. This lidocaine test is performed as another safety measure to avoid vascular injection (intravascular lidocaine is known to produce a metallic taste). Then 1.5 cc of dexamethasone 10 mg/mL is administered (Figure 15-15). For diagnostic purposes only, 0.8 cc of lidocaine 2% is given without steroids (diagnostic injection).

Technique for Thoracic and Lumbar Transforaminal Epidural Injections. The patient is placed in the prone position on the fluoroscopy table. Blood pressure, pulse, and pulse oxymetry are monitored. The fluoroscopy beam is rotated to visualize the neural foramen in an oblique plane with the superior articular process dissecting the corresponding pedicle. Once the neural foramen has been properly visualized, a skin wheal is made with 0.5 cc of lidocaine 1%. A 22-gauge needle is introduced through the skin and advanced to the 6 o'clock position under the pedicle (the safe triangle) under fluoroscopic guidance. Needle positioning is confirmed using the anteroposterior plane. The needle should not extend medial to the pedicle on the anteroposterior view. Contrast (0.3 cc of Omnipaque 300) is used to confirm the needle's position. When the contrast clearly outlines the exiting nerve root, the lidocaine test is performed with the injection of 1 cc of lidocaine 1%, followed by 2 cc of dexamethasone 10 mg/mL (Figures 15-16 and 15-17). For diagnostic purposes only, 0.8 cc of lidocaine 2% is given without steroids (diagnostic injection).

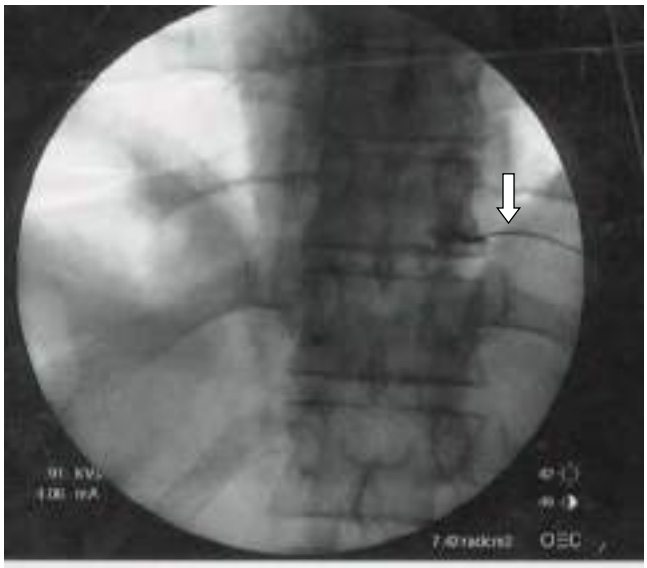

Figure 15-16 Right T10 transforaminal epidural injection.

Figure 15-15 Left C6 transforaminal epidural injection.

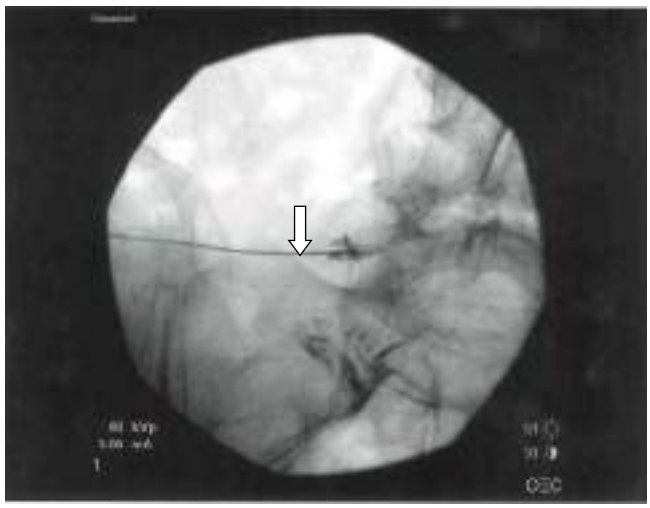

Figure 15-17 Left L5 transforaminal epidural injection. Note the presence of left S1 flow (an S1 transforaminal injection had been given just before the L5 injection).

Guiding Principles for Transforaminal Epidural Injections

- The needle must be carefully positioned in the safe triangle (see Figure 15-14).
- The needle's position must be confirmed radiographically in the anteroposterior plane.
- For a cervical transforaminal injection, oblique planes, rather than lateral planes, should be used to perform the injection. The depth of the needle cannot be noted if lateral planes are used.
- Live fluoroscopy should be used while contrast material is injected.
- If possible, dexamethasone should be used for cervical and thoracic injections. (Dexamethasone has less particulate substance than Depo-Medrol or Kenalog, which are suspected of causing vascular clogging.)
- Cervical and thoracic transforaminal injections should be administered only by a well-trained physician experienced in performing these procedures.
- With thoracic transforaminal injections, the risk of pneumothorax arises if the pleura is punctured. The interventionalist should always keep the needle medial to the costovertebral junction.

While performing the transforaminal epidural injections, the clinician must take special precautions to prevent vascular injections and spinal cord injuries.

Facet Joint Injections

Neither the clinical examination nor imaging studies can confirm a diagnosis of facet-mediated pain. The gold standard for this diagnosis is the use of a local anesthetic to block a particularly painful joint.[54] Barnsley et al.[55] evaluated the effect of intra-articular cervical facet joint steroid injections in 41 patients with chronic neck pain. The patients were carefully selected by means of differential diagnostic cervical facet joint block with a long-acting and a short-acting anesthetic. Under double-blind conditions, patients received intra-articular injections of either 1 cc of bupivacaine (20 patients) or 1 cc of betamethasone (21 patients). Patient follow-up was conducted either in the office or by telephone until the patient reported a return of 50% of the pain. The median time to a return of 50% of pain was 3 days in the steroid group and 3.5 days in the local anesthetic group. Only 20% of the patients had substantial relief after 1 month. The authors concluded that the improvement was due to either a placebo effect or secondary to facet joint distention. This study had some flaws; the sample number was small, and all the patients included had traumatic injury with whiplash.

Lilius et al.[56] evaluated 109 patients with chronic low back pain who did not respond to conservative management. Their patients were separated into three groups: the first received intra-articular steroid and a local anesthetic, the second received saline, and the third received pericapsular steroid and a local anesthetic. The authors reported improvement of pain in all three groups. The major flaw of this study was that the patients were selected without undergoing diagnostic injections to identify the level of therapeutic injections.

In a prospective study Carette et al.[57] compared the effect of intra-articular saline with that of intra-articular methylprednisolone in 101 patients after positive lidocaine joint injection. At 6 months 46% of the methylprednisolone group and 15% of the saline group reported marked pain relief.

In a prospective study Lynch and Taylor[58] evaluated 50 patients. Of these, 23 received extraarticular steroid injections and 27 received intra-articular steroid injections without a local anesthetic. Nine of the 27 patients who had received intra-articular injections had total improvement, whereas none of the control group (those who had received extraarticular injections) experienced total improvement. Only two members of the intra-articular group had no improvement.

Technique for Intra-articular Facet Joint Injections. These injections are performed only under live fluoroscopic visualization. For cervical facet joint injections, the patient is placed in the lateral position on the fluoroscopy table. A bolster is placed beneath the patient's head with the ipsilateral side bent 5° to 15° for better visualization of the upper joints. For C1-2 injections, the patient is positioned prone with the bolster placed beneath the forehead and the neck in slight extension of 5° to 10°. For lumbar facet joint injections, the patient is placed prone with or without a bolster under the ipsilateral side. The blood pressure, pulse, and pulse oxymetry are monitored. The skin is prepped and draped in the usual sterile manner. The target ipsilateral joint is properly identified in a plane perpendicular to the radiographic imager. A 25-gauge, 4-cm (1.5-inch) needle (for cervical injections) or a 22-gauge 9-cm (3.5-inch) spinal needle (for lumbar injections) is used. The needle is advanced to the midportion of the superior articular process (for level C1-2, the needle is introduced through the lateral third of the joint). After the depth has been checked, the needle is advanced to pierce the joint capsule (Figure 15-18). Approximately 0.15 cc of Omnipaque 300, a water-soluble contrast agent, is injected into the joint for proper identification. After a positive arthrogram has been identified, 0.8 cc of Xylocaine 2% is given as a diagnostic injection. A greater than 80% improvement in pain is considered a positive diagnostic injection. For therapeutic injections, 0.8 cc of Celestone (6 mg) (or another type of steroid) and 0.2 cc of lidocaine 1% are injected.

Medial branch blocks instead of intra-articular injections are primarily performed for the diagnosis of facet joint syndrome.[59] Technically, they are easier to perform than the intra-articular facet joint injections. The spinal needle is positioned at the junction of the superior articular process and the transverse process under fluoroscopic guidance (Figure 15-19).

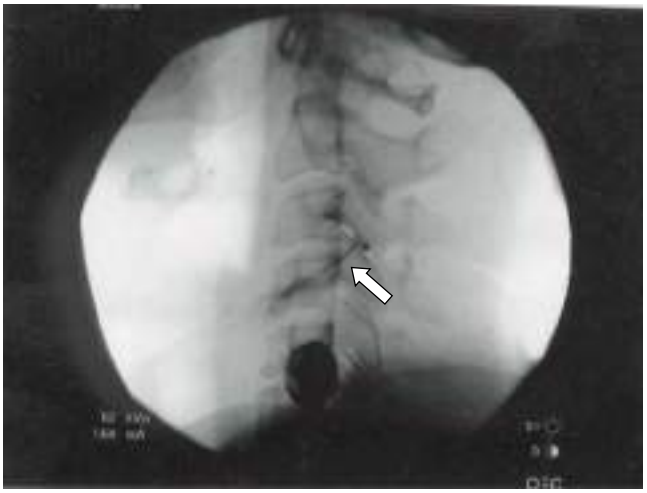

Figure 15-18 Left C3-4 intra-articular facet joint injection.

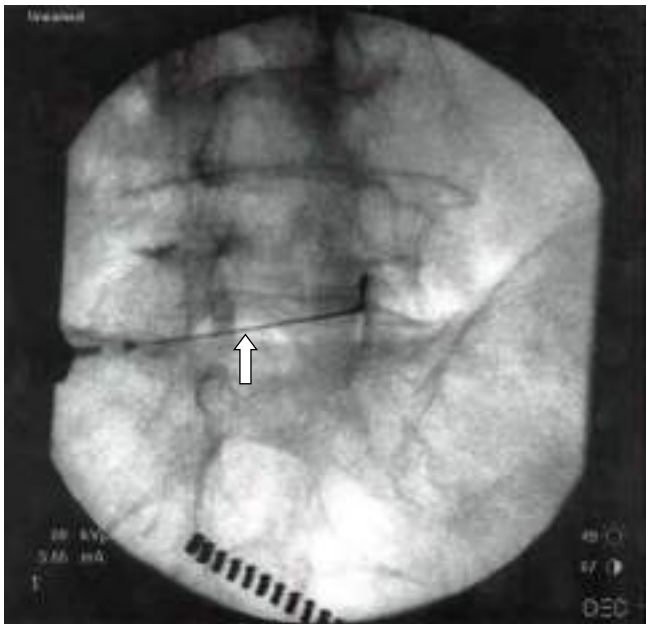

Figure 15-19 Right L5-S1 intra-articular facet joint injection.

Facet Joint Radiofrequency Ablation

From a spinal intervention perspective, radiofrequency ablation is considered the ultimate management of facet joint mediated pain. This procedure results in ablation of the medial branch nerves that provide sensory innervations to one or more facet joints. In a randomized, double-blind trial, Lord et al.[25] included 24 patients with chronic neck pain with a median duration of pain of 34 months. All the patients had developed pain after a motor vehicle accident. The radiofrequency procedure was compared with an identical procedure in which the machine was not turned on. The patients were split into two groups of 12 receiving each treatment. The radiofrequency level was selected using double-blind, placebo-controlled facet blocks. Follow-up consisted of clinic visits and phone interviews until the patient's pain had returned to the 50% level. The median time for pain return was 263 days in the active treatment group and 8 days in the control group. At 27 weeks, seven patients in the active group and one patient in the control group were pain free. The study had a good design and good methodology; however, the sample size was small.

In a prospective study, Dreyfuss et al.[60] included 15 patients with chronic low back pain who reacted positively to a double local anesthetic comparative block (with lidocaine and bupivacaine). Patients underwent lumbar facet joint radiofrequency therapy and were followed for 12 months. To determine the outcome of the study, the investigators evaluated a number of factors: the patients' use of prescription analgesic medications; the results of the McGill Pain Questionnaire and Short Form SF-36; the North American Spine Society treatment expectations; the patient's ability to perform isometric push and pull, dynamic floor to waist lifts, and above the shoulder lifting tasks; and the results of needle electromyography of the L2 to L5 bands of the multifidus muscles performed before and 8 weeks after the procedure. Sixty percent of patients had at least a 90% pain reduction, and 87% of the patients had a 60% pain reduction for 12 months.

McDonald et al.[61] followed 28 patients for 5 years. All the patients underwent radiofrequency treatment of the cervical spine after undergoing placebo-controlled blocks. The median pain relief time after the first procedure was 219 days.

A systematic review of therapeutic lumbar facet joint interventions for the treatment of chronic low back pain conducted by Falco et al.[62] concluded that there was good evidence for the use of conventional radiofrequency neurotomy for the treatment of such conditions.

Technique for Radiofrequency Ablation of the Facet Joints. Radiofrequency ablation is performed only under live fluoroscopic visualization. Blood pressure, pulse, and pulse oxymetry are monitored. For cervical facet joint radiofrequency ablation, the patient is placed in the lateral position on the fluoroscopy table. A bolster is placed beneath the patient's head with the ipsilateral side bent 5° to 15° to allow better visualization of the upper joints. For treatment of a lumbar facet joint, the patient is placed in the prone position. The skin is prepped and draped in the usual sterile manner. A grounding pad is applied to the patient's shoulder (or any other area of dry skin) and connected to the radiofrequency generator.

For the cervical spine, the target facet joint is properly visualized in a plane perpendicular to the radiographic imager. A 22-gauge, 4-cm (1.5-inch), specially insulated needle is introduced and advanced under fluoroscopic guidance in a ventral and medial direction until it abuts the superior articular process, transverse process, and pedicle. The C3 medial branch (third occipital nerve) needs to be lesioned in two or three locations along the C2-3 facet because it is larger.

For the lumbar spine, the fluoroscopy beam is rotated 10° to 20° to visualize the ipsilateral superior articular

process and the transverse process clearly. Then 0.5 cc of lidocaine 1% is injected subcutaneously. A 22-gauge, specially insulated spinal needle is introduced under direct fluoroscopic visualization. The needle is advanced until it abuts the junction of the base of the superior articular process, pedicle, and transverse process. The needle then is slightly "walked off" over the transverse process; this places the needle close to the medial branch at that level.

Once the needle is in the proper position, sensory testing is performed at 50 Hz with a voltage of 0 to 1 V. The patient is asked whether sensory symptoms ranging from pressure, tingling, burning, to pain are experienced. The symptoms must be localized in the paraspinal area and not in the extremities. If sensory symptoms are not elicited or are felt in the extremities, the needle's position is changed. Once sensory testing has been confirmed, motor testing is performed by switching the frequency to 2 Hz with a voltage of 1 to 10 V. The clinician's hand is placed over the immediate ipsilateral paraspinal area to check for rhythmic muscle contractions. When contractions are identified, the voltage is doubled and the clinician's hand is placed over the limb muscles supplied by the nerve root corresponding to the medial branch level. Neither the clinician nor the patient should feel any rhythmic contractions in the limb muscles. If contractions in the limb muscles are identified, the needle's position is changed. Sensory testing and motor testing confirm that the radiofrequency needle is positioned close to the medial branch and away from the corresponding nerve root.

Once correct positioning of the needle has been confirmed, 0.5 cc of lidocaine 2% is injected into the cervical levels and 3 cc of lidocaine 1% is injected into the lumbar spine. Radiofrequency lesioning is then performed at 80 °C (176 °F) for 90 seconds. The radiofrequency denervation of each facet joint implies lesioning of the medial branch at the joint level and the medial branch of the level cephalad to that joint.

Radiofrequency ablation is a safe procedure if performed according to the technique just described. The most common complication is the sensation of pain, which can last 7 to 10 days. Pain rarely lasts longer than 2 weeks[63] because of the denervation process of the ablated medial branches.

Sacroiliac Joint Injections

Injections into the SI joint are either diagnostic or therapeutic for SI joint syndrome. No physical examination test or imaging study can be used to confirm this diagnosis.[37,64] Diagnostic injections are used to further assess the pain emanating from the joint. If the patient has a positive response to the diagnostic injection, a therapeutic injection is administered.

Technique for Intra-articular SI Joint Injections. The patient is placed in the prone position on the fluoroscopy table. The skin is prepped and draped in the usual sterile manner. The blood pressure, pulse, and pulse oxymetry are monitored. The fluoroscopy beam is slightly rotated in an oblique position. The most caudal part of the joint is visualized with the ventral and the dorsal aspects superimposed. At the needle entry point, a skin wheal is made using 0.5 cc of lidocaine 1%. Under direct fluoroscopic visualization, a 22-gauge, 9-cm (3.5-inch) needle is introduced into the most caudal aspect of the SI joint. After the needle's positioning in the joint has been confirmed, 0.3 cc of contrast (Omnipaque 300) is injected. Intra-articular contrast should be properly visualized. For diagnostic injections, 1 cc of lidocaine 2% is used; for therapeutic injections, 0.8 cc of Celestone (6 mg) and 0.5 cc of lidocaine 2% are used.

DISCOGRAMS

Diagnostic Discograms

In 1970, Henry Crock first described **internal disc disruption syndrome (IDDS)** after conducting a retrospective analysis of patients who continued to experience leg and back pain despite multiple surgical procedures. He postulated that IDDS was caused by alterations in the internal structure and metabolic function of one or more discs, the alterations having developed after significant trauma.[65] Subsequent studies have established the morphology of the disrupted disc to be a degenerated nucleus pulposus with radial fissures extending to the periphery of the annulus fibrosus.[66] Patients with IDDS usually present with axial back pain that is dull or aching and difficult to localize and that often produces somatically referred symptoms.

Provocative discography is considered the best available test for diagnosing IDDS.[67] A discogram is considered only when the option of spinal fusion is entertained, whether for failure of conservative measures to control pain or for the management of spinal instability. A discogram confirms the disc level causing pain. However, discograms are plagued by a high false-positive rate of 5.6% for chronic pain, 15% for postdiscectomy, and 50% for patients with somatization disorder.[68] Because of that, even experienced physicians should perform the procedure meticulously. A patient undergoing a discogram should not be sedated and should be blinded to the disc level assessed. Sedation can cloud the patient's sensation of pain. It is important for the patient to be completely conscious so that the pain provoked during the test can be accurately described.

Technique for Diagnostic Lumbar Discogram

The patient starts the test in the side-lying position with a roll under the L4-5 area. Blood pressure, pulse, and pulse oxymetry are monitored. The fluoroscopy beam is rotated to visualize the intervertebral discs with parallel end plates and dissected by the superior articular process. To visualize the L5-S1 disc, the fluoroscopy beam should be tilted caudally to avoid the ipsilateral iliac crest. Using a double-needle technique (an 18-gauge outer discography needle and a 22-gauge inner discography needle),

the clinician places the needles into the disc using a posterolateral approach. After placement of the needles, the patient's position is changed to prone. Omnipaque 300 is used for disc injection, and needle placement is assessed using fluoroscopic imaging (Figure 15-20). The patient is blinded to the intervertebral disc injected. The pain response and its distribution are recorded after each disc injection (P0, no pain on injection; P1, partial concordant pain; P2, discordant pain; and P3, concordant pain with same intensity and distribution). A discographic injection is considered positive if the pain response is P3 at the injected level. Negative levels are considered control levels in each discographic study. The pain response encompasses the skin, underlying soft tissue, and viscera located in these areas.

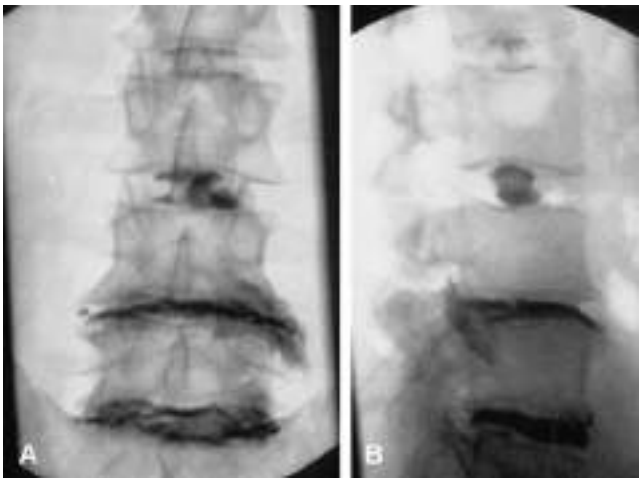

Figure 15-20 Fluoroscopic anteroposterior (**A**) and lateral (**B**) views of intradiscal contrast after a diagnostic lumbar discogram at L2-3, L3-4, L4-5, and L5-S1. The L4-5 and L5-S1 discs are degenerated, but only the L5-S1 level provoked concordant pain; therefore the L5-S1 level is the positive level.

Immediately after discography, a CT scan is performed. Discs that appear lobular or cotton ball shaped (grade 0, 1, or 2 on the Modified Dallas Discogram Scale)[69] are classified as normal; discs that have an irregular discogram pattern with extravasation of dye to or through the outer annulus (grade 3, 4, or 5 on the Modified Dallas Discogram Scale) are classified as abnormal (Figure 15-21).

Percutaneous Discectomy

Patients who have radicular pain and fail to improve with conservative management, including spinal nerve root blocks, are candidates for percutaneous discectomy, an evolving spinal procedure. This procedure aims to achieve disc decompression without the side effects of conventional surgical procedures. Regardless of the technique used,

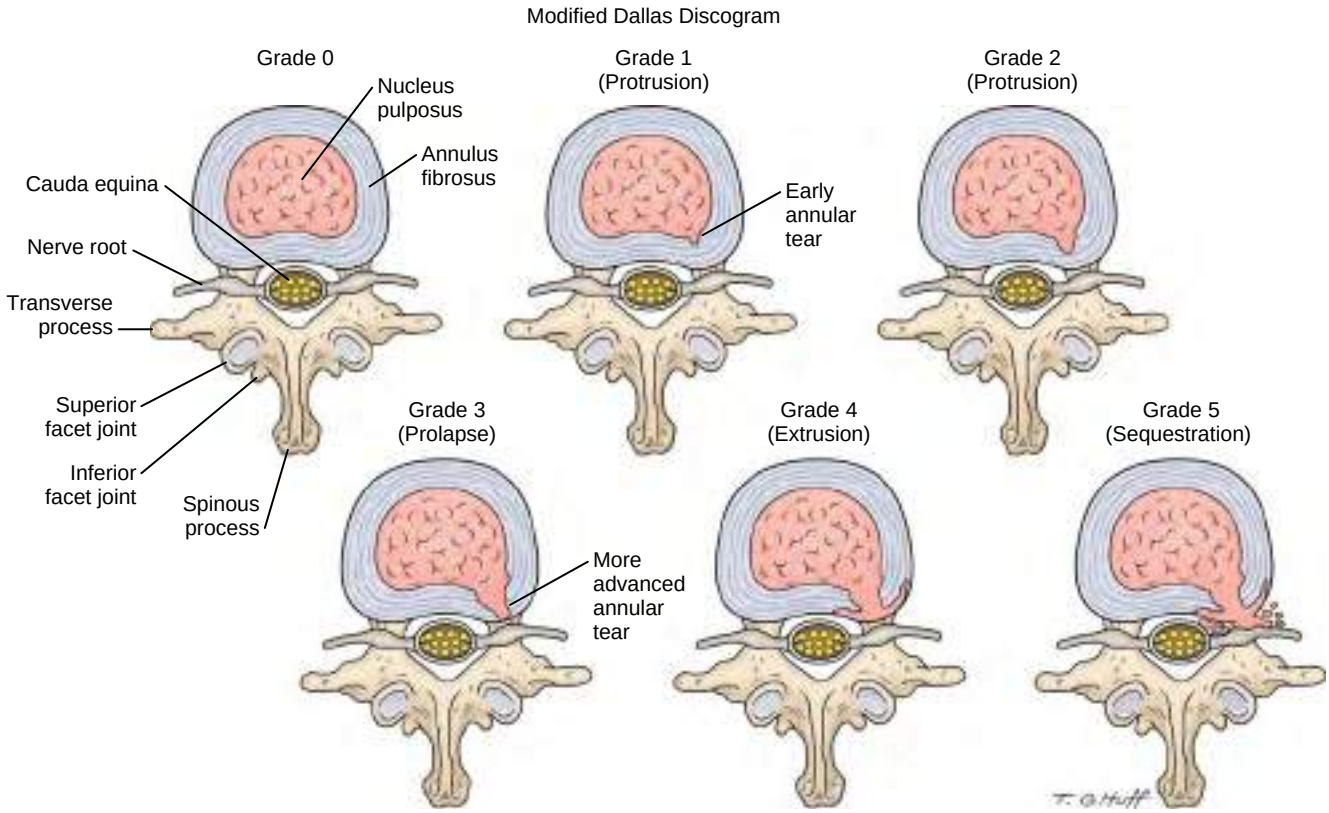

Figure 15-21 Modified Dallas Discogram Scale for CT classification of annular tears.

percutaneous disc decompression is based on the principle that a small reduction of volume in a closed hydraulic space, such as an intact disc, results in a disproportionately large drop in pressure. Once the intradiscal pressure declines, the disc is believed to downregulate inflammatory mediators and decrease in size, and a healing process is believed to commence, thereby alleviating the chemical, mechanical, and neural genesis of discogenic pain.[70]

Percutaneous discectomy was first introduced in 1964 with the use of intradiscal chymopapain injections (chemonucleolysis). However, chymopapain was reported to be associated with severe anaphylactic reactions and transverse myelitis, and its use has been discontinued.[71]

Hijikata[72] introduced instrumented percutaneous disc decompression in 1975. Although his procedure was reported to be effective, it did not become widely accepted. Among the reasons cited were the potential complications, including nerve root and/or vascular injury caused by the large canula (5 to 8 mm in diameter), repeated entrance into the disc space with an increased risk of infection, inability to relieve foraminal or lateral recess stenosis, lack of applicability among patients who had previously undergone surgery, difficulty performing the procedure on obese patients, and inaccessibility of the L5-S1 disc.

In 1985, Maroon and Onik introduced the automated lumbar discectomy device.[73] The device was criticized for its low success rate and for reports of major cauda equina injury. Laser discectomy became popular, but its use subsequently declined because of postprocedural complications, such as moderate-to-severe intraoperative pain secondary to the thermal effect of the laser, postoperative low back pain and spasm, bowel necrosis resulting from inadvertent perforation of the anterior annulus, nerve root injury, and inability to visualize the tip of the laser beam under fluoroscopy.[74] The technologically advanced devices nucleoplasty,[75] Dekompressor,[76] and hydrodiscectomy[77] were introduced most recently. Reports suggest that these devices are effective, especially in the management of small disc protrusions with radicular pain, and that they cause minimal and transient side effects and complications. Randomized studies to validate their use have yet to be performed to show supporting evidence, which up to now is limited.[78]

Technique for Lumbar Percutaneous Discectomy

The patient is placed in the side-lying position with a roll under the L4-5 area. The blood pressure, pulse, and pulse oxymetry are monitored. The fluoroscopy beam is rotated to visualize the intervertebral discs with parallel end plates and dissected by the superior articular process. To visualize the L5-S1 disc, the beam should be tilted caudally to avoid the ipsilateral iliac crest. Conscious sedation is used. A 17-gauge, 15-cm (6-inch) spinal needle is introduced into the disc using a posterolateral extrapedicular approach. The needle is positioned at the junction of the annulus and the nucleus. After the needle placement, the patient's position is changed to prone. The discectomy device's catheter is placed into the spinal needle. Under real-time imaging, the tip of the catheter is withdrawn simultaneously with the introducer needle until it is positioned approximately 1 mm distal to the proximal annular-nuclear interface. The catheter then is advanced slowly until it reaches the distal nuclear-annular interface. The process of decompression involves advancing and withdrawing the catheter to form channels in the disc. A minimum of six channels is created, at the 12, 2, 4, 6, 8, and 10 o'clock positions. Additional channels, up to 12, are created if resistance to catheter advancement is perceived. Postoperatively, patients are allowed unlimited walking, standing, and sitting. They are instructed not to perform any lifting, bending, or stooping. Return to sedentary or light work is permitted at 3 to 4 days after the procedure. A lumbar stabilization program is started 2 weeks after the procedure.

Intradiscal Electrothermoplasty

Intradiscal electrothermoplasty (IDET) was introduced in 1997 for the management of discogenic axial pain. The procedure consists of the insertion of a flexible catheter in a circumferential manner into the annulus of a painful disc. Heating the annulus via the catheter is thought to coagulate the nerve fibers in the annulus and inflammatory products, stiffen the collagen fibers, and heal disc tears.[63,79] IDET gained popularity among clinicians shortly after its introduction. It is used in the management of discogenic pain proved by discography. IDET is seen as a last step before lumbar fusion surgery is considered. It is performed primarily in the lumbar spine and seldom in the thoracic spine.

Technique for Intradiscal Electrothermoplasty

The patient is placed in the side-lying position with a roll under the L4-5 area. Blood pressure, pulse, and pulse oxymetry are monitored. The fluoroscopy beam is rotated to visualize the intervertebral discs with parallel end plates and dissected by the superior articular process. To visualize the L5-S1 disc, the beam should be tilted caudally to avoid the ipsilateral iliac crest. Conscious sedation is used. A 17-gauge, 15-cm (6-inch) needle is introduced until it contacts the annulus fibrosis. After the needle placement, the patient's position is changed to prone. A flexible electrode is introduced through the needle and navigated through the posterior annulus. The catheter is heated for 16 minutes at 90 °C (194 °F). After the procedure, the patient wears a lumbar corset for 6 weeks.

Complications of Intradiscal Procedures

When good techniques are used, these interventional procedures are minimally invasive and have few complications or side effects. The side effects are transient and include temporary worsening of radicular or axial pain. Discitis is a

possible complication, although the incidence is extremely low. Collis and Gardner[80] reported on 2187 disc injections and mentioned only one intervertebral disc infection. Wiley et al.[81] reported a review of the literature, which showed only 30 cases of discitis in approximately 5000 disc injections, an incidence of 0.6% per disc. Fraser et al.[82] reviewed 432 cases and found an overall infection rate of 2.3% of patients, or 1.3% per disc. The study breaks down the incidence of infection based on different techniques. The incidence of infection fell to 0.7% when a double-needle technique was used. Aprill[83] examined 2000 patients who had undergone discography involving a single-needle technique and reported only one case of acute discitis in that group.

PERCUTANEOUS VERTEBROPLASTY

Percutaneous vertebroplasty (PV) was first introduced in France in 1984 for the management of aggressive vertebral hemangiomas.[84] The procedure later was used in the management of painful vertebral compression fractures and painful vertebral malignancies. The procedure involves the injection of polymethylmethacrylate (PMMA; also called *bone cement*) into the vertebral body. PV is an outpatient procedure performed with the patient under conscious sedation. Sterile preparation is applied. The procedure is performed in the thoracic and lumbar spine using a transpedicular (posterior) approach. A 17-gauge needle is introduced into the vertebral body through the pedicles, and the needle is positioned in the junction between the posterior and middle thirds of the vertebral body. Once the needle's position has been confirmed, PMMA is injected. This process is performed either unilaterally or bilaterally.

Complications

Complications of PV are rare, and the use of good technique can obviate them. The most severe complication is injury to the spinal cord, nerve roots, or venous plexuses if the needle breaches the medial pedicle; this necessitates immediate surgical decompression. Pedicle fracture can occur, which is not destabilizing to the spine but may be painful for many weeks. Extravasation of bone cement into neural structures and blood vessels can occur, although the occurrence of this can be minimized by mixing the cement with the contrast and injecting them under live fluoroscopy.

KYPHOPLASTY

Kyphoplasty is a procedure for the management of compression fractures developed in the late 1990s.[85] A balloon is placed through a needle into the vertebral body. The balloon is inflated to reduce the fracture, and PMMA is injected under low pressure. The supporters of this procedure believe that the restoration of height of the vertebral body improves the biomechanics of the spine and may reduce kyphosis. The injection of PMMA under low pressure is also believed to reduce extravasation into surrounding structures.

SUMMARY

Nonsurgical interventional procedures for the spine are becoming a prominent management tool for painful spinal disorders. Physicians and surgeons currently consider using these procedures more frequently than recommending surgical interventions. These procedures, when performed by experienced physicians, have good outcomes and minimal complications. With advances in technology, improved techniques and the development of more effective equipment are expected. Interventions should always be followed up with an active spinal rehabilitation program after the patient's symptoms improve. Nonsurgical techniques, combined with a rehabilitation program, can restore function and minimize the recurrence of back pain.

CHAPTER 16

Spinal Pathology, Conditions, and Deformities: Surgical Intervention

ELIAS DAKWAR, ARMEN DEUKMEDJIAN, YOAV RITTER, C. DAIN ALLRED, GLENN R. RECHTINE II

INTRODUCTION

Successful surgical management of spinal pathology can be simplified into two basic concepts: decompression and stabilization. The neural elements, including the spinal cord and nerve roots, must be freed from impingement to halt the progression of neurological deficit and potentially to allow improvement in function. Segmental instability must also be addressed, because this leads to pain and deformity and may result in neurological impairment. This chapter focuses primarily on degenerative derangements of the spine; however, similar principles of decompression and stabilization hold true for spinal pathology caused by trauma, neoplasms, infection, and other etiologies.

Critical Questions Regarding Surgical Success

- Which neurological structure is compromised: spinal cord, nerve roots, or both?
- What is the source of compression (e.g., disc herniation, osteophyte, fracture fragment, tumor)?
- Does the compressive force arise from the anterior side, posterior side, or both?
- How many levels of the spine are involved?
- What is the spinal alignment?
- Are there different levels of segmental instability?
- What are the relevant medical co-morbidities?

Patient selection is perhaps more important than the technical aspects of surgery for achieving a successful surgical outcome in the treatment of spinal disorders. When surgery is indicated, careful planning of the operation is vital for success. This planning is based on a knowledge of the pathological process and its influence on local anatomy and neurological function. Armed with the answers to critical questions, the surgeon can select an operation that will adequately address the pathological condition, alleviate symptoms, and restore function.

CERVICAL DISC DISEASE

Degenerative cervical disc disease comprises a number of derangements of the cervical spine, ranging from isolated, single-level disc herniation to multilevel spondylosis with osteophyte formation. The clinical evaluation of patients with cervical disc disease requires interpretation of a detailed history, a meticulous examination, and appropriate diagnostic testing. Proper diagnosis and differentiation of patients with nerve root disorders (i.e., **radiculopathy**), spinal cord compression (i.e., **myelopathy**), cervical deformity, or axial neck pain give the clinician insight into the natural history of the process and direct the treatment plan.

Differential Diagnosis of Cervical Disc Disease

- Radiculopathy (nerve root)
- Myelopathy (spinal cord)
- Axial neck pain

Cervical spondylotic radiculopathy usually presents as upper extremity pain associated with dysesthesias or paresthesias in a dermatomal pattern. Symptoms stem from impingement of a single or multiple nerve roots as a result of the degenerative changes of the bony and soft tissue anatomy (e.g., intervertebral discs). The natural history of cervical radiculopathy is favorable. Radiculopathy appears to be a distinct disorder, because progression from radiculopathy to myelopathy is uncommon. Most patients' acute

symptoms improve with nonoperative management as the inflammatory cycle initiated by nerve root compression resolves. The short-term success of medical management is generally accepted; however, over a longer period, radiculopathy commonly recurs. Gore et al.[1] reported that 50% of patients with cervical radiculopathy who were treated conservatively had persistent symptoms at 15-year follow-up. In their long-term observations, Lees and Turner[2] reported that 30% of patients complained of intermittent symptoms, whereas 25% experienced persistent radiculopathy. On plain x-ray films, separating normal, age-related degenerative changes from those causing symptoms often is difficult. In asymptomatic adults older than 50 years of age, the prevalence of significant radiographic degenerative changes mirrors age; that is, in a cohort of 60-year-olds, approximately 60% will have radiographic spondylosis, even with no symptoms.

Surgery for radiculopathy is indicated for patients who have demonstrated symptoms of sufficient duration and magnitude despite conservative management. Generally, patients considered for surgery are those with at least 3 months of persistent or recurrent arm pain or neurological deficits that interfere with personal or professional function and those for whom nonsurgical treatment has failed. Nonsurgical conservative treatments may include oral steroids, muscle relaxants, nonsteroidal anti-inflammatory drugs (NSAIDs), and physical therapy. A correlation of clinical findings with an identifiable lesion on neuroradiography also portends more consistent relief of symptoms after surgery.

Indications for Surgery for Radiculopathy

- Persistent or recurrent arm pain of more than 3 months' duration
- Neurological deficits that interfere with function
- Failure of conservative treatments

Upper motor neuron symptoms, including hyperreflexia, fine motor dysfunction, and gait disturbances, are the typical manifestations of cervical spondylotic myelopathy (CSM). The normal aging process of the spine starts with disc desiccation and loss of height. This leads to a degenerative cascade of events that includes osteophyte formation, ligament hypertrophy, and facet and uncovertebral joint (joints of Luschka) degeneration. When abnormal biomechanics of the spine are coupled with degenerative changes that narrow the spinal canal or compress the spinal cord, the result is a myelopathy. Spinal cord compression is dynamic and can change with flexion or extension of the neck. Flexion stretches the spinal cord, whereas extension causes buckling of ligaments and narrowing of the spinal canal.

The natural history of myelopathy is less favorable than that of radiculopathy, with a tendency for acute episodes of neurological decline separated by periods of relative stability of symptoms. Clarke and Robinson[3] first reported on the natural history of myelopathy. They reported that in more than 100 patients, motor symptoms worsened over time, and none of the patients returned to a normal neurological status. Lees and Turner[2] reported similar findings for long-term observations. Nurick[4] classified patients into six grades based on their disability with ambulation. His observations demonstrated long periods of no disease progression after early deterioration. Sumi et al.[5] reviewed 60 patients with mild cervical myelopathy and used magnetic resonance imaging (MRI) findings on a T1-weighted image (T1WI) to evaluate those patients who could tolerate having a cervical myelopathy without surgical treatment compared with those who could not tolerate the condition. They classified the spinal cord based on its presenting anatomical shape. If both sides were round and convex, they classified the cord as "ovoid deformity"; however, if a single side or both sides exhibited an acute angle to the lateral border, they defined the cord as "angular-edged deformity." In their review of a total of 55 cases with a mean of 94 months' follow-up, they noted global deterioration in 25% of myelopathies. There was a significant difference with respect to patients with "ovoid deformity," of whom 70% tolerated their mild myelopathy, compared with only 58% of those patients with "angular-edge deformity." Sumi et al.[5] concluded that surgery was a viable option for patients with mild cervical myelopathy and the "angular-edge deformity."

Surgical intervention can also be recommended when moderate to severe symptoms significantly affect a patient's quality of life or ability to work. Such symptoms include unsteady gait, hand dysfunction, or a neurogenic bowel or bladder. Surgery also is indicated when a patient has a clinical history of disease progression and, in milder cases, when significant stenosis is seen on imaging studies.

Indications for Surgery for Myelopathy

- Moderate to severe symptoms that affect the patient's quality of life or ability to work
- Unsteady gait
- Hand dysfunction
- Neurogenic bowel or bladder
- Spinal stenosis
- Progressive disease

Axial neck pain is pain that is localized to the cervical area and does not radiate into the upper extremities. It can manifest as unilateral or bilateral pain, headaches, or stiffness. The most common cause of axial neck pain is cervical strain, commonly referred to as whiplash or whiplash-associated disorders (WADs). Treatment for whiplash is universally nonoperative, and in most cases symptoms resolve within 6 to 8 weeks. Patients with cervical degenerative disease associated with axial pain are more challenging to manage. Surgical outcomes have been unpredictable, and success has been limited when the

sole indication for operative intervention is neck pain.[6–8] However, more recent studies have reported that surgery has yielded beneficial results in patients with severe, persistent neck pain in whom the disease was limited to one or two levels while sparing the remaining discs. Garvey et al.[9] reported good or excellent results in 82% of their patients at follow-up beyond 4 years and concluded that single- or two-level cervical fusion could provide more reliable outcomes. Likewise, Palit et al.[10] demonstrated a 79% satisfaction rate among patients who underwent one- to three-level fusions. Despite these more promising reports, the surgeon should exercise considerable restraint in recommending operative care for axial neck pain, and the patient must understand the relative unpredictability of surgery in the relief of symptoms.

The main role of the cervical spine is twofold. First, the cervical spine is responsible for the head's location over the body. Second, horizontal gaze is very tightly controlled via the cervical spine. Scheer et al. and the International Spine Study Group[11] summarized some of the clinical correlations between cervical deformity, in particular, sagittal alignment and its relationship to axial neck pain and myelopathy. Evidence is mounting to support clinical correlation as it pertains to health-related quality of life with certain cervical spine radiographic parameters. Furthermore, sagittal alignment may play a leading role in adding to spinal cord compression, which in turn leads to cervical myelopathy.

Surgical Treatment of Cervical Radiculopathy

The surgical options for treating cervical radiculopathy include anterior cervical discectomy and fusion (ACDF), cervical disc arthroplasty, anterior corpectomy and fusion (ACF), posterior laminotomy with foraminotomy, and laminectomy or laminoplasty with or without fusion. The procedures most commonly performed for single-level cervical radiculopathy resulting from soft disc herniations are cervical arthroplasty, ACDF, and foraminotomy. The other procedures (ACF, laminectomy, and laminoplasty) are reserved for more advanced ankylosis and multilevel disease. (These are discussed in more detail in the section on the surgical management of myelopathy.) Robinson and Smith[12] first described a technique for ACDF in 1955. This procedure has the advantages of (1) halting further osteophyte formation, (2) leading to regression and remodeling of existing osteophytes after solid fusion, and (3) distracting the disc space, which reduces buckling of the ligamentum flavum and enlarges the neuroforamen.[13]

The Smith-Robinson technique uses a horseshoe-shaped, tricortical iliac crest bone graft (Figure 16-1). The graft height should be 2 mm more than the preexisting disc space, with a minimum height of 5 mm. Overdistraction can occur if an attempt is made to enlarge the disc space by more than 4 mm; this may result in overcompression, graft collapse, and pseudarthrosis. Various other graft configurations have been described, including the dowel-shaped Cloward graft, the iliac crest strut graft reported by Bailey and Badgley, and the keystone graft described by Simmons (Figure 16-2).[14–16] In addition to these techniques, which use autogenous bone graft, success has been reported with the use of allograft bone, carbon fiber composite cages, titanium-threaded cages, polymethylmethacrylate, coral, and ceramics. However, these have not been shown to be superior to autografting.[13] With respect to multilevel anterior cervical fusion procedures, Frenkel et al.[17] reported up to 20% pseudarthrosis. These authors used recombinant bone morphogenic proteins for multilevel ACDFs with good results. That being said, there have been multiple reports documenting worsening dysphagia and neck swelling

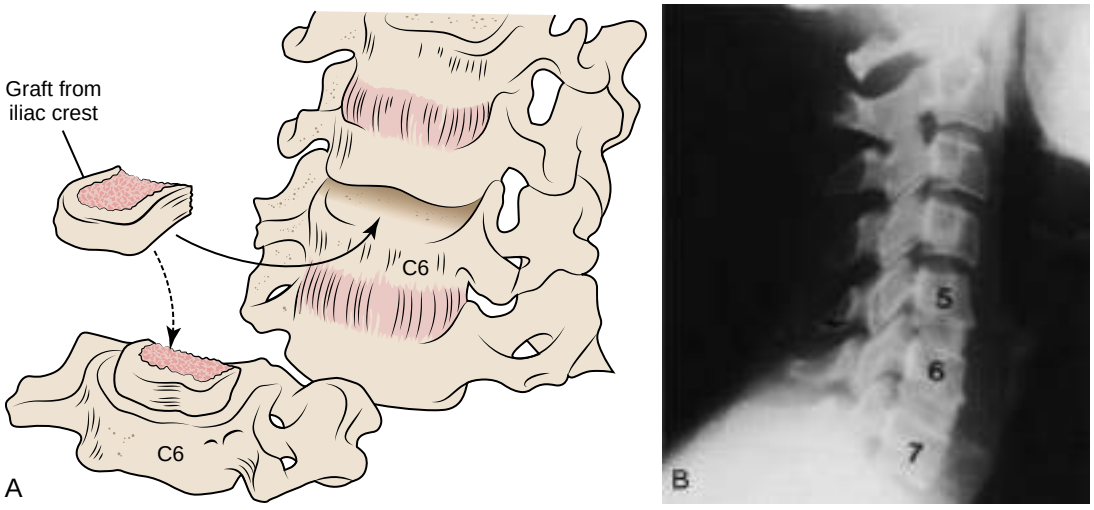

Figure 16-1 **A,** Illustration showing a Smith-Robinson graft (horseshoe-shaped tricortical iliac crest) placed in the disc space after excision of disc material. **B,** Lateral x-ray film showing ACDF at C5-C6 and C6-C7 using the Smith-Robinson technique. (**A** redrawn from Herkowitz HN, Garfin SR, Eismont FJ, et al, editors: *Rothman-Simeone: The spine,* ed 6, Philadelphia, 2011, Saunders; **B** from Herkowitz HN, Garfin SR, Balderson RA, et al, editors: *Rothman-Simeone: The spine,* ed 4, Philadelphia, 1999, Saunders.)

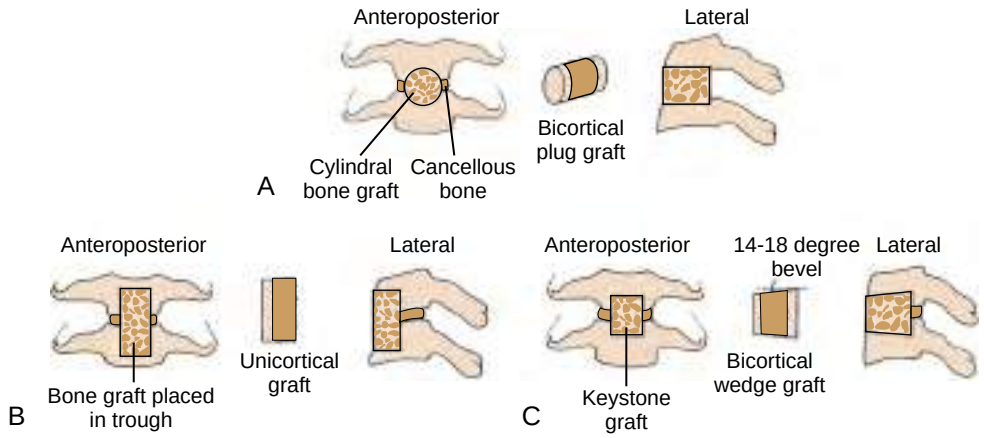

Figure 16-2 Schematic showing some of the various graft configurations for ACDF. **A,** Cloward dowel graft. **B,** Bailey and Badgley iliac strut. **C,** Simmons keystone graft. (Redrawn from Herkowitz HN, Garfin SR, Balderson RA et al, editors: *The spine,* ed 4, Philadelphia, 1999, Saunders.)

associated with the use of recombinant bone morphogenic proteins and overall their use should be considered only with strict caution.

The anterior cervical spine may be approached from the right or left side. After the skin and platysma have been incised, dissection is carried down to the spine, following the natural fascial planes. The sternocleidomastoid muscle and carotid sheath are retracted laterally, and the trachea, esophagus, and thyroid are moved medially. Along with the risk posed to these large structures, a risk of injury to the recurrent laryngeal nerve exists. The disc space is identified, and the annulus is incised. The disc contents and end plate cartilage are removed to the uncovertebral joints on either side and to the posterior longitudinal ligament (PLL) posteriorly. If sequestered disc material is behind the PLL or if a rent is noted in the PLL, the ligament is removed and the fragment is identified and excised; otherwise, the PLL may be left intact. The end plates are prepared to expose bleeding subchondral bone, and the contoured graft is placed into the disc space.

Controversy continues about the need for instrumentation in the surgical management of cervical disc disease. The purported advantages of internal fixation are to provide immediate stability, increase the fusion rate, prevent loss of graft fixation and position, improve postoperative rehabilitation, and reduce the requirement for a cervical orthosis.[18] Considerable debate exists about the efficacy of anterior cervical plating for single-level fusions. As the procedure is performed at an increasing number of levels, more compelling data support the use of rigid internal fixation because of the increased likelihood of bone graft nonunion (Figure 16-3).

Another option for the treatment of cervical radiculopathy at a single-level is disc arthroplasty. Upadhyaya et al.[19] reported on 1213 patients with symptomatic, single-level cervical disc disease who were randomly assigned to undergo either ACDF or disc arthroplasty (in three separate trials). A total of 621 patients received an artificial cervical disc, and 592 patients were treated with ACDF. Although both treatment arms yielded very good results, the arthroplasty was noted to yield a lower rate of

Figure 16-3 Lateral x-ray showing anterior discectomy and fusion (ACDF) of both C4/5 and C5/6 levels using cages and an anterior plate. As the number of fusion levels increases, internal fixation reduces the risk of pseudoarthrosis. (From Wang L, Hee HT, Wong HK: (iv) Cervical spondylotic myelopathy: a brief review of its pathophysiology, presentation, assessment, natural history and management, *Orthopaed Trauma* 25(3):181-189, 2011).

secondary surgery and a higher rate of neurological success. It was also associated with a lower rate of adjacent-level disease at 2 years.

Posterior approaches can also be used effectively in the surgical treatment of cervical radiculopathy. Laminotomy with foraminotomy is used primarily for unilateral radiculopathy at one or more levels. This technique is particularly useful for disc herniations or osteophytes that occur in relatively lateral positions. An incision is made posteriorly

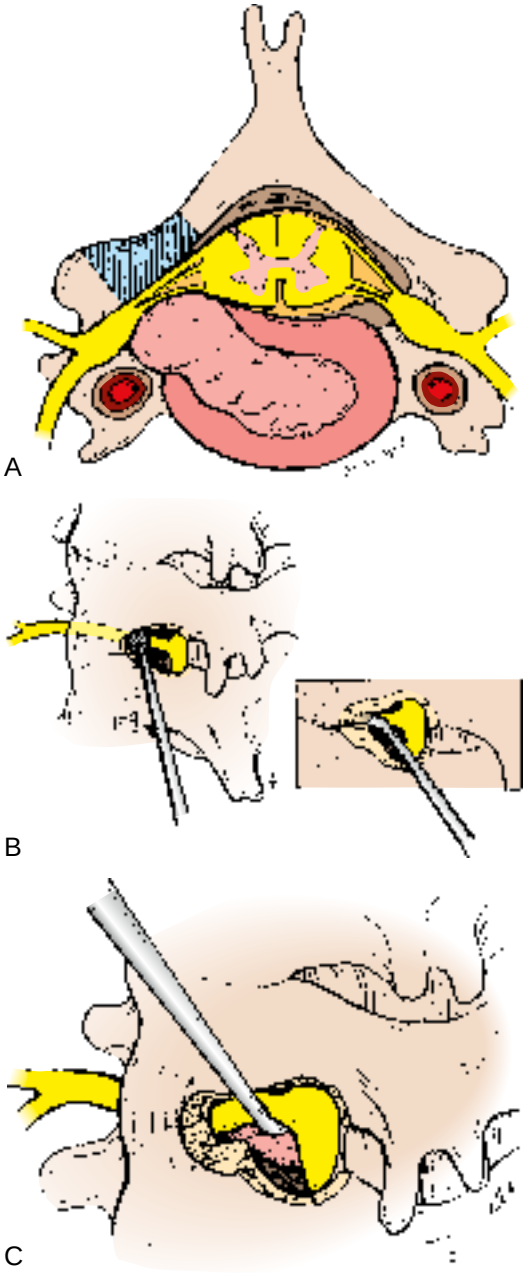

Figure 16-4 **A,** Posterolateral disc herniation causing nerve root compression. **B,** Laminotomy is performed; a portion of the laminae superiorly and inferiorly is removed, and the nerve root is identified. **C,** After foraminotomy, the nerve root is retracted, revealing the herniated disc, which is excised. (From Herkowitz HN, Garfin SR, Balderson RA et al, editors: *Rothman-Simeone: The spine,* ed 4, Philadelphia, 1999, Saunders.)

between the spinous processes at the affected level or levels, and dissection is carried down to expose the laminae on the symptomatic side. A keyhole-shaped laminotomy is performed using a combination of rongeurs, a high-speed burr, and angled curets (Figure 16-4). The nerve root can then be exposed, and a probe is used to ensure adequate decompression. If a soft disc herniation is present laterally, the nerve root can be retracted gently and the disc fragment excised. At least 50%, and preferably as much as 75%, of the facet joint surfaces should be preserved to prevent iatrogenic segmental instability.[20]

Surgical Options for Cervical Radiculopathy

- Anterior cervical discectomy and fusion (ACDF)
- Anterior corpectomy and fusion (ACF)
- Anterior cervical disc arthroplasty
- Posterior laminectomy with foraminotomy
- Laminectomy or laminoplasty with or without fusion

Surgical Treatment of Cervical Myelopathy

The goals of surgery in the treatment of CSM are to halt the neurological progression of the disease and to reduce pain. Although neurological improvement occurs in some cases, it cannot be reliably predicted, nor should it be the expected outcome for the patient or the clinician. Because neurological improvement cannot be ensured, when possible, surgical intervention should occur before the deficits progress to the level of disability. Patients who have had symptoms for more than 2 years show little or no improvement despite receiving treatment.[21] The choice of surgical technique and approach is based on the location of the neural compression, the number of involved levels, the presence of instability, the alignment in the sagittal plane, and the surgeon's familiarity and comfort level.

Surgical Considerations for Cervical Myelopathy

- Location of neural compression
- Number of levels involved
- Presence of instability
- Sagittal plane alignment
- Surgeon's experience

Because cervical spondylosis typically results in cord compression from anterior structures, the anterior approach allows for direct access to the pathological anatomy and decompression of the neural elements. Another advantage of the anterior approach is that it allows for better correction of sagittal plane deformity in patients with loss of normal cervical lordosis, a deformity that is more difficult to address with a posterior approach. Patients with compression of the cord primarily at the disc levels are candidates for ACDF using the techniques described previously. ACDF can be used successfully in single-level or multilevel disease; however, most surgeons do not advocate its use for more than three levels because of the increased risk of pseudarthrosis.[22] Posterior stabilization sometimes is added to improve rates of successful fusion when multiple levels are involved. As mentioned previously, iliac crest autograft is the gold standard, and the use of internal fixation becomes more important in two- and three-level procedures.

When myelopathy is caused by osteophytes, disc herniation, or ossification of the posterior longitudinal

ligament (OPLL) that extends above or below the disc space (behind the vertebral bodies), corpectomy is indicated for satisfactory decompression of the spinal cord. The term *corpectomy* implies removal of the central portion of the vertebral body and the discs above and below, as well as decompression of the joints of Luschka. The anterior approach for ACF is the same as that for ACDF, that is, following the natural fascial planes between the trachea, esophagus, and thyroid medially and the sternocleidomastoid muscle and the carotid sheath laterally to expose the anterior cervical spine. The appropriate discs are incised and removed back to the PLL. A rongeur is used to remove the bulk of the central portion of the vertebral body (Figure 16-5). After this initial trough is made, a high-speed burr is used to remove the remaining vertebral body back to the posterior cortex. Small angled curets are then used to remove the posterior cortex from the dura. The cervical spine is stabilized after corpectomy with strut grafts or cages made of titanium/PEEK.[23] The iliac crest or other interbody substitutes are used to promote structural support, to attempt to correct deformity, and to allow for fusion. Figure 16-6 shows the use of a fibular strut graft for a C3-C7 fusion after corpectomies. Internal fixation in the form of anterior cervical plating often is indicated to provide additional rigidity, reduce graft dislodgement, and possibly reduce the rate of pseudarthrosis (Figure 16-7). Postoperatively, a rigid cervical orthosis is often used. After prolonged surgery, the patient may remain intubated overnight to reduce the risk of respiratory complications.

Posterior surgery for the management of cervical myelopathy is indicated in patients with dorsal spinal cord compression, diffuse canal stenosis, multilevel spondylosis, and OPLL. Posterior surgery may be preferable to long anterior exposures for diffuse disease, because posterior approaches are less technically demanding and do not endanger structures such as the trachea, esophagus, and recurrent laryngeal nerve. For posterior decompression of the spinal cord to be effective, the cord must move posteriorly (dorsally) in the thecal sac. For this to occur, a lordotic alignment of the cervical spine is necessary; kyphosis in the sagittal plane is a relative contraindication to posterior surgery, because the spinal cord is less likely to move posteriorly when it is "draped over" the kyphotic vertebral bodies. Laminectomy (Figure 16-8) with or without fusion and laminoplasty are the principle posterior procedures used to treat myelopathy.

Isolated cervical laminectomy currently has narrow indications. Laminectomy alone can increase instability and lead to postoperative kyphosis, neurological deterioration,

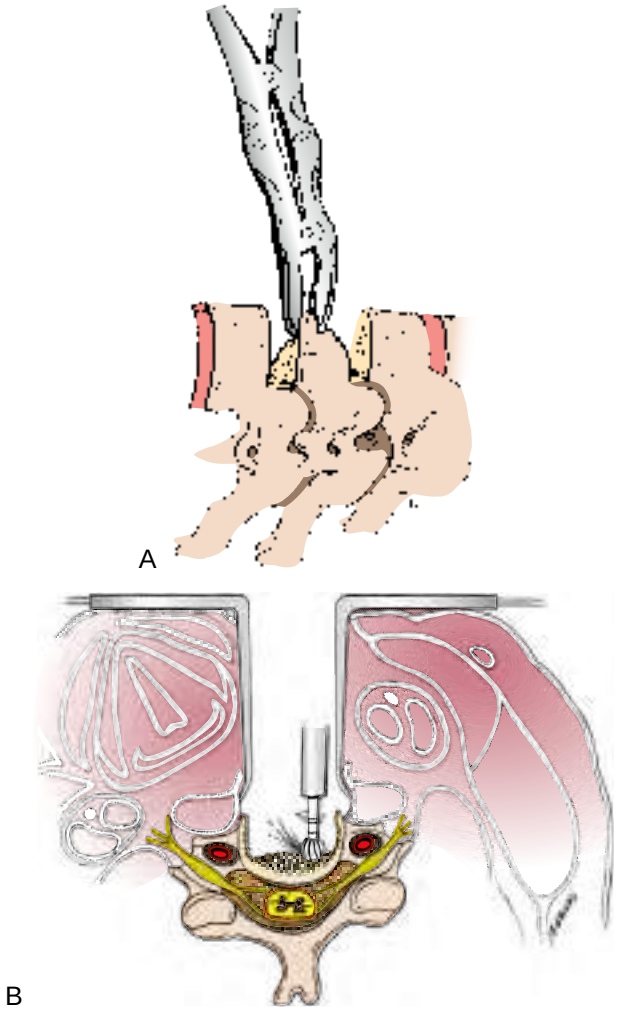

Figure 16-5 **A,** After removal of the disc above and below, a Leksell rongeur is used to remove the anterior two thirds of the vertebral body. **B,** A high-speed burr is used to remove the remaining bone back to the posterior cortex. The residual cortex is then removed with a small curet. (From Winter RB, Denis F, Lonstein JW, Smith M, editors: *Atlas of spine surgery,* Philadelphia, 1995, Saunders.)

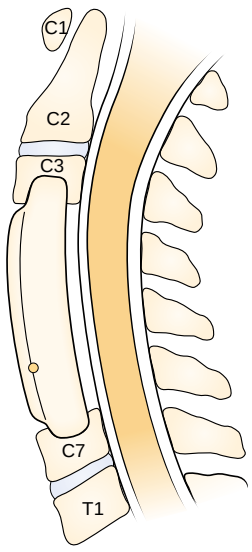

Figure 16-6 Schematic showing corpectomies of C4-C6 with placement of a strut graft from C3 to C7. Note that the vertebral bodies have been notched to secure the graft in position. (Adapted from Smith MD: Cervical spondylosis. In Birdwell KH, DeWald RL, editors: *The textbook of spinal surgery,* ed 2, Philadelphia, 1997, Lippincott-Raven, p 1411.)

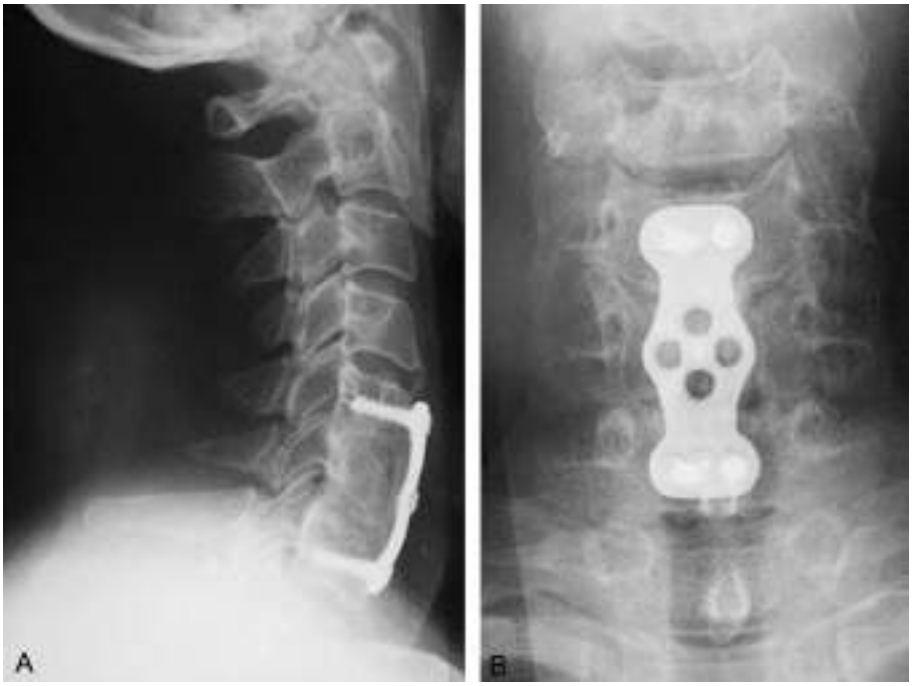

Figure 16-7 Lateral **(A)** and anterior posterior **(B)** postoperative cervical corpectomy and fusion x-rays of the cervical spine. Internal fixation provides additional stability. (From Medow JE, Trost G, Sandin J: Surgical management of cervical myelopathy: indications and techniques for surgical corpectomy, *Spine J*, 6(6):S233-S241, 2006.)

Figure 16-8 Posterior view of a cervical spine laminectomy. **A**, Use of high-speed bur to create a laminectomy trough. **B**, Incision of the ligamentum flavum and en bloc resection of the lamina from C3 to C7. **C**, Completed laminectomy with spinal cord decompressed. (From Jandial R, Garfin SR: *Best evidence for spine surgery: 20 cardinal cases*, Philadelphia, 2012, Saunders.)

and progression of OPLL. For these reasons, laminectomy without posterior stabilization probably should be reserved for patients with short segment posterior compressive lesions and a normal cervical lordosis. Kaptain et al.[24] reported that more than 20% of patients with no instrumented cervical laminectomy developed deformity progression. This percentile was significantly higher in patients who already had loss of cervical lordosis. With more diffuse disease, laminectomy should be combined with instrumentation and fusion. The procedure is performed through a posterior midline incision. The paraspinal muscles are dissected from the spinous processes and laminae bilaterally. A high-speed burr is then used to create two troughs at the lateral aspects of the laminae down to the inner cortex (see Figure 16-8, *A*). A Kerrison rongeur is used to complete the trough through the inner table and ligamentum flavum. The spinous processes and lamina can then be removed as a block, held together by the ligamentum flavum. The facet joints lateral to the troughs are left intact to the extent possible while still allowing adequate decompression. Partial facetectomy can have a significant effect on spinal stability.

Posterior cervical instrumentation and fusion are often indicated after posterior laminectomy, for failed anterior fusion, and for segmental instability. Traditionally, wiring techniques have been used to stabilize the posterior cervical spine. Figure 16-9 shows a commonly used triple wiring technique, which also secures two corticocancellous strips

Figure 16-9 Triple wiring technique in the posterior cervical spine. This serves as a tension band as well as securing two corticocancellous strip grafts in position bilaterally. (From Benzel EC, editor: *Spine surgery: techniques, complication avoidance, and management*, ed 3, Philadelphia, 2012, Saunders.)

of bone graft. Most wiring techniques require the spinous processes as points of fixation; however, after laminectomy, these have been removed. Screw fixation is currently the mainstay for stabilization; this can be a plate and screw construct or a rod and screw construct (Figure 16-10).

Combined anterior and posterior approaches are necessary in some patients. This circumferential approach most often is indicated for patients with a combination of severe sagittal plane kyphosis and multilevel stenosis, postlaminectomy kyphosis, or severe osteoporosis. In these challenging cases, the anterior procedure (multilevel corpectomy with strut graft) is directed at restoring sagittal alignment and decompressing the spinal cord. The posterior procedure (using lateral mass screws with plate or rod fixation) typically is used to enhance stabilization, minimize anterior graft complications, and reduce pseudarthrosis rates. These can be done as one procedure or as staged procedures on different days.

Because of the high incidence of spinal cord compression secondary to OPLL in Japan, Japanese surgeons have been very innovative in developing decompressive procedures. Laminoplasty was designed to reduce postoperative instability while maintaining spinal motion. Although various laminoplasty techniques have been described, the common goal of each is to expand the area of the spinal canal (effecting decompression) while preserving the posterior bony and ligamentous structures. Retaining the posterior elements allows segmental muscle reattachment, promoting stability and allowing motion.

The two most common laminoplasty techniques are the open door technique, in which the posterior arch is opened on one side with the contralateral side acting as a hinge, and the French door technique, in which the lamina is opened in the midline with bilateral hinges.[25,26]

The exposure for laminoplasty is a posterior midline approach, dissecting the paraspinal musculature from the posterior elements. Care is taken to preserve the interspinous ligaments and facet joint capsules. A high-speed burr generally is used to create lateral troughs in the lamina bilaterally. The trough can then be completed and opened on one side and hinged on the other (open door technique) (Figure 16-11, *A*). A midline osteotomy can also be performed; the lamina is opened centrally, hinging on the bilateral troughs (French door technique) (Figure 16-11, *B*). Various methods of holding the laminoplasty open have also been detailed, including wiring, sutures, small plates, and interposition bone grafts.

Surgical Treatment of Axial Neck Pain

Operative treatment for axial neck pain has narrow indications and should be used when all nonoperative options have been exhausted. Surgery may be indicated for a patient who continues to have unrelenting neck pain despite conservative treatment and has one- or two-level cervical degenerative disease. ACDF and cervical disc arthroplasty are the primary procedures used to treat axial neck pain. Both procedures eliminate the diseased disc (thought to be the major pain generator). A posterior approach may also be helpful in patients with failed anterior surgery or when posterior decompression is indicated. The anterior approach generally is preferred, because it does not involve extensive paraspinal muscle stripping and the disc is removed in its entirety.

Rehabilitation Considerations

Data in the literature provide little evidence on ways to optimize postoperative rehabilitation. The surgeon's preference and local opinion generally influence the rehabilitation process, lending anecdotal guidance to such things as the use of bracing and activity limitations. With the improvement of spinal instrumentation through the use of more rigid constructs, the use of postoperative bracing has decreased. The authors' guidelines are outlined in Table 16-1; however, there is a wide range of variability among surgeons.

THORACIC DISC DISEASE

Thoracic disc herniation is a relatively unusual diagnosis among patients who seek care for spinal problems. Because the presenting symptoms can be quite varied, this uncommon diagnosis often goes unrecognized. However, with the improvement in MRI and other advanced imaging techniques, patients are being diagnosed earlier and with greater accuracy. Figure 16-12 shows spinal cord impingement caused by soft and hard disc herniations. Disc herniations in the thoracic spine mostly affect middle-aged individuals. Nearly 80% are seen in

TABLE **16-1**

Rehabilitation Considerations After Surgery on the Cervical Spine

Expected Hospital Course	Outpatient Course	Red Flags
• Length of stay: 0-2 days • Ambulation and upper extremity range of motion (ROM) • Bracing: may or may not be used (surgeon's preference, 2-12 weeks)	• Aerobic conditioning, upper extremity stretching/strengthening • Active cervical spine ROM when brace is removed • No passive ROM for 3 months (at affected levels) • May shower when wound is healed • For fusions: no heavy lifting/exercise for 3 months	• Change in neurological examination findings or symptoms • Worsening pain • Difficulty swallowing • Erythema/fever/wound drainage

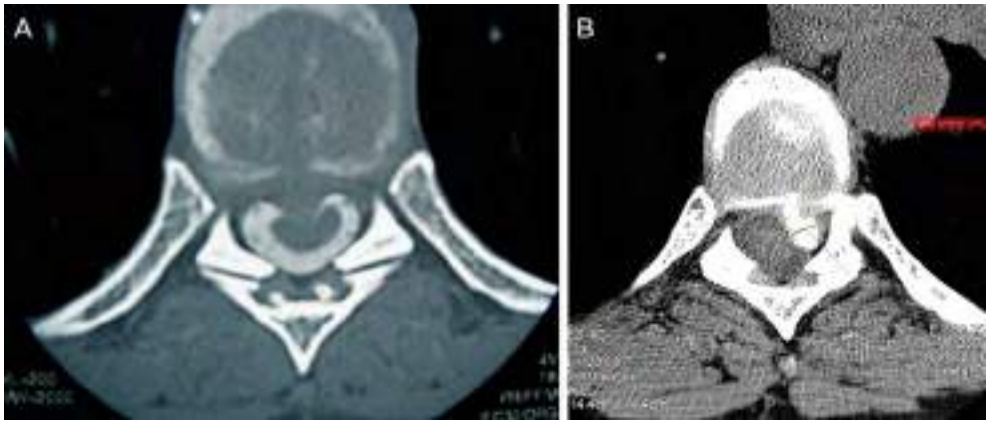

Figure 16-12 Thoracic disc herniations. **A,** Pre-operative computed tomography (CT)/myelogram showing central soft disc herniation at T6-T7. **B,** Pre-operative axial CT image showing a T8-T9 lateralized calcified thoracic disc herniation. (From Sheikh H, Samartzis D, Perez-Cruet MJ: Techniques for the operative management of thoracic disc herniation: minimally invasive thoracic microdiscectomy, *Orthop Clin North Am* 38(3):351-361, 2007.)

the fourth through sixth decades, with 33% occurring in those in their forties.[27] Surgery for thoracic disc disease is estimated to account for 0.15% to 1.8% of all discectomies performed.[28,29] No clear-cut syndrome has been described for this condition, because the presentation varies considerably. The most common initial symptom is pain (in 57% of patients), followed by sensory complaints and, least commonly, motor and bladder disturbances.[27] Three quarters of disc herniations in the thoracic spine occur between T8 and L1, with T11-T12 being the most affected level (26%).[27] This is thought to be related to the increased stress on the spine at the thoracolumbar junction.

Patients without myelopathy can be treated conservatively with narcotic pain medications, anti-inflammatory drugs, physical therapy, activity modification, and occasionally bracing. In general, surgery is regarded as the treatment of choice for symptomatic patients with myelopathy to prevent the sequelae of cord compression. Indications for operative intervention for herniated thoracic discs include progressive myelopathy, lower extremity weakness, and unremitting pain after conservative treatment.

Surgical Treatment

When surgery is indicated, the approach taken to remove the diseased disc is determined by its nature and location, the level of the pathology, and the surgeon's experience. Historically, thoracic myelopathy was treated with a direct posterior laminectomy and disc excision. This approach has been abandoned because of its unacceptably high rate of neurological deterioration, which results from manipulation of the spinal cord to access the disc for excision.[30] The widely accepted techniques for thoracic discectomy are the transthoracic approach, costotransversectomy, the transpedicular (posterolateral) approach, and video-assisted thoracoscopy (VATS). With the evolvement of minimally invasive surgery, another technique being used is the minimally invasive lateral retropleural approach.[31]

The transthoracic approach gives the widest exposure to the disc space (especially for central and intradural herniations), accessibility of multiple levels, and the ability to place a bone graft. However, with these advantages comes the morbidity of a thoracotomy.[28] A left-sided approach usually is preferred to avoid the inferior vena cava and the liver in the lower thoracic spine. With the patient in the lateral decubitus position, a standard thoracotomy is performed, and the chest cavity is entered one or two levels above the level of interest. Mobilization of the parietal pleura and segmental vessels and nerves is then performed. Partial or complete discectomy can be undertaken anteriorly without manipulation of the spinal cord (Figure 16-13). Fusion is indicated when stability is compromised by the decompression, as in the case of complete discectomy with partial corpectomy. A chest tube is placed at the end of the surgery.

For posterolateral and lateral disc herniations, the costotransversectomy approach may be used. This approach has the advantages of avoiding entry into the pulmonary cavity and providing access to all thoracic levels, but it requires disruption of the paraspinal musculature and more extensive bone resection. The patient is positioned prone, and a paramedian incision is made. The paraspinal muscles are retracted medially or split transversely. The posterior medial portion of the rib is resected, and the pleura is mobilized and retracted anteriorly. The transverse process and pedicle on the affected side are excised, providing access to the lateral aspect of the disc. The disc fragment is removed, often along with a posterolateral portion of the adjacent vertebral bodies. Disc herniations that do not cross the midline can be effectively decompressed with this technique without manipulation of the spinal cord, minimizing neurological complications.

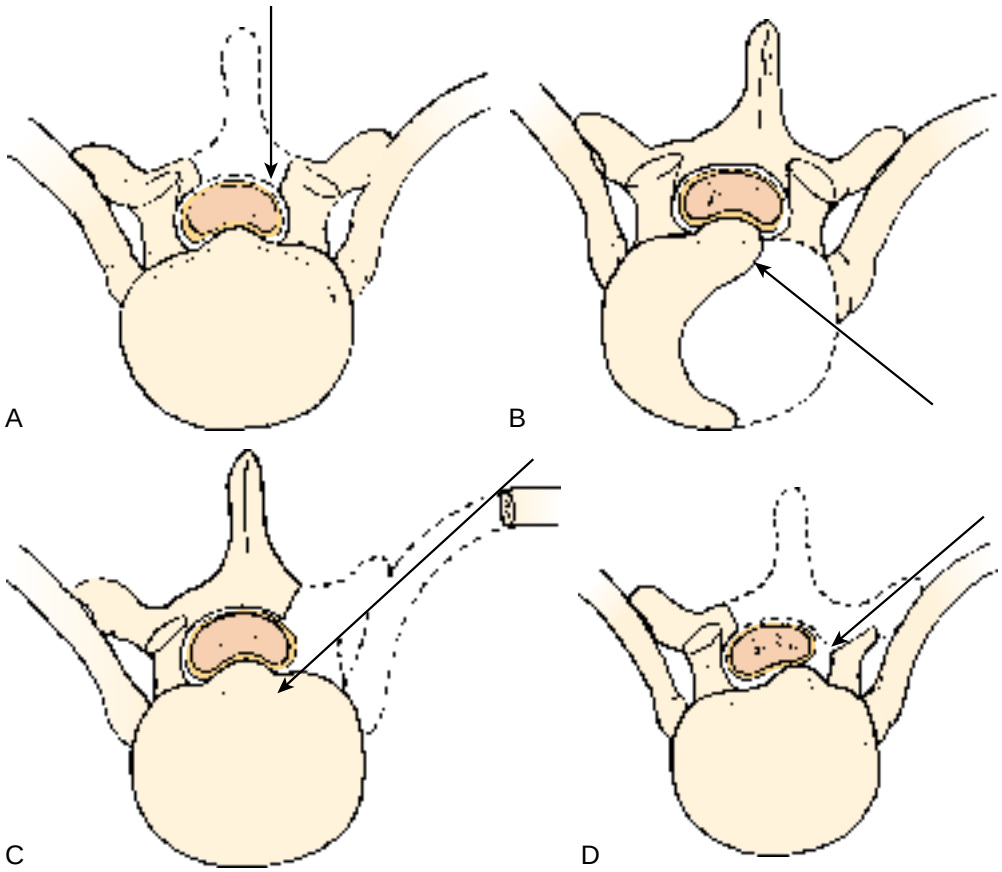

Figure 16-13 **A,** Decompression of thoracic disc herniations from a standard laminectomy approach requires manipulation of the spinal cord and results in a high rate of neurological injury. **B,** A transthoracic approach allows the most direct access to the disc without encountering the spinal cord. **C,** Decompression using a costotransversectomy approach allows safe excision of the disc posteriorly. **D,** For posterolateral and foraminal disc herniations, a transpedicular approach can give access to the lesion. (From Herkowitz HN, Garfin SR, Eismont FJ et al, editors: *Rothman-Simeone: The spine,* ed 6, Philadelphia, 2011, Saunders.)

A transpedicular (or posterolateral) approach to the thoracic spine is useful only for posterolateral or foraminal herniations. This approach gives only limited exposure of the disc, but it avoids thoracotomy, does not necessitate rib resection, and requires less extensive dissection. With the patient prone, a midline exposure is performed. The lamina, facet joint, and pedicle on the affected side are removed. The lateral portion of the involved disc can then be excised with small curets and pituitary rongeurs. Segmental stability may be compromised, depending on the amount of the facet and pedicle that are removed to facilitate visualization.

VATS may be able to provide the advantages of the anterior (or transthoracic) approach to thoracic disc pathology while minimizing the morbidity of thoracotomy (Figure 16-14). This approach is more technically demanding and has a steep learning curve for the surgeon and staff; incomplete decompression and failure to resolve symptoms can result from inadequate visualization or unreliable excision of disc material. Limited data are available on the effectiveness of VATS, because this technique is evolving; however, preliminary series in the literature appear promising.[32]

The operative technique for the minimally invasive surgery (MIS) lateral approach to the thoracic spine has previously been described.[33] After general endotracheal intubation, the patient is positioned in the true lateral decubitus position with the operative side up. Intraoperative fluoroscopy is used to ensure the patient is placed and secured in a true lateral orientation, with the working corridor to the disc space orthogonal to the floor (true 90° lateral trajectory).

For the retropleural approach, a 5- to 6-cm oblique incision is made directly over the rib that is overlying the targeted pathology on lateral fluoroscopy. Monopolar cautery is used to dissect through the subcutaneous tissue and muscle. The periosteum is elevated circumferentially off the rib, and approximately 6 cm of rib is resected. The plane between the parietal pleura and endothoracic fascia is developed in the cranial and caudal direction, as well as anteriorly, until the lateral surface of the vertebral bodies and disc spaces are visualized. A table-mounted retractor is then placed over the targeted level to maintain exposure. Once accurate placement of the retractor has been confirmed and adequate exposure

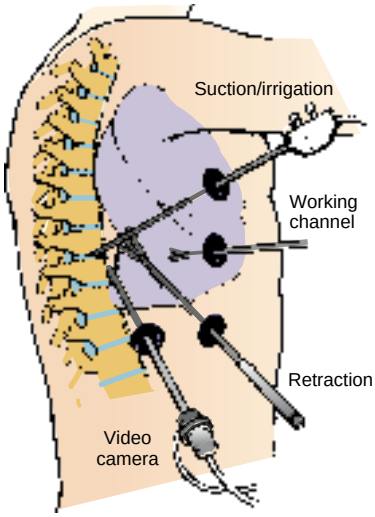

Figure 16-14 Diagram of the typical portals and instruments used in video-assisted thoracoscopy for decompression of a T8-T9 herniated disc. (From Herkowitz HN, Garfin SR, Eismont FJ et al, editors: *Rothman-Simeone: The spine,* ed 6, Philadelphia, 2011, Saunders.)

is achieved, the goals of surgery are accomplished in the traditional methods.

In a report from a multicenter study, Uribe et al.[31] described outcomes following MIS lateral approach for thoracic disc herniation in 60 consecutive patients treated at one of five international institutions with an average follow-up of 11 months. Myelopathy was improved in 83%; radiculopathy, in 87%; back pain, in 91%; and bladder and/or bowel dysfunction, in 88% of patients.

Rehabilitation Considerations

Little information is available in the literature about postoperative rehabilitation after surgery of the thoracic spine. Many surgeons routinely use rigid orthoses, whereas others believe that the inherent stability of the thoracic spine, combined with modern instrumentation (for more extensive procedures), is sufficient to forgo bracing. Table 16-2 presents the authors' preferred guidelines for rehabilitation.

LUMBAR DISC DISEASE

An estimated 80% of the population experiences low back pain at some time in their lives, resulting in one of the most common causes of disability among people living in industrialized nations.[34] In most patients, low back pain is self-limiting and requires no treatment; however, 7% to 14% of patients have symptoms that persist longer than 2 weeks, and 1% to 2% of patients eventually undergo surgery of the lumbar spine.[35] The most common disorders of lumbar discs can be divided into syndromes that cause predominantly back pain and those in which the primary complaint is leg pain (sciatica).

Statistics for Lumbar Disc Disease

- 80% of the population will experience low back pain
- 7%-14% will have symptoms longer than 2 weeks
- 1%-2% will undergo surgery

Discogenic pain syndromes of the lumbar spine present with low back pain as the chief symptom. Some associated buttock or sporadic leg pain also may be reported, but these are generally associated with irritation of the nerve root in the neural foramen. As the name implies, the lumbar intervertebral discs are thought to be the principal pain generators and are the focus of diagnosis and treatment. These syndromes can be classified into three categories: internal disc disruption (IDD), degenerative disc disease (DDD), and segmental instability. IDD usually follows trauma and is marked by damage to the internal structure and metabolic function of the intervertebral disc; imaging is generally normal. DDD, on the other hand, is atraumatic, with a gradual onset of symptoms that usually manifest in middle-aged individuals, and often involves anular tears, disc bulges, and disc herniation.[36] Radiographic findings include disc space narrowing, osteophyte formation, and end plate sclerosis. Segmental instability describes excessive motion, either

TABLE **16-2**

Rehabilitation Considerations After Surgery on the Thoracic Spine

Expected Hospital Course	Outpatient Course	Red Flags
• Length of stay: 3-7 days • Ambulation when able to be out of bed • Bracing: may or may not be used after chest tube is removed (surgeon's preference, 2-12 weeks)	• Aerobic conditioning, upper extremity/lower extremity stretching/strengthening • Active spinal range of motion (ROM) when brace is removed • No passive ROM for 3 months (at affected levels) • May shower when wound is healed • Brace off for shower, activities of daily living • No heavy lifting/exercise for 3 months	• Change in neurological examination findings or symptoms • Worsening pain • Shortness of breath • Erythema/fever/wound drainage

translational or rotational, of the spinal segments; this manifests as spondylolisthesis, lateral listhesis, rotatory subluxation, or scoliosis.

Disc Syndromes

- Internal disc disruption (IDD)
- Degenerative disc disease (DDD)
- Segmental instability

Lumbar disc herniation can cause impingement and inflammation of neural elements, most commonly the nerve roots. This leads to pain that radiates down the leg on the affected side, called *radiculopathy*. Irritation of the posterior primary ramus may result in localized back pain as well. In a healthy disc, the inner nucleus pulposus is contained by the annulus fibrosus. When fissuring or tearing of the inner annulus occurs but the outer portion remains intact, the nucleus can bulge or protrude posteriorly, causing nerve root impingement. As further fissuring occurs, the nucleus can push through and exit the annulus, causing extrusion of the disc material. When an extruded fragment becomes detached from the remaining nucleus pulposus, it is said to be sequestered (Figure 16-15).

Nonoperative treatment of symptomatic lumbar disc disease often results in a return to normal activity. Conservative treatment plans commonly consist of several modalities, including drug therapies and the use of a wide variety of physical therapy interventions, such as exercise, traction, and counterirritation techniques to manage pain (e.g., electrical nerve stimulation, acupuncture, biofeedback), as well as bracing and manipulation. Epidural and selective nerve root injections may be helpful. Facet blocks (see Chapter 15) may also be used to treat pain arising from microinstability of the facet joints.

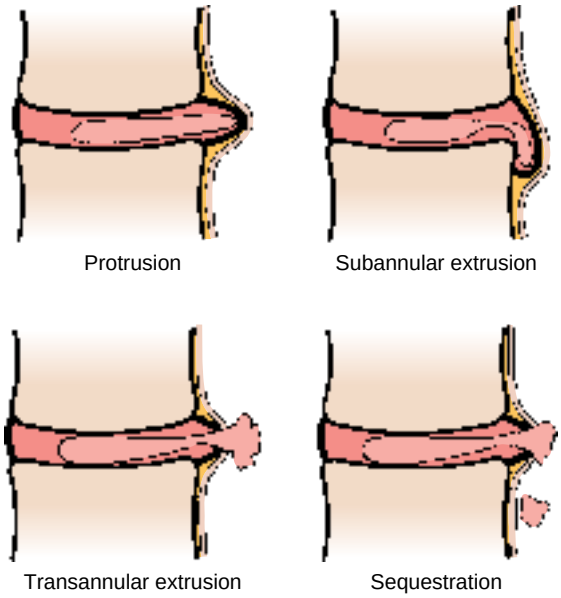

Figure 16-15 Classification of disc herniations. (Modified from Herkowitz HN, Garfin SR, Balderson RA et al, editors: *Rothman-Simeone: The spine*, ed 4, Philadelphia, 1999, Saunders.)

Urgent surgery is indicated for patients with cauda equina syndrome (CES) or progressive motor deficit. Findings in CES include urinary retention (check a postvoid residual bladder volume), fecal incontinence, "saddle anesthesia" (i.e., numbness over buttocks, anus, lower genitals, perineum, and posterosuperior thighs), and significant motor weakness not attributable to pain. In the absence of these findings, surgery generally is indicated only after conservative measures have failed. The major goal of surgery for these patients is pain relief. The most predictable results can be expected when the history, physical examination, and radiographic findings are consistent. Abnormal findings on MRI are not by themselves an indication for surgery.

If surgery is indicated, the surgeon must determine whether decompression alone (i.e., discectomy) or decompression in conjunction with stabilization is the treatment of choice for the patient. Initially, discectomy alone is the treatment of choice for lumbar disc herniation with radiculopathy. In the event of multiple recurrent disc herniations, significant pain that has failed all conservative treatment, or evidence of instability, spinal fusion is recommended.

Surgical Procedures for Lumbar Disc Disease

- Discectomy
- Posterior lumbar interbody fusion (PLIF)
- Transforaminal lumbar interbody fusion (TLIF)
- Lateral lumbar interbody fusion (LLIF)
- Anterior lumbar interbody fusion (ALIF)
- Artificial disc replacement

Discectomy

Surgery is indicated for patients with unilateral radiculopathic leg pain for whom imaging studies confirm a correlating lumbar disc herniation, for patients in whom nonoperative management fails after a trial of 6 to 8 weeks, and for patients with severe or worsening motor deficit.[37,38] Conventional, or open, discectomy is performed with the patient positioned prone on a frame or in the kneeling position; this allows the patient's abdomen to hang free, preventing pressure on the vena cava, which reduces intraoperative bleeding. The proper spinal level is identified, and a small midline incision is made. Subperiosteal dissection is performed, exposing the spinous process and lamina. When proper exposure of the posterior elements is obtained, laminotomy (or laminectomy) of the affected side is carried out with the appropriate rongeurs and curets. Care must be taken not to cross the pars interarticularis and remove the entire facet,

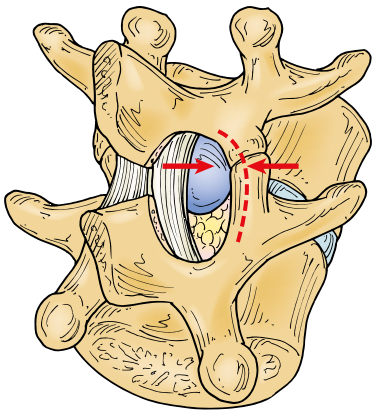

Figure 16-16 Technique for lumbar discectomy. Parts of the superior and inferior laminae and ligamentum flavum are removed to expose the nerve root and underlying disc herniation *(left arrow)*. The disc fragment is excised, and a blunt probe is used to ensure adequate decompression. Excessive bone removal (past dotted line) can cause iatrogenic instability. (From Benzel EC, editor: *Spine surgery: techniques, complication avoidance, and management,* ed 3, Philadelphia, 2012, Saunders.)

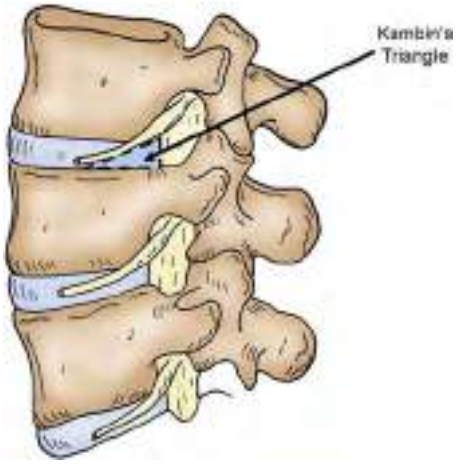

Figure 16-17 Drawing of lateral lumbar spine depicting Kambin's triangular safe working zone for percutaneous arthroscopic discectomy. This zone is a right triangle in which one arm is the thecal sac, the other arm is the end plate of the caudal body, and the hypotenuse is the exiting nerve root. (From Fessler RG, O'Toole JE, Eichholz KM, Perez-Cruet MJ: The development of minimally invasive spine surgery, *Neurosurg Clin North Am* 17:401-409, 2006.)

because this may result in iatrogenic instability. The ligamentum flavum is excised to expose the dura. The nerve root is inspected and retracted to reveal the underlying disc herniation (Figure 16-16). The PLL and posterior annulus are incised, and pituitary rongeurs are used to remove the herniation in a piecemeal fashion. A blunt probe can then be inserted to ensure that a sufficient amount of disc material has been removed for adequate decompression of the nerve root. After meticulous hemostasis is achieved, the wound is closed in layers.

Alternative forms of discectomy have been described, with the goal of reducing the size of the incision and limiting dissection, and thereby minimizing postoperative morbidity, reducing the potential for scar formation, and allowing for quicker mobilization and rehabilitation. Two of the more common alternative techniques are microdiscectomy and arthroscopically assisted microdiscectomy (AMD).

Using the operating microscope or loupes with a headlamp coaxial to the line of sight allows the surgeon to obtain illumination and visualization of deep spinal structures through a small incision. With this advantage, microdiscectomy can be performed through incisions 2 to 3 cm (1 to 1.2 inches) long. The surgical technique is similar to that for conventional discectomy, in which dissection of the paraspinals, laminotomy, and removal of the ligamentum flavum are required to allow visualization of the pathological disc and decompression of the nerve root. This operation can be safely performed as an outpatient procedure.[39] However, its role is somewhat controversial, because several reports show similar results for microdiscectomy and conventional open discectomy.[40,41]

AMD uses a percutaneous, posterolateral approach to the lumbar disc. The potential advantages of this technique are as follows: it does not require muscle stripping, bone resection, or retraction of inflamed nerve roots; it allows irrigation and dilution of inflammatory mediators; and it minimizes epidural bleeding and subsequent scar formation.[42] For AMD, the patient is positioned prone on a radiolucent table, and standard sterile skin preparation and draping are followed. Under fluoroscopic guidance, a needle is inserted approximately 10 cm (4 inches) from the midline and directed toward the triangular working zone and into the disc (Figure 16-17).[42] A guidewire is placed through the needle, and the needle is removed. An obturator and canula are then advanced over the guidewire, providing access for the arthroscope and instruments. This approach allows for manual removal of the disc fragments causing nerve root compression, as well as annular fenestration, which reduces intradiscal pressure and creates a "path of least resistance" away from the nerve root for any future herniations. Success rates of 70% to 90% have been reported for AMD, with minimal complications.[43,44]

Posterior Lumbar Interbody Fusion/Transforaminal Lumbar Interbody Fusion

Numerous authors have reported on the success of posterior lumbar interbody fusion (PLIF) techniques in the treatment of lumbar degenerative disease, spondylolisthesis, and discogenic back pain. PLIF allows for *direct* decompression of the neural elements, distraction and realignment of the disc space, and stabilization of the painful motion segment. Some debate exists as to the surgical indications for PLIF (or a modification, transforaminal lumbar interbody fusion [TLIF]); however, most would agree that only patients who still have persistent, disabling pain after an aggressive, prolonged nonoperative therapy program should be recommended for the operation. Provocative discography has also been recommended as a diagnostic tool to confirm that a particular disc space is the focus of pain generation.[45]

Patients undergoing a PLIF or TLIF surgery are positioned prone with the abdomen free, usually on a Jackson spinal table, which allows for easy access of fluoroscopy. In the traditional open approach, a longitudinal midline incision is made, and subperiosteal dissection is carried down to expose the posterior elements of the lumbar spine. A portion of the lamina and the superior and inferior facets is removed (bilateral for PLIF; bilateral or unilateral for TLIF) to allow access to the spinal canal. Further decompression may be performed as necessary. The neural elements may then be retracted to expose the lateral aspect of the disc. The disc space is entered, and the disc material is removed bilaterally. Care must be taken not to manipulate the thecal sac too much to get medial exposure. Intradiscal shavers of different widths are used to excise the remaining disc material and prepare the end plates for fusion. Structural grafts are then placed in the interspace to restore alignment and allow for fusion (Figure 16-18). In a PLIF, two structural grafts are placed in the lateral disc space, whereas in a TLIF, one graft is placed anteromedially. Multiple techniques and graft choices have been described, including autograft bone, allograft bone, and metal and carbon fiber cages filled with cancellous bone, and all of these choices come in a number of shapes and configurations. Although most variations of the PLIF technique involve grafting of the interspace and the use of implants, the need for posterior segmental instrumentation and the addition of posterolateral fusion are the subject of debate. PLIF may be performed as a stand-alone procedure, or pedicle screw fixation with or without intertransverse fusion can be added (Figure 16-19). With a TLIF, one entire facet, or sometimes bilateral facets, are removed for direct decompression and thus require posterior fixation for stability purposes. Recent advances have allowed for more minimally invasive approaches to posterior interbody fusions. For example, an MIS TLIF involves a unilateral or bilateral paramedian incision and uses muscle dilation rather than cautery to prevent postoperative muscle atrophy.[46] All methods have been reported successful.[47–49]

Anterior Lumbar Interbody Fusion

Anterior lumbar interbody fusion (ALIF) has become an increasingly popular surgical option because it allows reconstruction of the anterior column, improves sagittal alignment (i.e., restores lumbar lordosis), stabilizes the painful motion segment, enlarges the neuroforamina through distraction of the disc space, and avoids paraspinal muscle damage and scarring. The primary indication for ALIF is chronic low back pain, generally caused by DDD,

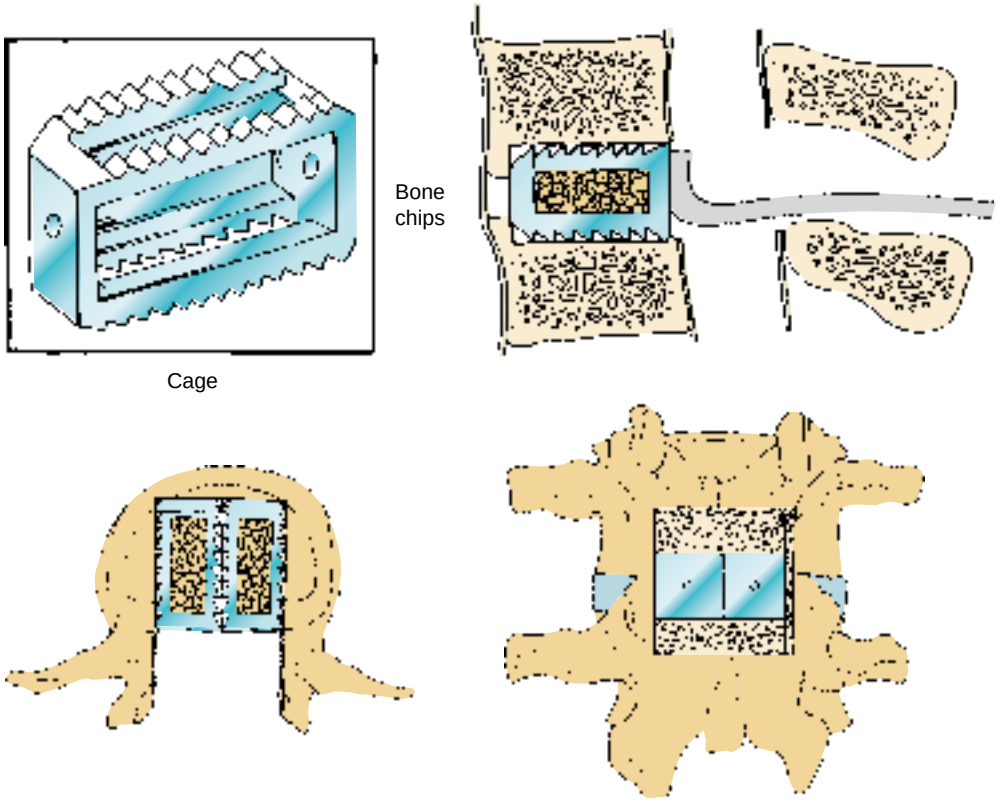

Figure 16-18 Posterior lumbar interbody fusion. The diagram shows the interbody positioning of two carbon fiber cages packed with cancellous bone graft. The cauda equina (not shown) is retracted to each side as the cage is impacted into the disc space. (From Benzel EC, editor: *Spine surgery: techniques, complication avoidance, and management,* ed 3, Philadelphia, 2012, Saunders.)

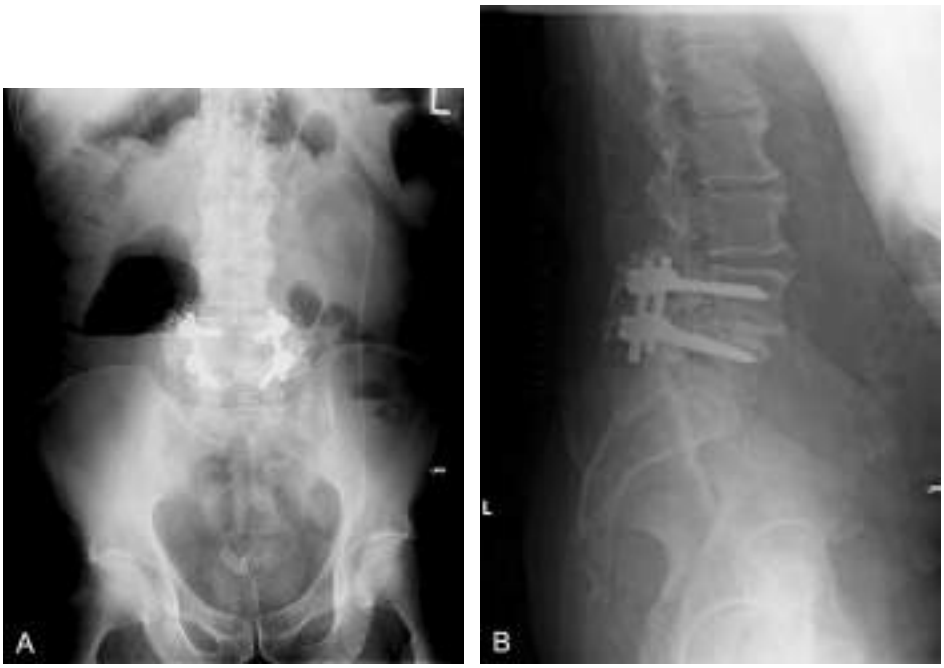

Figure 16-19 Anteroposterior **(A)** and lateral **(B)** x-ray films showing an instrumented PLIF of L4-L5. (From Benzel EC, editor: *Spine surgery: techniques, complication avoidance, and management,* ed 2, Philadelphia, 2005, Saunders.)

degenerative spondylolisthesis, or failed posterior surgery. As with other surgical techniques for the treatment of degenerative lumbar conditions, ALIF is indicated when disabling symptoms have persisted for a prolonged period and when conservative management options have been exhausted. It is used primarily in the treatment of L4-L5 and L5-S1, but it also may be used at more rostral levels. Neural compression is a relative contraindication for ALIF; decompression of the canal and neuroforamen is most safely and effectively carried out dorsally under direct vision. Indirect decompression of bilateral foramina may be accomplished with a large interbody graft using the lateral lumbar interbody fusion (LLIF), which is discussed in the following section.[50]

ALIF is performed with the patient supine on a radiolucent table. An anterior retroperitoneal approach is used, usually from the left side. An abdominal or vascular surgeon commonly performs the procedure in conjunction with the spinal surgeon. A paramedian incision is made low on the abdomen, the rectus sheath is incised, and the muscle is retracted. The retroperitoneal space is entered, and the peritoneum is mobilized and retracted to expose the lower lumbar spine. The iliac vessels are retracted to allow access to the disc space or spaces that are to be fused. The anterior longitudinal ligament and anterior annulus are excised, along with the remainder of the disc material. The subchondral bone of the end plates is prepared, and a graft slightly larger than the disc space is inserted to achieve the desired level of sagittal correction and distraction of the foramina. The choice of graft varies and, as with PLIF, successful outcomes and fusion have been achieved using tricortical autograft, shaped allograft, and cages. Hemostasis is achieved, followed by a standard closure. A nasogastric tube is used postoperatively until bowel function returns. Retrograde ejaculation is a recognized complication that may develop after ALIF. It most often occurs after L5-S1 fusion and is a result of injury to the autonomic nerves overlying that interspace.

Lateral Lumbar Interbody Fusion

Recent advances in instruments, retractors, and techniques have tremendously propelled lumbar fusions, allowing near-total removal of discs and placement of large interbody grafts, thus increasing rates of fusion. With the LLIF technique, the disc space is accessed laterally, through the psoas muscle, allowing for minimal tissue disruption, decreased blood loss, reduced postoperative pain, and shorter recovery time.[51,52] Dural retraction is avoided, as well as destruction and denervation of the posterior musculature and removal of the posterior arch with its potential for instability. Compared with anterior approaches, there is reduced risk of vascular injury. The surgeon is maximizing the strongest areas of the end plate, with the implant placement spanning the ring apophysis.

The LLIF technique is indicated in many of the same cases as those where TLIF, PLIF, or ALIF is indicated. However, the main contraindication for LLIF at this point is at the L5-S1 level due to the iliac crest as a barrier, as well as the presence of the iliac vessels and lumbosacral plexus at that level. The lateral technique is also useful for adjacent segment disease, to avoid the prior scar, and

to maximize fusion surface. Recently it has gained acceptance as an excellent tool in the treatment of spinal deformity, along with percutaneous pedicle screw fixation.

Preoperative imaging is essential, as it is with all spine surgery. If the majority of spinal stenosis or compression is dorsal in nature, a posterior approach may be more appropriate. However, the size of the neuroforamina is increased with placement of a large interbody graft, thus providing indirect decompression of the nerve roots. It is important also to recognize an extra lumbar segment (i.e., lumbarization of the sacrum) when it is present, because the lateral approach to the lower lumbar spine may not be feasible in these cases.[53] On MRI, the surgical level should have an adjacent healthy-appearing psoas muscle, and if it has moved anteriorly, then there is a likelihood of increased neural elements at the entrance to the disc space from the lateral side. Intraoperative neuromonitoring allows directional neuromonitoring with continuous electromyographic (EMG) monitoring of nearby nerves while traversing the psoas muscle. Fluoroscopy is essential during LLIF and will determine the outcome of each case.

The patient is placed in the lateral position and secured to the table using silk tape, with laterality determined preoperatively by the surgeon, taking into consideration MRI findings, elevation of iliac crest, symptomatology, and surgeon preference. The bed is then broken to open the disc space slightly and to allow improved access between the lowest rib and the iliac crest. Using fluoroscopy, the surgeon marks the skin with a target of the posterior third of the disc space. Using one or two incisions (the second used to guide the dilator), the surgeon uses blunt dissection to sweep the peritoneum anteriorly and feel for the transverse process and psoas muscle. The dilator is placed, and with constant checking of the neuromonitoring, sequential dilators are used until the retractor is placed. With the retractor anchored in place with a shim and articulating arm, a set of interbody instruments are used to prepare the interspace and place the graft. It is hypothesized that minimizing the time that the retractor is open will minimize risk of complications, including anterior thigh numbness or nerve injury.

Overall, LLIF is a powerful tool for lumbar interbody fusion, with short recovery times, relatively low complication risks, minimal blood loss, high fusion rates, and reduced overall health care costs compared with other maximally invasive procedures.[54]

Lumbar Artificial Disc Replacement

The U.S. Food and Drug Administration (FDA) has approved the use of lumbar artificial disc replacement for the treatment of symptomatic lumbar disc disease. The artificial disc is an alternative to fusion procedures. The proposed advantages of disc replacement are the ability to restore pain-free motion of the intervertebral segment and to protect adjacent segments from increased loading and failure. The current indications for disc replacement are quite limited; only about 5% of patients considered for surgical intervention meet the criteria.[55] Candidates for lumbar arthroplasty are patients 18 to 60 years old in whom nonoperative treatment for at least 6 months has failed, who have single-level DDD confirmed by MRI and discography, and who have no previous lumbar fusion, no instability, and no extruded disc material.[56] Proper patient selection has been advocated as the most important parameter for a successful clinical outcome.[57] There has been some difficulty in getting insurance reimbursement for these lumbar total disc replacements, which has stalled an otherwise potentially powerful tool.

The only implant currently approved in the United States is the SB-Charité disc prosthesis. Others currently in trials are the ProDisc-L (Depuy-Synthes), XL TDR (Nuvasive, Inc.), Maverick (Medtronic), and FlexiCore (Stryker Spine). The SB-Charité prosthesis consists of cast cobalt-chromium-molybdenum (Co-Cr-Mo) alloy end plates that engage the bone with small spikes and an ultra-high-molecular-weight polyethylene insert with a less constrained, mobile-bearing design (Figure 16-20). Short-term follow-up of these implants has demonstrated a relatively high success rate and has shown results equivalent to or slightly better than those in the ALIF control group (stand-alone BAK cages with autograft).[56] The approach for implantation is similar to that for ALIF, a left anterior retroperitoneal exposure of the lower lumbar spine. The disc is excised, and the end plates are prepared. The prosthetic end plates are sized and implanted, followed by a polyethylene spacer of the appropriate height to restore lordotic alignment of the segment. Long-term survival data are limited, as are reports of successful methods for revision or salvage when implant failure occurs.

Rehabilitation Considerations

Spinal surgeons vary widely in the use of postoperative bracing and activity restrictions after surgery to the lumbar spine, partly because of a lack of evidence-based literature. In a series of 50 open discectomies, Carragee et al.[58] urged patients to return to full activities as soon as possible, with no restrictions at all. They reported that this resulted in a quicker return to work and no increase in complications. This study is helpful for patients undergoing simple discectomy, but it should not be extrapolated to those undergoing fusion procedures. Patients who undergo arthroplasty do not require any postoperative orthosis. The authors' suggested guidelines for rehabilitation can be found in Table 16-3.

TABLE **16-3**

Rehabilitation Considerations After Surgery on the Lumbar Spine

Expected Hospital Course	Outpatient Course	Red Flags
• Length of stay: 0-3 days for discectomy, laminectomy; 3-7 days for instrumented fusions • Nasogastric tube (for anterior approach) • Ambulation and upper extremity/lower extremity range of motion (ROM) • Bracing: may or may not be used (surgeon's preference, 2-12 weeks)	• Aerobic conditioning, upper extremity/lower extremity stretching/strengthening • Active spine ROM/strengthening • No passive ROM for 3 months (at affected levels) • May shower when wound is healed • Brace off for shower, activities of daily living • No heavy lifting/exercise for 3 months	• Change in neurological examination findings or symptoms • Worsening pain • Bowel/bladder changes • Erythema/fever/wound drainage

LUMBAR SPINAL STENOSIS AND SPONDYLOLISTHESIS

The term *lumbar spinal stenosis* describes a complex set of symptoms, physical findings, and radiographic abnormalities caused by narrowing of the spinal canal. The etiologies of spinal stenosis are degenerative, congenital, traumatic, and iatrogenic in nature, as well as a few others. The most common form of spinal stenosis is degenerative and usually occurs in the sixth and seventh decades.[59] The degenerative changes result in hypertrophy of the facet joints, capsule, and ligamentum flavum. In addition, disc degeneration leads to posterior bulging and loss of height, which add to both central and foraminal narrowing.

As would be expected in most degenerative disorders, the symptoms of lumbar stenosis can have an insidious onset. Initially they may include a low back ache that worsens with activity and is relieved by rest. As the stenosis progresses, symptoms of neurogenic claudication can begin to interfere with daily activities. These symptoms are classically described as vague cramping, aching, or burning pains in the back, buttocks, and legs that are exacerbated by standing or walking and relieved by sitting, squatting, or flexing the lumbar spine.[60] Spinal stenosis must be differentiated from vascular claudication, a somewhat similar but distinct symptom complex caused by peripheral vascular disease. With **vascular claudication**, symptoms generally cease when movement is halted, even while still standing. With **neurogenic claudication**, symptoms remain while still standing and generally improve with bending over and opening the neuroforamen. Lower extremity ultrasound can be used to rule out vascular claudication.

Lumbar spondylolisthesis can be classified into five groups according to the underlying abnormality[61]:

congenital (dysplastic), isthmic (spondylolytic), degenerative, traumatic, and pathological. The most common form is isthmic spondylolisthesis, which is associated with a defect in the pars interarticularis; this form can be found in 5% to 7% of adults in the United States.[62] Many of these individuals are asymptomatic. Back pain and hamstring tightness are the most common presenting complaints, and few progress to high-grade slips. The degenerative form, caused by intersegmental instability resulting from long-standing degenerative changes of the disc and facet joints (usually at L4-L5), can cause or contribute to spinal stenosis and symptoms of neurogenic claudication.

A commonly adopted method of grading spondylolisthesis is the Meyerding classification, based on the ratio of overhanging part of the superior vertebral body to anteroposterior length of the adjacent inferior vertebral body (Table 16-4).

Conservative management is the mainstay of treatment for most patients with spinal stenosis or degenerative spondylolisthesis. Pharmacological treatment (NSAIDs, antidepressants, pain relievers, and muscle relaxants), injections, manipulation, bracing, exercise, traction, and physical therapy all have been reported to be helpful. Because the natural history of this disorder suggests that few patients will have short-term deterioration, a thorough trial of these nonoperative measures is suggested before surgery is considered.[63] Patients with moderate symptoms may be treated conservatively for 2 to 3 years. Surgery is considered when the slippage is rapid or neurological signs start to become evident (Figure 16-21).

Surgical Procedures for Lumbar Spinal Stenosis and Spondylolisthesis

- Laminectomy
- Posterolateral fusion (no instrumentation)
- Posterior lumbar interbody fusion (PLIF)
- Transforaminal lumbar interbody fusion (TLIF)
- Lateral lumbar interbody fusion (LLIF)

TABLE **16-4**

Meyerding Classification for Spondylolisthesis

Grade	% Overhang/Slip
I	0%-25%
II	26%-50%
III	51%-75%
IV	76%-100%
V (spondyloptosis)	>100%

Lumbar Laminectomy

Decompressive laminectomy for spinal stenosis of the lumbar spine is indicated in patients with intractable pain recalcitrant to nonoperative treatment and those with neurological deficits that significantly impair their lifestyle and ability to function. Because of the potential destabilizing effects of lumbar decompression, laminectomy without stabilization is reserved for patients with no significant deformity or instability. Laminectomy is a safe, effective procedure; it may have a success rate in the range of 85% to 90% for eliminating neurogenic claudication.[64,65]

Laminectomy is performed with the patient positioned prone on a spine frame or in the kneeling position with the abdomen hanging free. A midline incision is made over the lumbar spine, and dissection proceeds down to expose the spinous processes and laminae bilaterally. The proper level or levels are identified radiographically, and the spinous processes are removed. The decompression is divided into three stages. In the first stage, the central canal is decompressed by means of removal of the laminae and ligamentum flavum (Figure 16-22). A number of methods can be used for this, including use of a high-speed burr, Kerrison rongeurs, or osteotomes, depending on the surgeon's familiarity and experience. In the second stage, hypertrophied tissue is removed from the lateral recesses. A Kerrison rongeur is used to excise the medial aspect of the inferior and superior facets, along with excess ligamentum flavum, out to the level of the pedicle. In the third stage, each individual neuroforamen is decompressed. The nerve roots are identified, and a blunt probe is used to palpate the foramen. The bone spurs and soft tissue are removed until the probe can be passed freely into the foramen. Care must be taken to preserve the integrity of the pars interarticularis as well as that of the facets. The wound is closed in layers, and a suction drain is commonly used.

Minimally invasive and microsurgical techniques have also been developed for lumbar decompression. Little difference is apparent in the long-term outcomes of these procedures compared with those achieved with the standard approach.[66,67] These techniques use the advantages of coaxial light and stereopsis, which the operating microscope provides, to perform the decompression through smaller incisions and with less morbid dissections. This may lead to less pain, shorter hospital stays, and quicker rehabilitation.[39] Preservation of the spinous processes, along with the interspinous and supraspinous ligaments, may also minimize the risk of iatrogenic instability and can be more easily performed with the advent of newer retraction systems.

Posterolateral Fusion

Dorsolateral arthrodesis of the lumbar spine may be used to treat many disorders that result in deformity

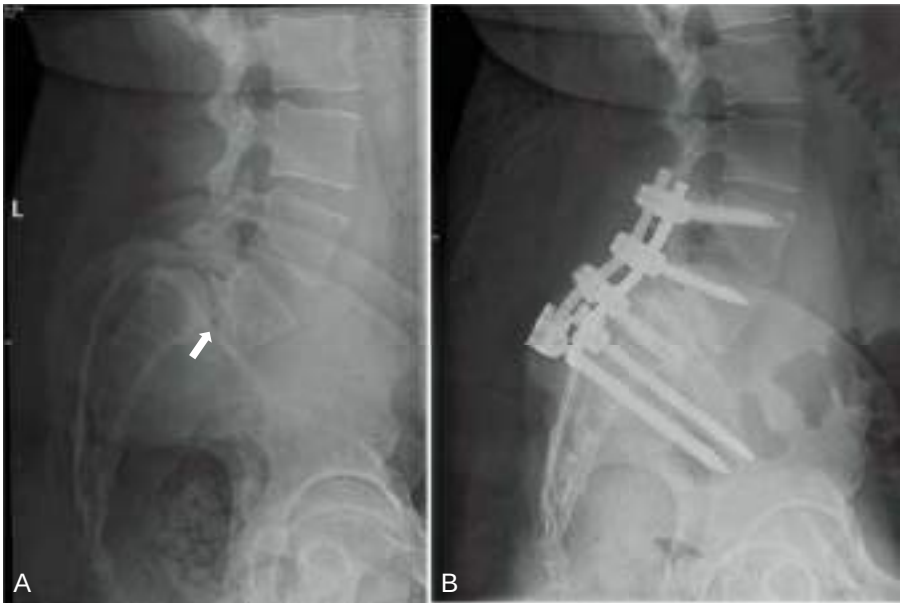

Figure 16-21 Lateral preoperative (**A**) and postoperative (**B**) radiographs of high-grade spondylolisthesis *(arrow)* demonstrating significant reduction after spinal instrumentation and fusion.

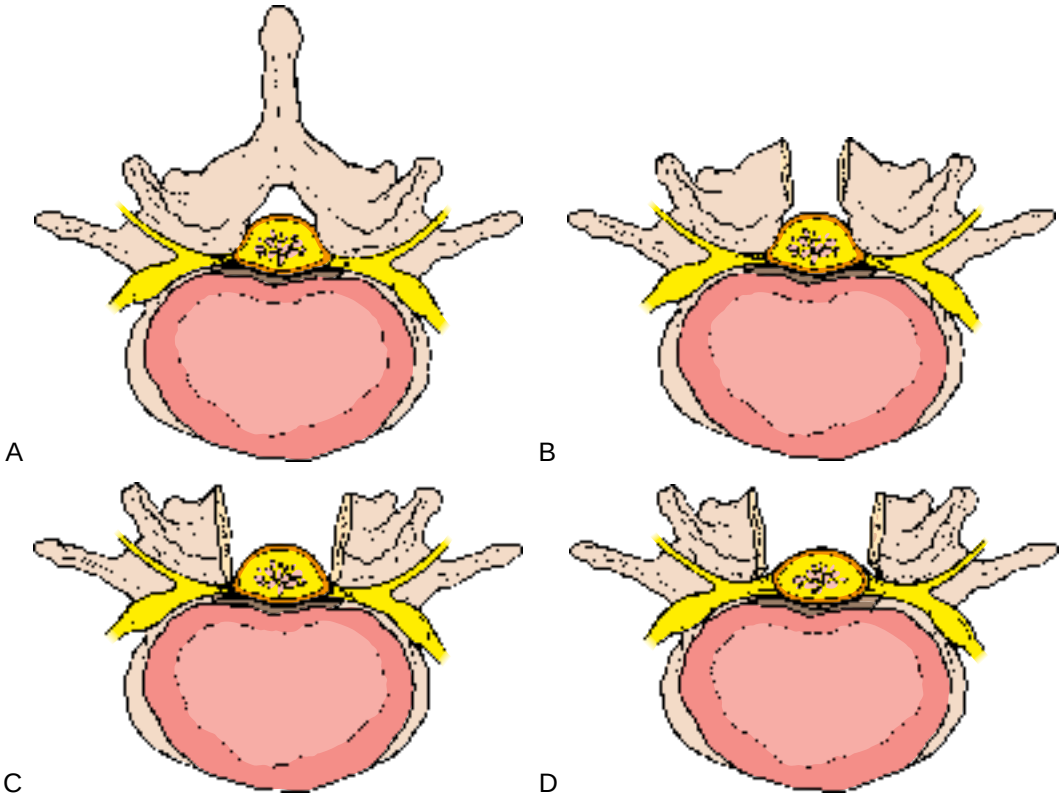

Figure 16-22 Lumbar laminectomy technique. **A,** Depiction of an axial view of the lumbar spine with typical hypertrophic degenerative changes. **B,** First stage: The spinous processes, midline laminae, and ligamentum flavum are removed to expose the dura. **C,** Second stage: Decompression of the lateral gutters is performed, with removal of the remaining laminae and the medial aspect of the superior facets. **D,** Third stage: Decompression of the neuroforamina is performed. (From Herkowitz HN, Garfin SR, Balderson RA et al, editors: *Rothman-Simeone: The spine,* ed 4, Philadelphia, 1999, Saunders.)

and instability. This procedure is widely recommended for many patients in whom trauma, tumor, or infection have rendered the spine unable to support physiological loading.[68] It also is indicated for instability secondary to previous surgery or isthmic spondylolisthesis. Its use in degenerative disorders, however, is the subject of considerable debate. No benefit has been shown to adding arthrodesis to routine discectomy or after laminectomy in the stable lumbar spine.[69] Controversy exists over the need for fusion in degenerative spondylolisthesis when decompression is performed for associated spinal stenosis. Recent data suggest that, when degenerative instability is present, more successful outcomes result when posterolateral arthrodesis is added to the decompressive operation.[70,71]

Indications for the addition of internal fixation, namely, segmental pedicle screw instrumentation, to posterolateral fusions are also debated. In patients with degenerative spondylolisthesis and spinal stenosis, segmental internal fixation has been reported to improve fusion rates, but this did not lead to improved clinical outcomes.[72] Instrumentation may help correct deformity, stabilize the spine, enhance arthrodesis rates, minimize the number of segments that need to be fused, and reduce rehabilitation time and brace wear. Instrumentation often is indicated in the treatment of fractures, when structural support is compromised by tumor or infection, for failed in situ fusion, or in cases of high-grade translational motion.

Patients undergoing posterolateral fusion are positioned kneeling on an Andrews table or prone on a radiolucent Jackson frame (especially for instrumented cases). Most often, a midline approach and subperiosteal dissection are done to expose the posterior elements. Exposure is continued out to the tips of the lateral processes. Decompression is then performed as needed. Decortication of the dorsal aspect of the transverse processes and the lateral aspect of the superior facets and pars interarticularis, as well as removal of the facet joint capsule and cartilage, prepares the spine bed for fusion. Instrumentation (if used) is then implanted, using screws that pass through the pedicles into the vertebral bodies interconnected with rods (Figures 16-23 and 16-24). The gutters overlying the lateral process are filled with bone graft, and the wound is closed in layers over a suction drain.

Complications of posterolateral fusion may include hemorrhage, infection, and neurological injury in the perioperative period. Later, pseudarthrosis, hardware failure, or recurrent symptoms may lead to failures of treatment. In cases of instability or risk of progression of deformity or spondylolisthesis, instrumented posterior spinal fusion is indicated (TLIF/PLIF) with or without interbody work. With improved fusion rates over posterolateral fusions and the ability to correct deformity, instrumented fusions are the treatment of choice when spinal fusion is required in patients with spinal stenosis or spondylolisthesis.

Rehabilitation Considerations

The authors' postoperative guidelines for laminectomy and dorsolateral fusion are the same as those for procedures treating lumbar disc disease (see Table 16-3). When the wound produces no drainage, early showering may be allowed. Carragee and Vittum[73] reported no increase in wound complications after posterior surgery when patients were allowed to shower 2 to 5 days after surgery, compared with a historic cohort by the same surgeon who kept the wound dry for 10 to 14 days.

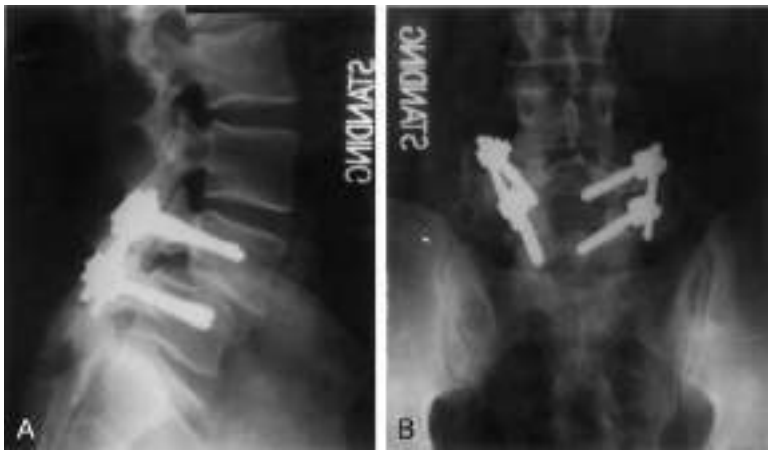

Figure 16-23 Postoperative lateral **(A)** and anteroposterior **(B)** views of a 31-year-old man who underwent pedicle screw instrumentation and posterolateral fusion for a grade II spondylolisthesis at L4-L5. SPINAL DEFORMITIES

Spinal deformity generally is categorized as frontal plane deformity (scoliosis) or sagittal plane deformity (kyphosis). However, scoliosis most often includes a rotational or torsional malalignment and sagittal plane disturbance (Figure 16-25). In children and adolescents, scoliosis is broadly classified as idiopathic, congenital, neuromuscular, or syndrome related. Most cases of pediatric scoliosis are idiopathic (Figure 16-26). Kyphosis may be related to congenital abnormalities, neuromuscular disorders, trauma, infectious or neoplastic processes, or metabolic disorders, but Scheuermann's disease is the diagnosis in most cases. The magnitude and progression (or risk for progression) of the curve are the major indications for surgical treatment of scoliosis.

In adolescent idiopathic scoliosis (AIS), the risk for curve progression is largely a factor of growth remaining and the magnitude of the present curve. In a growing child, bracing usually is indicated when the curve reaches 25° to 30°, with an upper limit of approximately 45°, beyond which curves are less amenable to bracing. Most data have shown that bracing halts curve progression, but correction cannot be anticipated. Weinstein et al.[74] concluded that bracing significantly decreased the progression of high-risk curves to the threshold for surgery in patients with AIS. Longer hours of brace wear were associated with greater benefit. The indications for surgical correction in AIS are a growing child who presents with a curve of 40° to 45°, progression of a curve to 40° in a child undergoing nonoperative treatment, and a curve greater than 50° to 60° in a skeletally mature adolescent.[75]

Scoliosis Treatment

- Bracing: Curve 25° to 45°
- Surgery: 1. Growing child with a curve of 40° to 45°
  2. Curve that progresses to 40° in a child undergoing bracing
  3. Curve greater than 50° to 60° in a skeletally mature adolescent

The normal range for thoracic kyphosis in the adolescent is generally considered to be 20° to 40°. Patients with Scheuermann's disease often have kyphosis greater than 45°, with associated end plate irregularities, Schmorl's nodes, and vertebral wedging on x-ray films. Deformity is the most common presenting complaint, and pain is another common symptom. Bracing for Scheuermann's disease has led to improvement in vertebral wedging and kyphotic angle but was less effective in patients with greater than 75° of initial kyphosis.[76] Surgical intervention may be indicated for rigid kyphosis greater than 75° and for those who have unrelenting pain despite conservative treatment.[77]

Deformity in adults presents a diagnostic as well as a therapeutic challenge for the clinician. Adult deformity most often can be divided into cases in which a curve was present before maturity, cases in which the curve developed de novo as a result of metabolic bone disease or degeneration, and cases in which degenerative changes are superimposed on pre-existing scoliosis. Nonoperative management is directed at treatment of symptoms, usually pain. Operative intervention is indicated to treat persistent, disabling pain that is refractory to conservative treatment; to correct and stabilize progressive deformity; to restore coronal and sagittal balance; and to decompress neural elements associated with spinal stenosis.[78]

Surgical Procedures for Spinal Deformities

- Posterior arthrodesis
- Anterior arthrodesis

Posterior Arthrodesis

Preoperative planning for surgical correction of thoracic and lumbar deformities is important. Standing posteroanterior (PA) and lateral x-ray films of the entire spine are used to gauge the magnitude of the deformity and spinal balance. Bending films are also commonly used to assess the flexibility of the curve. This information is used to determine which levels to include in the fusion and how much correction of deformity can be expected.

Posterior reconstructive surgery is performed with the patient prone on a radiolucent spine frame. A long midline incision is made, and subperiosteal dissection is carried deep to expose the spinous processes, laminae, and

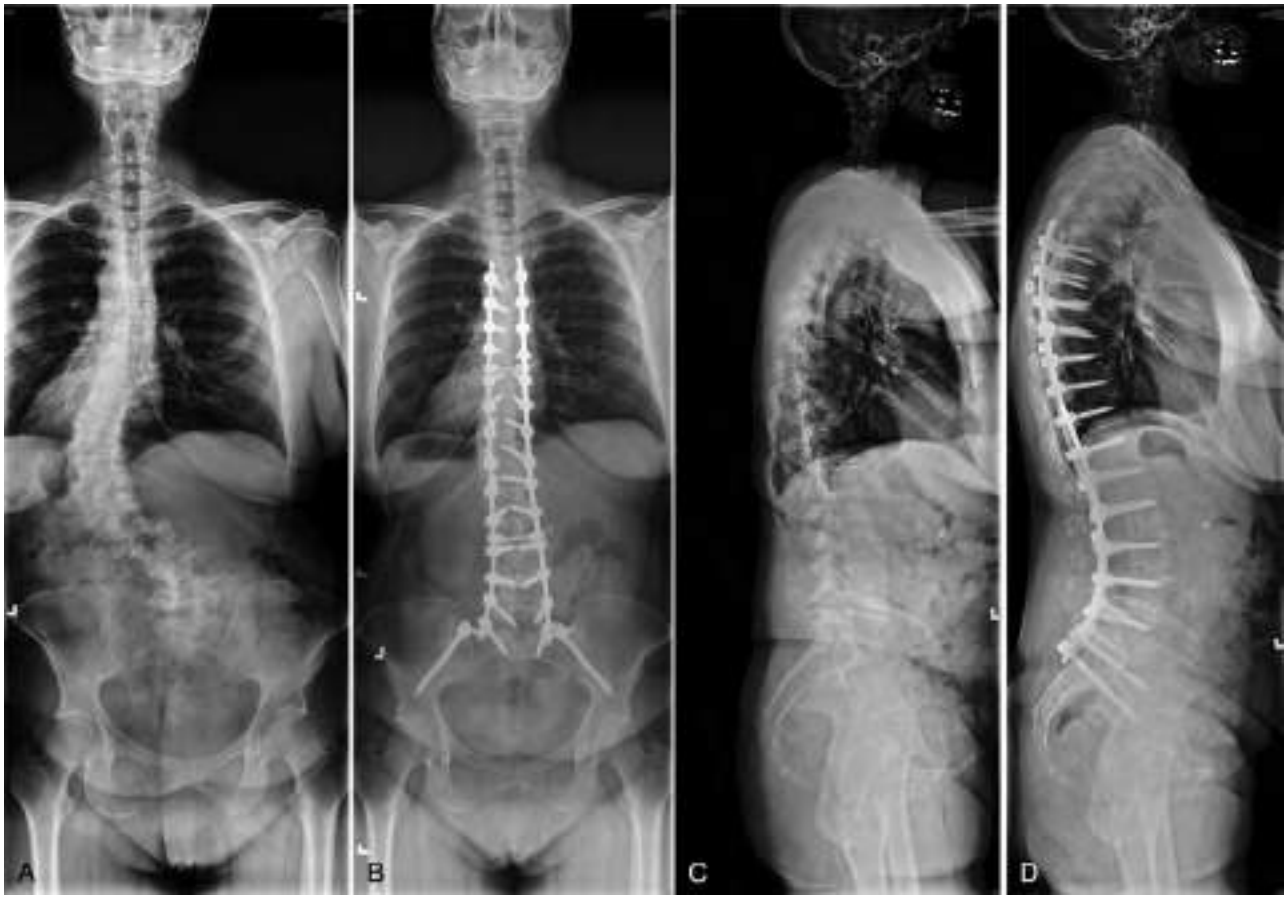

Figure 16-25 Preoperative (**A**) and postoperative (**B**) posteroanterior and preoperative (**C**) and postoperative (**D**) lateral radiographs of adult idiopathic scoliosis demonstrating significant correction of spinal deformity after spinal instrumentation and fusion.

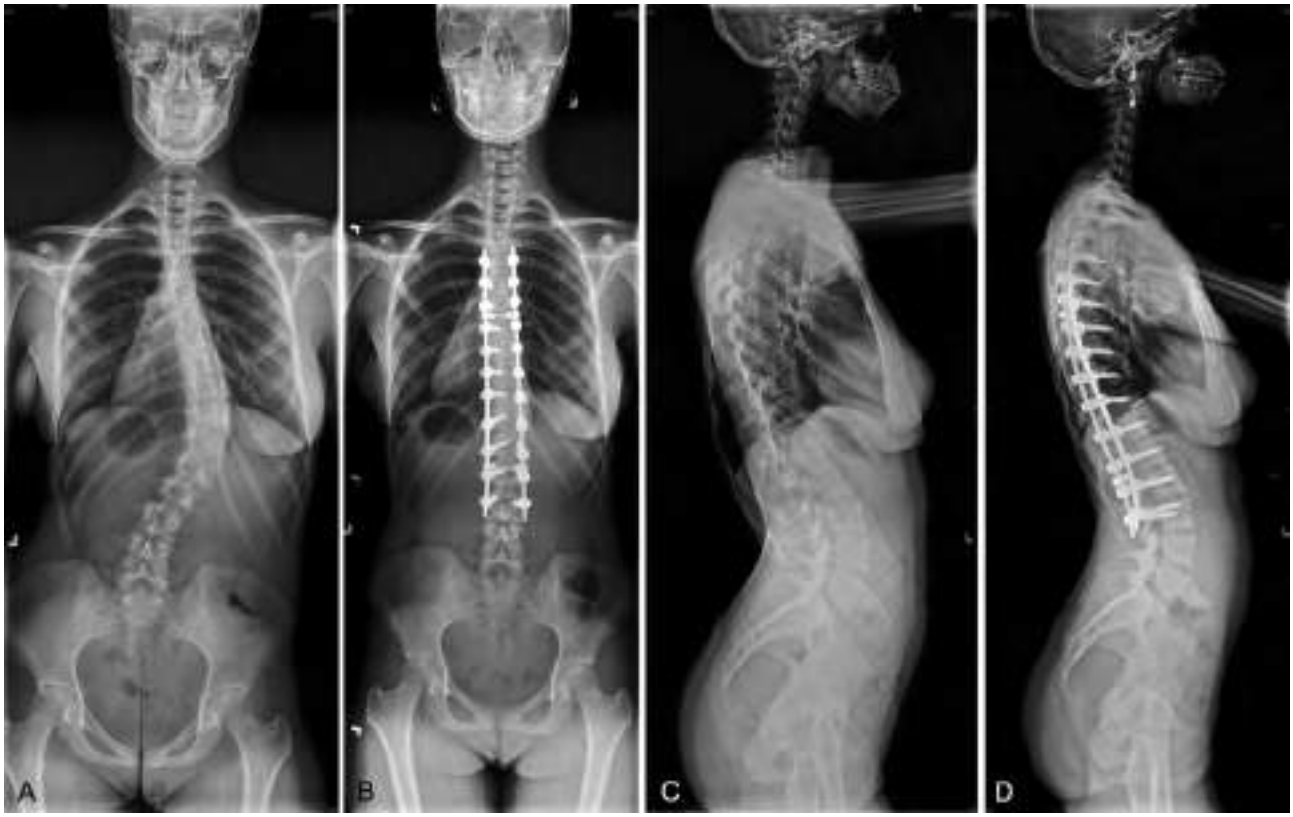

Figure 16-26 Preoperative (**A**) and postoperative (**B**) posteroanterior and preoperative (**C**) and postoperative (**D**) lateral radiographs of adolescent idiopathic scoliosis demonstrating significant correction of spinal deformity after spinal instrumentation and fusion.

lateral processes of the levels to be included in the fusion. Intraoperative x-ray film or fluoroscopy is used to positively identify the correct levels. The spinous processes generally are removed, the facet joint cartilage and capsule are excised, and decortication of the lateral processes and facet joints is performed to prepare the bed for later bone grafting.

Modern segmental instrumentation systems allow for multiple points of fixation along the spine. This enhances the procedure by adding stability to the construct, allowing for correction of deformity, improving fusion rates, and preserving normal sagittal plane alignment. Flat-back syndrome was common after nonsegmental Harrington rod fixation. Segmental fixation can be achieved using a number of techniques or combinations of techniques, including sublaminar wires or cables, hooks, and pedicle screws (Figures 16-27 to 16-29). These are affixed to rods, which are bent to accommodate the normal anatomy while providing correction of the existing deformity.

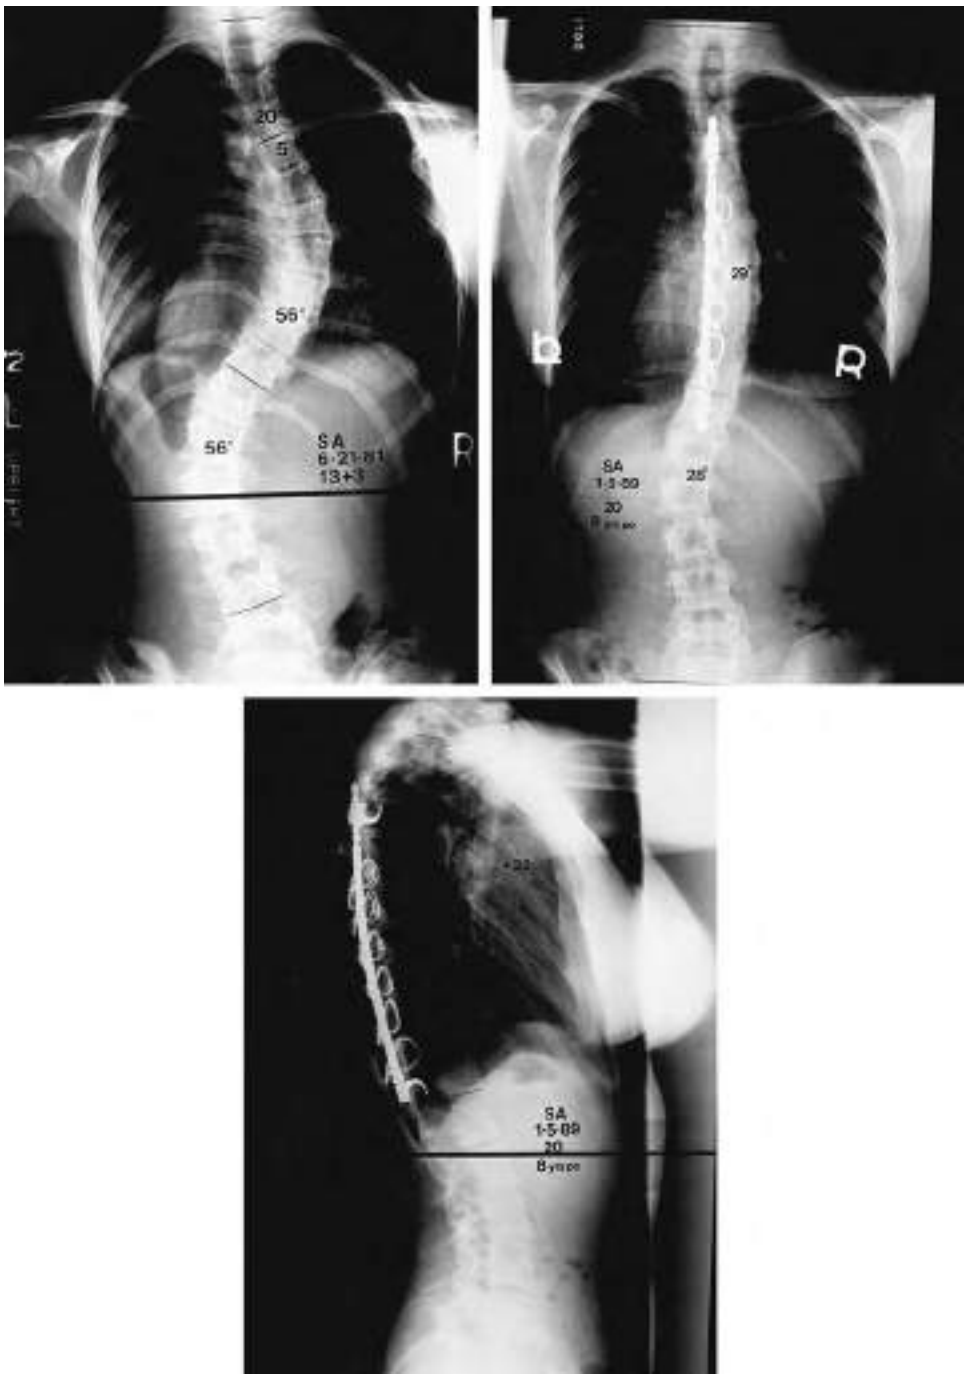

Figure 16-27 Preoperative x-ray films showing 56° curves in a 13-year-old girl with idiopathic adolescent scoliosis. She was treated with posterior fusion using the Harri-Luque technique (i.e., segmental fixation was obtained with sublaminar wires). The curves were corrected to 29° and 28°. (From Herkowitz HN, Garfin SR, Balderson RA et al, editors: *Rothman-Simeone: The spine,* ed 4, Philadelphia, 1999, WB Saunders, p 361.)

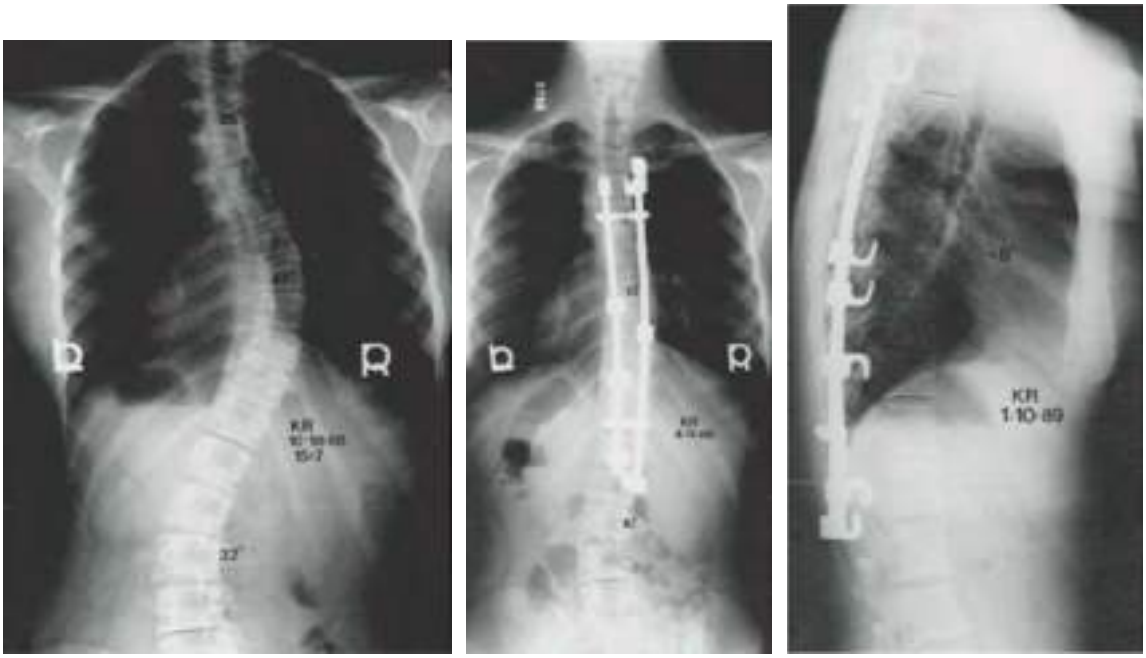

Figure 16-28 A 14-year-old with a 47° right thoracic curve. The condition was treated with posterior fusion from T4 to L1 using C-D instrumentation (hooks and rod construct). (From Herkowitz HN, Garfin SR, Balderson RA et al, editors: *Rothman-Simeone: The spine,* ed 4, Philadelphia, 1999, Saunders.)

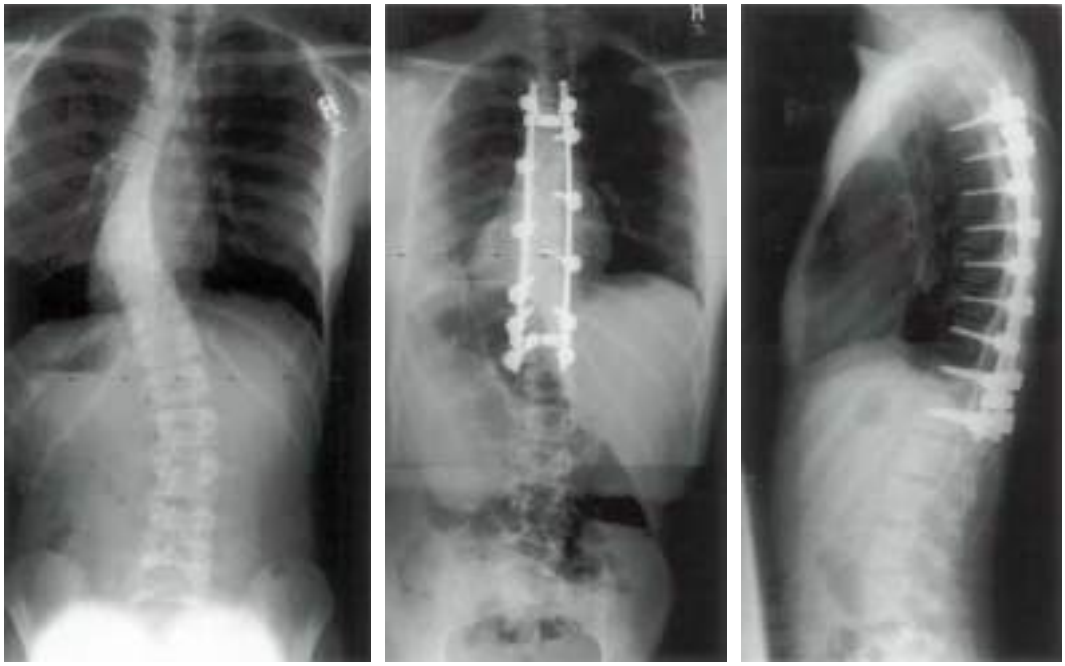

Figure 16-29 X-ray films of a 12-year-old girl with a left thoracic curve associated with a complex cervicothoracic syrinx. The syrinx was treated, and the patient underwent T4-T12 posterior fusion with pedicle screw fixation. Postoperative x-rays show near-complete correction of the curve. (From Benzel EC, editor: *Spine surgery: techniques, complication avoidance, and management,* ed 3, Philadelphia, 2012, Saunders.)

In adults, deformities associated with degenerative changes present added difficulty. These curves are stiff and cannot be passively corrected. Circumferential interbody techniques may be used to aid correction of the deformity and increase the fusion area. Osteotomies sometimes are needed in more severe cases to restore spinal alignment and balance (Figure 16-30). Decompressive surgery also is often required to relieve impingement of the cord or nerve roots.

After instrumentation, the posterolateral gutters are packed with autogenous cancellous bone graft. The wound is closed in layers. The rigidity of modern

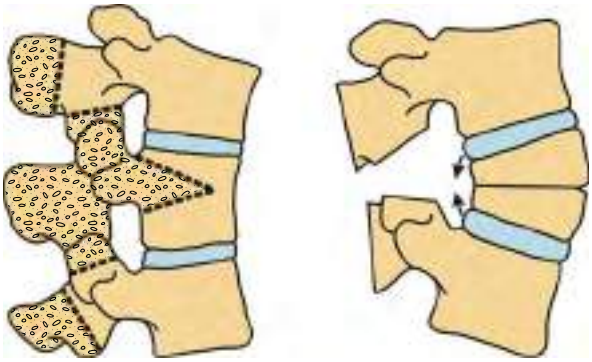

Figure 16-30 Schematic showing operative technique of lumbar pedicle subtraction osteotomy in the correction of lumbar kyphosis and sagittal imbalance (*stippled area removed*). (Modified from Benzel EC: *Spine surgery: techniques, complication avoidance and management*, ed 3, Philadelphia, 2012, Saunders.)

instrumentation reduces the need for postoperative bracing or casting. Patients may be mobilized early, and light activity advanced as pain permits.

Anterior Arthrodesis

For some thoracic and thoracolumbar curves, anterior instrumentation and fusion are preferred. The anterior approach has several potential advantages.[79] The crankshaft phenomenon, which may occur with continued growth after posterior arthrodesis, is essentially eliminated by anterior fusion. The hardware is anterior to the axis of rotation, making anterior fusion kyphogenic; this is helpful in AIS when hypokyphosis of the thoracic spine is present (although this can be a problem in the lumbar and thoracolumbar regions, where kyphosis is detrimental, or in the treatment of kyphotic deformities). In addition, anterior instrumentation in thoracolumbar curves allows correction while preserving additional lumbar motion segments.

The patient is placed in the lateral decubitus position, and the spine is approached from the side of the curve's convexity. Depending on the levels to be included, a thoracotomy, retroperitoneal approach, or combination of the two with detachment of the diaphragm is needed for adequate exposure. Thorascopic techniques have also been described, which have the potential to reduce the morbidity of the open exposures. The segmental vessels are ligated, and the psoas muscle is mobilized. The discs are excised, and the end plates are removed to expose bleeding surfaces for fusion. Screws are placed in the lateral aspect of the vertebral body and are measured to achieve bicortical fixation. A rod is placed into the screw heads, and correction is performed, converting scoliosis to lordosis (Figure 16-31). The disc spaces are packed with cancellous bone graft (usually from the rib, harvested during the exposure); vertebral compression and tightening of the screws follow, and the wound is closed. A chest tube and nasogastric tube are used postoperatively.

With adult deformity, an anterior approach often is combined with a posterior approach (described in the section on ALIF). This allows more complete excision of the disc, which improves the fusion area and allows oversized grafts to be placed to correct lumbar kyphosis.

Rehabilitation Considerations

Surgery to correct a spinal deformity often requires extensive exposures and operative times, with correspondingly longer periods of rehabilitation. It is important to begin

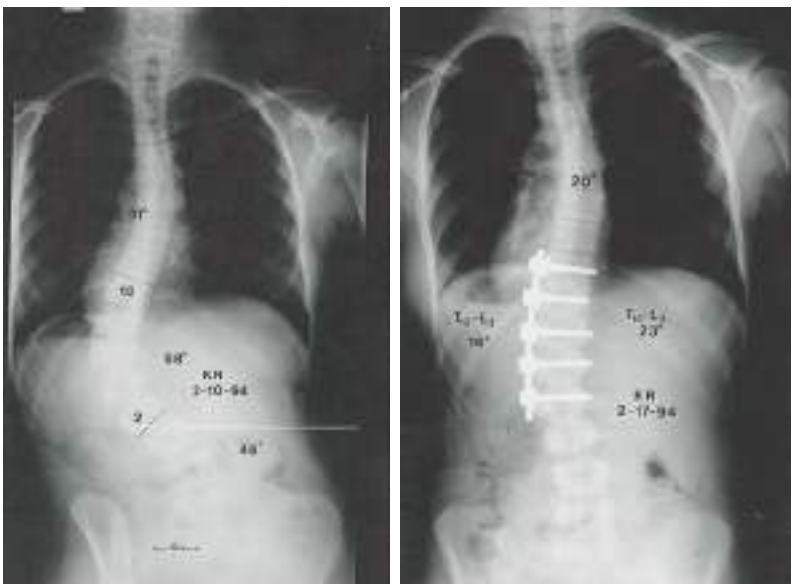

Figure 16-31 Adolescent girl with a progressive, 68° thoracolumbar curve that was treated with anterior instrumentation and fusion from T10 to L2. A standing postoperative x-ray film shows correction of the primary curve to 23°, with preservation of most of the lumbar segments. (From Herkowitz HN, Garfin SR, Balderson RA et al, editors: *Rothman-Simeone: The spine*, ed 4, Philadelphia, 1999, Saunders.)

TABLE **16-5**

Rehabilitation Considerations After Surgery for Spinal Deformity

Expected Hospital Course	Outpatient Course	Red Flags
• Length of stay: 4-7 days • Nasogastric tube (for anterior approach) • Ambulation when able to be out of bed • Bracing: may or may not be used after chest tube is removed (surgeon's preference, 2-12 weeks)	• Aerobic conditioning, upper extremity/lower extremity stretching/strengthening • Active spinal range of motion (ROM)/ strengthening • No passive ROM for 3 months (at affected levels) • May shower when wound is healed • Brace off for shower, activities of daily living • No heavy lifting/exercise for 3 months	• Change in neurological examination findings or symptoms • Worsening pain • Worsening deformity • Hardware prominence • Bowel/bladder changes • Erythema/fever/wound drainage

ambulation as soon as it is medically tolerated to minimize deconditioning and complications from prolonged bed rest. Chest tubes, nasogastric tubes, Foley catheters, and central lines are removed as early as possible to facilitate this. Table 16-5 outlines the expected postoperative course, as well as red flags that may signal the development of complications.

SUMMARY

Spinal disorders result from a wide array of pathological processes, but symptoms and disability generally are consequences of impingement of the neural elements and/or instability of spinal segments. The primary goals of surgery are to decompress the neural elements and stabilize unstable segments. Debate remains in many cases with regard to the approach used, the use of autograft versus allograft, and the need for and type of hardware used. New techniques, including artificial disc replacement, focus on restoring functional motion and avoiding fusion, with hopes of preserving adjacent segments. Bone graft substitutes and osteoinductive agents may also improve fusion rates and limit morbidity. Current and future studies will help guide the use of these new technologies and improve the operative care of spinal disorders.

CHAPTER 17

Highlights from an Integrated Approach to the Treatment of Pelvic Pain and Dysfunction

DIANE LEE*

INTRODUCTION

Optimal function of the pelvis is critical for the health of the musculoskeletal, urological, colorectal, sexual, and reproductive systems. Impaired pelvic function has been implicated in multiple conditions, including low back and pelvic pain, urinary impairments (retention, urgency incontinence), pelvic organ prolapse, constipation, fecal incontinence, and dyspareunia. Understanding the relationships between these systems and the consequences of impaired function of one on another is complex. Multiple health practitioners specialize in varying aspects of pelvic health, and treatment is often based on the practitioner's training and experience (e.g., manual therapy, core stability exercises, pelvic floor release and training, surgery, pessaries, injections, and/or medication). The best evidence-based treatment would consider all knowledge pertaining to pelvic health and thus require collaboration of multiple disciplines, a difficult task given the physical logistics of clinical practice. The organizers of the World Congress on Low Back and Pelvic Pain and the International Pelvic Pain Society have recognized the necessity of collaboration; both groups facilitate the exchange of knowledge between the multiple health disciplines involved in restoring pelvic health. To be fully evidence-based and informed practitioners, physical therapists can no longer work in isolation when treating patients with pelvic pain, incontinence, pelvic organ prolapse, and/or sexual dysfunction. In addition, conditions of the musculoskeletal pelvis (i.e., loss of mobility and/or control during functional tasks) should no longer be considered independent from those of the urological, reproductive, colorectal, and/or sexual systems. The evidence, particularly from studies of women and their experiences with pregnancy, suggests these conditions coexist. The body of knowledge pertaining to pelvic health is extensive and cannot be contained in one chapter. The intent of this chapter is to present an overview of specific pathologies pertaining to the various systems of the pelvis and highlight how *"The Integrated Systems Model for Disability and Pain"* (ISM) can help clinicians organize their knowledge on these topics and facilitate evidence-based (or informed) management of the often complex patient with pelvic pain and dysfunction.

PREVALENCE AND POSSIBLE CAUSES OF PELVIC PAIN AND DYSFUNCTION

Pelvic pain and dysfunction are common, particularly for parous women. Twenty percent of women experience pelvic girdle pain (PGP) during or after their pregnancy,[1–3] and 8% of these go on to have severe disability.[4–6] Forty-eight percent of primiparous women experience urinary incontinence in the last trimester of their pregnancy, and this number increases to 85% with subsequent pregnancies.[7] Five to seven years after delivery, 44.6% of women continue to have some degree of incontinence,[8] and this number increases with age, with 55% of women over the age of 65 experiencing some form of urinary incontinence. Incontinence is the second most common reason for admission into assisted living.[9] Fifty percent of parous women have some degree of symptomatic or asymptomatic loss of pelvic organ support.[10] Fifty-two percent of women surveyed for low back pain or PGP also reported some form of pelvic floor dysfunction (e.g., incontinence, sexual dysfunction, and or constipation).[11] Sixty-six percent of women with a diastasis rectus abdominis (DRA)

*The author, editors, and publisher wish to acknowledge Linda-Joy Lee for her contributions on this topic in the previous edition.

have at least one support-related (e.g., stress urinary incontinence, fecal incontinence, pelvic organ prolapse) pelvic floor dysfunction.[12]

Clearly the conditions are related and common among parous women. Why? A shared feature of all pelvic conditions is the failure to regain optimal strategies for transferring loads through the pelvis and its organs. The possible causes are multiple and include impairments of the:

1. Articular system (e.g., injury to either the sacroiliac joints [SIJs] and/or pubic symphysis [PS])
2. Neural system (e.g., pudendal nerve damage, leading to pain and/or weakness of the pelvic floor muscles [PFMs], including altered timing and recruitment [e.g., delayed, absent, excessive, sustained, asymmetric] of the deep muscles of the trunk [transversus abdominis (TrA)], PFMs, deep multifidus [dMf]) and loss of neural or dural mobility
3. Myofascial system (e.g., tearing of parts of the levator ani from the arcus tendineus fascia pelvis [anterior or posterior] or arcus tendineus levator ani [ATLA], stretching of the linea alba [LA] and rectus abdominis [i.e., DRA])
4. Visceral system (e.g., lengthening of the uterosacral and cardinal ligaments supporting the superior aspect of the vagina, altered tension in the broad and round ligaments and/or pubovesical ligaments supporting the bladder)

Systemic physiological impairments persisting from pregnancy into postpartum (e.g., endocrine, vascular, respiratory changes) can also create nonoptimal strategies for pelvic health. This list is merely suggestive because any change in the structure or function of the trunk (and anything that influences that) can promote nonoptimal recruitment strategies and impact how loads are transferred. Further impact to the structure and function of the various support mechanisms over time can potentially lead to more dysfunction.

How can a clinician organize and translate the increasing body of knowledge for best treatment of the patient with poor pelvic health? Is there enough research evidence to guide clinical practice for the complex patient who has impairments in multiple systems? Even if we understood all the research evidence, is it accurately reflected in clinical practice? What is an evidence-based practitioner?

EVIDENCE-BASED PRACTICE—WHAT IS IT?

Evidence-based practice (EBP) embraces all disciplines of health care and has become synonymous with best practice, but what does the term really mean? To some, it appears that EBP means that a clinician should only use assessment tests and treatment techniques and protocols that have been validated through the scientific process with high-ranking studies as valued by the levels of evidence.[13] In 2010 at the World Congress on Low Back and Pelvic Pain, Maurice van Tulder stated: *"We should not start using interventions until there is sufficient evidence for them."*

This is difficult to adhere to for many reasons, one being that there is not enough evidence for the wide variety of complexities met in clinical practice. Furthermore, even highly ranked evidence can conflict. For example, in a randomized controlled trial (RCT), Stuge et al.[14] found a significant decrease in pain and a 50% reduction in disability (measured by the Oswestry Low Back Pain Questionnaire) when specific stabilization exercises were prescribed for women with PGP after pregnancy. Conversely, Gutke et al.[15] found no significant change in pain and no change in disability (measured by the Oswestry Low Back Pain Questionnaire) in their subjects with PGP who were prescribed specific stabilization exercises after pregnancy. On paper, the two RCTs appear similar, but the results are dramatically different. Which evidence is the clinician to believe?

Many studies have sought to classify, or subgroup, individuals with various pain disorders (e.g., chronic, acute, peripherally versus centrally mediated) or movement behaviors[16–18] in an attempt to provide more evidence for management; however, not every patient encountered in clinical practice fits into any of the classifications proposed. Classification systems that begin with pain, or restrict assessment to a certain movement analysis, do not appear to meet the needs of every patient. In fact, treatment that relieves pain does not guarantee restoration of function and performance.[19–21] In addition, what has meaning for the patient often goes beyond pain (e.g., my right side just doesn't feel right; my hip "jams" when I lunge; I leak urine when I jump or run; I don't trust my knee to hold me when I stand on one leg). Restoring optimal strategies for health requires more than removing pain; it requires an understanding of what is necessary for function and performance and knowledge of the multiple mechanisms that can drive the nonoptimal strategy. When faced with the task of helping individual, complex patients, the research rarely fits completely.

The original definition of EBP includes more than research; consideration is also given to clinical expertise and patient-centered values and goals (Figure 17-1).[22] Sackett et al.[22] define EBP as the integration of best research evidence with clinical expertise and patient values.

Clinical Note

"External clinical evidence can inform, but can never replace individual clinical expertise, and it is this expertise that decides whether the external evidence applies to the patient at all, and if so, how it should be integrated into a clinical decision."

(Sackett et al.[22])

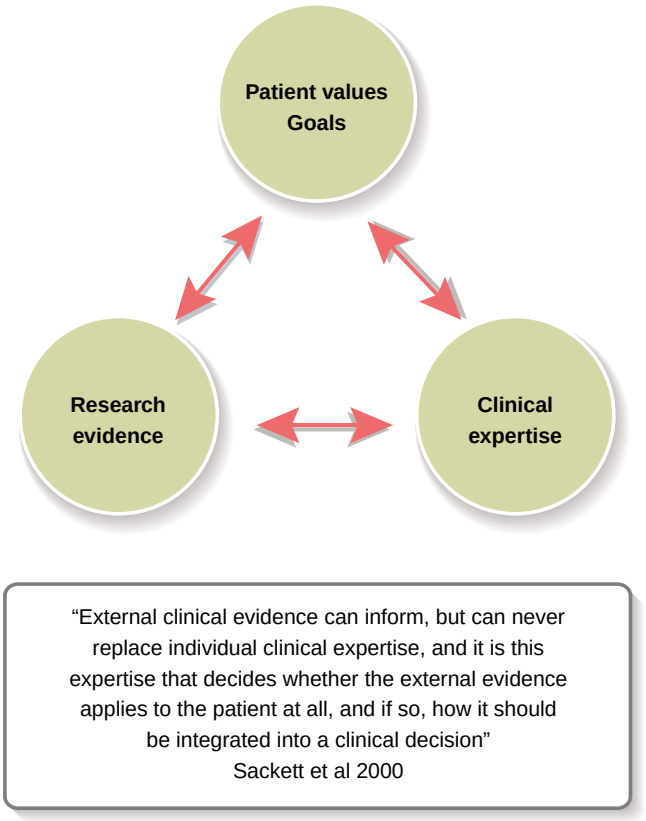

Figure 17-1 The three components of evidence-based practice as defined by Sackett et al.[22] (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

What is clinical expertise? Clinical expertise comprises both propositional (i.e., declarative) and nonpropositional (i.e., procedural, craft, and personal) knowledge[23]; in other words, knowing how and what to do and when to do it so that the right thing is done at the right time. A clinical expert is able to "find a finding" (i.e., skill acquisition) and then interpret the finding relative to the patient's values and goals (i.e., clinical reasoning) to determine how the finding can direct treatment.

In the opening keynote address of the 2012 International Federation of Orthopaedic Manipulative Physical Therapists (IFOMPT) conference in Quebec, Professor Gwen Jull said, *"The future of physiotherapy continues with an informed clinically reasoned assessment approach to direct management of the individual patient."*

The goal of this chapter is to facilitate clinical reasoning for the treatment of pelvic pain and dysfunction by exploring some of the research evidence and clinical expertise pertaining to pelvic health. Being able to organize one's knowledge (i.e., research evidence and clinical expertise) for immediate use in the clinical setting is critical for best treatment. Clinical reasoning is known to suffer when there is a lack of knowledge organization.[24] Take a moment and imagine all your knowledge pertaining to pelvic health (i.e., the musculoskeletal, urological, colorectal, sexual, and reproductive systems) organized within a framework similar to a closet for your clothing. Is your closet a disorganized collection of clothing, shoes, and accessories through which you have to dig to find the right shirt to go with the necessary shoes for the event planned? Are the right shoes missing? Or is your closet highly organized such that minimal time is spent putting together multiple options for a successful outfit? What would it take for your closet (and thus your treatment options) to be effective and efficient?

THE INTEGRATED SYSTEMS MODEL FOR DISABILITY AND PAIN (ISM): A FRAMEWORK TO ORGANIZE KNOWLEDGE

The ISM[25] is a framework (closet organizer), not a classification system, to help clinicians organize knowledge and develop clinical reasoning to facilitate wise decisions for treatment. Dr. Dan Siegel defines integration as "a process by which separate elements are linked together into a working whole. An integrated system is flexible, adaptive, coherent, energized and stable."[26] Doesn't this sound like what we are trying to achieve with our patients? What is a system? A body system, again defined by Siegel,[26] is a group of organs and/or structures with coordinated activities, achieving the same general function in the body. A system is composed of individual parts that interact with one another and share common characteristics, including structure, behavior, and interconnectivity. The Clinical Puzzle[27] (Figure 17-2) is a graphic conceptualization of the ISM and represents the person and his or her problem(s) (center of the puzzle) and the body systems that support optimal strategies for function and performance (i.e., articular, neural, myofascial, visceral [individual pieces], and physiological [center]). The outer circle of the Clinical Puzzle represents postures and movements that are essential for the patient to achieve their goals. The Clinical Puzzle is used to reflect on key findings from the assessment to clinically reason the best treatment plan.

The ISM approach is applicable to disability with or without pain (i.e., peripheral or centrally mediated) of any duration (i.e., acute or chronic) and is centered on the patient's values and goals, a key component of EBP. The assessment is meaningful to the patient's story and is not protocol-driven or based on clinical guidelines or prediction rules for regional pain. Every patient's experience and story is unique regardless of the location of his or her pain or impairment; thus no two assessments or treatment programs will be the same. This requires the clinician to have an inventory of assessment tests and to be able to clinically reason "on the fly" to choose subsequent tests that provide further information to support or negate an evolving hypothesis. For example, two women with a DRA can have a completely different exercise program yet a common goal of restoring optimal function of the abdominal wall. One may have a dominant internal

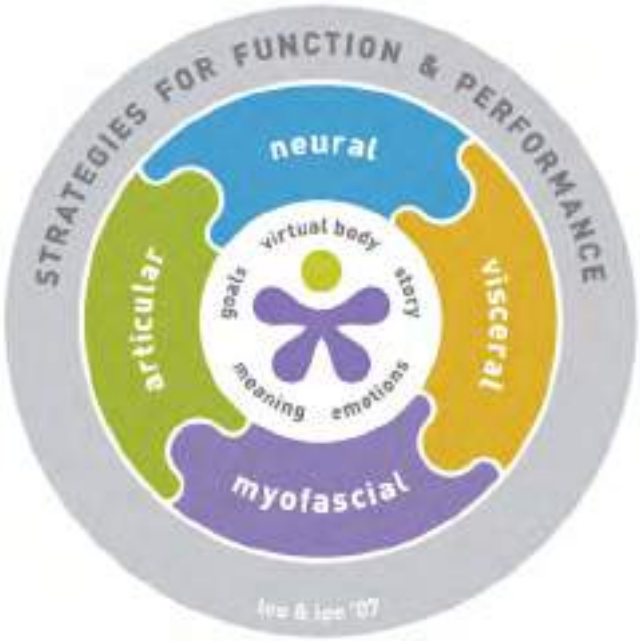

Figure 17-2 The Clinical Puzzle from The ISM.[25] The *Clinical Puzzle* conceptualizes *The ISM*. The outer circle of the puzzle represents the strategies for function and performance that the patient currently uses for meaningful tasks. The center circle of the puzzle represents several systems that relate to the person and the sensorial (i.e., sensations, perceptions), cognitive (i.e., beliefs, attitudes, motivations), and emotional (i.e., fears, anger, anxiety) dimensions of their current experience. It also includes systemic systems (such as endocrine balance, immune function) and genetic factors. It is the place where primary symptoms, goals, and barriers to recovery are noted. The four other pieces of the puzzle represent the various systems in which impairments are assessed and noted during the clinical examination. (From Lee DG, Lee LJ, McLaughlin L: Stability, continence and breathing: the role of fascia following pregnancy and delivery, *J Bodyw Mov Ther* 12:333-348, 2008.)

oblique (IO) strategy with delayed or absent activation of TrA, whereas another may have a dominant pelvic floor and external oblique (EO) strategy and asymmetric activation of TrA. Both strategies can result in separation of the recti (i.e., the impairment being diagnosed as a DRA); however, treatment of these two individuals is quite different. What is pulling excessively on the LA can be highly variable and requires individual assessment and treatment.

A key feature of this whole body and person approach is *Finding the Primary Driver*.[25] In short, this involves understanding the relationships between and within multiple regions of the whole body and how impairments in one region can impact the other. Specific tests are used to determine sites of nonoptimal alignment, biomechanics, and control (defined as failed load transfer [FLT]) during analysis of a task that is meaningful to the patient's story or complaint (meaningful task analysis). Subsequently the timing of FLT (which site fails first, second, third, etc.), as well as the impact of providing manual and/or verbal cues to correct one site on another, is noted. Clinical reasoning of the various results determines the site of the primary driver, or the primary region of the body, that if corrected will have a significant impact on the function of the whole body/person. Sometimes two areas of the body require intervention (co-drivers), and sometimes one area requires most treatment (primary driver), whereas another requires some attention for the best outcome (secondary driver).

Further tests of specific systems (e.g., articular, neural, myofascial, visceral)[28] then determine the underlying impairment causing the nonoptimal alignment, biomechanics, and/or control of the driver(s) for the specific task being assessed. Once the impaired system has been determined, specific techniques and training for release, alignment, control, and integration into movement (including strength and conditioning) can be implemented to improve the function of the driver(s) and thus impact the function of the whole body and person.[29–31] Determining what has meaning is different for every patient. Strategies for function and performance for any task will not change unless one can help patients experience something different, hopefully better, in their bodies.

Clinical Note

Melzak[32,33] describes the gestalt of one's experience as follows:

> *"The body is felt as a unity, with different qualities at different times…. [Together all outputs] produce a continuous message that represents the whole body… felt as a whole body possessing a sense of self… as a flow of awareness."*

Melzak's body-self neuromatrix (Figure 17-3) is useful for understanding how inputs to the matrix (i.e., the whole body nervous system) from:

1. cognitions (e.g., memories of past experiences, what we focus our attention on, what has meaning, beliefs),
2. sensations (e.g., cutaneous, nociceptive, visceral, musculoskeletal), and
3. emotions (e.g., fear, hyper vigilance, anger, sadness, grief)

lead to outputs potentially producing:

1. pain,
2. involuntary and voluntary action patterns (i.e., increased neuromuscular tone in certain muscles, organs), and/or
3. activation of the stress-regulatory system (e.g., cortisol, norepinephrine and endorphin levels, dampening of the immune system).

These outputs are essentially related to the sympathetic nervous system's flight, fight, or freeze response to threat. No two individuals will have the same experience or behavior in response to threat (real or imagined) because how they manifest their pain or illness is shaped in part by who they are,[24] what they think, and how they feel. Understanding the person with poor pelvic health begins by hearing his or her story and experiences (in all three dimensions—cognitive, sensorial, emotional) and learning what has meaning for him or her. Table 17-1 outlines the three dimensions of the person's experience that should be determined from his or her story.

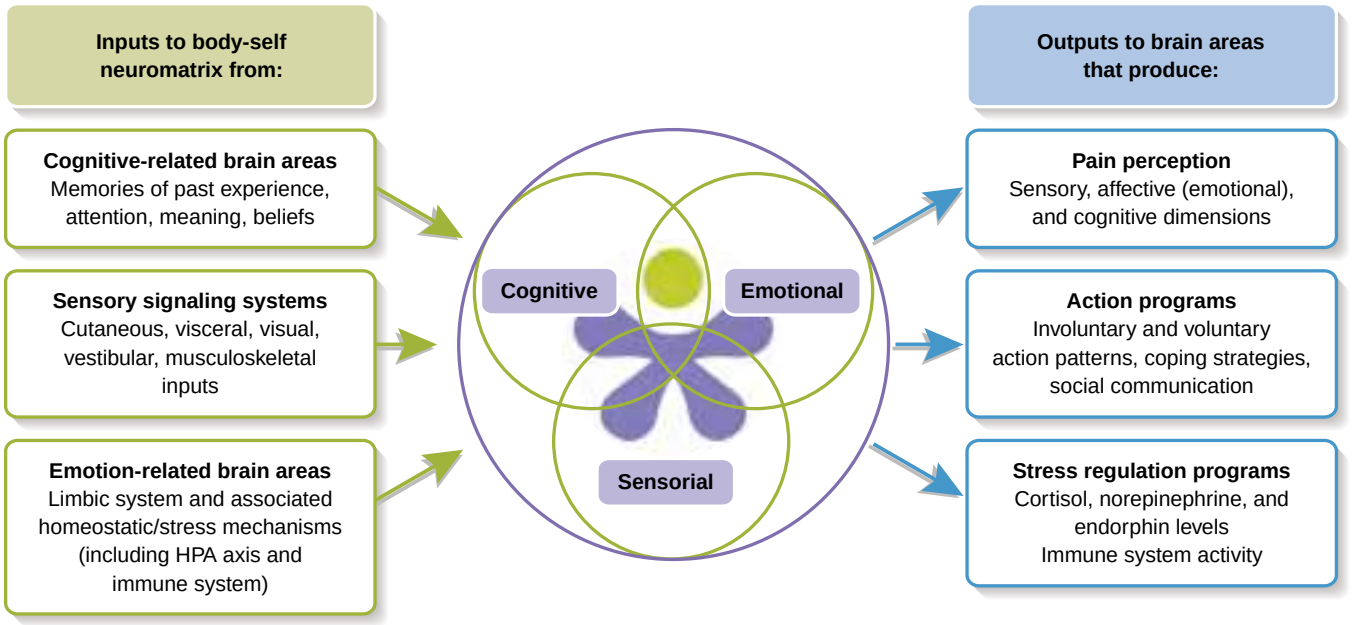

Figure 17-3 Melzak's body-self matrix[33] provides a framework for understanding the possible cognitive, emotional, and sensorial inputs to the embodied nervous system and how these inputs can collectively impact perceptions of pain, activate action programs (e.g., flight, flight, freeze), change social behavior, suppress the immune system, and stimulate stress responses. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

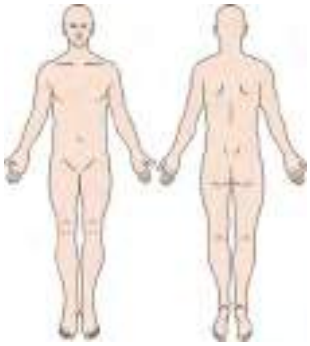
Key features from the patient's story are noted in the center of the Clinical Puzzle, including:

1. The patient's meaningful complaint—the primary symptom (i.e., thought, emotion, feeling) that has brought him or her for treatment.
2. The patient's meaningful task and goals—the aggravating posture or movement (e.g., "I have pelvic girdle pain when I run"), tasks which are difficult to perform (or avoided) and relate to their performance goals (e.g., "My hip 'jams' or 'doesn't feel right' when I do a lunge to the left and this is impacting many poses in my Yoga practice"), or tasks that create respiratory or urogynecological symptoms (e.g., "I get short of breath in spin class; I leak urine when I jump; I find sexual intercourse painful").
3. Any potential cognitive or emotional barriers to recovery or significant medical considerations.

Tasks for screening are then chosen based on the meaningful task and these are charted on the outer circle of the Clinical Puzzle. For example, if the meaningful complaint is PGP aggravated by sitting, then three useful screening tasks that are components of this meaningful task would be:

1. Standing posture (i.e., the position from which the task begins)
2. Squat
3. Sitting posture

Regional areas of the whole body are then assessed in each of the screening tasks to determine if the strategy is optimal or nonoptimal. An optimal strategy for any task will:



1. Have optimal alignment, biomechanics, and control
2. Distribute and balance pressure in all three canisters (cranium, thorax, abdomen)
3. Allow optimal respiration
4. Have sufficient mobility to accommodate perturbations to the system (breath, movement).

Optimal strategies look and feel good! Optimal strategies for the transference of load through the pelvis will support musculoskeletal, respiratory, urological, colorectal, sexual, and reproductive health. Nonoptimal strategies produce sites that fail to transfer load, and they often demonstrate poor alignment, biomechanics, and/or control or are associated with excessive increases in pressure, poor breathing patterns (e.g., breath holding), or rigidity inappropriate for the task. Nonoptimal strategies simply do not look good nor do they feel good.

If possible, the timing of FLT between the various sites is considered to determine which body region (e.g., foot, pelvis, thoracic ring, hip) fails first, second, or third (Figure 17-4). Then the clinician provides specific manual and verbal cues or corrections to one or more sites of FLT to determine which correction has the most positive impact (i.e., improvement in range of motion, decrease in effort, reduction in symptoms) on the screening task (#1, 2, 3 as previously indicated). The pelvis is corrected or controlled by manually restoring neutral alignment (if possible), centering the pelvic mass over the base of support (i.e., the feet), and then providing gentle compression. The patient then repeats the screening task to assess the impact of this correction on his or her ability to maintain optimal alignment of the thorax and move the hips. The thorax is corrected or controlled (being thoracic ring specific—see Chapter 11), and the task is repeated to assess any change in the patient's ability to stabilize the pelvic joints and move the hips. An enquiry is made as

TABLE **17-1**

Assessing the "Person"

Dimension	Description
Sensorial dimension of patient's experiences 	Where is their meaningful complaint (e.g., pain, burning, tingling, numbness) located in their body and what is its behavior (i.e., aggravating and relieving features)? Try to determine the autobiographical details (i.e., what happened when) of the sensations and make a determination if the symptoms are now peripherally or centrally mediated.
Cognitive dimension of patient's experiences 	A simple question such as "What do you think is going on?" can provide much information as to the patient's cognitive beliefs pertaining to their experience. Listen carefully as this is often when "flags" appear in the story that can be the primary driver, or barrier, to physical interventions. Education plays a large role here to retrain negative thoughts (or inaccurate thoughts) that can contribute to nonoptimal movement and postural behavior.
Emotional dimension of patient's experiences 	This is usually communicated both verbally and nonverbally. Watch for emotional posturing (defensive angry posturing is militant like whereas depressive giving-up posturing is collapsed) and behaviors that appear inconsistent with other features of the story. Not being able to answer the question asked, but only providing answers pertaining to how much pain he or she is in is another clue that the amygdala has this person "hi-jacked." Remember that individuals with poor pelvic health may have seen many professionals and be quite confused and frustrated. This is not an emotional barrier; this is the patient's reality.

Note: Understanding the person with poor pelvic health begins by hearing his or her story. The clinician needs to understand the "person behind the problem." This understanding can only be obtained by having time during the clinical sessions to truly hear the patient's story from his or her perspective.

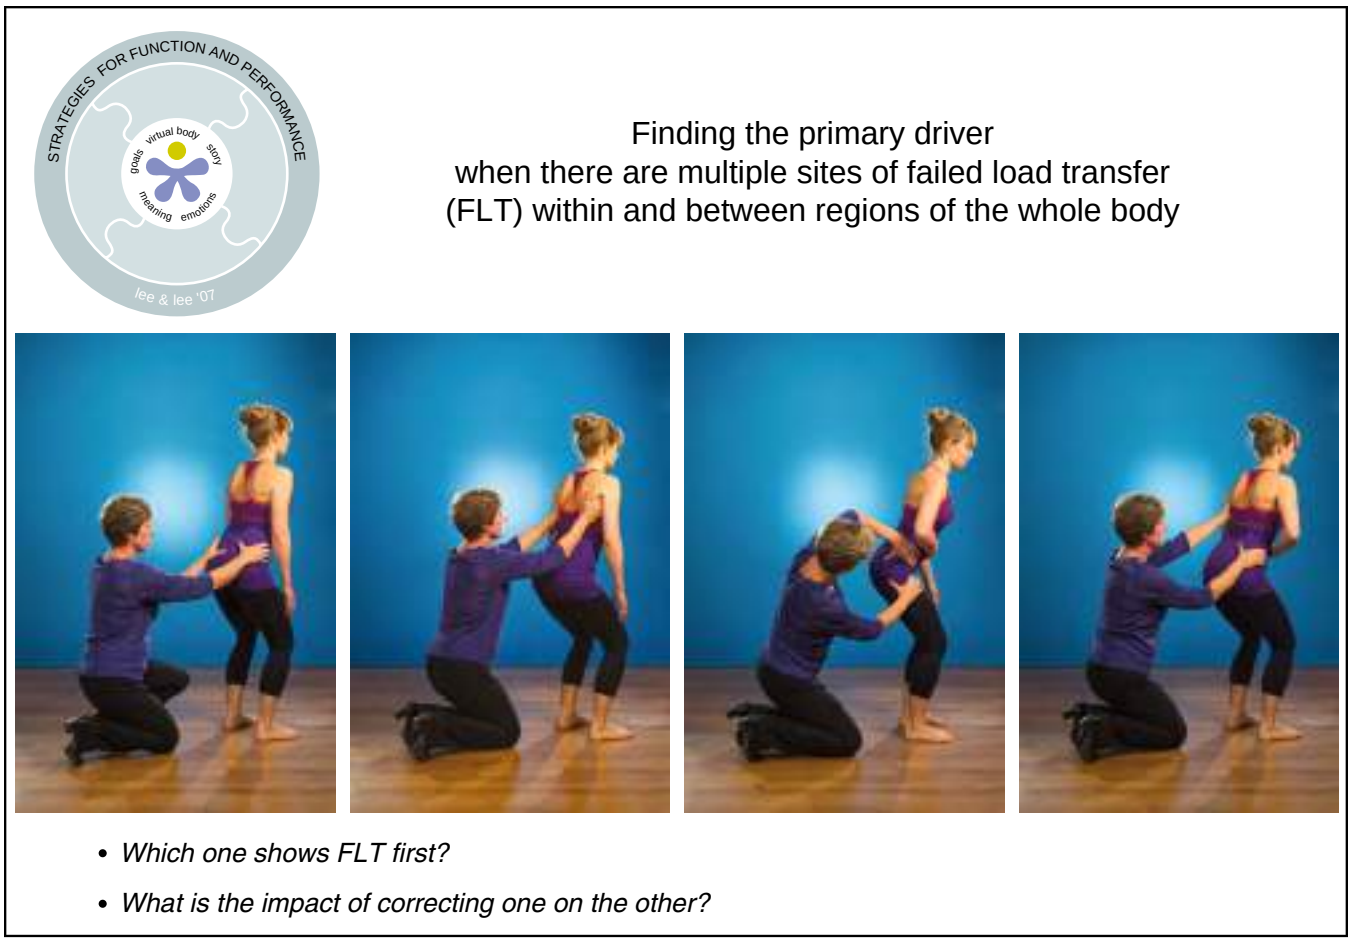


Figure 17-4 Determining the primary driver. Finding the primary driver for a squat task when the meaningful task is PGP in sitting. Regions of the body are assessed to determine if the alignment, biomechanics, and control are optimal or nonoptimal for the task. Here the clinician is monitoring from left to right the pelvis (in particular, the right SIJ), the mid thorax (in particular thoracic rings 3, 4, and 5), and the right hip joint. If two of more sites of FLT are identified, the clinician then must determine which one is the driver by noting the timing of the FLT and the impact of any correction. In the picture on the right, the clinician is assessing the timing of the FLT between an upper thoracic ring and the right SIJ. The site that fails first is often, but not always, the site of the primary impairment, the primary driver. To confirm this hypothesis, the clinician notes the impact of correcting the alignment, biomechanics, and control of the pelvis on the thorax and then the thorax on the pelvis. The site of correction that provides the best improvement in performance of the task determines the driver. (Copyright Diane G. Lee Physiotherapist Corp.)

to the difference in the "gestalt of the experience" when various body regions are corrected or controlled to not only confirm the hypothesis but also help the patient to become aware of the differing experiences of his or her body when sites distant from the pain are corrected or controlled. Collectively the timing and impact of various corrections on the screening determine the "driver" for that task. It is possible to have a pelvic-driven pelvis, thorax-driven pelvis, foot-driven pelvis, even a cranial-driven pelvis. Every pelvic pain patient is unique.

Once the driver is confirmed, the meaningful task is repeated to:

1. Confirm the hypothesis of the best place to begin treatment.
2. Create patient confidence and understanding as to how the regions of the body relate and why, sometimes, treatment has to begin distant from the site of their symptom(s).
3. Give the patient a different experience (gestalt) of his or her body and thus begin to change his or her "brain map" or body schema because changing a motor output begins by changing the sensory input.

The next step is to determine the specific or combination of system impairment(s) responsible for the nonoptimal strategy for the meaningful task (Table 17-2).

Clinical Note

"The advantage of a clinical reasoning approach is that it is responsive to new knowledge and evidence, is flexible and allows for change and growth"

Professor Gwen Jull at the 2012 IFOMPT conference in Quebec.

The ISM[25] is such a clinical reasoning approach. It is a framework, not a classification, that considers all three dimensions of the patient's experience and the barriers that each may present to the recovery process for both acute and persistent conditions. Most tasks

Conditions Associated with the Various Systems of the Clinical Puzzle

System	Associated Condition

	• Cognitive barriers (i.e., beliefs and memories from past experiences, thoughts "attended to")
	• Emotional barriers (i.e., anger, fear, depression)
	• Physiological and medical considerations
	  ◦ Hormone health (neuroendocrine)
	  ◦ Nutrition
	  ◦ Hydration
	  ◦ Disease (e.g., diabetes, cardiovascular)
	• Patient's values and goals (i.e., meaningful complaints and tasks)

	• Capsular sprain or tear • Ligament sprain or tear (grades I-III) • Labral or intra-articular meniscal tear • Intervertebral disc strain/tear/herniation/prolapse • Fracture • Joint fixation or dislocation • Periosteal contusion • Stress fracture • Osteitis, periostitis, apophysitis • Osteochondral and chondral fractures, minor osteochondral injury • Chondropathy (e.g., softening, fibrillation, fissuring, chondromalacia) • Synovitis • Apophysitis • Fibrosis/osteophytosis of the zygapophyseal and intervertebral joints, sacroiliac joint, hip joint

	• Intramuscular strain/tear (grades I-III)
	• Muscle contusion
	• Musculotendinous strain/tear
	• Complete or partial tendon rupture or tear
	• Fascial strain/tear
	• Tendon pathology—tendon rupture, partial tendon tears, tendinopathy (acute or chronic), paratendinopathy, pantendinopathy
	• Skin lacerations/abrasions/puncture wounds
	• Bursa—bursitis
	• Muscular or fascial scarring or adhesions
	• Loss of fascial integrity of the anterior abdominal wall including
	  ◦ Diastasis rectus abdominis
	  ◦ Sports hernia (tear of transversalis fascia)
	  ◦ Hockey hernia (tear of the external oblique)
	  ◦ Inguinal hernia
	• Loss of fascial integrity of the endopelvic fascia leading to cystocoele, enterocoele, and/or rectocoele

	• Peripheral nerve trunk or nerve injury (i.e., neuropraxia, neurotmesis, axonotemesis)
	• Central nervous system injury
	• Altered motor control
	  ◦ Absence of recruitment, inappropriate timing (early or late) of muscle recruitment,
	  ◦ Inappropriate amount (increased of decreased) of muscle activity (all relative to demands of task)
	  ◦ Overactivity or underactivity of muscles at rest
	• Altered neurodynamics
	• Sensitization of the peripheral or central nervous system
	• Altered central nervous system processing
	  ◦ Altered body schema or virtual body

Conditions Associated with the Various Systems of the Clinical Puzzle—Cont'd

System	Associated Condition
	• Inflammatory organ disease or pathology (e.g., appendicitis cystitis, acute ulcerative gastritis, pleuritis, endometriosis) • Infective disorders of the pelvic organs • Organ disease • Lack of organ mobility/motility

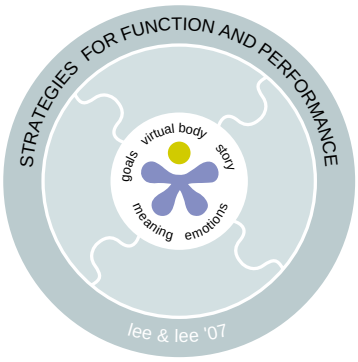
Note: Conditions can be combined; for example, it is possible to have a stiff joint and an overactive muscle further compressing the joint. The articular system impairment is not identifiable until the compression from the neural system impairment has been released.

Adapted from Lee D: *The pelvic girdle,* ed 4, Table 7-4a, Edinburgh, 2011, Elsevier.

involve the whole body; thus assessment must include analysis of the relationship between the body regions and the impact and interplay of each. It is no longer acceptable to just assess the pelvic girdle and its contents when presented with a patient with pelvic pain; the source may reside far removed from the location of the symptoms.

THE STATE OF THE EVIDENCE ON PELVIC FUNCTION AND ASSESSMENT DURING A COMMON TEST—SINGLE LEG STANDING AND CONTRALATERAL HIP FLEXION

Increasing scientific evidence and clinical expertise confirm a key role for the pelvis in lumbopelvic health, and paradigms for assessment and treatment of pelvic pain have changed considerably since 1990.[34,35] It has been argued that optimal function of the pelvis is essential for musculoskeletal, urological, colorectal, sexual, and reproductive health, and yet agreement is lacking for what optimal function of the pelvis requires. The biomechanics of the SIJs and PS are poorly understood for many of the tasks that aggravate people with PGP. Agreement is still lacking for when the SIJ should move and when it should not.



Pathology and intervention in musculoskeletal rehabilitation assumes that as clinicians we are able to reach a functional diagnosis—for this chapter a diagnosis that pertains to pelvic health. Not only is there disagreement on the biomechanics of the pelvic joints, but agreement is also lacking for best ways to evaluate the functional status of the pelvis.[34,35] The form and force closure theories proposed by Snjiders et al.[36,37] and the motor control requirements for effective load transfer through the pelvis[38–52] are well accepted, and yet the best ways to translate this knowledge into clinical practice to determine if the patient's form closure, force closure, and/or motor control mechanisms are healthy are widely debated. In addition, the best ways to restore optimal function of the pelvis are unclear (i.e., when and how should the SIJ or PS be mobilized or stabilized?). Although much evidence has been gained over the past 25 years, there is still much to do.

The intent of this chapter is to provide an overview of evidence-based (or informed) treatment for poor pelvic health and the clinical reasoning that supports treatment decisions. However, clinicians are a long way from agreeing on how to assess and determine the specific impairments of the pelvis, and this first needs to be acknowledged and discussed.

Standing on one leg and flexing the contralateral hip, a task known as the one leg standing (OLS), stork, Gillet, or kinetic test, is often used by clinicians and researchers to evaluate mobility and control of the pelvic joints (Figure 17-5). When a patient's meaningful task requires single leg loading (e.g., walking, running, climbing stairs, Vrksasana or tree pose in yoga), this is an appropriate screening task to assess. To interpret the findings, it is necessary to understand an optimal response—in other words, what should happen within the pelvis and between the pelvis and the hip, knee, and foot as well as between the pelvis and thorax, neck, and cranium when standing on one leg and flexing the contralateral hip. At this time, there are no studies that have considered the entire body when doing this task. A few studies have investigated the biomechanics of the pelvic girdle (mainly the osteokinematics) and the muscle recruitment strategies in subjects with and without pain during single leg standing with contralateral hip flexion.

Jacob and Kissling[53] determined that 0.4° to 4.3° of rotation (innominate relative to the sacrum) is possible in the non–weight-bearing SIJ in healthy, pain-free subjects between the ages of 20 and 50 years. Sturesson and coworkers[54–56] found no statistical differences in the available range of SIJ motion in subjects with PGP and impairment during single leg standing. These findings suggest that although mobility may vary between subjects, PGP is not predictive of more or less motion at the SIJ.

Hungerford et al.[57] found that the amplitude of SIJ motion was symmetric in healthy, pain-free subjects and asymmetric in those with PGP. However, Dreyfuss et al.[58] found that 20% of healthy, pain-free subjects had movement asymmetries of the SIJ, and again there appears to

Active Mobility Test for the Sacroiliac Joint

- *The innominate should posteriorly rotate relative to the ipsilateral sacrum during single leg standing with contralateral hip flexion*
- *The movement should be symmetric between sides*

Figure 17-5 Single leg standing with contralateral hip flexion. During this task, the non–weight-bearing innominate on the side of hip flexion should posteriorly rotate relative to the ipsilateral sacrum.[57] The amplitude of motion should be symmetric between the left and right sides. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

be no correlation between PGP and asymmetric SIJ motion. So the question remains as to when noted movement asymmetries of the SIJ are relevant to the clinical picture.

Asymmetric motion of the SIJs during single leg standing is a sign of FLT (i.e., nonoptimal alignment and biomechanics) and is a key feature of the ISM approach and requires that clinicians can reliably perceive these differences because one cannot interpret a finding one cannot find (Figure 17-6). Unfortunately, intertester reliability is lacking for SIJ mobility analysis during this test (Table 17-3).[58–62] Following a systematic review of commonly used mobility tests for the SIJ, Van der Wurff et al.[63] concluded: *"…at this time, it is questionable whether any SIJ tests are of any value for clinical [and that]… there are no indications that 'upgrading' of the methodological quality would have improved the final conclusions."*

Sturesson et al. felt that their studies[55,56] supported their position that movement of the SIJ in weight bearing was too small for clinicians to feel. Vleeming et al.[34] go further and state, *"Assumed SIJ motion during this test does not occur. The authors conclude that movement of the external pelvis relative to the hips gives the (manual) illusion that the SIJ are repositioned."* Vleeming believes clinicians were feeling an illusion of intrapelvic motion.[34,64] Most clinicians who use this test in clinical practice share the opinion that they can feel motion at the SIJ (i.e., intrapelvic motion differentiated from motion of the pelvic girdle on the femur at the hip joint) during single OLS on the non–weight-bearing side. Are clinicians being deluded by this illusion? Is the research evidence superior to clinical expertise with this test? Are clinicians being illuded by their senses and deluded by their beliefs? When the methods of the intertester reliability studies are considered, several questions arise. How did the testers perceive the information? Visually (i.e., watching the posterior superior iliac spine [PSIS] move relative to the sacrum), kinesthetically (i.e., feeling the PSIS move relative to the sacrum), or visually and kinesthetically or does this matter? Some clinicians appear to have better visual accuracy than kinesthetic, others have better

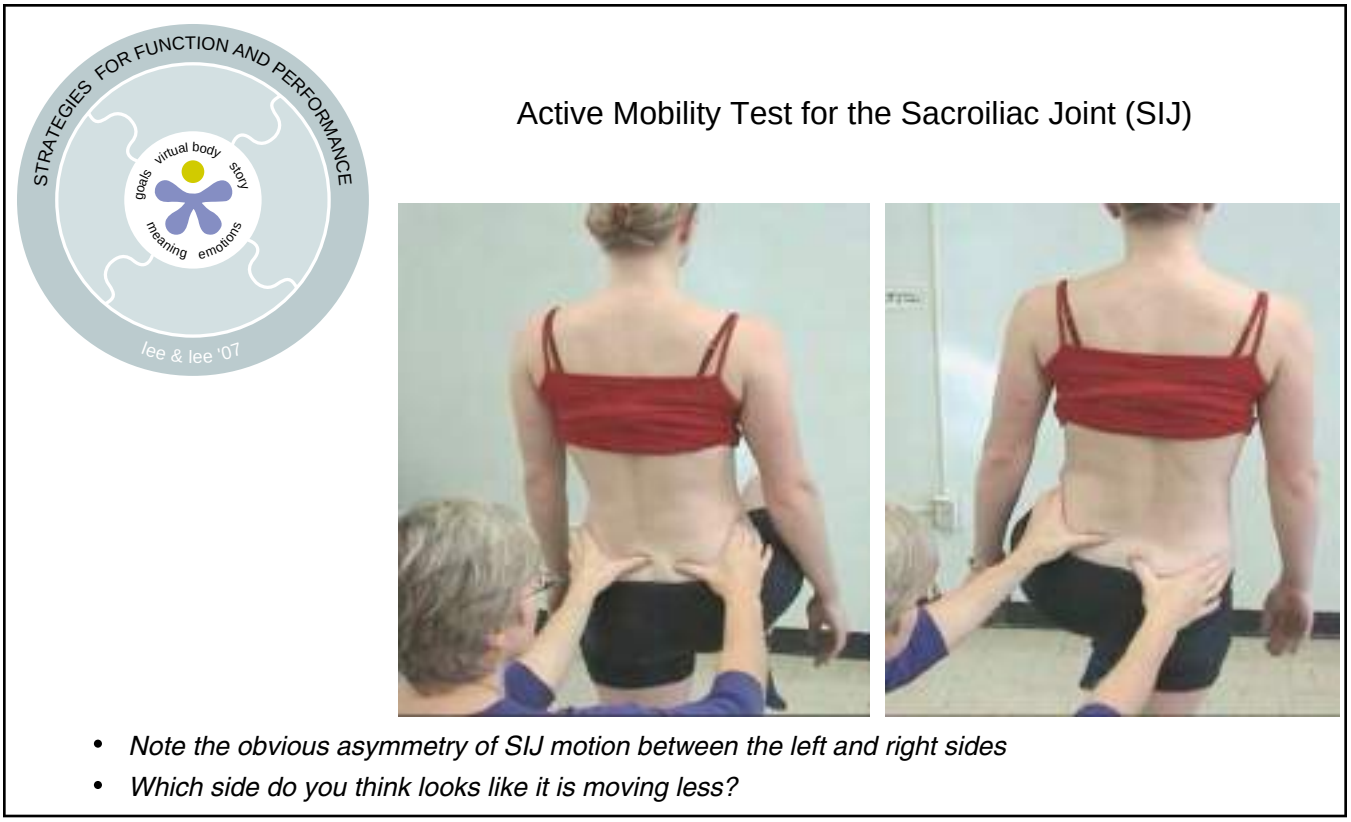


Figure 17-6 Single leg standing with contralateral hip flexion. When SIJ motion is reduced (for many different reasons) the amplitude of innominate motion relative to the sacrum is asymmetric and the pelvic girdle often compensates by tilting on the contralateral hip (i.e., extrinsic pelvic motion). This asymmetry can be seen and felt by trained clinicians. (Copyright Diane G. Lee Physiotherapist Corp.)

TABLE **17-3**

Reliability of Commonly Used Tests for Mobility of the Sacroiliac Joint

Study	Palpation Points	Tactile versus Visual	Finding
Dreyfuss et al. 1994[58]	S2 and inferior PSIS	No comment on tactile vs. visual	Unreliable
Potter and Rothstein 1985[59]	S2 and inferior PSIS	No comment on tactile vs. visual	Unreliable
Carmichael 1987[60]	Several palpation points	Both visual and tactile	Unreliable
Herzog et al. 1989[61]	S2 and inferior PSIS	No comment on tactile vs. visual	Reliable
Meijne et al. 1999[62]	Several palpation points	Both visual and tactile	Unreliable
van der Wurff et al. 2000[63]			Systematic review of all mobility and pain provocation tests of the sacroiliac joint confirm lack of reliability and validity of all mobility tests

Note: On closer investigation of the methods, much information is missing that could directly influence the results of these trials.
PSIS, Posterior superior iliac spine.

kinesthetic sense, and a few are good at both. When the clinician is instructed to rely on their predetermined best sense (i.e., visual or kinesthetic), their intertester reliability appears to improve when tested informally during course instruction. Multiple mechanisms may drive this difference; however, those who are less reliable when using vision often have unilateral mobility restrictions of their upper neck. Were the testers in the reliability studies (see Table 17-3) screened for asymmetric mobility of their upper neck? How much compression was applied to

the pelvis during the testing? The SIJ is easily influenced by the smallest amounts of compression,[65–69] which could be another confounding variable. There is no mention of compression control in any of the methods in the reliability studies reviewed.

Clinical Note

- Illusion: "A distortion of the senses, revealing how the brain normally organizes and interprets sensory stimulation. While illusions distort reality, they are generally shared by most people." (as defined by Wikipedia)
- Delusion: "A belief held with strong conviction despite superior evidence to the contrary." (as defined by Wikipedia)

Hungerford et al.[57] also investigated control of SIJ motion on the weight-bearing side during single leg standing (Figure 17-7). The innominate remained posteriorly rotated relative to the sacrum in the pain-free subjects, whereas in the PGP population, the innominate rotated anteriorly relative to the sacrum—a movement that clinicians have found to be able to reliably palpate.[70] This research suggests that when assessing control of the SIJ, anterior rotation of the innominate relative to the sacrum should be noted because this is a sign of FLT when the pelvis is loaded.

Standing on one leg is a whole body task and a key component of many more complex functional tasks. Although the pelvis plays an essential role in standing on one leg, the task requires more than optimal function of the pelvis. When the pelvis fails to transfer load optimally (i.e., loses control or fails to move when it should), it is important to consider the impact of the rest of the body on the pelvis and not just assume that the primary problem is within the pelvis (Figure 17-8).

Figure 17-7 Single leg standing with contralateral hip flexion. During this task, the weight-bearing innominate should remain posteriorly rotated relative to the ipsilateral sacrum. This is the close-packed, self-braced position for the SIJ. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

Finding the Primary Driver for a Single Leg Standing Task with Contralateral Hip Flexion

Multiple studies on subjects with low back and pelvic pain suggest that motor control changes in the trunk are variable, individual, and task specific. Some muscles are compromised (i.e., timing of activation is delayed or absent), whereas others are augmented (i.e., early and increased activation). The common link between tasks and individuals is that the strategy chosen is nonoptimal and there are often multiple sites of FLT; so when are the asymmetries of active mobility of the SIJs noted during single leg standing and contralateral hip flexion relevant to the clinical picture? Loss of intrapelvic control during loading is always relevant and movement asymmetry is relevant when it presents during a task that requires movement, regardless of the location of symptoms.

The following two brief case reports demonstrate the relationship between the thorax and pelvis during single leg standing and contralateral hip flexion. They will highlight how the primary driver was determined to be the seventh thoracic ring in the first case and the pelvis in the second case, even though their meaningful complaint and task were similar in both cases (i.e., chronic right posterior PGP aggravated by running or walking).

Case Report 1—Thorax-Driven Pelvic Pain and Impairment

A female triathlete presented with a primary complaint of chronic right PGP (meaningful complaint), aggravated by running (meaningful task). The single leg standing task was used to screen intrapelvic mobility and control in that it pertained to her meaningful task. During left single leg standing with right hip flexion (Figure 17-9, *A*), her pelvis laterally tilted (abducted) at the left hip (extrinsic pelvic motion) and minimal motion of the right SIJ (intrapelvic motion) occurred compared with the left SIJ during right single leg standing with left hip flexion (Figure 17-9, *C*). In other words, there was an asymmetric intrapelvic motion noted on active mobility testing. The right SIJ was not moving when it should and therefore was noted as a site of FLT (first site of FLT noted). In addition, her seventh thoracic ring translated to the left and rotated to the right during the OLS test. Although these are optimal biomechanics for rotation of a thoracic ring,[75] rotation should not occur during this specific task, and therefore this is considered a second site of FLT in this case. Increased tone in a specific fascicle of the right iliocostalis extending

Figure 17-8 Standing on one leg and flexing the opposite hip is a whole body task and consideration must be given to how the rest of the body is influencing pelvic alignment, biomechanics, and control. The primary driver for this task can be anywhere from the cranium to the foot. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

from the iliac crest to the right seventh rib was palpable (Figure 17-9, *B*).

During right single leg standing, the right, weight-bearing SIJ lost control (i.e., loss of intrapelvic control with the right innominate anteriorly rotated relative to the sacrum) (Figure 17-10). The right SIJ had already been identified as a site of FLT (i.e., asymmetric intrapelvic motion); however, this additional finding (i.e., loss of control) ruled out a diagnosis of a stiff, fibrotic or fixated SIJ, which would not lose control. The patient's seventh thoracic ring continued to translate to the left and rotate to the right and persistent increased tone was noted again in the right iliocostalis.

There were two sites of FLT for both of these tasks, the seventh thoracic ring and right SIJ. To determine the primary driver (i.e., best region to begin to treat), the timing of FLT was noted during both tasks. The seventh thoracic ring was translated laterally to the left and rotated to the right before initiation of weight transfer, and this translation and rotation increased before the right SIJ failed to move during left single leg standing and before the right SIJ lost control during right single leg standing. This suggests that the seventh thoracic ring was the primary driver, given that it failed before the SIJ during the task. Confirmation of this hypothesis required consideration of the impact of a correction of the pelvis on the seventh thoracic ring alignment, biomechanics, and control and then the impact of a pelvic ring correction on the seventh thoracic ring alignment, biomechanics, and control during both tasks. Correcting the seventh thoracic ring alignment and control[76] restored the mobility of the right SIJ during left single leg standing and control of

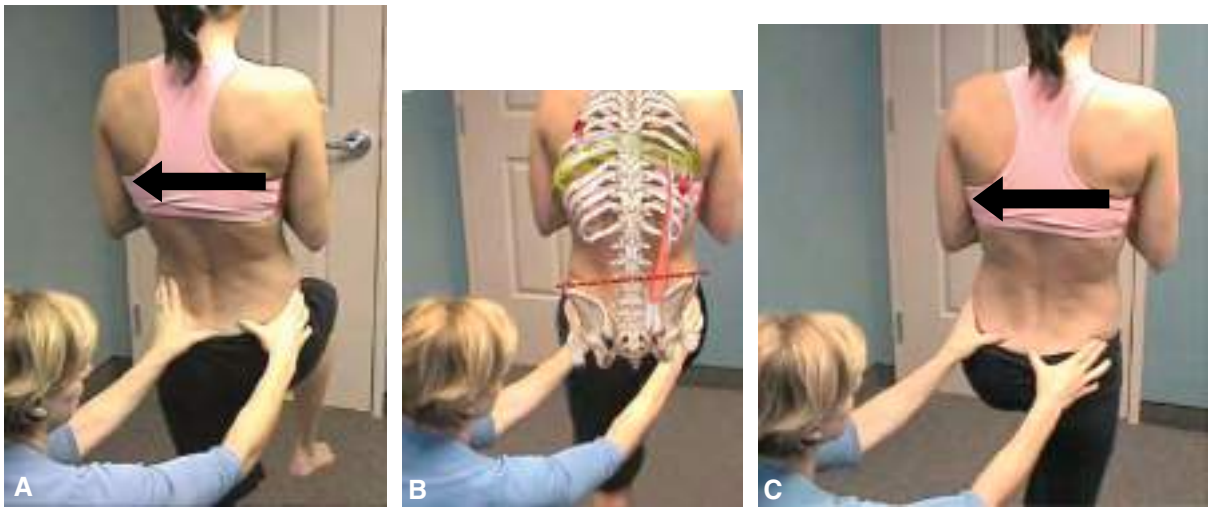

Figure 17-9 **A,** During this left single leg loading task, note that the pelvis has laterally tilted relative to the left femur (i.e., abducted at the left hip joint) and the thorax (in particular the seventh thoracic ring) has translated to the left and rotated to the right, both signs of FLT (i.e., nonoptimal alignment, biomechanics, and control) for this task. **B,** Increased activation of a specific fascicle of the right iliocostalis muscle (which arises from the right iliac crest and inserts into the posterior aspect of the right seventh rib) can create a vector of force that both destabilizes the right SIJ (causing the innominate to anteriorly rotate relative to the sacrum) and causes the seventh thoracic ring to translate to the left/rotate to the right. **C,** Note the difference in both the pelvic position relative to the femur and the position of the thorax relative to the pelvis in this right single leg standing task. Although not as easily seen, the seventh thoracic ring remained relatively left translated and right rotated during this task as well. (Copyright Diane G. Lee Physiotherapist Corp.)

Figure 17-10 The right SIJ and the seventh thoracic ring also failed to transfer load effectively in the right single leg loading task. Which is the driver for this task—the seventh thoracic ring or the pelvis? What are the next tests the clinician would choose to determine treatment? (Copyright Diane G. Lee Physiotherapist Corp.)

the right SIJ during right single leg standing. Correcting the pelvis (i.e., alignment and control) had no impact on the seventh thoracic ring, which remained left translated and right rotated during the task. Therefore, the seventh thoracic ring was considered to be the driver as it gave the best overall body response when corrected for this task.

Specific system tests (articular, neural, myofascial, and visceral) pertaining to the seventh thoracic ring confirmed that the specific hypertonic fascicle noted in the right iliocostalis lumborum pars thoracic (ILPT) was, in part, responsible for the nonoptimal alignment and biomechanics of both the seventh thoracic ring and the pelvic ring. This muscle was one of several trunk muscle dyssynergies. Because much of the neural drive for the abdominal wall and low back musculature comes from the lower thorax, it is plausible that low thoracic ring impairments could lead to some muscles being compromised and others augmented, as the evidence has clearly shown. However, what is not known from the research is the best way to restore synergy and optimal recruitment strategies. The patient's PGP was likely driven by nonoptimal function of thoracopelvic control mediated by an underlying neural system impairment (i.e., hypertonic fascicle of the right ILPT). Initial treatment focused on restoring optimal alignment, biomechanics, and control of the seventh thoracic ring (see Chapter 11), following which her PGP reduced and her pelvic alignment and control improved as well as her function and performance.

Case Report 2—A Thorax-Driven Pelvic Pain and Impairment Becomes a Pelvic-Driven Pelvic Pain and Impairment

This female patient presented with right-sided low back and PGP (meaningful complaint) aggravated by walking (meaningful task). The single leg standing task was chosen as an initial screening task to assess the patient's strategies for vertical loading through her low back and pelvis. She had three sites of FLT during right single leg standing: the right SIJ (i.e., the right innominate rotated anteriorly relative to the sacrum), right hip (i.e., the femur translated anterior when she shifted her weight to the right), and sixth thoracic ring (i.e., translated to the left

and rotated to the right). Initially, the sixth thoracic ring was found to be the primary driver because it failed first and when corrected resulted in improved position and control of both the right hip and the right SIJ. Increased activation of the right iliocostalis combined with underactivation of the right TrA was the noted neural system impairment, causing the FLT of the sixth thoracic ring. Two years later, the patient's thoracopelvic function was reassessed. Both the intensity and frequency of her lumbopelvic pain were less. However, there was still a control impairment of the right SIJ during right single leg standing. Her sixth thoracic ring continued to translate left and rotate right during this task; however, controlling the right SIJ now restored the control of the sixth thoracic ring, whereas correcting the alignment and providing control to the sixth thoracic ring did not control the right SIJ during this task as it did 2 years ago. An evaluation of the patient's core muscles[28] (i.e., a neural system assessment) revealed delayed activation of the right TrA in response to a pelvic floor cue. This delay in activation was not improved by correcting the sixth thoracic ring. When the patient was given a cue to specifically recruit the right TrA (imagine a guy wire connecting the right anterior superior iliac spine (ASIS) to the midline), a symmetric coactivation response of the left and right TrA was felt. This strategy controlled the right SIJ during right single leg standing. Massed practice to improve the coactivation of the right and left TrA was now advised to build a new brain map for a better strategy for pelvic control.

In summary, although single leg standing with contralateral hip flexion is commonly used to identify nonoptimal strategies for pelvic function, loss of intrapelvic control noted during this task does not necessarily mean the pelvis is the primary driver for the nonoptimal strategy noted.

SPECIFIC SYSTEMS TESTS TO DIRECT TREATMENT OF THE PRIMARY DRIVER

Once the primary driver for a specific task has been found, more tests can then be used to determine which impairments in which systems are responsible for the nonoptimal strategy (i.e., articular, neural, myofascial, or visceral). The clinician's ability to do this relies entirely on his or her ability to accurately perceive visual and kinesthetic information. Treatment will depend on the interpretation of this information through clinical reasoning and hypothesis development.

Joint Mobility Tests—What is Really Being Tested?

Passive physiological and passive accessory mobility tests provide information about more than just the joint, although historically the findings from these tests have been interpreted through the lens of the articular system. Overactive muscles can increase compression across a joint's surfaces, effectively reducing the size of both the neutral and elastic zones of motion. Underactive muscles can reduce compression, thus potentially increasing the size of the neutral and elastic zones. Vectors of pull on the skeleton from attachments of the viscera can also produce joint compression and alter passive and active joint mobility. Changes in fascial integrity and tension can also change joint mobility. Therefore, when testing active or passive physiological and passive accessory joint mobility, consideration must be given to more than just the amplitude of motion and the end feel to accurately interpret and clinically reason what the findings mean.

All joints have two zones of motion, a neutral and elastic zone (Figure 17-11).[50] The neutral zone is the part of the joint's range that is not influenced by the capsule or the capsular ligaments (i.e., there is no stress on the capsule or ligaments). In Maitland's[77] terminology, this range has been defined as 0 to R1 (first resistance). The amplitude of neutral zone motion varies between joints in the same body and between individuals (comparing the same joint). However, the amplitude of both zones should be similar between the left and right sides in the same individual. The elastic zone is the range that is influenced by increasing tension in various parts of the joint's capsule and associated ligaments. Cyriax[78] referred to the increasing tension at the end of a joint's range as "end feel" and Maitland[77] called this range R1 to R2 (from first resistance to the end of the joint's physiological range). It is important for clinicians to set their intention to feel the qualities of resistance throughout the entire range of motion (i.e., both neutral and elastic zones) and then to interpret the findings from this test with those from active mobility and control tests. Clinical reasoning involving the findings of all three tests generates a more likely and

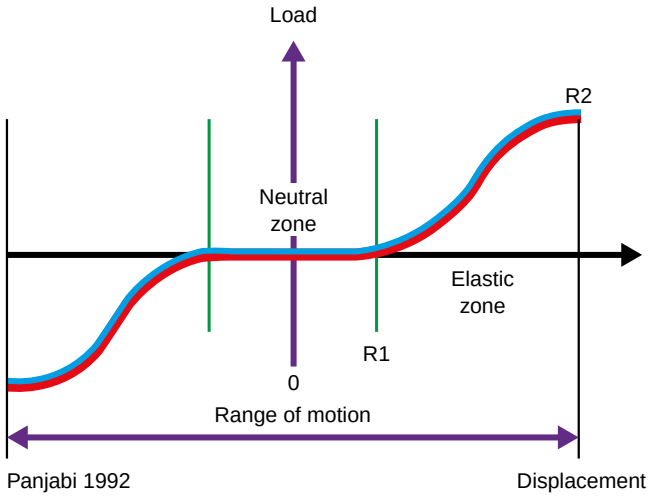

Figure 17-11 An adapted graphic representation of both Panjabi's[49,50] neutral and elastic zone representation of joint motion and Maitland's[77] joint movement diagram. Maitland's 0 to R1 is equivalent to Panjabi's neutral zone and R1 to R2 is equivalent to the elastic zone. Cyriax[78] described several different "qualities" of R1 to R2 which he called end-feel. (Copyright Diane G. Lee Physiotherapist Corp.)

Figure 17-12 Passive accessory mobility testing of the SIJ. With the joint in its neutral, non–close-packed position (i.e., sacrum slightly counternutated), the innominate should be able to glide anteroposteriorly at all three parts of the SIJ: the superior, middle, and inferior parts. There should also be a very small craniocaudal glide. Interpretation of the joint glide findings requires clinical reasoning of multiple findings including those on active, passive accessory and control testing. The inset on the top right of this figure shows the specific finger placement of the right hand during this test; medial to the iliac crest and the PSIS of the innominate. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

probable hypothesis as to the specific impairment impacting the joint's neutral and elastic zones of motion.

Passive accessory, or arthrokinematic, mobility testing is initially performed with the joint in its neutral or loose-packed position (Figure 17-12). The amplitude of the neutral zone should be the greatest in this position because the capsule and ligaments are under the least amount of tension. For the SIJ, the loose-packed position is counternutation of the sacrum.[67,68] Providing there are no vectors from any system compressing the SIJ, the sacrum will be counternutated when the patient lies supine with his or her hips and knees flexed and supported over a bolster. Any activation of the deep abdominals, PFMs, gluteals, hamstrings, or adductors of the thigh has the potential to increase compression across the SIJ[40,66,79,80] and thus reduce the size of the neutral zone. This must be considered when comparing mobility between sides.

Passive tests for efficacy of the form closure mechanism (i.e., the ability of the passive components of the joint to resist shear forces) require that the joint be positioned in the close-packed position and then the passive accessory mobility of the neutral and elastic zones assessed. When the joint is close-packed, there should be maximum congruence of the articular surfaces and maximum tension in the major ligaments, and no motion should be possible in the neutral zone. For the SIJ, this position is nutation of the sacrum because nutation increases tension in the sacrotuberous, sacrospinous, and interosseus ligaments.[67,68] This is a simple test for addressing a cognitive belief (of either the patient or the clinician) that the SIJ is unstable. If the joint has a true articular system impairment that has rendered it unstable, motion will still be palpable in the neutral zone even when the joint is close-packed. If neutral zone motion is well controlled in this close-packed position, the articular system can be ruled out as being the cause of the loss of joint control in loading tasks. If pain is provoked when the passive test moves beyond R1 (into the elastic zone), then one can conclude that there is nociceptive input arising from the ligaments of the SIJ.

Tests for efficacy of the force closure mechanism (i.e., the external forces necessary to control shear when a joint is in its neutral position) are inseparable from testing motor control strategies. When the recruitment strategy of the stabilizers of SIJ motion is optimal, there is no motion in the neutral zone even when the joint is positioned in neutral (i.e., the loose-packed position). The amount of activation necessary to control shear of a neutral joint varies according to the amplitude of the applied load.

Passive mobility testing remains essential in clinical practice, in spite of the difficulty to show intertester reliability for commonly used tests. How the results from these tests are interpreted has changed dramatically during three decades. It is now understood that joint mobility can be influenced by factors extrinsic to the joint and occasionally far removed. For example, impaired function at C3-4-5 can impact the range of motion at the hip through mechanisms mediated through changes in neural drive to the diaphragm through the phrenic nerve and thus distally to the hip via the psoas muscle. It is very common to find neuromuscular vectors responsible for nonoptimal alignment, biomechanics, and control of the mid-thorax impacting passive and active mobility as well as control of the SIJ. Vectors of pull from the visceral attachments to the skeleton can also compress and restrict SIJ motion, and it is manual testing that differentiates the underlying system impairments and thus directs specific treatment. In clinical practice, a diagnosis is not reached on one test alone. Restricted active and passive mobility of the SIJ does not always mean that the joint is stiff and requiring a mobilization technique or fixated and requiring a manipulation. Interpretive reasoning of the patient's story and all the clinical findings are necessary to reach a logical, sound hypothesis as to the primary driver and underlying system impairment(s). Once this is determined, pathology and intervention in musculoskeletal rehabilitation are clear. The reader is referred to other resources for further information on specific assessment techniques for the neural, myofascial, and visceral systems.[28]

THE PELVIC-DRIVEN PELVIS—PATHOLOGIES OR CONDITIONS

The next part of this chapter will focus on the management of the individual with pelvic-driven pelvic pain and impairment, whereby the best correction for the meaningful task is the pelvis. Clinical reasoning of the wide variety of possible findings from active, passive, and control tests for the SIJ will be discussed to facilitate an understanding of

the specific pathologies so that the principles for evidence-informed and reasoned intervention can follow. It is not possible to cover every single condition responsible for poor pelvic health; common ones have been chosen for this chapter. Table 17-4 highlights key differential features between the specific system impairments described in the following.

The Painful Sacroiliac Joint—An Articular System Impairment

Pain that is nociceptive and arising from the SIJ (i.e., peripherally mediated) is located directly over the posterior aspect of the SIJ and can radiate to the groin and down the posterolateral thigh.[81,82] The SIJ alone does not cause low back pain; however, complex patients often present with both low back and PGP. When the painful SIJ is driving the movement behavior, the patient has difficulty weight bearing on the involved side and often uses a cane. There is either a history of trauma to the pelvis or an autoimmune disorder that is creating the intra-articular synovitis. When assessing the individual's strategies for function and performance, there is very early loss of control of the SIJ when the patient is asked to load the painful side in standing. Compression of the pelvis during this task increases the unilateral PGP significantly. In supine, three or four of the known PGP pain provocation tests (i.e., distraction, compression, posterior thigh thrust, and sacral thrust) must be positive

TABLE **17-4**

Differentiating Features of Common Clinical Conditions (Pathologies) Pertaining Specifically to the Sacroiliac Joint

Pathology	Story	Active Osteokinematic Mobility	Passive Arthrokinematic Mobility	Test for Weight-Bearing Control	Intervention
Articular system—painful SIJ	Trauma or autoimmune disorder	Too painful to test	Too painful to test	Early loss of SIJ control, worsens with any pelvic correction or compression	Refer to specialist for intra-articular injection
Articular system—stiff SIJ	Trauma, not recent	Reduced	Reduced—all 3 parts Position—intrapelvic torsion	No loss of control	Specific SIJ grade 4 mobilization
Articular system—fixated	Trauma recent or if in the past multiple episodes with intermittent relief with manipulation	Reduced	Reduced—all parts Position—apparent shear of either the innominate or the sacrum	No loss of control when the joint is fixated	Specific distraction manipulation focused to the subluxed part of the SIJ
Articular system—"loose"	Past history of trauma with or without episodic fixation	Variable, may be reduced or not	Excessive Form closure mechanism tests may be normal, i.e., neutral zone, motion controlled, or abnormal depending on resting tone of deep muscular stabilizers	Loss of control early in task	Depends on whether laxity is due to loss of capsular integrity or neuromuscular resting tone Options: Motor control training or prolotherapy
Neural system—excessive compression	Nothing that differentiates	Inconsistent, reduced, or normal and varies with task and repetition of task	Often reduced at one particular part of the joint	Loss of control at a variable time in the task, sometimes early, sometimes late	Release the overactive muscles, facilitate the underactive muscles, motor control training for optimal synchronicity and synergy (brain training)

(*Continued*)

TABLE **17-4**

Differentiating Features of Common Clinical Conditions (Pathologies) Pertaining Specifically to the Sacroiliac Joint—Cont'd

Pathology	Story	Active Osteokinematic Mobility	Passive Arthrokinematic Mobility	Test for Weight-Bearing Control	Intervention
Neural system—insufficient or inappropriate compression	PGP aggravated by vertical loading tasks of variable duration	Often normal mobility (symmetric)	Often normal mobility with no part of the SIJ compressed Symmetric	Inconsistent loss of control, varies with repetition and task dependent	Motor control training to restore optimal synchronicity and synergy (brain training) then strength and conditioning for tasks desired in life
Myofascial system—diastasis rectus abdominis—nonsurgical	Pregnancy-related, excessive IAP secondary to a fatty omentum Nonoptimal abdominal wall strategies	Variable depending on compensatory strategy used to transfer loads through the low thorax, lumbar spine, and pelvis	Variable	Loss of control with neural system deficits of insufficient force closure secondary to nonoptimal motor control strategies	Motor control training to restore optimal synchronicity and synergy (brain training) then strength and conditioning for tasks desired in life
Myofascial system—diastasis rectus adbdominis—surgical	Pregnancy-related or excessive IAP secondary to fatty omentum	Variable depending on compensatory strategy used to transfer loads through the low thorax, lumbar spine, and pelvis	Variable	Loss of control with optimal neural system and motor control that is unable to generate tension in the linea alba sufficient to force close and stabilize the joints of the low thorax, lumbar spine, and/or pelvis	Recti plication and abdominoplasty followed by motor control training
Visceral system—causing excessive compression of the SIJ	Low abdominal symptoms	Often reduced	Various parts of the SIJ are compressed and the vector of pull comes from inside the pelvis, i.e., from the visceral structures	Loss of control	Restore "alignment" position and mobility of pelvic organs in order to reduce compression of the SIJ

SIJ, Sacroiliac joint; *PGP,* pelvic girdle pain; *IAP,* intra-abdominal pressure.

for a definitive diagnosis of a painful SIJ.[83] This is not a common pathology, or condition, seen in outpatient orthopedic physical therapy practice. More often one of the four SIJ pain provocation tests is positive and more likely related to nociception arising from one or more of the SIJ ligaments. Vleeming et al.[84] found that 98% of patients with a positive Active Straight Leg Raise Test[65] had pain arising from the long dorsal sacroiliac ligament, a ligament known to tense when the innominate anteriorly rotates or the sacrum counter-nutates.

Most modes of physical therapy (e.g., manual therapy, exercise, belts, taping) aggravate pain that is truly arising from the SIJ. In this author's experience, the best intervention for this pathology is an intra-articular injection of lidocaine and corticosteroid under fluoroscopic guidance. Once the joint pain subsides and pelvic correction and

compression improve the ability to transfer loads through the pelvis, physical therapy can begin.

When the ligaments of the pelvis are the source of the patient's pain, treatment is indicated; however, the location of pain (and the specific structure) is often not helpful in patient management. Clinical reasoning of the multiple findings on movement analysis is necessary to generate a sound hypothesis as to why the ligament is generating pain. Then the appropriate intervention is clear.

The Stiff Sacroiliac Joint—An Articular System Impairment

Patients with a stiff SIJ present with a history of trauma that may not be recent. They often have a compensatory "irritated" contralateral SIJ and/or lumbosacral junction due to the altered biomechanics induced by the asymmetric intrapelvic mobility this impairment causes. Therefore the site of pain is often misleading. On active mobility testing (i.e., osteokinematics), the innominate will fail to posteriorly rotate relative to the ipsilateral sacrum and the pelvis may or may not laterally tilt on the contralateral hip joint. On passive mobility testing (i.e., arthrokinematics), the amplitude of motion in the neutral zone is reduced compared with the opposite side. This reduction in motion is apparent at all three parts of the joint (i.e., superior, middle, and inferior), and the end feel in the elastic zone is short, firm, and nonspringy. There is no loss of intrapelvic control during single leg standing. The pelvis is often twisted such that the innominate on the stiff side is anteriorly rotated relative to the contralateral innominate. This articular system impairment requires a specific mobilization technique and should be directed at all three parts of the SIJ (Figure 17-13).[29] Full range of motion of the stiff SIJ should be achieved in one or two treatment sessions.

Figure 17-13 Passive mobilization technique for the stiff, "fibrotic" SIJ. After the SIJ is taken to the barrier for posterior rotation, the femur is slightly adducted and medially (internally) rotated. From here, the specific vector of resistance that is restricting motion of the SIJ is determined by applying a dorsolateral force (*arrow*) in a variety of directions. The clinician is looking for the vector of greatest resistance. Once this vector is found, a sustained grade 4 mobilization technique is used to release the joint. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

The Fixated Sacroiliac Joint—An Articular System Impairment

There is some debate as to whether this condition truly exists or whether it is merely a severely compressed joint. Every time the author begins to be convinced that it does not exist, she sees a patient who convinces her that on the rare occasion, especially in a young individual with insufficient form closure, this can occur. The individual with a fixated SIJ presents with a history of trauma and can remember exactly when and what happened. Often the first thing noticed is the inability to weight bear on the affected side after the injury. Walking is difficult in the early stages of this impairment, and in all cases an obvious limp is present. If the patient has seen other practitioners, he or she may report intermittent relief of pain and restoration of partial function when the SIJ was manipulated. However, the reduction of pain and restoration of function often do not last. The findings vary and depend on whether or not the SIJ is fixated at the time of examination. The following describes the findings of a fixated SIJ. Of note is the immediate impression on palpating the pelvis that something is "not right" in that the shape of the pelvis is distorted. The shape of the pelvis with a fixated SIJ differs from the common intrapelvic torsion, in which one innominate is anteriorly rotated to the other and the sacrum is rotated in between. The fixated SIJ causes the pelvis to feel as though it has been sheared either in the craniocaudal plane (i.e., innominate upslip or downslip) or in the anteroposterior plane (i.e., sacral anterior-posterior shear lesion). Active SIJ mobility is not only reduced, but it feels like the joint is fused as well. There is no loss of control, and the ability to weight bear depends on the level of pain at the time of examination. Passively it is impossible to find the joint line to even test arthrokinematic mobility of the fixated SIJ. This system impairment requires a specific distraction manipulation focused on the most compressed part of the joint (Figure 17-14).[29] Immediately after the manipulation, many mobility findings change, including the SIJ's active mobility (restored), passive mobility (may be excessive), and control (usually there is now loss of control). To prevent refixation when the pelvis is next loaded, the joint should be well supported (compressed) with either tape or a sacroiliac belt (see *Role of Taping and Pelvic Belts* later).

The Loose Sacroiliac Joint—An Articular System Impairment

The individual with a loose SIJ may have true laxity of the passive restraints (i.e., capsule and ligaments) or more

Figure 17-14 A high-velocity, low-amplitude thrust technique directed precisely at the fixated, or severely compressed, SIJ while stabilizing L5-S1 can have an immediate effect on improving the alignment and biomechanics of the SIJ. Subsequently, there is often loss of SIJ control, and the entire pelvic ring needs temporary support from an external force (e.g., taping or sacroiliac belt) until force closure and motor control strategies are restored. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

commonly a reduction in resting tone of the deep muscular stabilizers, giving a "false positive" for a loose joint. This patient may have been told that he or she has an "unstable SIJ," a cognitive belief with possible catastrophic results. A true loose SIJ is an articular instability and exists when the capsule and ligaments of the SIJ have been significantly stretched so that the force closure and motor control mechanisms cannot control shear between the innominate and the sacrum. This patient also reports pelvic trauma (with or without fixation of the SIJ), and when there is poor control, the ligaments of the joint are often nociceptive. Active mobility findings are variable and depend on the compensatory stabilization strategy chosen. Some strategies excessively compress the SIJ in an attempt to stabilize it and thus reduce mobility. Alternatively, the joint may appear to have symmetric, or excessive, mobility when compared with the noninjured side. Passively the amplitude of neutral zone motion is increased (R1 is much further from 0), and pain is readily provoked when the capsule and ligaments are stretched with motion testing in the elastic zone. The quality of the end feel in the elastic zone varies from "soft" to "empty" (i.e., no end feel). Tests for efficacy of the form closure mechanism are required to differentiate the true loose SIJ (i.e., an articular system impairment) from the loss of neuromuscular control (i.e., a neural system impairment). Integrity of the passive restraints is necessary for the SIJ to become close-packed.

If, on passive arthrokinematic mobility testing of the SIJ:

1. The innominate is mobile relative to the sacrum at all three parts of the joint, but
2. It is not possible to close-pack the SIJ, and
3. Motion is still palpable in the neutral zone when you attempt to tighten all the major ligaments of the SIJ, then the hypothesis (pathology) is an articular instability or true loose joint.

Treatment depends on whether the deep muscles can compensate and control shear or movement of the SIJ during specific loading tasks that are required in the individual's life. If yes, then the combination of motor control and movement training is the intervention.[30,31] If no, then prolotherapy for the posterior ligaments of the SIJ should be considered before training.

The Poorly Controlled, Excessively Compressed Sacroiliac Joint—A Neural System Impairment

Several muscles together with their fascial attachments can overly compress the SIJ and thus impact its function. The patterns are numerous; however, there are common features. First of all, nothing in the history clearly differentiates this system impairment. Symptom onset is often insidious and the patient may have difficulty identifying a precipitating event. Poor habitual postures or strategies for movement often underlie this impairment. Active mobility of the poorly controlled yet excessively compressed SIJ is variable and often inconsistent. At times, active mobility of the SIJ is reduced and at other times, normal. The amplitude of active mobility can vary between repetitions of the same task or between different tasks. Importantly, this individual would not be a good candidate for inclusion in an intratester reliability study for active mobility testing of the SIJ. Findings on passive mobility of the SIJ are also inconsistent with high variability in the amplitude of neutral zone motion between parts of the joint tested. Commonly, overactivation of the superficial fibers of the lumbar multifidus or the longissimus portion of the erector spinae compresses the superior part of the SIJ, reducing motion in the neutral zone but not in the middle or inferior parts of the joint. Piriformis can compress and reduce motion of the entire SIJ or just the middle part, whereas iliococcygeus and/or ischiococcygeus can compress the inferior part. Because of its fascial connections with iliococcygeus, obturator internus can also compress the inferior part of the SIJ when overactive. These are but a few of the common patterns of altered resting tone of muscles that can impact both active and passive mobility of the SIJ. The compressed SIJ secondary to a neural system impairment often loses control in weight bearing but not always and not consistently. Treatment requires restoring optimal alignment of the trunk and synergy of the deep segmental and superficial muscles, a complex topic that deserves a chapter of its own.[29–31] It is important to remember that the pelvis may not be the driver and treatment may begin elsewhere in the body.

The Poorly Controlled, Insufficiently Compressed Sacroiliac Joint—A Neural System Impairment

This neural system impairment is very common in both genders of all ages. It is a result of anything that disrupts optimal sequencing and timing of muscular activation. Dyssynergies of muscle activation (i.e., altered motor control[85–87]) can

disturb the force closure mechanism and create excessive stress and strain on the tissues that eventually become symptomatic. Treatment is often sought once symptoms persist or there is a loss of function. Patients may remember an event or a point in their life when the symptoms or loss of function began. A motor vehicle-, work-, or sport-related accident, pregnancy and/or delivery, surgery, abdominal illness, or an emotional crisis (e.g., divorce, death, loss of a significant relationship or position) can precipitate this condition. Sometimes the patient cannot identify a triggering event and will often ask, "How or why did this happen?" The active and passive mobility of the SIJ on the side of the PGP is often unremarkable, yet patients demonstrate an inability to control loads through the pelvis on this side. This may be a consistent or inconsistent finding, and it can sometimes depend on repetition of the aggravating task and sometimes depends on the task itself. There is no loss of articular integrity of the SIJ, and the tests for the form closure mechanism are normal. Evaluation of the recruitment patterning of the muscles that provide control to the SIJ reveals a wide variety of dyssynergies, including:

1. Delayed or absent activation or overactivation of left and right TrA muscles
2. Delayed or absent activation or overactivation of the PFMs (i.e., all three layers' left and right sides in a variety of patterns)
3. Delayed or absent activation or overactivation of the deep lumbosacral multifidus muscle
4. Overactivation of the transverse, vertical, or oblique fibers of the left and right IO muscles
5. Overactivation of the superficial fibers of multifidus, iliocostalis, longissimus muscles
6. Delayed or absent activation or overactivation of the obturator internus or externus muscles
7. Delayed or absent activation or overactivation of the gluteals, tensor fascial lata, adductors (long and short), sartorius, and quadriceps muscles

Any pattern can be present. Assessment is essential to guide the appropriate intervention for this condition. Similar to the excessively compressed SIJ, this condition requires restoration of optimal alignment of the trunk and synergy of the deep segmental and superficial muscles, a complex topic that deserves a chapter of its own.[29–31] It must be remembered that the pelvis may not be the driver and treatment may begin elsewhere in the body.

Diastasis Rectus Abdominis—A Myofascial System Impairment

It has been well established that TrA plays a crucial role in optimal function of the lumbopelvis and that one mechanism by which this muscle contributes to intersegmental[39] and intrapelvic[88] control is through fascial tension. A DRA muscle has the potential to disrupt the force closure mechanism and is a common postpartum occurrence.[12,89] Universally the most obvious visible change during pregnancy is the expansion of the abdominal wall, and, although most abdomens accommodate this stretch very well, others are damaged extensively (Figure 17-15).

One structure particularly affected by the expansion of the abdomen is the LA, the complex connective tissue that connects the left and right rectus abdominis muscles.[90] The width of the LA is known as the inter-recti distance (IRD) and normally varies along its length from the xyphoid to the PS. Beer et al.[91] measured the width of the LA with ultrasound imaging in 150 nulliparous women aged 20 to 45 years and found the mean width to be highly variable, reporting 7±5 mm at the xyphoid, 13±7 mm 3 cm above the umbilicus, and 8±6 mm 2 cm below the umbilicus. Mendes et al.[92] showed that ultrasound imaging is an accurate method for measuring IRD, and others have used this tool to measure the behavior of the LA during a variety of tasks.[93,94] A DRA is commonly diagnosed when the IRD exceeds what is thought to be

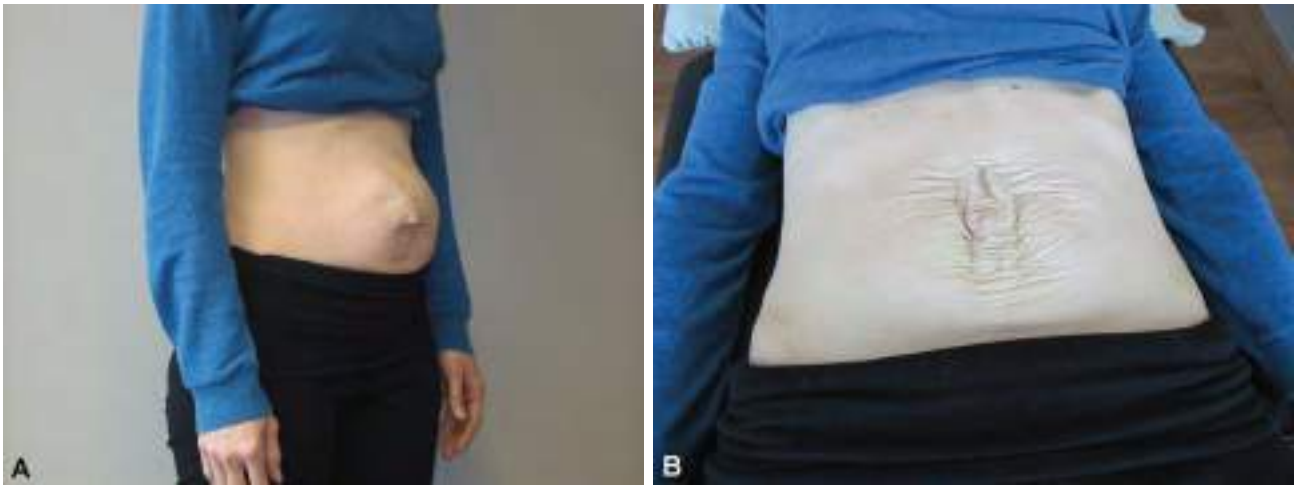

Figure 17-15 **A,** Standing relaxed abdominal profile of a woman with a DRA. **B,** When lying supine, the extensive damage to the midline abdominal skin is easily seen and this structural change extended through the layers of the superficial fascia to the LA. A comprehensive examination of the structure and behavior of the linea is necessary to determine whether trunk function can be restored with training or whether a surgical consultation should be considered. (Copyright Diane G. Lee Physiotherapist Corp.)

normal, although there is no standardized agreement as to what normal is.

There is little scientific literature on this condition. Boissonnault and Blaschak[95] found that 27% of women have a DRA in the second trimester and 66% in the third trimester of pregnancy. Fifty-three percent of these women continued to have a DRA immediately postpartum, and 36% remained abnormally wide at 5 to 7 weeks postpartum. Gilliard and Brown[89] reported that 100% of women had a DRA in their third trimester. Coldron et al.[93] measured the IRD from day 1 to 1 year postpartum and noted that the distance decreased markedly from day 1 to 8 weeks and that without any intervention there was no further reduction in the IRD at the end of the first year. In the urogynecological population, 52% of patients were found to have a DRA.[12] Sixty-six percent of these women had at least one support-related pelvic floor dysfunction (e.g., stress urinary incontinence, fecal incontinence, and/or pelvic organ prolapse). There are no studies to guide clinicians on what is the best treatment for postpartum women with DRA.

Clinically it appears that there are two subgroups of postpartum women with DRA:

1. Those who are able to restore optimal strategies for transferring loads through the trunk (including the pelvis) with or without achieving closure of the DRA through a multimodal treatment program, such as the ISM approach (Figure 17-16), and
2. Those who fail to achieve optimal strategies for transferring loads through the trunk, in spite of (a) having optimal function of the trunk musculature, (b) not having a loss of articular integrity of the SIJs or PS, and (c) in whom the IRD remains greater than normal (i.e., nonoptimal myofascial system).

In multiple vertical loading tasks (e.g., single leg standing, squatting, walking, moving from sit to stand, and climbing stairs), FLT through the joints of the lower thorax, lumbar spine, and/or pelvic girdle is consistently found.

The second subgroup of postpartum women with a DRA appear to have sustained significant damage to the midline fascial structures and can no longer generate sufficient tension through the abdominal wall for resolution of function (Figure 17-17). For this subgroup, a surgical plication of the recti along with an abdominoplasty to repair the midline abdominal fascia (i.e., the LA) and skin should be considered.[96]

The Poorly Controlled, Excessively Compressed Sacroiliac Joint—A Visceral System Impairment

The pelvic organs attach to the skeletal pelvis, and it is through these attachments that changes in pelvic alignment and excessive compression of the SIJ can be created. Assessment and specific treatment of the visceral system are outside the scope of this chapter except to acknowledge the presence of these conditions and suggest how they can be differentiated from articular, neural, and myofascial system impairments. The key differentiating finding of this system impairment is the location of the vector of force creating compression of the SIJ noted during passive arthrokinematic mobility testing. The pull (vector) can clearly be felt and comes from inside the pelvis and not from the muscles on the outside of the skeleton or from the pelvic floor. If the pelvic organs (e.g., bladder, uterus, ovaries, fallopian tubes, sigmoid colon) are approximated toward the compressed SIJ and the passive mobility test is repeated and mobility is restored, then articular, neural, or myofascial system impairments can be ruled out. The reader is referred to the Barral Institute (www.barralinstitute.com) for more information, courses, and resources on visceral system impairments and their role in pelvic pain and impairments.

PRINCIPLES OF TREATMENT AND THE INTEGRATED SYSTEMS MODEL FOR DISABILITY AND PAIN

Restoring pelvic health requires a clinician to have both tools for releasing the nonoptimal strategies that perturb alignment, mobility, and control of the pelvic joints, myofascia, and organs, and tools for training new strategies for function and performance through a wide variety of tasks. In the ISM approach the first step is to determine the best place in the body to intervene—in other words, identifying the primary driver because loss of pelvic alignment, mobility, and control may be secondary to impairments elsewhere in the body (e.g., foot, thorax, neck, cranium). It is beyond the scope of this chapter to describe the necessary interventions for pelvic pain and impairment that is driven by body regions extrinsic to the pelvis. This chapter will focus on the principles of treatment interventions for pelvic pain and impairment that are driven by specific system impairments within the pelvis, in other words the pelvic-driven pelvis. There are four components to most treatment sessions, and they can be summarized by the acronym RACM: Release, Align, Connect (or control), and Move (Table 17-5). The first part of treatment is to release whatever is causing the nonoptimal strategy for alignment, biomechanics, and control of the primary driver (in this instance the pelvis) (Figure 17-18).[29]

Releasing the Pelvic-Driven Pelvis

Cognitions and Emotions

On occasion, thoughts and feelings (i.e., cognitions and emotions) are the primary driver of the patient's pelvic pain and impairment and require "release" and understanding before any physical intervention or movement training. Releasing cognitive and emotional barriers (i.e., psychosocial factors) requires patient education that includes:

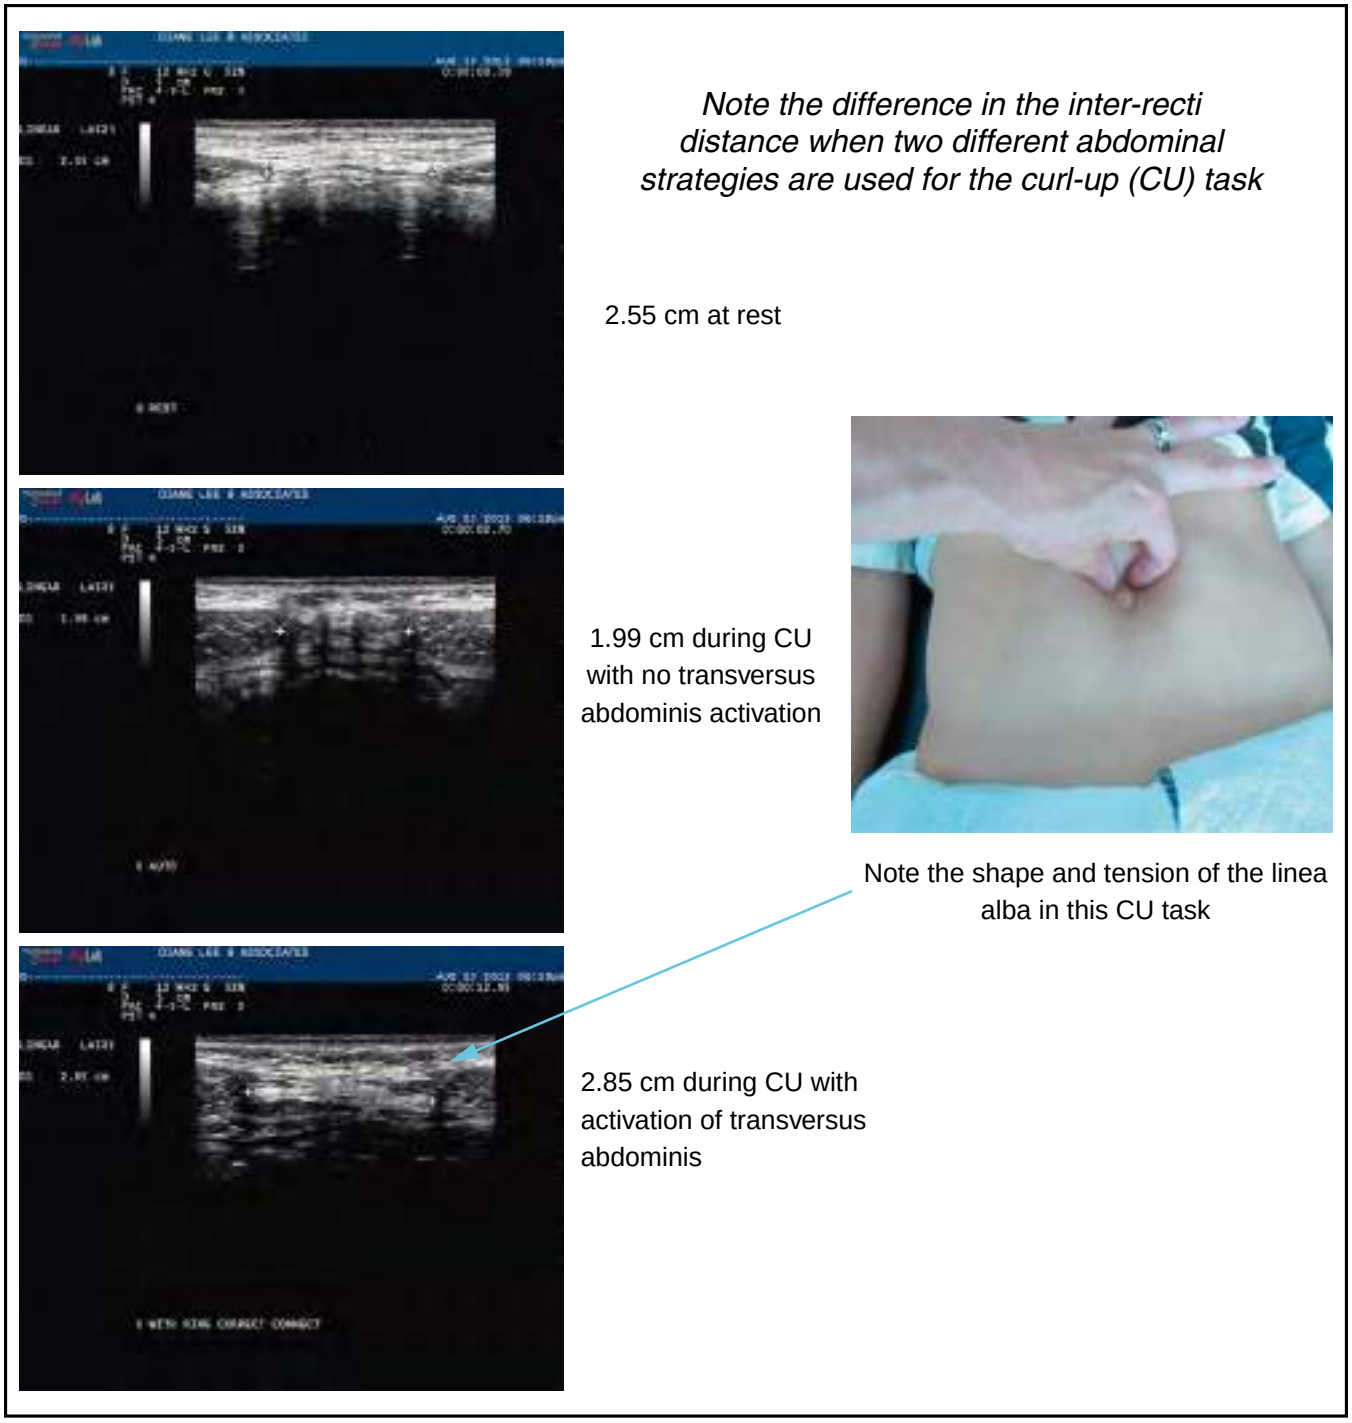

Figure 17-16 This woman has a functional diastisis of the rectus abdominus muscles (DRA) that did not require a surgical intervention. Note the difference in the tension (echogenicity) and shape of the LA during the short head and neck curl up (CU) task with two different abdominal strategies. Also note how the IRD narrowed with the nonoptimal strategy that failed to generate tension in the LA (the gap closed from 2.55 cm at rest to 1.99 cm with the CU task), whereas when a coactivation of the deep and superficial abdominals occurred tension was generated in the LA and the IRD actually widened from 2.55 cm at rest to 2.85 cm. This finding was noted across multiple research subjects[96] and suggests that one should not be trying to narrow the IRD in patients with DRA. Focus should be on restoring optimal strategies of abdominal wall function that improve effective load transfer through the trunk. (From Jones MA, Rivett D: Jones MA, Rivett DA, eds: *Clinical reasoning for manual therapists*, ed 2, Edinburgh, 2017, Elsevier.)

1. Knowledge of the neuroscience of pain,[26,97,98] as well as
2. Provision of a logical hypothesis derived from the patient's history and clinical findings that explains both their experience (e.g., pain, numbness—the sensorial dimension) and their disability.

It is imperative that safe environments are created for this patient to explore his or her cognitive, emotional, and physical fears (i.e., fear-avoidance behavior) and to address comments such as "I'll never get better." Thoughts can become reality if the patient is convinced they are true.

Figure 17-17 This woman's anterior abdominal wall required surgery to repair the midline LA. Despite having excellent motor control strategies, she was unable to stabilize the joints of her lower thorax, lumbar spine, or pelvic girdle due to the lack of force closure. Following surgery, specific motor control training restored function and reduced her multiple pain complaints. (Copyright Diane G. Lee Physiotherapist Corp.)

A significant part of treating a complex patient is to restore hope and have a treatment plan or intervention that resonates and seems reasonable. This is a starting point for facilitating change.[99] A primary goal of treatment is to "illuminate the path to change" and to empower the patient to take control of that path and be responsible for his or her pelvic health. For the patient with centrally sensitized pain, tools and techniques that reduce activity of the sympathetic nervous system and activate the parasympathetic nervous system can help to reduce the threat. These include various forms of meditation, Yoga Nidra, alternate nostril breathing (Nadi Shodhan or Anuloma Viloma Pranayama), and acupuncture, all helpful tools for empowering patients to take control of their nervous systems and change the input to their body–self neuromatrix. Change the sensory input, and the output will change. Helping the patient to create a cohesive story of their experience helps to integrate the amygdala (i.e., emotional memories of an experience) and hippocampus (i.e., autobiographical detail of that experience)[26] and again reduces the threat. Empower the patients with a sensitized nervous system such that they can take control and change their state of "flight, fright, or freeze" (i.e., states of threat) themselves.

Physical Impairments

Tools and techniques are also necessary to release the specific system impairments and change the sensory input to the neuromatrix from these sources. These include mobilization and manipulation techniques to release the stiff or fixated SIJ; release techniques for overactive muscles including release with awareness, muscle energy, and dry needling; fascial release techniques to restore inter- and intramuscular fascial mobility; techniques for restoring mobility of the dura and peripheral nerves (e.g., pudendal, sciatic, femoral, obturator, ilioinguinal, genitofemoral, lumbar plexus); and visceral release techniques. All of these release techniques are merely "clothes, shoes, and accessories in the closet," and the reader is encouraged to "shop" for lots of these tools. In my practice, the release with awareness technique combined with dry needling is highly useful for patients with pelvic pain.

Release with Awareness

This technique was first introduced in 2001[100] to treat "butt grippers"—individuals who habitually overactivate the ischiococcygeus muscles as part of their pelvic stabilization strategy. Release with awareness can be used on any muscle in the body that is facilitated due to increased neural drive—this is a neural system impairment. There is often a latent trigger point in the relevant muscle that the patient may not be aware of until the muscle is palpated. The trigger point is monitored with one hand with just enough pressure to increase the sensory awareness of the

TABLE **17-5**

Components of RACM—Release, Align, Connect and Control, and Move

Component	Description
Release	• Cognitive and emotional barriers are released with education as well as changing the "experience of the patient's body"—the clinical application of Melzak's body-self neuromatrix (see Figure 17-3) • Physical barriers require the clinician to have a wide variety of techniques to release articular, neural, myofascial, and visceral system impairments
Align	• Release cues and corrections are incorporated into movement practice to align the body both within and between regions
Connect and Control	• When necessary, specific connect cues are used to facilitate or "wake-up" more activation and coordination of the deep and superficial muscle systems of the trunk and also incorporated into the movement practice
Move	• The principles of neuroplasticity are used to rewire brain maps and create more efficient strategies for function and performance (put it all together to build a new brain map for the meaningful task) • Tissue healing and repair needs to be considered when adding loads to the movement program

Figure 17-18 The two primary components of the treatment program according to *The ISM*. First, use techniques and movement training to release the barriers creating the nonoptimal strategy and then retrain (i.e., build) new strategies based on the meaningful task following neuroplastic and tissue repair principles. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

patient but not so much that it provokes pain. The joint or the muscle itself is moved so as to shorten the length of the muscle. This immediately reduces the afferent input to the spinal cord from the primary annulospiral ending in the intrafusal muscle fiber by reducing tension on the muscle spindle (Figure 17-19). Within 10 to 15 seconds a reduction in the tone of the muscle at the trigger point will be felt, if you wait for it. If you poke, prod, or provoke the muscle, it will defend against that sensory input and the reduction in tone will not occur.

The second part of the technique requires patients to be aware and engaged in what is happening in their body. They are asked to bring their attention to any sensation in the muscle being palpated while being given verbal cues by the clinician that facilitate relaxation or letting go. Clinicians provide cues that "stop the patients from doing something" as opposed to "patients doing something in addition to what they are already doing." For example, to release the ischiococcygeus the clinician can give cues such as "let my fingers sink into this muscle, let the sitting bones widen and your tailbone float" as opposed to "pull the sitting bones apart." The goal is to reduce activation. Therefore patients have to figure out how to stop doing something as opposed to adding on another layer of muscle activation that will further compress and restrict the joint. When the clinician feels the patient's nervous system respond to the manual and verbal cues, the patient is encouraged with positive reinforcement that the patient is on the right path. Patients will often say, "But I didn't do anything," to which the clinician can reply, "I don't want you to do something. I want you to stop doing something." Meanwhile the clinician continues to move the joint in various combinations of movements that facilitate further relaxation of the muscle until no further release is obtained. If the clinician moves the joint from this point in any direction, another barrier will often be engaged. The osteopathic physicians call this a "still point." After a short period of time an "expansive release" occurs, following which the muscle(s) will relax further, allowing more lengthening and greater range of joint motion.

The last part of this *release with awareness* technique is to take both the muscle and joint through this new range (i.e., into stretch or elongation of the muscle and to the new end of joint range). More release techniques for specific muscles pertaining to the thorax, lumbar spine, and pelvis can be found in the 4th edition of *The Pelvic Girdle*.[29] If the technique is successful, there will be an immediate improvement in both the active and passive mobility of the joint.

Aligning the Pelvic-Driven Pelvis

Following release of the compressive vectors, alignment of the pelvis often improves; however, old habits are hard to break, and movement training is essential if the release obtained in the treatment session is to be maintained and transferred into functional tasks. When retraining a squat task for a patient who complains of pelvic pain with sitting, it can be helpful to incorporate the specific release cues used in the treatment session into their movement training to build a better strategy for this task.

Connecting and Controlling the Pelvic-Driven Pelvis

Releasing and aligning the primary driver (especially if the driver is outside the pelvis [e.g., thorax, neck, cranium, foot]) can result in a dramatic improvement in the recruitment strategy of the muscular stabilizers of the pelvis (see *Tiana's Story* later). When the pelvis is the driver of the pelvic pain/impairment, correcting the pelvic alignment often restores the activation and synergy of the deep muscles that stabilize the pelvis (i.e., TrA, the PFMs, and deep fibers of multifidus). On occasion, specific cueing is necessary to further augment or "wake-up" a muscle that has been inhibited for a prolonged period of time.[30] In the following are some "best cues" for activation of TrA, multifidus, and the various muscular layers of the pelvic floor.

Transversus Abdominis

Using MRI and ultrasound imaging, Hides et al.[101] investigated the response of the abdominal wall to the cue "draw in the abdominal wall without moving the spine," a cue often referred to as the drawing-in maneuver or the abdominal hollowing cue. Thickness of both the TrA and IO muscles increased significantly during this cue, suggesting that it results in coactivation rather than isolation of either abdominal muscle. There is ongoing debate in the literature as to the necessity of being able to isolate

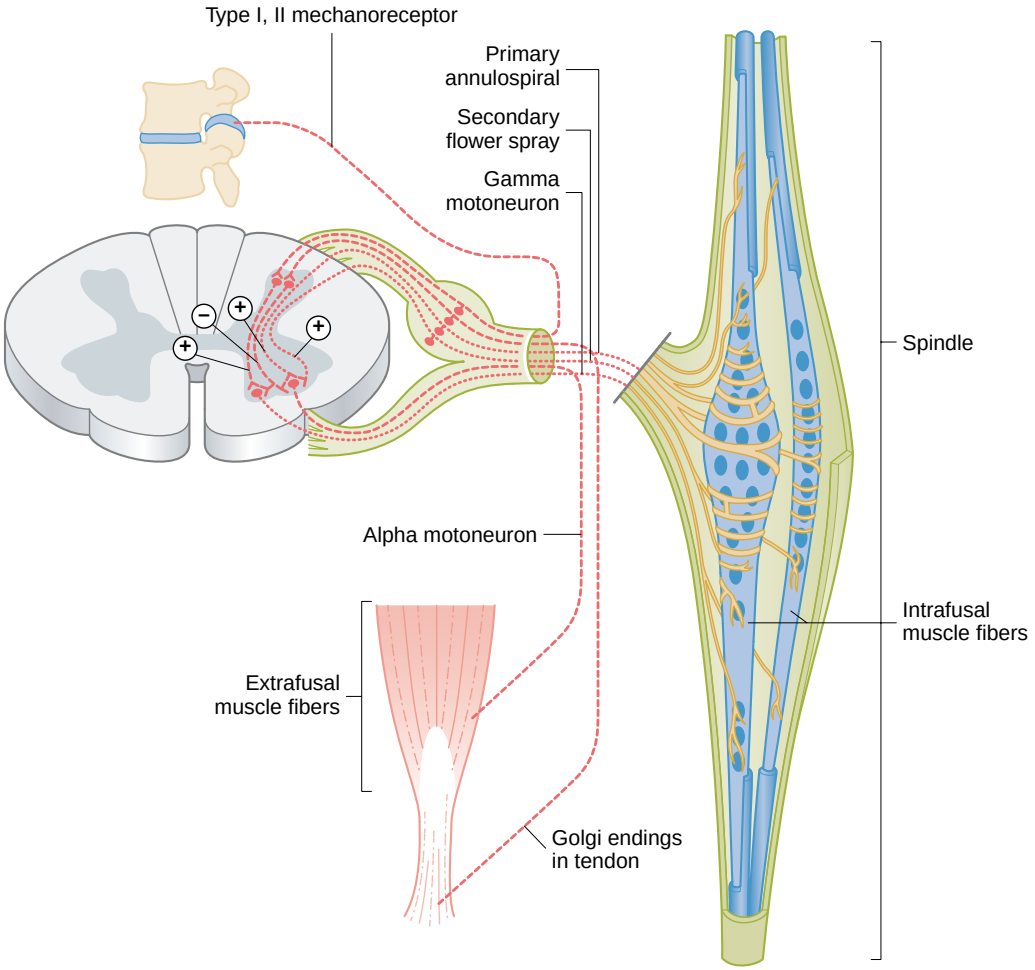

Figure 17-19 Activation of a muscle is influenced and controlled by many neural feedback loops involving the brain, spinal cord, and peripheral receptor systems. Changing the position of the joint and its associated muscles, tendons, and fascia can alter afferent input and thus efferent output to the related extrafusal muscle fiber. The result can be a decrease in activation of the targeted muscle at rest. This is called a *positional release*. Imagery and awareness can activate the higher centers that have a descending inhibitory influence on the efferent output to the extrafusal muscle fiber(s) and can further reduce a muscle's activation. (From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier.)

TrA from IO, and clinically it appears more important that there is synergy of all muscles such that the strategy matches the demands of the task by providing mobility and control where needed. Strategies are highly individual and task specific. After the pelvis is released and neutral alignment restored, the following cues, asked of the patient, help to facilitate more activation of TrA:

1. Imagine a force, or line, connecting the left and right hip bones (ASISs) together and gently connect along this line (a bilateral cue) (Figure 17-20).
2. Imagine your hip bones (i.e., ASISs) are like an open book and gently close the right (or left) book cover to the midline (a unilateral cue).

Tactile cueing is given in conjunction with these verbal cues so that the brain receives consistent sensory input from several sources.

The Pelvic Floor Muscles

In a chapter pertaining to pelvic health, it is important to note the multiple functions of the PFMs, including but not limited to voiding, defecation, sexual arousal, pelvic organ support, breathing, and movement control of the joints of the pelvis, lumbar spine, and indirectly, the low thorax.

Optimal function of the pelvic floor requires not only that the anatomy and nerve supply be intact[102–104] but also that there be optimal coordination of contraction and relaxation (i.e., motor control of all three layers) as well as adequate strength and endurance for the specific task.

The pelvic floor is composed of three muscular layers, and each layer contains several muscles and related fascia (Figure 17-21). The most superficial layer (layer 1) contains the ischiocavernosus, bulbocavernosis (i.e., bulbospongiosus), superficial transverse perineal muscles, and the external anal sphincter. This layer has direct continuity with the short adductors of the thigh. The middle layer (layer 2) cannot be palpated, or assessed, externally and contains the compressor urethrae, external urethral sphincter, urethrovaginal sphincter, and deep transverse perineal muscles. The middle layer has direct continuity

Teach a New Strategy for Function & Performance

Finding the Best Cue for Activation of Transversus Abdominis in Isolation from Internal and External Oblique

- *Imagine a force, or line, connecting the left and right hip bones (anterior superior iliac spines) together and gently connect along this line (a bilateral cue)*
- *Imagine your hip bones (anterior superior iliac spines) are like an open book and gently close the right (or left) book cover to the midline (a unilateral cue)*

Figure 17-20 Manual and verbal cues to activate TrA in isolation from the more superficial internal and EO muscles. It is critical that the right layer is palpated, otherwise when TrA contracts, no tension will be felt in the fascial layer. (Copyright Diane G. Lee Physiotherapist Corp.)

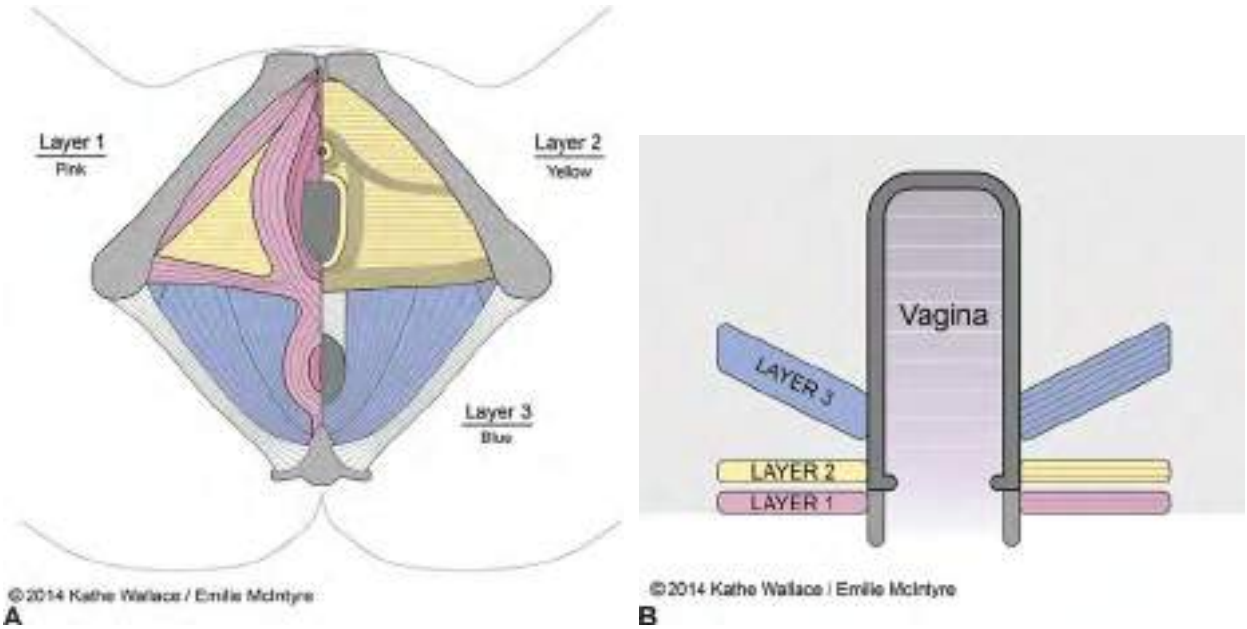

Figure 17-21 **A,** Inferior perspective of the three layers of the PFMs in the transverse plane. The first layer (*pink*) contains ischiocavernosus, bulbocavernosis, and the superficial transverse perineal muscles collectively known as the urogenital triangle and is easily palpated externally. The middle layer is not accessible to external palpation (*yellow*) and contains the perineal membrane (*yellow*), urethral sphincter (*circle* around the urethra), compressor urethra (extending from the pubic rami), urethrovaginalis (encompassing the urethra and the vagina), and deep transverse perineal muscles. The third and deepest layer is the levator ani (*blue*). The posterior part is accessible for external palpation and contains the puborectalis and iliococcygeus. The anterior and deeper parts of this layer (i.e., pubococcygeus, pubovisceralis, pubovaginalis) can only be palpated intravaginally. **B,** Coronal section through the three layers of the PFMs and illustrates the relationship and location of each layer to the vagina. Note that layer one is external to the vaginal entrance. (From Wallace K: *Reviving your sex life after childbirth, your guide to pain free and pleasurable sex after the baby*, pp 38, 115, Kathe Wallace, 2014. Copyright 2014 Kathe Wallace / Emilie McIntyre.)

with the fascia of TrA. The deepest layer of the pelvic floor (layer 3) is collectively called the levator ani, which is composed of the pubococcygeus (i.e., pubovisceralis, pubovaginalis), puborectalis, and iliococcygeus and has direct continuity through the arcus tendineus pelvis fascia and ATLA to the obturator internus and thus the hips. The posterior part of the levator ani can be palpated and assessed, externally.

In healthy individuals a gentle contraction of the pelvic floor results in an isolated contraction of TrA.[105] This does not occur in patients, especially those with pelvic pain, and this coactivation has not been found in those with urinary incontinence.[106] Assessment is always necessary to confirm the result of any given cue and many patterns will be found in clinical practice.

Many different dys-syngergies exist in the three muscular layers of the pelvic floor, and it is common to need to release certain muscles and activate (i.e., wake-up) others. After the pelvis has been released and neutral alignment restored, the following cues can help to either facilitate more activation or release excessive activation of the various layers of the pelvic floor. These cues come from collaboration with Holly Herman and Kathe Wallace and their collective experience working with thousands of women with pelvic floor dysfunction and pelvic pain.

1. To activate the superficial layer: for women—nod the clitoris toward the vagina; for men—draw the glans of the penis in towards the body
2. To release the superficial layer: for women—imagine the clitoris lengthening away from the vagina; for men—think about lengthening the penis, widen the ischial rami (i.e., relax the superficial transverse perineal muscles)
3. To activate the middle layer—gently squeeze the muscles around the urethra as if to slow down the flow of urine
4. To release the middle layer—imagine the urethral tube expanding
5. To activate the deepest layer: levator ani—gently squeeze the anal sphincter and draw the anus up and forwards toward the back of the pubic bone
6. To release the deepest layer: levator ani—think about relaxing the anal sphincter to allow the passage of "wind" and let the distance between the tailbone and pubic bone lengthen

If the reflex connection between the PFMs and abdominal wall is impaired and coactivation does not occur, combining the abdominal and PFM cues may be useful.

The position of the lumbopelvis can influence activity of the PFMs.[107] In women with stress urinary incontinence, a reduced lumbar lordosis has been noted. An increased thoracic kyphosis and loss of lumbar lordosis is also associated with an increased incidence of vaginal prolapse.[108,109] PFM training is recommended as the first line of treatment for women with stress, urge, or mixed incontinence as well as pelvic organ prolapse.[110–112] However, debate continues as to the best way to train the pelvic floor. Bump et al.[113] noted that 24% to 40% of women have decreased cortical awareness of their PFMs and will valsalva when attempting to do a PFM contraction. Alternatively, they may contract but not lift the levator plate. Others have good lift but are still incontinent.[114] When the PFMs are overactive, the lift of the levator plate may be restricted because this lift depends on the starting position of the PFMs.[115] Furthermore, the PFMs may be able to contract yet no tension is generated in the associated fascia due to loss of integrity.[103,104] Many individuals with pelvic pain and poor pelvic health present with asymmetry of resting tone, activation, and timing of contraction and relaxation of all, one, or a combination of the three layers of the pelvic floor. Asymmetric activation of the levator ani and ischiococcygeus has been found to displace the coccyx, innominate, and the femoral head,[116] providing evidence of the connectivity of this layer of the pelvic floor to the hip.

New perspectives from The ISM on how the PFMs function (e.g., activation, symmetry, relaxation) suggest that whenever the pelvis is twisted (i.e., intrapelvic torsion), there is a change in the neural drive to the PFMs and symmetry should not be expected. It is important to assess PFM function in both the habitual resting position of the pelvis and then with the pelvis manually corrected to neutral alignment to truly find the correlation between the activation pattern noted and the torsion. Then it is necessary to determine what is causing the torsion of the pelvis to direct treatment to the appropriate source of the problem (i.e., find the primary driver).

Multifidus

Multifidus is known to play a significant role in segmental control of the low back[117–119] and very likely the SIJ. Its deep segmental and superficial multisegmental fibers are differentially active during loading.[118] The central nervous system matches the activation of the deep and superficial multifidus to the demands of both the internal and external environments.[119] No studies have investigated whether this muscle coactivates with TrA or the PFMs, but clinically it appears to do so when strategies are optimal. Once again, the patterns of activation are highly variable in patients with PGP and/or poor pelvic health. It is known that within 48 hours of an acute low back injury, inhibition of the deepest fibers of multifidus occurs and recovery is not spontaneous. [120–122] No studies have specifically investigated whether the same inhibition occurs with an acute injury to the SIJ. Clinically, it appears that the deep fibers of the lumbosacral multifidus behave the same way such that both L5-S1 and the unilateral SIJ on the side of inhibition are affected.

The deep fibers of multifidus are contained in a fibro-osseus compartment and act like a hydraulic amplifier[123] to stiffen the thoracolumbar fascia before loading. For this to occur, a certain size, or capacity, of the muscle is required in addition to an appropriate timing of activation.

In patients with unilateral PGP, it is common to find augmentation or increased resting tone of the superficial fibers of multifidus coexisting with inhibition of the deep fibers. This overactivation compresses the superior part of the SIJ, reducing both its active and passive mobility. It is also common in low back and pelvic pain patients to find augmentation of various parts of the erector spinae (i.e., iliocostalis or longissimus). MacIntosh and Bogduk[124] have identified the specific insertion point of each fascicle of iliocostalis and longissimus, which is interesting to consider clinically (Figure 17-22). Overactivation of longissimus from T6 to T12 will pull the sacrum cranially (i.e., increase nutation) and enhance stabilization of the SIJs because sacral nutation increases form closure of the SIJs. Conversely, overactivation of iliocostalis from T4 to T12 will pull the posterior aspect of the iliac crest cranially (i.e., increase anterior rotation of the innominate) and reduce stabilization of the SIJs (unless the circumferential deep muscles can compensate) because anterior rotation of the innominate decreases form closure of the SIJ. Both longissimus and iliocostalis can induce a "twist" or intrathoracic rotation of the specific thoracic ring to which they attach through an inferior pull on either the transverse process or the posterior aspect of the rib (see Figures 17-9 and 17-10). Thus it is important to understand the relationship between the alignment, biomechanics, and control of the thorax and that of the pelvis and to determine which region is primarily at fault—in other words, find the primary driver!

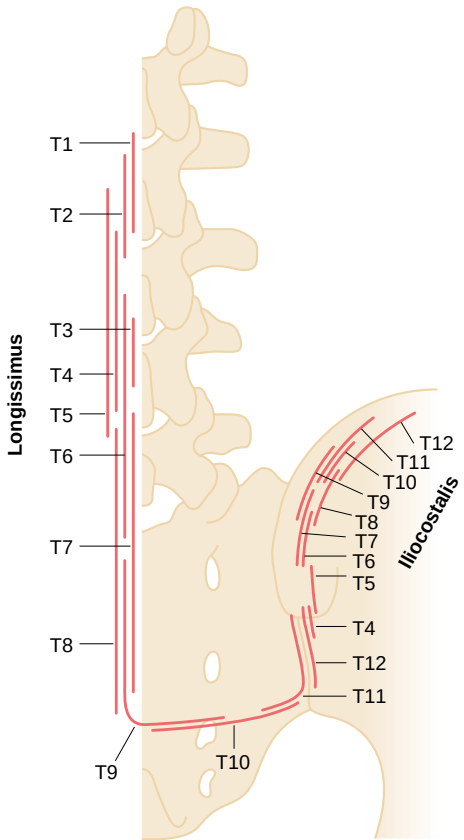

Figure 17-22 Note the specific point of insertion on the iliac crest of the fascicles of the iliocostalis muscle and on the lumbar and sacral spine of the longissimus muscle according to MacIntosh and Bogduk.[124] (Redrawn from MacIntosh JE, Bogduk N: The attachments of the lumbar erector spinae, *Spine* 16:783-792, 1991.)

Often the superficial fibers of erector spinae require specific release[29] before training of the deeper muscles[30] can begin. Sometimes, releasing the superficial muscles results in an "automatic wake-up" of the deeper muscles and no specific "cueing" or augmentation is required, whereas at other times, specific deep muscle training is required. Again, assessment is essential; no assumptions can be made in clinical practice. The following cues, asked of the patient, help to facilitate greater activation of the deep fibers of multifidus (after releasing and aligning anything that is causing the pelvis, lumbar spine, and/or thorax to twist):

1. For the sacral fibers: imagine a force, or line, connecting the posterior aspect of your hip bones (PSISs) together and gently connect along this line (bilateral cue)
2. For the lumbosacral fibers: imagine a line running from your groin through your pelvis to the L5 vertebra and connect along this line and then gently suspend (or lift, create space) this vertebra 1 mm above the one below (Figure 17-23).

Tactile cueing is given in conjunction with these verbal cues so that the brain can receive the sensory input.

Functional Muscle Units Revisited

Recently, new anatomical studies[125,126] have suggested that the back and abdominal muscles should no longer be considered independently because their fascial connections and compartments suggest that they are truly one integrated myofascial system (Figure 17-24). For example, Scheunke et al.[125] noted that forces induced by activation of the abdominals (i.e., all three layers) are transmitted to the transverse and spinous processes only if there is sufficient stiffness in the middle and posterior laminar fibers of the thoracolumbar fascia. This stiffness is, in part, generated by activation of multifidus (both deep and superficial fibers), longissimus, and iliocostalis. Again, synergy and coactivation of muscles appear to be more important than training deep versus superficial or local versus global muscles. In addition, muscular capacity (i.e., size) is critical for the generation of sufficient fascial tension, thereby enabling the effective transference of load. A DRA has the potential to disrupt this force closure mechanism if the activation of the abdominal and back muscles cannot generate sufficient tension in the LA for the transference of loads.

The goal for this part of the treatment session (connect and control) is to create (or remember) new neural networks (i.e., brain maps) for more efficient strategies. The initial training for connecting and control follows the principles of neuroplasticity and because clinicians know that "neurons that wire together, fire together,"[98] it is important to train coactivation patterns. It is also important

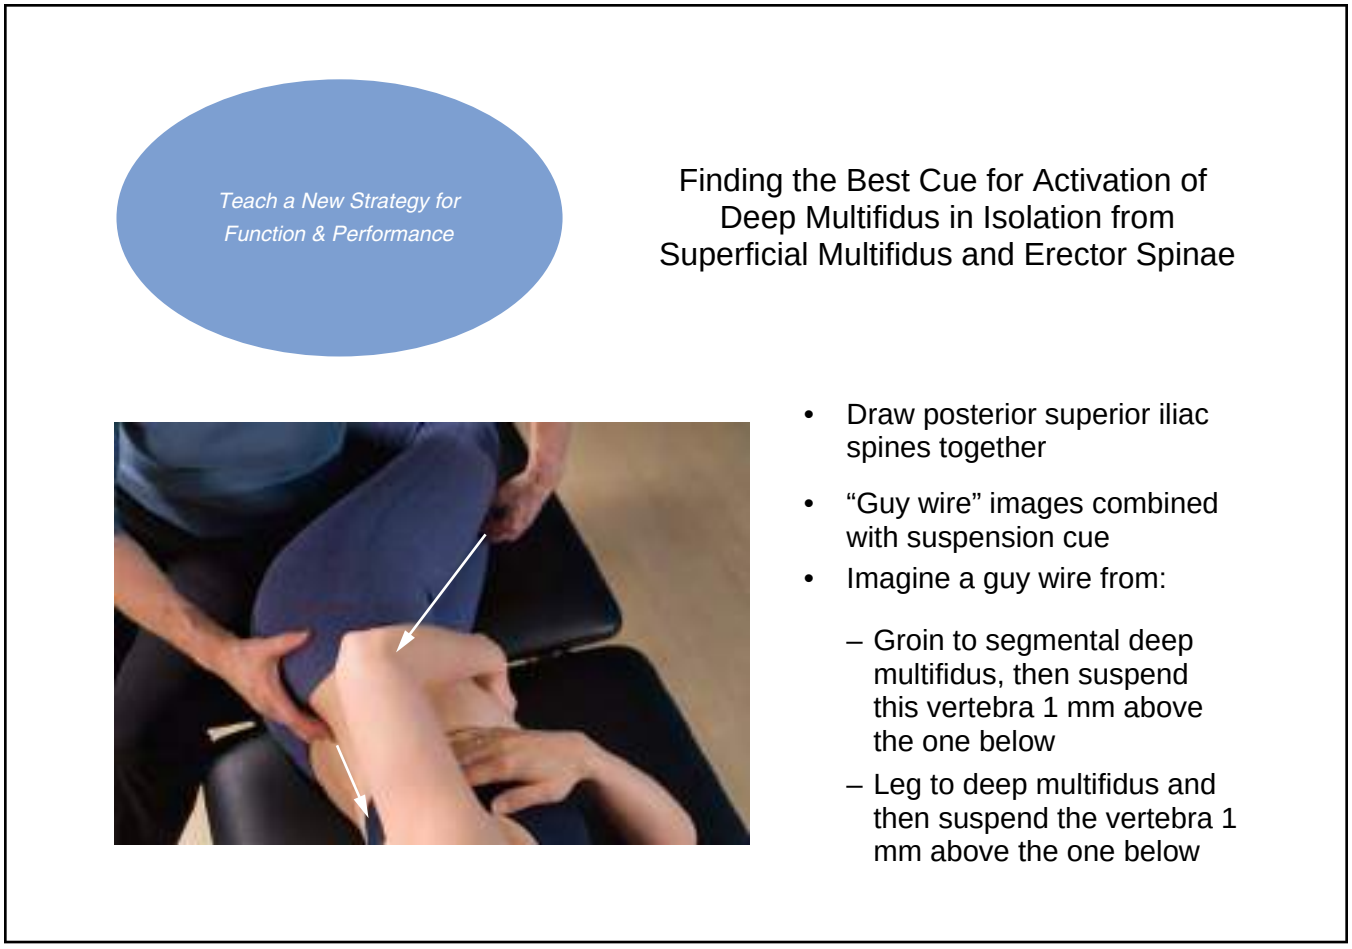

Figure 17-23 Manual and verbal cueing for activating the deep fibers of lumbosacral multifidus in isolation from the superficial erector spine. (Copyright Diane G. Lee Physiotherapist Corp.)

to ensure that the patterns being trained are task specific and meet the functional requirements of the patient.

Movement Training for the Pelvic-Driven Pelvis

The principles of neuroplasticity[98,127,128] are used to create or rewire new brain maps for more efficient strategies for function and performance. Neuroplasticity has been defined as *"The ability of the nervous system to respond to intrinsic and extrinsic stimuli by reorganizing its structure, function and connections."*[127] The nervous system is embodied[26] and therefore influenced by our thoughts, feelings, and actions. Change is constantly occurring through our entire life.

Key Factors for Facilitating Neuroplastic Change

- Focused attention with awareness
- Train tasks that have meaning
- High-quality massed practice
- Normalize the sensory input
- Provide positive feedback of performance of task
- Train specificity of task
- Prescribe visualization

Clinical Note

"There is overwhelming evidence that the brain is continuously remodeled in response to new or novel experiences. Therefore, an appreciation of the influence of the central nervous system on all forms of movement as well as pain should underpin all forms of rehabilitation."

(Snodgrass et al.[127])

Re-wiring new brain maps is not easy and requires focused attention or awareness without distractions that take attention away from the body's experience when training. Learning and change can occur when there is awareness and is facilitated when tasks are trained that have meaning. Although correct instruction of supine bent knee fallout exercises can facilitate strength and endurance of the muscles that stabilize the pelvis and these exercises do play a role in rehabilitation,[30] the enhanced performance may not cross over into functional tasks, such as a squat or single leg stand (let alone exalted warrior in yoga).

Massed practice of high-quality strategies that normalize the sensory input to the neuromatrix will increase

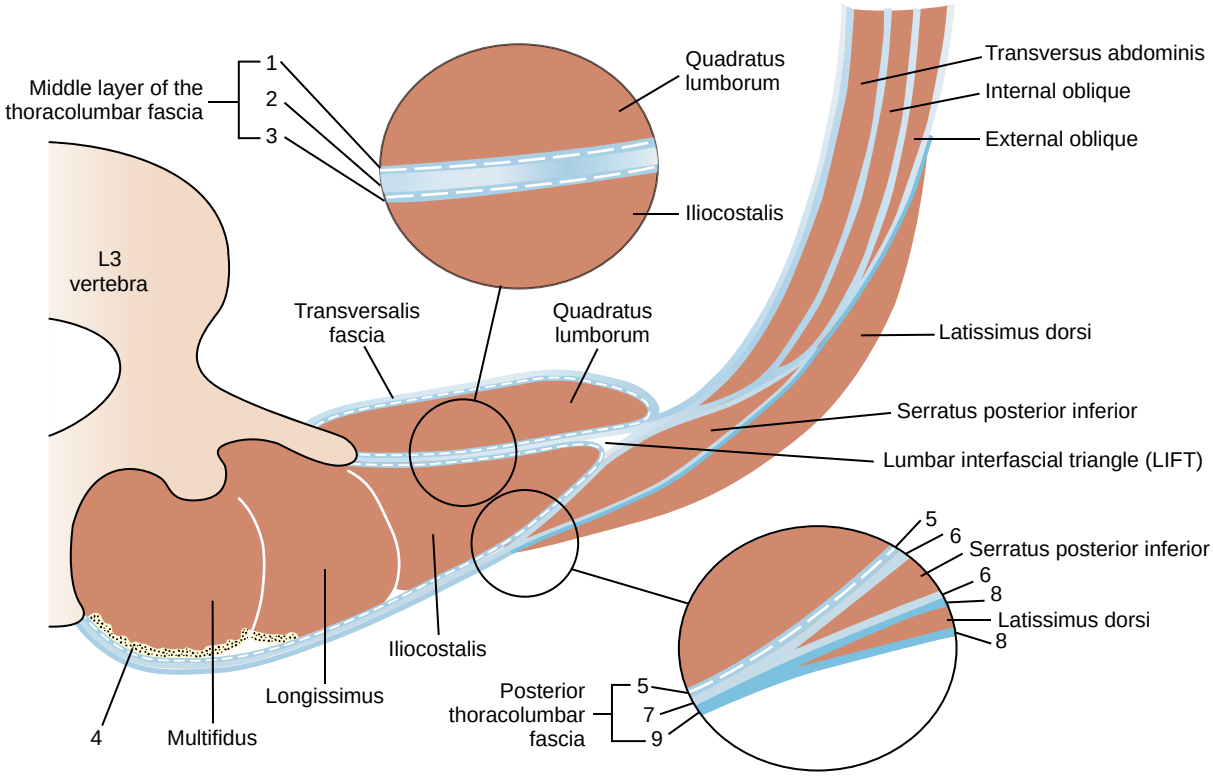

Figure 17-24 Anatomical and biomechanical studies provide evidence for training the deep and superficial systems synergistically because loads are distributed when there is appropriate coactivation such that mobility is not lost at the cost of stability. This is a transverse section of the posterior (PLF) and middle layer (MLF) of the thoracolumbar fascia and related muscles at the L3 level. Fascial structures are represented such that individual layers are visible, but not necessarily presented to scale. The serratus posterior inferior (SPI) often is not present caudal to the L3 level. The TrA muscle is covered with a dashed line on the peritoneal surface illustrating the transversalis fascia (TF). This fascia continues medially covering the anterior side of the investing fascia of the quadratus lumborum (QL). Anteriorly and medially, the TF also fuses with the psoas muscle fascia (not drawn). The IO and EO are seen external to TrA. SPI is highly variable in thickness and, more often than not, absent on the L4 level. Latissimus dorsi (LD) forms the superficial lamina of the PLF together with the SPI, when present. The three paraspinal muscles, multifidus, longissimus, and iliocostalis, are contained within the paraspinal retinacular sheath (PRS). The aponeurosis (tendon) of the paraspinal muscles (*4*) is indicated by stippling. The epimysium of the individual spinal muscles is very thin and follows the contours of each separate muscle within the PRS. The epimysium is not indicated in the present figure but lies anteriorly to the aponeurosis (*4*). The upper circle shows a magnified view of the different fascial layers contributing to the MLF. The picture shows that MLF is made up of three different structures: (*1*) this dashed line depicts the investing fascia of QL; (*3*) this dashed line represents the PRS, also termed the deep lamina of the PLF encapsulating the paraspinal muscles; (*2*) the thick dark line between the two dashed lines *1* and *3* represents the aponeurosis of the abdominal muscles especially deriving from TrA. Numbers *1*, *2*, and *3* form the MLF. The lower circle shows a magnified view of the different fascial layers constituting the PLF. The picture shows that on the L3 level, the PLF is also made up of three layers as the fascia of SPI is normally present on this level. (*5*) This dashed line depicts the PRS or deep lamina of the PLF encapsulating the paraspinal muscles; (*6*) the investing fascia of SPI is seen blending medially into the gray line marked (*7*) and representing the aponeurosis of SPI- posteriorly to the PRS; (*8*) this dark line represents the investing fascia of LD blending medially into the black line representing the LD aponeurosis (*9*) posteriorly to the SPI aponeurosis. Numbers *5*, *7*, and *9* form the PLF. Numbers *7* and *9* form the superficial lamina of the posterior layer (sPLF). (Redrawn from Schuenke MD, Vleeming A, Van Hoof T, Willard FH: A description of the lumbar interfascial triangle and its relation with the lateral raphe: anatomical constituents of load transfer through the lateral margin of the thoracolumbar fascia, *J Anat* 221:569, 2012.)

the speed of synaptic connectivity and thus the ease of use of the strategy. How much is enough? Research by Tsao and coworkers[129–131] suggested the following prescription for training new strategies for lumbopelvic control—the goal is to achieve three sets of 10, 10-second holds of the optimal strategy with a 2-minute rest in between sets and to perform this training at least twice, preferably 3 to 4 times per day. When compliant, the brain map will be consolidated and less conscious effort is required in as little as 2 weeks.[130] Patients need to have the awareness to know when they are using an optimal strategy for every training task and to only perform high-quality movement patterns. Attending to the effort it takes to perform the task (e.g., single leg lift, bent knee fallout, clam shell, squat, single leg stance with weight shift, lunge, exalted warrior) will inform patients when the strategy is optimal or not because good strategies feel good (e.g., effortless, light, less symptomatic). The gestalt of their experience improves when patients train strategies that are better for their pelvic health. Imagery, or visualization, of what a good strategy "looks like" can also help.

When designing movement training for the restoration of pelvic health, consideration must be given to the entire body or whole kinetic chain because everything can have an impact on function and performance of the pelvis.[31]

At minimum, the following regions should be monitored during training:

1. Local control of:
   a. 3 pelvic joints
   b. 2 hip joints
   c. 15 lumbar joints
   d. 130 thoracic joints (10 complete thoracic rings), and
2. Interregional control between the:
   a. Thorax and pelvis
   b. Shoulder girdle and pelvis
   c. Feet-knees and pelvis
   d. Neck-cranium and pelvis, and
3. Postural and motion control between the body and the environment.

Role of Taping and Pelvic Belts

After the system impairments driving the nonoptimal strategy have been released, it is not uncommon to find poor control of the joints of the pelvis. Compression of the pelvis will now improve both the experience and performance of meaningful tasks. Neuromuscular retraining to create new motor strategies takes time, and the provision of temporary support via taping or belting the pelvis can be useful for mechanical and neuroplastic learning purposes.[69,132–134] Although general compression of the pelvis can help, more often, specific compression of the pelvis is necessary. The COM-PRESSOR SI belt and The Baby Belly Belt™ (Figure 17-25) are designed to apply pelvic compression specifically where it is needed and this can be highly individual. Both belts have an additional elastic strap that is versatile and can be applied to the underlying belt either anterior or posterior to the SIJ. The elastic straps are applied according to which compression location makes the meaningful task easier to perform. If the task does not improve with compression anywhere in the pelvis, belts or taping will not be helpful.

Getting to "WOW"!

Changing patients' experience of their body in tasks that have meaning for them often elicits comments such as "Wow! What did you do?" This is the first step to creating new, more efficient ways for them to live, move, and simply be in their bodies. Dan Siegel[26] calls this "SNAG the brain," his acronym for Stimulate Neuronal Activation and Growth and in the ISM is called "Getting to WOW!".

CLINICAL CASE

To pull this all together, a clinical case of a young woman who does not have a pelvic-driven pelvis but rather a thorax-driven pelvis and her meaningful complaint, stress urinary incontinence, will be shared. From her story, the reader will be able to appreciate that many clinicians would have treated her pelvis directly; however, The Integrated Systems Model directed the clinician elsewhere. It is reproduced here with permission.[135]

Figure 17-25 The COM-PRESSOR sacroiliac (SI) belt (**A**) and The Baby Belly Belt™ (**B**) are two SI belts designed by Diane Lee for the application of specific compression to the pelvis. Both belts are adaptable in that compression can be applied to the front or back (or to the front on one side and the back on the other) of the pelvis and specific assessment determines the best location. (**A**, From Lee D: *The pelvic girdle*, ed 4, Edinburgh, 2011, Elsevier; **B**, from Lee DG: New perspectives from the Integrated Systems Model for treating women with pelvic girdle pain, urinary incontinence, pelvic organ prolapse and/or diastasis rectus abdominis, *J Assoc Chartered Physiother Womens Health* 114:10-24, 2014.)

Tiana's Story

Tiana is a 25-year-old nurse who does CrossFit training five to six times per week and as a consequence of this high-intensity training has had multiple muscle strains and injuries. As her ability and training increased, she noticed increasing urinary frequency. Recently, she noticed that if she did not void often she experienced stress urinary incontinence especially with tasks that loaded the trunk or increased her intra-abdominal pressure (i.e., box jumps). Tiana is nulliparous.

Tiana's Meaningful Complaint

Primary concerns for Tiana included the increasing frequency of her need to void and the increasing incidence

Figure 17-26 Tiana's meaningful task is a box jump. Note how in the landing phase of Tiana's box jump her weight is more to the right of her base of support. (Copyright Diane G. Lee Physiotherapist Corp.)

Figure 17-27 In standing, Tiana's pelvis was rotated to the right in the transverse plane (TPR right) and associated with a congruent right intrapelvic torsion (IPTR). (Copyright Diane G. Lee Physiotherapist Corp.)

of stress urinary incontinence during her CrossFit training. She was worried about the impact future pregnancies would have on her urinary continence. These key complaints, beliefs, and goals were entered into the center of Tiana's Clinical Puzzle.

Tiana's Meaningful Task and Screening Tasks

Tiana's meaningful task was a box jump and the tasks chosen to evaluate for strategy were standing posture and a squat task because each of these directly relate to her meaningful task (Figure 17-26). Tiana stood with her pelvis rotated in the transverse plane to the right (i.e., transverse plane to the right [TPR] right) and her pelvis in an intrapelvic torsion to the right (i.e., intrapelvic torsion to the right [IPTR] = left innominate anteriorly rotated relative to the right innominate, sacrum right rotated) (Figure 17-27). Her lower thorax (thoracic rings 8 to 10) was rotated to the left (i.e., TPR left lower), the seventh thoracic ring was shifted left and rotated right, and the sixth thoracic ring was shifted to the right and rotated to the left.

Correcting the alignment of the two thoracic rings (six and seven) improved the pelvic position, whereas correcting the alignment of the pelvis made the thorax posture and position worse. This suggested that the thorax was driving the pelvic position as opposed to the pelvis driving the thorax and that further investigation of what was causing the malalignment of the sixth and seventh thoracic rings was needed.

During a squat, the following sites of FLT (i.e., nonoptimal alignment, biomechanics, or control) were noted, including the timing of when they failed:

1. The seventh thoracic ring shifted further to the left and rotated to the right, and the sixth thoracic ring shifted further to the right and rotated to the left before
2. The left SIJ gave way (i.e., the left innominate anteriorly rotated relative to the sacrum)

When the alignment of the sixth and seventh thoracic rings was corrected, the left SIJ no longer failed. In comparison, when the left SIJ was controlled, the sixth and seventh thoracic rings continued to shift and rotate during the squat task, a sign of FLT. These findings suggested that the sixth and seventh thoracic rings were the primary driver and that further assessment should focus on determining what was causing the loss of alignment, biomechanics, and control of the sixth and seventh thoracic rings.

The supine bent leg raise task was not relative to her meaningful task of box jumping; however, for Tiana to know if she was correcting her thoracic rings properly, it was useful as part of her exercise training. Tiana found that more effort was required to lift her left leg (with the knee bent) than her right leg. No change in effort was noted when the twist was taken out of her pelvis (i.e., intrapelvic torsion right). However, the task was much easier to perform when the seventh thoracic ring was corrected (Figure 17-28). During this task, the sixth thoracic ring self-corrected when the seventh thoracic ring was corrected, so the focus of correction could be on just the seventh thoracic ring.

Hypothesis of Tiana's Primary Driver

Correction of the sixth and seventh thoracic rings improved the performance of Tiana's standing posture, squat task, and the ability to lift her left leg while supine. Thus these thoracic rings were hypothesized to be the primary driver. Further system analysis (i.e., neural, articular, myofascial, visceral [or combination]) was required to determine what was causing the nonoptimal alignment of the sixth and seventh thoracic rings across multiple tasks.

Figure 17-28 The active bent leg raise test was much easier for Tiana to perform on her left side when the seventh thoracic ring alignment was corrected, further supporting the hypothesis that the nonoptimal alignment and biomechanics of the seventh thoracic ring were impacting her ability to transfer loads effectively through her pelvic girdle in this task. (Copyright Diane G. Lee Physiotherapist Corp.)

Vector Analysis of Tiana's Primary Driver

When correcting the sixth and seventh thoracic rings, a resistant vector of force was felt from the left side of her upper abdominal wall. On palpation, increased tone was noted in the left EO muscle. The hypertonicity covered a number of thoracic rings and was regional, not fascicle specific. However, the primary impact was on the seventh thoracic ring. A specific fascicle of the EO muscle has the ability to anteriorly rotate one rib. However, this rib is part of an entire thoracic ring, such that when the rib anteriorly rotates on the left, it can potentially produce left translation and right rotation of the entire thoracic ring (Figure 17-29).[136] When the seventh thoracic ring was corrected, the sixth thoracic ring self-corrected, suggesting that the primary impaired thoracic ring was the seventh thoracic ring. The next question was, "What was the impact of this increased tone in the left external oblique muscle on the recruitment strategy of the entire abdominal wall?" This led to the next part of the examination, a neural system analysis of the abdominal wall.

Neural System Analysis of Tiana's Abdominal Wall

More palpable tension was noted superficially on the left side of Tiana's lower abdomen, likely due to the increased resting tone of the left EO muscle. When asked to gently contract her pelvic floor, increased activation of the left EO was palpable as an immediate first response. Ultrasound imaging revealed that the right TrA responded appropriately to this cue and the left TrA did not (Figure 17-30). When the seventh thoracic ring was corrected, there was less superficial abdominal tension and a symmetric activation of both the left and right TrA was felt and seen via ultrasound imaging (Figure 17-31).

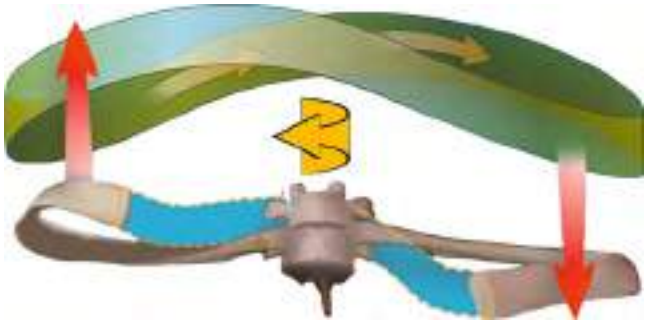

Figure 17-29 The left external oblique fascicle attaching directly to the left seventh rib can produce anterior rotation of this rib and thus right rotation of the entire seventh thoracic ring. (Copyright Diane G. Lee Physiotherapist Corp.)

Neural System Analysis of Tiana's Pelvic Floor

A transabdominal anteroposterior ultrasound evaluation of the pelvic organs and fascial support system revealed asymmetry of the bladder when the pelvis was resting in an IPTR (Figure 17-32, *A*). Contraction of the PFMs appeared to increase the asymmetry of her bladder. When the seventh thoracic ring was corrected (thus neutralizing the position of the pelvis), the shape of the bladder was more symmetric, as was the pelvic floor lift (Figure 17-32, *B*).

A transabdominal sagittal view of the pelvic floor contraction did not reveal any asymmetry because only the midline of the bladder and pelvic floor were imaged with this orientation. A good lift in an optimal location for urethral and bladder support was noted. A perineal real-time ultrasound view of Tiana's pelvic floor contraction when her pelvis was twisted (IPTR) revealed less lift (i.e., decreased amplitude) and less pelvic organ support during her cough (greater descent was seen) compared with when her pelvis was in a neutral position.

Intravaginal Examination of Tiana's Pelvic Floor

When Tiana's pelvis was in an IPTR, no activation of the left side of her levator ani was apparent on internal palpation (i.e., grade 0). The left side of the levator ani (i.e., iliococcygeus) was not hypertonic despite appearing to be elevated on the ultrasound examination. When her pelvic position was neutralized, better recruitment of the left side of her levator ani occurred immediately (i.e., grade 3); however, she could only hold this contraction for 5 seconds (i.e., an endurance deficit). Weakness and loss of endurance of the left side of the levator ani were still present in spite of removing the influence of the IPT on the recruitment strategy.

Hypothesis of Tiana's Story

The hypothesis was that Tiana had a muscle imbalance of abdominal wall (i.e., overactivation of the left EO muscle and underactivation of the left TrA muscle) creating a primary seventh thoracic ring shift to the left (i.e., seventh thoracic ring was right rotated). This thoracic ring shift appeared to be causing a compensatory rotation of the pelvis (i.e., TPR right and IPT right). There was insufficient activation of the deep muscle system (i.e., left TrA and PFM)

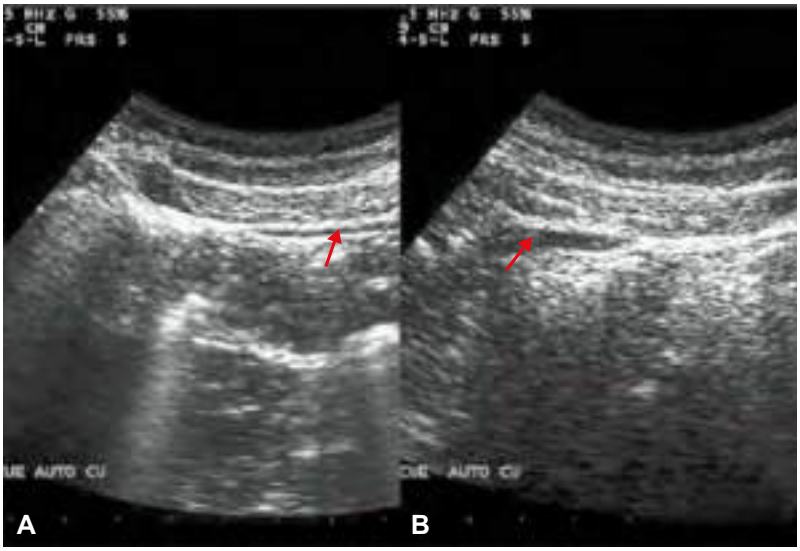

Figure 17-30 These are two ultrasound images captured from the video of the left (**A**) and right (**B**) sides of the abdominal wall in response to a verbal cue for Tiana to contract her pelvic floor muscles. Note the difference (*arrows*) in broadening and corseting of her transverse abdominis, in particular the lack of response on her left side. (Copyright Diane G. Lee Physiotherapist Corp.)

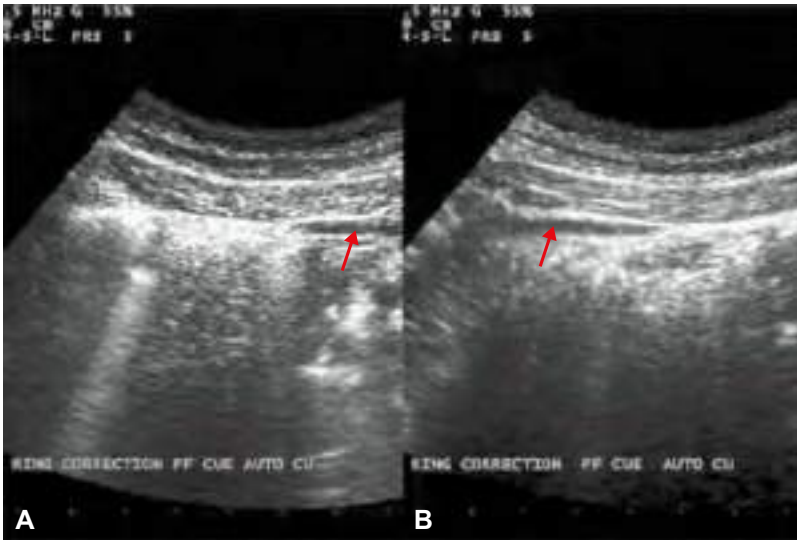

Figure 17-31 Note the increase (*arrow*) in the broadening of the left (**A**) transverse abdominis (TrA) (compared with Figure 17-30, *A*) with a verbal cue to contract the pelvic floor when the seventh thoracic ring is corrected. The broadening of the left (**A**) TrA is comparable with the right (**B**) TrA when the seventh thoracic ring is corrected (*arrows*). (Copyright Diane G. Lee Physiotherapist Corp.)

Figure 17-32 **A,** The shape of Tiana's bladder appeared asymmetric (imaged via ultrasound) when the pelvis was in a right intrapelvic torsion. **B,** Note the immediate change (*arrows*) in bladder shape when the pelvic alignment is corrected in response to the seventh thoracic ring correction. and this was a likely cause for the loss of control of the left SIJ. The mechanism that changed the recruitment strategy of the left side of her pelvic floor was unclear. What was clear was that the left side of her levator ani was not recruited when her pelvis was twisted (IPTR). Although the activation improved when the twist of her pelvis was removed, there was an underlying strength and endurance deficit on this side of her pelvic floor. Collectively, all of this was creating poor urethral, bladder, pelvic, and sixth and seventh thoracic ring support during tasks which increased loading through the pelvis and its organs (i.e., the box jump). Her complete Clinical Puzzle is illustrated in Figure 17-33.

Treatment

According to the treatment principles of the Integrated Systems Model approach, the first step was to release the vectors that were creating nonoptimal alignment of the seventh thoracic ring and then restore optimal recruitment synergies of the abdominal wall.

Tiana's Treatment Program

STEP 1: Release the left external oblique (EO) muscle and align the sixth and seventh thoracic rings

STEP 2: Home exercise:

1. Supine: hook lying—ask patient to align the seventh thoracic ring and then breathe with a lateral costal expansion strategy for three to four breaths. Then, take the patient's legs to the right on the inhale breath, hold and connect to TrA and the PFMs and then exhale to return the legs to neutral for three to four repetitions (Figure 17-34). Then, recheck the effort it takes to lift the left leg and it should be less.
2. Side-angle pose: position the left leg back and correct the seventh thoracic ring first. Next, unwind the right intrapelvic torsion, then rotate the thorax to the left to lengthen the left EO; hold this position for three breaths (Figure 17-35).

STEP 3: Connect and control and move

STEP 4: Home exercise:

1. Correct the alignment of the seventh thoracic ring, activate the pelvic floor (clinician feels for the contraction of the left side of the levator ani), and then perform three squats. (Note: The three home exercises should be performed before her CrossFit training workout.)

STEP 5: Strength and endurance training for the pelvic floor (home exercise)

1. Left side levator ani strength and endurance training: patient works up to 10 repetitions of 10-second holds in pelvic neutral, 3 times per day, at least 3 to 4 times per week. Clinician introduces both slow and fast contractions specific for CrossFit training after 4 to 6 weeks. Patient continues with intensive specific PFM training for at least 8 weeks.

FOLLOW-UP PLAN: Clinician reassesses symmetry of activation (i.e., motor control), strength, and endurance (i.e., performance) of the levator ani at 4 to 6 weeks, along with the ability to control the left SIJs, sixth and seventh thoracic rings, and maintain urethral closure during squats and box jumps. Pelvic floor muscle training can be progressed along with more advanced thoracopelvic alignment exercises as necessary at that time.

Figure 17-34 Release technique and home exercise practice for restoring adequate length and activation of the left external oblique (EO) muscle and thus the seventh thoracic ring. For the release technique, the therapist maintains the alignment of the seventh thoracic ring as the patient takes a deep lateral costal expansion breath and/or takes the knees to the right (thus, elongating the left EO). For the home exercise practice, the patient is taught to manually correct the seventh thoracic ring and to maintain the correction through the entire lateral costal expansion breath and while taking their knees to the right. (Copyright Diane G. Lee Physiotherapist Corp.)

Figure 17-35 Modified extended side-angle pose (modified Parsvakonasana in yoga) is a useful exercise for releasing and aligning both the thorax (ring specific) and the pelvis to restore the relationship and between the multiple rings of the trunk. The focus in these tasks should always begin with correcting the primary driver. (Copyright Diane G. Lee Physiotherapist Corp.)

Summary

Tiana's story illustrates how nonoptimal strategies in the thorax can drive the loss of thoracic and pelvic ring control, as well as urinary frequency and incontinence. This is not uncommon yet is often missed when these patients are assessed "from the bottom up." Urinary frequency and incontinence can be caused by impairments far removed from the pelvic floor and although local training of the PFMs is still relevant, the whole person and body need to be considered for optimal treatment of these conditions. The ISM[25] provides an ideal framework for determining where to focus treatment when treating the whole person.

CONCLUSION

The pelvis can no longer be considered as an individual entity in either assessment or treatment. It is part of a functional whole, and tests are required that reflect the essential role it plays in the function, or lack thereof, of multiple systems (i.e., posture and equilibrium, musculoskeletal, urogynecological, respiratory, digestive) and its relationship to multiple regions of the body. Nonoptimal alignment, biomechanics, and/or control from head to toe can impact function of the pelvic girdle and its organs and create a myriad of complaints. The ISM[25] helps to organize all of the available knowledge (only briefly touched on in this chapter) to understand when the pelvis is a victim (not the driver) and when it is the problem (the driver). Finding drivers requires the skill to not only interpret a finding but also find it reliably. For clinicians, visual and kinesthetic perceptions are foundational tools for assessing the human form in function. Understanding our individual strengths, weaknesses, accuracies, and misperceptions enhances our reliability and skills necessary to locate a finding. Clinical reasoning of the findings then determines its relevance to the clinical picture, which subsequently directs management of individual patients. Although clinical reasoning can be taught through texts and online media, there will always be a need for hands-on practical courses; this is the art and skill of physical therapy that is so difficult to measure with science.

CHAPTER 18

Hip Pathologies: Diagnosis and Intervention

TIMOTHY L. FAGERSON, OLADAPO M. BABATUNDE, MARC R. SAFRAN

INTRODUCTION

This chapter explores adult hip pathologies, their diagnoses, and appropriate interventions. Most hip conditions are discussed, except for hip joint arthroplasty and pediatric conditions, which are covered elsewhere in this text (see Chapters 19 and 29). Clinicians require a good working knowledge of hip pathologies, which will enable them to select, perform, and interpret the appropriate tests for the diagnostic process and then decide what interventions need to be included to treat the patient's condition most effectively. Obviously, a good working knowledge of hip anatomy is also important; thus the "**4 layer concept**" and the "**3G approach**: groin, gluteal, and greater trochanter triangles" have been elucidated upon in this regard.[1,2]

Adult hip pathologies can be divided into six subcategories based on the type of disorder (Table 18-1). It also can be helpful to think of hip disorders in relation to age because their prevalence rate often is age dependent (Table 18-2).

Another useful approach is to classify a condition based on the need for diagnostic imaging or laboratory tests to confirm the diagnosis and initiate appropriate medical or surgical management. Clinicians commonly use the following diagnostic classification system in the absence of imaging or other diagnostic testing to not only classify the patient but also assist in determining when to refer to other colleagues for further diagnostic testing. These can be applied not only to hip pathologies but also to all clinical problems.[3]

1. Diagnoses that can be made on the basis of the history and physical examination alone (e.g., sprains, strains, muscles imbalances, nerve entrapments). Rehabilitation should be initiated as appropriate.
2. Diagnoses that tentatively can be made on the basis of the history and physical examination, but further diagnostic imaging and laboratory studies are necessary to confirm the diagnosis (e.g., osteoarthritis [OA], rheumatoid arthritis [RA], herniated disc). Rehabilitation can be initiated to assist symptom management and maintain maximum function while a definitive diagnosis is pursued.
3. Red flag diagnoses (e.g., fracture, dislocation, osteonecrosis, infection, metastatic disease). These conditions require definitive medical or surgical intervention. Rehabilitation should follow when appropriate.

When possible, a diagnosis should be the lowest common denominator driving a clinical presentation. Table 18-3 presents a summary of musculoskeletal diagnoses for rehabilitation management.[4]

When one of these lowest common denominators cannot be identified or associated with an anatomical structure and pathology (i.e., if a tissue level or pathoanatomical diagnosis cannot be made), one of the next levels of rehabilitation diagnosis should be used, for example, weak left gluteus medius (i.e., an **impairment-based diagnosis**) or difficulty walking (i.e., a **functional limitation–based diagnosis**).[5] Such impairment-based or functional limitation–based diagnosis can be helpful in the physical rehabilitation realm when a clear **"active pathology"–based diagnosis** cannot be definitively made or where multiple tissue level problems exist together and do not fit a unifying diagnostic entity (Figure 18-1).

Pain is the primary reason a patient seeks outpatient clinical care. The exact location of hip-mediated pain varies. Khan and Woolson[6] reported that, of patients presenting for total hip replacement, 73% had groin pain (Table 18-4). Other common locations were the lateral hip (trochanter) and buttocks (gluteals).[6] Hip pain from OA can also refer to the anterior knee and to the low back. Sometimes these are the only symptoms produced by hip OA. Although groin pain often is associated with hip pathology, the groin is not the only place that symptoms originating from the hip are felt, nor is the groin region immune to pain referral from sources other than the hip. In contrast with the findings of Khan and Woolson,[6] a study by Wroblewski[7] rated the groin area as the fourth most common site of pain in patients with OA of the hip, behind the greater trochanter, the anterior thigh, and the knee. Hip OA can also cause medial buttock, shin, and low back pain (LBP).[7] In addition to

TABLE **18-1**

Types of Hip Disorders

Type of Disorder	Examples
Soft tissue disorders	• Bursitis • Tendonitis/tendinosis • Muscle strain • Osteitis pubis • Hip pointer • Snapping hip syndrome • Sports hernia • Contracture • Hip capsule contracture
Joint disorders	• Osteoarthritis • Femoroacetabular impingement • Labral tears • Loose bodies
Osseous disorders	• Osteonecrosis • Osteoporosis • Heterotopic ossification • Transient osteoporosis • Osteoid osteoma • Symptomatic herniation pit • Brodie's abscess
Fractures and dislocations	• Hip fracture • Femoral head fracture • Acetabular fracture • Stress fracture • Traumatic dislocation
Nerve entrapment syndromes (commonly described types)	• Piriformis syndrome • Meralgia paresthetica • Hamstring syndrome • Superior gluteal nerve entrapment
Pediatric disorders (not covered in this chapter)	• Developmental dysplasia of the hip (DDH) • Congenital coxa vara • Acute transient synovitis • Legg-Calvé-Perthes (LCP) disease • Slipped capital femoral epiphysis (SCFE) • Avulsion fracture

TABLE **18-2**

Hip Disorders Related to Age

Disorder	Age
Developmental dysplasia of the hip	Newborn/infancy
Congenital coxa vara	1-3 years
Acute transient synovitis	2-10 years
Legg-Calvé-Perthes disease	2-10 years
Slipped femoral capital epiphysis	10-16 years
Avulsed ASIS, AIIS, lesser trochanter	12-16 years
Osteoid osteoma (femoral neck)	5-30 years
Malignancy	Any age
Rheumatoid arthritis	Any age (20-40 years)
Stress fractures	14-25 years
Avascular necrosis	20-40 years
Paget's disease	≥40 years
Osteoarthritis	≥45 years
Hip fracture	≥65 years

ASIS, Anterosuperior iliac spine; *AIIS,* anteroinferior iliac spine.

TABLE **18-3**

Manual Therapy Diagnoses

Principal Diagnosis	Type of Problem
Pain	• Mechanical • Chemical
Misalignment	• Structural • Functional
Hypomobility	• Contracture • Adhesion • Restriction
Hypermobility	• Instability • Tissue insufficiency
Weakness	• Motor control • Muscle imbalance • Tissue weakness

Modified from Dyrek DA: Assessment and treatment planning strategies for musculoskeletal deficits. In Sullivan SD, Schmitz TJ, editors: *Physical rehabilitation: assessment and treatment,* ed 3, pp. 61-82, Philadelphia, 1994, FA Davis.

pain referred from the hip, the buttock, lateral hip, and groin are common sites of pain referred from the lumbar spine and sacroiliac joints.[8,9]

DIFFERENTIATING HIP DISEASE FROM LUMBAR DISEASE BY PHYSICAL EXAMINATION

Because the lumbar spine can refer symptoms to the hip region (and to a lesser extent vice versa), the clinician should always rule out involvement of the lumbar spine when a hip problem is suspected. The examination therefore may be extensive, involving the hip, lumbar spine, and pelvis. The concept of **regional interdependence** is very applicable to the lumbopelvic–hip region.[10,11] Brown et al.[12] identified a limp, groin pain, and limited hip medial rotation as signs that significantly predicted a hip problem rather than a lumbar problem.[12] Clinically, Cyriax's screening tests for a noncapsular pattern of the hip and a positive "sign of the buttock" have been identified as predictors for further workup.[13] With a capsular pattern of the hip, the pattern of hypomobility is one in which medial rotation and abduction and flexion are the most limited motions.[14] Extension and lateral rotation may also be limited; adduction is the least limited in a

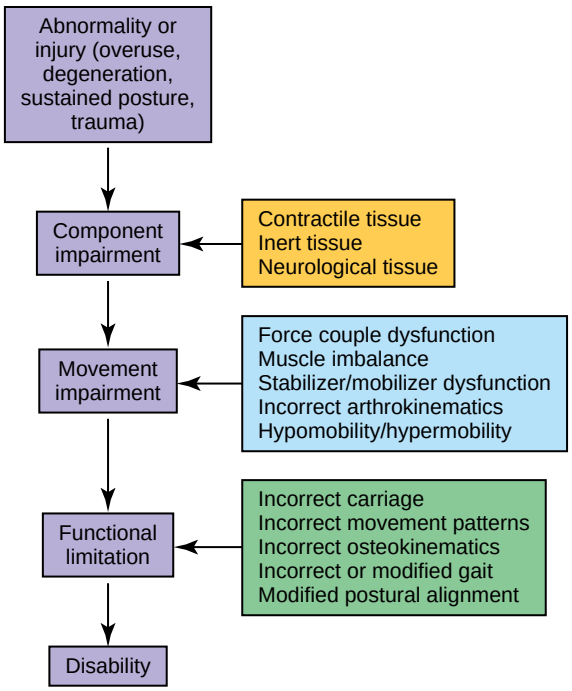

Figure 18-1 Diagnostic pathway for pathology. (Modified from Magee DJ, Zachazewski JE, Quillen WS, editors: *Scientific foundations and principles of practice in musculoskeletal rehabilitation*, p 403, St Louis, 2007 Saunders/Elsevier.)

Cyriax-described capsular pattern of the hip. It should be noted, however, that Klassbo et al.[15] warn against using hip capsular patterns as a diagnostic predictor of OA based on a study of passive range of motion (ROM) in subjects with and without hip OA.[15]

Cyriax[14] described the sign of the buttock as a means of differentiating a major lesion of the buttock (e.g., infection, tumor, fracture) from a minor lesion (e.g., bursitis, tendonitis, arthritis). Major lesions obviously are ***red flags*** indicating the need for further workup. For the sign of the buttock test, hip flexion is performed in the supine position, first with knee flexion and then with knee extension. Normally, hip flexion combined with knee flexion results in a greater hip flexion ROM than does hip flexion with knee extension because hamstring muscle tension limits the motion when the knee is in extension. However, if the hip flexion ROM is the same with the knee extended and the knee flexed (i.e., an empty end feel is noted, usually the result of pain), this is a positive sign of the buttock (Figure 18-2).[13,14]

TABLE **18-4**

Location and Frequency of Hip Pain in Patients with Intra-articular Hip Pathology

Location	Frequency (%)
Groin only	43
Trochanter only	18
Gluteal only	5
Groin/trochanter	12
Groin/gluteal	16
All locations	3
No hip pain	3
Groin only or groin with other locations	73

Modified from Khan NQ, Woolson ST: Referral patterns of hip pain in patients undergoing total hip replacement, *Orthopedics* 21:123-126, 1998.

Signs Predicting a Hip Rather Than a Lumbar Problem[12]

- Limp
- Groin pain
- Limited hip medial rotation
- Capsular pattern of the hip (i.e., medial rotation, abduction, flexion)
- Positive "sign of the buttock"

The lumbar spine can refer symptoms into the hip region and lower extremity even when the lumbar spine itself is symptom free (Figure 18-3). The L1 dermatome covers the anterior and lateral hip. The L2 dermatome covers the iliac crest (buttock) and medial thigh. The L3 dermatome covers the iliac crest (buttock) and medial thigh and knee. The cluneal nerves, which supply the skin over the buttocks from the iliac crest to the greater trochanter, originate as the lateral branches of the dorsal primary divisions of the upper three lumbar nerves. A disc herniation at L4-L5 can cause groin pain via the sinuvertebral nerve.[8]

Restricted hip movement often can be an etiological factor in LBP. Greater limitation of medial than of lateral rotation of the hip is seen more frequently in patients

Figure 18-2 Sign of the buttock test. **A**, Hip is flexed with knee straight until resistance of pain is felt. **B**, The knee is then flexed to see whether further hip flexion can be achieved. If further hip flexion can be achieved, the test is negative. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 674, St. Louis, 2014, Saunders/Elsevier.)

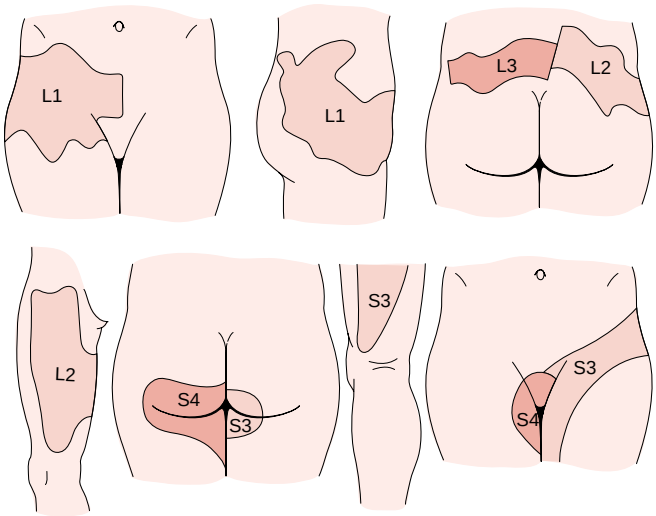

Figure 18-3 Dermatomes around the hip. Only one side is illustrated. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 731, St. Louis, 2014, Saunders/Elsevier.)

with LBP than in individuals without LBP.[16] Vad et al.[17,18] identified that professional golfers and professional tennis players with LBP had statistically significant limitations in lead hip rotation and lumbar extension.[17,18] Limited hip extension also has been correlated with an increased incidence of LBP.[19] Hip strength weakness and imbalance has also been correlated with LBP.[11]

During assessment, it should be also be noted that people with limited hip motion, as a result of OA or other hip pathology, will place more load on their lumbar spine during motion; that is, limited femoroacetabular motion will be compensated by increased lumbopelvic motion, much in the way people with frozen shoulder (i.e., limited glenohumeral motion) increase scapulothoracic motion to get their functional ROM. Also, hip pain, as in OA, may result in compensation, favoring the affected extremity, resulting in weakness of the hip abductors, which results in trochanteric bursal/gluteus medius pain.

ADULT HIP PATHOLOGIES

Soft Tissue Disorders

Soft tissue disorders are considered first, because the soft tissues are essentially the tissues the rehabilitation clinician can influence the most significantly with intervention. The ability of the living tissues of the body, especially the soft tissues, to adapt and deform to imposed demands makes strong repair and functional remodeling possible with appropriately directed intervention.

Rehabilitation clinicians usually conceptualize their role in health care using some variation of the **Nagi disablement model** (Figure 18-4).[5,20–22] Although it is often assumed from the Nagi model that impairments result from active pathology, the converse also is true: active pathology can be partly or fully caused by impairments (e.g., abnormal postural alignment and/or muscle imbalances can lead to OA). Obviously, impairments and pathology can each affect the other. Sahrmann[23] defines these differing mechanisms as the **pathokinesiology model** (i.e., pathology causing impairments) and the **kinesiopathology model** (i.e., impairments causing pathology).

Greater Trochanteric Pain Syndrome

It can be difficult to distinguish bursitis from gluteal tendinitis and other lateral hip etiologies by signs and symptoms alone. For this reason, use of the term *lateral hip pain* or *greater trochanteric pain syndrome* (GTPS) has been suggested when an anatomical source cannot be specified by physical examination.[24] GTPS has ex-

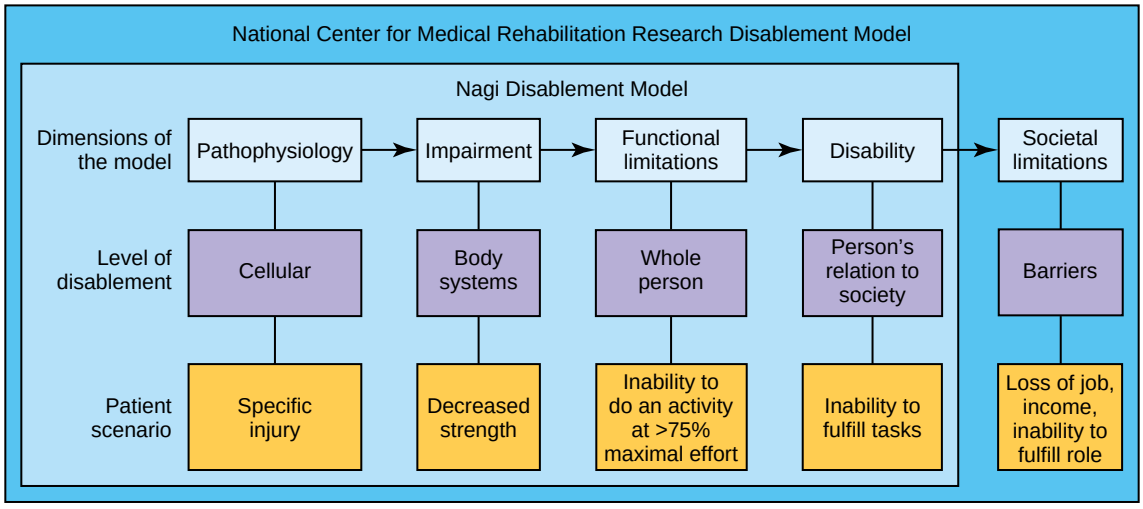

Figure 18-4 Modified disablement models: Nagi Disablement Model and National Centre for Medical Rehabilitation Research Disablement Model. (Modified from Synder AR, Parsons JT, Valovich McLeod TC et al: Using disablement models and clinical outcomes assessment to enable evidence-based athletic training practice. Part I: Disablement models, *J Athl Training* 43:428-436, 2008.)

panded as a clinical entity to cover several etiologies such as greater trochanteric bursitis (GTB), gluteus medius syndrome, gluteus medius and minimus tendinopathy, gluteus medius and minimus tears or strains, and lateral (external) snapping hip. The key to the best management relies on making an accurate diagnosis.

In these cases, imaging can be very helpful in identifying an etiology and to exclude any intra-articular causes of a patient's discomfort. Plain radiographs are initially obtained to investigate bony morphology and potential abnormalities, whereas diagnostic ultrasound can be used for soft tissue evaluation, particularly for fluid collections and tendinopathy. Magnetic resonance imaging (MRI) has become the mainstay for imaging because of the ability to comprehensively evaluate bone, chondral, and soft tissue causes for a patient's lateral hip pain. The following sections describe specific evaluation and management options for the most common anatomic causes of GTPS.

Greater Trochanteric Bursitis

In the region of the greater trochanter, three bursae are consistently present: two major bursae and one minor bursa (Figure 18-5).[25] The subgluteus maximus bursa lies between the greater trochanter and the fibers of the gluteus maximus and tensor fascia lata (TFL) muscles as they blend into the iliotibial band (ITB). The subgluteus medius bursa lies at the superoposterior tip of the greater trochanter and prevents friction between the gluteus medius muscle and the greater trochanter and also between the gluteus medius and gluteus minimus muscles. The subgluteus minimus bursa is a minor bursa lying between the gluteus minimus attachment and the superoanterior tip of the greater trochanter.

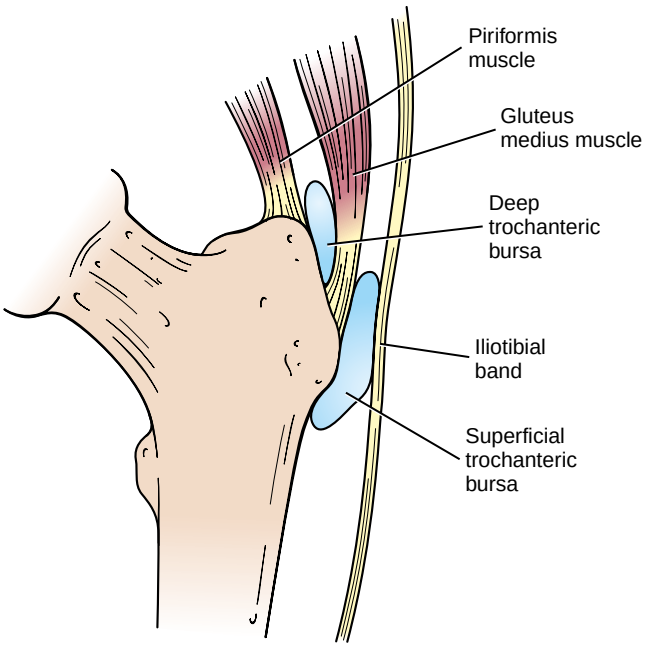

Figure 18-5 Schematic diagram of bursae around the greater trochanter.

GTB is more common in arthritic conditions, with fibromyalgia, and with leg length discrepancies. It also is more common in females than in males (2-4:1 ratio), with a peak incidence occurring between 40 and 60 years of age.[25] GTB, especially in athletes, may result from a fall onto a hard surface (traumatic GTB) or friction of the ITB over the greater trochanter during repetitive flexion/extension motion of the hip, such as occurs in running (similar to ITB friction syndrome at the knee). Those with friction-related GTB often have tightness of the hip abductors/ITB or gluteus maximus or weakness of the ipsilateral hip abductors.

GTB is characterized by an aching pain over the lateral aspect of the hip accompanied by distinct tenderness on palpation around the greater trochanter. Patients may also report pain when lying on the affected hip. A widely accepted diagnostic classification for trochanteric bursitis includes both of these features and one of three other findings (see following textbox).[26] Symptom relief through peritrochanteric injection of a corticosteroid and an anesthetic is required for more definitive diagnosis of GTB. In a study by Shbeeb et al.,[27] 77% of patients treated for GTB with glucocorticosteroid injection had relief at 1 week after the injection, and 61% had lasting relief at 26 weeks.

Clinical Criteria for Diagnosis of Trochanteric Bursitis

1. *Both* of the following symptoms must be present:
   - Aching pain in the lateral aspect of the hip
   - Distinct tenderness around the greater trochanter
2. *One* of the following three symptoms must be present:
   - Pain at the extreme of rotation, abduction, or adduction, especially positive Patrick's (FABER) test
   - Pain on forced hip abduction
   - Pseudoradiculopathy (i.e., pain extending down the lateral aspect of the thigh)

Modified from Shbeeb MI, Matteson EL: Trochanteric bursitis (greater trochanter pain syndrome), *Mayo Clin Proc* 71:565-569, 1996; data from Ege Rassmusen KJ, Fano N: Trochanteric bursitis: treatment by corticosteroid injection, *Scand J Rheumatol* 14:417-420, 1985.

Rehabilitation intervention for GTB can include modalities such as therapeutic ultrasound/phonophoresis, iontophoresis, and nonsteroidal anti-inflammatory drugs (NSAIDs) to alleviate the inflammatory response; however, treatment also should include manual therapy/mobilization techniques and therapeutic exercises to address potential causative factors, such as ITB contracture; hip flexion contracture; abnormal lumbopelvic alignment, general lumbopelvic–hip mobility, and stability; and gluteus medius weakness. The patient should be advised to avoid aggravating activities or positions, such as lying on the painful side or engaging in excessive walking or running, until the inflammatory process abates. Use of a contralateral cane can prove useful in acute and irritable cases of GTB.

Typically, GTB responds well to nonoperative management that includes rest, NSAIDs, physical therapy focused on stretching, flexibility, and strengthening. In cases when symptoms are persistent despite the appropriate nonoperative management, a corticosteroid injection into the bursa has been shown to provide good pain relief, as stated earlier. Surgical treatment is reserved for refractory cases. Although originally performed as an open procedure, most surgeons currently prefer to treat GTB through endoscopy (i.e., hip arthroscopy). The most commonly cited technique is to access the lateral compartment for greater trochanter bursectomy and inspection of the ITB and gluteal insertions. A motorized shaver to debride the bone and a radiofrequency device to maintain hemostasis are typically used. For cases in which greater trochanter wear is observed, a partial release of the ITB has been shown to be beneficial.[28]

Gluteus Medius/Gluteus Minimus Tears and Tendinosis

The quadriceps muscle has been described as "the key to the knee"; similarly, the key muscle for hip joint function is the gluteus medius muscle.[5] The gluteus medius is critical for balancing the pelvis in the frontal plane during one-leg stance, which accounts for approximately 60% of the gait cycle.[5,29] Janda[30] has described the one-leg stance as the most common posture for humans because it is the lowest common denominator during locomotion, the primary functional task that humans perform. When the gluteus medius is weak, Trendelenburg's gait pattern or a compensated Trendelenburg's gait pattern is seen (Figure 18-6). During one-leg stance, approximately three times the body weight is transmitted through the hip joint, and two thirds of that is generated by the hip abductor mechanism (Figure 18-7). To reduce this load in cases of hip pain or dysfunction, the patient often shows a compensating Trendelenburg's lean over the affected hip; this reduces the lever arm for body weight and therefore the counterbalancing hip abductor contraction. This counterbalancing effect can stress the lumbar spine, and a cane in the opposite hand is an excellent alternative.[31] The contralateral cane can act as a gait assist to unload the abductors as the patient is progressively rehabilitated. Walking is an excellent endurance and strengthening activity for the hip abductors and is preferred over specific abductor strengthening exercises if the abductors are easily irritated. A cane in the contralateral hand (Figure 18-8) can help create the noncompensatory mechanical environment that assists a weak gluteus medius and gluteus minimus in regaining their strength.

The gluteus medius has been likened to the supraspinatus in the shoulder, and the hip can sustain rotator cuff–like injuries.[32,33] If the hip "complex" were compared to the glenohumeral "complex," the likenesses would be as follows: the gluteus medius would be comparable to the supraspinatus, the gluteus minimus to the infraspinatus, the piriformis to the teres minor, the iliopsoas to the subscapularis, and the reflected head of the rectus femoris to the long head of the biceps brachii; these, along with the other deep rotators of the hip (i.e., the gemellus superior, obturator externus, gemellus inferior, obturator internus, and quadratus femoris muscles) would be considered the "rotator cuff" of the hip. The TFL and the gluteus maxi-

Figure 18-6 Compensated Trendelenburg's lurch over the left hip.

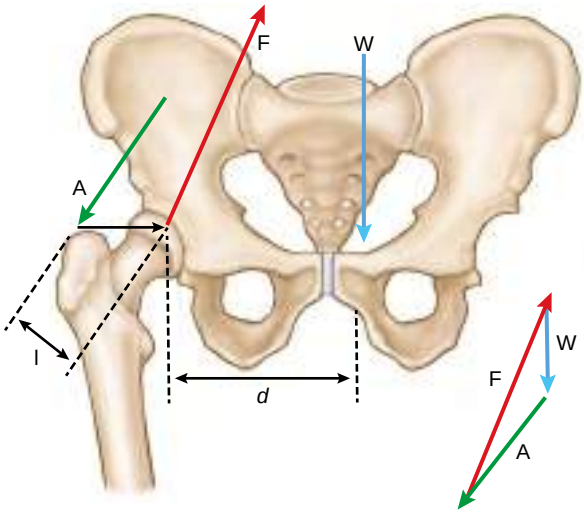

Figure 18-7 Forces acting on the hip joint during single-leg stand under conditions of equilibrium. Gravitational force (*W*), abductor muscle force (*A*), hip joint reaction force (*F*), abductor muscle moment arm (*l*), and force of gravity moment arm (*d*). (From Miller MD, Thompson SR: *DeLee and Drez's orthopaedic sports medicine*, ed 4, Philadelphia, 2013, Saunders/Elsevier.)

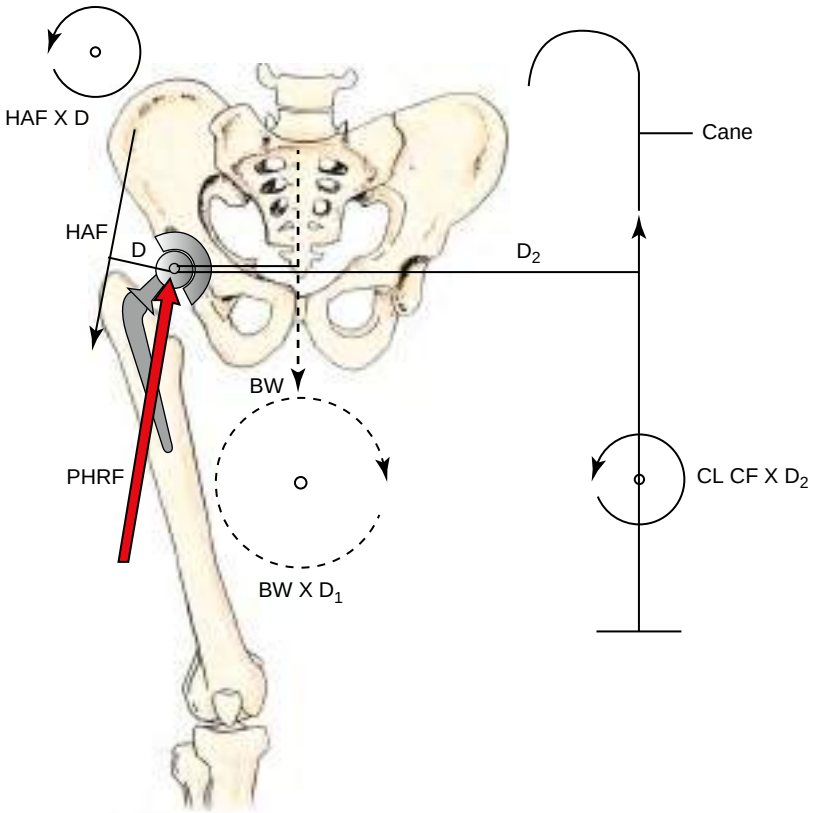

Figure 18-8 The balance of torques acting in the frontal plane about a right prosthetic hip while in single limb support. The diagram depicts a cane used contralateral to the prosthetic hip. Assuming static equilibrium, the sum of the clockwise torque produced by body weight (BW) (*dashed circle*) equals the combined counterclockwise torques produced by hip abductor force (HAF) and the contralateral cane force (CLCF) (*solid circles*). The prosthetic hip reaction force (PHRF) is shown directed toward the right prosthetic hip. The force vectors are not drawn to scale. *D,* Moment arm used by HAF; *D1,* moment arm used by BW; *D2,* moment arm used by CLCF. (Modified from Neumann DA: An electromyographic study of the hip abductor muscles as subjects with a hip prosthesis walked with different methods of using a cane and carrying a load, *Phys Ther* 79:1163-1173, 1999.)

mus, feeding into either side of the ITB proximally, act in a fashion similar to the deltoid in the shoulder; they provide a strong, superficial fascial umbrella around the hip. Sahrmann[23] emphasized the importance of enhancing motor control of the one-joint hip muscles (i.e., iliopsoas, gluteals, and deep lateral [external] rotator muscles), which control the position of the femoral head in the acetabulum, over the two-joint muscles (i.e., rectus femoris, hamstrings, TFL-ITB), which have distal attachments that are at a distance from the hip joint center.

"Rotator Cuff" Muscles of the Hip (with Shoulder Equivalents)

- Gluteus medius (supraspinatus)
- Gluteus minimus (infraspinatus)
- Piriformis (teres minor)
- Iliopsoas (subscapularis)
- Rectus femoris (long head of the biceps)
- Tensor fascia lata (deltoid)
- Gluteus maximus (deltoid)

Tendinosis and strains (tears) of the gluteus medius and gluteus minimus were a common finding in an MRI study of patients presenting with buttock, lateral hip, or groin pain.[34] Khan et al.[35] has reported that most cases of tendinopathy are, in fact, tendinosis, not tendinitis. The primary problem is collagen degeneration, not inflammation. Because differentiating tendinosis from tendinitis is difficult and because tendinosis is much more common than tendonitis, Khan et al.[35] suggested treating all cases initially as if the problem were collagen degeneration. The differences between overuse tendinosis and overuse tendonitis can be found in Table 18-5. Eccentric strengthening has been shown to be an effective method of treating tendinosis, probably because eccentric muscle action stimulates mechanoreceptors, which encourage tendon cells to produce collagen. Loading the tendon also improves collagen cross-linking and alignment, resulting in greater tensile strength.[35] As mentioned previously, walking is an excellent eccentric exercise for the gluteus medius, and it should be incorporated into any program. Other approaches (e.g., rest, ice, compression, ultrasound treatment, and anti-inflammatory medication) can and should be used when appropriate for acute injury.

TABLE **18-5**

Implications of a Diagnosis of Tendinosis Compared with a Diagnosis of Tendonitis

Trait	Overuse Tendinosis	Overuse Tendonitis
Prevalence	Common	Rare
Time required for recovery (early presentation)	6-10 weeks	Several days to 2 weeks
Time required for full recovery (chronic presentation)	3-6 months	4-6 weeks
Likelihood of full recovery to sport from chronic symptoms	About 80%	99%
Focus of conservative therapy	Encouragement of collagen-synthesis maturation and strength	Anti-inflammatory modalities and drugs
Role of surgery	Excision of abnormal tissue	Not known
Prognosis for surgery	70%-85%	95%
Time required to recover from surgery	4-6 months	3-4 weeks

From Khan KM, Cook JL, Taunton JE, Bonar F: Overuse tendinosis, not tendinitis, *Phys Sportsmed* 28:38-48, 2000.

Soft tissue mobilization (e.g., transverse frictions, passive stretching) can be helpful in the treatment of a collagen scar and can help improve tissue length.

Twelve musculotendinous structures (i.e., gluteus medius, gluteus minimus, TFL, ITB, gluteus maximus, the six short lateral rotators, and the vastus lateralis muscles) attach to or cross over the greater trochanter, making this region the "**Grand Central Station**" of the hip. The use of soft tissue mobilization techniques for muscles attaching to the greater trochanter is extremely beneficial for restoring optimal hip joint mechanics. Particularly beneficial is the application of sustained, deep pressure, load and release techniques to various points in the gluteus medius, gluteus minimus, and TFL muscles above the greater trochanter, combined with sustained ipsilateral passive hip abduction performed in the side-lying position (Figure 18-9). This technique helps release the abductor mechanism and thereby paradoxically improves hip abduction ROM by allowing the abductors to fold in on themselves. Loading the abductors just proximal to the greater trochanter with the hip in abduction also acts as a medioinferior mobilization of the hip capsule and pubofemoral ligament. Several case study–based reports have incorporated soft tissue techniques in a multimodal approach to treating the hip both nonoperatively and postoperatively.[36–38]

Figure 18-9 Hip abductor soft tissue release technique.

Corticosteroid injections in the setting of gluteus medius and minimus tears have demonstrated limited efficacy; however, surgery can be effective for patients with persistent pain despite an adequate trial of physical therapy.[39] There is some anecdotal experience suggesting that corticosteroid injections in conjunction with physical therapy may be beneficial for patients with gluteus medius and minimus tendinopathy and possibly smaller tears. Platelet-rich plasma (PRP) has also been found to be helpful anecdotally, although more research is needed in both of these areas.

Surgical treatment of persistent lateral hip pain from a gluteus medius/minimus tear is very similar to that of treating greater trochanter bursitis in that many surgeons prefer to use endoscopic techniques. Using a lateral entry point, the peritrochanteric compartment of the hip can be debrided. After inspection of the gluteal insertions, the decision can be made to debride or repair the tissues depending on the amount of tissue torn (Figure 18-10). Repair of the gluteus muscle can be achieved using suture anchors or transosseous tunnels.[40–42]

Proximal Iliotibial Band Syndrome

Proximal ITB tightness or contracture (whether that be true shortening, increased tone, tissue dehydration or a combination of these) can be a primary cause leading to a secondary effect such as GTB caused by compression and friction of the subgluteus maximus bursa between the tight ITB and the greater trochanter. Proximal ITB tightness may also be a secondary effect to a primary cause such as OA of the hip, labral tear, or gluteal tendinitis. The classic test for ITB contracture is **Ober's test**. For this test, the patient is in the side-lying position with the leg to be tested uppermost. In most cases the hip should be able to adduct so that the knee touches the table without the pelvis moving caudally. To prevent a

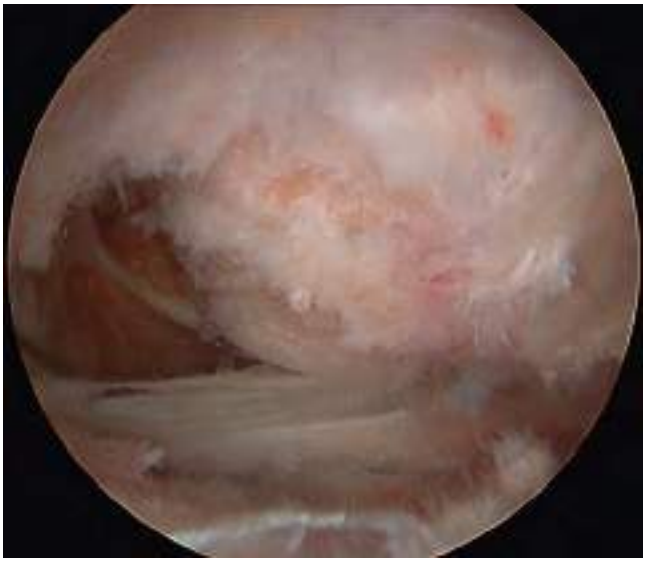

Figure 18-10 Arthroscopic picture of a medium full thickness avulsion tear of the gluteus medius.

false-negative result, the following are important: (1) the clinician should use one hand to firmly stabilize the patient's pelvis; (2) the hip should be extended to 0°, with the clinician using the other hand to engage the ITB over the greater trochanter; and, (3) the hip must not be allowed to flex or to rotate medially as the knee is lowered toward the table (Figure 18-11). To prevent a false-positive result, the clinician must ensure that the patient is fully relaxed and allows the leg to be lowered toward the table. Performing the test with the knee flexed 90° takes up slack in the rectus femoris and the anterior fascia lata and is more sensitive to change than performing the test with the knee extended. However, care must be taken to avoid excessive valgus stress to the medial knee when the knee is flexed for the test.

Figure 18-11 Ober's test.

ITB contracture is best treated using a combination of soft tissue mobilization and hold/relax-type stretching in the Ober's test stretch position. In addition, stretching of the rectus femoris and iliopsoas is important because these muscles are enveloped by the fascia lata. The patient should be taught self-stretching to maintain and improve what is achieved in manual therapy sessions (Figure 18-12). Foam rollers have become popular in the personal training arena as a means of self-mobilization of the ITB. Improving the strength and stability of the lumbopelvic region also is important to reduce tension in the ITB. The ITB and hip abductors can tighten in an ineffective attempt to compensate for lack of lumbar control and stability.

External and Internal Snapping Hip

Snapping hip is a phenomenon patients may experience in which there is an audible snap or pop as the hip moves through a ROM, usually when the flexed hip is extended.[43] It often is painless, but it can become symptomatic in athletic individuals. The syndrome is more common in young athletic females. The cause of the snapping or clicking can be intra-articular or extra-articular (Table 18-6).

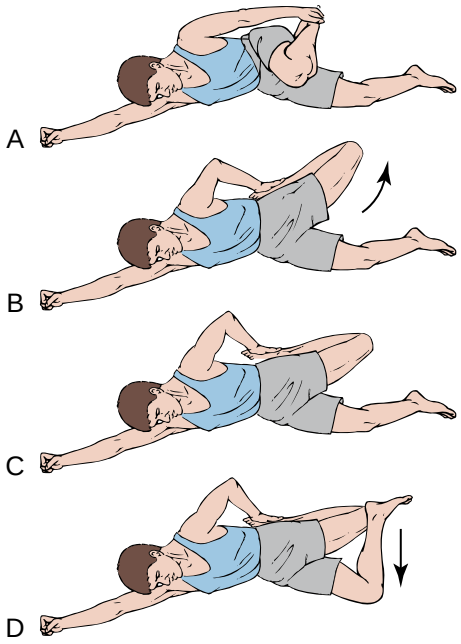

Figure 18-12 Iliotibial band stretch. The patient is in side lying with iliotibial band to be stretched uppermost. **A,** The patient flexes the upper hip and knee to grab dorsum of foot. **B,** While holding the foot, the patient extends and abducts the hip as far as possible. **C,** The patient holds the hip extended as far as possible with the knee flexed as far as possible (the heel should touch the patient's buttock on the same side) and adducts the hip. **D,** The patient lifts the opposite foot over the flexed knee and rests it on the outside of the opposite knee. The patient then uses the opposite foot (*right foot in this case*) to push the knee and thigh into further adduction. The patient should feel the stretch on the outside of the knee (*left knee in this case*) near the knee. (From Safran M, Zachazewski JE, Stone DA: *Instructions for sports medicine patients*, ed 2, p 338, Philadelphia, 2012, Saunders/Elsevier.)

Causes of Snapping Hip (Coxa Saltans)

INTRA-ARTICULAR	ANTERIOR		POSTERIOR
	Internal	External	
Loose bodies	Iliopsoas tendon snapping over pelvic brim	Iliotibial band snapping over greater trochanter	Long head of biceps femoris tendon sliding over ischial tuberosity
Synovial chondromatosis	Iliopsoas tendon snapping over femoral head	Gluteus maximus tendon snapping over greater trochanter	
Osteochondral injury	Iliopsoas tendon snapping over bony ridge on lesser trochanter		
Subluxation of the hip	Tendonitis of iliopsoas or rectus femoris		
Labral tears	Anterosuperior labrum most common site		

From Gruen GS, Scioscia TN, Lowenstein JE: The surgical treatment of internal snapping hip, *Am J Sports Med* 30:607-613, 2002.

External snapping hip can be caused by contracture or thickening of the ITB.[44] Often presenting as an audible or palpable sound as the ITB, TFL, or gluteus maximus slides over the greater trochanter during movement, this can be associated with or without pain. Diagnosis is made primarily by history and physical examination. A test for a snapping ITB is flexion of the adducted hip with the knee extended.[45] Often, patients can demonstrate the external snapping, while standing, by jutting their hip out to the affected side, and an obvious snap can be seen. Another test to demonstrate external snapping is having the patient lay in the lateral decubitus position with the affected hip away from the table. The patient then moves his or her hip, like riding a bicycle, with repetitive flexion and extension of the hip in neutral abduction. This often causes the hip to snap. Ober's test is also likely to show shortening of the ITB (see the section on ITB contracture). Plain radiographs and imaging such as MRI can be used to exclude other diagnoses such as a gluteus medius or minimus tear.[43]

Internal snapping hip is caused by the iliopsoas as it slides over the iliopectineal ridge or the anterior capsulolabral complex and femoral head. The classic test for snapping of the iliopsoas muscle over the anterior pelvic brim or hip is reproduction of the snap as the hip is extended from a position of flexion, abduction, and lateral rotation (the extension test). Although an audible clunk is often heard, it is helpful to identify the location of the snap or click by simultaneous palpation during the test. Often firm manual pressure during the extension test can reduce the snapping by preventing the lateral to medial subluxation of the tendon over the pelvic brim.[43] Other maneuvers that may reproduce internal snapping include lifting the leg of the supine patient about 46 cm (18 inches) from the examination table and having the patient actively move his or her leg from abduction-lateral (external) rotation to adduction-medial (internal) rotation. A third test has the supine patient move his or her leg from flexion-abduction-lateral (external) rotation to extension-adduction-medial (internal) rotation. Commonly, shortening of the iliopsoas muscle and malalignment of the pelvis are associated with snapping of the iliopsoas muscle.

Treatment of both internal and external snapping hips with NSAIDs and ice can be helpful in the short term. For long-term benefit, the cause of the snapping must be resolved, or at least its frictional effect must be reduced. Treatment can involve soft tissue mobilization and stretching techniques for myotendinous contractures, correction of muscle imbalances, correction of malalignment of the pelvic girdle, movement pattern adjustments to minimize or abolish the click, and prescription orthotics for patients with pronating feet.

If conservative measures do not resolve symptoms associated with snapping hip syndrome, injections into the bursa can be utilized. Surgery is reserved for those who have recalcitrant symptoms despite an adequate attempt of nonoperative management. For external snapping hip, surgery can be performed via a small open approach to the lateral hip; however, endoscopic approaches have been described and are becoming more common. Once the ITB is identified, the surgeon can resect, release, or lengthen the ITB using techniques such as removing a central ellipse of ITB, cutting the posterior portion of the ITB, or Z-plasty lengthening.[43,45] Surgery for internal snapping hip can also be performed with an open approach; however, endoscopic approaches have also been recently described. In these procedures the iliopsoas can be released from either the lesser trochanter

via a transcapsular technique at the level of the femoral neck of the hip in the peripheral compartment or off the anterior border of the acetabulum through a small capsulotomy.[46,47] All three techniques have promising results, and, in a study by Ilizaliturri et al.,[48] the transcapsular and resection off the lesser trochanter were found to have no differences in outcomes. A recent systematic review reported superior outcomes of endoscopic iliopsoas lengthening as compared with open iliopsoas lengthening.[49]

Flexion Contracture

Hip flexion contracture is common with hip dysfunction, probably as a result of protective guarding and the positioning of the hip into flexion (i.e., the resting position) in response to pain. The likely causes of hip flexion contracture can be one or more of the following: shortening of the iliopsoas muscle, shortening of the rectus femoris muscle, shortening of the TFL muscle, or contracture of the anterior hip capsule. Hip flexion contracture can occur in response to OA, after injury to the hip region, or as part of a repetitive, flexed posture or movement habit. As a consequence of hip flexion contracture, loading through the hip joint is shifted to a thinner region of hyaline cartilage in both the femur and the acetabulum, the pelvis is placed in anterior tilt with increased lumbar lordosis, and the hip extensors are placed in a state of constant, low-level muscle tension because the line of gravity shifts anterior to the center of mass.[50] Therefore it is important for the clinician to examine for flexion contracture and, if it is reversible, to intervene appropriately.

Causes of Hip Flexion Contracture

- Shortening of the iliopsoas
- Shortening of the rectus femoris
- Shortening of the tensor fascia lata
- Shortening of the anterior hip capsule

The **Thomas test** assesses for contracture of the iliopsoas muscle. In this test the hip opposite the affected one is flexed to the point of flattening the lordosis in the lumbar spine, and the involved hip then is extended. If the involved hip stays flexed (i.e., is not able to extend to 0°), this is a positive test result for a flexion contracture (Figure 18-13). For an accurate test result, it is very important to negate the lumbar lordosis. For a more sensitive assessment when compared with the opposite side and certainly when the maneuver is used for treatment, the clinician should flex the opposite knee fully to the chest. During treatment, a rolled towel can be placed immediately distal to the ischial tuberosity to minimize anterior rotation torque of the innominate during hip extension. If the hip stays abducted during Thomas's test, it is indicative of a tight TFL; if the knee cannot be flexed beyond 90° in the stretch position, this is indicative of shortening of the rectus femoris.

Figure 18-13 Thomas test. With the back flat to the table and the contralateral hip flexed, any flexion indicates a hip flexor contracture.

In addition to testing the length of the iliopsoas muscle, it is important that the clinician palpate the iliacus muscle at its origin at the internal superior rim of the iliac crest and palpate the psoas major muscle down to the inguinal ligament to assess for increased density (Figure 18-14).

To ensure that palpation of the psoas major muscle occurs, and not loading of some other abdominal structure, the examiner resists active hip flexion by asking the patient to push up with his or her thigh against the examiner's caudal hand while simultaneously, with the cephalad hand, the examiner palpates the psoas major muscle in the abdomen a few inches lateral to the umbilicus.

Clinical Note

Because of the abdominal contents, *extreme caution* should be observed if this soft tissue technique is to be used; the aortic pulse should be identified and then avoided with the soft tissue load, and female patients of childbearing age should be queried about pregnancy.

Figure 18-14 Iliacus soft tissue release.

Ely's test (i.e., prone knee flexion, then added hip extension) can be used to assess for contracture of the rectus femoris muscle; most athletes' knees can be flexed to touch the heel to the buttock in prone lying; however, the stretch should be stopped if pain is felt in the knee or lumbar spine. Hip joint capsuloligamentous contracture is distinguished from contracture of the rectus femoris by hip extension in the prone position with the knee extended and also by assessment of the end feel on a posteroanterior glide of the hip. Anterior hip capsule restriction can be treated with a combined hip extension and posteroanterior glide technique with the patient in the prone position.

Iliopsoas Syndrome (Iliopsoas Bursitis and Tendonitis)

Iliopsoas syndrome is defined as anterior hip pain associated with inflammation of the iliopsoas bursa or tendon. The condition often is the result of repetitive overuse of the bursa or tendon or sudden overload in sports. Iliopsoas bursitis or tendonitis can result from repetitive friction of the iliopsoas myotendon over the anterior femoral head or iliopectineal eminence. Signs and symptoms of this syndrome typically include tenderness in the femoral triangle over the iliopsoas myotendon, decreased hip extension ROM, hip flexion contracture, positive anterior snapping hip, and weakness of hip medial and lateral rotation at 90° hip flexion.[51] Additionally, pain with resisted hip flexion while seated may also be indicative of iliopsoas bursitis or tendinitis.

Signs and Symptoms of Iliopsoas Syndrome

- Tenderness in the femoral triangle
- Decreased hip extension
- Hip flexion contracture
- Anterior snapping hip
- Medial and lateral rotation weakness at 90° hip flexion
- Pain with resisted hip flexion while seated

Johnston et al.[51] described a hip rotation strengthening program for treatment of iliopsoas syndrome. The program consists of medial and lateral rotation strengthening exercises in sitting to the affected leg (Figure 18-15), performed daily for 2 weeks, 3 sets of 20 repetitions on the weaker rotation, 2 sets of 20 repetitions on the stronger rotation. After 2 weeks the frequency of this exercise is reduced to two to three times a week. At the 2-week point, side-lying abduction/lateral (external) rotation against TheraBand resistance is introduced (Figure 18-16), with 3 sets of 20 repetitions on the affected side and 2 sets of 20 repetitions on the uninjured side, which is continued daily for 2 weeks. At the 4-week mark a one-leg standing minisquat is introduced, keeping the knee tracking over the outside of the foot (Figure 18-17); the regimen is 3 sets of 20 repetitions on the affected side and 2 sets of 20 repetitions on the uninjured side. At this

Figure 18-15 Sitting hip medial (internal) and lateral (external) rotation (illustrated) resistance.

Figure 18-16 One-leg squat with contralateral abduction against a wall.

Figure 18-17 Side-lying hip abduction (clam) exercise with TheraBand. The focus should be on contraction of the posterior gluteus medius muscle and deep lateral (external) rotators.

point, all strength exercises were performed two to three times per week. The hip flexors, quadriceps, lateral hip/piriformis, and hamstrings are stretched daily. The patient is instructed to perform twice as many stretches on the affected side as the uninjured side and to repeat the stretches as often as possible during the day. The stretching program continues as long as the pain persists. Gluteal reeducation during gait is also incorporated with a conscious, voluntary contraction of the gluteal muscles of both the affected and the uninjured leg during the middle to late portion of the stance phase of the gait cycle. This is performed a maximum of 10 to 15 steps at a time, two or three times per day.[51] The advantages of this program are that it is cost-effective and practical for a patient to perform independently at home. Further research is necessary to corroborate the good results seen in the preliminary retrospective case series.[51]

Adhesive Capsulitis of the Hip

The capsule of the hip joint can develop a contracture similar to adhesive capsulitis in the shoulder (frozen shoulder). It can be primary or secondary and is most common in middle-aged women. Byrd and Jones[52] describe good response to manipulation under anesthetic followed by arthroscopy. The capsular pattern is the typical pattern of contracture of a joint capsule in cases of arthritis. At the hip joint, the most limited movements classically were described by Cyriax as "maximum loss of medial rotation, flexion, abduction and a minimal loss of extension."[14] Extension and lateral rotation can also be limited, and adduction is the least limited motion. In fact, as abduction range decreases, adduction range can be seen to increase in patients with progressing OA of the hip. Kaltenborn[53] described the hip capsular pattern as an extension more limited than flexion, medial rotation more limited than lateral rotation, and abduction more limited than adduction. The only difference between the descriptions of Cyriax and Kaltenborn are the contributions of flexion and extension to a capsular pattern. These authors agree that abduction is more limited than adduction and medial rotation more limited than lateral rotation in a typical capsular pattern.

The arthrokinematic motions at the hip are anterior glide, posterior glide, medial glide, long axis distraction, lateral distraction, and short axis distraction. (Short axis distraction is a pull in line with the angle of the femoral neck, whereas lateral distraction is a direct lateral pull of the proximal end of the femur.) These accessory motions are used for joint mobilization purposes, primarily to treat a capsuloligamentous restriction. Mulligan[54] described a technique combining arthrokinematic with osteokinematic motions that he called *mobilization with movement* (MWM). Short axis distraction combined with medial or lateral rotation is particularly effective for improving rotation ROM (Figure 18-18).[54] Manual posterior mobilization can be useful for assessing and treating a posterior hip capsule contracture that would limit flexion and medial rotation ranges of motion (Figure 18-19). The literature has shown support for the use of manual mobilization techniques in conjunction with a home exercise program.[55]

End feel is an important component of joint mobility assessment, both in osteokinematic assessment of the quality of overpressure and in arthrokinematic assessment of the quality of end range tissue resistance.[5] Normal end feels at the hip are soft tissue approximation for flexion and a firm, capsuloligamentous end feel for extension, medial and lateral rotation, abduction, and adduction. Abnormal end feels common at the hip are a firm capsular

Figure 18-18 Mulligan's mobilization with movement (MWM) technique to increase range of motion of hip medial (internal) rotation.

Figure 18-19 Posterior hip mobilization to stretch the posterior capsule of the hip.

end feel before the expected end range (e.g., from capsular contracture), an empty end feel from severe pain (e.g., very acute bursitis), and a bony block (e.g., from osteophytes in advanced OA).

General Muscle Strain Management

Management of muscle strains (tears) should follow a rational, evidence-based progression based on the extent, mechanism, symptoms, and healing stage of the injury. In the acute, or early, phase, the PRICEM regimen should be followed. Acute phase management should be used for the first 2 to 5 days and sometimes longer, depending on the extent of the injury. Rehabilitation then progresses through a subacute and late phase. Return to sport after a muscle strain may take anywhere from a few weeks to many months, depending on the extent of injury.[5] In addition to gluteus medius and minimus strains (see previous section), two of the more common muscle strain injuries in the hip region (i.e., hamstring strain and adductor strain) are reviewed.

Acute Injury Treatment Regimen

P	Protect injury, prevent further injury, promote healing
R	Relative rest
I	Ice/cryotherapy
C	Compression
E	Elevation
M	Modalities, medication, massage movement, mobilization

Proximal Hamstring Strains and Avulsions

Acute hamstring strains are common in sports involving high-speed movements (e.g., soccer, football, rugby) and also in dancers from prolonged end-range stretch positions.[56,57] Strains are often reported as the second and third most common injury (after knee and ankle sprains) in field sports, with it being most common in males and in positions involving explosive speed (e.g., running back, wide receivers in football).[58] Hamstring strains are, in fact, the most frequent injury in track and field and also the most common rugby training injury.[59,60] In a general sports medicine population, hamstring strains are the third most common hip or pelvic injury, after gluteus medius strain/tendonitis and GTB.[61]

Two types of hamstring injuries can occur: muscle strains/tears (grades I to III) and avulsions. Muscle strains tend to occur at the stress risers of the musculotendinous or tenoperiosteal junctions or at the site of scar tissue from a previous injury (i.e., an acquired form of stress riser). The most widely accepted theory about the hamstrings' vulnerability to injury is that they are a two-joint muscle functioning to eccentrically control knee extension and hip flexion at the same time. The biceps femoris muscle tends to be the most commonly injured component of the hamstrings, perhaps because the nerve supply to the short head of the biceps femoris is from the peroneal division of the sciatic nerve, whereas the long head of the biceps femoris and the other components of the hamstrings have their nerve supply from the tibial division of the sciatic nerve.[57,62] It is proposed that the differing nerve supplies to the biceps femoris may result in poor neuromuscular coordination between the two heads of the muscle and thus a greater susceptibility to injury.[63]

During walking and even jogging, the hamstrings are not fully recruited. It is with sprinting that high eccentric resistance from the hamstrings is required to decelerate the rapid leg swing (i.e., both knee extension and hip flexion); therefore, the hamstrings are most vulnerable to injury during sprinting. With running, the hamstrings have three primary functions: eccentric contraction to decelerate the leg swing that starts at approximately 30° flexion; eccentric contraction at foot strike to control and facilitate hip extension; and, eccentric contraction at push-off to assist the gastrocnemius in extending the knee.[62] If gluteus maximus recruitment for propulsive hip extension is insufficient at push-off, the hamstrings may have this additional role. Such hamstring dominance may be a factor predisposing the hamstring to injuries because inadequate recruitment from the gluteus maximus may result in overcompensation and strain of the proximal hamstrings.[64] Although the hamstrings are meant to assist the gluteus maximus in hip extension, they are not meant to be the primary or sole extensor.[65] For example, golfers can strain the proximal hamstring of the non–target-side leg from the propulsion required for the drive

in the golf swing. The gluteus maximus should contract strongly on the non–target-side leg during the forward swing. Inadequate recruitment from the gluteus maximus may result in overcompensation and strain of the proximal hamstrings.[64]

A hamstring injury also can occur during eccentric control of hip flexion in sports (e.g., lunging for a ball in tennis). The injury may occur when a player has not sufficiently flexed the knee, causing the hamstrings to strongly contract and lengthen at the same time. An important component of rehabilitation of such hamstring strains is emphasizing to the player the importance of bending the knees for practically everything so that, even when a lunging, top-heavy movement occurs, it does not result in sudden or cumulative tissue overload. Another theory on rehabilitation of this mechanism is to strengthen the hamstrings for this type of function with activities such as single-leg stand windmill touches (Figure 18-20). In the controlled rehabilitation environment, this activity is appropriate for the few times this movement might occur in sport. However, during sport performance, such as tennis, bending the knees should be strongly encouraged for injury prevention of hamstring strains as well as being better for stroke mechanics than lunging for the ball over a straight knee.

Strain or overload of the hamstring tissues also may result from a pelvic alignment fault or malalignment that changes the length/tension relationship of the hamstrings. Athletes with hamstring strains often show an anterior innominate tilt or rotation on the affected side, and manipulation of the sacroiliac joint can enable these patients to regain muscle function and return to activity more quickly than those treated with more conservative measures.[66] This same response has been identified with runners experiencing anterior or lateral hip pain.[67]

Figure 18-20 Windmill touches for eccentric hamstring contraction.

Recurrence of hamstring injuries is a concern because levels of recurrence range from 12% to 62%.[56,68] This recurrence suggests that rehabilitation may have been inadequate or that the athlete has returned to play too soon. These questions have driven research into what optimal hamstring rehabilitation is. Progressive eccentric loading and neuromuscular control exercises have emerged as key variables to be included in a rehabilitation program.[69] Fredericson et al.[70] recommended incorporating eccentric hamstring strengthening based on the rationale that it is the only proven treatment for chronic tendinopathies.[70]

Clinical Note

Progressive eccentric strengthening/loading and neuromuscular control exercises are the key features in a hamstring rehabilitation program followed by a progressive running and agility program.

Rehabilitation of hamstring strains using progressive agility and trunk stabilization exercises (Box 18-1) was reported to be more effective than a program emphasizing isolated hamstring stretching and strengthening.[69] Sherry and Best[69] reported that only one of 13 subjects in the core stabilization group sustained a recurrent injury during the 1-year follow-up, whereas in the static hamstring stretch/progressive hamstring strengthening group, 7 of 10 subjects had recurrent hamstring strains. A subsequent study[56] reported that a progressive running and eccentric strengthening program had similar good results as a progressive agility and trunk stabilization program in recovery of hamstring function and return to sport. No doubt each of these four variables are important in a comprehensive hamstring strain rehabilitation. Brukner et al.[68] have proposed a seven-part management plan in applying the limited evidence on recurrent hamstring strains: (1) biomechanical assessment and correction, (2) neurodynamics, (3) core stability/neuromuscular control/lumbar spine strengthening, (4) increase strength in hamstrings using an eccentric-biased program, (5) overload running program, (6) injection therapies, and (7) stretching/yoga/relaxation. Silder et al.[56] identified that MRI, despite applying optimal rehabilitation principles and being cleared for return to sport clinically, was still not normal even at 12 months following hamstring strain. This finding echoes the advice of Orchard and Best,[71] who recommend that players, coaches, and clinicians embrace the notion of *"carrying an injury"* so that, even when cleared to return to sport, the risk of reinjury be appreciated and necessary preventive steps taken in the initial weeks to months after returning to sport.

Patients with hamstring injuries who do not respond to PRICEM regimen and rehabilitation may be candidates for PRP injections. The literature has reported mixed results on the efficacy of these injections. Hamid et al.[72] found that PRP combined with a rehabilitation program decreased

BOX **18-1**

Progressive Agility and Trunk Stabilization Approach for Treating Hamstring Strains

PHASE 1*

1. Low- to moderate-intensity† sidestepping: 3×1 minute
2. Low- to moderate-intensity grapevine stepping (lateral stepping with the trail leg going over the lead leg and then under the lead leg), both directions: 3×1 minute
3. Low- to moderate-intensity steps forward and backward over a tape line while moving sideways: 2×1 minute
4. Single-leg stand, progressing from eyes open to eye closed: 4×20 seconds
5. Prone abdominal body bridge (abdominal and hip muscles are used to hold the body in a face down, straight plank position with the elbows and feet as the only points of contact): 4×20 seconds
6. Supine extension bridge (abdominal and hip muscles are used to hold the body in a supine hook lying position with the head, upper back, arms, and feet as the points of contact): 4×20 seconds
7. Side bridge (i.e., side plank) each side: 4×20 seconds
8. Ice in long sitting: 20 minutes

PHASE 2

1. Moderate- to high-intensity sidestepping: 3×1 minute
2. Moderate- to high-intensity grapevine stepping: 3×1 minute
3. Moderate- to high-intensity steps forward and backward while moving sideways: 2×1 minute
4. Single-leg stand windmill touches: 4×20 seconds of repetitive alternate hand touches
5. Push-up stabilization with trunk rotation (starting at the top of a full push-up, the patient maintains this position with one hand while rotating the chest toward the side of the other hand as it is lifted to point toward the ceiling; the patient pauses and then returns to the starting position): 2×15 repetitions on each side
6. Fast feet in place (jogging in place with increasing velocity, picking up the feet only a few inches off the ground): 4×20 seconds
7. Proprioceptive neuromuscular facilitation trunk pull-downs using a TheraBand: 2×15 repetitions to the right and left
8. Symptom-free practice without high-speed maneuvers
9. Ice for 20 minutes if any symptoms of local fatigue or discomfort are present

Modified from Sherry M, Best T: A comparison of 2 rehabilitation programs in the treatment of acute hamstring strains, *J Orthop Sports Phys Ther* 34:116-125, 2004.
†*Low intensity* is a velocity of movement that is less than or near that of normal walking; *moderate intensity* is a velocity of movement greater than normal walking but not as great as sports activity; *high intensity* is a velocity of movement similar to sports activity.
* Progression criteria: The patient is progressed from exercises in phase 1 to exercises in phase 2 when the individual can walk with a normal gait pattern and do a high knee march in place without pain.

mean time to return to play compared with rehabilitation in a randomized controlled trial of 28 patients. However, Reurink et al.[73] reported no difference in return to play in a double-blind placebo-controlled trial of 80 patients. With research on both sides of the PRP debate, it is clear that, at this time, more research is needed to definitively include or exclude PRP in the management of muscle strains.

Intramuscular corticoid steroid injections have also been described as a treatment for hamstring injuries. A study by Levine et al.[74] reported on a retrospective review of 431 National Football League players who suffered hamstring injuries. Of these, 58 players (13%) with severe discrete injuries were treated with intramuscular injection of corticosteroid and anesthetic. No complications were reported, and only 9 of the 58 players (16%) missed a game as a result of their injury. Other studies have not reported consistent clinical efficacy of intramuscular corticosteroid injections. In fact, one in vitro study has shown cortisone injections to have negative long-term consequences on muscle injury repair.[75] Thus the use of intramuscular corticosteroid injections in acute hamstring injuries remains controversial.[76]

Sometimes the injury can be so severe as to cause an avulsion of the hamstring insertion into the ischial tuberosity of the pelvis (Figure 18-21). In these cases, a good physical examination may show tenderness at the insertion or origin of the hamstrings. Although in some situations, nonsurgical management may be appropriate, these patients should have a discussion with a surgeon to determine whether surgery is best for them. Currently, the literature suggests a controversy about whether to repair acute hamstring avulsions. A study by Hofmann et al.[77] reported that hamstring avulsions managed nonsurgically yielded noticeable subjective strength deficits. Another study by Subbu et al.,[78] comparing those with acute repair versus those that are done in a delayed fashion, suggests that those with acute repairs do better. However, these studies are fraught with bias, as many patients do return to sports and do well with nonoperative treatment. Regardless, surgery is typically performed in hamstrings with a small open incision, although endoscopic techniques have also been described.[79] In both techniques, the avulsed hamstring tendon is identified and then secured to the insertion origin site using various methods such as suture anchors or interference screws.

Adductor Muscle Strains and Tendon Injuries

As in other regions of the body, contractile tissue injuries at the hip come in two forms: strain (a muscle tear) and tendonitis (acute inflammation) or tendinosis (chronic

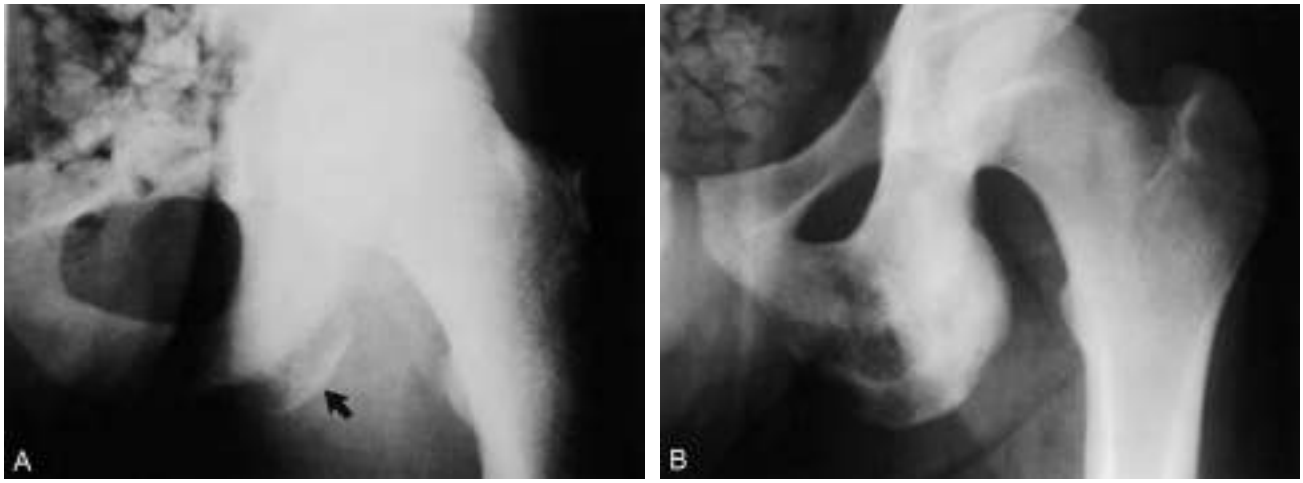

Figure 18-21 Ischial tuberosity avulsion fracture. **A**, Anteroposterior radiograph of the left hip demonstrates a crescentic hamstring avulsion fracture (*arrow*). Early callus formation is identified between the donor site and the fragment. **B**, Anteroposterior radiograph of the left hip in a different patient depicts abundant callus formation following avulsion fracture. The lesion was initially misinterpreted as tumor. (From Bencardino JT, Palmer WE: Imaging of hip disorders, *Radiol Clin North Am* 40:267-287, 2002.)

degeneration). Participants in sports such as soccer, hockey, and football are susceptible to adductor muscle pulls (i.e., a "groin" strain) because of the explosive lateral and rotatory hip movements involved, along with end range abduction stresses. Hyperabduction (overstretching) and forceful abduction of the thigh during adduction (e.g., during a soccer tackle) are the most common mechanisms of groin injury. Overuse adductor muscle injury also is common with repetitive, high-velocity limb movement that usually involves a change in direction (e.g., ice hockey or soccer). Adductor injuries usually are felt in the groin, and any of the adductor muscles can be affected, although the adductor longus is most commonly injured.[80]

Defects in the abdominal musculature (i.e., "sportsman hernia"), osteitis pubis, inguinal hernia, and referred pain from the hip joint or lumbar spine should be ruled out in any assessment of the hip. A general but useful test to differentiate abdominal injury from adductor injury is to have the patient perform a sit-up or a sit-up with trunk rotation; an abdominal injury is most likely to be painful with these maneuvers.

In a study comparing active and passive management of adductor strains, Holmich et al.[81] found the active treatment group (i.e., those who performed adductor strengthening, lumbopelvic strengthening and stabilization, and balance work) did much better than the passive treatment group (i.e., those who received transverse friction massage, transcutaneous electrical nerve stimulation, laser therapy, and adductor stretching). These findings support the notion that deficient collagen (i.e., quality and quantity) is part of the problem. An active loading program (that includes eccentric exercise) stimulates collagen synthesis and produces better long-term results than a passive loading program. Box 18-2 outlines an active loading program for adductor strain rehabilitation.

In addition to eccentric strengthening, prolotherapy (regeneration injection therapy) has demonstrated effectiveness at stimulating healing. Topol et al.[82] reported good results from dextrose prolotherapy injections in rugby and soccer players with groin pain. Schilders et al.[83] reported that pubic cleft injections gave relief for up to 1 year in competitive athletes with groin pain and normal MRI but recommended that injections be used diagnostically only if MRI demonstrated adductor enthesopathy (disorder of the tendon insertion). When conservative management has failed, selective adductor longus release has proven effective in professional athletes.[84]

Athletic Pubalgia ("Sports Hernia" or "Core Muscle Injury")

Athletic pubalgia is one cause of lower abdominal and/or groin pain that is often a **"diagnosis of exclusion"** in high-level athletes where other causes of groin pain have been ruled out.[85,86] Kachingwe and Greche[87] identified a cluster of five key findings in the clinical presentation of athletes with athletic pubalgia based on their research and a review of the literature.

This complex injury of the flexion/adduction apparatus of the hip occurs mostly in male elite athletes in ice hockey, soccer, and football who are involved in vigorous training and competition schedules and whose sport involves repetitive hyperextension of the hip along with

Key Findings for Diagnosing Athletic Pubalgia[87]

- Deep groin and/or lower abdominal pain
- Pain exacerbated by sport-specific activities (sprinting, cutting, kicking, shooting puck in hockey, hitting ball in golf) and/or sit-ups, and relieved by rest
- Tenderness on palpation of pubic ramus at insertion of rectus abdominus and/or conjoined tendon
- Pain with resisted hip adduction (at 0°, 45°, and/or 90° flexion)
- Pain with resisted abdominal curl-up

BOX 18-2

Postinjury Program for Adductor Strain

PHASE I (ACUTE)

- Rest, ice, compression, and elevation (RICE)
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Massage
- Transcutaneous electrical stimulation (TENS)
- Ultrasound
- Submaximum isometric adduction from knees bent to knees straight, progressing to maximum isometric adduction, pain free
- Non–weight-bearing hip progressive resistive exercise (PRE) with weight in antigravity position (all except abduction)
- Pain-free, low-load, high-repetition exercise
- Upper body and trunk strengthening
- Contralateral lower extremity (LE) strengthening
- Flexibility program for noninvolved muscles
- Bilateral balance board

Clinical milestone: Concentric adduction against gravity without pain

PHASE II (SUBACUTE)

- Bicycling/swimming
- Sumo squats
- Single-limb stance
- Concentric adduction with weight against gravity
- Standing with involved foot on sliding board moving in frontal plane
- Adduction in standing position on cable column or with TheraBand
- Seated adduction machine
- Bilateral adduction on sliding board moving in frontal plane (i.e., bilateral adduction simultaneously)
- Unilateral lunges (sagittal) with reciprocal arm movements
- Multiplane trunk tilting
- Balance board squats with throwbacks
- General flexibility program

Clinical milestone: Involved lower extremity passive range of motion (PROM) equal to that of the uninvolved side and involved adductor strength at least 75% that of the ipsilateral abductors

PHASE III (SPORT-SPECIFIC TRAINING)

- Phase II exercises with increase in load, intensity, speed, and volume
- Standing resisted stride lengths on cable column to simulate skating
- Sliding board
- On-ice kneeling adductor pull-togethers
- Lunges (in all planes)
- Correction or modification of ice skating technique

Clinical milestone: Adduction strength 90% to 100% of abduction strength and involved muscle strength equal to that of the contralateral side

Modified from Tyler TF, Nicholas SJ, Campbell RJ, et al: The effectiveness of a preseason exercise program to prevent adductor muscle strain in professional ice hockey players. *Am J Sports Med* 30:680-683, 2002.

trunk rotation.[86] Abdominal hyperextension with thigh hyperabduction around the pivot of the "pubic joint" has also been reported as a mechanism.[85] Often patients report an initial incident of a hyperextension injury of the hip in which the anterior pelvis or pubic symphysis is the pivot. Both the rectus abdominis and adductor longus tendons insert at the pubic symphysis and are the most common sites of pain in athletic pubalgia along with tears of the abdominal fascia.[85]

Meyers et al.[88] describe the concept of the "pubic joint," because much of athletic pubalgia pathology relates to tears of muscle attachments injured by the stresses of rotation about this dynamic pubic complex. There can be a variety of injuries involving muscle attachments in the region of the pubic symphysis primarily involving the rectus abdominus and adductor attachments (and occasionally the hip flexors).[85,86,88]

Meyers et al.[85] hypothesized that the abdominal component of the injury usually is the initial injury in athletic pubalgia and that it allows the pelvis to rotate anteriorly (as evidenced by the fact that in the cadaver, when a portion of the rectus abdominis is cut, the pelvis rotates anteriorly with ease). The anterior tilt of the hemipelvis causes a compartment syndrome in the proximal adductor muscles because the adductor muscles are now relatively unopposed as a result of injury to the lower abdominals (creating an unbalanced force couple).[85,88]

Meyers et al.[85] described their pelvic floor (abdominal) repair as a broad surgical reattachment of the inferolateral edge of the rectus abdominis muscle and its fascia to the pubis and anterior ligaments. They also performed an adductor release that involved complete division of all the anterior epimysial fibers of the adductor longus 2 to 3 cm (1 to 1.2 inches) distal to the insertion on the pubis, as well as multiple longitudinal incisions at the tendinous attachment site on the pubis.[85] Surgical repair for athletic pubalgia boasts a 95% success rate.[85,86] A typical postoperative rehabilitating protocol is outlined in Box 18-3. Athletes usually are able to return to competitive sports by 12 weeks after surgery.

A course of conservative management should be attempted for sports pubalgia before surgery is considered. A key component of conservative rehabilitation is core

BOX 18-3

Postoperative Protocol for Surgical Repair of a Sports Hernia

0-4 WEEKS

- Relative rest

4-6 WEEKS

- No resistive exercises
- Posterior pelvic tilt (5 to 6 second hold): sets of 10
- Gentle stretching (5 repetitions, hold 30 seconds each)
  - Side bending
  - Hip flexion
  - Quadriceps
  - Hamstrings
  - Adductors
- Pool exercises
  - Walking, forward and backward
  - Standing hip abduction/adduction/flexion/extension: 3×10 repetitions
  - Partial squats: 30 repetitions
  - Heel raises: 3×10 repetitions

6 WEEKS
- Progressive resistance exercises
  - Hip flexion/adduction/abduction/extension with body weight (add resistance in 1 pound [0.45 kg] increments as tolerated)
  - UE PREs: Light dumbbells
  - Cardiovascular exercises: 20 to 30 minutes in any combination of the following
    - Upper body ergometer (UBE)
    - Stairmaster
    - Stationary bike
    - Elliptical glider
- Pool exercises
  - Running, forward and backward
  - Side slides
  - Carioca
  - Jumping jacks
  - Swimming (flutter kick; *no butterfly*)

7 WEEKS
- Previous exercises, increase weights as tolerated
  - Strengthening
    - Abdominal crunches
    - Bridging
  - Jogging: 0.5 mile (0.8 km)
  - Backward jog: 100 yards (91.4 m) × 5 repetitions

8 WEEKS
- Previous PREs
- Trunk stabilization exercises
  - Lunges
  - Swiss ball
  - Crunches
  - Bridging
  - Obliques
  - Superman
  - Trunk extension
  - Reverse fly
- Jogging: mile (0.8-1.6 km)
- Backward jog: 100 yards (91.4 m) × 5 repetitions
- Agility drills
  - Sprinting: 50 yards (45.7 m); avoid sudden starts and stops
  - Figures-of-eight
  - Cariocas
- Plyometrics
  - Rope jumping
  - Side to side
  - Front to back

9 WEEKS
- Previous exercises
- LE PREs
- Sport-specific drills
  - Soccer—*No* shooting or long volleys

10-12 WEEKS
- Continued increase in exercise with the goal of return to play at 12 weeks after surgery

UE, Upper extremity; *PREs,* progressive resistance exercises; *LE,* lower extremity.

Modified from Meyers W, Ryan J: Drexel University College of Medicine, Department of Surgery, Hahnemann Sports Medicine Center.

strengthening, including emphasis on eccentric adductor and oblique abdominal strengthening.[89] A particularly effective form of core strengthening for athletic pubalgia uses diagonal elastic tubing resistance between the upper and lower extremities. Alex McKechnie[88] developed this approach and has had considerable success using it with professional athletes. A key component of this method is to have the patient simultaneously contract the pelvic floor and transversus abdominis and hold a low-level contraction while performing activities such as squats, lunges, and sport-specific moves repetitively, with additional core resistance coming from a TheraBand wrapped around each thigh and held in the contralateral hand (Figures 18-22 and 18-23) or by using the commercially available Core X System.

Joint Disorders

Osteoarthritis

OA is a complex disorder of synovial joints characterized by deterioration of articular cartilage and new bone formation, resulting in joint pain and dysfunction.[90] Radiographically, the deterioration of articular cartilage presents as joint space narrowing, and new bone formation presents as osteophytes. The hip is one of the more common sites of involvement, and OA of the hip affects approximately 1.5% of the adult population in the United

Figure 18-22 McKechnie squat with TheraBand. Note the TheraBand is wrapped around ankles, thighs, and hands so that when the TheraBand is stretched, it resists diagonal patterns of movement.

Figure 18-23 McKechnie lunge with TheraBand.

States.[91] Pain from OA of the hip usually is felt in the groin, lateral hip, and/or buttock.[6,7,91,92] Substantiated clinical presentation for hip OA is typically moderate anterior or lateral hip pain with weight bearing; age older than 50 years; morning stiffness for less than 1 hour; and limited hip medial (internal) rotation and flexion by 15° or more compared with the nonpainful side.[91,92]

OA can be divided into primary and secondary types. **Primary OA** occurs without some predisposing mechanical alignment factor. **Secondary OA** is the end result of another disease process. Eighty percent of OA of the hip is secondary in nature.[93] Predisposing factors to secondary OA of the hip are disorders such as osteonecrosis, Legg-Calvé-Perthes disease, developmental dysplasia of the hip, slipped capital femoral epiphysis, congenital coxa vara or coxa valga, and hip fracture.

The primary signs and symptoms of OA are joint pain and stiffness. Radiographically, OA is characterized by joint space narrowing in the weight-bearing region and by osteophyte formation (Figure 18-24). RA, on the other hand, shows uniform joint space narrowing, which progresses to protrusio acetabuli (i.e., protrusion of the femoral head through the acetabulum) at the end stage. Routine radiographic views of the hip usually are sufficient to diagnose OA. Routine views for the hip are an anteroposterior (AP) pelvic view (which captures both proximal femurs, the pelvis, and the distal lumbar spine), AP hip view, and lateral hip view (either true lateral or frog lateral).

Clinical Presentation of Hip Osteoarthritis

- Pain in the lateral hip, groin, and/or buttock, especially on weight bearing
- Age older than 50 years
- Morning stiffness for less than an hour
- Medial rotation and flexion limited by 15° or more compared to unaffected side
- Joint space narrowing and osteophytes on x-ray

Routine X-Ray Views for the Hip

- Anteroposterior (AP) pelvis
- AP hip
- Lateral view (either true lateral or frog lateral)

Figure 18-24 **A**, Normal hip joints on plain x-ray film, AP view. **B**, Osteoarthritis of the hip joint. Note the superior and lateral joint space narrowing, subchondral sclerosis, superior acetabular bone cyst, medial femoral neck, and lesser trochanteric sclerosis with buttressing. (From Frontera WR, Silver JK: *Essentials of physical medicine and rehabilitation,* Philadelphia, 2002, Hanley & Belfus.)

Advanced OA of the hip (i.e., radiographic evidence of OA with persistent severe symptoms or functional loss) can be effectively treated with total hip arthroplasty (THA), as discussed in Chapter 19. Because THA is not without risks and limitations, it is reserved for more advanced cases of OA that have not responded to medical management. A number of nonoperative (medical) approaches can be used to manage OA, including pharmacological and nonpharmacological measures. Nonpharmacological methods include patient education and physical and occupational therapy, which have been described as the foundation of treatment for patients with OA[94] and also help in postsurgical recovery should surgery become the treatment of choice.

Rehabilitation management of OA of the hip should be directed toward maintaining function, relieving symptoms, preventing deformity, and educating the patient in ways to protect the hip joint.[92] Function can be maintained by changing the person to fit the environment or by changing the environment to fit the person. Examples of factors that can be changed in the person are inflammation, joint alignment, ROM, and muscle length and strength. Changing the environment may involve activity modification, adaptive equipment, home modifications, and social services.

In published trials of nonmedicinal and noninvasive treatments for hip OA, aerobic-type exercise has been shown to have the greatest benefit.[95] Exercise therapy with the goals of improving muscle function (i.e., endurance, strength, and coordination), ROM, pain relief, and walking ability has been shown to be effective for OA of the hip.[96] However, in a study by Hoeksma et al.,[55] manual therapy for the hip was reported to be even more effective than exercise therapy in improving pain, stiffness, hip function, and ROM. The manual therapy these researchers used was stretching of the iliopsoas, quadriceps, TFL, sartorius, adductors, and gracilis with a hold time of 8 to 10 seconds for each muscle, repeated two times. The stretching was followed by a series of five traction manipulations (i.e., long axis traction), as described by Cyriax,[97] starting with the hip in the maximum loose-packed position; with each subsequent manipulation, the hip was placed in a position of more restriction.[55,97]

Combinations of manual soft tissue techniques, joint mobilization, and manual stretching are very effective in improving ROM and muscle length, reducing pain, and improving gait and other functions. A published case study[98] reported that ROM, strength, function, and gait can be improved and pain reduced in a person with hip OA who follows through with a rehabilitation program that includes manual therapy, therapeutic exercise, and education that addresses the presenting impairments. Patients with progressive OA may eventually need a hip replacement when walking becomes too painful, but the appropriate rehabilitation intervention can delay the operation and make for a better postoperative outcome. Delaying hip replacement too long, however, especially if function and exercise capability are significantly limited, is not wise, because it can result in worsening cardiovascular health in particular and prolonged or incomplete recovery.[99]

The decision to work on improving a joint's ROM depends on whether that joint's range can be expected to increase and whether the hip currently is functionally limited. The decision as to whether the joint's range can be increased depends primarily on the end feel. If the end feel is a bony block, the joint's range cannot be changed. If the end feel is not a bony block, the joint's range may be changeable. A balance between symptoms, range, and function must be found. Much of the pain from OA arises from the inflammatory process. In most cases, reducing inflammation produces concomitant symptom relief and functional improvements. A rationale for improving ROM is that restricted motion could be causing an inflammatory response as a result of abnormal joint surface arthrokinematics. If this hypothesis is not supported by treatment, the approach for improving ROM must be modified or discontinued.

It is important to teach the patient the principles of hip joint protection, especially considering that normal gait causes approximately three times the body's weight to load through the hip during walking (see Figure 18-7). These protection principles can be grouped into body weight reduction, load carrying modification, and assistive device use. For every pound of body weight lost, a 3-pound reduction in load through the hip occurs; therefore body weight reduction is an admirable goal. However, the weight-bearing exercise required to lose body weight can irritate the hip. Pool exercises, swimming, and upper body workouts can be used for weight reduction without exacerbating hip inflammation. Workouts on stationary bikes and rowing machines also are often well tolerated until OA is more advanced.

Hip Joint Protection Principles

- Weight reduction
- Exercise modification
- Load-carrying modification
- Use of assistive device

When the patient needs to carry something, it should be as light as possible and should be carried on the patient's back in a knapsack. If a unilateral load is carried, it should be carried on the side of the hip problem. A cane should be used on the side contralateral to the hip problem. Both the contralateral cane and ipsilateral load advice are based on the opposing torque forces.[100] For example, during one-leg stance on the right leg, the right hip has body weight creating a counterclockwise torque and the hip abductors creating a clockwise torque (see Figure 18-8).

Use of a cane in the contralateral (left) hand or holding a weight in the ipsilateral (right) hand also creates a clockwise torque about the right hip, thereby assisting the right hip abductors in clockwise torque generation.

Besides rehabilitation intervention, medication is an important component of nonoperative treatment for OA. The main indication for the use of medication in OA is pain relief.[94] Acetaminophen is recommended for mild to moderate pain because its efficacy is comparable with that of NSAIDs for this level of pain, and it has a more favorable side effect profile, provided the dosage does not exceed 4 g per day. NSAIDs are recommended for moderate to severe hip pain and in cases in which acetaminophen does not provide significant relief or the clinical presentation suggests significant inflammation.[94] Because of the cardiovascular risks associated with the cyclo-oxygenase-2 (COX-2) inhibitors, the nonselective traditional NSAIDs ibuprofen and naproxen are usually recommended as a first line of treatment. However, celecoxib (200 mg daily [qd]) and naproxen (500 mg twice per day [bid]) appear to be safer than other agents with regard to cardiovascular risk.[101] For long-term use of a nonselective NSAID, or in individuals with an increased risk of an upper gastrointestinal adverse event, a proton-pump inhibitor is recommended.[94]

Other pharmacological measures for hip OA are intra-articular injection of glucocorticosteroids, intra-articular injection of hyaluronan, and opioid analgesics (e.g., Tramadol).[94] Some patients find that glucosamine and/or chondroitin sulphate help take the edge off their symptoms.

Femoroacetabular Impingement

Although femoroacetabular impingement (FAI) was first recognized as a mechanism for early hip OA in 1965, it was not until recently that increased interest in this condition as a primary etiological factor behind labral tears and OA has been considered.[102,103] FAI has been identified as the most common cause of end-stage OA in young men and a common cause in young women.[104] Three mechanisms of impingement have been identified: **cam impingement**, caused by jamming of an abnormal femoral head (e.g., from pistol grip deformity) into the acetabulum with increasing hip flexion; **pincer impingement**, which occurs when the acetabular rim contacts the femoral head–neck junction at end range of flexion, causing a leverage of the opposite side of the femoral head up against the postero-inferior edge of the acetabulum; and the most common **mixed/combined type** that has components of both cam and pincer.[105]

Mechanism of Hip (Femoroacetabular) Impingement

- Cam
- Pincer
- Mixed/combined

Symptoms of FAI typically are seen in athletic, younger, and middle-aged individuals who experience groin pain with sports activity. The pain initially is intermittent and can be aggravated by increased athletic activity, especially in those involving end range hip movements, prolonged walking, and prolonged sitting.[105]

The **hip impingement test** is described as hip flexion to 90° and medial (internal) rotation of the adducted hip; this elicits groin pain with a positive test result.[105] Although this test is called the impingement test, it is not pathognomonic of FAI. The imaging workup should include an AP pelvis radiograph, along with a lateral view, which gives good visualization if either flattening of the normally concave femoral neck (i.e., a pistol grip deformity) and/or a nonspherical femoral head is present (Figure 18-25). The lateral view may either be a cross table lateral, a Dunn view, or modified Dunn view. Computed tomography (CT) scan can be a helpful adjunct in measuring acetabular version.

Conservative treatment involves activity modification to avoid the impingement positions and NSAIDs to reduce inflammation. To maintain a higher level of function and to manage pain, the surgeon and patient may opt for arthroscopic debridement/resection of the source of impingement through contouring of the femoral head and neck to a more normal anatomy (i.e., cheilectomy—surgery to remove bone spurs) or resecting part of the acetabulum that is overhanging. A periacetabular osteotomy may be needed if an acetabular torsion problem is present.[106] During surgery, debridement or repair of labral tears and debridement or microfracture may be indicated in the management of any chondral lesions that are present.[107] Further studies, including level I studies, are required to fully determine the cost benefit ratio and functional outcome of early operative intervention to prevent continued progression of OA of the hip.

Capsular Laxity and Microinstability

Capsular laxity and atraumatic hip instability can be a challenging diagnosis for the clinician and are less com-

Figure 18-25 Plain x-ray film of the pelvis showing a "pistol grip" deformity of both proximal femora. This deformity is so named because the nonspherical femora resemble pistol grips. (From Shetty VD, Villar RN: Hip arthroscopy: current concepts and review of literature, *Br J Sports Med* 41:64-68, 2007.)

mon reasons for hip discomfort. However, instability, even microinstability, can be a cause of significant hip dysfunction and lead to labral tears and/or chondral damage. Capsular laxity and instability may be either a result of microtrauma and overuse or ligamentous laxity in conditions such as Marfan's syndrome or Ehlers-Danlos syndrome. In these patients, the history is very important because the patients can usually describe the motion that reproduces symptoms. Patients may also state that their leg "gives out" or they have a painful pop. On physical examination, increased passive ROM may be noted with soft endpoints, especially with lateral (external) rotation in extension. Hyperextension of the hip with lateral (external) rotation may also reproduce their symptoms. Radiographs will either be normal or may demonstrate some evidence of dysplasia such as a lower center-edge angle.[108,109]

Rehabilitation for hip microinstability is focused on strengthening of the muscle around the hip, proprioception training, core strengthening, optimization of muscular balance, and patient education about "at-risk" postures and movement habits. Often, patients with microinstability have an element of dysplasia (i.e., undercoverage of the femoral head) that enables them to achieve the extremes of ROM often required in their craft (e.g., dancers, gymnasts). The ability to control open-chain extreme range with one hip and closed-chain extreme range with the other hip is often an activity requirement (e.g., ballet). When an athlete is recovering from an injury that may involve hip microinstability, Pilates has been advocated as an effective non–weight-bearing strengthening and motor control environment before progressing to the demands of weight-bearing routines.[110]

If rehabilitation does not resolve the patient's symptoms, surgery may be warranted. Typically, an MRI is obtained before surgery to identify other pathological conditions that may be contributing and that may need to be addressed at the time of surgery. The preferred method for treating capsular laxity and microinstability in cases in which there are no large bony abnormalities is through an endoscopic technique. After routine portal placement, the hip is evaluated for any osseous, chondral, labral, and soft tissue or capsular defects. If identified, these are treated appropriately. With regard to capsular laxity, both thermocapsular shrinkage and capsular plication have been described. Thermal capsulorrhaphy is performed using a radiofrequency probe to heat the capsule and shrink it, thus reducing capsular volume.[108] There have been reports on the success of thermocapsular shrinkage; however, many surgeons are concerned with complications such as chondrolysis and nerve damage secondary to the elevation of joint temperature that have been seen in the shoulder.[110,111] Arthroscopic capsular plication of the hip performed by placing sutures in the medial and lateral limbs of the iliofemoral ligament and securing knots to tighten the capsule. This is repeated until the desired effect is achieved. Short-term results have been promising.[111,112]

Postoperative management after capsular repair involves protecting the repair from elongation by restricting motions that would stress the repair until a sufficient cicatrix (i.e., scar) has formed. For example, after an anterior capsule repair (which is by far the most common), extension and lateral (external) rotation would be limited to neutral (0°) for the first 2 to 3 weeks followed by 3 weeks of gentle motion. A continuous passive motion (CPM) machine is often used for the first 2 to 4 weeks and weight bearing limited to 20 pounds foot flat for the first 2 to 4 weeks. It is important to encourage neutral rotation during gait and to prevent lateral (external) rotation when lying supine (CPM is useful for this and foot wraps are used when out of the CPM). Flexion may also be limited to 90° for the first 10 days and a hip brace worn to help with adherence to sagittal and transverse plane motion restrictions. A gradual progressive rehabilitation process is followed to obtain a good balance between hip stability and mobility with an approximate return to sport 4 to 6 months postoperatively.[113]

Labral Tears

With the advances in MRI imaging and the increasing use of arthroscopy at the hip, labral tears have been found to be more common than previously thought (Figure 18-26). Acetabular tears are one of the most common indications for hip arthroscopy. It is believed that labral tears may precipitate and/or accelerate the process of OA; however, recent studies have reported that up to 70% of asymptomatic individuals have labral tears.[114,115] Most labral tears (86%) are in the anterior quadrant of the labrum.[116] Chondral lesions double in the presence of a labral tear, and 40% of patients with a labral tear have severe chondral lesions.[116]

The mechanism for labral tears is often associated with either repetitive microtrauma associated with pivoting and twisting movements in sports or with a specific traumatic event. The specific traumatic event often involves extension and lateral (external) rotation, with the femoral head moving anteriorly and overstressing the anterior labrum.[116] However, atraumatic tears are also found, and recent research has indicated bony abnormalities such as FAI and dysplasia being present in a nearly 90% of patients who end up being treated with surgical arthroscopy.[117] Once the labrum has been torn, instability can occur in the joint and may lead to abnormal arthrokinematics and possibly further cartilage and labral damage. Less commonly, microinstability can be the primary cause of labral damage.[118]

The symptoms of a labral tear usually are mechanical in nature: buckling, catching, painful clicking, and restricted ROM. Several special tests have been described to assess for labral pathology; these tend to be variations of two primary tests[118-120]:

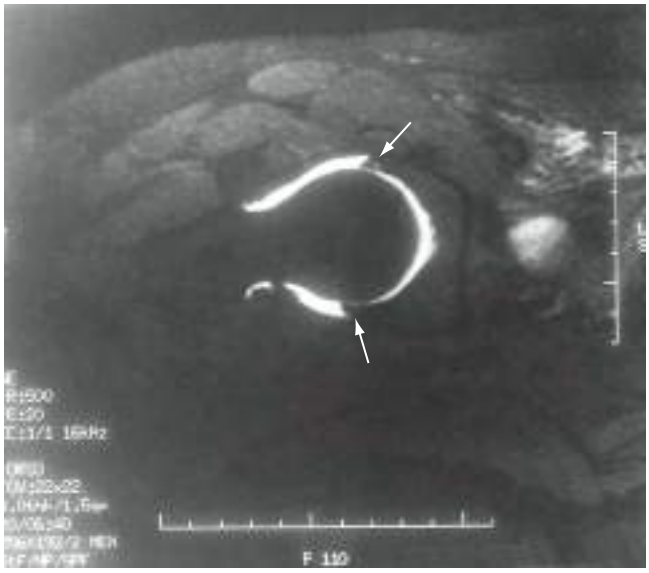

Figure 18-26 Magnetic resonance arthrogram showing an acetabular labral tear. (From DeLee J, Drez D, Miller M: *DeLee and Drez's orthopaedic sports medicine*, ed 2, Philadelphia, 2003, Saunders.)

1. The **hip impingement test** involves medial rotation of the flexed and adducted hip while it is held in at least 90° flexion and at least 15° adduction. If pain is not reproduced with the test performed slowly, a rapid application of the medial (internal) rotation at end range can reproduce symptoms. This test is suggestive of a wide range of anterior hip disorders, including anterior labral tear, anterosuperior impingement, and iliopsoas tendonitis.
2. The **hip apprehension test** consists of lateral (external) rotation of the extended hip. If symptoms are not reproduced, a rapid application of end range lateral (external) rotation can be performed. With a positive test result, this maneuver elicits apprehension or groin pain and suggests anterior hip instability, anterior labral tear, or posteroinferior impingement.

The **McCarthy hip extension sign** is a further test for labral pathology. In this test, both hips are flexed, and while the uninvolved hip is kept flexed, the involved hip is extended from the flexed position first in lateral (external) rotation and then in medial (internal) rotation. Reproduction of the patient's pain is a positive test result. McCarthy considered positive results on three different tests to be the key to predicting labral pathology: (1) pain with the McCarthy hip extension sign; (2) painful impingement with hip flexion, adduction, and lateral (external) rotation; and (3) inguinal pain on a resisted straight-leg raise.[121]

McCarthy's Signs Predicting Hip Labral Pathology

- Positive McCarthy hip extension sign
- Painful impingement on hip flexion, adduction, and lateral rotation
- Inguinal pain on resisted straight-leg raise (Stinchfield resisted hip flexion test)

The active and, if necessary, resisted straight-leg raise in the early range (test 3 in McCarthy's three-test battery) has been labeled the Stinchfield resisted hip flexion test, and the result is often positive with intra-articular disorders such as labral tears, arthritis, synovitis, occult femoral neck fractures, and prosthetic failure or loosening.[122] It also is positive with rectus femoris tendinitis and/or iliopsoas tendonitis/bursitis.

Fitzgerald[123] described the following variations to differentiate anterior from posterior labral tears. To test for *anterior* labral tears, the hip first is flexed with lateral (external) rotation and full abduction and then extended with adduction and medial (internal) rotation. A positive test result is hip pain with or without an associated click. To test for *posterior* labral tears, the hip is first fully flexed, adducted, and medially (internally) rotated. It then is extended with abduction and lateral (external) rotation. Again, a positive test result is pain with or without an associated click.[123]

Millis and Kim[120] found that MRI with gadolinium enhancement provides a more sensitive and specific diagnosis of labral tears than was previously possible (although it does not identify all tears present on arthroscopy), and arthroscopy provides a means to resect or stabilize the tear.[124]

Surgical treatment of labral tears is typically performed arthroscopically. Using portals in the hip, the surgeon can assess the joint and the degree of labral and or chondral involvement by doing a diagnostic arthroscopy (Figure 18-27). Next, the surgeon will proceed to either debride the unstable flap of labrum or repair it (often based on the location of the tear, as the labrum has limited blood supply, and thus, limited capacity to heal). For repairs, usually the substance of the labrum is intact, and the labrum injured at

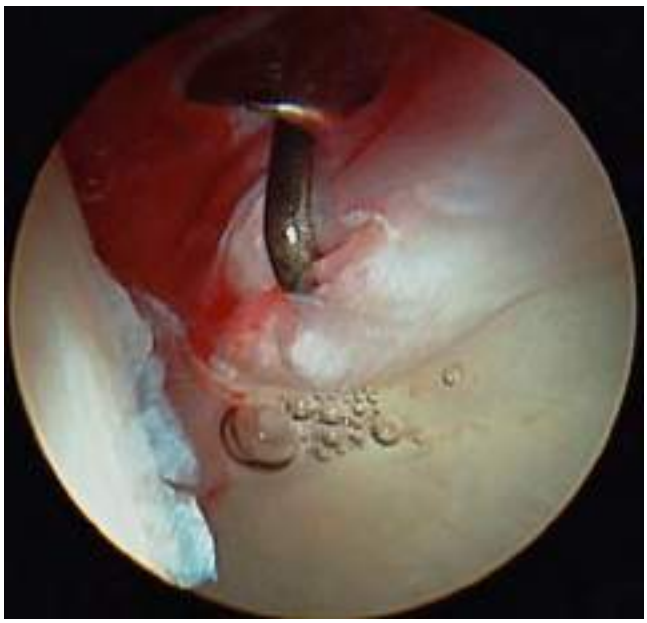

Figure 18-27 Labral tear seen arthroscopically.

the acetabular rim. The labrum is mobilized and a suture anchor is placed at the edge of the acetabulum. The sutures are then passed around or through the labrum and secured with knots or via a knotless technique.[125]

Focal Cartilage Injuries

Focal cartilage injuries can occur in association with FAI or in isolation. Focal cartilage injuries from FAI are typically the result of delamination from impingement and/or shearing from microinstability (Figure 18-28). Additionally, traumatic injuries can cause focal cartilage loss from axial loading or shear of the head within the socket (Figure 18-29). These types of injuries can often be difficult to diagnose and be an elusive source of hip pain. The pain typically occurs immediately after injury but may come and go. Persistent pain and symptoms of catching or clicking should warrant advanced imaging such as an MRI to evaluate the joint. If cartilage injury is found, it often does not respond well to nonoperative treatment, and referral to an orthopedic surgeon is recommended. Recent advances in hip arthroscopy and surgical techniques have provided surgeons with several options to treat these types of injuries. Both open and hip arthroscopy techniques can be used to perform chondroplasties or stabilize loose cartilage flaps or even microfracture areas of exposed bone (Figure 18-30). There have been some reports of chondral repair, although the capacity of the cartilage to heal is limited, and the viability of the chondral flaps has been shown to be abnormal.[126,127] Another surgical option is to do a cartilage transplant procedure; however, there are limited reports on this technique.[128]

Ligamentum Teres Injuries

There is no universal agreement on the ligamentum teres' contribution to hip function and pathology. Advances in hip arthroscopy has brought renewed interest in its function because it has allowed for direct visualization. Recent research suggests that the ligamentum teres may have analogous function to the anterior cruciate ligament (ACL) in the knee.[129] The ligament controls hip rotation in flexion. The ligamentum teres consistently tightens to limit hip abduction, medial (internal) rotation, and lateral (external) rotation, as shown by Martin et al.,[130] where they dissected eight cadavers and measured hip kinematics with regard to the ligamentum teres. Biomechanical testing has shown a similar load to failure, and anatomic studies have reported similar structure to the ACL.[131,132] Furthermore, the free nerve endings in the ligamentum teres suggest it may be involved in both proprioceptive and pain reception for the hip.[133] Another study by Martin et al.[134] reported increased hip excursion with a sectioned ligamentum teres particularly when the hip was laterally (externally) rotated in flexion and medially (internally) rotated in extension.

Diagnosis of ligamentum teres tears can be particularly challenging, as there are no definite history features or physical examination findings. Practitioners typically report that patients have nonspecific signs of hip irritability such as a positive log-roll test or pain with flexion, adduction and medial (internal) rotation. O'Donnell et al.[135] have recently reported a new test called the **ligament teres (LT) test.** The LT test is conducted with the hip flexed at 70° and 30° short of full abduction. The hip is then medially (internally) and laterally (externally) rotated to its limits of motion. Pain on either medial (internal) or lateral (external) rotation is consistent with a positive LT test result. O'Donnell et al.[135] found that this test was an effective way of assessing the presence of LT tears with moderate to high interobserver reliability. There is also a correlation with tears of the LT and symptoms of instability as reported by Martin et al.[130] who found that five of nine cases with arthroscopically proven ligamentum teres rupture had demonstrated symptoms of instability. Advanced imaging with MRIs has also proved to be challenging, because the findings are not always reliable. Byrd and Jones[136] were able to make the preoperative diagnosis of a ligamentum teres rupture in only 2 out of their 41 cases.

Surgical treatment has historically been focused on debriding the torn or injured ligamentum teres with a shaver or radiofrequency probe. If the cause of the ligament tear is present and identified, it should be addressed at the same time. There have also been reports of ligamentum teres reconstruction.[137,138] However, at this time, there is limited outcome data and reports have focused solely on techniques. More research is needed to determine not only whether this should be performed but also based on what indications.[139,140]

Loose Bodies

Loose bodies have been more frequently diagnosed in the hip with improved arthroscopic technology and technique—and more easily removed. In fact, treatment of symptomatic loose bodies has been described as the most widely reported and accepted application for arthroscopy of the hip.[141] Loose bodies are classified as ossified or nonossified. The ossified group is more frequently diagnosed because the ossification can be visualized on plain x-ray films. The primary symptom of loose bodies is anterior inguinal pain with locking episodes during hip movements. Other signs and symptoms include painful clicking, buckling, giving way, and persistent pain with activity.[141] Loose bodies can damage the articular cartilage of a joint, therefore prompt diagnosis and treatment are essential to prevent progression to OA.

Although arthroscopy has become the ideal method of addressing loose bodies definitively, Cyriax[14] described a technique for repositioning a loose body that may have some temporary benefit in lieu of arthroscopic removal. Cyriax[14] likened his technique for loose body treatment to repositioning a pebble in your shoe: you shake it around until it moves to a pain-free position. Cyriax[14] described loose bodies as presenting with sudden, sharp pain on weight bearing. The technique for "reducing" a loose body in the hip involves applying strong, long axis traction to the hip while it is in 80° flexion and then lowering the hip to 0° flexion while maintaining the traction and applying several small amplitude, high-velocity lateral (external) rotation maneuvers. If this method is unsuccessful, the procedure is performed again, but this time small thrusts into medial (internal) rotation are used. The effect on pain and function should be dramatic if indeed a mobile loose body is the culprit. The clinician should not persist if the treatment is not effective after several

attempts, but if it works, it should be repeated as needed. It should be noted that there are no outcome reports on Cyriax loose body manipulation technique. If conservative treatment does not provide lasting relief, arthroscopy may be necessary to remove the loose bodies (Figure 18-31).

Hip Arthroscopic Technique Considerations

It is important for a rehabilitation specialist to understand the basics of hip arthroscopy. To start, the setup for hip arthroplasty is very different than other orthopedic procedures. The patient can be positioned either lateral or supine on a special table that helps distract the hip while the surgeon is able to work inside the joint (Figure 18-32). The hip needs to be distracted to allow the surgeon access to the central compartment—within the confines of the acetabulum. Because the hip is a deep structure surrounded by layers of soft tissue, fluoroscopy is necessary to provide guidance during the surgery. Portal placement is the most fundamental and often the most challenging for the surgeon and is extremely important to optimize maneuverability and access around the hip joint. Additionally, poor placement can increase risk to important neurovascular structures around the hip (Figure 18-33). After successful establishment of both viewing and working portals, the surgeon then can use special hip arthroscopy tools to treat the pathology identified (Figure 18-34). The acetabular articular surface, the labrum, the ligamentum teres, and the femoral head articular surface are structures within the central compartment and can be seen and treated while the hip is distracted. With current techniques, traction is used to provide the distraction to the central compartment and is limited to 2 hours. Outside of the central compartment, cam deformities of FAI and usually loose bodies are seen along the femoral neck. These structures are within the joint capsule in an area called the peripheral compartment. An incision in the capsule in the peripheral compartment allows access to the iliopsoas for lengthening. Access to the

lateral structures that cause greater trochanteric pain, such as trochanteric bursitis, external snapping hip, and gluteus medius tears are performed without traction.

Rehabilitation after Hip Arthroscopy

Numerous papers and also basic science research on rehabilitation of the hip following hip arthroscopy have been published over the last decade.[142–145] An example of one such protocol is provided in Figure 18-35. To optimize outcome and to reduce risk of complications, rehabilitation professionals treating postoperative hip arthroscopy patients should familiarize themselves with rehabilitation guidelines, in addition to the surgical and patient-related factors of the individual case.

Rehabilitation should progress through four fundamental stages: (1) protection and mobility, (2) controlled stability, (3) strengthening, and (4) return to activity.[142] Progression is based on both criteria and healing time/experience. There are variations in rehabilitation guidelines based on whether surgery was a debridement only, involved a labral repair, involved cam or pincer impingement bone shaving/trimming, involved capsular repair, or involved chondroplasty with or without microfracture. The rehabilitation professional should make sure he or she knows the surgical details, postoperative orders, and rehabilitation progression guidelines of the surgeon and/or surgery type for each patient. Typically, the rehabilitation process is 3 to 6 months after hip arthroscopy, which

may vary depending on the type of surgery and individual patient response.

The ideas of Sahrmann[23] are worth incorporating into both the nonoperative and postoperative rehabilitation of patients with labral pathology. Sahrmann emphasized the importance of keeping the femoral head well seated in the acetabulum. This requires accurate diagnosis of the movement impairment syndrome, followed by prescription of the appropriate stretches, motor control and strengthening exercises, and patient education. Sahrmann has identified 11 movement impairments at the hip, of which anterior femoral glide is the most common. **Anterior femoral glide syndrome** can result in injury to the anterior labrum of the hip through a directional susceptibility of the hip into extension (common in runners and dancers), which causes the femoral head to increase pressure against the anterior joint structures, causing irritation and injury. Anterior femoral glide syndrome can also cause impingement of anterior hip structures (e.g., the iliopsoas myotendon and anterior labrum) as a result of inadequate posterior glide of the femoral head during hip flexion. For treatment, the clinician should advise the patient to avoid activities and exercises that load the anterior labrum (e.g., into end range extension and/or lateral [external] rotation); prescribe exercises and activities that encourage posterior glide of the femoral head (e.g., rocking back and forward in the quadruped position while hinging at the hips with the back held flat in the neutral spine position); and emphasize control of one-joint hip stabilizers (e.g., iliacus, gluteus maximus, and posterior gluteus medius) and deemphasize two-joint stabilizers (e.g., hamstrings, rectus femoris).[23]

Sahrmann's Movement Impairments of the Hip

- Femoral anterior glide syndrome without medial rotation
- Femoral anterior glide syndrome with medial rotation
- Femoral anterior glide syndrome with lateral rotation
- Hip adduction syndrome without medial rotation
- Hip adduction syndrome with medial rotation
- Femoral lateral glide syndrome
- Hip extension with knee extension
- Hip extension with medial rotation
- Femoral hypomobility syndrome with superior glide
- Femoral accessory hypermobility syndrome
- Hip lateral rotation syndrome (shortened piriformis)

Osseous Disorders

Osteonecrosis

Osteonecrosis is a multifactorial disease in which osteocyte death occurs in the femoral head via a variety of proposed pathogenic pathways. It has both clinically and radiographically recognizable patterns to aid diagnosis. Osteonecrosis can occur anywhere in the body but is most common in the head of the femur.

The two general subtypes of osteonecrosis are traumatic osteonecrosis and nontraumatic osteonecrosis. The traumatic type often occurs secondary to a hip fracture or dislocation, and, for this reason, displaced femoral neck fractures are treated by surgically replacing the femoral head. With a hip dislocation, the risk for osteonecrosis is increased if hip reduction is not performed within 8 hours.[146]

Types of Osteonecrosis

- Traumatic
- Nontraumatic

In the nontraumatic type of osteonecrosis, the symptoms are hip pain (often a fairly abrupt onset of severe pain), decreased hip ROM, and stiffness. These symptoms are not specific to this condition, and no specific physical examination tests exist for osteonecrosis. The examiner therefore needs to rely on the history as the clue to pursue diagnostic imaging that would result in a definitive diagnosis. The male-to-female ratio for osteonecrosis is 4:1. The most common age range for onset is between the third and fifth decades. Bilateral involvement is seen in more than 50% of cases. ***Red flags*** for nontraumatic osteonecrosis include a history of corticosteroid use, alcohol abuse, or sickle cell disease. Clinicians should keep in mind that plain radiographs are not sensitive to osteonecrosis in the early stages; therefore being alert to any historical red flags is crucial. MRI is sensitive and specific for diagnosing osteonecrosis (Figure 18-36), and the classic MRI finding is the crescent sign. The crescent sign is seen early on MRI as decreased signal indicative of the necrotic bone; when the crescent sign is observed on plain films at a more advanced stage of the disease process it is from a subchondral fracture between necrotic bone and healthy bone.

Red Flags for Hip Osteonecrosis

- History of corticosteroid use
- Alcohol abuse
- Sickle cell disease
- Gaucher's disease (a genetic disease in which fatty deposits accumulate in cells and certain organs including bone)

Treatment for osteonecrosis covers the gamut of surgical options for treatment of the hip. Mild cases respond well to surgical core decompression, in which a hole is drilled up into the femoral head to release pressure and provide a pathway for new blood vessels to grow into

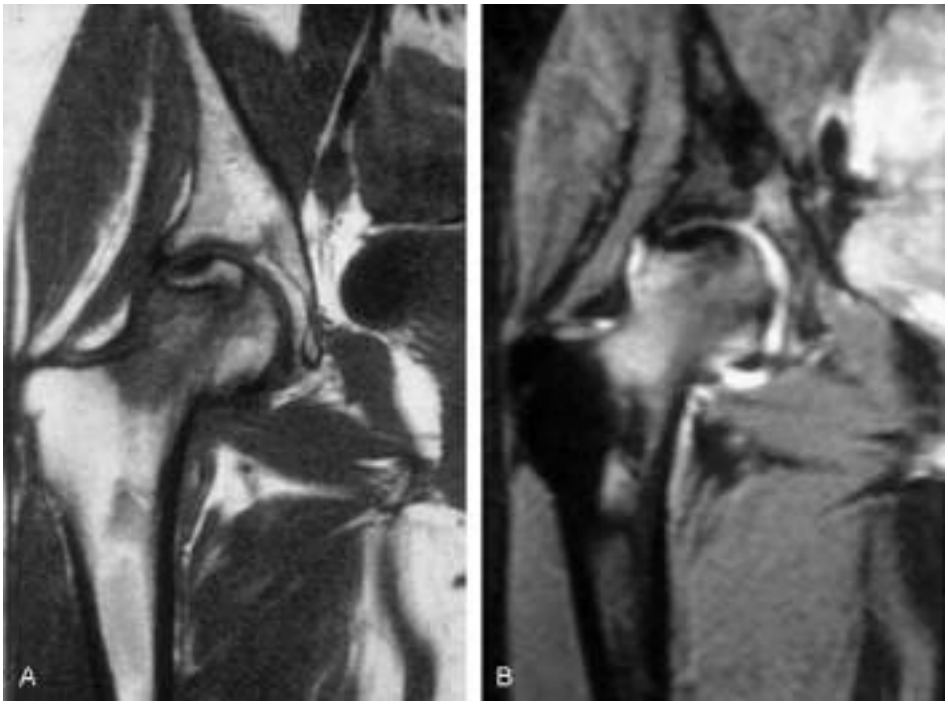

Figure 18-36 Osteonecrosis. Corresponding coronal T_1-weighted (TR/TE, 600/20) (**A**) and fat-suppressed fast T_2-weighted (TR/TE, 4000/70) (**B**) spin-echo magnetic resonance images reveal an area of osteonecrosis in the right femoral head, with associated articular collapse and joint effusion. Note the diffusely distributed abnormalities in the femoral head and neck compatible with marrow edema and the crescent sign on the superior femoral head. (From Resnick D, Kransdorf MJ: *Bone and joint imaging,* ed 3, p 1076, Philadelphia, 2005, Saunders.)

the area of necrotic bone. Moderately severe cases can be treated by osteotomy or vascularized fibular grafts. Severe or late stage cases require hemiarthroplasty or total hip replacement.[147]

It is important for clinicians to be aware of osteonecrosis because patients may be seen for hip pain that is mistakenly thought to be of soft tissue origin, when the real source of symptoms is osteonecrosis.[5] The prognosis is much better if the problem is diagnosed in the early stage, when core decompression can be performed.

Osteitis Pubis

Osteitis pubis is the most common inflammatory disorder affecting the pubic symphysis, which is part of the pelvis not of the hip.[148] It can, however, refer symptoms to the hip area. Generally, it is a self-limiting inflammation that occurs secondary to overuse, trauma, pelvic surgery, or childbirth. Although it can occur at any age, it is most common in males in their third or fourth decade. Those most at risk are athletes who participate in sports involving repetitive shearing forces at the pubic symphysis and multidirectional deceleration and acceleration forces (e.g., soccer, ice hockey). Long-distance runners are also prone to develop osteitis pubis. The gracilis muscle that attaches to the pubic symphysis has been implicated as a component in the etiology, and contracture or weakness (or both) of the gracilis often is seen with osteitis pubis.

A "groin burn" is a common complaint in patients with osteitis pubis. Depending on the irritability of the condition, the pain can be brought on by walking, running, climbing stairs, one-leg stance, pivoting, kicking, and even coughing or sneezing. Rest usually relieves the pain. A prolonged, bilateral adductor muscle contraction with the patient squeezing the clinician's fist between the knees can elicit groin pain. Resisted rectus abdominis contraction (i.e., a sit-up) can also be painful. Tenderness is present at the superior or inferior pubic ramus (or both), and often both sides can be tender. Occasionally, pelvic compression may exacerbate symptoms of osteitis pubis. Other conditions to consider in the differential diagnosis are groin strain, pubic rami stress fracture, hernia, and infectious osteitis pubis (most often occurring after urological or gynecological surgery).[148]

The imaging studies of choice are plain radiographs and radionuclide bone scans. The radiographic findings, which may be negative in the early stage of osteitis pubis, usually include decreased definition of the cortical bone (i.e., irregular cortical margins and patchy sclerosis), and widening of the pubic symphysis may be seen. To assess for pubic symphysis widening, one-leg standing (flamingo) views are recommended. Bone scans usually show unilateral uptake at the pubic symphysis. Imaging helps differentiate osteitis pubis from other causes of groin pain, such as athletic pubalgia. MRI may also be used to diagnose osteitis pubis.

Treatment should begin with rest from the causative activity (e.g., soccer or running) and avoidance of aggravating activities. NSAIDs and ice can be helpful for the inflammation. If NSAIDs are not helpful, a corticosteroid injection into the site of maximum tenderness can

be considered. Prolotherapy injections are also effective in some cases. Once the symptoms have abated, progressive rehabilitation stretching and strengthening of the hip musculature are initiated. Exercise in water can be particularly helpful. Heat-retaining compressive shorts can be helpful for dry land exercise and sport.[149]

Fractures and Dislocations

Hip (Proximal Femur) Fracture

Hip fractures are a common orthopedic injury with a high incidence, cost, and risk.[150] Worldwide, in the year 2000, there were estimated to be 1.6 million hip fractures, and, with the increasing elderly population, this is projected to increase to 6.26 million hip fractures worldwide by 2050.[151,152] More than 300,000 hip fractures occur each year in the United States, with a 1-year mortality rate of nearly 25%, a life expectancy reduction of 25%, and lifetime health care costs approaching $25 billion.[153] The morbidity rate after fracture is 32% to 80%.[153] One interpretation of this data is that a hip fracture is part of a downward spiral of health. Although partly true, this view ignores evidence that many older adults are able to tolerate and make improvements in physical attributes and function.[154–156]

Approximately 90% of elderly hip fractures result from a simple low-energy fall.[157] The most common risk factors for falls (and thus hip fractures) are age, gender, race, institutionalization/hospitalization, medical co-morbidities (e.g., cardiac disease, stroke, dementia, prior hip fracture, osteoporosis), hip geometry, medication, bone density and body habitus, diet, smoking, alcohol consumption, fluorinated water, urban versus rural residence, and climate.[158] Despite all these risk factors, a hip fracture occurs for many reasons that include, but are not limited to, poor balance reactions, decreased strength and weaker (i.e., osteoporotic) bone. Older individuals tend to fall on the hip because of their slower gait speed (Figure 18-37), whereas younger elders often fall forward onto an outstretched arm, resulting in a Colles' fracture at the wrist (Figure 18-38).[159]

Most hip fractures need to be treated surgically to allow for pain control and early mobilization of the patient to reduce the risks associated with prolonged bed rest and immobilization. The type of fixation required depends on the age of the patient and location and degree of displacement of the fracture. Hip fractures are most simply categorized as intracapsular or extracapsular. A femoral neck fracture is the typical intracapsular fracture, and an intertrochanteric fracture is the typical extracapsular fracture. This distinction is important because, in older patients a displaced femoral neck fracture usually requires an arthroplasty because the blood supply to the femoral head has been disrupted. However, in young patients, surgeons will typically attempt

Risk Factors for Falls and Hip Fractures[158]

- Age: Incidence increases with age
- Gender: Increased incidence in females > males
- Race: Increased incidence in Caucasians
- Social living situation: Increased incidence with institutionalization
- Medical history: Increased incidence with multiple co-morbidities
- Falls risk: Increased incidence with poor balance
- Strength and endurance: Increased incidence with poor muscular strength and endurance
- Hip geometry: Increased with longer and/or narrower femoral neck
- Medication: Increased risk with multiple medications
- Bone density: Increased risk with low bone density
- Diet: Increased with low calcium and vitamin D
- Smoking: Increased with excessive use
- Alcohol consumption: Increased with excessive use
- Fluorinated water: Decreased with fluorinated water

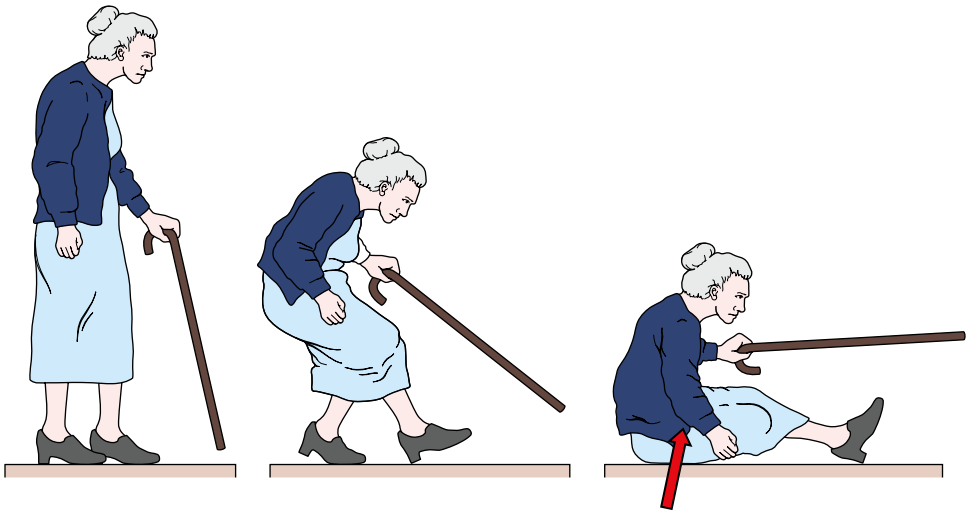

Figure 18-37 A fall that occurs while a person is standing still, walking slowly, or slowly descending a step has little forward momentum. With little forward momentum, the principal point of impact is near the hip. (Modified from Cummings SR, Nevitt MC: A hypothesis: the cause of hip fractures, *J Gerontol* 44: M107-M111, 1989.)

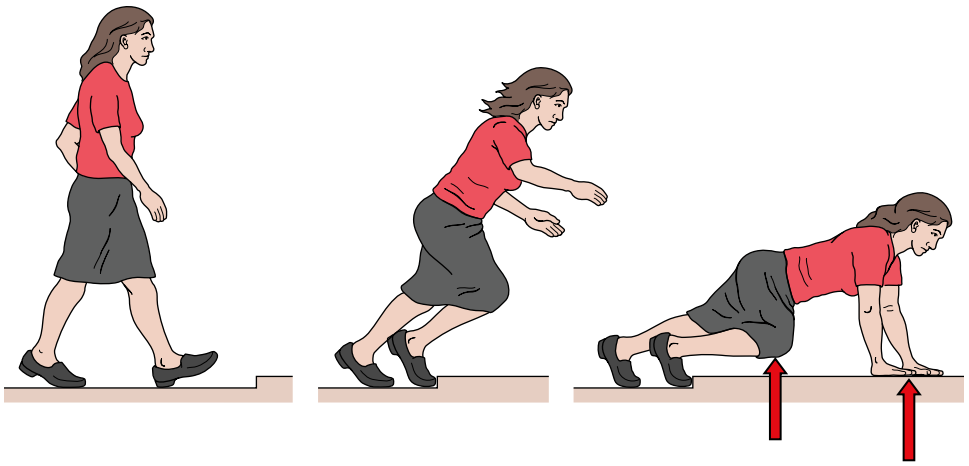

Figure 18-38 A fall that occurs while a person is walking rapidly has enough forward momentum to carry the individual onto the hands or knees instead of the hip. (Modified from Cummings SR, Nevitt MC: A hypothesis: the cause of hip fractures, *J Gerontol* 44: M107-M111, 1989.)

to do an urgent anatomic reduction to save the hip rather than perform a hip arthroplasty. The greater the displacement, the higher the risk of avascular necrosis of the femoral head. Thus, with a nondisplaced femoral neck fracture, a surgeon can often treat it with pins or screws.

Total hip arthroplasty (THA) has been advocated as the optimal treatment for displaced femoral neck fractures in the elderly because of the high rate of avascular necrosis as well as ease of mobilizing the patient earlier. THA is associated with more independent living, it is more cost-effective, and there is a longer interval to reoperation or death than with open reduction and internal fixation (ORIF) and unipolar or bipolar hemiarthroplasty.[160] A hemiarthroplasty replaces only the fractured ball side and does nothing to the acetabular side. There are two types of hemiarthroplasty: unipolar and bipolar. The bipolar implant has a pole of movement within the prosthesis that is designed to reduce wear on the acetabular cartilage. The bipolar endoprosthesis is more expensive than the unipolar design and is used with younger patients (those younger than approximately 70 years of age) who might require revision to a total hip replacement during their lifetime usually because of acetabular cartilage degeneration. The original unipolar design (e.g., the Austin-Moore prosthesis) tends to be used on less active and older patients who are unlikely to outlive the hip implant.

For intertrochanteric fractures (stable or unstable), the sliding hip screw, which is available in a variety of designs, is the implant of choice.[157] Unstable intertrochanteric fractures sometimes are treated with an intramedullary device, but no difference in functional outcomes has been seen between it and the sliding hip screw when used for stable fractures.[157] Figure 18-39 shows some of the implants commonly used in hip surgery.

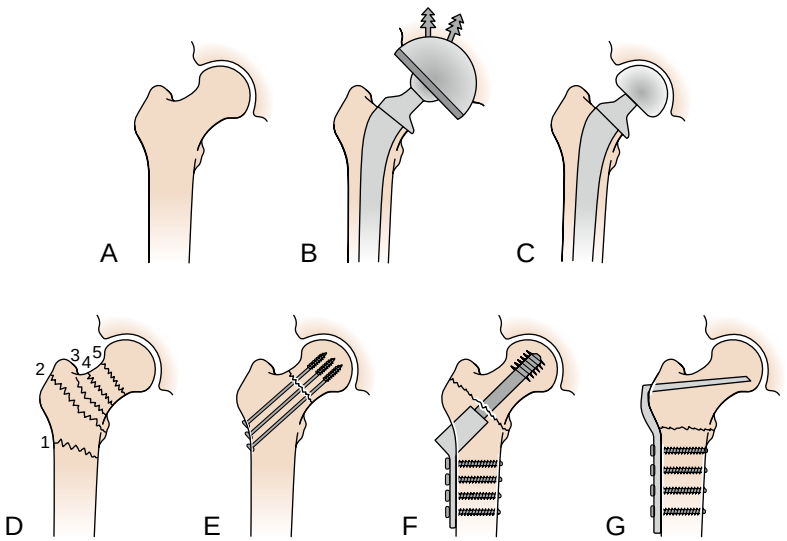

Figure 18-39 Various types of hip reconstructions and implants. **A**, Normal hip joint. **B**, Total hip arthroplasty (both femoral head and acetabulum replaced). **C**, Hemiarthroplasty (only femoral head and neck replaced). **D**, Levels of proximal femoral fractures: *1*, Subtrochanteric; *2*, intertrochanteric; *3*, basicervical; *4*, transcervical (femoral neck); *5*, subcapital. **E**, Multiple screw fixation of a femoral neck fracture. **F**, Screw and plate fixation of an intertrochanteric hip fracture. **G**, Blade plate fixation of a proximal femoral osteotomy. In this drawing, no rotation of the proximal fragment was performed (Modified from Shinar AA: Surgeries of the hip: the approaches and the basics. In Fagerson TL, editor: *The hip handbook*, p 239, Boston, 1998, Butterworth-Heinemann.)

Rehabilitation after a hip fracture must be intensive and multidisciplinary because appropriate rehabilitation efforts can restore many patients to a pre-fracture functional status.[5] Weight bearing as tolerated (WBAT) for gait has been found to result in improved function for hip fracture patients over partial weight-bearing (PWB) restriction, without deleterious effect to the surgical fixation.[161] In the acute care setting, more than one physical therapy visit per day has been shown to be predictive of achievement in basic function and of discharge home from the acute care setting.[150] Binder et al.[155] found that 6 months of extended outpatient rehabilitation, including progressive resistance training, for frail elderly patients with a hip fracture improved the patients' physical function and quality of life and reduced their disability compared with a low intensity "standard" home exercise program. Mangione et al.[156] found that a sample of frail elderly patients who had ORIF or hemiarthroplasty for a hip fracture could tolerate a moderate- to high-intensity home exercise program of either resistance training or aerobic exercise with appropriate supervision. A meta-analysis of 11 studies on extended rehabilitation after hip fracture, including those of Binder et al.[155] and Mangione et al.,[156] supports the findings that extended rehabilitation (often up to 12 months after surgery) is effective at improving functional abilities in this population.[162]

Traumatic Hip Dislocation

Dislocation of the hip in nonsurgical instances is rare. It usually occurs secondary to some form of trauma and often is associated with an acetabular and/or a femoral head fracture. Most traumatic hip dislocations are posterior (i.e., 85% to 90%), and this usually is related to a mechanism of injury in which the hip is flexed and in some degree of adduction and the knee is flexed while a dislocating force drives the femoral head posteriorly out of the acetabular socket.[163] The classic mechanism is the dashboard injury in motor vehicle accidents, although the use of seat belts is reducing the incidence of this injury. In contact sports (e.g., football, rugby, ice hockey, wrestling), a fall or tackle onto a flexed hip and knee can also drive the femur posteriorly.

Posterior hip dislocations can be recognized based on the mechanism of injury. The patient has considerable posterior thigh and buttock pain, and the leg appears shortened and is held in flexion, adduction, and medial (internal) rotation. Prompt recognition and early reduction are essential for a good outcome. Before reduction under anesthesia is attempted, plain radiographs should be taken to rule out a fracture of the femoral head or acetabulum. Reduction of a dislocated hip should be performed within 6 to 8 hours to reduce the risk of avascular necrosis of the femoral head, which occurs as a later complication in 10% to 15% of patients following posterior hip dislocation. For dislocated hips that are not reduced within 8 hours, the rate of femoral head osteonecrosis increases to 40%. Most traumatic dislocations of the hip are reduced using spinal or general anesthesia. However, before anesthesia is administered, one attempt at reduction can be made with an analgesic for pain and muscle spasm using the Allis or Stimson methods.[146] These methods use hip traction in 90° flexion with firm counterstabilization of the pelvis. The Allis method is performed with the patient in the supine position, whereas in the Stimson method the patient is prone with the hip flexed over the end of the examination table.[146]

Sciatic nerve palsy is a complication of hip dislocation that should be monitored by the clinician. Sciatic nerve injury occurs in 10% of posterior dislocations, and, although it resolves in most cases over time, in some cases, permanent footdrop can develop. Vascular insufficiency is rare but can occur with anterior or open dislocations. After hip reduction, radiographs should be obtained to make sure no loose bodies are preventing concentric reduction and that no fracture exists.

Once the dislocated hip has been reduced, management may require limited motion using a hip brace and patient education about risk positions. The risk position for posterior dislocation is combined flexion, adduction, and medial (internal) rotation. The risk position for anterior dislocation is combined extension and medial (internal) rotation. These movements, done rapidly, further increase the risk for re-dislocation.

Risk Positions for Hip Dislocation

- Posterior: Flexion, adduction, and medial rotation
- Anterior: Extension and lateral rotation

Acetabular Fracture

Acetabular fractures are socket-side hip fractures but are categorized with fractures of the pelvis, unlike fractures of the proximal femur, which are designated as hip fractures. Most acetabular fractures occur as a result of high-energy trauma, and they can be displaced or nondisplaced. Displaced acetabular fractures are treated with ORIF to allow earlier ambulatory function and to reduce the risk of posttraumatic arthritis. The ORIF hardware (i.e., screws and plates) is placed outside the joint to act as an "internal cast" until the bone heals. The hardware is not routinely removed.[164]

Perhaps more than in most other hip conditions or surgeries, application of a knowledge of in vivo force and pressure data is extremely important in the rehabilitation of surgical or nonsurgical acetabular fractures. Table 18-7 presents an evidence-based loading progression that is particularly useful for rehabilitation of acetabular fractures based on data from in vivo force and pressure measurements at the hip.[165] Most patients with an acetabular fracture begin with touch-down (i.e., feathering) weight bearing (TDWB), which, when performed correctly, results in less acetabular contact pressure than even non–weight bearing

TABLE **18-7**

Progression of Activities of Daily Living and Exercise Based on In Vivo Force and Pressure Data at the Hip

Low Load	Low-Moderate Load	Moderate Load	High-Moderate Load	High Load
TDWB gait performed correctly NWB gait PROM AAROM Submaximum quad sets Bridging Double leg stance Bicycle (no resistance)	PWB gait Chair rise *with technique** Stairs *with technique* AROM (supine and prone) *no resistance* Submaximum gluteal isometrics Bridging	FWB gait AROM (standing) *with support* One-leg stance *(with support)* Hip abduction (side-lying) *no external resistance* Low-resistance exercise (supine and prone)	AROM (standing) *no support* Maximum isometrics One-leg stance *no support* Slow jogging	Getting into and out of low chairs Going up and down stairs Accidental stumble Abductor resistance Jumping Running

* *With technique* refers to the use of a load-modifying variable, which a physical therapist can teach a patient. For example, for a chair rise, this could involve use of the armrests, having the affected leg out in front, sitting in a higher chair, or a combination of these. For stairs, *with technique* could involve ascent and descent one leg at a time, use of a banister and a crutch, or both.

Modified from Fagerson TL: *Home study course: current concepts of orthopaedic physical therapy—hip*, La Crosse, WI, 2001, Orthopaedic Section, American Physical Therapy Association.

TDWB, Touch-down weight bearing; *NWB,* non–weight bearing; *PROM,* passive range of motion; *AAROM,* active-assisted range of motion; *PWB,* partial weight bearing; *AROM,* active range of motion; *FWB,* full weight bearing.

(NWB), which can cause joint loading from hip muscle co-contraction. The exercise program should also follow a graduated loading progression that mirrors the healing stages of the fracture and is in synchronization with the physician's prescribed weight-bearing status.

Femoral Head Fracture

Femoral head fractures are rare and are typically seen with traumatic posterior hip dislocations. The first step is to reduce the hip fracture then assess the fracture of the femoral head and its displacement. Nonsurgical management is only for nondisplaced Pipkin type 1 fractures, whereas most surgeons recommended surgical treatment for any other type (Figure 18-40). Many different surgical techniques and approaches have been described depending on the fracture size and amount of displacement. The core features of surgery are (1) a safe approach and (2) adequate fixation or excision of the fragment. If the fracture cannot be reduced and fixed, then arthroplasty is another treatment option but is not ideal for younger patients.[166]

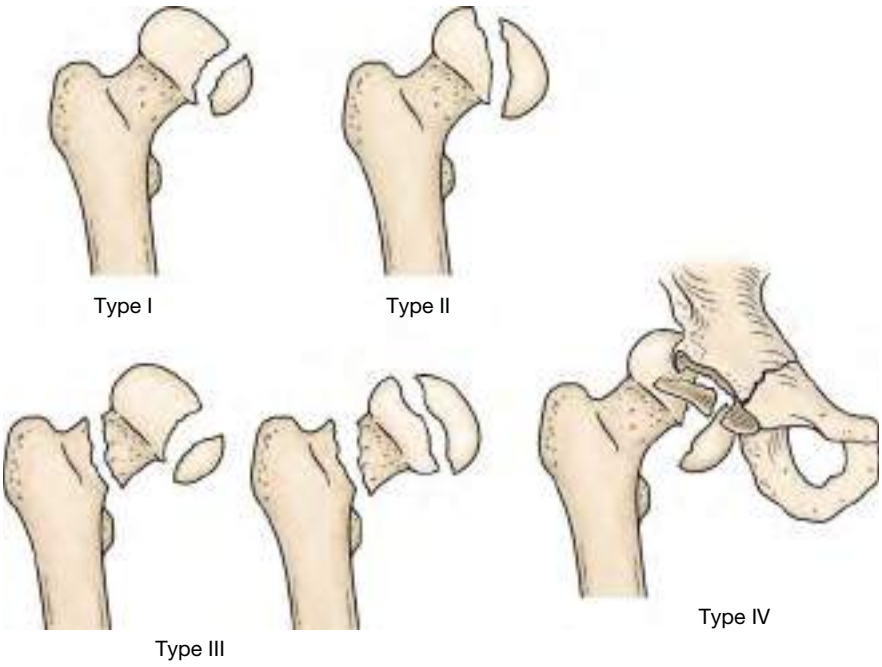

Figure 18-40 Pipkin classification for femoral head fractures. Type I: Femoral head fracture inferior to the fovea centralis. Type II: Femoral head fracture superior to the fovea centralis. Type III: Type I or II with an associated femoral neck fracture. Type IV: Type I, II, or III with an associated acetabular fracture.

There is very little in the literature about postoperative rehabilitation protocols for femoral head fractures. It is generally recommended to have a prolonged period of non–weight bearing for about 2 months followed by gradual progressive weight bearing for fractures that needed fixation. For excision cases, weight-bearing limitation may be very different depending on the surgeon. ROM and strengthening exercises can typically be started earlier, but this is also often decided on a case-by-case basis.

Stress Fracture

Stress fractures in the hip region usually are seen at the femoral neck, pubic rami, and proximal femoral shaft. Although most stress fractures occur in the lower leg and foot, 8.8% of lower extremity stress fractures are reported to occur in the hip and pelvic region.[167]

Stress fractures typically occur as a result of repetitive overuse that exceeds the intrinsic ability of bone to repair itself. Osteoclastic old bone resorption typically precedes osteoblastic new bone formation by 3 to 4 weeks, and increased stress to the bone during this time (e.g., an increase in running mileage) can result in microfractures, which result in a stress fracture if the increased stress to the bone is continued. Resting and unloading the bone can allow the osteoblastic new bone formation to catch up.[168]

Early detection and appropriate management of stress fractures of the proximal femur are very important because these fractures have a high rate of complication of nonunion, progression to complete fracture, and/or osteonecrosis.[169] A study of 23 athletes with femoral neck fractures found that the diagnosis was not confirmed, on average, until 14 weeks after the onset of symptoms, and this delay forced elite athletes to end their careers. This underscores the importance of keeping an open mind to diagnostic possibilities and ordering the necessary imaging earlier rather than later in the course of management.[170] The recommended imaging modalities for diagnosing stress fractures are bone scans or MRI because stress fractures often can be missed on plain x-ray films.[171] CT also can be used.

Safran et al.[172] identified that athletes diagnosed with femoral neck stress fractures have a higher incidence of pincer type FAI (particularly involving coxa profunda and acetabular retroversion). Patients with coxa profunda and acetabular retroversion are encouraged to improve their fracture risk factors such as maximizing bone density, core strengthening, and cross-training.[172]

The classic symptom of a lower extremity stress fracture is progressive, activity-related pain that is relieved by rest. Local tenderness often is present. A **single-leg hop test** usually reproduces symptoms, and percussion of bone distal to the fracture site may reproduce symptoms.[173] A femoral neck stress fracture causes anterior thigh or groin pain (often an ache) that is relieved by rest, although night pain may be present in chronic cases. An antalgic (painful) gait, pain at the extremes of hip rotations (especially medial [internal] rotation), and pain with axial compression are common findings.[174] Clinicians should consider referral for further workup for stress fractures if continuous therapeutic ultrasound increases the patient's pain, which has been reported for lower leg stress fractures, and although it is not a sensitive tool for this diagnosis, the occurrence of increased pain with ultrasound used in treatment of suspected soft tissue injury should be a prompt for further workup.[175]

Stress fractures can be defined as fatigue or insufficiency fractures. **Fatigue fractures** tend to occur in young and middle-aged individuals from repetitive mechanical stress (e.g., distance running or military training). **Insufficiency fractures** tend to occur in older individuals when the bone is weakened from disease states, such as osteoporosis or osteomalacia. Fullerton and Snowdy[176] defined femoral neck fractures as compression, tension, and displaced fractures. **Compression stress fractures** tend to occur in the inferomedial femoral neck, and because they tend to be more stable, they can be treated with protected weight bearing and follow-up x-ray films (to ensure that no fracture displacement occurs during the healing process) until the patient is pain free. **Tension stress fractures** occur on the superolateral femoral neck, and because they are potentially unstable, they should be treated surgically with multiple screws or a sliding hip screw. **Displaced stress fractures** should be treated with ORIF.[29]

Risk Factors for Stress Fractures[169]

- Participation in sports involving running and jumping
- Rapid increase in physical training program (intensity and/or duration)
- Poor preparticipation physical condition
- Recent change in training surface—harder
- Female gender
- Hormonal or menstrual disturbances
- Low bone turnover rate
- Decreased bone density
- Decreased thickness of cortical bone
- Nutritional deficiencies (including dieting)
- Extremes of body size and composition
- Running on irregular or angled surfaces
- Inappropriate footwear
- Inadequate muscle strength
- Poor flexibility
- "Type A" behavior

Nerve Syndromes

Theoretically, any nerve in the hip region can be injured. The nerves of the hip can be categorized into three groups of five nerves: five major nerves (sciatic, femoral, obturator, superior gluteal, and inferior gluteal); five minor nerves (nerve to the quadratus femoris and inferior gemellus, pudendal, posterior femoral cutaneous, nerve to the obturator internus and superior gemellus, and lateral femoral cutaneous); and five "referring" nerves

(iliohypogastric, ilioinguinal, genitofemoral, cluneal, and sinuvertebral). Irritation of nerve roots of the lumbar and sacral plexuses can also refer symptoms to the hip and buttock region.

Nerve injuries occur as a result of one of three mechanisms: compression, traction, or ischemia. The three types of nerve injury are neuropraxia, axonotmesis, and neurotmesis (described in more detail in Chapter 25). Most nerve injuries about the hip have been described as a complication of total hip replacement, in which injury to the sciatic nerve is by far the most common complication. Surgeons also are very aware that the incision must not be extended more than 6 cm (2.4 inches) directly proximal beyond the tip of the greater trochanter, to avoid causing denervation of a branch of the superior gluteal nerve.[177]

In the nonsurgical setting, most nerve injuries at the hip occur as the result of mechanical entrapment, which causes a neuropraxia. Neuropraxia is an intact neural structure with decreased function because of local pressure, which produces ischemia and contusion of the nerve. Usually full function is recovered after appropriate management. These nerve entrapments often are related to alignment, contractures, and repetitive or a single excessive overload or overstretch. The two most common nerve entrapments in relation to the hip are sciatic nerve entrapment by the piriformis muscle in the greater sciatic foramen and lateral femoral cutaneous nerve entrapment at the lateral edge of the inguinal ligament. Entrapments of other nerves in the hip region also have been reported in the literature, including the ilioinguinal nerve, femoral nerve, obturator nerve, genitofemoral nerve, lateral cutaneous branches of the subcostal and iliohypogastric nerves, and entrapment of the sciatic nerve at the level of the ischial tuberosity (sometimes called *hamstring syndrome*).[31]

Nerve entrapments or injuries are easiest to diagnose when the symptoms include specific neurological features (i.e., motor weakness, sensory changes [numbness or tingling], and reflex change). Nerve entrapments are most difficult to diagnose when the primary symptom is pain, especially buttock pain or groin pain that mimics a muscle strain or tendonitis. Causalgia-like pain or reflex sympathetic dystrophy occasionally complicates recovery after a nerve injury.[177]

Three nerve entrapments at the hip frequently described involve the sciatic nerve (i.e., piriformis syndrome), the pudendal nerve (i.e., pudendal neuralgia), and the lateral femoral cutaneous nerve (i.e., meralgia paresthetica).

Piriformis Syndrome

Piriformis syndrome is a confusing diagnosis because some practitioners believe that it is overdiagnosed, others that it is underdiagnosed, and some do not believe that it exists.[178] Often it is a **"diagnosis of exclusion"**, when no other reason for pain in the buttock can be determined. Piriformis syndrome may account for up to 5% of cases of low back, buttock, and leg pain. It most commonly is seen in the 30 to 40 age range, and it often is associated with some form of trauma to the buttock.[179] Buttock tenderness is present over the piriformis muscle (especially in the greater sciatic notch) and surrounding tissues, and referred leg symptoms can arise from sciatic nerve irritation or from trigger points in the muscle itself. Flexion, adduction, internal (medial) rotation (FLADIR) of the hip usually causes buttock pain with piriformis syndrome. Numerous tests for piriformis syndrome have been described in the literature. Basically, they involve either passive stretching or resisted contraction of the piriformis muscle, and a positive test result is reproduction of symptoms in or emanating from the buttock.[5]

The piriformis muscle is the only muscle that passes through the greater sciatic notch, along with six nerves (sciatic, superior gluteal, inferior gluteal, pudendal, posterior femoral cutaneous, and the nerve to the quadratus femoris) and three vessel sets (i.e., superior gluteal artery and vein, inferior gluteal artery and vein, and internal pudendal artery and vein). Therefore a problem with the piriformis logically would have magnified effects because of its close anatomical relationship to numerous other neurovascular structures. A change in sacral or innominate alignment can also change the position of or tension on the piriformis in relation to these structures and thus potentially cause buttock and/or referred pain.

Several definitions of piriformis syndrome have been presented in the literature.[179] These authors believe that treatment is best guided by an approach in which a diagnosis of piriformis syndrome is complemented by a statement of symptom mechanism and a statement of symptom distribution (e.g., "local buttock pain from fall onto buttock," or, "buttock and posterior leg pain to foot from sciatic irritation by piriformis muscle in greater sciatic notch"). Differentiating piriformis syndrome from other lumbopelvic causes of referred pain into the buttock and posterior leg is important.

Piriformis syndrome is characterized by symptoms in the sciatic nerve distribution. Pain in the buttock alone is not piriformis syndrome; the term *piriformis syndrome* is associated with sciatic nerve irritation by the piriformis muscle. As mentioned, the piriformis muscle is the only muscle that passes through the greater sciatic foramen, which makes it the most likely muscular source of sciatic entrapment.

Likely aggravating factors for piriformis syndrome are walking, stair-climbing, and activities involving trunk rotation. Less severe cases of piriformis syndrome can be exacerbated by repetitive or resistive lateral rotation (e.g., from kicking a soccer ball).[5] A positive piriformis test produces buttock pain with possible radiation into the leg. Travell and Simons[180] described the piriformis as "the double devil" because it can refer pain from irritation of the sciatic nerve or irritation of the piriformis trigger points.

Treatment can include gentle, static stretching; ice massage; a vapocoolant spray and stretch technique;

therapeutic ultrasound; and NSAIDs. Techniques to promote balanced and optimal alignment, mobility, and stability of the lumbopelvic region are also important. Gluteus maximus and gluteus medius strengthening with an emphasis of control of weight-bearing hip adduction and medial (internal) rotation has been demonstrated as an effective treatment for chronic piriformis syndrome.[181] A heel insert of up to 0.64 cm (0.25 inch) on the nonaffected side may take some tension off the piriformis. Rest from sporting activity for several weeks often is necessary.[5]

Pudendal Neuralgia

Pudendal neuralgia is a rare pain syndrome involving the cutaneous distribution of the pudendal nerve and/or its three branches. Entrapment of the pudendal nerve was first described in 1988 in a group of competitive male cyclists and is sometimes called **cyclist's syndrome,** because compression and ischemic response of the pudendal nerve can result from a narrow bicycle seat.[182] Pudendal neuralgia can also be the cause of debilitating pelvic pain after trauma, after delivery, or after surgery, often from fibrotic scarring. It is a **"diagnosis of exclusion"** but should be considered in patients with chronic hip and pelvic region pain. The Nantes diagnostic criteria for pudendal neuralgia includes 5 criteria.[183]

Nantes Diagnostic Criteria for Pudendal Neuralgia[183]

1. Pain in anatomic distribution of pudendal nerve
2. Pain aggravated by sitting
3. Not awakened by pain at night
4. No objective sensory loss on clinical examination
5. Pain is improved with anesthetic pudendal nerve block

Physical therapy is considered an important component of the overall management of the patient with pudendal neuralgia advisably by a therapist trained in pelvic floor work.[182] Weiss and Prendergast[184] reported that patients with pudendal nerve entrapment often presented with some or all of these comorbidities, and the clinician should treat what he or she finds: connective tissue restrictions, adverse neural tension, intrapelvic and extrapelvic muscle hypertonicity and/or myofascial trigger points, biomechanical abnormalities (e.g., sacroiliac joint dysfunction), decreased core strength, or faulty neuromuscular recruitment patterns.

If the patient still has debilitating pain after a course of physical therapy and other conservative therapies (e.g., medication, counseling) a CT-guided pudendal nerve block can often be diagnostic and therapeutic. If CT-guided injections of the pudendal nerve give relief, albeit not lasting, then the patient may be a candidate for surgical decompression of the pudendal nerve.[182]

Meralgia Paresthetica

Entrapment of the lateral femoral cutaneous nerve of the thigh as it emerges from the pelvis adjacent to the anterior superior ischial spine (ASIS) can result in tingling, numbness, and pain in the nerve's sensory distribution on the anterolateral thigh. This condition is called **meralgia paresthetica.** It can present during pregnancy, in obese individuals, in laborers who carry heavy tool bags around their waist, and from direct trauma near the ASIS during sports. Sensory testing can confirm the diagnosis, and a positive Tinel's sign may be elicited by tapping adjacent to the ASIS and inguinal ligament. The diagnosis should not be made before other hip, lumbar, or intrapelvic pathology has been ruled out. Treatments that can be beneficial include correction of mechanical contributing factors as well as rest, ultrasound, and NSAIDs if needed. In some cases, injection of an analgesic and a corticosteroid is warranted. In rare cases, when conservative measures have failed, surgical release of the nerve can be performed.[185]

SUMMARY

Applying the information presented in this chapter to live clinical situations requires good clinical judgment. The most logical method for making clinical decisions is the risk–reward ratio: balancing cost (i.e., risk) against benefit (i.e., reward). The F balance (Figure 18-41) is an expansion of the risk–reward ratio that can be particularly helpful to the clinician in making decisions about a person presenting with hip pathology. In rehabilitation terms, clinicians balance achievement of best possible function against the risk of tissue failure (i.e., tissue breakdown or damage). Controlled forces (e.g., movement, mobilization, exercise) are used to improve form (e.g., strength, flexibility, endurance, balance), and both controlled forces and improved form are used to optimize function (e.g., transfers, walking, stairs, sports activity). The patient should always be the focus of the rehabilitation process—"feel" at the center of the F balance refers to the importance of asking "How does the patient feel?" and incorporating his or her goals into the treatment plan.

CHAPTER 19

Physical Rehabilitation after Total Hip Arthroplasty

JEANNA ALLEGRONE, JAMES GREEN II, DAVID NICOLORO, DIANE M. HEISLEIN, ERIC O. EISEMON, EDGAR T. SAVIDGE, SANAZ HARIRI, HARRY E. RUBASH

INTRODUCTION

Indications for Total Hip Arthroplasty

The most common indication for primary total hip arthroplasty (THA) is osteoarthritis (OA). Clinically, symptomatic OA is defined as pain occurring on most days during the past month in addition to radiographic changes (i.e., osteophytes, subchondral sclerosis, and joint space narrowing). Approximately 10% to 12% of adults have symptomatic OA. Conversely, approximately 50% of people with radiographic evidence of OA are asymptomatic.[1]

Other indications for THA include rheumatoid arthritis, avascular necrosis, traumatic arthritis, certain hip fractures, benign and malignant bone tumors, arthritis associated with Paget's disease, ankylosing spondylitis, and juvenile rheumatoid arthritis (Table 19-1). Contraindications to THA include active local or systemic infections and medical conditions that significantly increase the risk of serious perioperative morbidity and mortality (see Table 19-1).[2]

Prevalence of Total Hip Arthroplasty

Rates of THA have increased worldwide, with more than 1 million procedures being performed annually.[3] Projections expect this trend to increase exponentially during the next 15 years.[4] The reasons for the increase are multifactorial, including a higher incidence of OA secondary to an aging population and a worldwide obesity epidemic. Furthermore, younger patients are now considered candidates for THA due to increased survivorship of the prosthesis (>80% at 25-year follow-up), along with evidence that early intervention for OA may provide better functional outcomes. By 2030, patients <65 years old are projected to represent 50% of the hip arthroplasty population.[3,5]

Prevalence of Total Hip Arthroplasties in the United States

- In 2005, nearly 238,000 primary THAs were performed in the United States. This represents a 1.7-fold increase in THA since 1993.[6]
- During the same period of time, the overall numbers of THA revisions have increased. However, the proportion of THA revision to primary THA has decreased from 20% to 15.7%.[6]
- By 2030, primary THA and revision THA are projected to increase by 174% and 137%, respectively, beyond the 2005 rates.[4]

Hip Osteoarthritis Patient Management and Surgical Decision Making

Diagnosis and management of hip OA can be delayed because of patient and clinician difficulty in identifying that the hip is the source of pain and the functional limitations. Compared with painful conditions in other joints, such as the knee, hip pain is particularly difficult to define for three reasons: (1) the joint is deep, therefore pain arising from it can be felt across a broader region; (2) pain from structures outside the hip (e.g., the lower back, groin, and urinary and genital tracts) can cause referred pain in the hip region; and (3) delineating a specific topographical area that can be defined as "the hip" is difficult.[7]

Nonsurgical treatment for OA is often recommended before THA. A systematic review identified several nonsurgical alternatives that could be effective in the management of hip OA pain before surgery, including self-management, education, exercise, weight reduction, acupuncture, and medical pharmaceutical management (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs], opioids, corticosteroids, glucosamine sulfate, diacerein, hyaluronic acid, and homeopathic remedies). This same systematic review identified THA as effective in improving the quality of life of hip OA patients who did not respond to nonsurgical treatments.[8]

TABLE 19-1

Indications and Contraindications for Total Hip Arthroplasty

Indications	• Osteoarthritis • Rheumatoid arthritis and juvenile rheumatoid arthritis • Avascular necrosis • Traumatic arthritis • Certain hip fractures (e.g., femoral neck fracture in an older, active adult) • Benign and malignant bone tumors • Arthritis associated with Paget's disease • Ankylosing spondylitis
Relative contraindications	• Age under 60 years • Obesity • Neurological disease (increases the risk of postoperative dislocation)
Absolute contraindications	• Active local or systemic infections • Unstable medical conditions that significantly increase the risk of serious perioperative morbidity and mortality (e.g., cardiac conditions, such as a recent myocardial infarction [MI]; also pulmonary, liver, genitourinary, or metabolic disease)

As of 2015, there are no international consensus guidelines to assist orthopedic surgeons as to when to perform THA.[3] In addition to symptomatic OA, functional limitations and physical examination findings can factor into the decision to operate, as well as other patient- and physician-related factors (see Table 19-1). A 2006 study identified differences between referring physicians' and orthopedic surgeons' opinion on the effect of disease severity and quality of life in the decision to pursue THA. They concluded that referring physicians were more likely to think that patients had to have a higher disease severity to warrant operation and were more apt to consider social factors and quality of life issues versus orthopedic surgeons.[9]

Appropriate patient selection is an important consideration for THA. Obesity, advanced age, and medical comorbidities may make a surgical candidate less optimal; however, these are not absolute contraindications for surgery (see Table 19-1). There is a 40% increased risk of complications for each decade above 65 years old. For younger patients, particularly those <50 years old, survivorship of the prosthesis needs to be considered, given the higher activity level of this patient population.[3] The timing of THA from onset of symptomatic OA is also an important consideration. Studies have shown that patients who wait less than 3 months for surgery have better functional improvement postoperatively than patients who wait 6 months or more.[3]

TOTAL HIP ARTHROPLASTY

Surgical Approaches

There are several different surgical approaches, as well as modifications to these approaches, to perform a THA. The three most common approaches are the anterior, anterolateral, and posterior approach. Each approach has specific advantages and disadvantages, and if done correctly, there is no significant difference in outcomes between the approaches.

The choice of approach is primarily based on the surgeon's experience and the ability to achieve a reproducible result. Occasionally, a patient-specific factor (e.g., neuromuscular disease, anatomical abnormality, or flexion contracture) will lead surgeons to vary their standard approach. Each approach has specific rehabilitation guidelines with respect to dislocation precautions, movement restrictions, and weight-bearing restrictions, and therefore it is important to be familiar with the major approaches and the rationale behind their associated precautions.

The anterior approach has increased in popularity in the United States as of 2015.[10,11] Patients are positioned supine on either a special traction table or regular operating room table. The skin incision starts approximately 3 cm distal and lateral from the anterior superior iliac spine (ASIS) and goes in a distal and lateral direction. The deep dissection goes through an intranervous plane between the sartorius muscle (supplied by the femoral nerve) and tensor fascia lata (supplied by the superior gluteal nerve). This approach is considered "muscle sparing" because it maintains the muscle attachments. Other than the reflected head of the rectus femoris muscle, which is directly over the anterior capsule, no muscles are incised or removed from their attachment to bone.[12] The hip is dislocated anteriorly during the procedure. The advantages of this approach are thought to be a low dislocation rate, decreased damage to the musculature, a faster rehabilitation rate, and potentially no need for dislocation precautions.[13–16] The disadvantages of this approach include the difficulty with exposure affecting implant positioning and risk of iatrogenic fracture, significant surgeon learning curve for performing the procedure, and anterior dislocations.[17]

The anterolateral approach is performed either supine or in a lateral decubitus position. The skin incision is started at the greater trochanter with the proximal portion angled toward the ASIS and the distal incision following along the shaft of the femur. After the iliotibial band and tensor fascia lata are incised, a common modification of this approach is performed with the anterior one third of the abductor muscles released directly off the greater trochanter. The abductor muscles are repaired during the closure. Similar to the anterior approach, the hip is dislocated anteriorly. The anterolateral approach is very versatile, allowing excellent exposure of the acetabulum and the femur and has a low dislocation rate. This approach is usually chosen for patients who are at

high risk for dislocation (i.e., patients with hip fractures, dementia, large range of motion [ROM], abductor muscle tears, or neuromuscular disease).[18] Due to the abductor muscles repair, active abduction is not immediately recommended to protect the repair for a period of approximately 6 weeks.

The posterior approach is the most common approach used for hip replacement. Patients are placed in a lateral decubitus position for surgery. The skin incision is centered on the greater trochanter, similar to the anterolateral approach. The proximal incision is in line with the posterior superior iliac spine, then follows the mid shaft of the femur from the tip of the greater trochanter distally. The abductor muscles are protected and the lateral (external) rotator muscles and capsule are taken off the back of the femur to allow the hip to be dislocated posteriorly. In addition to being a very familiar approach for most orthopedic surgeons, this approach has excellent exposure to the acetabulum and femur. It can be extended proximally to gain additional exposure to the posterior column of the acetabulum or distally to expose the femur.

Types of Fixation

The type of implant fixation can affect a patient's weight-bearing activities postoperatively. Fixation of the femoral or acetabular components can be achieved with or without the use of cement. Methyl methacrylate is used as cement to hold either the acetabular or most commonly the femoral components in place. A technique including a cemented femoral component and cementless acetabular component is called hybrid fixation. Fixation using cement is achieved at the time of surgery because it interdigitates with the host bone and forms a secure housing for the implant's smooth surface. Cementless implants obtain their initial hold in bone during surgery as they are impacted into either the prepared acetabulum or femur. The roughened stems allow for the host bone to grow around or into the actual implant on its roughened surface, which holds the implant in place. This process of ingrowth takes approximately 6 weeks.

Nontraditional Hip Arthroplasty Options

Surgical implant types for hip arthroplasty have evolved, resulting in more options for both surgeons and patients. In part, this evolution has been driven by the need for arthroplasty options for patients who, beyond the desire of restoring basic functional activity (e.g., walking and performing activities of daily living [ADLs]), have the additional goal of returning to recreational and sport-type activities. The desire to promote early return of function and minimize surgical trauma (and resulting pain and edema) has also prompted the development of alternative surgical approaches (such as the direct anterior and 2-incision minimally invasive THA).

Minimally invasive surgery (MIS) is a term used to describe either a smaller incision (typically half of the length of the traditional incision) or an approach that does not involve cutting tendons or splitting muscles. There has been considerable debate as to the possible benefits of MIS, including decreased blood loss and pain and earlier functional recovery. Disadvantages of MIS are primarily considered to be an increased prevalence of complications, such as fracture, infection, component malposition, undesired muscle damage, and heterotopic ossification.[19–21]

In the mid-1990s the renewed development of metal-on-metal (MOM) hip prostheses in England resulted in a prosthesis called the hip resurfacing arthroplasty (HRA).[22–24] This approach offers an alternative for younger patients, allowing return to high-level recreational and sport activities. Advantages of MOM are the theoretical long-term high tolerance to stress and load bearing that a traditional, non-MOM prosthesis does not allow without early implant failure.[22–24] Returning to all or near-all recreational activities has been observed in the HRA population.[25]

Despite successful outcomes, MOM implants have also revealed their own challenges. In HRA, many potential outcomes were theorized, such as avascular necrosis of the femoral head, femoral neck thinning (and possibly fracture), and edge wear of the metal implants, resulting in the release of metal ions into the surrounding tissues and blood stream.[26–28] Many, if not all, of these instances, require removal of the prosthesis and conversion to a traditional THA prosthesis.[27,28] At the time of this writing, multiple prosthetic developers have issued recalls on their MOM implants as a result of the wear and cobalt and chromium metal ion release. The impact of these ion releases is not fully understood, although local tissue destruction and formation of pseudo-tumors have been observed in these cases and attributed to the metal debris.[27–29]

Total Hip Arthroplasty Revision

Revision THA has a variety of indications. Patients typically present with a new onset of disabling pain, stiffness, and functional impairment after their primary THA, unrelieved by appropriate medical management and lifestyle modifications. A U.S. study using the Healthcare Cost and Utilization Project Nationwide Inpatient Sample database identified the primary indications for THA revision surgery as instability or dislocation (22.5%), mechanical loosening (19.7%), and infection (14.8%).[2,30] The most common types of revision are all component (41.1%), followed by femoral component only (13.2%), acetabular component only (13.2%), and isolated femoral head and acetabular liner exchange.[30]

Indications for Revision THA Surgery

- Disabling pain
- Stiffness
- Functional impairment
- Bone loss (on radiographs)
- Implant loosening (on radiographs)
- Malpositioned components (on radiographs)
- Fracture
- Recurrent dislocation
- Infection

In situations in which infection of the joint space has been identified before revision THA, patients often require removal of the prosthesis, with implantation of a temporary antibiotic-infused "spacer," followed by a period of intravenous antibiotic treatment (typically 6 to 8 weeks), and then reimplantation of a new THA prosthesis after resolution of the infection.

COMPLICATIONS OF TOTAL HIP ARTHROPLASTY

Hip dislocation is one of the most common complications following THA. Rates vary widely in the literature, between 0.3% and 10% incidence after primary THA, and up to 28% incidence after revision THA.[31,32]

Data from a study of U.S. Medicare recipients quantified the risk of the other most common short-term postoperative complications of primary elective THA and revision THA (Table 19-2).[33] During the 17-year time frame (1991 to 2008) in which these data were collected, the authors noted that overall medical and surgical complexity for elective primary THA and revision THA had increased in this elderly population. There was a trend toward higher rates of diabetes, congestive heart failure (CHF), obesity, and renal failure in this population, and the overall number of significant co-morbidities had increased. Despite this, complications of primary THA dramatically decreased over this time frame before stabilizing or slightly worsening in 2008, whereas the revision THA complications have increased.

TABLE 19-2

Ninety-Day Complications of Primary Elective Total Hip Arthroplasty (THA) and Revision of Primary Elective Total Hip Arthroplasty

Complication	THA (%)	Revision THA (%)
Mortality	0.8	3.0
Deep vein thrombosis	0.6	0.7
Pulmonary embolism	0.4	0.3
Wound Infection	0.6	2.5
Hemorrhage	0.7	1.4
Myocardial infarction	0.7	1.0
Sepsis	0.4	1.1
All-Causes Hospital Readmission	10.9	17.6

Data from Wolf BR, Lu X, Li Y et al: Adverse outcomes in hip arthroplasty: long-term trends, *J Bone Joint Surg Am* 94:8, 2012.

In addition to the above-mentioned complications, postoperative limp is another issue that can impact the outcome of THA. The most common causes of a postoperative limp are a leg length discrepancy (LLD) and abductor muscle disruption during surgery. LLD can occur in up to 3% of THA cases; however, it is generally accepted that discrepancies of <1 cm are well tolerated by patients.[31] Beyond the limp, significant LLD can lead to low back pain and functional impairments and can lead to litigation[31] and revision THA. Although the surgeon aims to keep the limb lengths equal, hip stability is a higher priority. An interplay exists between leg length and hip stability—that is, the longer the operative leg length, the tighter the soft tissue and therefore the more stable the hip. Conversely, the shorter the operative limb, the more lax the soft tissue around the hip and therefore, the greater the risk of dislocation.

The surgical approach can have an effect on limb length and postoperative limp. The anterior approach provides opportunity for direct measurement of leg length and thus has less than average LLD and preserves the major abductor muscle attachment.[10,31] The anterolateral approach has been associated with an elevated risk of a postoperative limp as high as 10% 2 years postoperatively and a 2.8% incidence of severe heterotopic ossification.[34] However, other studies have not shown a clinically significant difference in gait between the approaches (i.e., anterolateral, direct lateral, and posterior) at 1 year postoperatively.[35] The direct lateral approach can have variable effects on LLD but does disrupt the abductor muscle mechanism, which can be associated with postoperative limp.[10,31] Positioning for the posterolateral approach makes it difficult to accurately measure leg length, and overlengthening can more commonly occur.[31] However, with a strict posterior approach, the abductor musculature is spared, and thus, this approach is associated with a lower incidence of postoperative limp.[10]

Preoperative and postoperative patient education is essential with respect to actual or perceived LLD. Patients should understand the possibility that their limb might be lengthened during surgery to increase stability. Patients should be informed that the perception that the operative leg feels longer is a normal physiological reaction to THA. Patients who have a perceived LLD preoperatively have a higher likelihood of a perceived LLD postoperatively.[31] Less common causes of a limp are loose implants, biological problems (e.g., sepsis, neuromuscular imbalance, contractures), and extrapelvic causes (e.g., degenerative spine, knee, and ankle pathology).[36]

REHABILITATION FOLLOWING TOTAL HIP ARTHROPLASTY

Rehabilitation following THA is a multidisciplinary effort that requires effective and timely communication and coordination. Decisions about the rehabilitation plan of care and discharge are based on patient and surgical considerations but may be influenced by the different members of the health care team.

Patient function varies greatly for THA candidates. For example, for very sedentary individuals, the maximum functional requirement may be to ambulate short household distances; in contrast, high functioning individuals want to return to sports and recreational activities, such as tennis, golf, and hiking. Therefore, it is important that the patient remains the center of the decision-making process throughout the course of treatment, from the choice of prosthetic device and surgical technique to the rehabilitation plan of care.

The patient and family remain at the center of the team, which includes the orthopedic surgeon, primary care physician, physical and occupational therapists, nurse, case manager, and other specialists as needed. A patient may be discharged from the acute care hospital to a rehabilitation facility or home, based on the rehabilitation clinicians' input about function, the nurse's and physician's (or physician's assistant's) input about medical status, and the patient's and family's input about social supports and environmental constraints. Case managers coordinate with insurance companies to facilitate the appropriate resources and a timely transition to a rehabilitation facility or home with nursing and rehabilitation services.

Multidisciplinary Decision Making for Hospital Discharge

Hospital discharge requires input from:
- The rehabilitation clinicians, about function
- The nurse and physician or physician assistant, about the patient's medical status
- The patient and family, about special supports and environmental constraints
- Case managers, about available resources

A multidisciplinary, organized team approach including participation by the patient, surgeons, anesthesiologists, physical therapists, and occupational therapists is essential for improving patient outcomes. The literature shows that preoperative patient education is associated with reduced hospital length of stay (LOS) and improved patient reported outcome measures. MIS has been associated with better pain control, shorter LOS, and less use of assistive devices postoperatively. Aggressive pain management via use of regional and local analgesia may improve postoperative pain, reduce the use of narcotics, and therefore increase patient participation in physical therapy (PT) and ultimately reduce LOS. There is also evidence that early rehabilitation (including same day mobilization) decreases postoperative pain and reduces LOS.[37,38]

Patient-Related Factors

Throughout the episode of care, a variety of patient-related factors influence rehabilitation decision making, including the patient's previous level of function, social support, environment, co-morbidities, and age. Care should be taken to individualize the examination and evaluation of patients after THA because many individual patient-related factors will influence the patient's progression.

Factors Impacting Rehabilitation Decision Making

- Surgical approach used and any modifications
- Surgical complications
- Medication
- Limitations or restrictions imposed by the surgeon or the surgery
- Age
- Prior level of function
- Medical status and medical history
- Social supports
- Environmental constraints

Preoperative Level of Function

Patients functioning at a high activity level (e.g., recreational activities and sports) may have better strength, cardiovascular endurance, and flexibility than those with low activity tolerance and should be expected to return to a higher level of activity after surgery.[39] The previous level of function influences decisions about exercise prescription, the timing of intervention, and activity restrictions. Patients with low activity levels before surgery may have secondary impairments, such as diminished strength and ROM, as well as greater functional limitations, which may need to be addressed with basic exercise and early intervention. A healthy, highly functioning individual may not require as much skilled intervention until healing has occurred, at which point, functionally based high-level exercise may be prescribed that would be inappropriate for a sedentary patient.

Social Support and Home Environment

The availability of social support influences discharge decision making because patients who live alone may be unable to care for themselves at home and therefore may require a short inpatient rehabilitation stay before returning home.[40–44] Social support and home environment also play a large part in determining a patient's early rehabilitative plan of care because the presence of stairs or other fixed environmental barriers may necessitate the use of assistive devices and specific training in their use. It is important to identify any potential barriers early, to develop an appropriate plan of care to address each patient's individual needs.

Medical Co-morbidities

Trends have shown that patients undergoing THA have a greater number of medical co-morbidities and that an increased number of obese patients are undergoing the procedure.[45] The patient's medical history and co-morbidities must be factored into the decision-making process because these may affect healing time, postoperative complications, and overall functional mobility. It will also factor into the patient's specific functional needs and potential. However, obese patients (with high body mass index [BMI]) are shown to have greater improvement in function and greater satisfaction post-THA than normal-weight patients, potentially due to lower baseline function.[46] Furthermore, patients with serious co-morbidities may require a longer hospital stay and are more likely to require inpatient rehabilitation before returning home.[43,44,47] Diabetes has been shown as one of the strongest predictors of postoperative complications.[48] Specific medical co-morbidities need to be considered when developing an appropriate plan of care because certain interventions may be contraindicated given their co-morbid condition.

Age

Age has been shown to influence postoperative function, mortality, and risk of revision. Older patients undergoing THA are at higher risk of postoperative mortality and experience less improvement in function. However, younger patients are at higher risk of requiring revision surgery.[49] In addition, age can affect the postacute care discharge destination. Patients more than 70 years old are more likely to be discharged to an inpatient rehabilitation facility because of the increased incidence of co-morbidities, reduced mobility, and a greater likelihood of living alone.*

Postoperative Considerations

It is essential that the surgeon inform the rehabilitation clinician of the approach used, whether the approach was modified in any way (e.g., trochanteric osteotomy), and whether there were any intraoperative complications (e.g., femoral fracture). All these factors can affect the patient's postoperative weight-bearing status, ROM limitations, and exercise prescription.

Weight-Bearing Restrictions

The patient's weight-bearing status ultimately depends on the surgeon's preference and patient-specific intraoperative findings. Historically, surgeons allowed full weight bearing or weight bearing as tolerated (WBAT) only after cemented THA, based on the principle that adequate fixation is achieved only with cement. Uncemented THA has been associated with micro motion at the bone-prosthetic interface, causing concern for compromised stability and ingrowth of the prosthesis. Thus patients with uncemented THA have traditionally had reduced weight bearing orders for 4 to 12 weeks postoperatively.[51,52]

More recently, many surgeons allow WBAT for uncemented THAs. In uncemented THAs, press-fit stems often are strong enough to withstand the effects of early weight bearing while awaiting bony ingrowth. In fact, some prosthetic designs have been designed to withstand loads of 300% body weight.[52] In a long-term study of more than 300 patients who were allowed WBAT after cementless THA, 99.5% of patients had successful osteointegration of the femoral THA component by 3 months postoperatively, as confirmed by imaging.[51] A 2-year follow-up randomized controlled trial (RCT) comparing partial weight bearing (PWB) to WBAT after cementless THA demonstrated no significant difference in ROM, functional outcome scores, and pain at 3 and 24 months postoperatively. In this study, more patients who were allowed WBAT were able to wean from a cane versus the PWB group (74% to 67%) at 3 months, without compromised fixation at 2 years by imaging.[52]

If the optimum press fit is not possible in an uncemented THA, the patient is made PWB or touch-down weight bearing (TDWB) (i.e., the foot is allowed to touch the ground for balance and stability, without any weight acceptance) for 4 to 12 weeks to allow bone ingrowth into the porous component. Caution should be used with rehabilitation even after cemented THA because it is sometimes used when bone quality is questionable. Careful consideration should be given to exercise or functional movements that may impose an increased load across the femur or pelvis.

If an intraoperative complication arose, such as a crack in the proximal femur (often cerclage wires around the proximal femur indicate such a complication), the patient's weight-bearing status may be downgraded to TDWB. If an osteotomy of the greater trochanter was performed, the patient typically is restricted to TDWB or PWB for up to 12 weeks to allow the osteotomy to heal. It may seem intuitive that keeping a patient non-weight bearing on the affected extremity, rather than TDWB, would better protect the hip; however, keeping a patient non-weight bearing actually places more stress across the hip joint because patients must use their hip musculature to keep the leg lifted off the ground.

Dislocation Precautions

Although a variety of surgical procedures can be used for THA, the common approaches are posterior, posterolateral, anterior, anterolateral, and direct lateral. As detailed previously, they differ in the location where the primary incision is made through the integument, fascia, muscle, and joint capsule to gain access to the hip. Soft tissues that have been transected and then repaired are weaker and present a risk for hip dislocation. Consequently, it is important that the clinician understand the surgical approach and recognize the precautions that must be taken

*References 40, 41, 43, 44, 47, 50.

to prevent hip dislocation. A combination of certain movements poses the greatest risk for dislocation. A large part of the rehabilitation clinician's role is to instruct the patient in how to prevent a hip dislocation, which includes education and reinforcement throughout functional movements. For example, a patient who had a posterior approach THA should not bend forward to put on or take off shoes, and compensatory strategies using an assistive device are required for independence in this activity. Dislocation precautions also affect therapeutic exercise interventions. End-range exercise for strengthening, flexibility, and ROM should be avoided until the soft tissues have healed adequately and the surgeon has discontinued hip dislocation precautions.

After surgery, the surgeon wants the patient to avoid the very maneuver that was used intraoperatively to dislocate the hip. For example, to dislocate a hip during a posterior or posterolateral approach, the hip must be flexed, adducted, and medially (internally) rotated. It follows logically that precautions against posterior hip dislocation consist of no hip flexion past 90° in conjunction with hip adduction past midline and hip medial rotation past neutral (Table 19-3). Figure 19-1 depicts an example of modifying ADLs to maintain the hip flexion precaution for the posterior approach THA. A pillow may be positioned between the patient's legs in supine to prevent adduction. Abduction braces are sometimes used to keep the hip in slight lateral (external) rotation and abduction for a patient with a high risk of dislocation after a posterior approach THA. However, there is little evidence in the literature to support use of the brace.[53] Studies looking at bracing after closed reduction of a dislocation[54] and bracing after all-cause revision THA[55] concluded that there is no benefit to bracing versus no brace to prevent short-[55] or long-term[54] dislocation.

Precautions against anterior dislocation include avoiding hip extension and lateral rotation beyond neutral (as detailed in Table 19-3). To help reinforce these precautions, the patient can be positioned in bed with a trochanteric roll at the lateral hip to prevent lateral rotation

TABLE **19-3**

Treatment Precautions to Prevent Hip Dislocation or Delay Muscle or Bone Healing

Type of Procedure	Precautions
Posterior or posterolateral approach	No hip flexion past 90° in conjunction with hip adduction past midline and hip medial rotation past neutral
Anterior or anterolateral approach	No hip extension or lateral rotation beyond neutral
Transtrochanteric or lateral approach	No active abduction

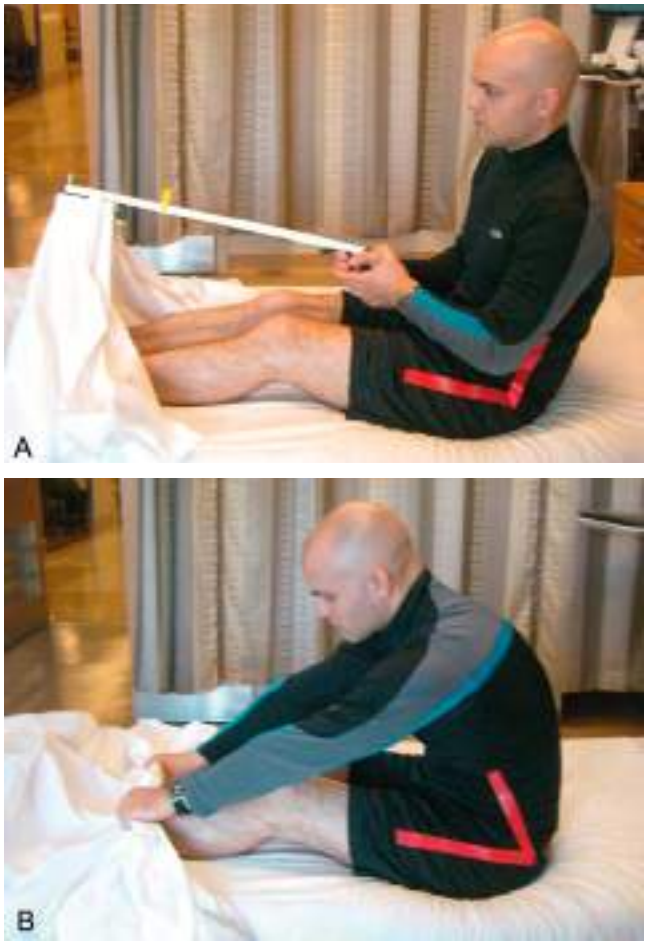

Figure 19-1 Maintaining ≤90° hip flexion after a posterior approach THA. **A,** Correct method using tool. **B,** Incorrect method.

(Figure 19-2). Patients can be educated to avoid bridging past neutral hip extension in hook lying and to avoid pivoting or lunging away from the operated side while standing to avoid the combination of hip extension and lateral rotation.

When a transtrochanteric approach is used, "trochanter off" precautions are prescribed. This is not a dislocation precaution but a restriction of active contraction of the musculature attached to the trochanter to allow the bone to heal. This approach involves bony repair of the greater trochanteric osteotomy; therefore the repair must be protected to minimize the risk of nonunion. Because the abductor muscles (e.g., gluteus medius and minimus) insert into the greater trochanter, no active abduction is allowed for at least 6 weeks after surgery (see Table 19-3). Patients sometimes have active abduction restriction after a lateral approach, to protect the reattachment of the abductor muscles to the trochanter after surgery.

Studies have differed in their assessment of risks for hip dislocation by surgical approach. The literature demonstrates that 75% to 90% of dislocations happen posteriorly.[32,56,57] Historically, higher rates of dislocation have been observed for the posterior or posterolateral versus

Figure 19-2 **A,** Improper positioning of the lower extremity with hip lateral rotation. **B,** Corrected by positioning with a trochanteric roll to maintain neutral position after an anterior approach THA.

anterolateral approach.[32,53,58–60] More recently, a comprehensive meta-analysis found that the combined dislocation rate was 1.27% for the transtrochanteric approach, 3.23% for the posterior approach (3.95% without a posterior capsular repair and 2.03% with the repair), 2.18% for the anterolateral approach, and 0.55% for the direct lateral approach.[61] A 2006 systematic review reported no significant difference between the dislocation rate for the posterior approach versus the direct lateral approach (1.3% versus 4.2%, respectively) but reports that the evidence is not strong enough to be conclusive about this complication risk.[62] A subsequent RCT[63] documented a 3% dislocation rate for the lateral approach compared with zero dislocations for the posterior approach over an average 38-month follow-up. In contrast, a study based on the Swedish Hip Arthroplasty Register found the posterior approach had an increased risk of dislocation (relative risk [RR] 1.3, confidence interval [CI] 1.1-1.7) compared to the direct lateral approach.[64] In a community-based population, Khatod et al.[65] did not find a correlation between the surgical approach and the rate of dislocation.

A larger femoral head diameter is associated with a lower long-term cumulative risk of dislocation in all operative approaches, but especially with the posterolateral approach.[59] Soft tissue repair when the posterior approach is used has been shown to reduce the dislocation rate from 4.46% to 0.49%. Most surgeons currently repair the posterior capsule[32,53,61,66–68] and short lateral (external) rotators[31] to achieve these improved results. In a systematic review of the literature, when the soft tissue was repaired in the posterior approach, the dislocation rate was comparable for the anterolateral, direct lateral, and posterior approaches (0.7%, 0.43%, and 1.01%, respectively).[69]

Several patient-related factors are associated with increased risk of hip dislocation. Historically, women were thought to be twice as likely as men to dislocate, but recent studies have challenged this finding.[53] Patients with neuromuscular and cognitive disorders, such as cerebral palsy, muscular dystrophies, psychoses, dementia, and alcoholism, have been associated with higher dislocation rates.[32,53] Weakness, noncompliance with hip precautions, and balance issues are underlying causes for this finding.[32] Other risk factors include prior hip surgery, history of fracture, developmental dysplasia, osteonecrosis, or inflammatory arthropathy.[53] In fact, prior open hip surgery is likely to double the risk of instability due to scarring, laxity, and soft tissue compromise.[32]

The need for patient dislocation restrictions after an anterolateral approach THA has been called into question. A prospective, randomized study evaluated the effect of postoperative functional restrictions on the prevalence of dislocation after an uncemented, anterolateral approach THA.[70] The study participants were divided into a "restricted" group and an "unrestricted" group. Both groups were asked to limit the ROM of the hip to less than 90° flexion and 45° lateral and medial rotation and to avoid adduction for the first 6 weeks after surgery. In addition to these baseline restrictions, during the first 6 weeks after surgery, patients in the restricted group (1) had an abduction pillow placed between their legs in the operating room before bed transfer and used pillows to maintain abduction while in bed; (2) used elevated toilet seats and elevated chairs in the hospital, in the rehabilitation facility, and at home; and (3) were prevented from sleeping on their side, driving, and being a passenger in an automobile. Of the 303 THAs studied, the only dislocation was

in the restricted group, and it occurred as the patient was transferred from the operating table to a bed with an abduction pillow in place. Patients in the unrestricted group returned to side sleeping sooner, rode and drove in automobiles more often, returned to work sooner, and had a higher level of satisfaction with the pace of their recovery than those in the restricted group. An additional expenditure of approximately U.S. $655 per patient was made in the restricted group for additional adaptive equipment.

A small, 2009 randomized prospective study also studied patients who had an anterolateral approach[71] and restricted versus unrestricted activities. The restricted group was instructed to avoid hip flexion greater than 90°, crossing legs at the thighs, and riding in a car for 1 month postoperatively versus the "early" group who were advised only to avoid crossing their thighs. There were no dislocations in either group, but significant differences were found in functional progression. The unrestricted group progressed earlier to use of a cane, weaning off all assistive devices, walking without a limp, and driving compared with the restricted group.

In a study of 6623 consecutive cemented primary Charnley THAs (90% via transtrochanteric approach, 9% via anterolateral, and 1% posterolateral), the cumulative risk of a first-time dislocation was 1% at 1 month and 1.9% at 1 year; it then rose at a constant rate of approximately 1% every 5 years to 7% at 25 years for patients who had not had a revision by that time.[72] This study is one of the few that have studied the long-term risk of dislocation; however, surgical techniques have improved since this study which likely has decreased the long-term risk of dislocation. More research on this topic should shed additional light on whether all THA patients need to adhere to dislocation precautions postoperatively, possibly depending on their surgical approach.

Little consensus is found among surgeons on the length of time the patient should follow these dislocation precautions. The duration ranges from a few weeks to lifelong, depending on the surgeon's preference. The capsule and connective tissues should heal by 6 to 12 weeks; therefore patients are advised to follow the hip dislocation precautions for at least this duration of time.

STAGES OF REHABILITATION MANAGEMENT

Rehabilitation from THA requires a multidisciplinary approach and often begins before surgery. Patients may have preoperative education followed by inpatient rehabilitation while in the acute care hospital. Postacute care rehabilitation may occur in an inpatient rehabilitation, home care, or outpatient setting. Patients will often receive care in more than one setting to achieve full return to their desired function, ranging from short-distance ambulation to sports-level activity. Transition from one stage to the next is dictated by the patient's functional abilities within the constraints of the person's individual environment, available supports, and co-morbidities. For multiple reasons, the length of the acute care stay has been declining from the early 1990s to the time of this publication, with earlier transition to the next postacute care phase of rehabilitation (inpatient rehabilitation, home care, and/or outpatient), depending on the needs of the patient.

Like primary THA, rehabilitation following a revision THA needs to be individualized to the patients based on the same inherent preoperative, perioperative, and postoperative considerations, challenges, and surgeon orders. Similar short- and long-term outcomes that have been observed following primary THA have been observed in revision THA.

Preoperative Rehabilitation

Before undergoing surgery, many patients attend a THA education class (if offered by the facility in which they are having surgery), which may include a physician and/or surgeon, nurse, rehabilitation clinicians, and a case worker, discharge planning nurse, or social worker. Patients are educated about preparing for surgery, the surgical procedure, the postoperative course, applicable precautions, early postoperative exercise, functional mobility with a walker and/or crutches, and discharge planning from hospital to home or to inpatient rehabilitation or extended care facility (ECF).[73,74]

One of the primary roles of preoperative education is the influence it can have on patient expectations regarding long-term outcome after surgery, course of hospitalization, and transition from the hospital into the postacute care phase.[74,75] Evidence has shown that patients who receive preoperative education demonstrate improved achievement of preoperative expectations (such as symptom relief and improved function), significantly less preoperative anxiety, and decreased incidence of postoperative complications (such as hip dislocation).[74–77] Education about hip dislocation precautions, the proper use of assistive devices, early postoperative exercise, and mobility may be more effective before surgery, when pain, the effects of anesthesia, and postoperative anxiety do not interfere with the patient's ability to concentrate and process information. The textbox on the following page outlines a sample syllabus for a preoperative education class.

The literature is conflicting on the effect of preoperative educational sessions on short- and long-term THA outcomes. In one study, patients who received preoperative education and therapy to increase strength and ROM performed transfer activities sooner postoperatively than those who did not receive preoperative training; however, no significant difference was seen in pain or in the **Harris Hip Score (HHS)**.[78] In another randomized, controlled prospective study, Giraudet-Le Quintrec et al.[76] compared patients who had received a preoperative information leaflet (control group) with patients who had attended a collective, multidisciplinary information session 2 to 6 weeks before surgery. The patients who had attended

Sample Syllabus for Preoperative Education on Total Hip Replacement

- Definition of items used during your hospital stay
- Preparing your home before surgery and items to bring with you
- Planning your discharge
- Admission to the hospital
- Operating room
- Recovery room
- What to expect each day in the hospital
- Total hip replacement dislocation precautions
- Prevention of dislocation after total hip replacement
- Instructions for sitting and rising from a chair
- Walker, crutches, and cane use
- Gait training
- How to climb stairs
- How to get into and out of a car
- How to get into and out of a stall shower or tub shower
- Rehabilitation
- Exercises
- Sexual activity after hip replacement
- Skin care
- Wound care, signs of infection, signs of a blood clot
- When to call your doctor and what to do in an emergency
- How to contact your surgeon
- How to contact the orthopedic nurse education coordinator
- When to return for follow-up appointments
- Antibiotic prophylaxis after a total hip replacement
- Venous thromboembolism prophylaxis

the information session were significantly less anxious just before surgery than the patients in the control group. They also had less pain before surgery, and they were able to stand sooner; however, the trend toward lower anxiety scores was not statistically significant after surgery.[75,76]

Discussions and decisions about discharge planning and destination (i.e., home or rehabilitation facility) should begin preoperatively via formalized screening. Studies have shown that factors available to providers before surgery, such as age, gender, presence of co-morbidities, living situation, and presurgical function, are all factors in the recommendation for discharge destination.[79,80] Since 1999, use of formalized preoperative screening tools has also assisted in anticipating likely discharge destination after the hospital stay. Oldmeadow et al. developed the **Risk Assessment and Prediction Tool (RAPT)** for total joint arthroplasty patients (Figure 19-3).[81] Information such as age, gender, preoperative walking ability, preoperative use of assistive walking aids, and available social supports are collected by the multidisciplinary team. This information is entered into a formula that generates a prediction score for likely discharge destination (i.e., home versus inpatient rehabilitation). This tool has been validated in multiple studies to aid early discharge planning.[82,83] Early planning to arrange alternative short-term living arrangements or support may allow patients who live alone to avoid discharge to an inpatient rehabilitation setting.[81]

Acute Care Rehabilitation

Over time, the LOS in hospital after THA has decreased dramatically, due to the rising costs of THA and increased volume of patients. Among Medicare recipients in the United States, LOS after primary THA has decreased from 8 to 3 days between 1991 and 2008. A similar decrease has been observed for revision THA over the same time frame, from 9 to 4 days.[33] Currently, there are fast-track and enhanced recovery programs (ERPs) that target an even shorter LOS (≤2 days). Hospitals are tasked with minimizing hospital stay to reduce costs. Rehabilitation professionals are, therefore, tasked with optimizing patient outcomes in a shorter perioperative period of time.[37]

In the acute care setting, the primary role of physical and occupational therapists with patients who are post THA is to promote mobility and functional independence.[84–87] For many patients, demonstrating independence with functional activities, such as bed mobility, transfers, ambulation, stair walking, and self-care activities, is achievable during the acute care stay (which can be as short as 2 to 3 days).[85–88]

Rehabilitation after THA is usually started within the first 24 hours following surgery and continues throughout the acute care stay until the patient meets goals for discharge home or is transferred to an inpatient rehabilitation facility.[85,86,88] With changes in the demographics of patients, surgical techniques, surgical blood loss mitigation, anesthetic techniques, and optimized pain control, rehabilitation clinicians should anticipate being able to successfully mobilize patients within hours of the completion of surgery.[85,86,88,89] As part of preparing for patient care in the acute care phase, rehabilitation clinicians must take into account medical aspects of patients after THA that are often unique to the acute care environment, including pain management, hemodynamic issues, and medical complications.

Pain Management

Optimizing pain management in the acute care phase is essential to promote both early mobility and achievement of patient and clinician goals.[90–92] Given that rehabilitation is going to be occurring within the time frame of the normal physiological inflammatory response to soft tissue and bone trauma (i.e., the first 48 to 72 hours), pain perceived and reported by patients after THA is anticipated to be at its peak.[93,94] Both multimodal pharmaceutical and nonpharmaceutical pain management approaches have proven successful in the acute care environment.[90–92] Multimodal pharmaceutical management typically consists of narcotic and nonnarcotic and nonsteroidal anti-inflammatory medications.[90–92] Nonpharmaceutical pain management may consist of ice, compression (via abdominal binders deliberately placed lower around the hips), and promotion of early ROM and movement (as promotion of exercise and ROM before THA has been shown to decrease pain).[86,93,95]

The Risk Assessment and Prediction Tool (RAPT) for Hip or Knee Arthroplasty

This Risk Assessment and Prediction Tool (RAPT) is a very useful tool developed independently by the American Congress of Rehabilitation Medicine and the American Academy of Physical Medicine and Rehabilitation.

The RAPT approach is recommended for use in helping general practitioners (GPs) assess their patients.

With support from this simple guideline, GPs are able to assess whether a patient is a suitable candidate for an integrated surgery and prehabilitation and rehabilitation program as part of their treatment program.

To be completed by the patients undergoing elective Hip or Knee replacement surgery prior to discussion with your orthopedic surgeon or attending pre-admission clinic.

Name _____

DOB _____

Address _____

Surgeon _____

Study	Value	Score
1. What is your age group?	50-65y 66-75y >75y	=2 =1 =0
2. Gender?	Male Female	=2 =1
3. How far, on average, can you walk? (a block is 200m)	Two blocks or more (± rests) 1-2 blocks (the shopping centre) Housebound (most of time)	=2 =1 =0
4. Which gait aid do you use? (more often than not)	None Single-point stick Crutches/frame	=2 =1 =0
5. Do you use community supports? (home help, meals-on-wheels, district nurse)	None or 1 per week Two or more per week	=1 =0
6. Will you live with someone who can care for you after your operation?	Yes No	=3 =0
	Your score (out of 12)	

KEY: Destination at discharge from acute care predicted by score:

Scores <6	extended inpatient rehabilitation
Scores 6-9	directly home after additional acute intervention
Scores >9	directly home

Patient's expectation of discharge destination is also a determinant. The prediction indicated by the score is discussed with the patient and the destination agreed to.

Patient's preference	Prediction	Agreed destination

Figure 19-3 The Risk Assessment and Prediction Tool (RAPT) for Hip or Knee Arthroplasty. (Modified from 2004 American Congress of Rehabilitation Medicine and the American Academy of Physical Medicine and Rehabilitation.)

For rehabilitation clinicians, coordinating administration of pain medications by nursing staff before therapy sessions is essential (especially given that different medications have their own frequency and timing of administration). With this approach, the patient is best able to tolerate the rehabilitation activities and interventions from a pain perspective.

Clinical Note

Ideally, rehabilitation clinicians should coordinate their patient treatment times with the administration of pain medications given by the nursing staff.

Hemodynamic Issues

As a result of blood lost from the surgery, patients who are post THA often have decreases in hematocrit (HCT) and hemoglobin (Hgb) within 24 hours following surgery.[96–98] Despite decreased HCT/Hgb, literature has demonstrated that safe mobilization of patients is possible as long as hemodynamic stability is maintained and symptoms of hemodynamic intolerance are monitored.[99,100] If a patient demonstrates repeated hemodynamic instability with position change or activity in the presence of a low HCT, the decision for blood transfusion may be made to prevent continued hemodynamic instability.[101] Although not contraindicated, clinical treatments during a blood transfusion should be performed cautiously, with a focus on a patient's hemodynamic tolerance to activity and care to maintain the integrity of the intravenous line providing the transfusion.

Assessment of the patient's hemodynamic status before initiating and during clinical sessions is essential. Although there is a plethora of evidence supporting successful mobilization out of bed in the very early postoperative period, rehabilitation clinicians do need to be aware of possible adverse hemodynamic responses to activity and position changes that may compromise a patient's safety. As a result of acute changes in blood and fluid volumes, the side effects of pain medicines and anesthesia, cardiac medicines taken by patient for co-morbidities, and in some cases, prolonged horizontal body positioning in bed, patients in the first 24 hours following surgery may demonstrate activity-induced hypotension (or bradycardia) with movement into sitting or standing or walking positions.[102,103] This is typically accompanied by subjective reports of lightheadedness, nausea, and/or fatigue. Acute hypotension can lead to syncope along with potential hypoxia and injury to key vital organ systems.[102,104–106] In addition, if a patient were to have a syncopal episode while standing or walking, this could result in additional injury to the patient and potentially the health care provider due to an uncontrolled or controlled fall to the ground.[104]

Clinical Note

It is essential that rehabilitation clinicians monitor the patient's vital signs prior to and during changes in patient position, especially during the early postoperative period.

To prepare for this possible adverse reaction, rehabilitation clinicians should take baseline resting vital signs on all patients during all treatment sessions during this early postoperative period and continue to check the vital signs with all changes in patient body position. Prior studies have defined a systolic blood pressure (SBP) decrease of >10 mm Hg during exercise as "exercise-induced hypotension."[107] However, the change in SBP should be considered in relation to the patient's baseline blood pressure (BP). Clinicians should mobilize patients with caution if decreasing BPs are observed with activity. It is strongly recommended that if the decreasing BP is accompanied by associated symptoms, activity should cease and patients should be returned to a supine position. Once supine, it is expected that SBP will return to baseline level and resolution of adverse signs and symptoms will occur. If a patient does not demonstrate improved hemodynamics and resolution of symptoms in supine, placing the patient in a **Trendelenberg position** (supine with head 15° to 30° lower than feet) may assist with stabilization of cardiovascular symptoms. If the patient's symptoms do not resolve or worsen, the patient should be evaluated by the medical team.

Medical Considerations

Clinicians also must be aware of other, infrequent contraindications to rehabilitation intervention, including new-onset arrhythmia, active work-up for acute cardiac event or pulmonary embolus (PE), or acute change in mental status that prevents the patient from following commands and participating in physical therapy treatment.

Contraindications to Rehabilitation

- New onset arrhythmia
- Acute cardiac event
- Pulmonary embolism
- Acute change in mental status

Deep vein thrombosis (DVT) prophylaxis has progressed significantly between 2006 and 2014, resulting in significant decreases in the occurrence of DVT postoperatively. Literature has reported DVT occurrence after THA to be between 1.3% and 10.0%.[108] DVT prophylaxis is achieved through a multimodal approach, including medication, mechanical compression devices, compression hosiery, and early mobilization of the patient. Medication options and standards for DVT prophylaxis have evolved, with the American College of Chest Surgeons stating that aspirin use for DVT prophylaxis is acceptable in patients with low risk for DVT and is compliant with the Joint Commission's "Surgical Care Improvement Project" (SCIP).[109] Oral medicines such as Coumadin and injectable medicines such as Lovenox are also used routinely for DVT prophylaxis.[109–111] Rehabilitation clinicians should be aware of signs and symptoms that may indicate presence of DVT and warrant consultation with the patient's

clinical care team for further evaluation and diagnostic workup. Physiological signs, although relevant, have been shown to be poor predictors of the presence or absence of DVT.[112] Therefore Homan's sign has been shown to be largely unhelpful in identifying DVT in patients.[113] However, the Wells Criteria[114] have been well validated for clinical probability in the assessment of DVT. Clinical signs of DVT alone are not diagnostic but warrant referral for further evaluation.[115]

Wells Clinical Prediction Rules for Likelihood of Deep Vein Thrombosis (DVT)

- Active cancer
- Paralysis, paresis, or recent plaster immobilization of lower extremities
- Recently bedridden for >3 days or major surgery within 4 weeks
- Localized tenderness along distribution of deep venous system
- Entire leg swollen
- Calf swelling >3 cm when compared with asymptomatic leg
- Pitting edema
- Collateral superficial veins (non-varicose)
- Previously documented DVT
- Alternative diagnosis as likely or greater than that of DVT

Scoring: +1 for each factor above except –2 for last criterion (alternative diagnosis likely). A cumulative score of ≥2 is likely DVT, whereas <2 means DVT is unlikely.

Modified from Wells PS, Anderson DR, Rodger M et al: Evaluation of D-dimer in the diagnosis of suspected deep-vein thrombosis, *New Engl J Med* 349:1228, 2003.

Interventions

In the acute care setting, physical therapists focus their postoperative care in three areas: functional mobility training, therapeutic exercise, and patient education.

Functional Mobility Training. The mainstay of rehabilitation in the inpatient setting is functional mobility training, which is progressed or limited according to patient tolerance and surgical and weight-bearing precautions.[84–88] Typical activities for functional mobility training include bed mobility (e.g., supine to sit, sit to supine, rolling), sit to stand, bed to chair transfers, ambulation with assistive devices, and stair training.[84–88] The most current evidence recommends patients be progressed as tolerated with functional activities, irrespective of the postoperative day from surgery.[85] When determining "tolerance," the clinician should consider the patient's overall fitness level/cardiovascular conditioning, pain levels with activity, and hemodynamic response to activity.

Functional mobility training should emphasize safe, efficient mobility that complies with any applicable ROM and weight-bearing precautions and minimizes pain. Further consideration is given to assistive devices, and starting ambulation with a walker will allow patients to maximize their ability to maintain balance while initiating early weight bearing on the operated limb. Progression to other assistive devices (such as crutches or a cane) is dependent on both patient factors and postoperative activity limitations, and may take place at different points in the overall recovery process.

As a patient progresses to walking activities, instruction on gait pattern and correction of modifiable gait deviations also becomes a focus of treatment. Patients may demonstrate gait deviations that are related to compensations made presurgery or postsurgery as a result of pain or discomfort, weakness, joint and soft tissue restrictions, or edema or swelling. Patients should be given verbal, visual, and manual cues to correct any modifiable gait deviations as soon as possible without compromising the patient's safety, activity tolerance, or ability to meet any goals for discharge.

Therapeutic Exercise. Exercise prescription is important in the early postoperative phase to address impairments of pain, edema, ROM, strength, and motor control, and to prevent secondary complications.[84–86]

Supine exercises performed in bed include active-assisted ROM (AAROM) and active ROM (AROM) at the hip, knee, and ankle and isometric exercise of the quadriceps and gluteals.[84–86,116] As functional mobility progresses to sitting, standing, and ambulation, the therapeutic regimen should include sitting and standing AROM exercises. Typical exercises prescribed during the acute care stay are listed in Table 19-4. [84–86]

Patient Education. In the acute care phase, patient education focuses on multiple topics.[84,86,117] Instruction in activity modification in the setting of any applicable postoperative surgeon-specific limitations (such as weight-bearing status and hip dislocation precautions) and surgical side effects (i.e., pain and edema) is often led by rehabilitation clinicians.[84,86] This includes potential modifications for moving from supine to sit and vice versa; standing from and sitting onto beds, chairs, toilets; self-care management for ADLs; gait sequencing on level surfaces and stairs; and use of assistive devices for walking and ADLs. These instructions and recommendations

TABLE **19-4**

Postoperative Exercises

Supine	• Ankle pumps • Heel slides • AROM and AAROM hip abduction and adduction to neutral • AROM hip lateral rotation and internal rotation to neutral • Quadriceps and gluteal isometrics
Sitting	• AROM knee flexion and extension • AROM hip external rotation
Standing	• AROM hip abduction • AROM hip extension • AROM hip flexion (marching) • Heel raises

AROM, active range of motion; *AAROM,* active-assisted range of motion

are to maximize independence and safety of patients after THA and limit preventable adverse events (such as hip dislocation).

Edema and nonpharmaceutical pain management are also key areas of education that rehabilitation clinicians provide. These include the use of cryotherapy at and around the surgical site to assist in edema and pain reduction.[86] Ice has long been shown to assist with management of edema and pain, and as a result contributes to improved outcomes.[117] Limb and joint positioning is also important to assist patients in maximizing comfort and preventing passive migration of the surgical hip into undesired positions (that may increase either the patient's pain or risk of dislocation).

Discharge Planning. Rehabilitation clinicians play a primary role in providing recommendations for an appropriate discharge plan from the acute care setting following THA (including destination, and frequency and intensity of rehabilitation services).[81,82,118] An appropriate discharge plan for patients following THA is essential to both achieve a safe level of function and promote the patients' achievement of their individual long-term goals. The two primary postacute care discharge destinations are "home" or an extended care facility (ECF).[79,81,82,118]

Home represents the patient's own home or that of a care plan partner. ECF represents a health care facility, such as acute rehabilitation hospital or skilled nursing facility.[79] When considering home as a destination, rehabilitation clinicians must also consider whether the patient will receive care in the patient's home (i.e., home care) or in an outpatient setting. Frequency and intensity of services are based on the scope of the patient's health care needs (i.e., physical and/or occupational therapy [OT], along with other skilled health care needs) and the anticipated duration of need for rehabilitation services to meet the patient's goals for recovery.

The rationale for a given discharge recommendation depends on a number of individual patient factors including those discussed previously as well as the patient's medical and functional ability status during and at the time of discharge from acute care.[47,118,119] Once a patient's discharge recommendation is agreed upon by the patient and members of the health care team, the patient's plan of care will be progressed accordingly by PT and/or OT.

Although there are no absolute guidelines, the consensus in the literature is that a patient is appropriate for a home discharge plan when he or she demonstrates:[85,118,120]

- Independence with supine to sit and sit to supine movements (typically from a flat position to simulate a patient's bed at home)
- Independence with sit to stand and stand to sit movements from bed, chair, and toilet (with any needed modification to elevate toilet height if patient has posterior hip precautions)
- Independence with ambulation with needed assistive device of 100 to 150 feet (30.5 to 45.7 m)
- Supervised or independent ambulation on stairs

These guidelines are not all encompassing, and a small percentage of patient situations may allow for a patient to safely transition home without having achieved all of the above-listed functional tasks.

For all other patients who have not yet achieved these goals, discharge to an ECF is typically recommended. For these patients, an ECF allows for the continued opportunity to work with rehabilitation clinicians on a frequent basis and provides a longer time period to achieve these goals. In addition, the ECF may allow for more consistent continued management of co-morbidities and/or post-surgical conditions (e.g., pain control, wound care) that is not possible with home care services.

Inpatient Rehabilitation in the Extended Care Facility

For patients following THA who have transitioned to an ECF, rehabilitation clinicians must consider the patient's physiological state of recovery as well as the resources of the ECF when establishing plan of care. Physiologically, assuming the patient has transitioned to an ECF 72 hours or more following his or her procedure, the patient should be beyond the peak inflammatory response to the surgical trauma.[93,121] Acute pain levels should be well controlled by this point; blood and fluid levels have also likely stabilized.[121] However, individual patient factors may prolong the time frame for healing and pain resolution, and the ECF setting allows for further management of these issues over a broader time frame, which can lead to more rapid and meaningful progress toward functional and discharge goals.

The ECF setting also provides greater access to rehabilitation services compared with home care. Whether it is in the skilled nursing facility setting or acute inpatient rehabilitation setting, clinicians are typically able to provide 2 to 3 hours of therapy per day versus a similar number of hours per week in home care.[121,122] For patients with certain co-morbidities or limited social support upon discharge, this higher frequency of therapy can be of great benefit by allowing these patients to overcome impairments (such as diminished endurance and activity tolerance) or provide greater opportunities to practice key functional tasks independently.

Interventions

In the inpatient rehabilitation setting, the focus of rehabilitation is very similar to the acute care setting. That focus is a continuation of functional mobility training, therapeutic exercise, patient education, as well as ADL training that was initiated in the immediate postoperative period.[121,122] Similar to the acute care setting, patients work toward demonstrating independence with bed mobility, transfers, ambulation with appropriate assistive device, and stair negotiation.[121,122] Therapeutic exercise for patients in this setting may expand to include sitting, standing, and possibly resisted exercises, given that pain tolerance has likely improved. Patient education continues to focus on activity modification in the setting of

applicable postoperative precautions or guidelines, assistive device use, and ADLs.[121,122]

Home Care Rehabilitation

Rehabilitation in the home care setting is parallel to care in the ECF. Goals of treatment are a continuation of care initiated in the acute care setting. Typically, a home care clinician visits patients during the first several weeks after surgery, when tissue healing and pain limit the intensity and type of treatment. Home safety should be at the forefront of a clinician's mind, and recommendations should be made for environmental modifications because many patients may not receive home OT following discharge from the hospital.

As in the acute care setting, the home care therapist must screen for DVT and infection, to reduce risk of significant postoperative complications. Because the physical therapist may be the only provider consistently seeing the patient in the home setting, he or she should also routinely inspect the surgical incision for any erythema or drainage indicative of potential wound infection.

Functional milestones for discharge from home care services have not been defined in the literature, but Medicare provides a guideline to assist in this decision process. A patient is eligible for home care services if leaving the home requires a "considerable and taxing effort."[123] Home care clinicians prescribe exercise, balance training, and functional training to enable mobility outside the home. Generally, patients at some point should be able to ambulate out of the home with close to normal gait speed and negotiate curbs and stairs. Once no longer homebound, the patient may continue with the exercise program independently and may transition to outpatient rehabilitation when recommended by the surgeon and physical therapist.

Home Safety

Safety is always a priority when discharging a patient home because balance and stability are limited as a result of pain, decreased motor control, decreased ROM, and narcotic use. A fall may increase the risk of dislocation, fracture, and other trauma that would negatively affect recovery and outcome. Loose area rugs and throw rugs should be removed, exposed wiring and cords should be protected, and hallways and common walkways (e.g., the path to the bathroom) should be lit at night. Grab bars and railings may be recommended for safe mobility in the home.

Home Safety Tips for Total Hip Arthroplasty Patients

- Loose area rugs or throw rugs should be removed
- Electrical cords should be protected
- Hallways and walkways should be lighted
- Grab bars and railings should be installed where appropriate
- Raised and firm seating surfaces should be used (if posterior precautions)
- Shower and tub chairs and raised toilet seat should be used if needed

Interventions

Taking into account the patient's particular home environment, functional training teaches safe function within the home. Emphasis is on safe negotiation of the home environment, including stairways, landings, bathrooms (including toilet and shower and bath transfers), and other common areas. Outdoor mobility on curbs and inclines may also be incorporated into treatment as needed. As function and stability improve and pain diminishes, patients may begin using a unilateral assistive device, such as a cane, instead of crutches or a walker. A cane or single crutch in the contralateral hand reduces the hip abduction moment and hip joint reaction forces in the involved hip,[124] allowing a normalized gait despite hip abduction weakness while providing support during bony and soft tissue healing.[125]

Cryotherapy and analgesic interventions should be continued as needed to adequately control pain and allow patients to fully participate in their rehabilitation sessions. Both narcotic and nonnarcotic pain management strategies should be timed to provide optimum pain control before the therapy visits. The use of ice should be continued as well at the surgical site for edema and pain reduction.[86,117]

Therapeutic Exercise

Evidence exists for the use of early resistance training of the quadriceps muscle for increasing muscular strength as well as functional performance, specifically in sit-to-stand performance. As function improves, exercise should incorporate functional weight bearing and eccentric exercise in addition to "open chain" exercise (i.e., non–weight-bearing movement of the lower extremity). Sashika et al.[126] demonstrated improved gait speed and hip abduction strength after THA with a 6-week home program that emphasized weight-bearing eccentric exercise compared with isometrics and open chain exercise alone. Eccentric hip abduction strengthening using low, nonprogressive resistance continues to show an increase in hip abduction strength even within 2 or more months after surgery.[127]

Outpatient Rehabilitation

Referral to outpatient rehabilitation is based on the surgeon's recommendation and the patient's continued functional limitations. Outpatient rehabilitation may begin as soon as a patient is capable of arranging for and attending clinic visits. Consideration must be given to the time frame for bony and soft tissue healing, as well as any relevant precautions or contraindications when selecting examination and intervention techniques. Intervention is driven by the patient's functional abilities and examination findings, as well as surgical precautions (see Table 19-3). Strength, stability, and gait deviations can continue to limit functional mobility, ambulation, and return to the desired activity level 6 months to 1 year after surgery.[128–134]

Therapeutic Exercise

As bony and soft tissue healing progress, patients are able to tolerate increasingly higher intensity exercise. Many patients show decreased hip strength months after THA[128,133,134] compared with healthy individuals because of pain and immobility that were present before surgery, surgical disruption of nerves and muscles,[135] and decreased activity and weight bearing after surgery. Hip abductor muscle weakness may contribute to a limp during gait (Trendelenburg gait as depicted in Figure 19-4) and decreased function. Maximal strength training, specifically open chain hip abduction and leg presses, has been shown to be safe and effective following hip arthroplasty,[136] but it may not be tolerated by or appropriate for all patients.

Progressive resistive exercise individualized for the patient's age and ability has been shown to increase hip strength after THA, as well as gait speed and distance.[128,130,137] Common strengthening exercises at this stage may include bridging, side-lying hip abduction, and lateral (external) rotation with resistance. In addition, intervention that includes weight bearing and postural stability training improves strength, stability, and function up to 12 months compared with AROM and isometrics alone.[130] Wall slides, mini-squats, and weight-shifting exercise help promote strength, postural stability, and balance and proprioception. Table 19-5 details common exercises for the outpatient phase of THA rehabilitation.

Figure 19-4 Trendelenburg's sign, seen with hip abduction weakness on the right.

TABLE **19-5**

Common Exercises for the Outpatient Phase of Rehabilitation

Range of motion	• Hip flexor stretching (modified Thomas test, rectus femoris stretch) • Hamstring stretch • Gastrocnemius stretch • Passive range of motion (PROM) hip flexion and lateral rotation
Strengthening	• Side-lying hip abduction and lateral rotation with resistance • Bridging • Wall slides • Mini squats • Calf raises • Step up and downs
Balance and proprioception	• Tandem stance and single-leg stance (stable and unstable surfaces) • Balance boards

ROM exercises (see Table 19-5) continue to address motion restrictions that are functionally relevant, particularly hip extension and flexion, which may affect terminal stance in gait and lower body dressing, respectively. Consideration of the surgical approach and hip dislocation precautions is crucial with all ROM and strengthening exercises. Communication with the patient's surgeon will help to clarify how long the patient must adhere to the surgeon's hip dislocation precautions. Further consideration is important with uncemented THAs because twisting closed chain exercises may cause loosening of the femoral stem in the medullary canal. Cardiovascular conditioning should be incorporated into the patient's overall treatment program. The use of a stationary bike[138] is ideal because this will cause less wear on the hip joint than other high-impact weight-bearing exercises.[39] The patient's functional goals are central in prescribing therapeutic exercise. The ROM, strength, and balance requirements for a particular task must all be considered when an exercise program is devised.

Caution: Exercises and Uncemented Total Hip Arthroplasty

- Twisting closed chain exercise may place undue stress on the hip and lead to loosening of the femoral stem

Manual Therapy Treatment

Soft tissue mobilization may improve scar mobility, restore muscle length, and improve hip ROM. Joint mobilization to the affected hip generally is considered a contraindication because of the time frame for healing, especially with revision and uncemented surgeries, as well as the altered mechanics of the implant itself.

Aquatic Therapy

Aquatic therapy is an increasingly used tool for postoperative rehabilitation. Although aquatic therapy has been studied in the immediate postoperative phase,[139,140] it is common to wait for wound healing to occur to minimize the risk of both wound infection and contamination of the aquatic environment.[140] Advantages of aquatic therapy include decreased loading due to buoyancy in the water and hydrostatic forces creating varying resistance as velocity of movement changes. Aquatic therapy has been shown to increase hip strength and function while decreasing pain and stiffness when compared to land-based therapy.[139,141]

Functional Milestones and Return to Recreation or Sports

Function typically progresses from ambulation with a walker or crutches to a cane and finally to ambulation without an assistive device, depending on the patient's previous level of function and co-morbidities. The final functional milestones to be reached typically are high-level activities for recreation and sports, such as golf, tennis, biking, and hiking. The time frames and guidelines for return to sports and recreational activities depend on the surgeon's preference, surgical procedure (i.e., approach and fixation), and patient's previous and current functional abilities.[39]

In 2007, Klein et al. surveyed a total of 549 surgeons from the Hip Society and American Association of Hip and Knee Surgeons regarding their recommendations for activity following a "standard" primary THA.[142] Surgeons were asked to categorize their recommendations into one of four categories (allowed, allowed with experience, not allowed, or undecided). This survey also showed that 32% of surgeons allowed return to activity at 1 to 3 months postoperatively, whereas 59% waited until 3 to 6 months before allowing activity. The textboxes outline the consensus guidelines on which sports are or are not allowed and which ones surgeons were undecided about.

Surgeon Consensus Guidelines for Return to Sport Following Total Hip Arthroplasty: Activities Allowed[142]

- Bowling
- Dancing (ballroom, jazz, square)
- Doubles tennis
- Elliptical
- Golf
- Hiking
- Low-impact aerobics
- Road cycling
- Rowing
- Speed walking
- Stairclimber
- Stationary cycling
- Stationary skiing
- Swimming
- Treadmill
- Walking
- Weight machines

Surgeon Consensus Guidelines for Return to Sport Following Total Hip Arthroplasty: Activities Allowed with Experience[142]

- Cross-country skiing
- Downhill skiing
- Ice skating and roller blading
- Pilates
- Weight lifting

Surgeon Consensus Guidelines for Return to Sport Following Total Hip Arthroplasty: Activities Not Allowed[142]

- Baseball and softball
- Contact sports (football, basketball, soccer)
- High-impact aerobics
- Jogging
- Racquetball and squash
- Snowboarding

Surgeon Consensus Guidelines for Return to Sport Following Total Hip Arthroplasty: Undecided if Activities Allowed[142]

- Martial arts
- Singles tennis

Patients who participate in athletic activities that are too strenuous after joint replacement put themselves at greater risk for traumatic complications (e.g., dislocation, periprosthetic fracture, and implant breakage) compared with sedentary patients who have joint replacements. Another major consideration for return to recreation and sports is the wear placed on prosthetic-bearing surfaces. Body weight and the number of steps affect component wear; therefore activities that require more weight-bearing steps cause greater wear on the prosthesis. Activities such as jogging, hiking, and power walking impose up to 5 times body weight across the joint, whereas cycling imposes less than 1.5 times body weight. Despite prosthetic wear, these activities are beneficial from a strength, flexibility, and cardiovascular standpoint. Therefore, a balance is required between the health benefits of exercise and some increased risk of prosthetic wear. If an activity is to be performed with high frequency and long duration, as is required in sports, then low-impact activities, such as swimming, cycling, golf, and doubles tennis, should be recommended. If only occasional recreational activity is desired, higher-impact activities, such as hiking, power walking, and singles tennis, may be safe because of the low frequency and short duration of the activity.[39]

OUTCOMES AND ASSESSMENT TOOLS

Interest in assessing the outcome of hip arthroplasty has grown significantly in an effort to inform best practice and to provide patients with objective information regarding the expected outcomes of the procedure specific to their clinical presentation. The HHS is perhaps the most commonly used system for assessing patients who have undergone THA. This instrument is used by the clinician to rate the patient's pain, function, and joint mobility. Scores range from 0 to 100 with higher scores indicating better outcomes. The **36-item Medical Outcomes Study Short-Form Health Survey (SF-36)** supplements the HHS well by also capturing quality of life domains that are influenced by THA.[143] The SF-36 is often considered the "gold standard" of health outcome assessment tools. This self-reported outcome tool examines eight dimensions, including physical function, social function, physical and emotional role, pain, mental health, vitality, and general health. Scores range from 0 to 100 with higher scores indicating better health status. Due to the broad nature of the areas examined, it is less sensitive to changes in functional ability following THA and typically is used in conjunction with instruments that are more specific to THA.

The **Western Ontario and McMaster Universities Arthritis Index (WOMAC)** is an arthritis-specific evaluation tool that also is frequently used to assess patients who have had THA.[144] Pain, stiffness, and function are self-rated on a Likert scale with an ordinal scale of 0 to 4. A maximum score of 20, 8, and 68, respectively, can be reported for each subcategory as well as a global score by summing the three subscale scores. Lower scores indicate lower levels of symptoms or physical disability. A study of the SF-36, WOMAC, and HHS has shown them all to have high validity and reliability in assessing the outcome of THA.[145,146]

The **Hip Disability and Osteoarthritis Outcome Score (HOOS)** examines five domains of pain, symptoms, ADLs, sport and recreation, and hip-related quality of life by self-report. It has been validated for use in patients with hip arthroplasty and has been found to be more responsive than the WOMAC.[147] The **Lower Extremity Functional Scale (LEFS)** is a common tool used to assess a broad range of lower extremity disorders and is more sensitive to change in function than the SF-36. This scale rates the patient's ability to perform 20 physical tasks on a Likert scale of 0 to 4 with higher scores indicating better function and a maximum score of 80. It has excellent psychometric properties and is easy to administer and score.[148] The **University of California–Los Angeles activity scale** has been found to be a valuable tool for assessing patients' overall activity level postoperatively.[149] This scale provides a simple rating from 1 to 10 to describe the patient's activity level from no physical activity to regular participation in impact sports, similar to the **Tegner Activity Level Scale**.[150]

Despite the number of self-reported assessment tools available for use in patients following THA, there is a known discord between self-report and performance-based measures of function following hip arthroplasty.[151] Self-reported measures tend to show the most significant improvements in the early phases of rehabilitation, whereas performance-based measures may take a longer time into recovery to demonstrate change. In addition to the use of the above-described self-reported scales of function, common performance-based assessments for patients following THA include the **6-Minute Walk Test (6MWT)**, the **Timed Up and Go Test**, and other time-based measures, such as gait speed, timed sit to stand, and timed stair climbing. The 6MWT is a reliable performance-based test examining the maximum distance hip arthroplasty patients can ambulate in 6 minutes over a 50-m walkway at a self-selected speed. Patients can use assistive devices as needed and results can be compared over time to measure improvement.[152] The Timed Up and Go assessment examines the time it takes the patient to stand from a chair, walk 3 m, and return to the chair. This test was designed to assess mobility, balance, walking ability, and fall risk in the older adults and has been used in the OA population as a predictor of function post arthroplasty.[153]

SUMMARY

The prevalence of both primary and revision THAs has increased dramatically from 1993 to 2005, and this trend is expected to continue between 2005 and 2030. This is partially due to an aging population, obesity epidemic, and improved prosthetic survivorship (which expands THA appropriateness to a younger population). OA continues to be the most common indication for primary THA. Anterolateral and posterior surgical techniques are most commonly used for THA, but the direct anterior approach is becoming more common, particularly in the United States. Each surgical approach has its advantages, disadvantages, and implications for rehabilitation, which specifically affect postoperative weight-bearing status, dislocation precautions, and rehabilitation progression. Typically, an uncomplicated THA patient is allowed WBAT. Although most THA patients have hip dislocation precautions, outcome data have fueled debate regarding the need for dislocation precautions, particularly for the anterolateral or anterior approaches, and some surgeons do not require hip dislocation precautions for certain patients.

Successful rehabilitation after THA requires effective communication and coordination among all members of the health care team, the patient, and the patient's family. Decision making on the plan of care, intervention, and discharge destination is influenced by surgical factors, patient characteristics, the stage of tissue healing, and the PT examination. It is vital that the rehabilitation clinician consider all factors to ensure the optimum surgical outcome and to allow the patient to be progressed appropriately throughout the episode of care. In the current era of

decreased hospital LOS, early and accelerated rehabilitation programs have become more common.

Revision THAs and minimally invasive THAs are addressed with decelerated and accelerated rehabilitation plans of care, respectively. The most commonly used THA outcome tools are the HHS, SF-36, and WOMAC. Research examining THA outcomes has become increasingly available, due to the interest in promoting evidence-based practice among surgeons and rehabilitation clinicians.

CHAPTER 20

Knee: Ligamentous and Patellar Tendon Injuries

ERIC M. BERKSON, DAVID NOLAN, KRISTINA FLEMING, ROBERT SPANG, JEFF WONG, PETER ASNIS, JAESON KAWADLER*

INTRODUCTION

Successful nonsurgical and surgical management of knee ligament and patellar tendon injuries requires knowledge of the functional anatomy and biomechanics of the knee. This understanding forms the basis for the physical examination of the knee and foundation for treatment options. When a patient sustains a knee ligament injury or patellar tendon injury, the clinician must be able to integrate this information to evaluate the knee and to develop an appropriate treatment regimen.

This chapter presents the scientific background of the principles of treatment of knee ligament and patellar tendon injuries. The functional anatomy and biomechanics of the knee are presented as a foundation for clinical decision making. Specific ligamentous injuries are then discussed in terms of epidemiology, operative and nonoperative approaches to treatment, and rehabilitation.

FOUNDATION FOR SURGICAL AND NONSURGICAL MANAGEMENT OF LIGAMENT AND PATELLAR TENDON INJURIES OF THE KNEE

Functional Anatomy and Biomechanics of the Knee

The knee joint consists of articulations among the femur, tibia, and patella. The distal end of the femur and the proximal end of the tibia form the tibiofemoral joint, whereas the distal end of the femur and the articular side of the patella form the patellofemoral articulations, which participate in the flexion-extension movement of the knee. The proximal tibiofibular joint assists in lateral stability of the knee.[1] The femoral condyles are convex in the anterior and posterior and the medial and lateral directions. They are separated by the trochlear groove, which guides the patella during flexion and extension. The intercondylar notch serves as the site of attachment for the anterior and posterior cruciate ligaments. The width of the intercondylar notch may be an important consideration for the risk of injury to the cruciate ligaments and for the development of loss of extension after reconstruction of the anterior cruciate ligament (ACL). The transverse anterior to posterior dimension of the lateral femoral condyle is greater than that of the medial femoral condyle (Figure 20-1).[2] As a result, the lateral femoral condyle projects farther anteriorly than the medial femoral condyle, providing a bony buttress to minimize lateral displacement of the patella. The radius of curvature of the femoral condyles decreases from anterior to posterior and is shorter on the medial side than on the lateral side.[3] The anterior to posterior length of the articular surface of the medial femoral condyle is longer than that of the lateral femoral condyle.[2] The longer articular surface of the medial femoral condyle facilitates lateral (external) rotation of the tibia as the knee approaches terminal extension.

The medial tibial plateau is concave from anterior to posterior and from medial to lateral, whereas the lateral tibial plateau is convex from anterior to posterior

*The authors, editors, and publisher wish to acknowledge Michael M. Reinold, James J. Irrgang, Marc R. Safran, and Freddie H. Fu for their contributions on this topic in the previous edition.

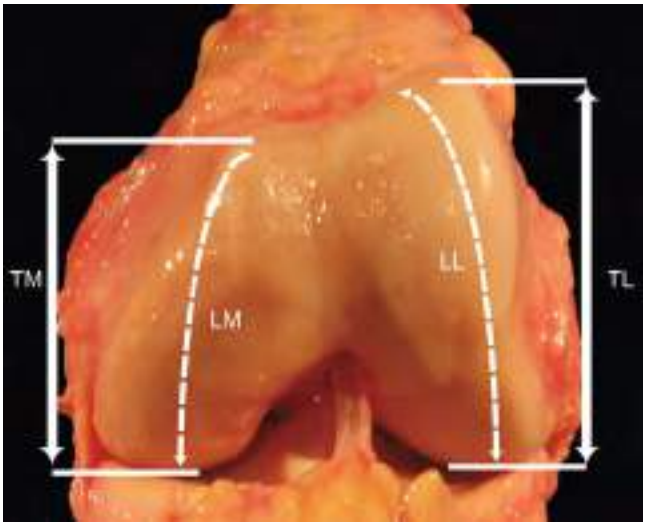

Figure 20-1 Cadaveric specimen of the distal femur. The transverse anterior-posterior dimension of the lateral femoral condyle *(TL)* is greater than that of the medial femoral condyle *(TM)*. The anterior to posterior length of the articular surface of the medial femoral condyle *(LM)* is longer than the anterior to posterior length of the articular surface of the lateral femoral condyle *(LL)*. (TL>TM; LM>LL.)

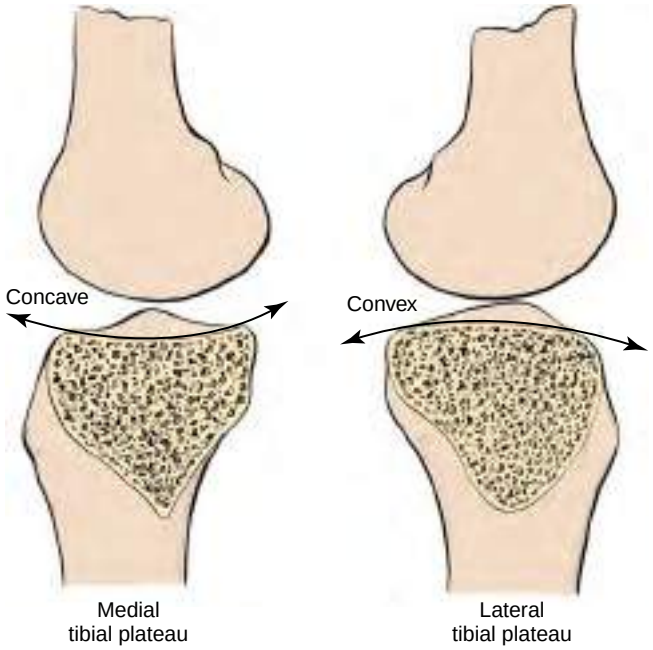

Figure 20-2 The medial tibial plateau is concave anterior to posterior, whereas the lateral tibial plateau is convex anterior to posterior. (From Kapandji IA: *The physiology of the joints: annotated diagrams of the mechanics of the human joints*, Edinburgh, 1970, Churchill Livingstone.)

Static (Passive) Restraints of the Knee

- Ligaments, primarily:
  - Medial collateral ligament
  - Lateral collateral ligament
  - Anterior cruciate ligament
  - Posterior cruciate ligament
  - Posterior oblique ligament
  - Posterolateral corner
- Joint capsule
- Menisci (2)
- Iliotibial band

Dynamic (Active) Restraints of the Knee

- Quadriceps
- Hamstrings
- Gastrocnemius
- Gracilis
- Sartorius
- Popliteus

(Figure 20-2). The concavity of the tibial plateaus is increased by the presence of the menisci. The bony configuration of the knee lends little inherent stability. Stability of the knee depends on static and dynamic restraints. The static restraints include the joint capsule, ligaments, and menisci. Dynamic stability is provided by muscles that cross the knee, including the quadriceps, hamstrings, popliteus, and gastrocnemius.

The ligamentous restraints of the knee include the collateral, cruciate, and capsular ligaments. The medial collateral ligament (MCL) is a broad band that runs from the medial epicondyle of the femur to insert on the tibia approximately 10 cm below the medial joint line (Figure 20-3). The MCL, which has been described as a thickening of the medial capsule, is divided into deep and superficial layers. The deep MCL is intimately attached to the medial meniscus and consists of the tibiomeniscal and femoromeniscal ligaments. The superficial band of the MCL runs from the medial epicondyle to insert distal to the tibial plateau. The ligament joins the posterior joint capsule where it forms the posterior oblique ligament.[4,5] Because the superficial band of the MCL is farther from the center of the knee, it is the first ligament injured when a valgus stress is applied. The MCL courses anteriorly as it runs from the femur to the tibia.

The lateral (fibular) collateral ligament (LCL) is a cordlike structure that runs from the lateral epicondyle of the femur to the fibular head (Figure 20-4). The LCL courses somewhat posteriorly as it passes from the femur to the fibular head. It is separated from the lateral meniscus by the popliteus tendon, which partly explains the increased mobility of the lateral meniscus.

The ACL arises from the tibial plateau just anterior and medial to the tibial eminence. From the tibia, the ACL courses superiorly, laterally, and posteriorly to insert on the posterior margin of the medial wall of the lateral femoral condyle (Figure 20-5). The ACL is composed of two distinct bundles: the anteromedial bundle, which is taut in 60° or more of flexion, and the posterolateral bundle, which is

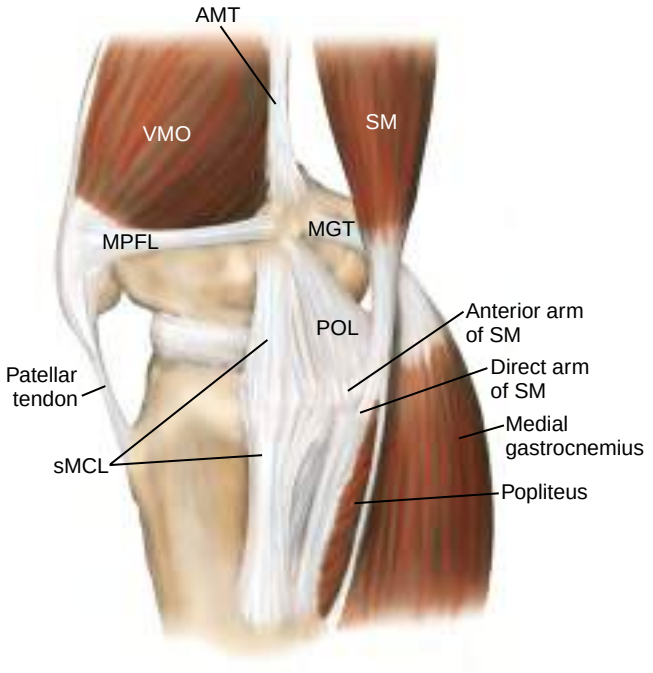

Figure 20-3 Structures of the medial side of the knee. *VMO*, Vastus medialis obliquus muscle; *MPFL*, medial patellofemoral ligament; *POL*, posterior oblique ligament; *sMCL*, superficial medial collateral ligament; *SM*, semimembranosus muscle; *MGT*, medial gastrocnemius tendon; *AMT*, adductor magnus tendon. (From LaPrade RF, Engebretsen AH, Ly TV et al: The anatomy of the medial part of the knee, *J Bone Joint Surg Am* 89:2003, 2007.)

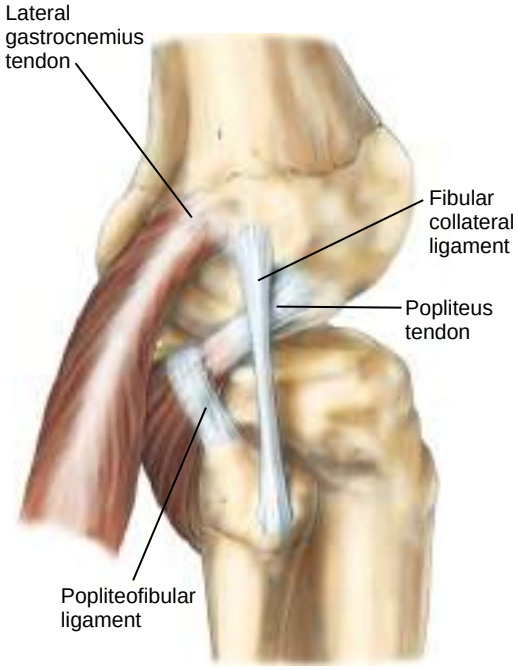

Figure 20-4 Structures of the lateral side of the knee. Illustration demonstrates the isolated fibular collateral ligament, popliteus tendon, popliteofibular ligament, and lateral gastrocnemius tendon (lateral view, right knee). (From LaPrade RF, Ly TV, Wentorf FA, Engebretsen L: The posterolateral attachments of the knee: a qualitative and quantitative morphologic analysis of the fibular collateral ligament, popliteus tendon, popliteofibular ligament, and lateral gastrocnemius tendon, *Am J Sports Med* 31:856, 2003.)

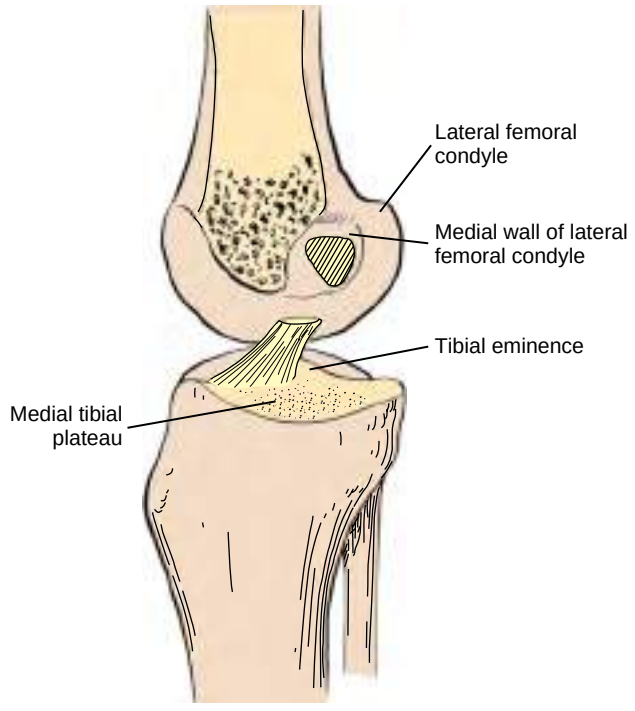

Figure 20-5 The anterior cruciate ligament arises from the tibial plateau anterior and medial to the tibial eminence and courses superiorly, laterally, and posteriorly to insert on the medial wall of the lateral femoral condyle. (From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 625, Philadelphia, 1996, WB Saunders.)

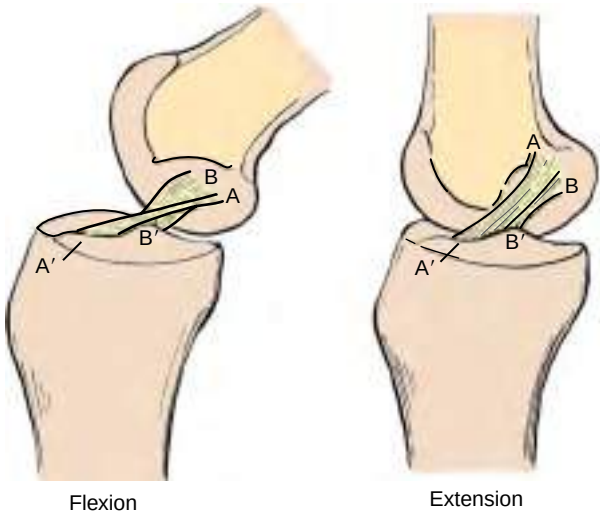

Figure 20-6 The anterior cruciate ligament is composed of two bundles. The anteromedial bundle (A-A′) is taut in flexion. The posterolateral bundle (B-B′) is taut in extension. (From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 625, Philadelphia, 1996, WB Saunders.)

taut in extension and medial (internal) and lateral (external) rotation (Figure 20-6). The anteromedial and posterolateral bundles both provide anteroposterior (AP) stability to the knee, whereas the posterolateral bundle has been shown to also provide rotational stability to the knee.[6–8]

The posterior cruciate ligament (PCL) arises from the posterior margin of the tibia just inferior to the tibial plateau. From the tibia, the PCL courses superiorly, anteriorly, and medially to insert on the lateral wall of the medial femoral condyle (Figure 20-7). The PCL has been described as consisting of two bands: the anterolateral band, which is taut in flexion, and the posteromedial band, which is taut with the knee in extension.

A synovial fold covers both cruciate ligaments. The ACL and PCL are therefore intra-articular but are considered extrasynovial. The predominant blood supply of the cruciate ligaments comes from the middle geniculate artery and a few branches of the inferior medial and lateral geniculate arteries. Branches of these arteries form a plexus within the encompassing synovial sheath.[9] Disruption of this plexus is the source of the hemarthrosis typically seen after ACL injury. The intra-articular position of the ACL is one factor in the difficulty in spontaneous healing of ACL tears.

The meniscofemoral ligaments course in a direction similar to that of the PCL. They arise from the posterior horn of the lateral meniscus and course superiorly and medially to insert on the lateral wall of the medial femoral condyle. The ligament of Humphrey lies anterior to the PCL, and the ligament of Wrisberg lies posterior to the PCL. The meniscofemoral ligaments become taut with internal rotation of the tibia.

The posterolateral corner (PLC) of the knee has a complex anatomy consisting of the biceps femoris, the LCL, and the popliteus complex (see Figure 20-4). Dynamic and static components, including the popliteofibular ligament, the fabellofibular ligament, and the arcuate complex, add to this stability and prevent excessive posterior translation, varus rotation, and posterolateral rotation. The arcuate complex consists of the arcuate ligament, popliteus tendon, LCL, and posterior third of the lateral capsule.[10] The arcuate ligament arises from the fibular head and LCL to course superiorly and medially to insert along the popliteus tendon and lateral condyle of the femur. The popliteofibular ligament (PFL) is present in 98% of knees, but the anatomy of the PLC can vary significantly.[11] The presence of a fabella, a variable sesamoid bone in the tendinous portion of the gastrocnemius muscle, correlates with the presence of a fabellofibular ligament.

The medial and lateral menisci lie between the tibial plateaus and femoral condyles (Figure 20-8). The menisci improve stability of the knee by increasing the concavity of the tibial plateaus. Both menisci also serve a secondary role as a stabilizer of the knee. The posterior horn of the medial meniscus serves a secondary stabilizing effect resisting anterior tibial translation.[12,13] Levi et al.[14] documented a 58% increase in anterior tibial translation with a medial meniscectomy in the flexed ACL-deficient knee. The lateral meniscus also serves as a stabilizer, which is particularly important in axial and rotatory loading of the knee.[15] The menisci also absorb shock and distribute weight bearing over a greater surface area.

The outer third of the menisci is vascularized by the middle genicular artery, and the inner third of the menisci is considered to be avascular. Peripheral tears of the menisci therefore have the potential to heal and often are repaired surgically; however, tears in the inner third

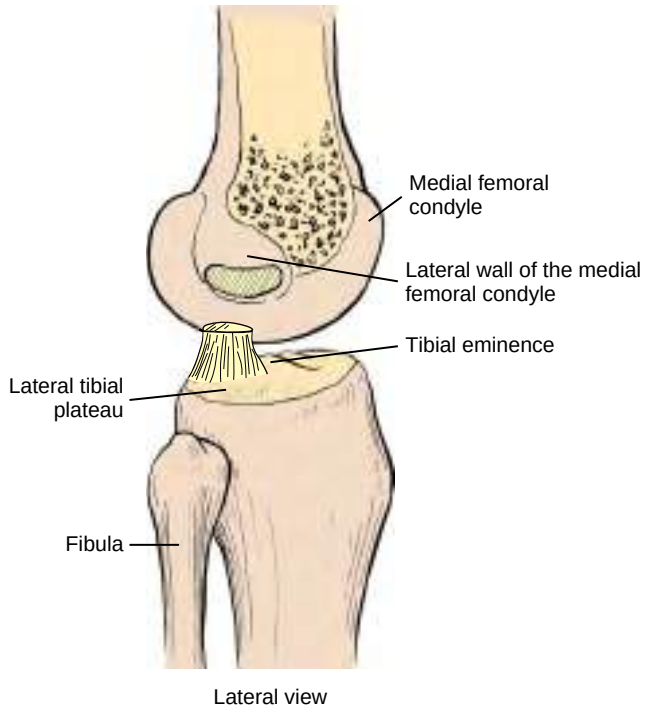

Figure 20-7 The posterior cruciate ligament arises from the posterior margin of the tibial plateau and courses superiorly, medially, and anteriorly to insert on the lateral wall of the medial femoral condyle. (From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 625, Philadelphia, 1996, WB Saunders.)

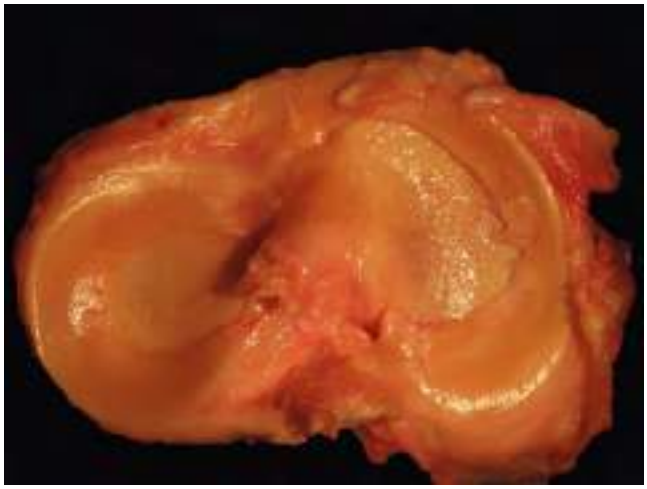

Figure 20-8 The medial and lateral menisci lie between the tibial plateaus and femoral condyles and have different shapes because of the structure of the tibial plateau. The medial meniscus is longer in the anteroposterior direction with a smaller anterior horn than its posterior. The lateral meniscus is more symmetrical but has fewer capsular and ligamentous attachments and is thus more mobile.

(the avascular "white–white" zone) do not heal, and partial meniscectomy often is required. Baratz et al.[16] reported the effects of a partial or total meniscectomy on the articular contact area and stress in the human knee. Total meniscectomy resulted in a concentration of high contact forces on a small area of the tibial plateau. Partial meniscectomy resulted in a smaller increase in contact stress. With a total meniscectomy, the increased tibiofemoral contact forces that result may predispose the patient to long-term degenerative changes. Therefore, partial meniscectomy is preferred to minimize this risk. Because of the convex articulation of the tibia on the lateral side, partial meniscectomy of the lateral meniscus results in greater contact stresses and increased risk for progression of osteoarthritis than the medial side.[17]

During flexion and extension of the knee, the menisci move posteriorly and anteriorly, respectively (Figure 20-9). This movement is a result of the bony geometry of the tibiofemoral joint. Posterior movement of the medial meniscus during flexion also is partly because of the insertion of a portion of the semimembranosus into the posterior horn of the medial meniscus. Similarly, fibers from the popliteus tendon inserting on the posterior horn of the lateral meniscus pull the lateral meniscus posteriorly during flexion. AP movement of the lateral meniscus is greater than that of the medial meniscus, which reduces the susceptibility of the lateral meniscus to injury. During rotation of the knee, the menisci move relative to the tibial plateaus. During lateral (external) rotation of the tibia, the medial meniscus moves posteriorly relative to the medial tibial plateau, whereas the lateral meniscus moves anteriorly relative to the lateral tibial plateau. During medial (internal) rotation of the tibia, movement of the menisci relative to the tibial plateaus is reversed.[3]

Flexion and extension of the knee combine rolling and gliding of the joint surfaces to maintain congruency of these surfaces. During flexion of the knee, the femur rolls posteriorly and glides anteriorly. During extension, the femur rolls anteriorly and glides posteriorly. The combined rolling and gliding of the joint surfaces maintains the femoral condyles on the tibial plateaus. Disruption of the normal arthrokinematics of the knee results in increased translation of the joint surfaces, which can lead to progressive degenerative changes of the articular surfaces.

Muller[18] described the ACL and PCL as a four-bar linkage system that maintains the normal arthrokinematics of the knee (Figure 20-10, *A*). Two of the four bars are the ACL and PCL. The remaining two bars are the line connecting the femoral attachments of the ACL and PCL and the line connecting the tibial attachments of the ACL and PCL. The ACL and PCL are inelastic and maintain a constant length as the knee flexes and extends. As a result, the four-bar linkage system controls rolling and gliding of the joint surfaces as the knee moves. During flexion, the femur rolls posteriorly. This increases the distance between the tibial and femoral insertions of the ACL. Because the ACL cannot lengthen, it guides the femoral condyles anteriorly (Figure 20-10, *B*). Conversely, during extension of the knee, the femoral condyles roll anteriorly and the distance between the femoral and tibial insertions of the PCL increases. Because the PCL cannot lengthen, it pulls the femoral condyles posteriorly as the knee extends (Figure 20-10, *C*). Disruption of the ACL or PCL disrupts the four-bar linkage system and results in abnormal translation of the femoral condyles. Disruption of the normal arthrokinematics of the knee may lead to repetitive injury of the menisci and joint surfaces and to the development of progressive degenerative changes over time.

Ligamentous Restraints of the Knee

The primary restraint to anterior translation of the tibia is the ACL, which provides approximately 85% of the total restraining force to anterior translation of the tibia.[19,20]

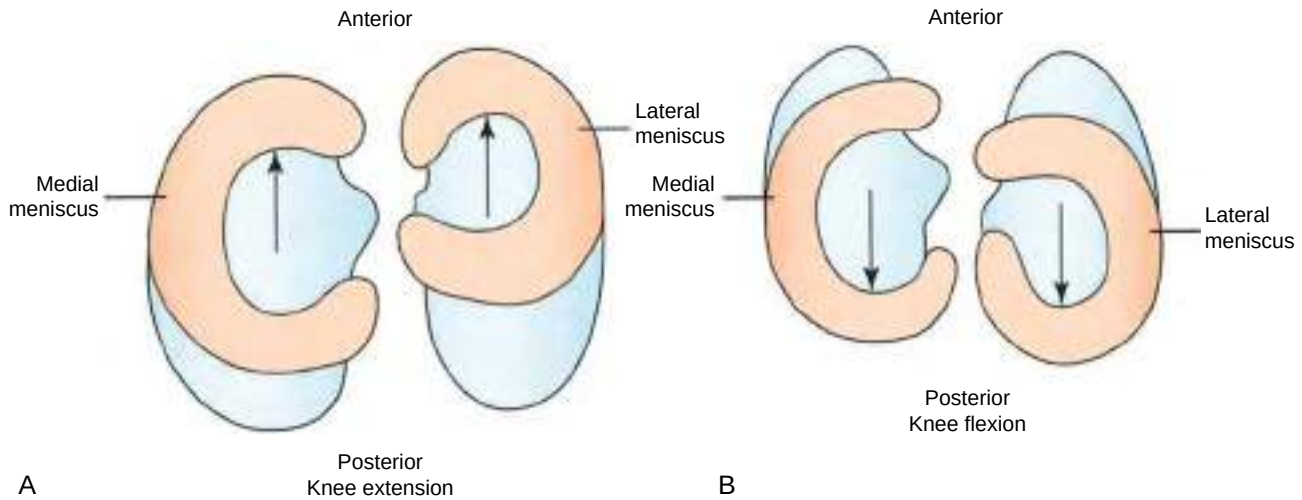

Figure 20-9 The menisci move anteriorly with extension (**A**) and posteriorly with flexion (**B**). The right knee is shown. (Redrawn from Kapandji IA: *The physiology of the joints: annotated diagrams of the mechanics of the human joints,* Edinburgh, 1970, Churchill Livingstone.)

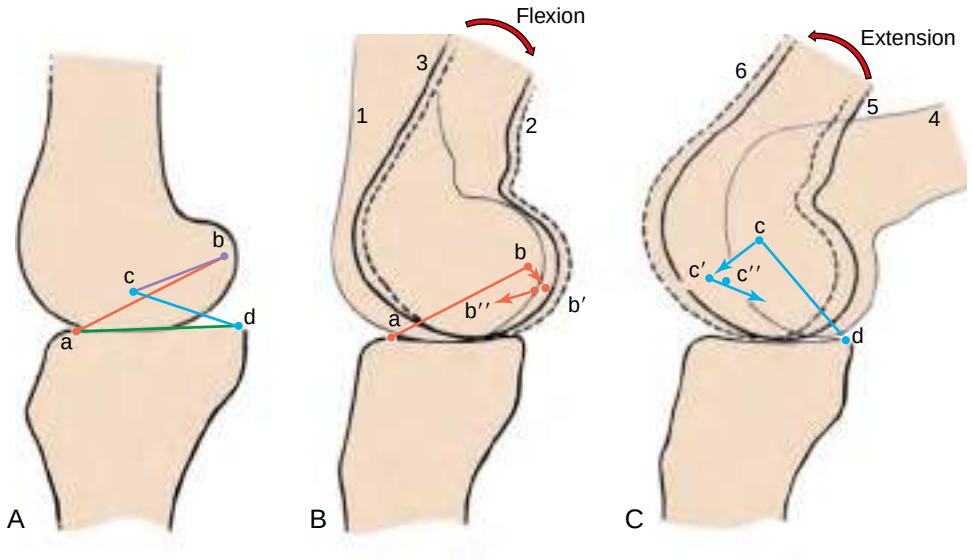

Figure 20-10 Four-bar linkage system. **A**, The four bars consist of the anterior cruciate ligament (ACL) *(line ab);* the posterior cruciate ligament (PCL) *(line cd);* the line connecting the femoral attachments of the ACL and PCL *(line cb);* and the line connecting the tibial attachments of the ACL and PCL *(line ad)*. **B**, During flexion, the femur rolls posteriorly; this increases the distance between the tibial and femoral insertions of the ACL. Because the ACL cannot lengthen, it guides the femoral condyles anteriorly. *1*, The position of the femur in extension; *2*, position of the knee if anterior sliding of the femur did not occur with rolling during flexion; *3*, actual position of the femur with flexion because of the pull of the anterior cruciate ligament causing the femur to slide forward during the roll. **C,** During extension of the knee, the femoral condyles roll anteriorly, and the distance between the femoral and tibial insertions of the PCL increases. Because the PCL cannot lengthen, it pulls the femoral condyles posteriorly as the knee extends. *4,* The position of the femur in flexion; *5*, position of the knee if posterior sliding of the femur did not occur with rolling during extension; *6*, actual position of the femur with extension because of the pull of the posterior cruciate ligament causing the femur to slide backward during the roll. (Modified from Kapandji LA: *The physiology of the joints: annotated diagrams of the mechanics of the human joints,* Edinburgh, 1970, Churchill Livingstone.)

The remaining 15% of the restraining ligamentous force to anterior displacement of the tibia is provided by the collateral ligaments, the middle portion of the medial and lateral capsules, and the iliotibial band (Table 20-1).

The primary restraint to posterior displacement of the tibia is the PCL. The PCL provides approximately 85% to 95% of the total restraining force to posterior translation of the tibia.[19] The remaining 5% to 15% of the total ligamentous restraining force to posterior displacement of the tibia is provided by the collateral ligaments, the posterior portion of the medial and lateral capsules, and the popliteus tendon. The ligaments of Humphrey and Wrisberg also provide restraint to posterior translation of the tibia, and their ability to do so increases with medial (internal) rotation of the tibia (see Table 20-1).

The primary restraint to valgus rotation is the MCL. The ACL and PCL serve as secondary restraints to valgus rotation. When the knee is in full extension, the posterior capsule becomes a significant restraint to valgus rotation (see Table 20-1). For varus rotation, the primary restraint is the LCL, and the ACL and PCL serve as secondary ligamentous restraints. The restraining force provided by the ACL and PCL, as well as the posterior capsule, increases when the knee is in full extension (see Table 20-1).

Lateral (external) rotation of the tibia is restrained by the collateral ligaments and PLC complex, whereas

TABLE **20-1**

Primary and Secondary Restraints of the Knee

Tibial Motion	Primary Restraint	Secondary Restraints
Anterior translation	ACL	MCL, LCL; middle third of medial and lateral capsule; iliotibial band
Posterior translation	PCL	MCL, LCL; posterior third of medial and lateral capsule; popliteus tendon; anterior and posterior meniscofemoral ligaments
Valgus rotation	MCL	ACL, PCL; posterior capsule when knee is fully extended
Varus rotation	LCL	ACL, PCL; posterior capsule when knee is fully extended
Lateral (external) rotation	MCL, LCL	
Medial (internal) rotation	ACL, PCL	Anterior and posterior meniscofemoral ligaments

ACL, Anterior cruciate ligament; *MCL,* medial collateral ligament; *LCL,* lateral collateral ligament; *PCL,* posterior collateral ligament.
From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 627, Philadelphia, 1996, WB Saunders.

medial (internal) rotation is restrained by the cruciate ligaments, the posteromedial capsule, and the ligaments of Humphrey and Wrisberg (see Table 20-1).

The quadriceps and hamstrings serve as dynamic stabilizers of the knee. In doing so, they assist the passive restraints in controlling kinematics of the knee. These muscles work synergistically with the cruciate ligaments to dynamically control motion of the knee. Unopposed contraction of the quadriceps is synergistic to the PCL and antagonistic to the ACL. Conversely, isolated contraction of the hamstrings is synergistic to the ACL and antagonistic to the PCL. It is theorized that activities that promote co-contraction of the hamstrings and quadriceps minimize tibial translation, and activities of this type have been advocated for rehabilitation of knee ligament injuries.[21] Dynamic stabilization of the knee to control abnormal motion depends on muscular strength and endurance, as well as on the development of appropriate neuromuscular control.

Role of Proprioception

Researchers have shown increased interest in the role of proprioception in the prevention and progression of knee injuries.[22–25] A systematic review by Cooper et al.[26] detailed decreased proprioception in populations with ACL deficiency as well as the postoperative ACL reconstruction population. Proprioception has been described as a variation in the sense of touch. It includes the senses of joint motion (i.e., kinesthesia) and joint position. Proprioception is mediated by mechanoreceptors in the skin, the musculotendinous units, ligaments, and the joint capsule. These sensory receptors transduce mechanical deformation to a neural signal, which modulates conscious and unconscious responses. Although local receptors are disrupted in ligamentous rupture, it is theorized that other knee joint receptors may play a compensatory role in aiding in the stability of the knee, via increased muscle spindle sensitivity and protective muscle activation.[26] The role of proprioception in providing smooth, coordinated movement and dynamic stabilization has been well documented.[24,27–29]

Proprioceptive reflexes originating from the joint capsule or musculotendinous units likely also play a role in knee stability, although they have been reported to have relatively long latency in humans.[30] This was demonstrated by Solomonow et al.,[24] who reported increased hamstring electromyographic (EMG) activity in a patient with an ACL-deficient knee during maximum slow-speed isokinetic testing of the quadriceps. The increased hamstring EMG activity occurred simultaneously with anterior subluxation of the tibia at approximately 40° knee flexion and was associated with a sharp decrease in quadriceps torque and inhibition of quadriceps EMG activity. Because the ACL was ruptured, reflex contraction of the hamstrings could not have been mediated by receptors originating in the ACL. They proposed that this reflex contraction is mediated by receptors in the joint capsule or hamstring muscles.

Several clinical studies have evaluated proprioception in terms of threshold to detection of passive motion and reproduction of passive joint position. Barrack et al.[22] reported deficits in threshold to detection of passive motion in subjects with a unilateral ACL-deficient knee. Barrett[28] reported high correlations between measurements of proprioception and function ($r = 0.84$) and patient satisfaction ($r = 0.90$) in 45 patients who had undergone ACL reconstruction. Standard knee scores and clinical examination results correlated poorly with the patient's own opinion and the results of functional tests. Lephart et al.[25] studied the threshold to detection of passive movement in patients who had undergone ACL reconstruction. Testing was performed at 15° and 45° flexion. Three trials were performed, moving into flexion and extension. The results indicated that the threshold to detection of passive movement was less sensitive in the reconstructed knee than the noninvolved knee. Also, the threshold to detection of passive motion was more sensitive in both the reconstructed knee and the normal knee at 15° flexion than at 45° flexion. Sensitivity to detection of passive motion was enhanced by the use of a neoprene sleeve, which has implications for bracing after ACL injury and/or reconstruction. Use of a sleeve or compressive wrap or garment may help the patient develop a greater sense of perception of the knee during rehabilitation and progressive activity.

Several studies have also examined the relationship between neuromuscular/proprioceptive training and single-leg hop test scores in a population of patients with ACL deficiency.[31–33] Groups who engaged in neuromuscular training as part of their rehabilitation program displayed significantly improved single-leg hop test scores compared with those of a standard training group. Liu-Ambrose et al.[34] failed to note similar results in patients after surgical ACL reconstruction. It was hypothesized that patients with ACL deficiency may rely more heavily on compensatory muscle activation than patients who undergo ACL reconstruction because of the lack of integrity of the static stabilizing structures of the knee.[34]

Furthermore, Liu-Ambrose et al.[34] examined the effect of proprioceptive training on concentric and eccentric quadriceps and hamstring strength. The proprioceptive training group demonstrated significantly greater improvement in concentric quadriceps strength and eccentric hamstring strength over a 12-week period, compared with a standard strength-training group.

Beard et al.[35] and Fitzgerald et al.[32] examined passive laxity using a KT1000 and KT2000 after a proprioceptive training program. Neither study reported an increase in sagittal plane motion after rehabilitation programs in either the treatment or the control groups. Therefore, it can be concluded that neuromuscular training programs involve minimal risk and can provide improvements in strength, proprioception, and functional outcome testing (i.e., hop testing).

Injury to the knee may result in abnormal sensory feedback and altered neuromuscular control, which may lead to recurrent injury. Proprioceptive training after knee injury and/or surgery should attempt to maximize the use of sensory information mediated by the ligaments, joint capsule, and/or musculotendinous unit to stabilize the joint dynamically. Proprioceptive training requires repetition to develop motor control of abnormal joint motion and may be enhanced with the use of EMG biofeedback. Initially, control of abnormal joint motion requires conscious effort. Through repetitive training, motor control of abnormal movement becomes automatic and occurs subconsciously. It should be noted, however, that the extent to which an individual can develop neuromuscular control of abnormal joint motion to stabilize the knee dynamically is currently unknown.

Biomechanics of Exercise

Open kinetic chain (OKC) exercise is exercise in which the distal segment is free to move, resulting in isolated movement at a given joint. At the knee, OKC exercise results in isolated flexion and extension. OKC knee extension is a result of isolated contraction of the quadriceps, and OKC knee flexion occurs as a result of isolated contraction of the hamstrings. Baratta et al.[29] and Draganich et al.[36] reported low levels of co-activation of the quadriceps and hamstrings during OKC knee extension. It is hypothesized that the hamstrings become active during the terminal range of extension to decelerate the knee and act as a synergist to the ACL to minimize anterior tibial translation produced by contraction of the quadriceps. During OKC knee extension, the flexion moment arm increases as the knee is extended from 90° flexion to full extension (0°). This requires increasing quadriceps and patellar tendon tension, which can increase the load on the patellofemoral and tibiofemoral joints.

During closed kinetic chain (CKC) exercises, the distal segment is relatively fixed; therefore movement at one joint results in simultaneous movement of all other joints in the kinetic chain in a predictable manner. The lower extremity functions as a CKC when a person squats over the fixed foot, resulting in simultaneous movement of the ankle, knee, and hip. CKC exercises for the lower extremity result in contraction of muscles throughout the lower extremity. During CKC exercises for the lower extremity, the flexion moment arms at the knee and hip increase as the squat is performed, and increased force of contraction of the quadriceps and hamstrings is required to control the knee and hip, respectively.

OKC and CKC exercises have different effects on tibial translation and ligamentous strain and load. During active OKC knee extension, the shear component produced by unopposed contraction of the quadriceps depends on the angle of knee flexion (Figure 20-11). Sawhney et al.[37] investigated the effects of isometric quadriceps contraction on tibial translation in subjects with an intact knee. Tibial translation was measured with the KT1000 Ligament Arthrometer (MEDmetric, San Diego, CA) at 30°, 45°, 60°, and 75° flexion. OKC isometric quadriceps contraction against 10 pounds (4.5 kg) of resistance applied to the distal aspect of the leg resulted in anterior tibial translation at 30° and 45° flexion. No significant tibial translation occurred at 60° or 75° flexion. It was determined that the quadriceps-neutral Q angle (i.e., the angle at which quadriceps contraction produces no anterior or posterior tibial translation) occurs at 60° to 75° flexion (see Figure 20-11, *A*). OKC knee extension at angles less than the quadriceps-neutral position results in anterior translation of the tibia. This was reported by Grood et al.[20] in intact cadaveric knees. Anterior translation of the tibia during OKC knee extension increased with loading of the quadriceps at angles less than 60° flexion. Sectioning of the ACL increased anterior translation during loaded and unloaded OKC knee extension. Anterior tibial translation produced by the quadriceps at knee flexion angles less than the quadriceps-neutral angle is a result of the anteriorly directed shear component of the patellar tendon force (see Figure 20-11, *B*). OKC knee extension at knee flexion angles greater than the quadriceps-neutral position results in posterior tibial translation. This is the result of a posteriorly directed shear component of the patellar tendon force at these angles of knee flexion (see Figure 20-11, C).

OKC knee flexion is produced by isolated contraction of the hamstrings. This has been shown to result in posterior translation of the tibia and was reported by Lutz et al.,[38] who found posterior tibial shear forces during isometric OKC knee flexion at 30°, 60°, and 90° knee flexion. The posterior shear force increased as flexion progressed from 30° to 90° flexion.

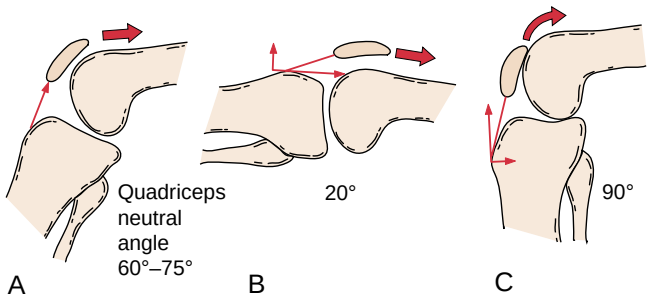

Figure 20-11 During open-chain knee extension, tibial translation is a function of the shear force produced by the patellar tendon. **A**, Quadriceps neutral position. The patellar tendon force is perpendicular to the tibial plateaus and results in compression of the joint surfaces without shear. **B**, At flexion angles less than the angle of the quadriceps neutral position, orientation of the patellar tendon produces anterior shear of the tibia. **C,** At angles greater than the angle of the quadriceps neutral position, patellar tendon force causes a posterior shear of the tibia. (From Daniel DM, Stone ML, Barnett P, Sachs R: Use of the quadriceps active test to diagnose posterior cruciate ligament disruption and measure posterior laxity of the knee, *J Bone Joint Surg Am* 70:386-391, 1988.)

Several methods of biomechanical analysis have been used to study rehabilitation of the knee, including cadaveric, EMG, kinematic, kinetic, mathematical modeling, and in vivo strain gauge measurements. These studies are best evaluated by delineating the findings according to the tissue or structure examined, such as the ACL, the PCL, and the patellofemoral joint.

Anterior Cruciate Ligament

Most biomechanical research on rehabilitation of the knee has focused on the ACL. After years of theoretical and anecdotal assumptions, researchers now are better able to scrutinize more closely the efficacy of OKC and CKC exercises. Markolf et al.[39] examined the effect of compressive loads on cadaveric knees to simulate body weight. These authors reported that compressive forces reduce strain on the ACL, compared with OKC exercises, thus providing a protective mechanism. Fleming et al.[40] investigated this theory using in vivo strain gauge measurements in the ACL. This method allows direct measurement of ACL strain during activity. The authors noted that strain on the ACL increased from –2% during non–weight bearing to 2.1% in a weight-bearing position. Although an increase in ACL strain was observed in a weight-bearing position, it still is unclear whether a 2% strain is detrimental to a healing ACL graft. Clinical experience has demonstrated that early weight bearing does not result in poor functional outcomes in postoperative ACL reconstructions.

CKC exercises have also been theorized to reduce ACL strain by providing co-contraction of the hamstrings and quadriceps. Wilk et al.[41] examined the EMG activity of the quadriceps and hamstrings during the CKC squat and leg press and the OKC knee extension. These authors noted that co-contraction occurred from 30° to 0°, during the ascent phase of the squat, when the body is positioned directly over the knees and feet, but it did not occur at other ranges of motion or during the CKC leg press or OKC knee extension. Therefore not all CKC exercises produce a co-contraction of the quadriceps and hamstrings. Rather, several factors appear to affect muscle activation during CKC exercises, including the knee flexion angle, body position relative to the knee, and the direction of movement (i.e., ascending or descending). Clinically, exercises performed in an upright and weight-bearing position with the knee flexed to approximately 30° (e.g., squats and lateral lunges) may be used during knee rehabilitation to promote co-contraction of the quadriceps and hamstrings.

Wilk et al.[41] also used mathematical modeling to estimate the shear forces at the tibiofemoral joint during the squat, leg press, and knee extension exercise (Figure 20-12). The authors reported that a posterior tibiofemoral shear force was observed during the entire range of motion (ROM) during both the CKC squat and leg press (peak, 1500 Newtons [N]), and during deep angles of OKC knee extension from 100° to 40° (peak, 900 N). Anterior tibiofemoral shear force (peak, 250 N) and, theoretically, ACL strain were observed during the OKC knee extension exercise from 40° to 10°.

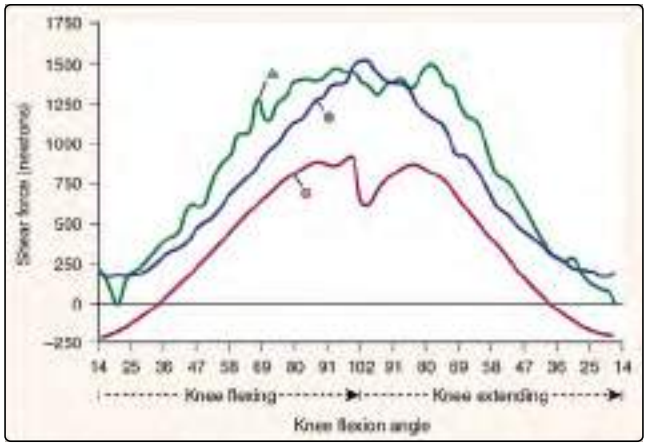

Figure 20-12 Tibiofemoral shear forces observed throughout the range of motion during closed kinetic chair squat (*green triangle*) and leg press (*blue circle*) exercises and open kinetic chain knee extension exercises (*red circle*). (Redrawn from Wilk KE, Escamilla RF, Fleisig GS et al: A comparison of tibiofemoral joint forces and electromyographic activity during open and closed kinetic chain exercises, *Am J Sports Med* 24:522, 1996.)

Similar to the results of Wilk et al.,[41] Beynnon et al.,[42] using in vivo strain gauge measurements, found that the greatest amount of ACL strain (2.8%) occurred during 40° to 0° OKC knee extension. This strain was found to increase significantly in a linear fashion with the application of an external 45 Newton boot (3.8%). However, the authors also reported an ACL strain of 3.6% during the CKC squat exercise. In contrast, application of external loading did not significantly increase the amount of strain on the ACL (4%).

Based on the findings of Fleming et al.,[40] Wilk et al.,[41] and Beynnon et al.,[42] both OKC and CKC exercises should be performed during rehabilitation of a reconstructed ACL, although the patient often is limited to 90° to 40° during the OKC knee extension when heavy resistance is applied.

The bicycle and stair climbers also are commonly used during ACL rehabilitation. Fleming et al.[43] analyzed six different bicycle riding conditions, manipulating speed and power. These authors found no significant differences among these conditions (minimal mean ACL strain of 1.7%). The greatest amount of strain was observed when the knee reached the greatest amount of extension. Similarly, Fleming et al.[44] analyzed two cadences of stair climbing (80 and 112 steps per minute) and noted a similar 2.7% strain on the ACL. Again, the greatest strain was observed during terminal knee extension. Therefore both bicycling and stair climbing are two safe exercises that put low strain on the ACL compared with other rehabilitation exercises (Table 20-2). Furthermore, the finding that the greatest

TABLE 20-2

In Vivo Strain on the Anterior Cruciate Ligament

Activity	ACL Strain
Isometric quadriceps contraction at 15°	4.4%
Squatting with resistance	4.0%
Active knee flexion with resistance	3.8%
Lachman's test (150 N of anterior shear at 30°)	3.7%
Squatting without resistance	3.6%
Active knee flexion without resistance	2.8%
Quadriceps and hamstring co-contraction at 15°	2.7%
Isometric quadriceps contraction at 30°	2.7%
Stair climbing	2.7%
Anterior drawer test (150 N anterior shear at 90°)	1.8%
Stationary bicycle	1.7%
Quadriceps and hamstrings co-contraction at 30°	0.4%
Passive knee range of motion	0.1%
Isometric quadriceps contraction at 60° and 90°	0.0%
Quadriceps and hamstrings co-contraction at 60° and 90°	0.0%
Isometric hamstring contraction at 30°, 60°, and 90°	0.0%

Modified from Fleming BC, Beynnon BD, Renstrom PA et al: The strain behavior of the anterior cruciate ligament during stair climbing: an in vivo study, *Arthroscopy* 15:185-191, 1999.

amount of strain occurred as the knee moved into terminal knee extension was similar to the results seen by Wilk et al.[41] and Beynnon et al.[42] during OKC and CKC exercises.

Posterior Cruciate Ligament

Historically, rehabilitation after injury to the PCL has had mixed results. Poor functional outcomes have often been attributed to residual laxity after surgical reconstruction. The biomechanics of the tibiofemoral joint during exercise must be understood so that the rehabilitative process does not have deleterious effects on the PCL.

Posterior tibiofemoral shear forces that occur during specific activities, such as level walking,[45] ascent up and descent down stairs,[46] and resisted knee flexion exercises,[47,48] have been documented.[49] Level walking and descent down stairs have a relatively low posterior tibiofemoral shear force, 0.4×body weight (BW) and 0.6×BW, respectively (Table 20-3). However, high posterior shear force has been noted during several commonly performed activities of daily living (ADLs), such as climbing stairs (1.7×BW at 45° knee flexion)[46,50] and squatting (3.6×BW at 140° knee flexion), which may have an effect on residual laxity after surgery. Further studies have reported that isometric knee flexion at 45° places a posterior shear force of 1.1×BW on the tibiofemoral joint.[48]

TABLE 20-3

Posterior Tibiofemoral Shear Forces

Source	Activity	Knee Angle (Degrees)	Force (× Body Weight)
Kaufman[47]	60°/sec flexion isokinetic	75	1.7
	180°/sec flexion isokinetic	75	1.4
Morrison[45,46]	Level walking	5	0.4
	Descending stairs	5	0.6
	Ascending stairs	45	1.7
Smidt[48]	Isometric flexion	45	1.1

Tremendous shear forces on the PCL and the tibiofemoral joint occur during OKC resisted knee flexion. Posterior tibial displacement is attributed to the high EMG activity of the hamstring muscles during resistive knee flexion. Lutz et al.[38] reported a maximum shear force of 1780 N at 90°, 1526 N at 60°, and 939 N at 30° during isometric knee flexion. Kaufman et al.[47] also noted a PCL load of 1.7×BW at 75° during isokinetic knee flexion exercise. Because PCL stress increases with the knee flexion angle, isolated OKC knee flexion exercises should be avoided for at least 8 weeks after surgery or in patients who did not undergo surgery, until symptoms subside.

Excessive stress on the PCL has also been observed during deeper angles of OKC knee extension. Several studies have proven that resisted knee extension at 90° flexion causes a posterior tibiofemoral shear and potential stress on the PCL.[24,37,38,41,51] Wilk et al.[41] documented a posterior shear force from 100° to 40° with resisted OKC knee extension. The greatest amount of stress on the PCL was seen at angles of 85° to 95° during active resisted knee flexion. Conversely, the lowest amount of posterior shear force occurred from 60° to 0° of resisted knee extension.[41] Kaufman et al.[47] also reported that posterior shear forces were exerted until 50° to 55° knee flexion. Jurist and Otis[51] documented stress on the PCL at 60° flexion during an isometric knee extension exercise when resistance was applied at the proximal tibia. To reduce the excessive posterior shear force on the PCL, OKC resisted knee extension should be performed from 60° to 0°.[49]

The stress applied to the PCL during CKC exercises depends on the knee flexion angle produced during the exercise. Wilk et al.[41,52] reported an increase in posterior shear force as the knee flexion angle increased during CKC exercise. Stuart et al.[53] also documented a linear increase in posterior shear force from 40° to 100° knee flexion during the front squat maneuver. Therefore, to reduce PCL stress during CKC exercises, leg presses and squats should be performed from 0° to 60° knee flexion.[49]

Patellofemoral Joint

The effects of OKC versus CKC exercises on the patellofemoral joint must be considered in a rehabilitation regimen after knee ligament injury and/or surgery. The patellofemoral joint consists of the articulation between the patella and the distal end of the femur. The patella is embedded in the knee extensor mechanism and is the largest sesamoid bone in the body. Proximally, the quadriceps inserts into the patella through the quadriceps tendon. Distally, the patella is connected to the tibia through the patellar tendon. The patella protects the anterior aspect of the knee, increases the effective moment arm of the knee extensor mechanism, and centralizes the divergent forces produced by the quadriceps. The tendency of the patella to sublux laterally (i.e., produced by the Q [quadriceps] angle, the vastus lateralis, and the lateral retinacular structures) must be counterbalanced by the oblique fibers of the vastus medialis. Maintaining this balance is crucial to normal function of the knee extensor mechanism.

The patella is a triangular bone with the base directed superiorly and the apex directed inferiorly. The patella is described as having three facets on its posterior aspect. A central ridge that runs from superior to inferior divides the patella into medial and lateral facets. The odd facet lies on the medial border of the patella and engages the femur only during the extreme range of flexion. The posterior margin of the patella is covered by a thick layer of articular cartilage, which is thicker centrally than peripherally. This layer of articular cartilage is thicker than at any other joint in the body, perhaps up to 5 mm thick.[54] It is important for reducing friction and aiding lubrication of the patellofemoral joint.

The stability of the patellofemoral joint depends on static and dynamic restraints. Static restraints consist of the shape of the patellofemoral joint and the medial and lateral patellofemoral ligaments. The lateral femoral condyle projects farther anteriorly than the medial femoral condyle and serves as a buttress to minimize lateral displacement of the patella. Dynamic stability of the patellofemoral joint is provided by the quadriceps. The vastus medialis oblique (VMO) and medial retinaculum provide medial stabilization of the patella. The vastus lateralis, lateral retinaculum, and iliotibial band pull the patella laterally. The Q angle is the angle formed by lines that connect the anterior superior iliac spine to the midpatella and the midpatella to the tibial tubercle. The Q angle results in lateral displacement of the patella when the quadriceps contracts. Lateral displacement of the patella is dynamically resisted by the VMO and medial retinaculum. Weakness of the VMO allows the patella to track laterally. In addition, tightness of the lateral retinaculum and overpull from the vastus lateralis and iliotibial band can result in lateral displacement of the patella.

Prevention and/or treatment of patellofemoral symptoms after knee ligament injury or surgery should seek to maintain or restore the balance of the medial and lateral stabilizers of the patellofemoral joint.

Hungerford and Barry[55] described the patellofemoral contact pattern as the knee moves through a full ROM (Figure 20-13). The patella initially makes contact with the femur in the trochlear groove at approximately 20° flexion. Initial contact is between the trochlear groove and the inferior pole of the patella. As flexion progresses, the contact area on the patella progresses superiorly, so that by 90° flexion, the entire articular surface of the patella, except for the odd medial facet, has articulated with the femur. As flexion continues beyond 90°, the quadriceps tendon articulates with the trochlear groove and the patella moves into the intercondylar notch area of the femur. At full flexion, the odd medial facet and lateral facet of the patella articulate with the intercondylar notch. The odd medial facet articulates with the femur only at the end range of flexion.

Knowledge of the patellofemoral contact pattern is useful for determining the limits of motion when patients with patellofemoral symptoms perform OKC and CKC exercises. It should also be noted that the patellofemoral contact area increases from 20° to 90° flexion. This increase helps distribute patellofemoral joint reaction forces over a larger area to reduce patellofemoral contact stress per unit of area. (Chapter 22 presents a more detailed discussion of the impact of patellofemoral forces and mechanics during rehabilitation and activity.)

Clinical Note

Generally, exercises for the patellofemoral joint should be performed in the pain-free and crepitus-free ROM.

Alterations in the Q angle often are associated with patellofemoral disorders. They may alter the contact areas and thus the amount of joint reaction forces of the

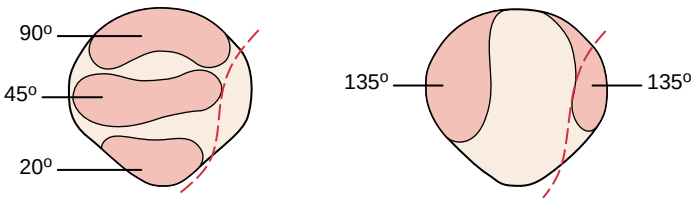

Figure 20-13 Areas of contact of the patella during different degrees of flexion. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 767, St. Louis, 2014, Saunders/Elsevier.)

patellofemoral joint. Huberti and Hayes[56] examined the in vitro patellofemoral contact pressures at various degrees of knee flexion from 20° to 120°. The maximum contact area occurred at 90° knee flexion, where contact pressure was estimated to be 6.5×BW. An increase or decrease in the Q angle of 10° resulted in increased maximum contact pressure and a smaller total area of contact throughout the ROM.

Clinical Note

Clinicians can use contact pressure information to prescribe rehabilitation interventions to ensure that exercises are performed in ranges of motion that place minimal strain on damaged structures.

Patellofemoral joint reaction force is a function of quadriceps and patellar tendon tension and of the angle formed between the quadriceps and patellar tendons (Figure 20-14). This force compresses the patellofemoral joint, with increasing patellar and quadriceps tendon tension and an increasing angle of knee flexion. Patellofemoral joint reaction forces during functional CKC activities were calculated by Reilly and Martens[57] and were found to be 0.5×BW during level walking, 3.3×BW on stairs, and 7.8×BW during a full squat. These results are consistent with activities that increase patellofemoral symptoms.

OKC and CKC exercises produce different effects on patellofemoral joint reaction force and contact stress per unit area. During OKC knee extension, the flexion moment arm for the knee increases as the knee is extended from 90° flexion to full extension (0°), which results in increased quadriceps and patellar tendon tension and increasing patellofemoral joint reaction forces. For CKC exercises, the flexion moment arm of the knee increases as the angle of knee flexion increases. In the case of OKC exercises, the patellofemoral joint reaction forces may be concentrated in a relatively small contact area, resulting in larger contact stresses per unit area; this can create forces that ultimately result in symptoms such as pain and possibly degenerative change. Conversely, for CKC exercises, the flexion moment arm of the knee increases as the knee flexion angle increases. Greater quadriceps and patellar tendon tension is required to counteract the increasing flexion moment arm. By controlling the position of the foot, ankle, knee, and hip in this weight-bearing position, it may be possible to influence the position and "tracking" of the patella, which results in increasing patellofemoral joint reaction force as the knee flexes. This force is distributed over a larger patellofemoral contact area, minimizing the increase in contact stress per unit area.

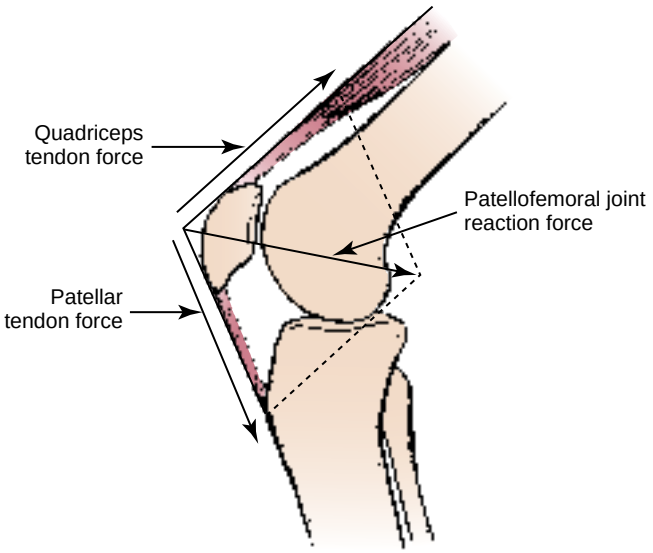

Figure 20-14 Patellofemoral joint reaction force. This is a function of patellar and quadriceps tendon tension and the angle formed between the quadriceps and patellar tendons. This force increases with increasing patellar and quadriceps tendon tension and an increasing angle of knee flexion. (From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation*, p 633, Philadelphia, 1996, WB Saunders.)

Clinical Note

Closed kinetic chain (CKC) exercises replicate functional activities, such as ascending and descending stairs, but open kinetic chain (OKC) exercises often are important for isolated muscle strengthening when specific muscle weakness is present.[58]

Steinkamp et al.[59] analyzed patellofemoral joint biomechanics during the leg press and extension exercises in 20 normal subjects. Patellofemoral joint reaction force, stress, and moments were calculated during both exercises. At 0° to 46° knee flexion, the patellofemoral joint reaction force was less during the CKC leg press. Conversely, at 50° to 90° knee flexion, joint reaction forces were lower during the OKC knee extension exercise. Joint reaction forces were minimal at 90° knee flexion during the knee extension exercise. Similar findings have been reported by Escamilla et al.,[60] who studied patellofemoral compressive forces during the OKC knee extension and the CKC leg press and vertical squat. OKC knee extension produced significantly greater forces at angles less than 57° knee flexion, whereas both CKC activities produced significantly greater forces at knee angles more than 85°.

Clinical Note

The results of studies by Steinkamp et al.[59] and Escamilla et al.[60] should influence clinicians' choice of the ROM in which they have their patients perform OKC and CKC exercises to develop quadriceps strength while protecting the patellofemoral joint.

In analyzing the biomechanics of the OKC knee extension, Grood et al.[20] reported that quadriceps force was greatest near full knee extension and increased with the addition of external loading. The small patellofemoral contact area observed near full extension, as previously discussed, and the increased amount of quadriceps force generated at these angles may make the patellofemoral joint more susceptible to injury. At lower angles of extension (i.e., closer to full extension, or 0°), a greater magnitude of quadriceps force is focused onto a more condensed location on the patella. Therefore, if the results of Steinkamp et al.,[59] Escamilla et al.,[60] and Grood et al.[20] are applied, it appears that during OKC knee extension, as the contact area of the patellofemoral joint decreases, the force of quadriceps pull subsequently increases; as a result, a large magnitude of patellofemoral contact stress is applied to a focal point on the patella while it is seated in the trochlear groove in a position to articulate with the femur. In contrast, during CKC exercises, the quadriceps force increases as the knee continues into flexion. However, the area of patellofemoral contact also increases as the knee flexes, leading to a wider dissipation of contact stress over a larger surface area.

In 1999, Witvrouw et al.[61] prospectively studied the efficacy of OKC and CKC exercises during nonoperative patellofemoral rehabilitation. Sixty patients participated in a 5-week exercise program consisting of either OKC or CKC exercises. Subjective pain scores, functional ability, quadriceps and hamstring peak torque, and hamstring, quadriceps, and gastrocnemius flexibility were all recorded before and after rehabilitation and at 3 months after the program ended. Both treatment groups reported a significant decrease in pain, increase in muscle strength, and increase in functional performance at 3 months after intervention.

The studies seem to show that both OKC and CKC exercises can be used to maximize the outcomes for patellofemoral patients if they are performed within a safe ROM. Exercises prescribed by the clinician should be individualized according to the patient's needs and the clinician's assessment. If CKC exercises are less painful than OKC exercises, then that form of muscular training is encouraged. In addition, for postoperative patients, regions of articular cartilage wear must be considered carefully before an exercise program is designed. Clinicians most often allow OKC exercises, such as knee extension at 90° to 40° knee flexion. This ROM provides the lowest patellofemoral joint reaction forces while providing the greatest amount of patellofemoral contact area. CKC exercises, such as the leg press, vertical squats, lateral step-ups, and wall squats (i.e., wall slides), are performed initially at 0° to 16° and then progressed to 0° to 30°, where patellofemoral joint reaction forces are lower. As the patient's symptoms subside, the ranges of motion performed are progressed to allow greater muscle strengthening in larger ranges. Exercises are progressed based on the patient's subjective reports of symptoms and the clinical assessment of swelling, ROM, and painful crepitus.

EVALUATION OF KNEE INJURIES

Subjective Assessment and History

A thorough history and physical examination are essential for making the correct diagnosis and determining appropriate treatment. Most injuries about the knee can be diagnosed with a thorough clinical evaluation, which often can eliminate the need for advanced imaging. (A full discussion of the history and physical examination can be found in *Orthopedic Physical Assessment*, Chapter 12, volume I of this series.)

The history can help determine the patient's activity level before injury and expectations after recovery. This can help in the planning and timing of treatment and in ensuring that patients have a realistic expectation of the outcome after the injury. For athletes, understanding current and past level of play, hours played per week, skill level, potential, and athletic goals is important because these factors play a role in surgical decision making.[62]

The clinician first must determine whether the injury is of traumatic origin. With traumatic injuries, the patient should be asked about the mechanism of injury and the location of the pain. This information provides a clue as to which anatomic structures are at risk. The examiner should determine whether the foot was planted, whether the injury was a twisting injury, whether the injury resulted from direct contact, and the direction of the forces involved. It is important to determine whether the patient had injured the same knee before and, if so, how it was treated. Was the patient able to leave the scene unassisted or was assistance required? This may indicate the severity of the injury. The patient may be able to relate hearing or feeling a pop at the time of injury, which may indicate a cruciate ligament tear or osteochondral fracture. Determining whether any deformity was present that may have been reduced before the patient was evaluated is helpful in diagnosing a patellar or tibiofemoral dislocation or periarticular fracture. Determining the time course of swelling of the knee after injury also is helpful because an acute effusion or hemarthrosis may differentiate an intra-articular fracture or torn cruciate ligament from a peripheral meniscal tear or patellar dislocation.

The same history is required for a subacute or chronically dysfunctional knee because the injury may have been initiated by a traumatic event but never treated. The examiner must determine when the symptoms began in relation to a traumatic event. The patient must relate whether the primary complaint is popping or clicking, giving way (instability), locking, pain, or swelling. The relationship between activity and the patient's symptoms can also be helpful in determining the cause of the problem. Pain on

takeoff (and, to a lesser extent, landing) when jumping often is because of extensor mechanism problems (i.e., patella, patellar tendon, quadriceps tendon), whereas instability on landing suggests ACL insufficiency or quadriceps weakness. A history of popping or clicking frequently is elicited, and these sounds can be caused by a variety of conditions, both pathological and normal.

Instability often is described as giving way, sliding, slipping out of socket, buckling, or having a sensation that the knee may give out. Giving way usually indicates intra-articular pathology, including a displaced meniscal tear or cruciate ligament injury, resulting in a loose body or rotary instability. Impending giving way may be due to patellar subluxation or weakness of the extensor mechanism. Most patients with chronic rotatory instability can ambulate and perform ADLs without pain or instability. These patients complain of buckling during activities such as running, jumping, pivoting, or cutting. True locking is a mechanical block to full extension with uninhibited flexion, and it usually indicates a displaced meniscal tear. Other causes of locking include loose bodies, joint effusion, hamstring spasm, posterior capsulitis, and sometimes disruption of the quadriceps mechanism.

A history of swelling commonly is obtained after an injury; however, the time from injury to the onset of swelling and the location and amount of swelling should be determined, as well as its response to rest, activity, and medications. The development of a large, acute hemarthrosis within 2 to 6 hours after injury occurs secondary to an ACL rupture approximately 70% of the time,[63] although it also may be due to an intra-articular or osteochondral fracture. Alternatively, an acute hemarthrosis may be due to patellar dislocation; however, because the capsule is torn, the swelling usually is not as large as with a cruciate ligament disruption or fracture. An effusion that develops 1 day or more after injury usually is a hydrarthrosis, which occurs secondary to a meniscal tear, synovitis, or sympathetic effusion. Chronic synovitis and its attendant effusion indicate intra-articular inflammation. It usually is caused by a meniscal tear, advanced chondromalacia patella (e.g., patellar dysfunction, or excessive lateral patellar compression syndrome), rotatory instability, or loose bodies. The differential diagnosis must also include pigmented villonodular synovitis, osteochondritis dissecans, inflammatory and/or rheumatological arthritis, and other causes of synovitis.

Physical Examination

A thorough physical examination complements a good history. We recommend that the reader review *Orthopedic Physical Assessment*, Chapter 12, volume I of this series for a detailed explanation of how to complete various physical examination techniques associated with examination of the knee. An understanding of the rationale for using specific examination techniques is required to diagnose ligamentous instability. The physical examination entails multiple steps, including inspection, ROM and strength testing, more specific tests, and palpation.

The motion resulting from a clinical test in a relaxed patient depends on the position of the limb at the start of the test, the point of application and direction of the force, and the examiner's ability to detect displacement. Manual examination of the knee compares the two sides to differentiate normal laxity from pathological instability. In a normal patient, left-to-right and side-to-side differences usually are negligible; therefore an internal control often exists for most patients. Most knee ligament tests assess for pathological motion by stressing a specific ligament or ligament complex. The motion detected during this examination depends on whether the primary or the secondary restraints have been disrupted (see Table 20-1). When a primary restraint is disrupted, pathological motion occurs, but its extent is limited by the remaining structures, called *secondary restraints*. Disruption of a secondary restraint does not result in pathological motion if the primary restraint is intact; however, disruption of the secondary restraint when the primary restraint is disrupted enhances pathological motion. For all clinical laxity tests, the femur is held steady and the tibial translation or rotation (i.e., joint space opening) is measured. A summary of the examination of the knee is presented in Box 20-1.

Specific Tests

Please see *Orthopedic Physical Assessment* for detailed explanations about properly performing each test.

Medial Collateral Ligament

Testing begins by palpation at the proximal or distal end of the ligament. This is important prognostically because proximal MCL injuries may have a slower recovery of full ROM compared with distal injuries.[64] The **abduction (valgus stress) test** assesses the integrity of the MCL and medial instability (Figure 20-15). This should be performed first in full extension and again in 20° to 30° knee flexion, which relaxes secondary restraints. It is imperative to examine both knees because some ligamentous laxity may be normal in some individuals. The severity of injury to the MCL and associated structures can be determined by the amount of medial joint line opening. If increased medial joint line opening is seen in the affected knee at 20° to 30° flexion, the posterior oblique ligament and posteromedial capsule may be injured.

If excessive medial joint opening is seen in full extension, a more severe injury to the secondary structures must be assumed. Medial joint line opening with the knee in full extension indicates injury to the MCL (superficial and deep fibers), posterior oblique ligament, ACL,

BOX 20-1

Physical Examination of the Knee

STANDING POSITION
- Mechanical alignment and symmetry of the lower extremity
- Foot type
- Gait
- Heel-and-toe walking
- "Duck" walk

SITTING POSITION
- Palpation:
  - Medial joint line
  - Lateral joint line
  - Patellar tendon
  - Tibial tubercle
  - Proximal tibia (pes anserine bursa, Gerdy's tubercle)
- Sulcus–tubercle angle (Q angle at 90°)

SUPINE POSITION WITH KNEES EXTENDED
- Palpation:
  - Warmth
  - Swelling
  - Patellar facets
  - Quadriceps tendon
  - Lateral collateral ligament in figure-of-four position
- Active and passive flexion and extension
- Patellofemoral and tibiofemoral crepitus
- Sag sign
- Godfrey's sign
- Quadriceps active test
- Anterior and posterior drawer tests
- Lachman's test
- Varus–valgus stress test
- O'Donoghue-McMurray test
- Dial test
- Reverse pivot shift test
- External rotation recurvatum test
- Quadriceps atrophy
- Hamstring and calf tightness

SIDE-LYING POSITION
- Ober's test

PRONE POSITION
- Heel height difference (flexion contracture)
- Apley's compression/distraction test
- External rotation of the tibia at 30° and 90° flexion
- Reverse Lachman's test
- Quadriceps flexibility

From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 639, Philadelphia, 1996, WB Saunders.

PCL, posteromedial capsule, medial quadriceps expansion and retinaculum, and semimembranosus. With this more severe injury, the results of one or more rotatory instability tests are also positive. Where complete injury to medial structures is present, a positive dial test may result (Figure 20-16).[65]

Lateral Collateral Ligament

Adduction (Varus Stress) Test. The varus stress test assesses the integrity of the LCL and, thus, lateral instability (Figure 20-17). Both knees are tested first in full extension and again in 30° knee flexion.

The severity of injury to the LCL and associated structures can be determined by the amount of lateral joint line opening in extension and slight flexion. With the knee in full extension, capsular and other secondary restraints (e.g., the biceps femoris and popliteus) resist varus stress, even when the LCL is disrupted. Flexion helps relax the secondary restraints for primary testing of the LCL.[66]

If excessive lateral joint line opening is seen in full extension, a more severe injury to the secondary structures must be assumed. Lateral joint space opening with the knee in full extension indicates some degree of injury to the LCL, posterolateral capsule, arcuate–popliteus complex, iliotibial band, biceps femoris tendon, ACL, PCL, and lateral head of the gastrocnemius. With this more severe injury, the results of one or more rotatory instability tests are also positive.

Anterior Cruciate Ligament

Lachman's Test. Outside of the operating room, Lachman's test is the most sensitive clinical test for determining disruption of the ACL, particularly the anteromedial band.[67–69] Lachman's test isolates the ACL, which acts as the primary restraining force preventing anterior translation of the tibia relative to the femur (Figure 20-18, *A*). Similar to testing of the MCL and LCL, the leg is held in approximately 20° to 30° of flexion to relax secondary stabilizers. The amount of anterior translation and the quality of the end point indicate potential injury to the ACL. The grade of laxity is measured in comparison to the normal contralateral knee, not as the degree of absolute translation. Greater laxity of the uninjured knee may be associated with poorer outcomes after reconstruction.[70] The degrees of anterior translation can be affected by several other factors. A large effusion or displaced meniscal tear can diminish the degree of translation. Muscular guarding and the position of the foot can also affect the side-to-side difference. With an incompetent PCL, the tibia sags posteriorly at rest, giving a false sense of increased anterior translation. Also, a false-negative result on Lachman's test can occur if the ACL scars to the PCL to the roof of the intercondylar notch. A pseudo-end point is detected in these cases. A meta-analysis of 20 studies showed the overall sensitivity of Lachman's test was 81% and specificity 81%; with anesthesia, the sensitivity was 91% and specificity was 78%.[71]

Anterior Drawer Test. The anterior drawer test is the oldest test but has been shown to be the least sensitive for detecting ACL injuries because it is generally positive only with loss of both ACL and the secondary restraints such as the posterior horn of the medial meniscus. False-negative results also can occur with a displaced ("bucket handle")

Figure 20-15 Abduction (valgus) stress test. **A**, Gapping of the medial aspect of the knee. **B**, Knee is tested in full extension and slightly flexed (20° to 30°). **C**, Valgus stress applied with thigh supported on examination table. (**A** and **C,** From Magee DJ: *Orthopedic physical assessment*, ed 6, p 812, St. Louis, 2014, Saunders/Elsevier.)

Figure 20-16 Tibial lateral (external) rotation (dial) test. Side-to-side differences in tibial external (lateral) rotation are compared at 90° of knee flexion. A side-to-side difference of more than 15° suggests posterolateral corner involvement.

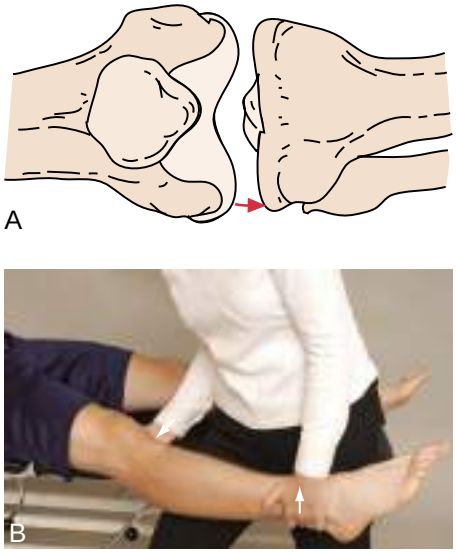

Figure 20-17 Adduction (varus stress) test. **A**, One-plane lateral instability "gapping" on the lateral aspect. **B**, Positioning for testing lateral collateral ligament in extension. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 814, St. Louis, 2014, Saunders/Elsevier.)

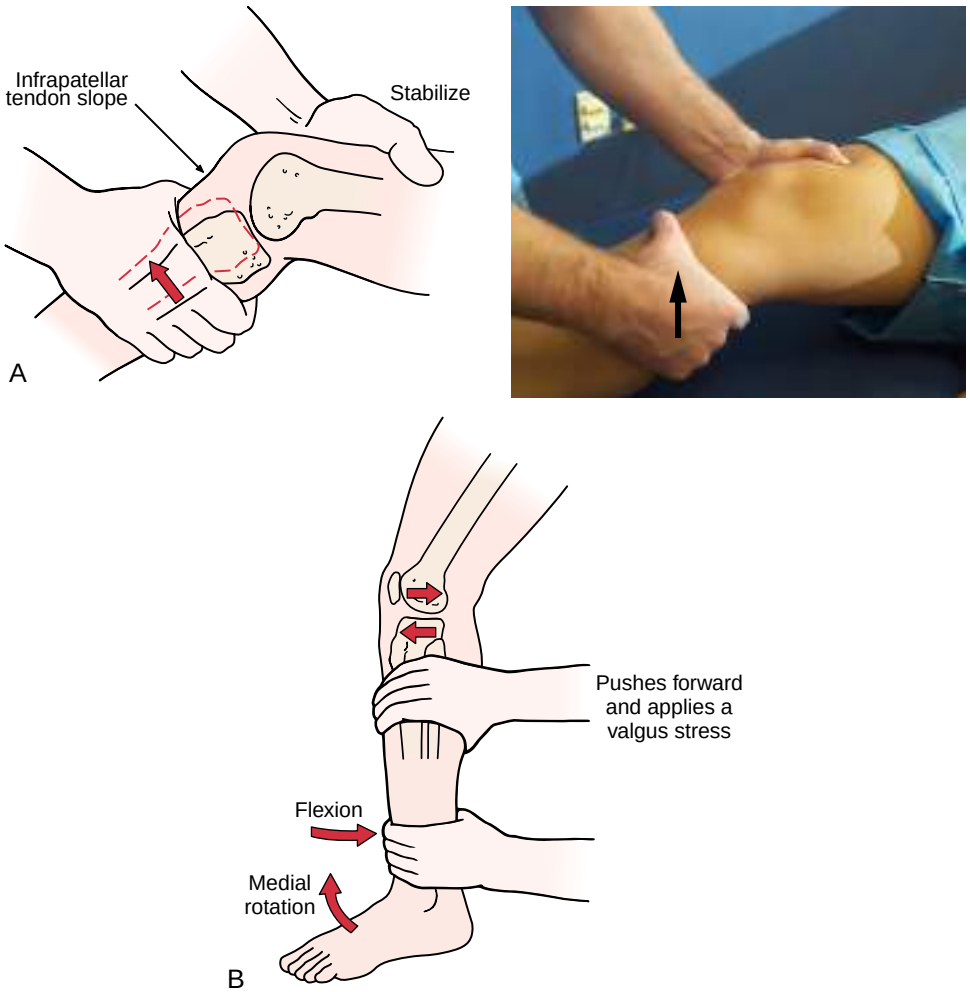

Figure 20-18 Physical examination of the ACL. **A**, Lachman's test is performed with the knee in about 30° of flexion and provides the most sensitive and specific test for the ACL in the office setting. **B**, The pivot shift test. This test is performed with the patient supine. The examiner places the heel of one hand behind the head of the fibula and the other hand on the foot. With the knee in full extension and hip in slight flexion and abduction, lateral (external) rotation of the tibia is combined with an axial load and valgus force to the knee. A positive pivot results at about 20° of flexion as the lateral tibial plateau reduces back into position. This test is very specific but often requires muscle relaxation in the operating room to increase sensitivity. (**A** [*line art only*] and **B,** From Magee DJ: *Orthopedic physical assessment*, ed 6, pp 817, 824, St. Louis, 2014, Saunders/Elsevier.)

meniscal tear, hamstring spasm, and hemarthrosis. For the anterior drawer test, the sensitivity has been reported to be 38% and specificity was 81%.[71]

Pivot Shift Test. The pivot shift test is used to test for injury to the ACL and to assess anterolateral rotatory instability of the knee.[72–74] During this test, the tibia subluxes anterolaterally on the femur (Figure 20-18, *B*).[74] This recreates the anterior subluxation-reduction phenomenon that occurs during functional activities when the ACL is torn. A positive pivot shift test is pathognomonic for ACL deficiency. Unfortunately, the sensitivity of the test is affected by guarding and muscular splinting. The sensitivity improves dramatically if the test is done with the patient under anesthesia.[75] Varying the position of the hip (i.e., into abduction and slight flexion) and lateral (external) rotation of the tibia can enhance the pivot shift.[72] Many other modifications have been proposed to improve the accuracy of the pivot shift test.[76] This test can differentiate partial tears of the ACL from complete injuries. A tear is considered complete if rotational instability is demonstrated by a positive pivot shift test result. Meta-analysis showed the pivot shift test to have sensitivity of 28% and specificity of 81%, which improved with anesthesia to 73% sensitivity and 98% specificity.[71] Because of its specificity, the pivot shift test, particularly under anesthesia, can be considered the most important assessment in the evaluation of an ACL injury.

Posterior Cruciate Ligament and Posterolateral Corner

Posterior Drawer Test. An isolated tear of the PCL leads to increased posterior translation of the tibia that increases with knee flexion. The most accurate means of diagnosing this injury is the posterior drawer test with the knee flexed at 90°.[77,78] The test is performed as described

Figure 20-19 Posterior drawer test. The posterior drawer test is performed with the knee in 90° flexion. The examiner palpates the hamstrings posteriorly to make sure they are relaxed. The thumbs are placed in the anterior joint line to palpate posterior translation of the tibia when a posterior force is applied. (From Ball JW, Dains JE, Flynn JA, et al: *Seidel's guide to physical examination*, ed 8, St. Louis, Mosby, 2015.)

in *Orthopedic Physical Assessment* (Figure 20-19). The amount of translation and the end point are again compared with those in the contralateral (normal) knee. If excessive posterior translation is evident, the PCL (primarily the anterolateral bundle), arcuate–popliteus complex, posterior oblique ligament, and ACL may be injured.

Truly isolated acute PCL tears often produce only minimally increased posterior translation when the secondary restraints of the knee are intact, particularly the posterior capsule and posteromedial and posterolateral structures. Some studies have suggested that the meniscofemoral ligaments are strong and may act as secondary stabilizers to PCL function. A posterior drawer test with the leg in medial (internal) rotation is reduced if the posterolateral structures or, as some investigators have suggested, the meniscofemoral ligaments are intact.[79] Some investigators believe that a posterior drawer cannot occur with an intact arcuate–popliteus complex, although laboratory studies have revealed that a posterior drawer of no more than 10 mm (0.5 inch), as compared with the contralateral side, can occur with an isolated PCL injury. False-negative results can occur with a displaced bucket handle meniscal tear, hamstring or quadriceps spasm, and hemarthrosis. In combination, tests for PCL injury have an accuracy of 96%, sensitivity of 90%, and specificity of 99%.[80] Although it is important also to assess the end point of the posterior drawer test, the end point may return to a normal, firm feel in chronically PCL-deficient knees. Thus the quality of the end point is not as sensitive as with Lachman's test.

Tibial External Rotation (Dial Test) (see Figure 20-16). Because isolated PCL injury does not increase tibial rotation, a PLC injury should be suspected if there is any increased lateral (external) rotation. The dial test examines the side-to-side difference in lateral (external) rotation of the tibia at 90° and then at 30° of knee flexion.[66,81,82] Because the PCL serves as a secondary restraint when the PLC is injured, it is best tested at 90°. Increased lateral (external) rotation at 30° suggests PLC injury. Increased lateral (external) rotation at both 30° and 90° suggests both a PCL and PLC injury.

Step-off Test. The step-off test is a sensitive uniplanar test for determining PCL injury and posterior instability. Normally, the medial tibial plateau protrudes anteriorly 1 cm beyond the medial femoral condyle when the knee is flexed to 90° (Figure 20-20).[83] This step-off is lost when there is a posterior sag of the tibia associated with injury to the PCL and other secondary restraints to posterior translation of the tibia. Similarly, a **posterior sag test** involved viewing the knee from the lateral side with the hip flexed to 45° and the knee flexed to 90° and is positive in a PCL-deficient knee when loss of the tibial tubercle prominence is seen. The examiner must be aware of tibial tubercle enlargement (as a result of Osgood-Schlatter disease) or tibial plateau osteophytes, which can give a

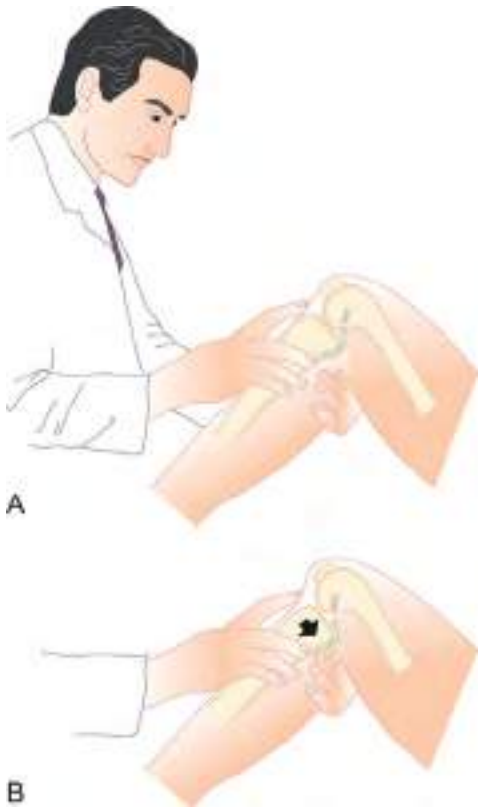

Figure 20-20 Step-off test. **A**, Normal relationship of the tibiofemoral joint. The medial tibial plateau protrudes anteriorly approximately 1 cm (0.5 inch) beyond the medial femoral condyle. **B**, With injury to the posterior cruciate ligament, the step-off is lost. The medial tibial plateau now lies either in line with or posterior to the medial femoral condyle. (Adapted from Miller MD, Harner CD, Koshiwaguchi S: Acute posterior cruciate ligament injuries. In Fu FH, Harner CD, Vince KG, editors: *Knee surgery*, vol 1, Baltimore, 1994, Williams & Wilkins.)

Figure 20-21 Godfrey's test. This posterior sag test is performed with the patient's hips and knees flexed to 90°. Examiner watches for posterior shift, which is not evident in this case. (From Magee DJ: *Orthopedic physical assessment*, ed 6, p 820, St. Louis, 2014, Saunders/Elsevier.)

false-negative result. Different degrees of posterior sag represent varying degrees of injury to the PCL, arcuate–popliteus complex, posterior oblique ligament, and ACL. The quadriceps active drawer test[84] and Godfrey's sign (Figure 20-21) also can be used to test the PCL.

Hughston's Posteromedial and Posterolateral Drawer Signs. Although an isolated injury to the PCL has little effect on tibial rotational laxity or varus or valgus angulation, concomitant injury to the secondary extra-articular restraints results in some aspects of rotatory instability. Posteromedial and posterolateral drawer tests assess rotatory instability combined with PCL injury and are analogous to the Slocum test for rotatory instability associated with ACL injury.[85] With the patient positioned as for the posterior drawer test, the foot is medially (internally) rotated 30°. Posteromedial rotatory instability is present if most of the posterior translation occurs on the medial side of the knee and/or if the amount of posterior translation increases or does not change. Posteromedial rotatory instability is a result of varying degrees of injury to the PCL, posterior oblique ligament, MCL (deep and superficial), semimembranosus muscle, posteromedial capsule, and ACL (posteromedial corner).

Next, the patient's foot is placed in 15° lateral (external) rotation as the examiner sits on the patient's forefoot. If most of the posterior translation occurs on the lateral side of the knee and/or if the amount of posterior translation increases or does not change, posterolateral rotatory instability is present, indicating an injury to the PCL, arcuate–popliteus complex, LCL, biceps femoris tendon, posterolateral capsule, and ACL (i.e., posterolateral corner). Over-rotating the foot can lead to a false-negative test because this can tighten other secondary and tertiary restraints.

Figure 20-22 External rotation recurvatum test. To perform this test, the examiner grasps the individual's big toes and lifts the leg, allowing both knees to go into passive hyperextension. The test result is positive if the affected knee hyperextends to a greater degree than the noninvolved knee and appears to be in valgus alignment. Also, the tibial tuberosity is displaced laterally as the lateral tibial plateau subluxes posteriorly. (Redrawn from LaPrade RF, Ly TV, Griffith C: The external rotation recurvatum test revisited, *Am J Sports Med* 36:709–771, 2008.)

External Rotation Recurvatum Test (Figure 20-22). In some cases of posterolateral rotatory instability, lifting the big toe of the individual causes a hyperextended knee, which rotates into valgus to a greater extent than the uninvolved side.[85]

Reverse (Jakob) Pivot Shift Test. The reverse (Jakob) pivot test is the most sensitive test for posterolateral rotatory instability and is analogous to the pivot shift for ACL deficiency.[86,87] Unfortunately, the test is not pathognomonic for PCL injury because up to 35% of normal knees may have a positive reverse pivot test result.[88]

Instrumented Testing of the Knee

Evaluation of the ligamentous instability of the knee has been classically defined by its associated physical examination findings. Lachman's test is a sensitive indicator of ACL injury, and the pivot shift is highly specific. These tests, however, suffer from different interobserver and intraobserver variability. Several knee ligament arthrometers have been developed as a means to standardize and quantify ligamentous examinations. Several ligament testing devices are commercially available for clinical use to quantify laxity of the knee. These include the KT1000 Knee Ligament Arthrometer, the Acufex Knee Signature System (Acufex Microsurgical, Norwood, MA), the Genucom Knee Analysis System (FaroMedical, Toronto, Canada), the Rolimeter (Aircast, Boca Raton, FL), and the Stryker Knee Laxity Tester (Stryker Corp., Kalamazoo, MI). Of these, the KT1000 arthrometer has been most widely used (Figure 20-23).

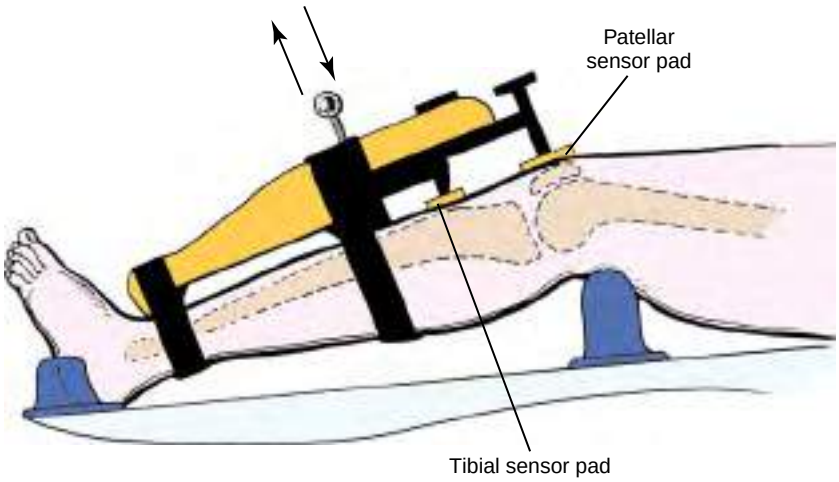

Figure 20-23 Use of the KT1000 arthrometer (MEDmetric, San Diego, CA) to quantify tibial translation. Relative movement of the tibiofemoral joint is measured as motion between the patellar and tibial sensor pads. (From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 650, Philadelphia, 1996, WB Saunders.)

The reliability and validity of these devices have been widely studied.[89–101] The Acufex and Genucom arthrometers appear to be less reliable than the KT1000 with higher standard deviation (SD) of measurements.[95,96] Intratester reliability and intertester reliability for the KT1000 have been reported to be high, both within and between days.[100] Wroble et al.[96] indicated that the 90% confidence limit for right-left difference with the KT1000 was ±1.6 mm when measured at 89 N and ±1.5 mm when measured at 134 N. A confidence interval of this magnitude is within acceptable limits for the clinical diagnosis of ACL injuries. In vitro and in vivo studies have shown the KT1000 to be a valid measure for the detection of ACL injury. The correlation between measurements made with the KT1000 and those made with direct transducer readings in cadaveric knees was 0.97.[89] The mean anterior displacement in ACL-intact cadaveric knees was found to be 5.8 mm, which increased to 12.1 mm when the ACL was sectioned. In vivo studies reported that 92% of normal subjects had a side-to-side difference in anterior displacement of less than 2 mm, whereas 96% with confirmed unilateral disruption of the ACL had a side-to-side difference in anterior displacement more than 2 mm.[89] Based on this research, the KT1000 appears to be a clinically applicable instrument that can be used to assess anterior laxity in patients with an ACL-deficient knee.

Importantly, before using the KT1000 to assess AP laxity of the knee, the clinician must screen for PCL injury. This is done by observing for lack of a step-off between the medial femoral condyle and the medial tibial plateau. The posterior sag test or the active quadriceps drawer test (or both) also can be done to rule out injury to the PCL. Failure to detect a PCL-deficient knee before testing with the KT1000 may result in a false-positive result for anterior laxity, so the test procedure must be modified. Please refer to *Orthopedic Physical Assessment* for more specifics regarding KT1000 testing.

Clinical Note

Before doing instrumented testing of the knee for ACL injury, the knee must be cleared for PCL deficiency.

The major criticism of instrumented testing of the knee, including use of the KT1000, has been that it does not quantify rotation. A clinical failure with a positive pivot shift, could have a normal Lachman's test result and normal KT1000 parameters. For this reason, various techniques[102] have been developed to assess rotation stability of the knee via MRI,[103] inertial and gyroscopic sensors,[104,105] and optical tracking systems.[106]

Special Diagnostic Studies

Radiography

Radiographs of the knee should be obtained after any acute trauma. If the trauma was severe and the patient reports pain when the knee is moved, radiographs should be obtained before the physical examination is started. Fractures must be ruled out before the knee is moved through any ROM or manipulated because displacement of the fracture may damage other structures, including neurovascular structures.

Our standard radiographic series for the knee includes a 45° flexion weight-bearing posteroanterior (PA), AP, lateral, and merchant views. Because ligaments and menisci are radiolucent, radiography is used for the most part to exclude other causes of knee pain, swelling, deformity, and/or loss of function. Other radiographs obtained in special circumstances that may be beneficial include a long cassette AP weight-bearing view to assess alignment; stress radiographs in cases of suspected rotational injury; a cross-table lateral view to look for hemarthrosis with a fat-fluid level, an indication

of a fracture; and lateral (external) and medial (internal) rotation views to look for loose bodies or oblique fracture lines.

Standard Radiographic Series for the Knee

- 45° flexion weight-bearing posteroanterior view
- Anteroposterior view
- Lateral view
- Merchant view

When viewing standard radiographs of the knee, the examiner should look for any obvious intra-articular or osteochondral fractures, calcifications, joint space narrowing, epiphyseal damage, osteophytes or lipping, loose bodies, tumors, accessory ossification centers, alignment deformity (varus–valgus), patellar alta or baja, asymmetry of the femoral condyles, and dislocations. Secondary signs can be seen on plain radiographs to help diagnose ligamentous or meniscal injury.

Soft tissue swelling as seen on radiographs is helpful when the injured structures are surrounded by fat. An MCL injury may reveal only soft tissue swelling on the medial aspect of the knee. A bloody effusion, often associated with intra-articular ligament damage, is detected as a soft tissue density in the suprapatellar pouch on the lateral view. Fat in the effusion, or lipohemarthrosis, suggests a fracture (e.g., osteochondral or intra-articular) and is identified as a fat-fluid level on a cross-table lateral projection. Although fat globules occasionally are seen in many other types of effusions, the accumulation of fat is much greater in cases of trauma.[107] Meniscal tears, although often associated with effusions, do not produce as large an effusion as a cruciate ligament disruption or intra-articular fracture. Furthermore, the timing of the radiograph in relation to the time of injury is important because cruciate ligament injuries are associated with acute effusions, but meniscal tears usually do not produce a significant effusion for at least 12 hours.

Although extensive fractures about the knee are readily identified by standard radiographs, careful evaluation of the films may be required to detect avulsion injuries at the attachment sites of ligaments. This is particularly true in children, in whom cruciate ligament injuries frequently involve avulsion fractures. An avulsion of the ACL insertion may be seen on the flexion AP radiograph or on the lateral view by identifying the displaced fragment superior and anterior to the tibial spine.[108] **Segond's fracture**, also known as the **lateral capsular sign**, is an avulsion fracture of the lateral capsule posterior to Gerdy's tubercle on the proximal lateral tibia.[109] This fracture, seen on AP radiographs, is an indirect sign of ACL injury. The thin fragment of bone is vertically oriented and located proximal and anterior to the fibular head and should not be confused with a lateral ligamentous injury. Avulsion of the tibial insertion of the PCL may be seen on lateral radiographs in the posterior intercondylar area. A PCL avulsion may be a small flake of bone or a large bony fragment. Lateral ligamentous injury may be identified on an AP or external rotation view as an avulsion of the biceps femoris or LCL insertion from the fibular head, or the "**arcuate sign**."[110] Uncommonly, the MCL or LCL may avulse from the femoral condyle with a bony fragment. These injuries can be identified on AP radiographs.

A lateral radiograph can be used to identify a **lateral femoral notch sign**, a deepening of the terminal sulcus and a sign of an ACL-deficient knee.[111,112] Located on the lateral femoral condyle at the junction between the weight-bearing tibial articular surface and the patellar articular surface, the terminal sulcus is the usual location of the impaction injury caused by collision of the femoral condyle with the posterior tibial plateau. Depressions more than 2 mm in this area may represent osteochondral fractures and are often correlated with higher energy pivoting injuries and lateral meniscal tears.[113]

Chronic knee injuries may also produce abnormal findings on radiographic studies. A chronic MCL injury may result in calcification at the site of injury. When this occurs at the femoral origin of the MCL, it is called **Pellegrini-Stieda disease**. Although the natural history of isolated cruciate ligament injuries is debated, most authors agree that if left untreated, the unstable knee develops degenerative osteoarthritic changes. Osteoarthritic change in the cruciate-deficient knee tends to occur first in the medial compartment, but the compartment with meniscal pathology often develops degenerative changes.[114] This is best seen on 45° flexion, weight-bearing PA radiographs.[115] Degenerative changes identified on radiographs in a patient with a history of trivial trauma with signs of possible meniscal pathology may suggest a degenerative meniscal tear.

Stress radiography has been advocated for knee ligament injuries, but it is difficult to carry out after acute trauma.[111] In a chronic injury or in the anesthetized patient, these radiographs are more easily obtained and can be valuable. Stress radiography is particularly popular in Europe to document knee instability in the sagittal and frontal planes[116–120]; however, it is not used as often in the United States. For MCL injury, manual stress radiographs show significant medial joint gapping.[121] Recently, the importance of stress radiography in evaluating PLC and other rotational stabilities of the knee has been advocated (Figure 20-24).[122]

Arthrography

Traditionally, single-contrast and double-contrast arthrography served as the gold standard for evaluating the menisci and plica and, to a lesser extent, the cruciate

Figure 20-24 Stress radiographs of the knee. **A**, Non–weight-bearing AP radiograph in a suspected posterolateral corner injury. **B,** Varus stress radiograph in the same knee. The degree of opening of the lateral compartment (*) has correlated with posterolateral corner injury and can aid in decision making regarding surgical intervention. (From Gwathmey FW Jr, Tompkins MA, Gaskin CM, Miller MD: Can stress radiography of the knee help characterize posterolateral corner injury? *Clin Orthop Relat Res* 470:770, 2012.)

ligaments and articular surfaces.[123–129] However, this method is limited in that it is an uncomfortable, invasive procedure that requires a great deal of expertise to perform and interpret, and it exposes the patient to irradiation. It was more widely used before the advent of arthroscopy and magnetic resonance imaging (MRI). Arthrography has been largely replaced by those two modalities in most centers, but it still may be used in specialized situations to resolve a specific question or when the availability or quality of MRI is limited.

Radionuclide Scintigraphy

Radionuclide scintigraphy uses technetium-99 methylene diphosphonate (MDP) to screen for a variety of abnormalities. In general, the scintigram reflects the relative blood flow to an area and the degree of bone turnover (i.e., osteogenesis and osteolysis). The test is sensitive but nonspecific. It provides more information about osseous physiology than structural characteristics. The technique traditionally has been used to evaluate arthritic joints, stress fractures, tumors, osteonecrosis, infection, osteolysis, metabolic or metastatic bone disease, and reflex sympathetic dystrophy. Increased osseous metabolic activity, as determined by scintigraphy, has also been seen with knee disorders previously considered to involve only soft tissue failure, including symptomatic tears of the ACL.[130–136]

Diagnostic Ultrasonography

Ultrasonography has been used to evaluate various structures of the knee, including the menisci and ligaments.[137] It is most useful in the evaluation of patellar tendonitis and partial patellar tendon tears. This technique is technician dependent, and although it is inexpensive, it has not been popularized for routine use in the evaluation of ligamentous and meniscal injuries. It is used in the United States primarily for evaluating patellar tendonitis and masses about the knee.

Computed Tomography

Ever since the early application of computed tomography (CT) to the musculoskeletal system, this technique has been used to evaluate many disorders of the knee.[138–140] However, CT scanning is best used for bony detail because soft tissue detail is better seen with MRI or arthroscopy. Many conflicting descriptions have been reported with respect to the need for and type of intra-articular contrast material and patient positioning in the CT scanner. Therefore, clinical use of CT scanning after meniscal and ligamentous injury currently is not widely accepted.

Magnetic Resonance Imaging

MRI is a sensitive, noninvasive, nonionizing radiation means of evaluating the structural integrity of the knee. It is particularly helpful for visualizing soft tissue structures. At first, MRI met some resistance because initial studies were less accurate than double contrast arthrography, and the procedure was time-consuming and expensive.[141–144] Improvements in hardware and software, as well as increasing expertise in the interpretation of these studies, have overcome these problems, and MRI has become the procedure of choice for evaluating acute knee injuries.[145–150] Partial and complete tears of ligaments and menisci, as well as other pathological changes, such as bone bruises and effusions, can be identified with MRI. Evaluation of the knee by MRI is reader dependent, but its accuracy approaches 100% in diagnosing lesions of the PCL, ACL, medial meniscus, and lateral meniscus (diagnosis is least accurate with the lateral meniscus).[145,148,150–153] Some clinicians believe this technique is overused,[154] and in the future its use may be limited by the expense. Nonetheless, MRI can help diagnose injuries when the patient cannot relax for an adequate examination and can provide additional information about concomitant intra-articular knee injuries.

Increased signal intensity in the subchondral bone (i.e., bone bruises) has been found in specific patterns. Up to 80% of patients with an ACL injury show increased subchondral signal in the posterior aspect of the lateral tibial plateau and the anterior aspect of the lateral femoral condyle as a result of abnormal impaction of these surfaces secondary to the transient subluxation of the lateral compartment after an ACL injury (Figure 20-25).[155–157] This pattern is distinctly different from bone bruises seen after patellar dislocation and PCL injury. Bone bruises are less common after isolated PCL injuries.

Figure 20-25 MRI of a knee demonstrating bone bruises (*) on the posterolateral tibia and at the anterior lateral femoral condyle characteristic of the knee subluxation seen with ACL injury.

Indications for an MRI

- An acutely injured knee in which an ACL tear is likely but it is unclear whether the patient has associated meniscal or chondral pathology
- Complete evaluation for preoperative planning for a knee with multiple-ligament injuries
- Unclear diagnosis based on the history, physical examination, and standard radiographs
- A patient who cannot relax or cooperate during the physical examination
- Clinical course not commensurate with the clinical diagnosis
- A high-level athlete with an acute injury who needs an immediate, thorough evaluation to determine the extent of injury and the need for surgical or nonoperative treatment
- Evaluation of an occult fracture or to assess physeal injury
- Investigation of the cause of poor ROM after ligament reconstruction surgery

Other uses of MRI include evaluation for soft tissue masses, tumors, osteonecrosis, osteochondritis dissecans, and extensor mechanism injuries, including tendonitis.

Arthroscopy

Arthroscopy currently is the most commonly performed orthopedic procedure in the United States. It allows for direct visualization of all intra-articular structures, and it can be used to diagnose and surgically treat lesions of the knee. For many acute knee injuries, the best opportunity for complete recovery is with prompt, appropriate surgical treatment. The benefit of arthroscopy, therefore, is that all pathology can be correctly identified and treated as needed. Arthroscopy uses smaller incisions than open surgery, allows better visualization with less morbidity, and can be performed without the use of a tourniquet. Partial tears of the ACL sometimes cannot be differentiated from complete tears, even with an examination under anesthesia. Using arthroscopy, the surgeon can determine whether the ACL is partially or completely torn. Furthermore, if the ligament is partially torn, the extent of injury can be ascertained to guide treatment. Arthroscopy can also be used to evaluate meniscal pathology and determine whether the lesion should be left alone, repaired, or excised. It also has been shown that complete, isolated PCL disruptions may yield a negative posterior drawer sign, even under anesthesia, but these can be diagnosed with arthroscopy.[158]

Although invasive, arthroscopy is a relatively low-risk procedure; it has a complication rate of less than 1% and an infection rate of approximately 0.1%.[159–161] Although the risk of anesthesia exists, some authors have reported local anesthesia to be effective and safe.[162–166] This is important because several investigators are evaluating the efficacy of diagnostic and therapeutic office arthroscopy.[167–170] Nonetheless, diagnostic arthroscopy has been largely replaced by MRI.

EPIDEMIOLOGY, BIOMECHANICS, AND CLASSIFICATION OF KNEE LIGAMENT INJURIES

Straight Plane versus Rotatory Instabilities

The terminology used to classify knee ligament injuries is the source of much confusion. This partly arises from the use of inappropriate terminology to describe and classify movement of the knee. Noyes et al.[171,172] defined terms that should be used to describe the motion and position of the knee. Motion of the knee is accompanied by rotation and translation of the joint surfaces. *Translation* refers to movement that results when all points of an object move along paths parallel to each other. A fixed point on one surface engages successive points on the opposing surface, much like a tire sliding on an ice patch when the brakes are locked. In the knee, translation of the tibia has three independent components, known as *translational degrees of freedom:* medial-lateral translation, anterior-posterior translation, and proximal-distal translation. Translation of the tibia is commonly reported in millimeters of motion.

Rotation occurs when successive points on a given surface meet successive points on an adjacent surface. The surface appears to be going in circles about an axis of rotation. Rotation of the joint is similar to a tire rolling down a road. In the knee, rotation has three independent degrees of freedom. Flexion and extension rotation occurs in the sagittal plane about an axis located through the femur, which lies in the coronal plane. Abduction and adduction rotation occurs in the coronal plane through an axis in the sagittal plane. Internal (medial) and external (lateral) rotation occurs in the transverse plane around a vertical axis, which is located near the PCL. Rotation of the knee is measured in degrees of motion.

Motion of the knee involves a complex combination of rotation and translation of the joint surfaces. Based on

the convex–concave rule, flexion of the knee is associated with posterior translation and rotation of the tibia. When the tibia is fixed, flexion of the knee occurs as posterior rotation and anterior translation of the femur. Extension of the knee involves anterior rotation and translation of the tibia. When the tibia is fixed, extension of the knee involves anterior rotation and posterior translation of the femur. This combination of rotation and translation is necessary to keep the femur centered over the tibial plateau throughout the ROM. As described earlier, rotation and translation of the joint surfaces during movement of the knee are controlled by the geometry of the joint surfaces, tension in the ligamentous structures, and muscular contraction. Disruption of ligamentous or musculotendinous structures alters the normal arthrokinematics of the knee and may lead to progressive degeneration of the joint surfaces.

The terms *laxity* and *instability* often are used interchangeably. The meaning of these terms must be clarified to improve communication among health care professionals in the evaluation and treatment of knee ligament injuries. The term *laxity* can be used to indicate slackness or lack of tension in a ligament or to describe looseness of a joint. *Laxity* also is used to indicate the amount of joint motion or play that results with the application of forces and moments. Laxity of a joint can be normal or abnormal; therefore the adjective *abnormal* should be used to indicate laxity that is pathological. In addition, *laxity* can refer to either translation or rotation, and this should be clearly specified. For example, *anterior laxity* of the knee can refer either to anterior translation or to rotation of the tibia. If *anterior laxity* is used to describe translation of the tibia, the more precise (and preferable) term is *anterior translation*. The amount of laxity often is recorded as the difference between the involved and noninvolved knees, and this should be clearly indicated. Owing to the ambiguity in the use of the term *laxity,* Noyes et al.[173] recommended that it not be used to describe joint motion or displacement. They recommended that the term be used in a more general sense to indicate slackness or lack of tension in a ligament. When referring to motion of the knee, it is preferable to describe the specific motion as *translation* or *rotation*.

According to Noyes et al.,[171] the term *instability* can be used to describe the symptom of giving way or the physical sign of increased mobility of the joint. To avoid ambiguity, they recommend avoiding use of the term *instability* to indicate an episode of giving way. They prefer to use it to indicate a physical sign that is characterized by an increased or excessive displacement of the tibia resulting from traumatic injury to the stabilizing structures.

Ligamentous injury to the knee results in varying degrees of abnormal laxity or instability, as just described. Hughston et al.[174] classified instability that arises as a result of a knee ligament injury as straight plane or rotatory instability, with straight plane implying equal translation of the medial and lateral tibial plateaus. Rotatory instabilities involve unequal movement of the medial and lateral tibial plateaus and can include anteromedial, anterolateral, and posterolateral instabilities. Anteromedial rotatory instability occurs when the medial compartment ligaments, including the posterior oblique ligament, are torn. Anteromedial rotatory instability may be accentuated by a tear of the ACL. With anteromedial rotatory instability, a valgus stress test at 30° flexion is positive. In addition, increased anterior translation of the medial tibial plateau is seen when an anterior drawer test is performed with the tibia laterally (externally) rotated, and the medial pivot shift test may be positive.

Anterolateral rotatory instability occurs with injury to the middle third of the lateral capsular ligaments and is accentuated by a tear of the ACL. With anterolateral instability, an anterior drawer test results in increased anterior translation of the lateral tibial plateau. The lateral pivot shift test also is positive.

Posterolateral rotatory instability implies greater posterior translation of the lateral tibial plateau compared with the medial tibial plateau when a posterior drawer force is applied. Posterolateral instability occurs with a tear of the arcuate complex, which results in a positive varus stress test at 30° flexion. The external (lateral) rotation recurvatum test also is positive.

Combined rotatory instabilities, such as anteromedial and anterolateral rotatory instability, also can occur.

Butler et al.[19] developed the concept of primary and secondary ligamentous restraints. For each plane of motion of the knee, one ligamentous structure serves as the primary restraint. This structure is responsible for restraining most of the motion in a given direction. For example, the ACL is the primary restraint for anterior translation of the tibia, providing approximately 85% of the restraining force.[19] As the name implies, secondary restraints are structures that take on a secondary role in restraining motion in a particular direction. For example, the secondary restraints for anterior tibial translation are the collateral ligaments, the middle portion of the medial and lateral capsule, and the iliotibial band. These structures are responsible for providing approximately 15% of the total restraining force to anterior translation of the tibia.[19]

Care must be taken to avoid thinking solely in terms of straight plane stability versus rotatory instabilities and primary versus secondary restraints. There are many components to stability including bony, capsular, ligamentous, and musculotendinous structures that contribute to a functionally stable knee. As such, it is vitally important to accurately diagnose instability and, in particular, to look for concomitant injuries because missed instability components negatively impact outcomes. For example, knees with untreated combined ACL–MCL injuries showed increased valgus laxity and a reduction in tissue quality of the healed MCL.[175] Early ACL reconstruction in combined ACL and MCL injuries may

provide a more stable environment for MCL healing.[176] In combined ACL and PLC injuries, failure to address the PLC injury will lead to failure of the ACL reconstruction. Thus, one must consider that rotatory instabilities and combined injuries exist, and that missed injuries lead to poor results.

The amount of ligament laxity or instability after injury to the ligamentous structures of the knee depends on the extent of injury and the amount of force applied. Injury to the primary restraint that leaves the secondary restraints intact may result in a minimal increase in laxity during manual examination of the knee. However, if both the primary and secondary restraints are injured or stretched, clinical tests for laxity may demonstrate a large increase in motion compared with the noninvolved side. For example, isolated injury to the ACL may result in only a slight increase in anterior tibial translation if the secondary restraints are intact. Over time, with repeated episodes of giving way, the secondary restraints may stretch out, resulting in increased anterior tibial translation. Similarly, when posterior drawer testing shows more than 10 mm posterior tibial translation, associated ACL and/or PLC injury should be suspected in addition to PCL injury. It is important to note that the secondary stabilizers are not as effective as the primary stabilizers in restraining motion in a particular direction. Therefore, over time, the secondary restraints tend to stretch out gradually when the primary restraint has been lost.

Another important consideration for clinicians in performing and interpreting a clinical laxity test is the amount of force applied to the knee. Forces applied during a clinical laxity test are small, ranging from 9.1 to 18.1 kg (20 to 40 pounds). This is much less than the forces involved in in vivo activities, which may exceed 45.4 kg (100 pounds) with strenuous exercise.[19] As a result, clinical laxity tests may not accurately describe the stability of the knee in performing strenuous physical activities. The clinical laxity test may demonstrate only a slight degree of increased laxity. When more strenuous activities are performed, higher loads are placed on the knee, which may result in greater laxity and in complaints of giving way.

Anterior Cruciate Ligament

The ACL is one of the most commonly injured ligaments in the knee. The ACL is the primary stabilizer for resisting anterior translation of the tibia on the femur and serves to control hyperextension of the knee. The ACL also serves as a secondary stabilizer to resist internal (medial) and external (lateral) rotation, as well as varus and valgus stress. The ACL can be injured by contact or noncontact mechanisms of injury. Pathomechanics include a valgus force applied to a flexed, laterally (externally) rotated knee with the foot planted, or hyperextension, often combined with medial (internal) rotation. Less common mechanisms of injury include hyperflexion or a direct valgus force.

Mechanisms of Injury to the Anterior Cruciate Ligament

- Valgus force applied to a flexed, laterally rotated knee with the foot planted
- Hyperextension (often combined with medial rotation)
- Hyperflexion
- Direct valgus force

Daniel et al.[62] reported that the incidence of acute ACL injury among members of a managed health care plan was 31 per 100,000 members annually. Ninety percent of ACL injuries occurred in patients 15 to 45 years of age. Most ACL injuries occur as a result of sports activities, particularly those that place high demands on the knee (e.g., those involving jumping and hard cutting).[177] Skiing may be a particularly high-risk activity; the incidence of ACL injury among adult skiers is 1 in 2000.[178]

A narrow intercondylar notch or the notch geometry itself may place a patient at greater risk of injury.[179] LaPrade and Burnett[180] reported a higher incidence of acute ACL injuries in individuals with a narrow notch width index. The notch width index is the ratio of the width of the anterior outlet of the intercondylar notch divided by the total condylar width at the level of the popliteal groove. These researchers' prospective study involved 213 athletes at a Division I university, representing 415 ACL-intact knees. Intercondylar notch stenosis was found in 40 knees (i.e., a notch width index less than 0.2), and 375 individuals had a normal notch width index. During the 2-year follow-up period, seven ACL injuries occurred, six in knees with a narrow notch, and one in a knee with a normal notch width. Souryal and Freeman[181] reported similar results in 902 high school athletes followed prospectively. The overall rate of ACL injury during the 2-year follow-up was 3%. Athletes who sustained noncontact ACL tears had a statistically smaller notch width index. Of the 14 athletes with noncontact ACL injuries, 10 had a notch width index at least 1 SD below the mean. Notch geometry has been proposed as one anatomic factor leading to an increased risk of ACL injury in women.

Female athletes have a four to eight times the risk for ACL injury over their male counterparts. Malone[182] reported that women participating in National Collegiate Athletic Association (NCAA) Division I basketball were eight times more likely than their male counterparts to sustain an ACL injury. Females appear to have some unique characteristics that may predispose them to ACL injury, including a wider pelvis, increased genu valgum, altered muscular recruitment patterns, increased ligament laxity, and different biomechanical movement patterns during athletic participation.[182–185] Females have increased quadriceps to hamstring strength ratios and land in a more erect posture, which may place greater strain on the ACL.[172,186] Altered valgus knee torques and neuromuscular control of the trunk predict ACL injury risk in female

athletes and have been the subject of neuromuscular training interventions designed to prevent ACL injury.[187,188]

Of ACL ruptures, 75% occur in the midsubstance, 20% involve the femoral attachment, and 5% involve the tibial attachment.[189] Associated injuries include meniscal tears in 50% to 70% of acutely injured knees and in up to 90% of chronic, ACL-deficient knees,[63,158,190] chondral injuries in 6% to 20% of ACL-injured knees,[63,158] collateral ligament injuries in 40% to 75% of ACL-injured knees,[190,191] and occasionally capsular injuries and knee dislocations.

Up to 80% of patients have reported hearing or feeling an audible crack or pop at the time of initial injury.[63] The acute hemiarthrosis from the ACL tear produces knee swelling within the first 2 to 6 hours after injury. A slower appearance of knee swelling, however, can be indicative of capsular injury, or even an acute on chronic ACL injury.

Classification of ACL injuries is based on the extent of the tear and the resulting instability and is largely a clinical diagnosis. Patients with partial tears have increased anterior translation, as documented by the Lachman's test or instrumented laxity testing, but they have a negative pivot shift test under anesthesia. If loss of ligament function and rotational instability are demonstrated by a positive pivot shift test, the ACL tear is considered complete. Although this determination can often be made in the clinic, an examination under anesthesia may be required to establish a definitive diagnosis.

The natural history of an ACL-deficient knee is still unclear. A torn ACL does not heal, although research investigating the use of bioenhanced ACL repair with a bioactive scaffold has reported some promise.[192–194] ACL deficiency leads to rotatory instability in many patients and results in functional disability. This instability can occur with ADLs in some, with sports activities such as running and stopping (i.e., deceleration), cutting, and jumping in others, and with no functional instability in still another undetermined group. Repetitive episodes of instability may result in meniscal tears, which can result in arthritis. Debate exists as to whether isolated ACL tears, without meniscal pathology, result in degenerative changes within the knee joint.[62,73,190,192,195–197] ACL-deficient patients who undergo meniscectomy without ACL reconstruction develop degenerative changes more quickly; this is more apparent in patients having higher activity levels.[198] A direct relationship exists between giving way (i.e., instability) and the activity level, but many patients with an ACL-deficient knee can return to sports at a less stressful level of activity. Furthermore, functional instability may also be related to meniscal pathology. As is discussed later in this chapter, meniscal injury directly relates to the level of disability, pain, and swelling and the frequency of reinjury.

Posterior Cruciate Ligament

Although the true incidence of PCL injuries is unknown, they are thought to account for 3% to 40% of all knee injuries.[199–202] PCL injury may be more common than realized. PCL injuries are easily missed because clinicians are less familiar with the clinical examination findings.

The PCL is the strongest ligament in the knee,[203] and a significant force is required to rupture it. Most PCL injuries occur as a result of athletic, motor vehicle, or industrial accidents. The mechanism of most athletic PCL injuries is a fall on the flexed knee with the foot and ankle plantar-flexed.[79,204] This imparts a posteriorly directed force on the proximal tibia, which ruptures the taut ligament that is parallel to the force vector, usually resulting in an isolated PCL injury.[205] Similarly, in a motor vehicle accident, the knee is flexed and the tibia is forced posteriorly on impact with the dashboard. Another mechanism of injury to the PCL is a downwardly directed force applied to the thigh while the knee is hyperflexed, such as when landing from a jump.[75] Hyperflexion of the knee without a direct blow to the tibia can also result in an isolated PCL injury.[206]

Mechanisms of Injury to the Posterior Cruciate Ligament

- Fall on a flexed knee with the ankle plantar flexed
- Dashboard injury
- Downward force to the thigh while the knee is hyperflexed
- Hyperflexion

Other mechanisms can result in injury to the PCL, but these usually also involve injury to other ligaments. Forced hyperextension does not commonly result in injury to the PCL.[207] Rather, hyperextension is more likely to lead to injury to the posterior knee capsule, popliteal vessel, and/or ACL.[200] A posteriorly directed force applied to the anteromedial tibia with the knee in hyperextension may also cause injury to the posterolateral corner[200] and results in lateral and posterolateral instability. Significant varus or valgus stress injures the PCL only after rupture of the appropriate collateral ligament. Therefore, when the PCL is torn, the integrity of the rest of the knee must be carefully evaluated.

Clinical Note

If the posterior cruciate has been torn, the integrity of the other ligaments, posterior corners, capsule, and menisci must be carefully examined.

Seventy percent of PCL disruptions occur on the tibial side, with or without an associated bony fragment; 15% occur on the femoral side, and 15% involve midsubstance tears.[189] Associated injuries with acute "isolated" PCL tears include chondral defects in 12% and meniscal tears in 27%, which occur more commonly in the lateral compartment.[208] As with chronic ACL tears, the

incidence of meniscal and chondral lesions is higher in chronic PCL-deficient knees,[208] although in contrast with acute injuries, these more commonly involve the medial compartment.

The patient often reports an audible crack or pop at the time of the initial injury. The patient also notes mild to moderate swelling within the first 2 to 6 hours; however, unlike with ACL injuries, these individuals may return to activity, and the injury often is thought to be a minor event. Patients frequently complain of an unstable gait, but pain with weight bearing or anterior knee pain is common. Pain in patients with a chronic PCL-deficient knee also may be partly due to degeneration of the medial or patellofemoral compartments.[207] Walking down stairs loads the patellofemoral compartment and will often exacerbate the pain.

As with the classification of ACL injuries, grading of PCL injuries depends on the extent of the tear and the degree of resulting laxity. A grade I PCL sprain involves microscopic partial tearing of the ligament, which overall remains intact. The ligament fibers are stretched, causing hemorrhage and microscopic disruption of the ligament. Examination of a grade I PCL injury reveals no increased laxity compared with the contralateral knee, and the end point is firm. A grade II sprain is also a partial tear, although the injury results in partial loss of function, as determined by a slight increase in posterior translation during a posterior drawer test; however, a definite end point is noted, and the reverse pivot shift test is negative. This may be a macroscopic or microscopic tear that results in hemorrhage and stretching of the ligament, but the ligament is still in continuity and functions to some degree. A grade III sprain of the PCL is a complete tear of the ligament. Loss of both ligament function and joint stability are seen; the posterior drawer test result is 2+ to 3+; and the posterior sag test, Godfrey's sign, the quadriceps active drawer test, and the reverse pivot shift test are positive. Posterior tibial translation is excessive, and the end point is soft.

The natural history of the PCL-deficient knee remains controversial, and experience with treatment of PCL ruptures is not as advanced as with ACL injuries because PCL injuries are less common and more difficult to treat surgically. Some of these patients experience almost no functional limitation and compete in high-level athletics, whereas others are severely limited during ADLs.[204,206,209,210] Parolie and Bergfeld[204] suggested that, if adequate quadriceps strength can be obtained, most patients do well with nonoperative treatment. Dejour et al.[211] suggested that patients are symptomatic for the first 12 months, during which time they learn to adapt to the PCL injury. After this time, patients do well, and a high percentage returning to sports. They also reported the development of degenerative changes involving the medial and anterior compartment in chronic PCL-deficient knees,[211] but this finding has not been reported by others.[79,204,209]

Not all authors agree on the success of nonoperative treatment. Clancy et al.[79] reported degenerative changes in the medial compartment in 90% of patients at a 4-year follow-up. Dandy and Pusey[212] followed patients for an average of 7.2 years. Of these patients, 70% had pain while walking, and 55% had patellofemoral symptoms. No correlation was seen between ligament laxity and functional results in the group. Keller et al.[210] reported on a series of 40 patients at the 6-year follow-up. They found the longer the interval between injury and follow-up, the lower the knee score. The presence of radiographic degenerative changes directly correlated with lower knee scores despite excellent muscular strength. In PCL-deficient knees, altered kinematics result in a shift in the tibiofemoral contact location and increased medial compartment cartilage deformation beyond 75° of knee flexion.[213] Similarly, with long-term follow-up (15 years), Dejour et al.[211] found progressive deterioration of outcomes. Eighty-nine percent of patients with isolated PCL injuries had pain, and 79% of knees had degenerative changes. These researchers described the natural history of PCL deficiency as having three phases: functional adaptation, functional tolerance, and osteoarthritic deterioration.

A recent larger study by Shelbourne,[214] however, prospectively evaluated a series of 68 patients with isolated PCL injuries treated nonoperatively for an average of 17.6 years. Subjective clinical scores were good and patients remained active.[214] Surprisingly, moderate to severe arthritis was noted in only 11% of patients.

Whether surgical reconstruction for PCL tears can alter the development of long-term degenerative changes is unclear. Furthermore, in some patients the PCL apparently may heal although in a lengthened position.[215] This may explain the variable results of long-term studies of the PCL-deficient knee.

Medial Collateral Ligament

The MCL is the most commonly injured ligament in the knee.[199] However, the incidence of grade III injuries to the MCL may be lower than the incidence of high-grade ACL tears.[199] The MCL is injured by a valgus stress to the knee that exceeds the strength of the MCL. This most commonly occurs from a blow to the lateral aspect of the knee during a sports event. Uncommonly, a noncontact valgus injury to the knee, such as occurs in skiing, can produce an isolated tear of the MCL. Approximately 60% of skiing knee injuries affect the MCL.[216] The most injurious sports for MCL injury include wrestling, hockey, judo, and rugby.[217] Males are at greater risk than female athletes, and the average amount of time lost per injury has been reported as 23 days.[217]

Mechanism of Injury to the Medial Collateral Ligament

- Valgus stress to a weight-bearing knee

MCL injuries most commonly involve the femoral insertion site, which accounts for approximately 65% of all MCL sprains. Approximately 25% of MCL sprains involve the tibial insertion. The remaining 10% of MCL injuries involve a deep portion of the MCL at the level of the joint line.[189] Associated tears of the medial meniscus occur in 2% to 4% of grade I and grade II MCL sprains, but medial meniscal tears generally do not occur with grade III MCL sprains.[218–220] This is most likely because compression of the medial compartment is required to tear the medial meniscus, whereas injury to the MCL requires tension that unloads the medial compartment.

The diagnosis of an MCL injury can be made from the history and physical examination alone and usually does not require MRI or arthroscopy. However, if the physical examination is difficult to perform because of pain or muscle spasm or if damage to other intra-articular structures is suspected, an MRI can be helpful for determining the full extent of the injury. The patient often recalls being hit by another athlete while the foot was planted, feeling the impact on the lateral aspect of the knee and pain on the medial aspect of the knee. In rare cases, patients may note a pop at the time of injury, but they more commonly state that they felt a tearing or pulling on the medial aspect of the knee. Swelling occurs quickly at the site of injury, and ecchymosis may develop 1 to 3 days after injury. With a grade I or II sprain, the patient may be able to continue to play, but with a grade III sprain, the patient usually cannot continue to participate in sports. These patients usually walk with a limp and with the knee partially flexed because extension stretches the ligament and causes further pain. The patient may not have an effusion if the injury is isolated to the MCL.

Classification of MCL sprains depends on the extent of the tear and the degree of laxity that results. A grade I sprain involves microscopic tearing of the ligament, which overall remains intact. The ligament fibers are stretched, causing hemorrhage and microscopic disruption of the ligament. Examination of the MCL by the aforementioned tests reveals no increase in laxity compared with the contralateral knee, and the end point is firm. However, tenderness is present along the ligament. A grade II sprain of the MCL is also a partial tear, but the injury results in partial loss of function, as determined by a slight degree of increased joint opening (i.e., 3 to 5 mm) on a valgus stress test with the knee in 30° flexion and a definite end point is noted. In full extension, the knee joint opens less than 2 mm more than the contralateral knee. A grade II sprain may represent macroscopic or microscopic tearing, resulting in hemorrhage and stretching of the ligament, but the ligament is still in continuity and functions to some degree. An acute grade II MCL injury is tender to palpation, and the patient notes pain with stress testing. A grade III sprain is a complete tear (i.e., both superficial and deep fibers) of the ligament. Loss of ligament function occurs, and a joint space opening of more than 5 mm compared with the noninvolved knee is seen on a valgus stress test at 30° flexion while an opening of more than 3 mm compared with the noninvolved knee occurs in full extension. Also, no definite end point is noted with stress testing. Significant joint opening in full extension indicates medial capsular injury and possibly injury to the cruciate ligaments.

Transection of the MCL results in 2° to 5° of laxity or 3 to 5 mm of joint opening when a valgus stress is applied, whereas transection of both the MCL and the posteromedial capsule results in 7° to 10° of laxity, indicating that both MCL and capsule play an important role in resisting valgus stress.[221] The severity of tenderness does not correlate with the extent of injury. A grade III sprain usually hurts less than a grade II or grade I injury because complete tearing eliminates stress to ligament fibers.

Use of MRI has allowed for accurate diagnoses of MCL sprains. Ligament tears can be classified by their involvement of the deep and superficial portions of the MCL. This is important, as a "complete" tear of the deep MCL is a very different clinical entity than a "complete" tear of the superficial MCL.

The natural history of isolated MCL tears is a process of healing after the injury, regardless of the degree of injury.[219,220,222–226] Patients with proximal injuries involving the femoral insertion tend to have a higher incidence of stiffness. Also, proximal MCL injuries heal with less residual laxity compared with injuries involving the tibial (distal) end. Partial and complete MCL tears significantly increase the load on the ACL, an important factor to consider in patients with multiligamentous injuries.[227]

Posteromedial Corner of the Knee

In addition to MCL injury, it is important to consider and assess for injury to the posterior oblique ligament (POL) and posterior capsule, which have been shown to be important valgus and rotational stabilizers of the knee.[228,229] In one series of surgically treated isolated and combined medial-sided knee injuries, 99% of the knees were found to have an injury to the POL, 70% had injury of the semimembranosus capsular attachment, and 30% were found to have complete peripheral detachment of the meniscus.[230]

In addition to valgus stress testing in flexion, the clinician must assess for opening of the medial joint space with the knee in full extension. The POL, posteromedial capsule, MCL, and cruciates all contribute to knee stability in full extension. Asymmetrical joint opening in full extension makes an isolated MCL injury unlikely, and one

should suspect concomitant injury to the posteromedial capsule and POL, and possibly the ACL in addition to the MCL injury. An anterior drawer test in lateral (external) rotation may provide additional information regarding medial-sided injuries. With POL and capsular injury leading to grade III laxity in full extension, patients may have an avulsion of the posterior horn of the medial meniscus root that may require surgical intervention. The POL has also been shown to have an important role in preventing additional posterior tibial translation in the knee with PCL injury.[231]

Investigating the extent of injury to the POL and posterior capsule is important in decision making because nonoperative treatment of these injuries may be more likely to lead to unsatisfactory results. The resulting rotational instability, in addition to valgus laxity, may not be tolerated by athletes participating in pivoting sports.

Lateral Collateral Ligament

Isolated injuries to the LCL of the knee are uncommon. In fact, they tend to be the least common injury to the knee, causing only 2% of all knee injuries that result in pathological motion (i.e., grade III injuries).[199] The injury usually is the result of a direct varus stress to the knee, generally with the foot planted and the knee in extension.[159] Injury to the LCL tends to occur as a result of nonsport, high-energy activities[159,199] because a direct blow to the medial aspect of the knee is an unusual occurrence in sports. Varus stress to the knee may also occur during the stance phase of gait, with sudden imbalance and a shift of the center of gravity away from the side of injury resulting in tension on the lateral structures. This mechanism does not require an external force to the knee. Another cause of a varus stress to the knee is a sideswipe injury, in which one knee has a valgus stress and the other a varus stress. The varus injury often has a rotational component.

Mechanism of Injury to the Lateral Collateral Ligament

- Varus stress to a weight-bearing, extended knee

Straight varus injuries can result in LCL disruptions. These injuries tend to be tears from the fibular head, with or without avulsion in 75% of cases, from the femoral side in 20%, and midsubstance tears in 5%.[189] Associated peroneal nerve injuries are common (up to 24%) because the nerve is tethered as it courses around the fibular head.[159] These nerve palsies have a poor prognosis for complete recovery.[232]

Patients with injury to the LCL may hear or feel a pop in the knee and have lateral knee pain. An intra-articular effusion may represent a capsular injury or an associated meniscal or chondral lesion. Because the LCL is extra-articular, isolated LCL lesions do not commonly result in an effusion of the knee.

Often, LCL injuries occur in association with injury to other ligaments in the knee. A severe varus stress results in an LCL disruption, followed by disruption of the posterolateral capsule and PCL. The PLC should be assessed with stress tests for increased varus rotation and lateral (external) rotation at 30° and 90° and compared with the opposite knee (Dial test).[81,82]

Classification of LCL sprains depends on the extent of the tear and the resulting degree of laxity. A grade I sprain involves microscopic partial tearing of the ligament, but the ligament overall remains intact. The ligament fibers are stretched, causing hemorrhage and microscopic disruption within the ligament. Varus stress testing reveals no increase in laxity compared with the contralateral knee, and the end point is firm; however, tenderness is present along the ligament. A grade II sprain is also a partial tear, but the injury results in partial loss of function, as determined by a slight increase in joint opening with varus stress testing (i.e., 3 to 5 mm) compared with the noninvolved knee with the knee in 30° flexion and a definite end point is noted. In full extension, the knee joint opens less than 2 mm more than the contralateral knee. A grade II LCL sprain may represent macroscopic or microscopic tearing, resulting in hemorrhage and stretching of the ligament, but the ligament is still in continuity and functions to some degree. A grade II acutely injured LCL is tender to palpation, and the patient notes pain with stress testing. A grade III sprain is a complete tear of the ligament. Loss of ligament function occurs, and a joint space opening of more than 5 mm compared with the noninvolved knee is seen with varus stress testing in 30° flexion. An opening of 3 mm or more than the noninvolved knee is seen in full extension. In addition, no definite end point is noted with varus stress testing. Palpation of the ligament in the figure-of-four position reveals absence of tension in the ligament proximal to the fibular head.

The natural history of the untreated, complete LCL disruption has yet to be determined. Only a few studies with a limited number of subjects have involved isolated LCL injuries. DeLee et al.[159] suggested that severe, straight lateral instability with more than 10 mm of joint opening compared with the contralateral knee usually implies that the ACL or the PCL (or both) has been injured. From the few studies that have been reported, truly isolated LCL injuries appear to do well with nonoperative treatment.[159,223,226]

Posterolateral Corner of the Knee

Most PLC injuries occur during athletics, motor vehicle accidents, and falls.[233–236] A typical mechanism involves a posterolaterally directed force to the anteromedial tibia, leading to hyperextension and a varus force being

applied to the knee. Other mechanisms include knee hyperextension or severe tibial lateral (external) rotation in a partially flexed knee.[237] A study investigating ultra-low-velocity knee dislocations in obese patients found 50% had injury to the lateral-sided structures.[238] The PLC (Figure 20-26) is the primary stabilizer of lateral (external) tibial rotation at all knee flexion angles.

Isolated PLC injuries are rare, because they are more commonly associated with concomitant ligamentous injuries such as ACL and PCL tears or with tibial plateau fractures. Approximately 9% of patients presenting with a knee hemarthrosis had a PLC injury in one study.[239] Recognizing vascular injury is of crucial importance, particularly in the dislocated or multiligamentous injured knee. Most patients have swelling diffusely over the posterolateral joint, and all have tenderness.[240] Varus stress examination is important, with both knees in full extension as well as at 30° of flexion. Tests directed at the PLC can be performed.

PLC injuries are most commonly classified based on varus instability. Grade I injuries are sprains, without significant varus instability. Grade II injuries are partial, with minimal laxity (i.e., approximately 6 to 10 mm). Grade III injuries are complete disruptions with more than 10 mm of laxity. Rotational stability should also be assessed, for example, via the Dial test. Varus-stress radiographs showing increased lateral joint space widening of 4.0 mm suggests an isolated grade III PLC injury; widening of 6.6 mm suggests a combined posterolateral corner and ACL tear, while widening of 7.8 mm suggests posterolateral corner, ACL, and PCL injuries.[241]

An alternative classification system attempts to incorporate lateral (external) rotation instability in addition to varus instability. This divides injuries into type A or isolated rotational injury to the PFL and popliteus tendon complex. Type B is a rotational injury with mild varus component, indicating injury to PFL and popliteus tendon as well as LCL attenuation. Type C posterolateral instability has significant rotational and varus components due to complete disruption of the PFL, popliteus tendon complex, LCL, lateral capsule, and cruciate ligament(s).[242]

Correctly recognizing and treating PLC injuries and resultant rotatory instability is of critical importance because failure to address such injuries has a negative impact on outcomes. Concomitant cruciate ligament reconstructions have inferior outcomes when combined with grade II posterolateral injuries treated conservatively.[243–245] Thus posterolateral injuries and rotatory instabilities must be recognized and addressed so as to not jeopardize outcomes.

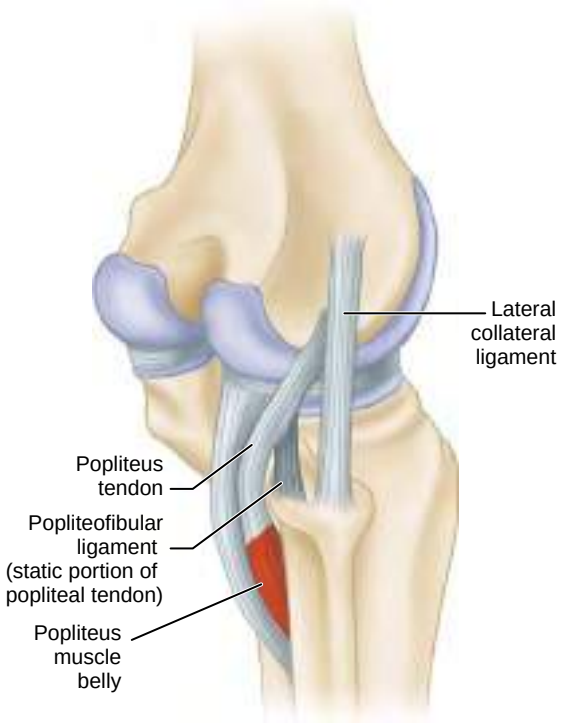

Figure 20-26 Structures of the posterolateral side of the knee. The popliteofibular ligament or static portion of the popliteus tendon arises from the posterior aspect of the fibular head then travels with the main popliteus tendon to its insertion site on the lateral femur. This static portion of the popliteus tendon is nearly isometric and is positioned to resist posterolateral tibial rotations. (From Canale ST, Beaty JH: *Campbell's operative orthopaedics,* ed 12, Philadelphia, 2013, Elsevier.)

DISLOCATIONS AND MULTIPLE-LIGAMENT KNEE INJURIES

Knee dislocations and other, less severe multiple-ligament injuries account for approximately 20% of all grade III ligament injuries of the knee.[199] This diverse group of injuries has a variable severity and co-morbidity. Other than combined ACL–MCL injuries, combined ligament injuries account for fewer than 2% of all knee ligament injuries.[199] Frequent combinations of two-ligament injuries include the ACL–MCL (most common), PCL–MCL, PCL–LCL, ACL–LCL, and ACL–PCL.

To dislocate the knee, at least three ligaments must be torn.[246] In most knee dislocations, both cruciate ligaments and one collateral ligament are torn. Fractures occasionally are associated with knee dislocations, but these fracture-dislocations are considered a different entity from a dislocated knee and involve injury only to the ligaments.

A person may dislocate the knee by simply stepping in a hole and hyperextending the knee (low energy) or from a high-energy blow to the knee, such as can occur in a motor vehicle accident. Athletes have sustained low energy knee dislocations during collisions in baseball, rugby, football, and soccer.

Neurovascular injury is uncommon with knee injuries that involve only two ligaments. However, an LCL injury combined with a cruciate ligament injury can result in enough lateral joint opening to produce injury to the peroneal nerve.

Although the knee can dislocate in any direction, the most common directions are anterior and posterior.[247,248]

Knee dislocations may involve damage to multiple structures within the knee, including the cruciate and collateral ligaments, capsular structures, menisci, articular surface, tendons, and neurovascular structures. The nerves and blood vessels in the popliteal space of the knee are easily stretched and torn during dislocation of the knee, and neurovascular injury must be ruled out in all cases. Associated injuries include vascular damage in 20% to 40% of knee dislocations and nerve damage in 20% to 30%. Some knee dislocation case series reports have an amputation rate of the involved extremity of up to 49%.[247,249,250] Posterior knee dislocations are associated with the highest incidence of popliteal artery injury,[247] and posterolateral rotatory dislocations have the highest incidence of nerve injury.[251] Some evidence suggests that low-velocity knee dislocations may uncommonly result in neurovascular injury.[252] On the other hand, ultra-low-velocity knee dislocations in morbidly obese individuals have a very high rate of vascular injury.[253] The likelihood of combined neurovascular injury tends to increase as body mass index (BMI) increases.[238] These individuals may also have a greater incidence of postoperative complications.[254]

Evaluation of vascular status should include palpation of pulses and comparison of the ankle-brachial index (ABI). This test involves taking the blood pressure at the ankle and on the arm at rest and is repeated at both sites after 5 minutes of treadmill walking. It is used to predict the severity of peripheral arterial disease (PAD). If pulses are asymmetrical or if an abnormal ABI is obtained, an arteriogram is required. Recent evidence suggests that serial vascular examinations may replace the arteriogram if ABIs are normal.[255]

Osteochondral and meniscal injuries are rare, particularly with low-velocity knee dislocations. This is most likely due to a distraction force being required to dislocate the knee, whereas osteochondral and meniscal injuries are caused by compressive forces.[251]

The patient with a multiple-ligament injury frequently gives a history of severe injury to the knee, although, as noted earlier, the mechanism may be trivial. The patient often hears a pop. Swelling occurs within the first few hours, but it is not always large because of the associated capsular injury and extravasation of the hemarthrosis into the surrounding tissue. The patient may note deformity of the knee if the knee dislocated and remains unreduced. The patient complains of instability and inability to continue with sports and ADLs.

Tibiofemoral dislocations are classified by the direction in which the tibia translates in relation to the femur. As mentioned, the knee can dislocate in any direction. For example, if the tibia lies anterior to the femur, the injury is an anterior dislocation. Posterior, medial, and lateral dislocations of the knee also can occur. Rotatory dislocations occur when the knee dislocates in more than one direction; these include anteromedial, anterolateral, posteromedial, and posterolateral dislocations. Unfortunately, knee dislocations can reduce spontaneously; therefore this classification scheme is not useful. Furthermore, the amount of tibial displacement that occurs at the time of injury cannot be estimated from physical or radiographic findings. It therefore is helpful to describe the dislocated knee by the ligamentous structures that have been disrupted.

The natural history of knee dislocations and multiple-ligament injuries is unknown. This is because of the uncommon nature of these injuries and the many types of dislocations and mechanisms of injury (e.g., low velocity versus high velocity) that can occur. However, vascular injury associated with a knee dislocation, if left untreated or if not repaired within 8 hours of the time of injury, results in an 86% amputation rate. If surgery to correct vascular injury is completed within 6 to 8 hours, the amputation rate is only 11%.[252] Associated nerve injuries have a poor prognosis for recovery, regardless of the treatment.[256,257]

The development of instability, loss of motion, and arthritis at the knee is unclear with nonoperative treatment. The level of function of patients with multiple-ligament injuries is worse than those with an isolated knee ligament injury. Knee dislocations treated with immobilization and aggressive rehabilitation have surprisingly good results with regard to stability, absence of pain, and the range of knee flexion up to 90°.[258] The incidence of arthritis after multiple-ligament injuries has yet to be determined, but increased instability would be expected to result in a greater degree of arthritic change. Controversies exist regarding the treatment of knee dislocations and multiligament reconstruction, particularly with regard to role of arteriography, acute surgical treatment, role of joint-spanning external fixation, and approach to ligamentous repair or reconstruction.[259]

TREATMENT OF KNEE LIGAMENT INJURIES

Guidelines for Progression of Rehabilitation

Progression of the rehabilitation program after knee ligament injury and/or surgery should proceed in a logical sequence. Generally, the phases of this progression overlap. For example, muscle function may be addressed before full ROM and flexibility has been restored. Progression of the patient through the sequence must be individualized and depends on the nature of the injury and/or surgery, principles of tissue healing, individual signs and symptoms, and the response to treatment. Adequate time must be allowed for tissue healing and remodeling. During rehabilitation, care must be taken to avoid overaggressive treatment, which is indicated by a prolonged increase in pain after treatment and/or regression in the patient's progress.

Clinical Note

Overaggressive treatment may lead to increased pain after treatment or regression of the patient's progress.

Determinants of Rehabilitation Progression

- Nature of injury
- Nature of surgery
- Tissue healing principles
- Tissue healing timelines
- Patient's signs and symptoms
- Patient's response to treatment

The initial phase of the rehabilitation program should promote tissue healing and reduce pain and swelling. During this period, treatments such as cryotherapy and compression may be beneficial for decreasing pain and swelling. A balance must be achieved between mobility and immobility. The healing tissues must not be overloaded; however, some amount of stress is believed to be necessary for proper tissue strength and alignment, as discussed later in the chapter. Overaggressive treatment during this period can disrupt the healing process, but prolonged immobilization also can have adverse effects. Prolonged immobilization is associated with decreased bone mass, changes in the articular cartilage, synovial adhesions, and decreased muscle strength and increased stiffness of ligaments and the joint capsule, which lead to joint contracture and loss of motion. Disuse results in atrophy and diminished oxidative capacity of muscle. Immobilization appears to affect slow muscle fibers more than fast muscle fibers.[260,261]

The time required for soft tissue healing varies. The response of soft tissue to injury is acute inflammation, which typically lasts several days or until the noxious stimulus has been neutralized. During this period, applications of cold and compression may be used to limit and control acute inflammation. Inflammation is followed by fibroplasia, which involves the proliferation of fibroblasts and the formation of collagen fibers and ground substance. Fibroplasia usually lasts for several weeks and results in the formation of granulation tissue, which is fragile, vascularized connective tissue. During this period, protected motion is encouraged because it stimulates collagen formation and alignment. Excessive loading of the healing tissue should be avoided because it may disrupt the healing tissue and reinitiate the inflammatory process. Over time, granulation tissue matures and remodels and can withstand greater loads. This process is gradual and depends on the stresses imposed on the tissue; stresses should be gradually and progressively increased to allow the tissues to adapt to the functional demands placed on them.

Rehabilitation of the knee should ensure that full symmetrical motion to the involved knee is restored. Loss of motion after knee ligament injury and/or surgery adversely affects function. Loss of extension affects gait and results in patellofemoral symptoms. Loss of flexion interferes with activities such as stair climbing, squatting, and running. In the early phases of rehabilitation, passive, active-assisted, and active ROM exercises can be used to increase and/or maintain motion of the knee. In the latter stages of rehabilitation, active and passive stretching can be used to restore motion. Stretching should be sustained (e.g., L3D technique—low load, long duration) and should use low force to maximize creep and relaxation of connective tissue to produce permanent elongation. Application of heat before and during the stretch and maintaining the stretch during cooling may also help produce permanent elongation.[262] Neurophysiological stretching techniques, such as contract/relax or contract/relax/contract, can help restore motion if the limitation is caused by muscular tightness.

Mobilization of the patella also may be helpful in restoring motion. Inferior glide of the patella is necessary for flexion, and superior glide is necessary for normal functioning of the extensor mechanism. Decreased superior mobility of the patella interferes with the ability of the quadriceps to pull through the knee extensor mechanism and results in the development of a knee extensor lag. Medial glide and lateral tilt of the patella are necessary to stretch the lateral retinacular structures. The force used during patellar mobilization must be appropriate for the degree of inflammation present. Overly aggressive patellar mobilization aggravates pain and swelling, which can contribute to loss of motion. Mobilization of the tibiofemoral joint is rarely necessary but can help restore motion if the limitation of motion is due to hypomobility of the tibiofemoral joint.

Rehabilitation after knee ligament injury and/or surgery must restore function of the muscles that cross the knee as well as the muscles that influence segments proximal and distal to the knee. After acute knee injury or in the immediate postoperative period, the emphasis should be on regaining motor control. Often acute pain and swelling result in inhibition of the quadriceps muscles, and a knee extensor lag develops. During this period, quadriceps sets, straight-leg raises (SLRs), co-contraction in weight bearing (i.e., CKC), and isometric hamstring exercises can be performed. Facilitation techniques such as vibration and tapping, as well as biofeedback and electrical stimulation, may be helpful in regaining motor control. Generally, gaining quadriceps control is more difficult than gaining control of the hamstring muscles.

Resistive exercises are initiated when the individual has regained full active motion of the knee. Initially, resistive exercises should be performed with light resistance and high repetitions to improve muscle endurance. This minimizes stress on healing structures about the knee and improves the aerobic capacity of slow twitch muscle fibers. OKC exercises can be used to provide isolated exercise for the hamstring and quadriceps muscles. Precautions must be taken to avoid overloading healing tissues and to prevent the development of patellofemoral symptoms. CKC exercises can be used to improve muscle function

in functional patterns while minimizing patellofemoral stress. CKC exercises are progressed as tolerated and may include wall slides, minisquats, step-ups, and leg presses. Cycling is an excellent exercise for developing endurance of the lower extremity musculature while minimizing stress on the patellofemoral and tibiofemoral joints. Other forms of endurance exercise for the lower extremities include step machines, cross-country ski machines, and swimming.

In the later phases of rehabilitation, resistive exercises can be progressed to high-resistance, low-repetition exercises to develop muscle strength and power. High-resistance, low-repetition OKC exercises are used to improve isolated muscle strength, but care must be taken to avoid overloading the patellofemoral joint, as described earlier in this chapter. High-resistance, low-repetition CKC exercises can be used to improve strength in functional patterns with less risk of patellofemoral symptoms; however, patellofemoral mechanisms should always be considered with the rehabilitation of any knee injury.

Exercises should incorporate the concentric and eccentric phases of contraction. Concentric muscle function is necessary to accelerate the body, whereas eccentric muscle function is necessary to decelerate the body and to act as a shock absorber. During a concentric contraction, the muscle shortens as it contracts, whereas during an eccentric contraction, the muscle elongates as it contracts. The force–velocity relationship is different for concentric and eccentric contractions. During a concentric contraction, muscle force decreases as the speed of shortening increases. During an eccentric contraction, muscle force increases as the speed of lengthening increases. Eccentric contractions produce higher levels of force as a result of lengthening of the series elastic component and facilitation of the stretch reflex. Failure to incorporate eccentric exercise into the rehabilitation program results in the development of muscle soreness and an increased risk of reinjury with return to activity. Econcentric (i.e., pseudoisometric) exercises should also be included in the middle and late stages for two joint muscles (i.e., quadriceps, hamstrings, and gastrocnemius) because this action is how these muscles act functionally (e.g., flexing hip and knee at same time, as in running, causes the rectus femoris to shorten at the hip and lengthen at the knee while the hamstrings lengthen at the hip and shorten at the knee).

For athletes who require power to perform their sport, plyometric exercises should be incorporated into the final stages of the rehabilitation program. Plyometric exercises develop power and speed and incorporate lengthening of the muscle immediately before a powerful concentric contraction. These exercises include depth drops and jumps from heights of 15 to 46 cm (6 to 18 inches), bounding, hopping, and ricochets. The plyometric program must be carefully planned and implemented to avoid injury.

Once the strength and endurance of the lower extremity musculature have been established, neuromuscular control must be developed to enhance dynamic stability of the knee. This requires learning how to recruit muscles with the proper force, timing, and sequence to prevent abnormal joint motion. Initially, it requires conscious effort, often with the help of biofeedback. Through practice and repetition, control of abnormal joint motion becomes automatic and occurs subconsciously.

Proprioceptive neuromuscular facilitation techniques, such as rhythmic stabilization and timing for emphasis, may be helpful for developing dynamic stability. A variety of functional activities also can be used to develop dynamic control of abnormal joint motion. These activities generally are progressed from slow to fast speed, from low to high force, and from controlled to uncontrolled activities. The emphasis should be on establishing proper movement patterns to enhance dynamic stability of the joint. EMG biofeedback may be used to ensure that muscles are being recruited in the proper sequence to maintain joint stability. Activities for enhancing dynamic stability progress from walking, jogging/running, acceleration/deceleration, sprinting, jumping, cutting, pivoting, and twisting.

Anterior Cruciate Ligament Injuries

Treatment of ACL injuries must be individualized and depends on the extent of pathology and the level of disability experienced by the patient during sports and ADLs. Therefore decisions regarding the treatment of the ACL-deficient knee must be made in collaboration with the patient, physician, physical therapist, and athletic trainer. The type of treatment depends on many factors, including age, activity level, occupation, desire to continue sports, amount of functional instability, presence of associated injuries and arthritic changes, and amount of laxity. The patient's willingness to modify activity to a level compatible with functional stability is the most important factor governing treatment options.

Most studies of the natural history of conservative treatment of ACL injuries have shown poor results in young patients. Persistent instability is common. Noyes et al.[263] reported a 65% incidence of giving way during activity, which was associated with persistent pain and disability for several days thereafter. Hawkins et al.[264] reported that 86% of patients in his case series had similar findings. Furthermore, the ability to return to strenuous activity is limited without reconstruction; only 14% to 22% of patients in this younger age group return to the same level as their previous activity.[264–266]

In older patients, who accept limitations on their activities, results generally are better. Ciccotti et al.[267] evaluated a series of 40- to 60-year-old patients who were treated conservatively for ACL tears. Ninety-seven percent had a grade 2 or grade 3 on Lachman's test, and 83% had a positive result on the pivot shift test; the overall satisfaction rate was 83%.

Even so, without treatment, ACL insufficiency predisposes the patient to injury of other knee structures. The risk for additional lesions of the menisci and cartilage increases with time, potentially as a result of decreased rotational stability.[192,266,268–272] Progressive degeneration of the knee has been cited, especially when associated with meniscal tears.[266,273] At 20-year follow-up, osteoarthritic changes have been noted to occur with ACL insufficiency in 21% to 100% of patients and in 14% to 37% of patients after ACL reconstruction.[274]

A systematic review of outcomes after ACL injury evaluated 27 cohorts containing 1585 patients who had undergone reconstruction and compared 13 cohorts containing 685 patients treated nonoperatively.[275] Results at a mean of 14 years demonstrated patients who underwent ACL reconstruction had fewer subsequent meniscal injuries, less need for further surgery, and better improvement in activity level. Both groups had similar rates of development of radiographically evident osteoarthritis.

Researchers have attempted to classify patients by defining risk for instability. Factors associated with a good outcome for nonoperative treatment include intact collateral ligaments, absence of meniscal injury and/or arthritis, and participation in low-demand sports that do not require running, jumping, or cutting. At the same time, side-to-side laxity alone has not been shown to predict the need for surgery, and classification algorithms to date have not been successful in defining operative or nonoperative patients.[276–278]

Surgical reconstruction of the ACL-deficient knee should be considered if instability of a knee prevents the patient from participating in sports and other activities. It also should be considered if associated collateral ligament damage or meniscal injury is present or if a large increase in anterior tibial translation is seen with laxity testing. Surgery should be considered in most patients who have high expectations and plan to compete in sports that place high demands on the knee.

Partial tears of the ACL involving more than 50% of the ligament are more likely to progress to complete tears if treated nonsurgically.[173] In general, however, there is little correlation between the percentage of the tear and the clinical outcome.[173] Also, the extent of tearing may be difficult to quantify accurately. For this reason, the distinction between a partially torn ACL and a complete tear usually is a clinical one. A positive result on the pivot shift test, regardless of whether the patient is awake or under anesthesia, defines functional instability and an incompetent ACL.

ACL tears in skeletally immature individuals have been increasing in incidence. Although nonoperative management, including delayed reconstruction in this population, is appealing, clinical results of nonoperative management of complete tears of the ACL generally have not been favorable.[279–281] Up to 50% of children in this setting do not return to athletic activity.[282] Partial tears in this population can also be difficult. Kocher studied a population of 45 skeletally immature patients with partial tears of the ACL and found that 31% required surgical reconstruction.[283] Partial tears that were more than 50% or involved the posterolateral bundle of the ACL were more likely to require further intervention. Surgical reconstruction techniques remain controversial, but physeal (i.e., growth plate) sparing techniques allow near-anatomic reconstructions with far less risk for growth disturbance.[284]

Nonoperative Treatment

Nonoperative treatment after injury to the ACL generally has fallen out of favor because advances in surgical and rehabilitative techniques have improved outcomes and reduced morbidity. Nonetheless, conservative treatment of ACL injuries may be indicated for more sedentary individuals who have an isolated injury without damage to other structures and who are willing to modify their lifestyle to avoid activities that cause pain, swelling, and/or episodes of instability. Nonoperative treatment of ACL injuries does not mean that the injury is ignored. Treatment should actively involve the patient and includes exercise, functional training, bracing, and patient education.

Treatment after acute injury to the ACL should focus on resolving inflammation, restoring ROM, regaining muscle control, and protecting the knee from further injury. Cryotherapy and compression can be used to decrease pain and swelling. ROM exercises should be performed to restore motion, which should improve as pain and swelling subside. Failure to regain motion, particularly extension, may indicate a torn meniscus, and further diagnostic studies and/or surgery may be indicated. Isometric exercises for the quadriceps and hamstring muscles should be initiated to regain motor control and minimize atrophy. Assistive devices should be used for ambulation while the knee is still actively inflamed. The use of assistive devices can be discontinued once the patient has regained full extension without a quadriceps lag and can walk normally, without gait deviations.

More aggressive rehabilitation can begin once inflammation has resolved and full ROM has been restored. The emphasis at this time should be on improving the strength and endurance of the muscles that cross the knee. Particular emphasis should be placed on the muscles that pull the tibia posteriorly (i.e., the hamstrings and gastrocnemius). The normal quadriceps to hamstring ratio at a slow contractile velocity is approximately 3:2. It has been suggested that rehabilitation of an ACL-deficient knee should strive to develop a hamstring-dominant knee so that the quadriceps to hamstring ratio approaches 1:1. This seems to be a logical goal for rehabilitation of ACL injuries, but it should not be achieved at the expense of quadriceps weakness.

OKC and CKC exercises can be used to improve strength and endurance. OKC exercises can be used to provide isolated exercise for the hamstring and quadriceps

muscles. Precautions must be taken to prevent the development of patellofemoral symptoms with OKC knee extension. Standing and seated calf raises can be used to develop the gastrocnemius and soleus, respectively. CKC exercises can be used to develop strength and endurance of the muscles of the lower extremity in functional patterns while minimizing patellofemoral stress. CKC exercises are progressed as tolerated.

Once the strength and endurance of the lower extremity muscles have been established, neuromuscular control must be developed to enhance dynamic stability of the knee. Emphasis should be placed on learning to recruit the posterior muscles to minimize anterior translation of the tibia.

Sherrington[285] proposed co-activation of the antagonist during contraction of the agonist. Baratta et al.[29] and Draganich et al.[36] demonstrated co-activation of the hamstrings during resisted OKC knee extension. Antagonist–agonist co-activation probably originates from the motor cortex in the phenomenon known as *direct common drive*.[286] Activation of the muscle spindle can also facilitate contraction of the antagonist.[24] As the knee extends, muscle spindles lying within the hamstrings are activated and facilitate contraction. By training the hamstrings to stabilize the knee dynamically, the clinician can capitalize on the phenomenon of co-activation.

A functional brace may be helpful as the patient returns to activity but does not fully stabilize an ACL-deficient knee. Exactly how knee braces work is unclear, but many patients report improved function with the use of a knee brace. Whether functional braces provide a physical restraint to abnormal joint motion is doubtful. Several studies[287–289] have indicated that knee braces may restrain tibial translation at low-force levels but are ineffective at controlling abnormal joint motion at functional force levels. It has been proposed that knee braces function by improving proprioception. Lephart et al.[25] reported enhanced awareness of joint movement sense with the application of a neoprene sleeve. Application of a knee brace may stimulate cutaneous receptors and enhance proprioception. In addition, knee braces may enhance conscious or subconscious awareness of the injury, helping the individual to protect oneself from further injury. Studies of bracing in ACL-deficient knees have not offered a definitive answer. One prospective randomized study of ACL-deficient knees with functional bracing demonstrated no difference in functional outcome measures or peak torque of the hamstrings or the quadriceps muscles, although subjective stability is increased.[290] A study of ACL-deficient skiers, however, demonstrated a statistically decreased risk of subsequent knee injury.[291]

Another important component of nonoperative management of ACL injuries is modification of the patient's lifestyle to avoid activities associated with pain, swelling, and episodes of instability. Repeated episodes of instability cause further injury to the joint, including stretching of secondary restraints and injury to the menisci and joint surfaces. Recurrent pain and swelling with activity indicate additional damage to the joint. Activities that are not tolerated by the joint should be eliminated to prevent irreversible degenerative changes. Activities that place high stress on the ACL-deficient knee include those that involve jumping, landing, cutting, pivoting, and rapid acceleration or deceleration on the involved extremity. Nonoperative management is likely to fail in patients who are unwilling or unable to modify their lifestyle to avoid activities associated with increased pain, swelling, and instability. These individuals should consider surgical reconstruction.

Clinical Note

Activities that place high stress on the knee ligaments and in the ACL-deficient knee include jumping and landing, cutting, pivoting, and acceleration and deceleration.

Surgical Treatment

Because the ACL tends to stretch before it tears, surgical treatment of ACL injuries usually requires reconstruction with an autograft or allograft. From a historical perspective, results of direct repair have been poor,[191,292,293] and reconstructions using synthetic ligaments have led to early failure and the development of wear particle debris that leads to reactive synovitis.[294–296]

Although ACL reconstruction has been performed since the beginning of the twentieth century and is one of the most common orthopedic procedures, there is still debate in orthopedic literature about the optimal technique. Timing, graft choice, number of tunnels, tunnel location, fixation techniques, and rehabilitation protocols still continue to be refined.

The timing of surgery after acute injury is an important consideration in minimizing the risk of postoperative loss of motion. A decreased incidence of loss of motion and a faster return of quadriceps strength were noted when surgery was delayed 3 to 4 weeks after acute ACL injury.[252,297,298] Other studies have demonstrated excellent results with early reconstruction and a postoperative rehabilitation protocol emphasizing terminal extension and early ROM. A meta-analysis, performed in 2010, demonstrated no clinical difference between early reconstruction (i.e., within 3 weeks of injury) and late reconstruction (i.e., after 6 weeks of injury).[299] Even so, most authors recommend delaying surgery until inflammation has subsided (about 2 to 3 weeks) and ROM and muscle function have been restored, and the only strong indication for immediate surgery is avulsive ligamentous injuries and reparable meniscal injuries.[300–302]

Currently, ACL reconstruction is most commonly performed using an arthroscopically assisted technique with the goal of recreating the normal anatomy of the ACL.

An arthroscope is inserted into the knee through two or three small portals. A tibial tunnel is drilled with an intra-articular exit point at the posterior half of the native ACL insertion. A second tunnel is drilled in the femur at the origin of the native ACL. Different options exist for drilling the femoral tunnel arthroscopically, including through the tibial tunnel (trans-tibial), via a separate anteromedial portal, or use of an inside-out technique drilling through the femur itself. Regardless of technique, tunnels are precisely positioned to recreate the native footprints of the ACL on the tibia and femur.

Multiple surgical variables contribute to the success of the operation. Tunnel placement, graft type, graft fixation, tension, rotation, and notch preparation affect the biomechanics of the reconstruction. Graft fixation can be performed by multiple techniques. If a patellar tendon graft is used, fixation usually is achieved with interference screws (Figure 20-27). Soft tissue grafts (e.g., hamstring) can be fixed with an EndoButton, spiked washers, or a special interference screw. Enlarging the intercondylar notch with a "notchplasty" should be considered if the graft impinges in this area. This is especially important in female patients where a narrowed notch is one factor leading to increased prevalence of ACL injury. Excessive notchplasty, though, may have biomechanical implications on tunnel placement and anterior laxity and is avoided when not necessary.[303]

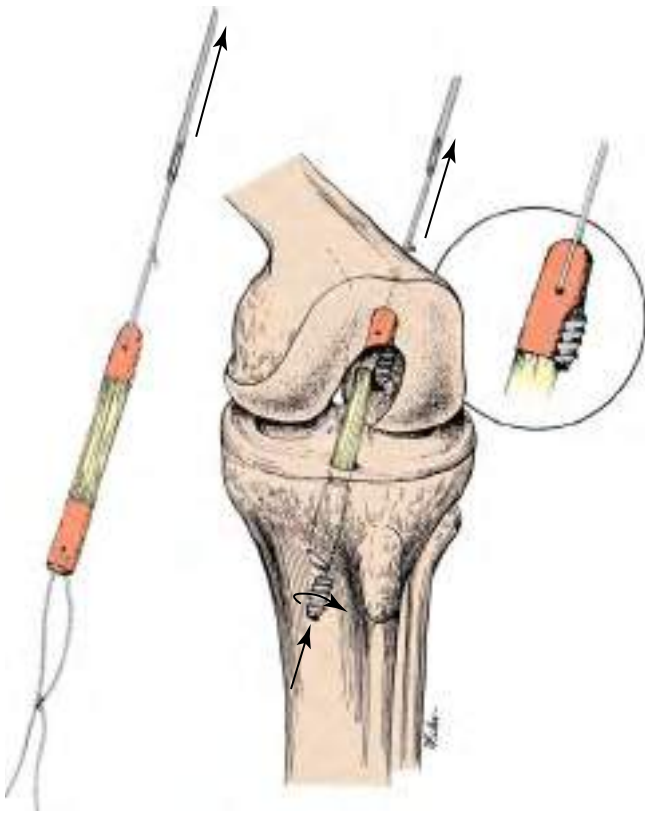

Figure 20-27 Anterior cruciate ligament reconstruction using a bone–patellar tendon–bone graft. Interference screw fixation is used to fix the graft within the tunnels. (From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 665, Philadelphia, 1996, WB Saunders.)

ACL reconstruction techniques have evolved with advances in the biomechanical evaluation of the knee. Computer-assisted surgery, high-resolution MRI, evaluation of in vivo three-dimensional kinematics, as well as a better understanding of the ligamentous anatomy, recently provided new insights into functional performance of ACL reconstructions. These analyses have led to an increased emphasis on optimization of graft placement and an anatomic reconstruction technique. Too vertical of a placement of the femoral tunnel of the ACL preferentially reconstructs the anteromedial bundle at the expense of the posterolateral bundle and leads to persistent rotational instability of the knee. Attempts at addressing this problem with double-bundle,[304] anteromedial tunnel drilling,[305,306] or even two-incision approaches[307,308] have shown equivalent positive clinical outcomes. Current reconstructive techniques focus on positioning the femoral and tibial tunnels in optimal anatomic positions to recreate both the anteromedial and posterolateral bundles and thus simulating the biomechanics of the ACL better than previous techniques.

Multiple types of grafts are available to reconstruct the ACL. Autograft reconstructions, including bone–patellar tendon–bone (BPTB),[79,309,310] hamstring tendons,[311–313] and quadriceps tendon,[314] have the advantage of ease of availability, earlier incorporation into bone, and avoidance of possible disease transmission. The use of allograft tissue (i.e., tissue from another human being) for reconstruction has the advantage of avoidance of donor morbidity and a shorter surgical time.[315–317] Meta-analyses of BPTB autografts versus allografts have shown equivalent clinical outcomes once irradiated, and chemically processed allografts were excluded.[318,319] Allografts may have a higher failure rate in young active patients. A retrospective cohort study found that patients 25 and younger had a 29.2% failure rate with allograft tissue compared with an 11.8% failure rate with BPTB autografts.[320] At the same time, better results were seen in allografts in older individuals.

Comparison of BPTB and hamstring autografts showed lower rates of graft failure (4.9% versus 1.9%) and less anterior laxity in the BPTB group. The BPTB group, however, had higher reported percentage of anterior knee pain and increased risk for lysis (i.e., loosening) of adhesions.[321] Hamstring autografts may be associated with hamstring weakness and an increased risk of infection. A Cochrane Review demonstrated no significant clinical difference between hamstring and BPTB autografts.[322] In fact, no single graft source has been found to be clearly superior to others.[323] Ultimate decision for graft choice is an individual one commonly guided by physician experience and recommendations.[324]

Differences in graft tissue strength, stiffness, and graft fixation strength lead to differences in surgical technique

TABLE 20-4

Ultimate Load to Failure and Stiffness of Various Graft Selections

Graft Selection	Ultimate Strength to Failure (Newtons)	Stiffness (Newton-Meters)
Native anterior cruciate ligament (Woo et al.[327])	2160	240
Patellar tendon (Race and Amis[328])	2977	455
Quadrupled hamstring (Hamner et al.[326])	4140	807
Quadriceps tendon (Staubli et al.[329])	2353	326

and postoperative rehabilitation. Although the quadrupled hamstring tendon graft is approximately 91% stronger than the native ACL and 39% stronger than the patellar tendon, all autografts and patellar tendon allografts have greater tensile strength and stiffness than the native ACL (Table 20-4).[325,326] Because of this, graft fixation strength must be factored into the equation when a rehabilitation program is developed.

Brand et al.[330] reported biomechanical data on various graft fixation techniques for ACL reconstruction. These authors reported that the tibial fixation strength for a patellar BPTB graft had a load to failure of 678 to 758 N[331] while femoral fixation with an interference screw was 640 N.[332,333] Soft tissue fixation strength for an EndoButton with no. 5 suture on the femoral side was 800 N.[334,335] Noyes et al.[336] have estimated the strength required for ADLs to be 454 N.

The authors' clinical approach to designing a rehabilitation program based on ACL graft selection is to be less aggressive initially with soft tissue grafts, such as the quadrupled hamstring grafts. This approach is based on the premise that soft tissue to bone healing takes approximately 12 weeks, whereas bone to bone healing occurs in approximately 8 weeks in most cases. With our current operative technique, patients generally return to sports within 6 to 9 months.

Postoperative Management for Reconstruction of the Anterior Cruciate Ligament

Rehabilitation after ACL reconstruction must consider graft type, initial graft strength, fixation, and healing and maturation of the graft. Initial graft strength depends on the type, quantity, and quality of the material used and is described earlier in detail.

Graft strength is strongest at the time of reconstruction. Over time, the graft undergoes necrosis and remodeling. Healing and maturation of autogenous BPTB grafts in the animal model[337–340] and in humans[337,341] have been described, as have healing and maturation of allograft BPTB grafts in animal models[341–345] and humans.[342] Initially, the graft is avascular. By 6 weeks, the graft is enveloped in a synovial sheath. Revascularization begins 8 to 10 weeks after surgery and is nearly complete by 16 weeks. Histologically, the graft shows signs of avascular necrosis 6 weeks after reconstruction. The graft is invaded by mesenchymal cells 8 to 10 weeks after reconstruction. These cells proliferate and form collagen by postoperative week 16. One year after reconstruction, the graft takes on the appearance of a ligament, with dense, oriented collagen bundles. Graft strength decreases during the period of necrosis and then increases as the graft remodels and matures.

Although the graft takes on the appearance of a normal ligament, it does not function the same as the native ACL. Evidence suggests that, at 6 months after surgery, allografts demonstrate a greater decrease in their structural properties from the time of implantation, a slower rate of biological incorporation, and prolonged presence of an inflammatory response compared with autografts.[345] Although long-term clinical results have not demonstrated a significant difference between allograft and autograft reconstruction, rehabilitation after allograft reconstruction may need to be less aggressive than that after autograft reconstruction. Despite the research, little is known about the graft's ability to withstand loads and strain during healing and maturation. Therefore, it is difficult to base rehabilitation after ACL reconstruction strictly on the time required for healing and maturation of the graft. Recent research favors the use of criterion- and milestone-based rehabilitation progressions.

Clinical Note

Rehabilitation should be less aggressive after allograft reconstruction than autograft reconstruction.

Interest has developed in accelerated rehabilitation after ACL reconstruction, which initially was popularized by Shelbourne and Nitz in 1990.[346] These researchers discovered that an early accelerated rehabilitation program resulted in an earlier and more complete return of full extension and an earlier return to final flexion without any adverse effect on the stability of the knee, as indicated by side-to-side differences in knee laxity scores.[346] In addition, isokinetic testing of the quadriceps revealed a higher mean percentage of involved to noninvolved scores from 4 to 10 months postoperatively. However, these differences in isokinetic scores were eliminated 1 year after surgery. No differences were seen in the patients' subjective assessment of their knee function. A second surgical procedure to recover loss of extension was required less often in patients who underwent the accelerated program. Based on these results, the use of an accelerated rehabilitation program after ACL reconstruction was

recommended because it resulted in earlier restoration of motion, strength, and function without compromising stability of the knee.

Loss of motion, especially in extension, has been described as a common complication after ACL reconstruction.[301,347–351] Sachs et al.[350] reported a 24% incidence of a knee flexion contraction more than 5° after ACL reconstruction. This was positively correlated with quadriceps weakness and patellofemoral pain. Harner et al.[301] reported an 11% incidence of loss of motion, which they defined as a knee flexion contracture of 10° or more and/or knee flexion less than 125°. All patients with loss of motion experienced loss of extension, and two thirds also had loss of flexion. Factors significantly related to the development of loss of motion included reconstruction within 4 weeks of the initial injury, concomitant knee ligament surgery involving the medial capsule, and gender (i.e., male). Patients with loss of motion tended to have had an autograft rather than an allograft and to be older, but these trends did not reach statistical significance. Also, patients who developed loss of motion used a postoperative brace that limited full extension more often than did patients who had normal motion after surgery. Loss of extension after ACL reconstruction leads to an abnormal gait, altered joint arthrokinematics, increase patellofemoral and tibiofemoral contact pressures, and even quadriceps weakness.

The goal for postoperative management after ACL reconstruction is to provide a stable knee that allows return to the highest level of function while minimizing the risk for loss of motion. To reduce the risk of loss of motion, postoperative management after ACL reconstruction should emphasize control of inflammation, restoration of full extension symmetrical to the noninvolved knee, early ROM and quadriceps exercises, and restoration of normal gait.

Clinical Note

To reduce risk of loss of ROM, rehabilitation should emphasize the following:

- Inflammation control
- Early ROM
- Restoration of full extension (actively and passively)
- Quadriceps exercises
- Restoration of normal gait

Adams et al.[352] outlined an excellent multiphased criterion-based rehabilitation approach that encompassed all aspects of the rehabilitation until return-to-sport. The phases include the presurgical phase, the immediate postoperative phase, the early postoperative phase, the intermediate postoperative phase, the late postoperative phase, and the transitional phase. Each phase with the appropriate milestones are outlined in Table 20-5.

TABLE **20-5**

Criterion-Based Milestones for Treatment Progression

Phase	Milestones
Immediate postoperative	• Knee ROM 0°-90° • Active quadriceps contraction with superior patellar glide
Early postoperative	• Knee flexion >110° • Pain-free ambulation without crutches • Stationary bicycle without difficulty • Full knee extension during gait • Reciprocal stair-climbing • Straight-leg raise without extension lag • Knee Outcome Survey ADL subscale >65%
Intermediate postoperative	• Knee flexion within 10° of contralateral side • Quadriceps index >60% of contralateral side
Late postoperative	• Normal gait pattern • Quadriceps index >80% of contralateral side • Symmetrical ROM (compared with contralateral side) • Knee effusion of trace or less
Transitional postoperative	• Maintenance of quadriceps index >80% • Hop tests >80% of contralateral side at 12 wk • Knee Outcome Survey Sports subscale >70%

ROM, Range of motion.

Modified from Adams D, Logerstedt DS, Hunter-Giordano A et al: Current concepts for anterior cruciate ligament reconstruction: a criterion-based rehabilitation progression, *J Orthop Sports Phys Ther* 42:601-614, 2012.

In the **preoperative phase**, an emphasis is placed on regaining full ROM, decreasing joint effusion, and normalizing quadriceps strength. Patients who achieve minimal to no joint effusion, full return of ROM, and the ability to perform an SLR without an extensor lag have been shown to experience better postoperative outcomes.[300]

Preoperative Phase Goals

- Regain full ROM
- Decrease joint effusion
- Normalize quadriceps muscle strength

The **immediate postoperative phase** encompasses the first week and focuses on early ROM and reactivating the quadriceps muscles. Neuromuscular electrical stimulation (NMES) has been found to be an effective way to facilitate quadriceps activation and has been shown to improve postoperative outcomes.[353] This improves the patient's ability to generate a quadriceps contraction, as effusion and subsequent arthrogenic inhibition generally result in decreased volitional quadriceps activation after surgery. OKC exercises initiated at this time include hip abduction and adduction and knee extension in a restricted ROM (90° to 40°). This restricted range has been shown to reduce strain on the healing ACL graft.[41] The milestones to progress to the early postoperative phase of the rehabilitation progression are 0° to 90° ROM and the ability to actively perform a quadriceps contraction with a superior (i.e., upward) patellar glide.

Goals of Immediate Postoperative Phase (Week 1)

- Reduce pain
- Reduce swelling
- Establish ROM 0° to 90°
- Reactivate quadriceps muscles
- Initiate OKC exercises (90° to 40°)

The **early postoperative phase** generally occurs during the second postoperative week and is marked by the introduction of CKC and terminal knee extension strengthening. Weight-bearing exercise can include wall slides, minisquats, leg press, weight-shifting, and forward/lateral step-ups, all within a pain-free ROM. The patient also can begin riding a stationary bicycle during this phase, once 100° of knee flexion has been achieved. Milestones to progress to the intermediate phase of the rehabilitation program are knee flexion more than 110°, full active knee extension during gait, ambulation without an assistive device, use of a bicycle without difficulty, reciprocal stair climbing, SLR without an extensor lag, and a knee outcome survey ADL subscale score more than 65%.

Goals of Early Postoperative Phase (Week 2)

- Achieve terminal knee extension
- Introduce CKC exercises
- Begin stationary bike
- Improve pain-free ROM

The **intermediate postoperative phase** incorporates neuromuscular training, balance, and proprioceptive exercises, as well as continued quadriceps strengthening. Proprioceptive exercises can be utilized to improve outcomes without increased risk of injury. The milestones to progress to the late phase of the rehabilitation program are knee flexion ROM within 10° of the contralateral side and a quadriceps index score of more than 60%. The quadriceps index is defined as the ratio of uninvolved to involved quadriceps strength and can be measured isometrically with a dynamometer at 60° of knee flexion.

Goals of Intermediate Postoperative Phase

- Reestablish neuromuscular control
- Establish normal ROM
- Improve proprioception
- Improve strength

Once the incision has fully healed, an aquatic therapy program can be initiated, which will allow the patient to begin early running and agility drills in the pool. The buoyancy of the water assists the patient by reducing the percentage of BW and the loads applied to the lower extremity.

In the **late postoperative phase**, intensity of strengthening continues to increase to include low work to rest ratios. That is, high intensity, near-maximal bouts of exercise allowing for appropriate recovery time. Balance and proprioception exercises are progressed to include perturbations and distractions (e.g., a ball toss). To advance to the transitional postoperative phase, the patient must achieve a quadriceps index of more than 80%, a normal gait pattern, full ROM, and knee effusion of trace or less (as graded by a stroke test) (Table 20-6). Once a patient demonstrates understanding of normal and abnormal soreness patterns and the previously listed criteria have been met, a jogging progression may also be initiated within the late postoperative phase. It is outside the scope of this text to discuss a detailed jogging progression; however, the patient should remain pain free during all activities; the program should be reviewed and activities decreased if lasting soreness is experienced after any training session.

TABLE **20-6**

Grading Knee Effusion Using the Stroke Test

Grade	Presentation
0	No wave produced on downstroke
Trace	Small wave on medial side with downstroke
1+	Larger bulge on medial side with downstroke
2+	Effusion spontaneously returns to medial side after upstroke
3+	It is not possible to displace the fluid from the medial side of the knee

From Sturgill LP, Snyder-Mackler L, Manal TJ, Axe MJ: Interrater reliability of a clinical scale to assess knee joint effusion, *J Orthop Sports Phys Ther* 39:845-849, 2009.

Goals of Late Postoperative Phase

- Continue strengthening
- Establish neuromuscular control drills
- Achieve quadriceps index of more than 80% along with a normal gait pattern

The **transitional postoperative phase** includes plyometrics and sport-specific training and can begin as early as 8 weeks postoperatively, as long as the patient has met the previously listed criteria. Early plyometrics begin with double leg box jumps (i.e., jumping up to small step) and then are progressed to flat ground jumping and eventually double leg drop jumps. Emphasis is placed throughout the plyometric progression on proper jumping and landing techniques. Once the patient is able to consistently demonstrate proper hip and knee alignment with double-leg jumping in all directions, a similar single-leg jumping program can commence.

Goals of Transitional Postoperative Phase

- Continue sport-specific training
- Initiate early plyometric activity
- Ensure normal functional movement patterns
- Emphasize normal functional gait during activity

Functional testing before return to sport is essential to determine the athlete's strength, neuromuscular control, confidence in the limb, and ability to tolerate loads related to sport-specific activities.[354] A series of 4 single-leg hop tests have been studied and proved to be valid and reliable performance-based outcome measures.[355] The hop tests described include single hop for distance, 6-meter timed hop, triple hop for distance, and crossover hop for distance. Variation exists in exact passing return-to-sport criteria, but greater than or equal to 90% of the contralateral side in hop testing and the quadriceps index is suggested prior to clearing an athlete for return to participation.[353]

Another critical consideration in the rehabilitation of a patient after ACL reconstruction, in addition to physical and surgical factors, is the *patient's psychological readiness to return to sport*. Research has supported the use of the **ACL–return to sports after injury (ACL–RSI) scale** as a measure of an athlete's fear of psychological readiness, and includes questions such as "Are you fearful of reinjuring your knee by playing sports?" and "Are you confident you can perform at your previous level of sports participation?" Athletes who returned to sport at 12 months postoperatively scored higher on the ACL–RSI both in a preoperative assessment, as well as at 4 months postoperatively, compared with athletes who did not return to sport.[356] Furthermore, Ardern et al.[356] revealed a relationship between psychological readiness to return to sport, the patient's estimated number of months it would take to return to sport, locus of control, and return to sport by 12 months postoperatively. An ACL–RSI score of less than 56 points has been found to indicate an increased risk of failing to return to preinjury level of participation. In these populations, health coaching, patient education, and change in locus of control can all be effective techniques to improve the likelihood of successful rehabilitation and return to sport.

Clinical Note

Patients must be physiologically and psychologically ready to progress through the different levels of rehabilitation and especially before return to the activity that caused the physical injury.

Posterior Cruciate Ligament Injuries

Although similar in presentation, PCL injuries differ from ACL injuries due to their potential for intrinsic healing. Isolated injury to the PCL does not produce the same degree of functional instability and disability seen with injury to the ACL. Many patients with an isolated PCL injury can return to their previous level of function with minimal symptoms. The level of function and patient satisfaction appear to be related to the ability of the quadriceps to stabilize the knee dynamically. Parolie and Bergfeld[204] reported the long-term results of 25 patients with PCL injuries who were managed without surgery. All patients who returned to their previous level of function and were satisfied with their results had isokinetic quadriceps torque values on the involved side more than 100% of those on the noninvolved side. Conversely, patients who were not satisfied with their knees had isokinetic torque values on the involved side that were less than 100% of those on the noninvolved side. Shelbourne and Muthukaruppan[357] prospectively evaluated 215 patients treated nonoperatively for an isolated PCL injury grade II or less and found subjective scores did not correlate with degree of laxity. Others have noted that the level of function after PCL injury did not appear to be related to the degree of instability.[204,212]

Although clinical outcomes have been found to be good in the short term, concern over long-term degenerative changes from the altered arthrokinematics of the PCL-deficient knee have been proposed. PCL-deficient knees experience increased contact pressures in the patellofemoral and medial compartments.[358] Long-term evaluations of patients treated nonoperatively have demonstrated some risk of this increased degenerative disease.[211,359] In contrast, Shelbourne et al.[214] prospectively evaluated a series of 68 patients with isolated PCL injuries treated nonoperatively for an average of 17.6 years. Subjective clinical scores were good and patients were able to remain active. Moderate to severe arthritis was noted in only 11% of patients.[214]

As PCL reconstruction has not demonstrated successful restoration of normal knee kinematics,[360] treatment for isolated grade II or less PCL injuries has generally been nonoperative, with surgery reserved for those patients failing a conservative treatment protocol. There is less controversy regarding multiple ligament injuries, grade III PCL injuries, or avulsive ligamentous injuries for which operative reconstruction of the PCL is recommended.

Nonoperative Management

Even though PCL injures may have an inherent ability to heal themselves, gravitational forces and hamstring muscle tension can often cause the tibia to be positioned posteriorly relative to the femur. Healing of the PCL in this elongated position can cause an increase in chronic instability and disability.[361] Some authors have gone so far as to advocate use of a cylindrical cast to avoid this laxity.[362] Use of a dynamic anterior drawer brace or hinged knee brace[363] may provide some support to prevent posterior translation of the tibia.

Treatment after acute injury to the PCL is similar to the management of acute ACL injuries. Nonsurgical treatment approaches rely on physical therapy and temporary bracing or immobilization to restore normal tibiofemoral positioning.[364] Rehabilitation should focus on resolving inflammation, restoring ROM, and regaining motor control of the knee. PRICE (i.e., protect, rest, ice, compression, and elevation) is used to reduce pain and swelling, while active assistive and passive motion exercises are performed to restore full ROM. ROM should be performed in the prone position to prevent hamstring activation and posterior sag of the tibia due to gravity, which would place increased stress on the healing ligament.[364] As the least amount of stress placed on the PCL occurs between 40° and 90°,[365,366] ROM exercises should be limited to 90° for the first 2 weeks. Isometric exercises for the quadriceps, such as prone quadriceps sets are used to minimize quadriceps atrophy. Hamstring exercises are avoided at this time and can be delayed up to 12 weeks after injury[364] because they contribute to increased posterior laxity. Also, the hamstring muscles do not appear to be as susceptible as the quadriceps muscles to disuse atrophy. Assistive devices are used for ambulation while the knee is still actively inflamed and are discontinued when the patient has regained full extension without a quadriceps lag and can walk normally, without gait deviations.

OKC knee flexion exercises should be avoided because they contribute to increased posterior tibial translation by incorporating hamstring activation. For patients with a PCL-deficient knee, hamstring strengthening is performed using OKC and CKC hip extension with the knee near terminal extension, which minimizes posterior tibial translation. During CKC exercises, the hamstrings function to counteract the flexion moment arm at the hip. Their effect (i.e., producing posterior tibial translation of the knee) is offset by simultaneous activation of the quadriceps muscles. Proprioceptive training for the PCL-deficient knee should emphasize recruitment of the quadriceps muscles to control posterior translation of the tibia dynamically.

More aggressive rehabilitation can begin once inflammation has resolved and full ROM has been restored. The emphasis at this time is on improving the endurance and strength of the quadriceps muscles. OKC knee extension exercises should be modified if the patient complains of pain or crepitus. CKC exercises are initiated and progressed as tolerated to improve the endurance and strength of the muscles of the lower extremity in functional patterns. Patients may begin a jogging progression once they demonstrate full ROM, 85% limb symmetry index, and trace or less effusion at rest and after activity. Sport-specific drills may commence once the patient performs a jogging progression pain free and exhibits 85% limb symmetry on dynamic stability testing (i.e., hop testing). Sport-specific drills may include changes in speed and direction and progress from proactive to reactive drills (i.e., reacting to an opponent).

Generally, patients with a PCL-deficient knee do not complain of instability during physical activity, and a functional brace is not necessary. If a patient does complain of instability, a functional brace specifically designed for a PCL-deficient knee and specifically limiting posterior tibial translation is recommended. This is a critical distinction, as most functional knee braces are designed for ACL-deficient knees and will not assist in the control of posterior tibial translation. Many patients with a PCL-deficient knee complain of patellofemoral symptoms, and may benefit from the use of a neoprene patellar sleeve.

Because of the tendency for progressive deterioration of the anterior and medial compartments of the knee, patients with a PCL-deficient knee should be educated to avoid activities that cause pain and swelling. Repetitive activities that involve high loading of the patellofemoral and tibiofemoral joints may accelerate this degenerative process and should be avoided.

Return to sport generally is delayed for several months, but the time frame in elite athletes can be as little as 6 to 8 weeks with the expected risk of increased residual joint laxity.[364] Patients who fail conservative treatment should be reassessed and considered for surgical repair or reconstruction. Chronic isolated PCL injuries may require serial PCL stress radiographs to objectively gauge injury progression and dictate treatment modifications.[364]

Surgical Treatment

Clinicians must take into account a number of important variables when deciding how best to manage a PCL injury. These include the type of injury; whether associated structures have been damaged; the patient's symptoms, activity level, goals, and expectations; and the acuity or chronicity of the injury. The goal of treatment is to restore the stability and normal kinematics of the knee and

to allow the patient to return to the preinjury level of activity. The best way to achieve this is still the subject of debate.

For interstitial tears of the PCL, the decision to perform surgery is based on the degree of resulting functional instability and injuries to associated ligamentous structures. Surgical reconstruction is recommended for isolated PCL disruptions that result in more than 10 mm of increased posterior tibial translation compared with the noninvolved side or when injury to the PCL is accompanied by injury to other ligamentous structures. Acute repair of a PCL avulsed from the bone or avulsed with bone may be possible with a single screw or suture technique. Most series have shown that reconstructions do better in chronic cases, because the potential for stretching out of secondary restraints increases with time.

It is important to note that a posterior drawer of more than 15 mm can indicate a combined injury to the PCL and posterolateral structures.[66] An occult injury to the PLC shoulder be evaluated and concomitantly treated.

PCL tears can be reconstructed using an open or an arthroscopic technique. We prefer performing PCL reconstruction using an arthroscopically assisted technique. Although it is technically more demanding, it is believed to reduce operative morbidity and to hold promise for improved clinical results. As with reconstruction of the ACL, PCL reconstruction has been performed using a variety of graft materials, including patellar and Achilles tendon allografts, patellar tendon, fascia lata, medial head of the gastrocnemius, semitendinosus–gracilis, and meniscus autografts, and synthetic replacements. Procedures in which the medial head of the gastrocnemius,[83,367–371] the semitendinosus–gracilis,[368,369] the iliotibial band,[370] the meniscus,[371,372] Gore-Tex synthetic ligament,[373] and primary unaugmented repair[374–376] have all failed to produce consistent, objective results.

Techniques for PCL reconstruction can be divided into transtibial and tibial inlay. Transtibial techniques utilize a tunnel in the tibia exiting posteriorly. The graft makes an acute turn as it exits the tibia toward the femur. This "killer turn" has been implicated as a cause of graft failure. To address this potential problem, a tibial inlay technique has been advocated where the PCL graft is affixed to the posterior tibia directly.[377] Biomechanical studies of these techniques suggest that posterior laxity may increase to a greater degree with cyclic loading in the transtibial technique compared with the tibial inlay.[378] Clinical studies, however, have reported no meaningful difference between the two techniques. Attempts have been made to reduce the effects of the "killer turn" by smoothing the tunnel,[379] approaching from the anterolateral tibia,[380] and using an aperture fixation at the posterior portion of the tunnel.[381]

Single- versus double-bundle reconstruction of the PCL is also controversial. Single-bundle PCL reconstruction consists of reproducing the anterolateral bundle of the ligament because this is the largest and strongest band, and it functions primarily with the knee in flexion. The procedure is performed by drilling the tibial tunnel (so that it reproduces the distolateral portion of the tibial insertion site) and drilling the femoral tunnel (so that it reproduces the anterior portion of the femoral insertion site). An Achilles tendon allograft is passed through the femoral and tibial tunnels. The authors prefer to use an Achilles tendon allograft because of its length and strength, availability, lack of morbidity to the patient, and ease of passage; one end of the graft is without a bony block and can easily be passed through the acute angle required to go from the femoral to the tibial tunnel. The femoral side, which includes the Achilles bone plug, is fixed with an interference screw, and the tibial side is fixed to the tibia with a screw and soft tissue spiked washer (Figure 20-28).

Although a single-bundle reconstruction may reduce posterior tibial translation at the time of surgery, anatomical and biomechanical studies have shown that the two bundles of the PCL have different roles in the normal arthrokinematics of the knee. The anterolateral bundle becomes taut in flexion, and the posteromedial bundle becomes taut in extension. For this reason, a double-bundle technique has been advocated for reconstruction of the PCL. This procedure, which uses two separate grafts to restore both the anterolateral and posteromedial bundles of the PCL, requires two femoral tunnels and one common tibial tunnel. During reconstruction, the anterolateral

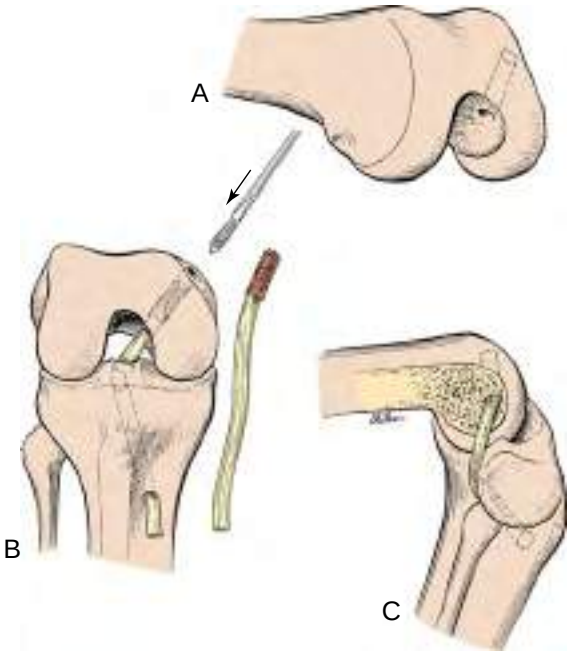

Figure 20-28 Posterior cruciate ligament (PCL) reconstruction. **A**, PCL reconstruction is performed with an Achilles tendon allograft passed through the femoral and tibial tunnels. **B**, The femoral side is fixed with an interference screw. **C**, The tibial side is fixed with a soft tissue spiked washer and screw. (From Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 670, Philadelphia, 1996, WB Saunders.)

bundle is tensioned in flexion, and the posteromedial bundle is tensioned in extension. Harner et al.[382] reported that double-bundle reconstruction more closely restores the normal tibial translation and biomechanics of the knee than the single-bundle technique. Several authors have described the double-bundle procedure in detail.[50,383,384] Nonetheless, the advantages of the double-bundle technique have not been confirmed in the literature, and much debate still exists over the best technique for PCL reconstruction.

Postoperative Management for Reconstruction of the Posterior Cruciate Ligament

Little is known about the healing and maturation of PCL grafts. Bosch et al.[385] studied PCL graft fixation in sheep using a free patellar tendon graft and demonstrated good bone to bone incorporation at 6 weeks. In their study, postoperative management consisted of immediate partial weight bearing and ROM beginning 2 weeks after surgery. Clancy et al.[339] demonstrated revascularization of free patellar tendon grafts 8 weeks after surgery in rhesus monkeys. As yet, no studies on graft fixation and incorporation after PCL reconstruction have been performed in humans.

The rehabilitation program after PCL reconstruction has evolved dramatically over the past several years as a result of advances in researchers' understanding of the anatomy and biomechanics of the knee and improved surgical techniques.

The goals of rehabilitation include restoring full range of knee motion, preventing wear of the articular cartilage, gradually increasing the stress applied to the healing PCL graft, and improving dynamic stabilization of the knee joint. Rehabilitation of PCL injuries focuses on regaining quadriceps strength and control. In fact, earlier quadriceps contraction in the gait cycle can increase dynamic stability in the knee enough to overcome the instability from an incompetent PCL.[386] Rehabilitation therefore focuses on regaining or exceeding normal quadriceps strength.[387]

Overall Goals in PCL Rehabilitation

- Restore full ROM
- Prevent excess articular cartilage wear
- Gradually increase stress to PCL
- Improve dynamic stabilization
- Regain quadriceps strength
- Minimize posterior tibial translation

It is important to minimize posterior tibial translation during rehabilitation.[38] This is accomplished by protecting against gravity-induced posterior sag and by avoiding OKC hamstring exercises. CKC exercises, such as the squat, produce less tibiofemoral shear force and increase overall dynamic stability about the knee joint. OKC quadriceps extension exercises should begin in the prone position to prevent posterior sag of the tibia. SLRs may be introduced once the quadriceps is able to lock the joint in terminal knee extension and no lag is present. The patient can then progress knee extension exercises in the sitting and supine positions.

Clinical Note

After PCL surgery, posterior translation of the tibia must be minimized during active and passive ROM and exercise training, and functional activities.

Several early progressive rehabilitation protocols after PCL reconstruction have been proposed and evaluated.[364,388] Our current milestone-based program consists of five phases designed to progress the patient gradually to full, unrestricted activities by 6 to 9 months after surgery, although individualized for each patient (Table 20-7). The protocol focuses on quadriceps strengthening and restoration of ROM while avoiding stress on the graft. The protocol has been developed based on the findings from the Pierce, O'Brien, Wohlt, and LaPrade review.[364]

Immediately after surgery, the knee is wrapped with a compression dressing and continuous cryotherapy is applied. The patient is educated on how to reduce swelling and pain using the PRICE method. The patient's knee

TABLE 20-7

Criterion-Based Progression of Postoperative Isolated PCL Reconstruction

Phase	Treatment Goals
Phase I (0-6 wk)	Protect reconstruction Reactivate quadriceps Decrease effusion
Phase II (6-12 wk)	Normalize gait Restore ROM Improve quadriceps strength Improve balance
Phase III (13-18 wk)	Improve neuromuscular control Continue quadriceps strengthening Progress hamstring strengthening
Phase IV (19-24 wk)	Continue quadriceps strengthening Continue neuromuscular control Improve muscular and cardiovascular endurance
Phase V (25-36 wk)	Initiate jogging progressions Initiate plyometric progression Initiate sport-specific/agility drills as indicated

ROM, Range of motion.

Modified from Pierce CM, O'Brien L, Griffin LW, Laprade RF: Posterior cruciate ligament tears: functional and postoperative rehabilitation, *Knee Surg Sports Traumatol Arthrosc* 21:1071-1084, 2013.

remains locked in full extension in a knee immobilizer throughout the first day and the patient is taught to ambulate with bilateral axillary crutches, bearing weight as tolerated. A dynamic anterior drawer brace, or other PCL brace, is used with therapy when prescribed by the surgeon.

Phase I (0 to 6 weeks) focuses on protecting the reconstruction, reducing knee effusion, regaining quadriceps control. Passive knee flexion is performed in the prone position and is limited to 90° for the first 2 weeks, then progressed as tolerated. Hyperextension is to be avoided until 12 weeks postoperatively. Isolated hamstring exercises are contraindicated for the first 4 months because of the large posterior shear force generated with hamstring contraction. ROM and patellar mobilizations, particularly superior patellar glides, are performed four to five times throughout the day to help restore motion. NMES is applied in conjunction with these exercises to facilitate a quadriceps contraction.[389–391] Cryotherapy is commonly used for 15 minutes after treatment to control pain and effusion.

Goals of Phase I PCL Rehabilitation (0 to 6 Weeks)

- Protect the repair
- Reduce swelling
- Restore quadriceps control
- Restore ROM
- Mobilize patella
- Avoid hyperextension
- Avoid isolated hamstring exercises for 16 weeks

Precautions after Isolated PCL Reconstruction

Timeframe	Precautions
0-2 weeks	ROM 0°-90°; then gradual progression to full ROM
0-6 weeks	Weight bearing as tolerated (WBAT) with bilateral crutches; then discharge when patient exhibits normal gait
0-6 weeks	Locked in full extension in knee immobilizer, except during ROM and quadriceps strengthening
0-4 months	No open-chain or isolated hamstring strengthening

At 6 weeks, the patient may begin to ambulate with one crutch. Once the patient demonstrates a normal, pain-free gait pattern, he or she may completely discontinue crutch use. The knee immobilizer may be discontinued after 6 weeks, once the patient is able to perform an SLR without an extension lag.

Phase II (generally 6 to 12 weeks) focuses on normalization of gait, restoration of full ROM, continued quadriceps strengthening, and balance/proprioception exercises. Minisquats are performed from 0° to 45°. Because the loss of proprioception after PCL injury is well documented,[392] the authors begin proprioceptive drills, such as weight shifting on a stable platform. Neuromuscular control drills that train muscular coactivation for dynamic stabilization are also incorporated at this time. The stationary bicycle may be used for quadriceps strengthening, motion stimulation, and cardiovascular training when ROM permits and is not to exceed 115° knee flexion. Also at this time, an aquatic therapy program consisting of pool walking, light kicking, and other land exercises that are permitted via protocol is added. CKC exercises are progressed through the squat progression, which entails squat to squat with calf raise to squat with weight shift.[364] Lateral step-downs are also incorporated to encourage single-leg strengthening and motor control. Hamstring bridges are performed on a ball with the knees extended and double leg press can begin. The patient may progress to phase III of the rehabilitation program once he or she demonstrates normal, pain-free gait, full knee ROM, good control with single-leg step-down, and single-leg balance for more than 15 seconds.

Goals of Phase II PCL Rehabilitation (6 to 12 Weeks)

- Normalize gait
- Restore full ROM
- Improve quadriceps strength
- Improve proprioception/balance

Phase III generally spans about 13 to 18 weeks postoperatively and emphasizes continued quadriceps strengthening and neuromuscular control. Balance exercises are performed on variable surfaces and perturbations are added. Progressive hamstring strengthening with a bent knee is also implemented in this phase, with single-leg bridges and *isolated* hamstring strengthening delayed until week 16.

Goals of Phase III PCL Rehabilitation (13 to 18 Weeks)

- Quadriceps strengthening
- Neuromuscular control
- Progressive hamstring exercises

Phase IV (generally 19 to 24 weeks) emphasizes single-leg strength and endurance with an increasing emphasis on power and the initiation of sport-specific drills near the end of the phase. The patient may also increase duration and resistance on the stationary bicycle to address muscular and cardiovascular endurance.

Goals of Phase IV PCL Rehabilitation (19 to 24 Weeks)

- Emphasize single-leg strength and endurance
- Begin activity-specific drills

During **phase V** (generally 25+ weeks), plyometric exercises are used to enhance dynamic joint stabilization and neuromuscular control. The rapid dynamic loading of the musculature during plyometric drills helps train the stretch–shortening cycle of the musculature. Plyometric drills are progressed from the leg press machine to box jumps, then flat-ground jumps, drop jumps, and single-leg jumps. A jogging progression is initiated once the patient demonstrates full ROM, no effusion at rest or after activity, and more than 85% quadriceps strength index. Agility drills and sport- or activity-specific training drills may be incorporated at this time if the patient demonstrates more than 85% limb symmetry in hop testing and has performed a jogging progression without incident. If satisfactory results are seen on the clinical examination, the return to sport phase is initiated and gradually progressed in intensity over the course of 4 to 6 weeks.

Goals of Phase V PCL Rehabilitation (25+ Weeks)

- Dynamic joint stabilization
- Neuromuscular control
- Plyometric exercises
- Activity-specific drills

The authors periodically assess the knee laxity of patients with a reconstructed PCL throughout the program. A KT2000 arthrometer (MEDmetric, San Diego, CA) is used to assess the AP laxity of the knee joint at 2, 4, 6, 8, and 12 weeks and at 4, 6, 12, and 24 months after surgery. The test is performed at the quadriceps-neutral angle to ensure that AP laxity is measured accurately. Serial assessment of knee laxity is useful to the rehabilitation specialist for evaluating the integrity of the graft. Some physicians have utilized a PCL stress radiograph to objectively assess the healing of the PCL.[364] The rehabilitation program is assessed on the basis of the results of the arthrometric testing and is adjusted accordingly.

In the authors' experience, patients typically can return to noncontact sports at 6 months after surgery and to contact sports at 7 to 9 months. The authors tend to be more cautious with skiers because of the highly dynamic nature of the sport; we generally permit skiing at 8 to 9 months after surgery.

Medial Collateral Ligament Injuries

The MCL possesses the greatest capacity to heal of any of the four major knee ligaments and a conservative nonsurgical approach to isolated injuries of the MCL has demonstrated good results in up to 90% of cases.[99,196,219,220,222–226,393,394] Even so, in those cases that fail conservative management, or are associated with other ligamentous injuries, surgical repair and/or reconstruction may be necessary.

Acute treatment of isolated MCL injuries depends on the stability of the joint, the grade of injury, and the location of the tear. Grade I and grade II MCL sprains that are stable when valgus stress tested are treated with a brief period of immobilization and protected weight bearing with crutches. Controlled knee flexion and extension begins as soon as symptoms allow and sometimes necessitate the use of a hinged knee brace.

Grade III MCL injuries are more complex. Indelicato[220] classically prospectively evaluated 36 patients with grade III MCL complex injuries to compare operative versus nonoperative treatment. Although patients in the operative group had better stability (94% versus 85% good to excellent results), no functional difference was noted between groups. For this reason, most isolated grade III MCL injuries are also initially treated nonoperatively.[395]

Results of nonoperative treatment programs have indicated some residual instability with greater knee laxity noted in higher grade injuries. Up to 70% of patients had residual knee laxity in a study of football players with an early aggressive rehabilitation program.[396] Even in Indelicato's original study, notable laxity was seen in both operative and nonoperative groups.[220] Due to the generally excellent clinical results in these studies, it is thought that this residual valgus laxity has little effect on knee function. Even so, it can often be difficult to determine which medial injuries are indeed isolated compared with those involving more of the posteromedial capsule and posterior oblique ligament. Nonoperative management can lead to residual instability in this setting, especially in pivoting activities. Posteromedial corner injuries have been increasingly recognized and may serve as a separate indication for surgical intervention.[229,397,398]

Patients with combined ACL–MCL injuries may also require specific attention to the MCL during treatment. There is notable load sharing of the ACL and MCL. Increased forces on a reconstructed ACL are seen with MCL deficiency.[227,399,400] A goat model has supported the concept that ACL reconstruction can reduce forces on the MCL.[401] Knees with untreated combined ACL–MCL injuries have shown increased valgus laxity and a reduction in tissue quality of the healed MCL.[175] Early ACL reconstruction in combined ACL and MCL injuries may provide a more stable environment for MCL healing.[176] Because of this, the authors' preferred treatment approach utilizes a 4- to 6-week preoperative rehabilitation program that allows for MCL complex healing. This also decreases preoperative swelling and allows the patient to regain normal ROM and strength, maximizing the postoperative outcome. An intraoperative assessment of the MCL is made after ACL reconstruction, and a repair or reconstruction of the MCL is performed if necessary.

Combined PCL and medial-sided injuries also represent an indication for surgical reconstruction of both ligaments for similar reasons.[402,403]

For acute injuries requiring surgical intervention, repair is attempted at the site of injury. This repair is usually at the distal MCL on the tibia because femoral-sided injuries may heal more reliably. Tightening of the posterior capsule and posterior oblique ligament is performed based on clinical assessment and with an understanding of risk of postoperative stiffness. Several anatomic techniques have been described for this repair.[404,405]

Surgical reconstruction is performed using an allograft or autograft. Anatomic reconstructions have been advocated by several authors and focus on recreation of both the superficial and deep portions of the MCL.[229,405] For those knees requiring reconstruction of the posteromedial knee, improved mechanics and stability has been seen in additional reconstruction of the posterior oblique ligament.[406,407]

Nonoperative/Postoperative Management of Medial Collateral Ligament Injuries

Acute nonoperative treatment of isolated MCL injuries depends on the stability of the joint. Grades I and II MCL sprains that are stable with valgus stress testing are treated symptomatically without the use of a rehabilitation brace. Patients with isolated grade III MCL injuries who are unstable with valgus stress testing and who have a soft end point are treated with a hinged rehabilitation brace for 4 to 6 weeks. The brace typically is set to permit 0° to 90° of motion. The brace controls valgus stresses, allowing the ligament to heal while permitting limited motion of the knee.

Nonoperative treatment of acute grade III MCL injuries initially focuses on edema control and quadriceps reactivation, with the focus then shifting to restoration of full ROM. Valgus stress testing and side-to-side movements are discouraged in the first 3 to 4 weeks to ensure proper healing of the ligament. Once the clinical examination reveals improved stability to valgus stress, balance and proprioceptive exercises can begin. Assistive devices are used for ambulation until the patient demonstrates full extension of the knee without an extensor lag and can walk normally, without gait deviations. Healing is generally complete by 5 to 7 weeks, at which point an ACL reconstruction can be performed, if indicated. As soon as appropriate return of strength, ROM, and balance has been achieved, progression to sport-specific exercises can also be initiated.[398]

Typical Nonoperative Time Frames for Return to Sport after Isolated MCL Injury

Grade	Timeframe
I	1-2 wk[218,408]
II	3-6 wk[218,408]
III	8-12 wk[225]

In the postoperative management of isolated MCL reconstruction patients, communication between each member of the rehabilitation team is essential. In general, 0° to 90° of motion should be achieved by the second postoperative week and full ROM by the sixth week. Additional immediate emphasis is placed on edema management, patellofemoral mobilizations, and quadriceps reactivation. SLRs and hip strengthening are encouraged early, with careful avoidance of valgus stresses at the knee. CKC strengthening can begin as soon as the patient is cleared for full weight bearing, generally by 6 weeks after surgery. With appropriate return of strength, ROM, and balance, plyometric progressions can begin at approximately 16 weeks. It is important to recognize that concurrent anterior or posterior ligament reconstruction will dramatically alter the postoperative course, and communication with the surgeon is essential to ensure appropriate management.

Criteria for Return to Sport after Isolated MCL Reconstruction

- Full, symmetrical ROM
- No knee effusion during or after activity
- Pain-free jogging progression
- Pain-free multidirectional plyometrics/speed/agility training
- 85% limb symmetry index (hop testing, isokinetic strength, functional testing)
- Ability to avoid valgus stresses with all activities listed here

Lateral and Posterolateral Corner Injuries of the Knee

Treatment decisions regarding the PLC are based on the extent of injury and functional instability. Isolated grade I LCL sprains that are stable with varus stress testing are treated symptomatically and produce consistently good results. Physical therapy is directed at quadriceps strengthening and ROM. Grade II injuries also do well with a nonoperative approach but can be associated with residual functional instability.[409] Surgical intervention is considered for residual functional instability or with concomitant ACL or PCL injuries where reconstruction of the PLC may also provide protection for the reconstructed cruciate ligaments.[245] Grade III LCL injuries have inferior outcomes compared with those treated surgically, and surgery is generally recommended in this setting.[409,410]

Nonoperative Management of Posterolateral Corner Injuries

Isolated grade I and II PLC injuries may be treated conservatively, as long as the patient does not present with concomitant ligamentous injury for which surgery would be indicated. Nonoperative rehabilitation is similar to the

postoperative protocol described in detail later in this chapter; however, more accelerated progressions are typically tolerated, because treatment is not dependent on graft healing times. Lunden et al.[235] outlined a comprehensive, multiphased nonoperative rehabilitation progression (Table 20-8).

The focus of **phase I** is edema management, restoration of ROM, and reactivation of the quadriceps. Once the patient achieves full knee extension, has 120° of knee flexion, and is able to perform an SLR without an extensor lag, he or she can be progressed to phase II.

Phase II emphasizes normalization of gait and continued quadriceps strengthening. Gastrocnemius, hamstring, and lumbopelvic muscle strengthening are also initiated in this phase, with careful avoidance of varus stresses at the knee (i.e., antigravity hip abduction). The patient may progress to phase III when he or she demonstrates a normal gait pattern.

Phase III is marked by the initiation of neuromuscular training, including balance and proprioception exercises. Functional strength is emphasized in this phase, with cueing for the patient to avoid tibial lateral (external) rotation and knee varus. Hop testing, timed balance, and squat depth testing are also performed late in this phase. The patient may begin sport-specific drills (**phase IV)** when he or she achieves 85% limb symmetry index on all functional testing. A medial compartment unloader brace may be indicated for high-level activities in patients with continued lateral knee instability.

TABLE **20-8**

Criterion-Based Progression of Nonoperative Posterolateral Corner Injuries

Phase	Treatment Focuses	Milestones
Phase I	Edema management Restoration of ROM Reactivation of quadriceps	Full extension ROM >120° knee flexion Straight-leg raise without lag
Phase II	Normalization of gait Continued quadriceps strengthening Lumbopelvic strengthening	Normal, pain-free gait
Phase III	Neuromuscular control Functional strengthening	>85% limb symmetry index (hop testing, squat depth, timed balance)
Phase IV	Sport-specific drills	Return to sport

ROM, Range of motion.

Modified from Lunden JB, Bzdusek PJ, Monson JK et al: Current concepts in the recognition and treatment of posterolateral corner injuries of the knee, *J Orthop Sports Phys Ther* 40:502-516, 2010.

Surgical Management of Posterolateral Corner Injuries

Surgical management of posterolateral corner injuries involves decisions regarding repair or reconstruction of the involved structures. Historically, standard of care called for primary repair of PLC structures within a 3-week time span following injury. Recent studies have called this into question. LaPrade[410] noted poor healing potential of the LCL and popliteus tendon. Levy et al.[259] reported a 40% failure rate of repair compared with 6% failures for reconstruction in patients with multiligamentous injuries. Stannard reported similar rates of failure.[411] Geeslin and LaPrade[412] found better results with combined repair and reconstruction. Because of this, primary repair alone has been limited to the acute setting where structures are in good condition and have been avulsed off their attachments, and surgical reconstruction of the PLC is more common. The authors' preferred technique is to repair avulsions of the LCL when it avulses off the fibular head with the biceps tendon as soon as possible after injury. The repairs are then frequently reinforced with a staged reconstructive procedure at a later date. Timing for surgical intervention has become less important given that reconstruction can be performed in the acute and chronic setting.

Several techniques for surgical reconstruction exist. A biceps tenodesis uses a portion of the biceps and or a strip of the biceps tendon to reinforce the LCL and popliteofibular ligament.[413,414] Assessing alignment of the knee may improve outcomes, especially in the setting of multiple ligament injuries. A high tibial osteotomy can be used to correct coronal alignment while a change in slope may decrease force on the posterolateral corner.[415]

Reconstruction of the lateral collateral ligament, popliteus tendon, or PFL can be performed via LaPrade's anatomic technique or an anatomic repair that is fibula based. In LaPrade's technique, grafts are fixed to the fibular head, and as a final step, the graft is brought through from the posterior to the anterior tibia.[416–418] A fibula-based reconstruction avoids fixation within the fibular head and does not utilize the transtibial tunnel (Figure 20-29).[419–421]

In all reconstructions of the LCL and posterolateral corner, the common peroneal nerve must be identified and protected. The LCL remnants are sutured to the graft to provide added healing potential and possibly proprioceptive function.[422]

Postoperative Management of Posterolateral Corner Injuries

The variability in surgical techniques is described in detail earlier in this chapter; therefore the clinician must have an understanding of the technique used and the structures involved before beginning a rehabilitation program. The following information describes a rehabilitation progression that has been modeled for LaPrade's anatomic

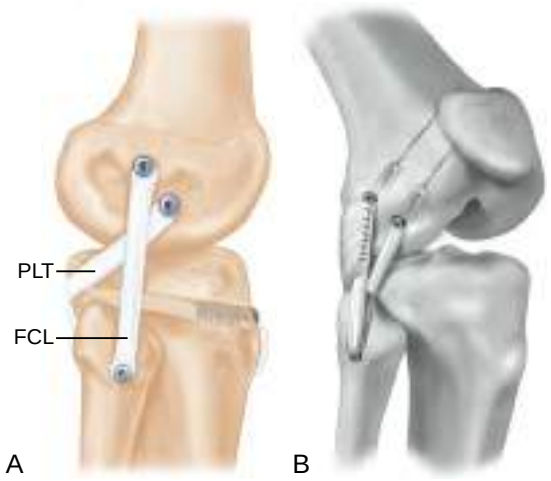

Figure 20-29 Anatomic posterolateral corner reconstructions. **A**, Diagrammatic representation of LaPrade's reconstructive technique. *PLT*, Popliteus tendon; *FCL*, fibular collateral ligament. **B**, Posterolateral capsular shift with a fibular sling. The capsular shift attempts to increase rotational stability by attaching the posterolateral capsule to the fibular collateral ligament (FCL) graft. (**A,** Redrawn from LaPrade RF, Johansen S, Wentorf FA et al: An analysis of an anatomical posterolateral knee reconstruction: an in vitro biomechanical study and development of a surgical technique, *Am J Sports Med* 32:1410, 2004. **B,** From Moulton SG, Geeslin AG, LaPrade RF: A systematic review of the outcomes of posterolateral corner knee injuries, Part 2: Surgical treatment of chronic injuries, *Am J Sports Med*, Aug 2015 [Epub ahead of print]).

technique explained earlier, involving the popliteus tendon, popliteofibular ligament, and LCL.

After PLC reconstruction, the patient is instructed to remain in a knee immobilizer locked in full extension at all times for the first 6 weeks, except when performing ROM and quadriceps strengthening exercises. The patient will also remain non–weight bearing for 6 weeks. For the first 4 months postoperatively, the patient will be instructed to avoid tibial lateral (external) rotation, especially in sitting. This can occur with movements such as sitting cross-legged, standing and pivoting, and engaging/disengaging cycling cleats. OKC hamstring strengthening is also avoided for 4 months and CKC squatting exercises are limited to 70° flexion.

Precautions after Isolated Posterolateral Corner Reconstruction

Timeframe	Precautions
6 wk	Non–weight bearing
6 wk	Locked in knee immobilizer in full extension, except during ROM and quadriceps strengthening
4 mo	No tibial external (lateral) rotation, especially in sitting
4 mo	No open-chain hamstring strengthening
4 mo	No CKC squats beyond 70° knee flexion

Adapted from Lunden JB, Bzdusek PJ, Monson JK et al: Current concepts in the recognition and treatment of posterolateral corner injuries of the knee, *J Orthop Sports Phys Ther* 40:502-516, 2010.

Phase I of postoperative rehabilitation generally encompasses the first 6 weeks. The immediate focus of rehabilitation is edema management, gentle ROM, and quadriceps reactivation. The patient remains in the knee immobilizer in full extension for the first 1 to 2 weeks to allow for the proliferation of fibroblasts and the formation of collagen. Excessive hyperextension is avoided.[235] Gentle ROM is then progressed to achieve 90° by the end of week 2 and full ROM by week 6. Once 100° of knee flexion has been reached, the patient can begin riding the stationary bicycle, with careful avoidance of tibial lateral (external) rotation. Isometric quadriceps strengthening is performed with quadriceps sets and SLR with NMES, and the patient is encouraged to perform up to 30 repetitions, five to six times per day.[235] The patient remains in the immobilizer when ambulating until able to perform an SLR without an extension lag. Lumbopelvic strengthening is also prescribed in this phase, but it is critical that the clinician be mindful of avoiding varus stresses at the knee, such as those incurred during antigravity hip abduction. To progress to phase II of the rehabilitation program, the patient must demonstrate no signs of knee effusion, an ability to perform an SLR without extension lag (i.e., 0° of knee extension) in supine, and more than 120° of knee flexion.

Phase II is marked by progression to full weight bearing. The patient is gradually weaned off crutches until the patient demonstrates a normal gait pattern, which generally takes about 2 weeks. If a **varus thrust** (a lateral bowing of the knee while weight bearing) was observed preoperatively, careful attention is directed at avoiding this motion during gait. Hamstring strengthening is performed with the knee extended (e.g., bridges with the feet on a ball or chair, progressing to standing single/double leg deadlifts) to avoid posteriorly directed forces at the knee. Balance and proprioception are a critical focus of the second postoperative phase, allowing the patient to regain neuromuscular control and confidence in the limb. CKC strengthening is initiated with partial BW leg press, then progressed to standing double-limb squats, without exceeding 70° of knee flexion. Perturbations can be applied in a static squat or lunged position to improve dynamic stability. Swimming with a flutter kick can begin at 8 weeks postoperatively, but the patient should be instructed to avoid flip turns and strokes that involve whip-kicks. To progress to phase III of the rehabilitation progression, the patient must demonstrate: no evidence of joint effusion at rest or with activity, normal pain-free gait pattern, and maintenance of full knee ROM.

Phase III continues with core and lower extremity strengthening, and a brisk walking progression may commence once the aforementioned criteria have been met. The patient is instructed to begin walking for 20 minutes and increase by 5 minutes per week. In order to begin a jogging progression, the patient must be able to ambulate pain free 3 to 5 km with brisk bouts on variable terrain.

Additionally, Lunden et al.[235] recommend that the patient be able to perform 20 repetitions of single-limb squatting with good neuromuscular control prior to beginning a jogging program. Once jogging has begun, step-ups and squatting may be performed at depths of more than 70°, and lateral and rotational components are added. A forward lunge can be utilized with the affected limb leading, with a medicine ball chop toward the medial side to promote varus control.[235] Proprioception exercises are advanced to include perturbations on unstable surfaces and distractions (e.g., ball tosses) to simulate sports activities.

Clinical Note

It has been recommended that a patient be able to do 20 single-leg squats with good control before beginning a jogging program.

Functional testing is similar in this population, as with many other knee injury populations, and can include hop testing, isokinetic or isometric strength testing, squat depth, and single-leg balance testing.[235] Furthermore, a truncated version of the star excursion balance test has been found to be reliable and is used to measure dynamic balance and limb confidence.[423] Like many of the other rehabilitation programs discussed in this chapter, once the patient achieves 85% limb symmetry index on the measures described earlier, he or she may begin sport-specific activities. It is also critical to qualitatively evaluate the patient's performance during functional tests to ensure proper jumping and landing techniques and dynamic avoidance of varus stress. Following this rehabilitation program, a patient can generally expect to return to activity and sports participation in 6 to 9 months, without the presence of concomitant ligamentous injury.

Multiple-Ligament Knee Injuries

Treatment of multiple-ligament injuries of the knee includes a wide spectrum of pathology and requires evaluation of many factors. A knee dislocation can be limb threatening because it is associated with a high incidence of neurological and vascular injuries. Immediate surgical intervention is necessary if the multiple-ligament injured knee is associated with a vascular injury or compartment syndrome. A grossly unstable knee can be stabilized initially with an external fixator. Delayed ligament reconstruction can be completed at a later time after all acute issues have been addressed.

Many knee dislocations reduce spontaneously. If three or more ligaments of the knee are injured, a knee dislocation should be suspected, and appropriate neurovascular examinations should be performed. Initial clinical assessment of a patient with a suspected knee dislocation should include a physical examination and measurement of an ABI. An arteriogram should be obtained in patients with an abnormal physical examination.

Knee dislocations can result from low- or high-energy injuries. Low-energy injuries often are athletic injuries and have a better prognosis because fewer associated injuries are involved. High-energy injuries have a higher incidence of other organ system injuries and neurovascular compromise. However, ultra-low-velocity injuries in patients with a BMI of 40 or higher may have a very high rate of neurovascular injuries, and a significantly increased incidence of postoperative complications.[253,254,424]

Based on the work of Taylor et al.[258] on nonoperative versus operative treatment of knee dislocations, it is reasonable to conclude that nonoperative management could result in a functional knee, depending on the patient's age and functional demands. However, most authors support surgical reconstruction in an attempt to restore stability and improve functional outcomes.[248,300,425–428] Surgical management of a knee with a multiple-ligament injury may also prevent or delay the onset of arthritis by improving joint stability. Functional deficiency that results from a multiple-ligament knee injury must be evaluated relative to the patient's age, occupation, and recreational interests and the neurovascular status of the affected extremity before a decision is made to treat the condition surgically. Absolute indications for surgery include irreducible dislocations, dysvascular (i.e., defective blood supply) limbs, and open injuries.

When the authors opt for surgical management of this injury, reconstruction usually is delayed for 3 weeks after injury to allow soft tissue swelling to decrease. "Sealing" of the capsular injury occurs within a week, which permits the use of arthroscopically assisted techniques. Delayed reconstruction can also prevent the risk of arthrofibrosis by allowing time to regain motion after injury.[251,429] Even so, early repair of the PLC can be considered before 3 weeks to allow for the possibility of a primary repair of these structures. In this case, the PLC is repaired in this initial stage, and cruciate ligament reconstruction is performed several weeks later, after ROM has been regained. A few studies have suggested that acute ligament reconstruction (i.e., less than 2 to 3 weeks after injury) results in better functional outcome scores.[301,430] However, multiple confounding factors make the results difficult to interpret because surgery in patients with severe soft tissue trauma or other concomitant injuries often mandates delayed definitive reconstruction. These patients often have worse outcomes given the delayed timing of surgery and other injuries sustained from their initial trauma. Thus, prospective trials with closely matched groups are necessary to clearly delineate the benefits of early versus late ligamentous reconstruction after a knee dislocation.

In general, the treatment of each individual ligament injury is similar to that for an isolated injury of that ligament. Knees with an MCL injury are braced for the first 4

to 6 weeks to allow healing preoperatively. Reconstruction of the cruciate ligaments is then performed concomitantly. The authors prefer reconstruction using allograft tissue to reduce surgical time and patient morbidity. Use of allograft tissue also ensures the availability of graft tissue and minimizes difficulty with graft passage. The procedure is performed arthroscopically for reconstruction of the ACL and PCL. Open reconstruction is used for LCL/PLC and/or MCL/posteromedial corner injuries.

Postoperative rehabilitation for acute ligament reconstructions depends largely on the procedure performed and requires communication between the surgeon and therapist. ROM limits, time immobilized in extension, weight-bearing status, and brace use will depend on the extent of surgical reconstruction, the quality of the repair, and surgeon preferences. Return to functional activities also varies but is typically longer than that of individual ligaments.

TREATMENT OF PATELLAR TENDON INJURIES

Patellar Tendinopathy

Patellar tendinopathy is one of the most common causes of anterior knee pain in the athletic population. Activities that involve repetitive jumping, such as basketball and volleyball, have a high rate of patellar tendon pathology because of the repetitive eccentric contractions of the quadriceps muscles. Theories about the etiology of these injuries vary and include both intrinsic factors (e.g., muscle tightness, strength imbalances) and extrinsic factors (e.g., sport, training frequency), and both likely contribute to the pathological process.

The progression of symptoms has been described by Blazina et al.[431] and can be classified into four stages. Stage I tendinopathy typically occurs after a recent change in sports activity or a change in the intensity of the current sports activity. This stage is characterized by pain that is experienced after activity. Symptoms do not typically limit participation at this stage of the pathology. Stage II is characterized by pain at the start of activities that subsides, only to return as the patient begins to fatigue toward the end of participation. Stage III involves constant symptoms that limit the activity. Stage IV is defined as tendon rupture.

The stages of pathology defined by Blazina et al.[431] correspond well with the stages of tendinopathy defined by Nirschl.[432] He described an acute period of inflammation of the tendon and paratenon sheath surrounding the tendon (**stage I**). As the chronicity of symptoms continues, the underlying tendon tissue begins to develop tendinosis, whereas the paratenon continues to show an inflammatory response (**stage II**). Eventually the pathology becomes chronic enough that inflammation subsides and tendinosis of the tendon continues (**stage III**). To develop an appropriate treatment program for patellar tendinopathy, it is imperative that the clinician differentially diagnose the appropriate stage of pathology and treat the patient accordingly.

On clinical examination, the patient often is point tender to palpation at the inferior patellar pole at the site of origin of the patellar tendon. The patient also may have symptoms in the midportion or distal attachment of the tendon, although these findings are less common. Resisted quadriceps contraction may elicit symptoms, and the patient often has tightness of the quadriceps musculature. The patient will likely complain of difficulty descending stairs, jumping/hopping, and squatting. Witvrouw et al.[61] prospectively evaluated predictive factors in the development of patellar tendinopathy and reported that the most common factor was the loss of quadriceps soft tissue flexibility. Decreased ankle dorsiflexion ROM has also been strongly correlated with an increased risk of patellar tendinopathy.[433] MRI studies show abnormal signals in the tendon but are often time-consuming and expensive. Ultrasound has become the method of choice for evaluation of tendons because it is inexpensive, noninvasive, repeatable, and allows for dynamic examination and administration of ultrasound-guided injections.[434,435] Hypoechoic regions can be visualized in symptomatic patellar tendons; furthermore, asymptomatic patellar tendons with areas of hypoechoicity are at an increased risk of developing patellar tendinopathy.[435]

Nonoperative Treatment

Conservative treatment for patellar tendinopathy must be appropriate for the stage and progression of pathology. The primary goals of rehabilitation are to control the applied loads and create an environment for proper healing. For patients in stage I and early stage II tendinopathy with an acute onset of symptoms and pain after activity, treatment aims at reducing the inflammatory response and balancing the strength and flexibility of the lower extremity. Traditional anti-inflammatory treatments are used, including cryotherapy and nonsteroidal anti-inflammatory medications. The use of modalities, including iontophoresis, ultrasound, and electrical stimulation, has not been supported for the treatment of tendinopathy in recent research.[436] Patients should attempt to minimize activities that irritate the tendon, and the concept of "relative rest" should be encouraged. The patient should continue to work on enhancing quadriceps strength, lower extremity muscle balance, and soft tissue flexibility. Abstaining from all activities and relying on rest and ice often cause further loss of strength and flexibility, which can result in a recurrence of symptoms when activities are resumed.

The treatment of more chronic stage II and stage III tendinopathies varies greatly from that used for the acute condition. As the chronicity of the pathology progresses, inflammation subsides and tissue degeneration occurs, creating a tendinosis rather than tendonitis. Thus, anti-inflammatory treatments are avoided, and a healing

environment is encouraged by attempting to stimulate blood flow to the area. Several authors have encouraged the use of eccentric exercise for patellar tendinopathy to increase the amount of force applied to the tendon.[437–439] Furthermore, eccentric decline squats have been identified as an excellent exercise to increase and isolate the load through the patellar tendon, showing 25% to 30% higher loads as opposed to flat-ground squats.[436,440] Young et al.[441] demonstrated that decline squats are more effective than a traditional eccentric training program at reducing pain and improving physical function in a group of elite volleyball players. In addition to decline squats, deep transverse friction massage is recommended to encourage a healing environment and promote normalized collagen alignment.[436] Drop squats are added late in the eccentric training program to replicate high-speed eccentric loads. A gradual progression through plyometric and running activities precedes the return to full activity participation, which can generally be achieved within 2 to 3 months.[436]

In the treatment of patients with chronic patellar tendinopathy, the authors recommend a decline squat program including 2 sets of 15 decline squats, twice daily. Exercising into slight pain (up to 5 out of 10 on the VAS) is encouraged, without exceeding a 70° squat depth, to minimize patellofemoral joint loads. Furthermore, the clinician or the patient should perform deep transverse friction massage to the patellar tendon for 5 to 10 minutes per day.

As noted earlier, intrinsic factors are often the primary cause of this condition; therefore an evaluation of the entire kinetic chain is essential to neutralize potential risk factors. A comprehensive program will often include posterolateral hip strengthening and/or foot mobilizations, as indicated.

Platelet-rich plasma (PRP) is a recent nonoperative treatment modality that has been gaining interest. PRP is a sample of autologous blood with concentrations of platelets above baseline values. It is created through a two-phase centrifugation process where the liquid and solid components of anticoagulated blood are separated. The platelet-rich preparation can then be isolated and injected locally into an affected area in the body. In addition to platelets, PRP contains cells such as monocytes and neutrophils that can potentially create beneficial effects in tissue healing by causing a localized inflammatory effect. The inclusion of white blood cells in PRP can vary. Proteins such as platelet-derived growth factor, vascular endothelial growth factor, endothelial cell growth factor and basic fibroblast growth factor can be detected at high concentrations in PRP. Currently, more than 40 commercial systems are available, which can result in variable contents and concentrations of growth factors and cells in the PRP preparation.[442] A recent randomized trial comparing PRP injection to dry needling for patellar tendinopathy showed that a regimen of eccentric exercises and leukocyte rich PRP injection with dry needling accelerates recovery relative to exercise and dry needling alone at 12 weeks. However, functional outcome scores between the two groups showed no difference at 26 weeks.[443] Another study has evaluated outcomes after three consecutive PRP injections delivered 1 week apart for patients with chronic patellar tendinopathy refractory to conservative treatment. Charousset et al.[444] reported that functional scores all significantly improved at the 2-year follow-up, and 75% of patients returned to their presymptom sporting level at 3 months after the procedure. Follow-up MRI also showed improved structural integrity of the tendon at a 3-month follow-up.[444] The cost-effectiveness and clinical evidence of PRP injections remains somewhat unclear in the setting of patellar tendinopathy, and more research is required to clearly delineate if there is a true clinical benefit with this technique.

Surgical Treatment

Surgery generally is performed for chronic tendinosis that has not responded to conservative treatment after 3 to 6 months. The surgery typically involves debridement of degenerative tissue, which creates an inflammatory response and facilitates a healing response. An anterior incision is made directly over the area of tendinosis, and dissection is carried down to the underlying tendon. The paratenon is preserved, and the patellar tendon is divided longitudinally. Degenerative patellar tendon tissue is debrided, and the patellar tendon is reapproximated with a high-tensile-strength suture. Several surgeons advocate additional stimulation of a healing response by drilling adjacent bone with a Kirschner wire (K-wire).

Postoperative rehabilitation focuses on minimizing pain and swelling and gradually restoring strength and ROM in the knee. ROM is initiated immediately to stimulate healing and collagen tissue organization. The patient typically achieves full knee extension immediately, and full knee flexion is restored gradually over the first 4 to 6 weeks. Bahr et al.[438] have outlined a comprehensive rehabilitation program. In the first week postoperatively, the patient performs quadriceps sets and pain-free ROM exercises, as well as standing weight-shifting. In the second postoperative week, the patient may begin weaning from crutches, and he or she may ambulate without an assistive device once he or she has a pain-free, nonantalgic gait. Stationary cycling may begin in the third week, in addition to minisquats with arm support. By weeks 4 and 5, the patient may begin step-ups and step-downs using a 2-inch step, respectively. Eccentric strengthening is initiated in the sixth postoperative week, but unlike nonoperative patellar tendinopathy, the patient is discouraged from exercising into pain. Return to jogging can generally begin at 3 to 4 months. In contrast, Shelbourne et al.[445] outlined an aggressive rehabilitation program that involved active and passive full flexion and extension ROM on the same

day as the patient's surgery as well as unrestricted full weight bearing.[445] Patients in their study performed supervised resisted concentric and eccentric leg press using a portable, low-resistance leg press machine, once they arrived to their inpatient hospital room and twice per day for the first week. At that point, patients were allowed to begin step-up exercises and step height was progressively increased as pain allowed. Sport-specific drills were allowed once the patient achieved 85% isokinetic quadriceps strength, typically at about 2 months postoperatively. In this study, 14 of 16 patients were able to resume sports participation at their presymptom level in an average of 8.1 months. It is important to note that all of the patients in this study were elite-level athletes, including NCAA Division I and professional football, volleyball, basketball, and track athletes.[445]

Patellar Tendon Rupture

Patellar tendon rupture is a disabling injury that results in complete disruption of the extensor mechanism and the inability to actively obtain and maintain knee extension. Ruptures (grade III strains) often occur in sports as a result of a violent contraction of the quadriceps muscle as the foot is planted and the knee moves into flexion, producing an eccentric contraction of the quadriceps muscles. Forces causing rupture of the patellar tendon typically are more than 17×BW.[446] In patients younger than 40 years of age, these forces are highest at the insertion of the tendon and therefore commonly produce tears at the inferior pole of the patella. Ruptures of the patellar tendon may be more prominent with systemic inflammatory disease, diabetes mellitus, or chronic renal failure. In these patients, rupture of the patellar tendon may more likely occur midsubstance than at the tendo-osseous junction.

One of the most commonly observed causative factors in patellar tendon rupture is chronic patient complaints of patellar tendinopathy. Kelly et al.[447] reported a correlation between preexisting patellar tendinosis and patellar tendon rupture. The relatively poor vascularity and chronic degeneration of tissue associated with patellar tendinosis, combined with repetitive microtrauma, eventually may result in complete rupture of the tendon.

Patients almost always report an acute incident and present with pain, swelling, and the inability to actively extend the knee. They may, however, be able to hold the knee in extension using the iliotibial band especially if gravity is eliminated. A palpable defect often is noted upon examination. The patient also has a visible antalgic and quadriceps avoidance gait pattern as the hip musculature and iliotibial band attempts to substitute for the lack of quadriceps control. Plain film radiographs are commonly taken as part of the evaluation. A superiorly oriented patella, or patella alta, on the lateral view may indicate rupture of the tendon. A MRI can confirm the diagnosis of a ruptured tendon and can aid the assessment for concomitant pathology.

Surgical Management

The treatment of an acute tear of the patellar tendon depends on the extent of the tear. If the patient is able to perform an SLR without a quadriceps lag (i.e., inability to fully extend the knee), nonoperative treatment can be considered. However, in most cases, patellar tendon rupture results in a disruption of the extensor mechanism and should be repaired surgically.

An anterior longitudinal incision over the knee permits exposure of both the patellar tendon and the patella. Because most ruptures occur at the tendo-osseous junction at the inferior pole of the patella, the patellar tendon cannot usually be simply reapproximated. Instead, three longitudinal drill holes spaced slightly apart are made in the patella. A running locking stitch is placed in the patellar tendon, and sutures are passed from the tendon through the drill holes in the patella and tied over a bony bridge at the proximal aspect of the patella. The paratenon of the patella is repaired, and the patient is placed in a knee immobilizer or cast.

Postoperative Treatment for Patellar Tendon Repair

The rehabilitation program following a patellar tendon repair is critical to the long-term success of the procedure. Rehabilitation must protect the healing tendon while gradually returning the patient to functional activities. Traditional rehabilitation programs involve approximately 6 to 8 weeks of immobilization and unloading of the lower extremity after surgery. Although this may be appropriate for patients with poor tissue status, a very active person or competitive athlete who wants to return to vigorous activities may risk the development of joint stiffness and arthrofibrosis if this pathway is followed. We prefer a program that gradually progresses ROM and weight bearing but does not overload the healing tissue; this is believed to minimize the risk of complications such as knee flexion limitations, patella immobility, and patella baja.[448] The specific pace of the rehabilitation program is based on the quality of surrounding tissue and the fixation strength of the repair. Communication with the surgeon is vital to develop an appropriate postoperative program.

The immediate postoperative goals include reducing pain and swelling, restoring patellar mobility, initiating early, controlled quadriceps muscle contraction, and gradually restoring ROM. The patient is instructed to use a brace locked in extension for ambulation. Immediate toe touch weight bearing is initiated, progressing to about 25% of BW by week 2 and 50% of BW by week 3. The patient typically progresses to weight bearing as tolerated without crutches by 6 weeks. At this time, the patient may unlock the brace during ambulation but is advised to continue wearing the brace for approximately 8 weeks.

The restoration of passive ROM is one of the most difficult goals to achieve. Full knee extension is encouraged immediately after surgery, although flexion is limited to 30° for the first 5 days and to 45° by the end of week 1. Motion is gradually progressed to 60° by week 2, 75° by week 4, and 90° by week 6. The rate of progression should be carefully monitored, and a continuous passive motion (CPM) machine may be useful at home. ROM is gradually progressed to 105° by week 8, 115° by week 10, and at least 125° by week 12.

Restoring Flexion after Patellar Tendon Repair

First 5 days	30°
Week 1	45°
Week 2	60°
Week 4	75°
Week 6	90°
Week 8	105°
Week 10	115°
Week 12	125°

Initial isometric exercises for the quadriceps and other lower extremity muscles are encouraged. These exercises include quadriceps setting and multiangle SLRs by the end of week 2. Use of the pool and gentle cycling may also be beneficial for the patient when ROM and incision healing permits, typically by 4 to 6 weeks. Gentle CKC exercises, such as weight shifting and minisquats to 30°, are initiated during week 4 and progressed to include the leg press, wall squats, front lunges, and other lower extremity exercises by weeks 10 to 12. Active OKC knee extension is avoided for the first 8 to 12 weeks. Patients who want to begin a running program are allowed to do so after a satisfactory clinical examination and appropriate functional goals have been met. Running typically begins around 5 to 6 months after surgery, with a gradual return to sports activity at 7 to 9 months.

ASSESSMENT OF FUNCTIONAL OUTCOME

Historically, outcome studies related to treatment of knee ligament injuries have focused on reporting physical impairment of the knee, including limitations in ROM, strength, and stability. Functional performance tests may be better predictors of functional limitations and disability than measurements of physical impairment after knee ligament injury. Deficits in functional performance tests probably would result in functional limitations and disability for a patient. Functional performance tests that reproduce the stresses and strains on the knee that occur during activities may be more likely to demonstrate functional limitations and disability. For example, carioca that involves a cross-cutting maneuver reproduces the pivot shift associated with anterolateral instability. This maneuver would be expected to be more stressful than a one-legged hop for distance in an individual with an ACL-deficient knee. Additional research is needed to identify functional performance tests that can accurately predict functional limitations and disability after a knee ligament injury.

Functional limitations and disability experienced by a patient after a knee ligament injury may have multiple causes. Disability may be related to a combination of factors, such as the type and extent of injury, symptoms, and physical impairment and to psychological factors, such as apprehension, lack of confidence, and fear of reinjury. This diversity has led researchers to use a combination of quality of life and disease-specific evaluation tools.

Multiple measures of patient outcomes have been used to measure clinical success. Questionnaires can be used to measure general health status, pain, functional status, or patient satisfaction. Physiological outcomes, utilization measures, or cost measures can also be defined as end points. Assessment tools can be driven by the health care provider or by patients themselves. Objective measures used by the health care provider can include ROM, strength, endurance, structural measures (radiographs), proprioception, and joint laxity. Subjective measures, derived from patient-driven data, include general health, pain perception, psychometric evaluations, disability predictions, and overall patient satisfaction. Subjective measurements have been found to be valid measurements of outcome and, in many cases, were more reliable than the "objective" tests health care providers have relied on for years. The most appropriate set of tools depends on the question to be evaluated and the patient population; usually a combination of these techniques is required.

Some common knee outcome measures include the Short-Form 36 (SF-36), the Modified Lysholm Scale, the Cincinnati Knee Rating Score, the Activities of Daily Living Scale, the Knee Injury and OA Outcomes Score, the Quality of Life Outcome Measure for Chronic ACL Deficiency (ACL-QoL), and the International Knee Documentation Committee (IKDC). Test-test reliability (reproducibility), responsiveness (i.e., the ability to detect clinically important change), and construct validity are usually defined for each outcome tool. Successful application of these tools to assess functional outcome requires an understanding of the patient population and the research question at hand.[449] An instrument validated for one population may not be the correct tool to measure a different population. The Western Ontario and McMaster Universities (WOMAC) Osteoarthritis Index, for example, was developed and validated to assess osteoarthritis outcomes in a relatively older population.[450] The usefulness of its comparisons in a population of younger patients with knee instability is uncertain. See *Orthopedic*

Physical Assessment for more information about the functional assessment of the knee.

SUMMARY

Successful treatment and rehabilitation of ligamentous and patellar tendon injuries of the knee requires a full understanding of the anatomy and biomechanics of the knee. Although imaging techniques continue to advance technologically, the physical examination remains the most important diagnostic tool. Each knee injury must be treated as an individual and unique case; however, application of the principles outlined in this chapter can lead to improved outcomes over time.

CHAPTER 21

Injuries to the Meniscus and Articular Cartilage

THOMAS J. GILL IV, OWEN P. MCGONIGLE, ALEX PETRUSKA, DAVID J. MAYMAN

INTRODUCTION

Injuries to the articular cartilage and meniscus of the knee are common. They can be caused by work activities and athletic injuries as well as activities of daily living and degeneration. They can occur as isolated injuries or in combination with injury to ligaments and other knee structures. Meniscal tears and chondral injuries can cause significant clinical symptoms of pain, swelling, loss of motion, and locking, often requiring surgical intervention. Arthroscopic treatment of meniscal tears has become one of the most common procedures in the United States.[1]

To evaluate and treat these injuries, the clinician must have an understanding of the anatomy, histology, and function of the meniscus and articular cartilage. This chapter reviews the anatomy and histology of both the articular and meniscal cartilage and the signs and symptoms of injuries to these structures; diagnostic studies and treatment alternatives are then discussed.

MENISCUS

Anatomy

The meniscus was first described by Bland-Sutton[2] in 1897 as "the functionless remnants of intra-articular leg muscles." Since that time the meniscal anatomy has been studied extensively. From a gross anatomical perspective, the menisci are two fibrocartilaginous structures that have strong bony attachments to the anterior and posterior tibial plateau.

In the C-shaped medial meniscus, the anteroposterior (AP) dimension of the posterior horn is larger than the AP dimension of the anterior horn. Some variation is seen in the bony attachments of the medial meniscus. Berlet and Fowler[3] have described four types of anterior horn meniscal attachments, three of which attached to bone. The type four variant had no firm bony attachment, but this type was found in only one of 34 specimens. A similar attachment was described by Nelson and LaPrade[4]; 14% of their specimens had no direct bony attachment of the anterior horn. The remainder of the medial meniscus is attached to the knee joint capsule. The capsular attachment of the meniscus to the tibia is called the **coronary ligament.** The posterior bony attachment consistently lies anterior to the tibial insertion of the posterior cruciate ligament. Johnson et al.[5] studied the surface area of the meniscal bony attachments and found that the anterior horn of the medial meniscus has the largest footprint (61.4 mm^2) and that the posterior horn of the lateral meniscus has the smallest (28.5 mm^2) (Figure 21-1).

The lateral meniscus, which is more semicircular in shape, also has anterior and posterior bony attachments. The lateral meniscus covers a larger area of the tibial articular surface than the medial meniscus. A lateral disc-shaped or discoid meniscus that covers the entire tibial articular surface has been reported in 3.5% to 5% of cases.[6] Discoid menisci are the result of a developmental anomaly and may have a familial pattern; they are rarely found medially, are generally thicker than normal, and lack normal posterior attachments. The bony attachment sites of the normally shaped lateral meniscus, the anterior and posterior horns, are much closer together in the lateral meniscus than in the medial meniscus. The anterior horn attaches just adjacent to the anterior cruciate ligament (ACL). The bony attachment site of the posterior horn is located behind the tibial spines and anterior to the insertion site of the medial meniscus. The Wrisberg variant of the discoid meniscus lacks a posterior bony attachment, which leaves the posterior meniscofemoral ligament of Wrisberg as the only posterior stabilizing structure; this often allows excess motion and posterior horn instability. The anterior meniscofemoral ligament of Humphrey runs from the posterior horn of the lateral meniscus to the posterior cruciate ligament and femur. In the posterolateral corner of the knee, the popliteus tendon lies between the knee joint capsule and the lateral meniscus. This region is

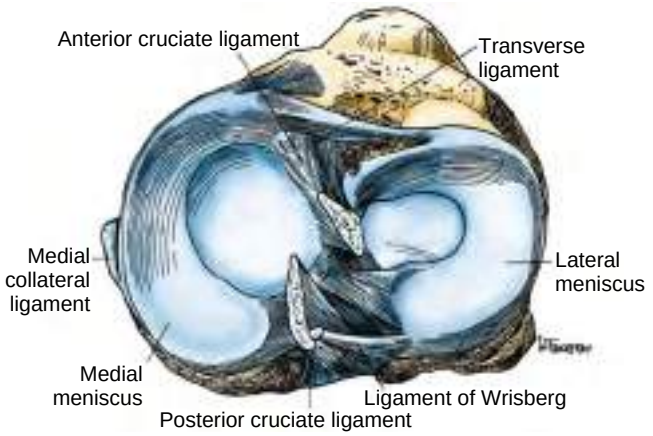

Figure 21-1 Anatomy of the menisci. (From Warren R, Arnoczky SP, Wickiewicz TL: Anatomy of the knee. In Nicholas JA, Hershamn EB, editors: *The lower extremity and spine in sports medicine*, p 687, St. Louis, 1986, Mosby.)

called the **popliteal hiatus.** Attachments also are found between the tibia and meniscus through the capsule, but these are not as well developed as on the medial side. Because of the differences in the attachment to the tibia, the lateral meniscus has more mobility through knee joint motion (Figure 21-2). Thompson et al.[7] have demonstrated 11.2 mm of posterior excursion of the lateral meniscus during knee joint flexion, compared with 5.2 mm of excursion of the medial meniscus.

Blood Supply

The entire meniscus is vascular at the time of birth. By 9 months of age, the inner one third has become avascular. The vascularity of the meniscus decreases until approximately age 10, at which time it reaches its adult condition. Ten percent to 25% of the lateral meniscus is vascular, and 10% to 30% of the medial meniscus is vascular (Figure 21-3).[8]

The vascular supply of the menisci is the superior and inferior branches of the medial and lateral genicular arteries. These vessels form a perimeniscal capillary plexus. The region of the popliteal hiatus is a relatively avascular zone of the lateral meniscus. Cell nutrition to the inner 70% to 90% of the menisci comes from diffusion or mechanical pumping.[9]

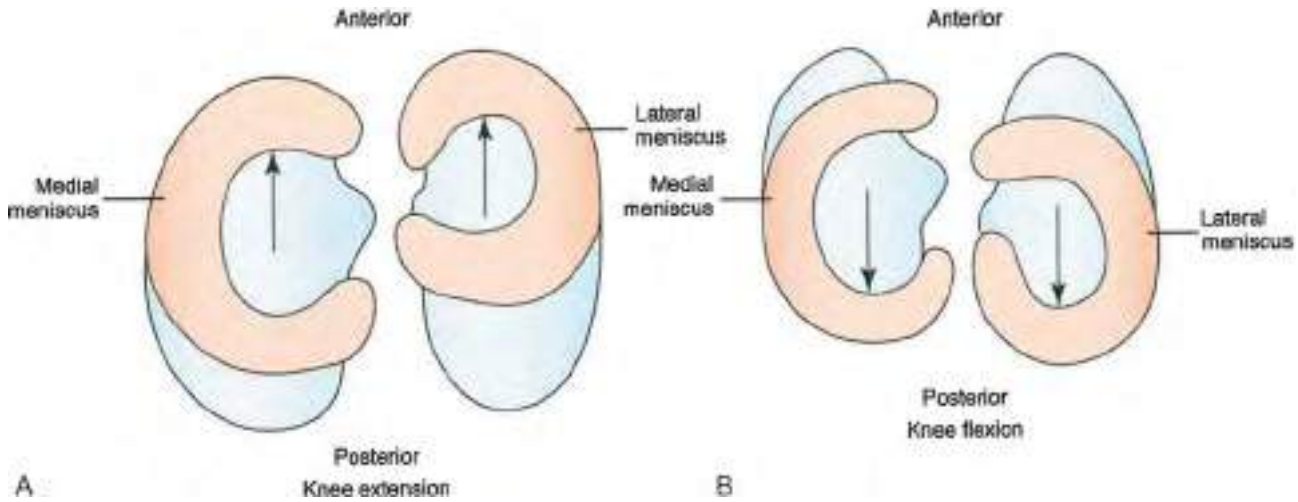

Figure 21-2 Menisci move anteriorly with extension (**A**) and posteriorly with flexion (**B**). The right knee is shown. (Redrawn from Kapandji IA: *The physiology of the joints: annotated diagrams of the mechanics of the human joints,* Edinburgh, 1970, Churchill Livingstone.)

Innervation

The menisci are innervated by myelinated and unmyelinated nerve fibers. Neural elements are most abundant in the outer portion of the meniscus. The anterior and posterior horns of the meniscus are innervated with mechanoreceptors that may play a role in proprioceptive feedback in the knee.[10]

Function

The menisci are critical structures in the knee. They take load from the femur and distribute it over the entire articular surface of the tibial plateau. The menisci transmit at least 50% to 70% of the load when the knee is in extension. Load transmission increases to 85% at 90° flexion.[11] Radin et al.[12] showed that removal of the medial meniscus resulted in a 50% to 70% decrease in femoral condyle surface contact area and an increase in joint reactive forces of 100%. Total lateral meniscectomy led to a 40% to 50% decrease in contact area and an increase in contact stresses of 200% to 300%.[12–14] In addition to being increased, stresses within the joint are distributed unevenly, resulting in increased compressive and shear forces across the joint.

The meniscus plays an important role in shock absorption.[15] Compression studies using bovine menisci have demonstrated that articular cartilage is approximately twice as stiff as meniscal fibrocartilage.

The menisci also can play a large role in joint stability.[16] Medial meniscectomy in a knee with an intact ACL does not affect knee stability; however, medial meniscectomy in an ACL-deficient knee results in an increase in anterior tibial translation of up to 58% at 90° flexion. Allen et al.[17] showed that the resultant force in the medial meniscus of an ACL-deficient knee increased 52% in full extension and 197% at 60° flexion under a 134-N load. Shoemaker and Markolf[18] demonstrated that the posterior horn of the medial meniscus is the most important structure in the knee for resisting an anterior tibial force applied to an ACL-deficient knee.

The inner two thirds of the menisci are important for shock absorption and for increasing joint contact surface area and therefore for reducing contact stresses. The peripheral ring of the menisci is important for load transmission, shock absorption, and knee stability.

Functions of the Menisci

- Load sharing
- Reducing joint contact stresses (by increasing contact surface area)
- Shock absorption
- Passive joint stabilization
- Limiting extremes of flexion and extension
- Proprioception

Epidemiology

The mean annual incidence of meniscal tears is 60 to 70 per 100,000,[19,20] and the ratio of males to females varies from 2.5:1 to 4:1. Approximately one third of all meniscal tears are associated with a tear in the ACL.[21] The peak incidence of meniscal tears associated with ACL injury occurs at 21 to 30 years of age in males and at 11 to 20 years of age in females. A traumatic cause is more likely in younger patients, whereas older patients are more likely to have degenerative meniscal tears.

Patients with an acute ACL injury are more likely to have a lateral meniscal tear than a medial meniscal tear.[22] In contrast, patients with chronic ACL-deficient knees are more likely to develop a medial meniscal tear; the role of the medial meniscus as an AP joint stabilizer in ACL-deficient knees is thought to be the reason for this phenomenon.

DIAGNOSIS OF MENISCAL TEARS

Meniscal tears can be diagnosed through a combination of a careful history, a thorough physical examination, and the appropriate diagnostic tests.

History

Younger patients usually have a history of a weight-bearing, twisting, or hyperflexion injury. These patients usually present with acute joint line pain and swelling. Loss of extension with a mechanical block (locking) suggests a displaced bucket handle tear and usually requires acute surgical treatment.

Patients may complain of catching, popping, or locking. These symptoms occur with meniscal tears, but they also may be symptoms of chondral injury or patellofemoral chondrosis. Degenerative tears of the meniscus usually occur in patients more than 40 years of age. These tears frequently present with a traumatic history of swelling and joint line pain, and they often are associated with some degree of chondral damage.

Physical Examination

Whenever the clinician suspects meniscal pathology, a complete physical examination of the low back and lower extremities must be performed.

Examination of the knee should begin with inspection of the skin and surrounding tissues. Quadriceps atrophy should be assessed. The knee should be examined for evidence of an effusion. Range of motion (ROM) should be assessed and compared to the opposite side. The ligamentous structures should be tested. The joint should be palpated to assess for joint line tenderness, tenderness at ligamentous insertion points, and tenderness in the region of the pes anserine bursa. The patellofemoral region also should be palpated.

Numerous special tests have been used to assess for meniscal pathology. Taken in isolation, the various physical examination tests for meniscal tears do not have high sensitivities, specificities, or positive predictive values. These tests include joint line palpation, the flexion McMurray test, and Apley's grind test. These tests have been shown to have mixed results. Evans et al.[23] looked at the flexion McMurray test to determine intraobserver reliability and accuracy. They found that a medially based "thud" with rotation and flexion was the only McMurray sign to correlate with meniscal pathology. This finding had 98% specificity but only 15% sensitivity for medial meniscal tears.[23] Weinstabl et al.[24] found that joint line tenderness was the best clinical sign of a meniscal tear, with a sensitivity of 74% and a 50% positive predictive value. The presence of an ACL injury makes joint line tenderness less helpful. Shelbourne et al.[25] showed an accuracy of 54.9% for medial meniscal tears and 53.2% for lateral meniscal tears. Terry et al.[26] examined the accuracy of a thorough history, physical examination, and plain radiographs to predict meniscal pathology preoperatively. The overall clinical evaluation had a sensitivity of 95%, specificity of 72%, and positive predictive value of 85% for tears of the medial meniscus; it had a sensitivity of 88%, specificity of 92%, and positive predictive value of 58% for tears of the lateral meniscus. All tears were confirmed arthroscopically.[26]

Diagnosis of Meniscal Pathology

- History of twisting while weight bearing
- History of hyperflexion of the knee
- Joint line tenderness
- Minimal to moderate synovial swelling
- Pain or forced flexion
- Limited extension with spring block end feel
- Magnetic resonance imaging
- High level of suspicion

Diagnostic Studies

Several types of imaging studies can be used as an adjunct to the history and physical examination. Radiographs, arthrography, magnetic resonance imaging (MRI), and arthroscopy have all been used to help define meniscal pathology.

Radiography

Plain radiographic films should be obtained in the evaluation of all knee pathology. A standard knee series should include a posteroanterior/anteroposterior (PA/AP) weight-bearing view in 30° flexion (Rosenberg view), a true lateral view, and a tangential image, such as a Merchant or skyline view (Figure 21-4). These images will not confirm the diagnosis of a meniscal tear, but they are still important.

Figure 21-4 Standard radiographic views. **A,** AP weight-bearing view of the knee showing medial joint space loss. **B,** Lateral radiograph of the knee. **C,** Tangential view of the patellofemoral joint.

Plain radiographic films can be used to assess the knee for joint space narrowing, osteophyte formation, subchondral cysts, and subchondral sclerosis, all findings of osteoarthritis of the knee. Early degenerative changes are better seen on PA/AP views in 30° flexion because degenerative changes usually are more severe on the posterior femoral condyles than on the distal femur.[27,28] Non–weight-bearing radiographic films are not useful for determining joint space narrowing. The tangential view is best for assessing the patellofemoral joint, which can be a cause of medial or lateral knee pain. Plain radiographic films can also help determine whether any other bony pathology is present. If any question arises about lower limb alignment, 3-foot (1.0 m) standing films should be obtained to determine the anatomical and mechanical axis of the lower extremity.

Standard Knee Radiographic Films

- PA/AP weight-bearing view in 30° flexion (Rosenberg view)
- Lateral view
- Merchant or skyline view

Magnetic Resonance Imaging

MRI has proven to be a great advance in the diagnosis of knee pathology, but the scans must be read in the context of the patient's history and the physical examination findings. Some of the advantages of MRI are: (1) it allows the clinician to see the ligamentous and cartilaginous structures in the knee, (2) it does not require the use of ionizing radiation, and (3) it is noninvasive. Disadvantages of MRI include: (1) a relatively high cost, (2) the amount of time required to obtain the scan, and (3) the tight space in which the patient must lie unless an open magnet machine is used. Normal menisci appear as low signal intensity on all image sequences.

Clinical Note

MRI scans must be read in the context of the patient's history and the physical examination findings.

Based on its MRI appearance, the meniscus tear or injury can be categorized according to a four-grade system (Figure 21-5). Grade 0 represents a normal meniscus. Grade I and grade II show some degree of intrameniscal signal, but the signal does not abut the free edge of the meniscus. With grade III menisci, the intrameniscal signal exits through the articular surface of the meniscus. The grade III pattern is consistent with a meniscal tear.[29]

MRI is a powerful tool in the diagnosis of meniscal pathology. Several studies have shown meniscal tears on MRI scans of asymptomatic patients. Boden et al.[30] studied 74 asymptomatic patients. Sixty-three were under age 45, and eight of these (13%) were found to have meniscal tears. Eleven patients were over age 45, and four (36%) had positive findings on MRI.[30] LaPrade et al.[31] found MRI scans to be positive in 5.6% of knees in asymptomatic patients 18 to 39 years of age who had normal physical examination findings.[31]

Arthroscopy

Arthroscopy is the gold standard for the diagnosis of meniscal tears. Arthroscopic examination allows direct visualization of the tibial and femoral articular surfaces of the meniscus and the meniscocapsular junction. It also allows visualization of the lateral meniscus at the popliteal hiatus and probing to determine whether hypermobility is present.

Classification of Meniscal Tears

Meniscal tears can be classified as oblique, vertical longitudinal, radial (or transverse), horizontal cleavage, or complex (Figure 21-6). Several authors have evaluated the incidence of these tear patterns. Metcalf et al.[32]

Figure 21-5 Categorization of menisci according to MRI results. **A,** Grade 0: normal meniscus. **B,** Grade I: mild intrameniscal signal. **C,** Grade II: intrameniscal signal. **D,** Grade III: complex tear of the medial meniscus.

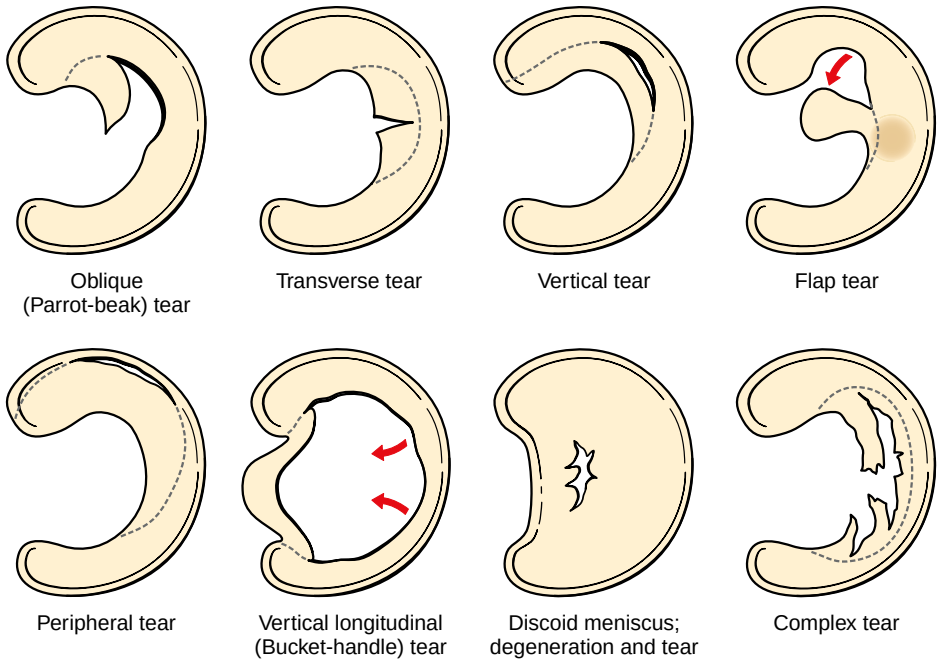

Figure 21-6 Types of meniscal tears.

Figure 21-7 Arthroscopic view of an oblique (parrot beak) tear of the meniscus. Symptoms likely result from the flap getting caught in the joint and pulling on the meniscocapsular junction. This also could lead to propagation of the tear.

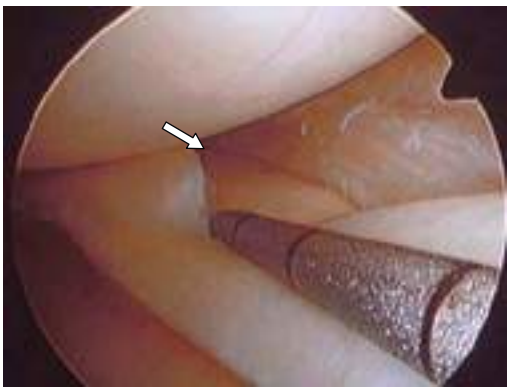

Figure 21-8 Arthroscopic view of a bucket handle tear of the meniscus.

determined that 81% of tears were oblique or vertical longitudinal. As patients get older, the incidence of complex tears increases. Most meniscal pathology is found in the posterior horns.

Oblique tears are most commonly found at the junction of the posterior and middle thirds of the meniscus. These tears are commonly called "flap" or "parrot beak" tears (Figure 21-7).

Vertical longitudinal tears, also called "bucket handle" tears, occur most often in young patients. These tears are commonly associated with ACL tears. Binfield et al.[33] showed a 9% incidence of bucket handle tears of the medial meniscus in ACL-deficient knees. Bucket handle tears occur more often in the medial meniscus, probably because of its more rigid attachments and susceptibility to shear forces. A study by Binfield et al.[33] evaluated knees that on average had suffered an ACL injury 23.3 months earlier. This interval is sufficient from the time of original injury for knee instability to generate medial meniscal tears. Vertical longitudinal tears occur most often in the posterior horn of the meniscus and can involve the entire meniscus (Figure 21-8).

Bucket handle tears are unstable and, if large enough, can dislocate into the intracondylar region, causing a mechanical block to extension (locking). Incomplete vertical longitudinal tears can occur on the femoral or tibial surface of the meniscus (Figure 21-9).

The clinical significance of incomplete bucket handle tears is questionable. Fitzgibbons and Shelbourne[34] found that incomplete vertical longitudinal tears of the lateral meniscus that had been found at the time of ACL

Figure 21-9 Arthroscopic view of an incomplete vertical longitudinal tear of the meniscus.

Figure 21-12 Arthroscopic view of a complex meniscal tear. Note the shredding of the meniscus.

reconstruction remained asymptomatic after ACL reconstruction if they were stable at the time of surgery.

Radial, or transverse, tears of the meniscus usually are located at the junction of the posterior and middle thirds of the meniscus. Complete radial tears disrupt the circumferential fibers of the meniscus (Figure 21-10). Jones et al.[35] showed that a complete radial tear completely disrupts the function of the meniscus, leading to significantly increased joint contact stresses.

Horizontal cleavage tears start near the inner margin of the meniscus and extend toward the capsule. Shear forces within the meniscus during load transmission likely cause a separation of the horizontally oriented collagen fiber bundles. The incidence of horizontal cleavage tears increases with age (Figure 21-11). Parameniscal cysts are most often associated with these tears. These cysts often form when horizontal cleavage tears reach the parameniscal region.[36]

Complex tears of the meniscus, often called **degenerative tears,** occur in multiple planes (Figure 21-12). Most patients with complex tears are more than 40 years of age. These tears most often occur at the posterior horn of the medial or lateral meniscus and are commonly associated with degenerative changes in the articular cartilage of the knee.

TREATMENT OF MENISCAL TEARS

Indications for Surgical Treatment

Not all meniscal tears require surgical intervention. Before deciding on surgery for meniscal pathology, the clinician must exclude other causes of knee pain, such as degenerative chondral changes. For surgery to be considered, symptoms of meniscal injury should limit activities of daily living, work, or sports. Some meniscal tears heal spontaneously; therefore a trial of conservative management with activity modification and rehabilitation should be attempted before surgical intervention. Henning et al.[37] showed that some tears heal spontaneously or remain asymptomatic, including short vertical tears (less than 10 mm), stable vertical longitudinal tears, partial-thickness tears (less than 50% of meniscal depth) on the tibial or femoral surfaces, and small radial tears (less than 3 mm).

In patients with evidence of knee osteoarthritis and an atraumatic degenerative meniscal tear, a prolonged trial of conservative treatment may be warranted. Nonoperative management has been shown to provide equivalent outcomes to partial meniscectomy at 6 and 12 months, after

presentation with symptoms.[38] However, greater than 30% of patients who are treated nonoperatively will ultimately elect to undergo a partial meniscectomy due to persistence of symptoms.

Evidence has also questioned the utility of arthroscopic debridement of degenerative meniscal tears in middle-aged patients with little to no concomitant osteoarthritis.[39,40] These studies have been criticized for a very narrow patient inclusion criteria, and many have cautioned against the application of their findings to all patients with degenerative meniscal tears. Until further evidence is available, surgical decision making must be individualized and rely on mechanical symptoms, degenerative versus traumatic onset of symptoms, other possible pain generators (arthritis, plica, synovitis), and effect of previous nonoperative treatments.

Indications for Meniscal Surgery

- Symptoms limit activities of daily living, work, or sports
- Conservative treatment has not improved symptoms

If the meniscal injury is associated with an ACL injury, the timing of surgery usually is dictated by the acute rehabilitation after the ACL injury. Factors such as swelling and ROM dictate the timing of ACL reconstruction. Meniscal pathology usually can be addressed at the time of ACL reconstruction. If a displaced bucket handle meniscal tear is limiting recovery of extension after an ACL injury, the meniscal tear should be dealt with on an urgent basis to allow the patient to regain full extension before proceeding with ACL reconstruction.

Surgical Intervention

Surgeons should develop a standard approach to knee arthroscopy. A diagnostic arthroscopy of the entire knee should be performed as the initial portion of all knee arthroscopies. This diagnostic arthroscopy can be performed in a number of ways, but each surgeon should choose one routine and stick to it to avoid missing pathology. The final decision as to whether the meniscal tear should be repaired or excised should be made after the diagnostic arthroscopy. Most meniscal tears are not amenable to repair. These tears usually require partial meniscectomy to relieve the patient's pain and mechanical symptoms. When a partial meniscectomy is performed, as much of the functioning meniscus as possible is left to maximize the function of the remaining meniscus and minimize the effect on joint biomechanics.

Indications for meniscal repair can be divided into patient factors and meniscal factors. Patient factors include the chronicity of symptoms, patient's ability to tolerate the longer rehabilitation required after repair, and risk of failure of the repair. The patient's age also should be factored into the equation because younger patients are likely to have a greater chance of progression to arthritis after meniscectomy. Meniscal factors that are favorable for repair include a complete vertical tear longer than 10 mm, a tear within the peripheral 10% to 30% or within 3 to 4 mm of the meniscocapsular junction (red-red zone), an unstable tear that can be displaced by probing, a tear without secondary degeneration or deformity, and tears in stable knees or associated with concomitant ligamentous reconstruction.[30] If both patient and meniscal factors indicate that the tear is amenable to surgical repair, then repair should be performed.

As previously mentioned, some meniscal tears heal spontaneously or remain asymptomatic. If one of these tears is seen at the time of diagnostic arthroscopy and the knee is stable or is undergoing ACL reconstruction, the meniscus can be left alone, or **trephination (i.e., surgical excision of a circular piece of tissue)** and rasping can be performed without surgical stabilization.[37] Weiss et al.[41] reviewed 52 patients with stable vertical longitudinal meniscal tears (i.e., tears with less than 3 mm of displacement with probing) and performed repeat arthroscopy. Complete healing was noted in 65% of these patients. Only six patients required further treatment, and four of those had suffered a new traumatic event.[41]

Meniscal Resection

Total meniscectomy used to be a very common procedure. Fairbank[42] first described the damaging effects of total meniscectomy in 1948. As long-term results became available, the progression to osteoarthritis was noted; consequently, total meniscectomy has become a very uncommon procedure.[43,44] With arthroscopic techniques, partial meniscectomy has become feasible (Figure 21-13).

When meniscal repair is not indicated, surgeons now perform a partial meniscectomy. Metcalf et al.[32] established guidelines for meniscal resection. All mobile fragments of the meniscus that can be pulled past the inner margin of the meniscus into the center of the joint should

Figure 21-13 Arthroscopic view of a partial meniscectomy.

be resected. The remaining meniscal rim should be smoothed to remove any sudden changes in contour that may lead to further tearing. A perfectly smooth rim is not necessary. A probe should be used to gain information about the stability or mobility of the remaining meniscus. The meniscocapsular junction and the meniscal rim should be retained, if at all possible, to preserve the load transmission properties of the meniscus. Motorized and manual instruments should be used. Manual instruments are more accurate, and motorized shavers can remove loose debris and smooth frayed edges.

Partial Meniscectomy

Studies on the short-term outcome of partial meniscectomy have shown 80% to 90% good results at less than 2-year follow-up.[45] A number of long-term follow-up studies have shown progression of arthritis radiographically after partial meniscectomy. Fauno and Nielsen[46] found that with 8 years of follow-up, radiographic changes occurred in 53% of knees that had undergone partial meniscectomy, compared with 27% of untreated, contralateral knees. Schimmer et al.[47] found good or excellent results in 91.7% of partial meniscectomies at 4 years, but this dropped to 78.1% at 12 years. Articular cartilage damage associated with the meniscal tear had the greatest impact on the long-term outcome. Sixty-two percent of patients who had articular cartilage damage at the time of the index operation had a good or excellent result at final follow-up. In patients with no articular cartilage damage, 94.8% had good or excellent results.[47] In a review of the literature, Fabricant and Jokl[48] found age and sex had no association with clinical or radiographic outcomes up to 15 years postoperatively. Patients with flap tears had slower return to sports and more revision surgery than those with bucket handle tears. They found no difference in outcomes between medial and lateral meniscectomies. Patients with less than 50% of their meniscal rim remaining after partial meniscectomy had worse radiographic outcomes at 12 years than those with greater than 50% remaining.[48]

Postoperative Rehabilitation. Rehabilitation after partial meniscectomy usually is uneventful. Postoperatively, rehabilitation focuses on pain control, joint mobilization and ROM, gait training, minimization of effusion, regaining full strength, and a progressive return to preinjury or preoperative activity. These goals can be achieved either in a formal rehabilitation setting or with home treatment. Icing and elevation can help minimize pain and effusion in the knee. ROM exercises can be started immediately after surgery. Patients may bear weight as tolerated. Quadriceps strengthening exercises can begin immediately after surgery. Patients should avoid twisting and repetitive impact activities for 4 to 6 weeks after surgery. Short-term recovery following surgery has been found to be slower in women and those with worse arthritis found at the time of surgery. Body mass index (BMI), age, and degree of meniscal resection were not found to have an effect.[49]

Meniscal Cysts

As mentioned, meniscal cysts occur most often with horizontal cleavage tears. A retrospective review of 167 knee MRIs with findings of either intrameniscal (38%) or parameniscal (62%) cysts showed 59% of cysts were located in the medial meniscus and 41% in the lateral meniscus. Fifty-eight percent of these cysts were associated with a meniscal tear found on MRI.[50] These cysts usually can be decompressed at the time of partial meniscectomy from within the joint. Metcalf et al.[32] showed that meniscal cysts rarely recur if the meniscal pathology is dealt with appropriately. The results of arthroscopic decompression of cysts range from 90% to 100% without recurrence. If the cyst is not easily identified from within the joint, a needle can be passed percutaneously through the cyst into the joint and the location of the cyst identified arthroscopically. The cyst then can usually be decompressed by probing or shaving from within the joint.[51,52] If the cyst cannot be decompressed arthroscopically, an open cyst excision should be performed.

Meniscal Repair

Some meniscal tears can heal without fixation. As previously mentioned, meniscal tears that can be left to heal without fixation include vertical longitudinal tears less than 10 mm long, incomplete tears, and stable tears that move less than 3 mm with probing.[34] In such cases, the surgeon can attempt to enhance the healing response with abrasion of the synovial surfaces and meniscal trephination.[53] Synovial abrasion causes a vascular pannus that migrates into the tear and helps to produce a healing response. Meniscal trephination is a variation of creating vascular access channels. Horizontally oriented holes are made using a spinal needle through the peripheral vascularized region of the meniscus. Fox et al.[54] showed a 90% success rate in healing incomplete tears with trephination.

When a meniscal tear is found to be amenable to repair and the patient understands the risks of meniscal repair and the rehabilitation required (described later in this chapter), a series of steps must be taken to maximize the chances of success of the repair. First, the meniscal bed must be prepared. Loose edges of the tear should be debrided. The torn meniscal edges should be abraded with a rasp or shaver. Rasping of the synovial fringe is also helpful in creating a synovial pannus that can creep into the tear and aid the healing response. Tears that extend into the avascular zone have a lower healing rate. Some think that this can be improved somewhat with trephination.

Open Repair Techniques. Open meniscal repair was first reported by Annandale[55] in 1885. Meniscal repair did not become widely used until it was popularized by DeHaven[56] and Wirth.[57] Open meniscal repair currently is most useful with multiple-ligament injuries, in which the collateral ligament injuries may require open repair, or tibial plateau fractures that require open reduction and internal fixation. With open repair, the meniscus can be

sutured directly. The success rate for open meniscal repair is high in multiple-ligament injuries likely because of the peripheral nature of the tears and the acuteness of the injury and the ensuing hemarthrosis. Rockborn and Gillquist[58] reported a 71% success rate in a 13-year follow-up of patients with open meniscal repairs. Brucker et al. reported on average 20.6-year follow-up of open meniscal repair in 26 patients. Eight patients (30%) were noted to have rerupture of the meniscus. Of the 18 remaining, 72% reported excellent results and on average there was no significant increase in arthritis development or progression compared with the contralateral knee.[59] Some surgeons still advocate open meniscal repair, suggesting that meniscal preparation and suturing are more readily achieved with an open approach and that the incisions do not need to be much larger than with inside-out arthroscopic repairs.

Arthroscopic Repair. Arthroscopy allows evaluation and treatment of meniscal tears that are not possible with open techniques. Three basic suturing techniques have been used with arthroscopic procedures: the inside-out technique, outside-in technique, and all-inside technique. Arthroscopic repairs also can be performed using bioabsorbable implants and suture anchors.

Inside-Out Technique. The inside-out technique was first popularized by Henning et al.[37] in the early 1980s. This technique uses double-armed sutures with long needles, which are positioned through arthroscopically directed cannulas. Skin incisions are then made between the two needles. Soft tissues are dissected down to the capsule, with care taken that no neurovascular structures are trapped between the sutures, and the sutures are then tied, reducing the meniscus. A significant advantage of this technique is that it allows accurate suture placement in the meniscus. The main disadvantage of this technique is the risk to neurovascular structures and the need for incisions between the sutures.

When this technique is performed on the medial side of the knee, branches of the saphenous nerve are most commonly injured.[60] Injuries to the saphenous nerve can cause localized numbness or a painful neuroma. The standard medial incision is a vertical incision approximately 3 cm (1.2 inches) long that starts just above the joint line and runs distally. The incision is made with the knee in 90° flexion. The infrapatellar branch of the saphenous nerve runs approximately 1 cm (0.5 inch) proximal to the joint line. The saphenous nerve usually lies below the subcutaneous fat on the deep fascia covering the sartorius muscle. Keeping the knee in 90° flexion allows the sartorius and saphenous nerve to fall posteriorly. Once the subcutaneous tissue has been bluntly dissected down to the sartorius fascia, the fascia is opened in the direction of its fibers and a plane is dissected down to the knee joint capsule. A retractor can then be placed in this plane, protecting the saphenous nerve. The needles can be visualized as they pass through the capsule.

On the lateral side of the knee, the peroneal nerve is most at risk. The popliteal artery and tibial nerve are at risk as the sutures move more posteriorly. The lateral capsule should be exposed before needles are inserted from within the knee joint. An incision is made on the lateral side of the knee just posterior to the fibular collateral ligament. Dissection is again performed with the knee in 90° flexion. The peroneal nerve is protected by finding the interval between the biceps femoris and iliotibial band and retracting the biceps and peroneal nerve posteriorly. The lateral gastrocnemius muscle is found and its fascia is divided in the direction of its fibers. Fibers of the lateral head of the gastrocnemius are dissected off of the posterior capsule. A retractor then can be placed posteriorly in the knee to protect the neurovascular structures. Once this dissection has been performed, needles can be safely passed from inside the knee and retrieved as they exit the capsule, without risk of neurovascular injury.

After the appropriate exposure and neurovascular protection have been obtained, attention can be returned to the meniscal pathology. The meniscal bed is prepared (Figure 21-14), and sutures then can be passed through the meniscus, exiting the knee joint capsule. The sutures should be passed in a vertical mattress pattern for maximum strength; ideally, they should be placed at 2- to 3-mm intervals (Figure 21-15).[61]

Figure 21-14 Arthroscopic view of a bleeding edge in the red zone of the meniscus.

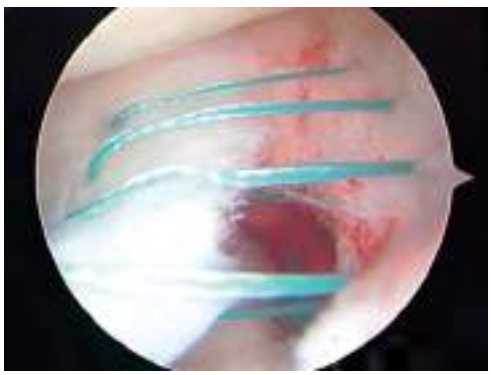

Figure 21-15 Arthroscopic view of vertical mattress sutures in place, ready to be tightened and tied.

Outside-In Technique. The outside-in technique was developed as an attempt to avoid the neurovascular complications that can occur with the inside-out technique. The outside-in technique uses a spinal needle passed percutaneously through the subcutaneous tissue, through the meniscal tear, into the knee joint. A suture then is passed into the joint through the needle and brought out through the anterior portal. A knot is tied in the free end of the suture, and the suture is pulled back into the joint, reducing the meniscal tear. Adjacent sutures are tied to each other outside the capsule.[62] A small incision is made between the two sutures, the soft tissues are cleared between the sutures down to the capsule (with care taken that no neurovascular structures are caught between the sutures), and the sutures are then tied as in the inside-out technique.

Modifications of the original outside-in technique have emerged. In one such modification, a needle is placed percutaneously as previously described to pass the first suture into the knee, followed by a parallel needle with a wire suture retrieval loop. The first suture is passed through the loop and pulled out of the knee joint through the second needle, leaving one intact suture that can be tied outside the capsule. This essentially leaves the patient with the same final configuration of sutures as an inside-out technique.

The outside-in technique is most useful for tears in the anterior or middle third of the meniscus. To perform this technique for posterior tears, the surgeon must use an open approach to allow safe passage of the needles into the knee joint.

All-Inside Technique. The all-inside suture repair is useful for tears of the posterior portion of the medial or lateral meniscus. The all-inside technique is advantageous in that it does not require any accessory incisions and therefore has a decreased risk to neurovascular structures, making it faster and easier than traditional repair techniques. The newest generation all-inside devices are passed through an anterior arthroscopic portal. The insertion device is passed through the meniscus tear in the desired location and an anchor is deployed extraarticularly behind the peripheral meniscus on the capsular surface. The insertion device is withdrawn into the joint and the process is repeated to place the second anchor in its desired location. A nonabsorbable suture attached to both anchors forms a suture bridge over the meniscal tear. The suture has a pretied, sliding, self-locking knot which is tensioned to close the gap in the meniscus and compress the meniscal repair site. Both horizontal and vertical suture orientation is possible.

Meniscal Repair Devices. A number of devices have been developed to allow meniscal repair without the risk of neurovascular injury or the need for secondary incisions (Figure 21-16). These devices have progressed through several "generations" with increasing strength of repair while decreasing complications from their use.

First-generation devices, described by Morgan[63] in 1991, used curved suture hooks through accessory posterior portals to pass sutures across the tear. Sutures were then retrieved and tied arthroscopically. The technique was technically demanding, and it continued to place the neurovascular structures at risk.

Figure 21-16 Examples of meniscal repair implant devices that vary in design and permit an all-inside meniscal repair without the need for accessory portals or incisions. (From Miller MD, Cole BJ: *Textbook of arthroscopy,* Philadelphia, 2004, Saunders/Elsevier.)

The second generation of all-inside meniscal repairs introduced the concept of devices placed across the tear and anchored peripherally. These generally consisted of a polyethylene bar with an attached suture, deployed through a sharp needle or cannula to capture the peripheral meniscus or capsule. Adjacent sutures were then secured with arthroscopic knots pushed onto the meniscal surface. The complications associated with these devices came from the arthroscopic knots leading to chondral abrasion and the inability to tension the knots after placement.

The third generation consisted of a similar design as the second generation but with bioabsorbable fixation devices, including arrows, screws, darts, and staples. Initial repair results were quite good with some studies showing a 91% healing rate.[64,65] These results were noted to significantly deteriorate with longer term follow-up. Kurzweil et al.[66] reported an overall failure rate of 28% with the meniscus arrow, at average follow-up of 54 months. Numerous device-specific complications have also been reported, including transient synovitis, inflammatory reaction, cyst formation, device failure, device migration, and chondral damage.

The fourth generation as described earlier in the technique section was developed to address concerns with the previous generations of fixation devices. These devices are flexible, and suture based, have a lower profile, and allow for variable compression and retensioning across the meniscal tear.

Studies comparing early generations of all-inside repair devices to inside-out repair techniques showed the all-inside techniques to have higher failure rates. With the newer-generation implants, biomechanical studies have demonstrated strength and load-to-failure characteristics comparable to mattress suture constructs and significantly better than earlier-generation devices.[67] Rosso et al.[68]

compared repair strengths between all-inside devices and inside-out suture repair and found no difference in biomechanical properties and failure rates between techniques after 100,000 loading cycles.

Results of Meniscal Repair. Meniscal repairs have been evaluated using second-look arthroscopy, double-contrast arthrography, MRI, and clinical examination with the absence of symptoms referable to meniscal pathology. To evaluate the success rates for meniscal repair found in the literature, readers must take into account the definition of successful repair. Success rates are higher for patients who undergo ACL reconstruction at the time of meniscal repair than for patients who have isolated meniscal repairs. Cannon and Vittori[69] looked at stable knees and knees that underwent ACL reconstruction at the time of meniscal repair. Of the stable knees, 50% healed, whereas 90% of the knees that underwent concomitant ACL reconstruction healed. The location of the tear within the meniscus must also be considered. Buseck and Noyes[70] reviewed 66 repairs associated with ACL reconstruction. All patients underwent second-look arthroscopy. Eighty percent were completely healed, 14% were partially healed, and 6% failed. Ninety-eight percent of tears in the outer one third healed. Finally, the length of follow-up must be evaluated. Many studies have been published on the short-term results of meniscal repair, but success rates decline if patients are followed for longer than 2 years.[71]

Numerous studies have presented outcomes on specific all-inside implant systems with success rates ranging from 63% to 96% excellent-to-good clinical results.[72–77] Many of these studies are limited by short-term follow-up periods as discussed previously. Short-term outcomes with new fixation devices have been particularly promising; however, long-term outcomes are still needed to proclaim their equivalence or superiority to older treatment strategies. Grant et al.[78] performed a systematic review comparing all-inside (with devices from all generations) to inside-out techniques in patients with isolated meniscal tears. They found the failure rate for inside-out technique was 17% and all-inside was 19%. Functional outcomes were also reviewed and found to be no different between the two groups. Given the diverse and evolving evidence on meniscal repair technique, the surgeon should ultimately be guided by the clinical scenario surrounding the tear: concomitant injuries, tear chronicity, tear location, tear pattern, and surgeon comfort with available fixation techniques.

Indicators of Successful Meniscal Repairs

- Repairs are performed at the same time as ACL reconstruction
- Lateral meniscal repairs are more successful than medial meniscal repairs
- Tear is in the peripheral one third of the meniscus
- A functioning meniscus is present

Postoperative Rehabilitation. Rehabilitation after meniscal repair depends on whether ACL reconstruction was performed at the same time. Although many protocols exist, the principles of rehabilitation include an initial period of non-weight bearing and limitation of flexion. Standard meniscal repair guidelines are presented in Table 21-1.

TABLE **21-1**

Rehabilitation Protocol after Meniscal Repair

	Weeks 1-2	Weeks 3-4	Weeks 5-6	Weeks 7-8	Weeks 9-16	Weeks 17-20	Weeks 21-24
Brace	Immobilized	Immobilized	No brace	No brace	No brace	No brace	No brace
WB	NWB	PWB	WB as tolerated	WB as tolerated	WB as tolerated	WB as tolerated	WB as tolerated
ROM	0°-90°	0°-90°	0°-120°	Full ROM	Full ROM	Full ROM	Full ROM
Exercises	Isometric Quad Exercises • Quad sets • SLR	Isometric Quad Exercises • Quad sets • SLR	Begin closed-chain exercises	Closed-chain exercises Hamstrings Stationary bike	Closed-chain exercises Hamstrings Stationary bike Stair climber	Running, straight	Cutting
Manual therapy	Patellar mobilization	Patellar and joint mobilization Passive ROM to 90°	Patellar and joint mobilization Passive ROM to 120°	Patellar and joint mobilization			

NWB, Non–weight-bearing; *PWB*, partial weight bearing; *ROM*, range of motion; *WB*, weight bearing; *Quad*, quadriceps; *SLR*, straight leg raise.

If ACL reconstruction is performed concomitantly with the meniscal repair, more aggressive ROM exercises should be performed. Flexion should be limited to 90° for the first 4 to 6 weeks. Arnoczky et al.[79] showed that the meniscus is subject only to small amounts of motion and stress between 15° and 60° flexion. After 6 weeks, more aggressive closed kinetic chain activities can be started. Return to pivoting sports should not be allowed before 6 months.

Complications of Meniscal Repair. The most common complication of meniscal repair is failure of healing and the need for subsequent partial meniscectomy. Other complications specifically associated with meniscal repair include injury to the saphenous nerve or vein, peroneal or tibial nerve, and popliteal artery or vein. Loss of motion after repair also can be associated with meniscal repairs.[62,80,81] Deep vein thrombosis, pain, infection, and hemarthrosis can occur but are not seen at a higher rate than with partial meniscectomy. Shelbourne and Johnson[82] reported a 25% incidence of stiffness when ACL reconstruction was performed at the same time as repair of a locked bucket handle meniscal tear. Meniscal repair performed at the same time as ACL reconstruction does appear to be a risk factor for postoperative stiffness; however, meniscal healing rates are higher when meniscal repair and ACL reconstruction are performed at the same time.

Complications of Meniscal Surgery

- Nerve injury (saphenous, peroneal, tibial)
- Vascular injury (saphenous, popliteal)
- Loss of range of motion (stiffness)
- Deep vein thrombosis
- Pain
- Infection
- Hemarthrosis

Meniscal Transplantation

Transplantation of the meniscus was first described by Milachowski et al.[83] in 1989. The experience with human meniscal transplantation was preceded by clinical studies in animals and cadavers. Cadaveric models have shown decreased contact pressures and increased contact surface areas after meniscal transplantation. Both the anterior and posterior horns of the meniscus must be securely attached in their anatomical positions to gain these biomechanical advantages. When both anterior and posterior attachments are released, the decrease in contact stresses is completely lost. If one attachment site is lost, some biomechanical benefit is obtained, but it is significantly reduced.[84]

Arnoczky et al.[85] transplanted cryopreserved medial meniscal allografts in 14 dogs. These menisci healed to the capsule by fibrovascular scar. At 3 months they maintained a normal gross appearance. Histological studies showed that the transplanted menisci maintained a normal cellular distribution. Jackson et al.[86] used a goat model to compare autograft to fresh allograft and cryopreserved allograft. At 6 months the implanted menisci appeared very similar histologically to the controls. A slight decrease was seen in the cellularity in the central portions of the menisci. Peripheral vascularity was almost normal. The water content of the meniscus was increased and the proteoglycan content was decreased compared with controls. In another study, Fabriciani et al.[87] demonstrated little difference between cryopreserved and deep-frozen meniscal transplants. Their study showed nearly complete remodeling at 6 and 12 months. Debeer et al.[88] showed that 95% of the deoxyribonucleic acid (DNA) in a human transplanted meniscus was identical to that of the recipient at 1 year, which indicated that the host had repopulated the meniscal cells.

Indications for Meniscal Transplantation. The ideal patient for meniscal transplantation is one who previously has undergone complete or near-complete meniscectomy and has joint line pain, early chondral damage, a stable knee, and normal lower limb alignment. Meniscal transplantation can be considered at the same time as ACL reconstruction in an ACL-deficient knee. If axial malalignment is present, tibial or femoral osteotomy should be considered to correct it. Meniscal transplantation is contraindicated in patients with advanced chondral changes.[89] At this point, no evidence supports meniscal transplantation in asymptomatic patients who have undergone complete or near-complete meniscectomy. As longer-term results become available, the indications may expand to cover asymptomatic young patients with complete meniscectomies.

Indications for Meniscal Transplantation

- Previous complete or near-complete meniscectomy
- Joint line pain
- Early chondral damage
- Stable knee
- Normal lower limb alignment

Graft Sizing. Graft sizing is extremely important. To obtain the beneficial biomechanical effects of meniscal transplantation, the transplanted meniscus should vary less than 5% from the original meniscus. Various studies have used computed tomography (CT) scans, MRI, and plain radiography for meniscal allograft sizing. A study by Shaffer et al.[89] showed that MRI was accurate to within 5 mm of width and length measurements in 84% of cases, compared with 79% of cases measured with plain radiographs. Most tissue banks use plain radiographs for allograft sizing.[90]

Surgical Technique. The insertion of meniscal allografts has been described using an open technique with collateral ligament detachment, an open technique without collateral ligament detachment, an arthroscopically assisted technique, and an all-arthroscopic technique. The results of meniscal transplantation seem to depend on patient selection, graft sizing, and secure graft fixation more than surgical technique. As described previously, to increase the contact surface area and reduce contact stresses, the surgeon must securely fix the anterior and posterior horns. Soft tissue fixation, fixation with bone plugs, and fixation with a bony bridge inserted into a trough in the tibial plateau have been described as techniques for secure anterior and posterior horn fixation (Figure 21-17).

Results. The results of meniscal transplantation vary significantly with patient selection. Hommen et al.[91] showed that patients with lower preoperative Lysholm scores also had inferior postoperative results. Stollsteimer et al.[92] reported better results with weight <225 lb and Outerbridge grade of <2 in all compartments. Noyes[93] reported on a series of 96 meniscal allografts. MRI and arthroscopic evaluations were used in this study to determine graft success rates. Twenty-two percent healed, 34% partially healed, and 44% failed. When these results were broken down, normal knees had a 70% healing rate, with the other 30% partially healed, whereas knees with severe arthrosis had a 50% failure rate and 50% partial healing. Cameron and Saha[94] reported on 67 meniscal allografts with 87% good or excellent results using a modified Lysholm rating score. These authors performed 34 tibial osteotomies and suggested in their conclusions that limb alignment was important to their success rates. Other studies have shown that meniscal transplantation performed with appropriately sized grafts with secure fixation in patients with normal alignment and only early chondral changes can predictably reduce pain and increase knee function.[90] A systematic review by Hergan et al.[28] found 68% to 89% of patients rated their postoperative activity level as normal to nearly normal. As with meniscal repair, a longer-term follow-up of clinical outcomes seems to show deterioration of clinical results over time.[95] Overall failure of the meniscal transplant varies in studies between 0% and 37.5%[96] with early failure (<2 years) of approximately 10%. However, these results are somewhat ambiguous because the definition of failure was not universally defined among studies.

The theoretical chondroprotective effect of meniscal transplant has yet to be definitively shown in the literature. Studies evaluating this have produced different outcomes. Homen et al.[25] found compartment degeneration in 10 of 15 patients, whereas Roumazeille et al.[97] reported no average change in 22 patients. The variation in findings may be partially due to lack of standardized evaluation methods, with multiple different grading scores used to evaluate joint changes across multiple studies.

Postoperative Rehabilitation. Rehabilitation protocols vary among surgeons who perform meniscal allograft transplantation but these protocols are generally similar to those for meniscal repair. Patients are kept non-weight or partial weight bearing for the first 4 to 6 weeks. ROM is allowed but is limited to 90° flexion for the first 4 to 6 weeks. Muscle strengthening is progressed gradually with closed-chain quadriceps and hamstring exercises. Pivoting activities are restricted for the first 6 months. Return to sports participation should be guarded given a high meniscal tear rate. In particular, restriction of high-impact activities with cutting and pivoting is warranted.

Summary

The treatment of meniscal pathology is a continually changing field. The art and science of meniscal repairs have advanced tremendously. The future holds potential for meniscal allograft transplantation and for the development of meniscal replacements.

ARTICULAR CARTILAGE LESIONS

The treatment of full-thickness articular cartilage lesions in the knee is a field that is quickly evolving. Untreated articular cartilage lesions have little or no potential to heal. However, some studies show that a large number of patients will have isolated chondral defects and remain asymptomatic without treatment. Messner and Maletius[98] reviewed a series of 28 patients with isolated chondral lesions; 22 had either good or excellent clinical results without treatment 14 years after diagnosis. Most of these 22 patients had abnormal radiographic findings suggesting progressive degenerative changes. Although these data suggest that isolated chondral defects may predispose patients to the development of further degenerative changes in the knee, long-term prospective data

have not been obtained that link isolated chondral defects to progressive degenerative arthritis of the knee that compromises a patient's level of function.

History

The clinical presentation of a full-thickness chondral defect can vary. Some patients complain of loose body–type symptoms with locking, catching, and clicking. Other patients complain of crepitus with intermittent mechanical symptoms, and a third group presents with pain as the only symptom. The clinician should obtain a careful history to determine whether the symptoms are indeed coming from within the knee joint and, if so, whether they are coming from the medial, lateral, or patellofemoral compartment.

Physical Examination

A thorough physical examination should be performed for all patients suspected of having chondral defects of the knee. The clinician should begin the examination by watching the patient stand and walk, noting limb length and alignment and observing any gait abnormalities, such as valgus or varus thrust during the stance phase of gait. A low back examination and a complete distal neurological and vascular examination should also be performed. Examination of the hip is critical in any patient presenting with knee symptoms. A systematic examination of both knees should be performed. Thigh circumference and ROM should be compared between the two sides. Pain experienced by the patient during ROM should be noted. The knee should be examined for an effusion.

Knee stability should be examined, including testing of the anterior and posterior cruciate ligaments, the tibial (medial) collateral ligament, the fibular (lateral) collateral ligament, and the posterolateral (popliteus) corner. The knee should be palpated for any local tenderness. The extensor mechanism should be examined for continuity, and the alignment of the extensor mechanism (Q angle) should be measured. The mechanics of the patellofemoral articulation should be examined, and the clinician should observe for a **patellar "J" sign** (i.e., deviation of the patella cephalically and laterally in the pattern of an upside-down J), lateral tilt of the patella, lateral retinacular tightness, and patellofemoral crepitation.

Diagnostic Imaging

Diagnostic imaging should begin with plain radiographic films. A standing PA flexion view should be included in the standard knee series. A tangential view of the patellofemoral joint (e.g., Merchant view) should also be included. These plain radiographic films can show joint space narrowing, osteochondral defects, and patellofemoral tilt or subluxation. However, isolated chondral defects often cannot be seen on plain radiographic films.

The imaging study of choice for chondral defects is MRI because of its excellent sensitivity and specificity for this type of lesion. Bredella et al.[99] reported on 130 patients undergoing knee arthroscopy for suspected internal derangement. Of 86 arthroscopically proven abnormalities, 81 were detected with MRI. MRI performed with a T2-weighted, fast spin-echo sequence with fat saturation had a sensitivity of 94% and a specificity of 99% compared with arthroscopy (Figures 21-18 and 21-19).

Nonoperative Management

The goal of nonoperative management of chondral lesions is to minimize symptoms and allow maximum activity. Maintenance of ROM, muscle strengthening, and a variety of therapeutic modalities to reduce pain and inflammation all can minimize symptoms. Orthotics, bracing, and gait

Figure 21-18 T2-weighted MRI scan of a chondral defect (outlined by *white dotted line*) of the posterior condyle.

Figure 21-19 T1-weighted MRI scan of a trochlear chondral defect (*circled*).

training can minimize the stresses on the affected region of the joint. Weight loss in overweight patients can dramatically improve symptoms by reducing patellofemoral and tibiofemoral contact stresses.

Surgical Management

The ultimate goal of surgical treatment is restoration of the microarchitecture of the articular cartilage, which allows complete restoration of the biomechanical and physiological function of the knee. A number of techniques for cartilage repair and regeneration have been developed. The following sections present a detailed look at each of these modalities and review the basic science, surgical techniques, and rehabilitation principles and results.

Abrasion Arthroplasty

The idea of doing something to eburnated bone to cause a reparative tissue response was first proposed by Pridie[100] in 1959. He recommended joint debridement, removal of osteophytes, retention of the patella, shaving of fissured articular cartilage, and drilling of eburnated bone. He described fibrous, reparative-type tissue filling and covering 0.5 cm (0.25 inch) cortical drill holes through the femoral condyle. Most of his poor results involved patients in whom he also performed a patellectomy. Akeson et al.[101] attempted to confirm Pridie's findings in laboratory animals. They removed the articular cartilage and subchondral bone of dog femoral heads. At 1-year follow-up, they concluded that excessive loading destroyed the initial reparative tissue. These results also showed that the proteoglycan concentrations in the reparative tissue were less than half that of normal articular cartilage. Mitchell and Shepard[102] studied rabbit knee joints. They found that after multiple small holes were drilled into the subchondral bone, reparative tissue was stimulated to cover large areas of articular surfaces. The reparative tissue grew out from the drill holes and then spread over the exposed bone. This tissue began to fibrillate and break down within 1 year.[102] These two studies were the first to demonstrate that a fibrocartilaginous repair tissue could be stimulated to form on large areas of articular surface. However, these studies also showed that this reparative tissue did not have the proteoglycan concentration of articular cartilage and that it started to break down quickly with excessive loading.

Abrasion arthroplasty using motorized instrumentation was introduced by Johnson[103] in 1981. Whether the abrasion should be intracortical or cancellous bone should be exposed is the subject of debate. Hjertquist and Lemperg[104] reported that cartilage tissue of mature appearance forms only if the debridement is superficial enough to maintain a cortex.

Surgical Technique. The procedure introduced by Johnson in 1981 is essentially an extension of that described by Pridie. Along with debridement of the joint, a superficial layer of subchondral bone (1 to 3 mm deep) is removed to expose interosseous vessels. This theoretically results in a hemorrhagic exudate that forms a fibrin clot and allows fibrous repair tissue to form over the area of exposed bone. Minimizing excessive subchondral bone destruction is an important and challenging part of the procedure. With increasing debridement and destruction of the subchondral bone, the risk of thermal necrosis to the surrounding area increases.

Rehabilitation. Regeneration of articular cartilage benefits from motion and from limiting the compressive force on the articular cartilage from weight bearing. Patient adherence to a program of motion with limited or no weight bearing is critical. To assist with this, the use of continuous passive motion (CPM) often is considered. Weight bearing often is restricted for up to 12 weeks, with daily CPM, especially in the early postoperative period. Active and passive ROM are encouraged throughout the postoperative course until weight bearing and strength training can begin.

Results. Eight knees were biopsied in Johnson's original series.[103] Of those eight biopsy specimens, only one showed any type II collagen typical of hyaline cartilage. All other biopsy specimens showed a combination of type I and type III collagen. Bert and Maschka[105] reviewed a series of 59 patients who underwent abrasion arthroplasty with a minimum 5-year follow-up. Of the 59 patients, 15 had conversion to total knee arthroplasty. Biopsies were performed on any remaining fibrous tissue. The fibrous tissue was stained with safranin O to look for proteoglycan. The fibrous surface did not stain, indicating the lack of proteoglycan.

Microfracture

Microfracture is a surgical option used to treat small areas of damaged cartilage (<2 cm). A small sharp pick (awl) is used to create small holes (microfractures) in the bone to stimulate circulation and the growth of fibrocartilage. Microfracture can be performed on the patellar, tibial, or femoral articular surface. The general indication for microfracture is a full-thickness chondral defect in either a weight-bearing region or a region of contact between the femur and patella. Microfracture can also be performed after debridement of unstable chondral flaps. Contraindications to microfracture include axial malalignment, partial-thickness chondral defects, and a patient who is unable or unwilling to comply with a strict postoperative rehabilitation protocol, including minimal weight bearing. Joint space narrowing, bipolar lesions, subchondral bone loss, chronic lesions, and inability to use a CPM machine may affect the outcome but are not strict contraindications.

Surgical Technique. Microfracture can be performed arthroscopically with a combination of shavers, curettes, and picks. The technique has been described by Steadman et al.[106] Three portals are made, allowing use of an inflow canula, the arthroscope, and the working instruments.

A diagnostic arthroscopy is performed, and the full-thickness chondral defect is identified. Any other work that needs to be performed in the knee is completed before the microfracture procedure is begun. The chondral defect is then inspected, and all cartilage remnants are debrided (Figure 21-20).

The articular cartilage surrounding the defect is inspected and any loose, delaminated cartilage is removed. A perpendicular edge of healthy cartilage is obtained circumferentially around the lesion. The calcified cartilage layer is removed, while care is taken not to debride through the subchondral plate.

An arthroscopic awl with the appropriate angle then is used to create perforations in the subchondral plate that are perpendicular to the surface. The awl allows the surgeon to make holes (microfractures) in the subchondral bone with control and without any worry of heat necrosis (Figure 21-21). Attention first is given to the periphery of the lesion. Holes are made at 3- to 4-mm intervals around the periphery and are approximately 3 to 4 mm deep. Once the holes have been made around the periphery, the remaining surface of the lesion is addressed. Holes should be spaced as close together as possible without fracturing

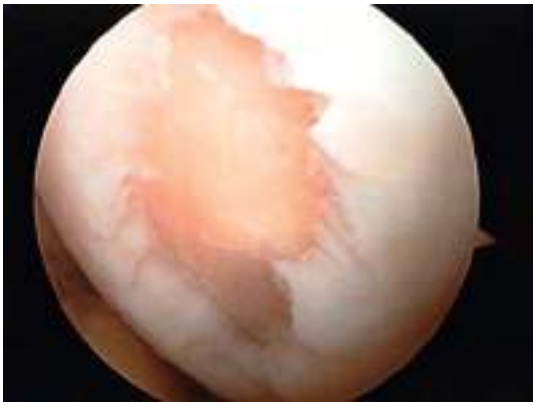

Figure 21-20 Arthroscopic view of a chondral defect debrided to subchondral bone. The calcified cartilage layer has been removed.

Figure 21-21 Arthroscopic view of a microfracture technique. Multiple pick holes are spaced 3 to 4 mm apart.

Figure 21-22 Arthroscopic view of a microfracture after reduction of pump pressure shows bleeding from all holes.

the subchondral bone between two holes (approximately 3 to 4 mm). After the holes have been made, a shaver is used to remove all bony debris. The pump pressure then is turned down to enable the surgeon to visualize fat droplets and blood exiting from all holes (Figure 21-22).

Any holes that do not show bleeding should be checked and possibly made deeper to allow bleeding. After the surgeon has made sure that all holes have been made appropriately, the knee is irrigated, instruments are removed, and the joint is evacuated of fluid. Incisions are closed, and a sterile dressing is applied. The key to this procedure is to establish a clot of pluripotent marrow cells that can then differentiate into stable cartilage under the right conditions.

Clinical Point

A strict rehabilitation program is essential after microfracture treatment of chondral lesions of the knee.

Rehabilitation. Microfracture creates an environment in which pluripotent marrow cells can be stimulated to produce cartilage. However, the rehabilitation program ultimately determines the success of the procedure. To design an appropriate rehabilitation program after microfracture, the clinician must think about the region that was affected and the kinematics of the knee. The ideal rehabilitation program encourages motion but limits weight bearing and shear stresses on the affected region. For these reasons, the rehabilitation protocol is very different for weight-bearing femoral condyle lesions than it is for patellar or trochlear lesions. All patients are put in a CPM machine postoperatively, and the patient is asked to use the CPM machine up to 10 hours/day.[107] The rate of motion usually is 1 cycle per minute. The CPM is started in a comfortable range and increased as tolerated. Patients with femoral condyle lesions are kept on toe-touch weight bearing with crutches for 6 to 8 weeks. At 8 weeks, the patient can progress to weight bearing as tolerated and can begin a more vigorous program of active motion. Strength training with weights or machines

should be avoided for 16 weeks. Return to sports that involve cutting, pivoting, and jumping can be allowed at 4 to 6 months.

Patients who have patellar or trochlear lesions are allowed to bear weight as tolerated immediately after surgery; however, the knee must be protected from loaded motion where the defect is engaged. At the time of arthroscopy, the knee joint can be taken through a ROM to see specifically where the lesion is in contact with the opposing articular surface. In general, a patient with a trochlear or patellar microfracture can be put in a hinged knee brace with the brace set to move from full extension to 20° flexion. The knee should be taken out of the brace for CPM but should be braced at all other times to avoid shear forces across the lesion. The brace can be discontinued at 8 weeks. A study by Gill et al.[108] suggested that the period of restricted weight bearing should be increased to 12 weeks. This study evaluated the healing process in cynomolgus macaques. Histological analysis was performed 6 and 12 weeks after microfracture. At 6 weeks, limited chondral repair and ongoing resorption of subchondral bone were seen. By 12 weeks, the cartilage defects were completely filled and showed more mature cartilage and bone repair. Further studies in humans are needed to determine whether this additional length of time makes a clinically significant difference in the long-term outcome.

Results. Steadman et al.[109] looked at a series of 75 knees in 72 patients who underwent microfracture for full-thickness traumatic chondral defects. Follow-up was 7 to 17 years. Their three inclusion criteria were: (1) a traumatic full-thickness chondral defect, (2) no meniscal or ligamentous injury, and (3) patient age less than 45 years. Significant improvements were found according to the Lysholm and Tegner knee rating scales. At 7 years after surgery, 80% of patients stated that they were better than before surgery. Some patients took up to 2 years to obtain maximum improvement. Mithoefer et al.[110] performed an evidenced-based systematic analysis of the efficacy of the microfracture technique for articular cartilage repair in the knee. Twenty-eight studies and 3122 patients were included. The study found that microfracture effectively improved knee function during the first 24 months after surgery, but results were conflicting with longer-term follow-up, and there was insufficient evidence to suggest improved function beyond that point. Other factors they found to positively affect outcome were age less than 40 years, duration of symptoms less than 12 months, lesion less than 4 cm^2, BMI less than 30 kg/m^2, and higher preoperative activity level.

Mosaicplasty

Autologous osteochondral grafting has shown great promise in that it is a means to transplant bone and hyaline cartilage to a region of a chondral or osteochondral defect. Lane et al.[111] showed that the hyaline cartilage remains viable 12 weeks after transfer. However, two problems were encountered with single plug osteochondral transfers: donor-site morbidity and surface incongruity at the recipient site. Mosaicplasty was developed in an attempt to minimize these problems. Mosaicplasty involves the transfer of multiple small osteochondral plugs to a region of chondral or osteochondral defects. The use of multiple small grafts allows for maintenance of donor-site integrity and contouring of the new surface.

Surgical Technique. Autologous osteochondral mosaicplasty involves harvesting and transferring small, cylindrical osteochondral grafts (2.7 to 8.5 mm in diameter) from non–weight-bearing areas of the femur and transplanting them to prepared recipient sites in the region of the chondral or osteochondral defect.

Combination of different graft sizes allows for coverage of approximately 80% of the lesion. The areas between the osteochondral cylinders will fill with fibrocartilage. At the time of the procedure, a diagnostic arthroscopy is performed. The chondral or osteochondral defect is identified and inspected. All loose cartilage fragments are debrided back to stable, normal articular cartilage. The defect then is sized to determine the number and sizes of grafts needed. If the defect can be accessed adequately arthroscopically, the procedure can be performed arthroscopically. A miniarthrotomy may be required. The grafts can be obtained from either the medial or lateral peripheral margins of the femoral condyles at the level of the patellofemoral joint (Figure 21-23), distal medial trochlea, or intercondylar notch.[112] The appropriate-sized tube chisel is introduced perpendicular to the donor site, and the harvester is driven into the donor site. For chondral defects, a 15-mm graft is taken. For osteochondral defects, a 25-mm graft is obtained. The chisel is twisted to break the cancellous bone, and the graft is removed. All grafts are harvested with a similar technique (Figure 21-24).

Attention is then turned to the recipient site. Recipient tunnels are created with drill bits and then an appropriately sized dilator. The grafts are inserted with an adjustable plunger device. It is extremely important to ensure that a smooth surface is created, without prominent or sunken grafts (Figure 21-25).

Figure 21-23 View of a graft donor site on the periphery of the lateral femoral condyle.

Figure 21-24 Single osteochondral plug.

Figure 21-25 Defect filled with multiple osteochondral plugs. (From Insall JN, Scott WN: *Surgery of the knee*, ed 3, p 358, New York, 2001, Churchill Livingstone.)

After all grafts have been put in place, the knee is irrigated and all wounds are closed. Some surgeons place a drain in the knee to try to prevent large postoperative hematomas.

Rehabilitation. Rehabilitation after osteochondral autograft transplantation focuses on early return of ROM and protected weight bearing. ROM exercises can be initiated immediately after surgery. Patients are kept to toe-touch weight bearing for 6 weeks to allow healing of the bony portion of the graft. Patients are allowed to progress to weight bearing as tolerated after 6 weeks and can return to sports activity as soon as they have regained adequate ROM and strength.

Results. The results of multiple osteochondral autograft transplantation have been promising. Chow et al.[113] reported on 33 patients with 2- to 5-year follow-up. Eighty-seven percent of patients reported their knee as being normal or nearly normal using the International Knee Documentation Committee (IKDC) assessment. Jakob et al.[114] reported on 52 patients with 2- to 5-year follow-up. Ninety-two percent of patients had improvement in knee function at the final follow-up. Hangody et al.[115] reviewed 831 patients undergoing mosaicplasty. Good-to-excellent results were obtained in 92% of patients with femoral condylar defects, 87% of patients with tibial defects, and 79% of patients with patellar or trochlear defects. Three percent of patients reported donor-site morbidity, and 4% reported painful postoperative hemarthroses. Erdil et al.[116] presented mid-term follow-up of 65 knees after mosaicplasty with an average follow-up of 82 months. They reported improved outcomes using the Tenger activity scale, Lysholm scale, and the IKDC subjective knee evaluation form. They found no correlation between functional results and age, defect location, or additional knee pathology. They reported that only four patients required repeat arthroscopy for continued subjective complaints. In these patients, the resurfaced area showed intact cartilage. In contrast to the findings of these studies, Bentley et al.[117] reported that only 69% of patients had good or excellent clinical results as assessed by the modified Cincinnati and Stanmore scores. Painful postoperative hemarthroses continue to be a significant complication after mosaicplasty. Feczko et al.[118] used a German Shepherd model and tested donor-site plugs. They found that compressed collagen minimized blood loss from the donor sites while still allowing gradual substitution with bone and formation of a fibrocartilage cap at the articular surface.

Gudas et al.[119] conducted a prospective randomized trial comparing mosaicplasty (28 patients) to microfracture (29 patients) in athletes (mean age 24.3 years). They found both groups to have significant clinical improvement; however, mosaicplasty had 96% good-to-excellent results compared with 52% in microfracture at an average of 37 months follow-up. They concluded that in young athletic patients, mosaicplasty was superior to microfracture.

Autologous Chondrocyte Transplantation

Chesterman and Smith[120] first successfully isolated and grew chondrocytes in culture in 1965. They took epiphyseal chondrocytes from rabbits, grew them in culture, and then implanted them into articular defects in the tibia. They did not show any significant repair. In 1982, Grande et al.[121] began growing articular chondrocytes in culture and then transplanting them into a patellar defect covered with a periosteal flap. These initial results were presented in 1984 and showed 80% filling of the defect with hyaline-like cartilage. In 1987, the first autologous chondrocyte transplantation was performed in the human knee in Sweden. Brittberg et al.[122] reported on the results of the first 23 procedures. Fourteen of 16 patients with femoral lesions had good or excellent results, whereas only two of seven patients with patellar lesions had good or excellent results.

Surgical Technique. Autologous chondrocyte transplantation requires two operative procedures. The first procedure is a diagnostic arthroscopy and harvesting of chondrocytes. The cultured chondrocytes are implanted during the second procedure. A diagnostic arthroscopy

is performed, and the chondral defect is assessed. The defect is not debrided. Any meniscal lesions should be dealt with during the first procedure. Once it has been decided that the patient could benefit from autologous chondrocyte transplantation, cartilage is harvested, typically from the upper medial or upper lateral condyle of the femur. Cartilage most often is taken from the upper medial condyle of the femur at the level of the patellofemoral joint. Three to four slices of cartilage, 3 to 4 mm by 10 mm, should be harvested down to subchondral bone. Two hundred to 300 mg of articular cartilage is required for enzymatic digestion and cell culturing. After harvesting of the cartilage, the knee is irrigated, all arthroscopic instruments are removed, and wounds are closed. The cartilage tissue is sent to a commercial laboratory where it is enzymatically degraded to isolate the chondrocytes. The chondrocytes are cultured over 4 to 6 weeks and sent back for reimplantation during the second procedure.

The second procedure involves implantation of the cultured chondrocytes into the articular defect under a periosteal or collagen membrane patch. A small peripatellar incision is performed to expose the chondral defect. The area of the defect is debrided, with cut vertical edges creating an abrupt transition from healthy cartilage to defect. The excised area is debrided down to subchondral bone without causing bleeding. If bleeding occurs from the subchondral bone, it must be stopped before implantation of the chondrocytes. Depending on the desired patch material, a separate incision can be made to harvest a periosteal flap, which usually is obtained from the upper medial tibia. The desired flap is sutured into the healthy cartilage surrounding the defect. In a periosteal flap the cambium layer of the flap must face the subchondral bone of the defect. Sutures are placed at 5- to 6-mm intervals, and intervals between the sutures are sealed off with fibrin glue. An opening is left in the periosteal patch for injection of the chondrocytes. After injection of the cells, closure of the periosteal patch is completed with sutures and fibrin glue (Figures 21-26 to 21-28).

Collagen patches, although not currently Food and Drug Administration (FDA)-approved for use in autologous chondrocyte implants (ACIs), are becoming increasingly common in use. A collagen patch offers a couple of advantages over the periosteal patch. First, there is decreased patient morbidity by avoiding periosteal harvesting. Second, there is decreased graft hypertrophy (25% with periosteal sleeve versus 5% collagen patch),[123] a complication which can be a significant source of postoperative symptoms (i.e., popping or catching) and lead to reoperation for debridement. The use of a collagen matrix does add significant cost to the initial surgery; however, Samuelson et al.[124] found them to be more cost effective than periosteal patches due to the high rate of complications associated with periosteal patches.

Rehabilitation. Rehabilitation after autologous chondrocyte transplantation can be broken down into ROM, CPM, weight bearing, strengthening, and functional training. Patients can begin working on ROM immediately after surgery. Trochlear groove patients should not work on active extension for the first 4 weeks because active extension increases patellofemoral contact stresses. CPM should be used as much as possible for the first 6 weeks. Most patients should be non–weight bearing for at least the first 2 weeks. Patients then can progress to partial weight bearing. All patients should be in a hinged knee brace that is locked in extension for ambulation. Femoral condyle patients can progress to weight bearing as tolerated at 6 weeks. Trochlear patients can progress to weight bearing as tolerated as soon as they are

comfortable as long as they are in the knee brace locked in extension. This keeps the patella out of the trochlear groove and protects the repair. Strengthening can begin in the first 2 weeks with isometric quadriceps sets and straight leg raises. Closed-chain activities can be started at 6 weeks. Positions that stress the region of chondrocyte implantation should be avoided. For anterior femoral condyle lesions, loading in full extension should be avoided. For posterior femoral condyle lesions, loading in flexion should be avoided. For trochlear lesions, deep squats should be avoided. Functional training can begin between weeks 8 and 12.

Clinical Point

It is imperative that the surgeon inform the rehabilitation team of the range of motion allowed to prevent loading, as determined from intraoperative viewing of the lesion during knee range of motion. This allows optimum rehabilitation and protection of the repair.

Positions to Avoid with Autologous Chondrocyte Transplantation

- Anterior femoral condyle lesions—avoid loading in full extension
- Posterior femoral condyle lesions—avoid loaded flexion
- Trochlear lesions—avoid deep squats

Low-impact activities, such as cycling, rollerblading, and skating, can be started 9 to 12 months after surgery. Repetitive impact loading, such as jogging and aerobics, can be started at 13 to 15 months, and high-level sporting activities can be started 16 to 18 months after surgery.

Results. Peterson et al.[125] reported on 101 patients treated with ACIs with 2- to 9-year follow-up. Ninety-two percent of patients with isolated femoral lesions had good or excellent results. Sixty-five percent of patients with patellar defects had good-to-excellent results. Second-look arthroscopy was performed in 53 patients. Of these, 26 had a hypertrophic response of the periosteum or graft. Seven of these 26 were symptomatic. The incidence of graft failure was 7%. Peterson et al.[126] followed a group of 61 patients treated for isolated femoral or patellar defects for 5 to 11 years to determine the durability of the repair tissue. At 2 years, 50 of 61 patients had good-to-excellent results. At 5- to 11-year follow-up, 51 of 61 patients had good-to-excellent results.

Several studies have been performed to evaluate the outcome of ACIs compared with the outcomes with microfracture and mosaicplasty. Knutsen et al.[127,128] performed a randomized clinical trial comparing microfracture and ACI for isolated chondral defects. Eighty patients were enrolled in the study. Microfracture was performed on 40 patients, and ACI was performed on the other 40. An independent observer performed the follow-up data collection at 12 and 24 months and the lead author for the 5-year follow-up. Both groups showed improvement at all follow-up time points. According to the Short Form-36 (SF-36) outcome measurement tool, the microfracture group had a significantly greater improvement in the physical component at 24 months, but this did not persist at the 5-year follow-up. No difference in improvement was seen between the treatment arms based on the International Cartilage Repair Society (ICRS), Tegner, Lysholm, and SF-36 mental component scores. Biopsy specimens were obtained from 84% of patients at 2 years. Histological evaluation of repair tissues showed no significant differences between the two groups. Interestingly, no association was found between the histological specimens and the clinical outcome; however, none of the patients with the highest quality appearing cartilage failed. Horas et al.[129] compared ACI with osteochondral cylinder transplantation. Forty patients with isolated femoral defects were randomized to ACI or osteochondral cylinder transplantation. Using Lysholm scores, recovery from ACI was slower than recovery from osteochondral cylinder transplantation. After 2 years, clinical results were equal between the two groups. Histomorphological examination of the ACI patients showed a stable resurfacing of the defect in all patients. The tissue consisted mainly of fibrocartilage, with localized areas of hyaline-like regenerative cartilage close to the subchondral bone. Examination of biopsies from the osteochondral cylinder transplantation showed remaining gaps between the graft and intact articular cartilage, but no histological difference was seen between the osteochondral transplants and the surrounding original cartilage. Bentley et al.[117] compared ACI to mosaicplasty in a prospective, randomized controlled trial (RCT). Fifty-eight patients underwent ACI,

and 42 underwent mosaicplasty. The average size defect was 4.66 cm^2. At 1 year, good-to-excellent results were seen in 88% of the ACI patients versus 69% in the mosaicplasty patients. This difference did not reach statistical significance. Second-look arthroscopy at 1 year demonstrated excellent or good repairs in 82% after ACI and 34% after mosaicplasty. The authors concluded superiority of ACI over mosaicplasty despite limited follow-up time. Vanlauwe et al.[130] evaluated microfracture versus ACI in another RCT. Outcome scores showed no difference at 6, 12, 18, and 60 months. Biopsy at 18 months showed improved structural regeneration in ACI compared with microfracture patients. The authors also noted that in a subgroup analysis of outcomes after 60 months, ACI resulted in better outcomes in patients who had their procedure less than 3 years after onset of symptoms.

SUMMARY

The treatment of chondral injuries has become an increasingly popular field. As outlined in this chapter, a number of different options are available to today's orthopedic surgeon. The different techniques have varying advantages and disadvantages, which must be considered when deciding on a treatment plan. Many of the studies evaluating these modalities report only short- to intermediate-term outcomes, and perhaps as long-term outcomes become available ideal usage for each of these options will become better defined. The rehabilitation team needs to understand the biology of the repair technique, the biomechanics of the knee, and how the location of the chondral defect affects the biomechanics to develop the best rehabilitation program and offer the best rehabilitation advice to each patient.

CHAPTER 22

Patellofemoral Joint

CHRISTOPHER M. POWERS, RICHARD B. SOUZA, JOHN P. FULKERSON

INTRODUCTION

Patellofemoral pain (PFP) is one of the most common disorders of the knee.[1] Patellofemoral-related problems are prevalent in a wide range of individuals, but the highest incidence is seen in physically active people, such as runners, tennis players, and military recruits.[2–4] In general, the incidence of patellofemoral-related problems is higher in females than in males.[5]

Despite the high incidence of PFP in the general population, the pathophysiology of this disorder is sometimes elusive. This is supported by the fact that no clear consensus exists on how PFP should be treated. For example, a myriad of conservative procedures have been advocated (e.g., bracing, taping, foot orthotics, strengthening, stretching), and numerous surgical techniques have been described. Initially, nonoperative care is preferred, but surgical intervention is considered if conservative care fails.

The problem of PFP is highlighted by the fact that 70% to 90% of individuals with this condition have recurrent or chronic pain.[6] Although interventions for PFP have resulted in positive short-term outcomes, long-term clinical outcomes are less compelling. This is illustrated by the fact that 80% of individuals who completed a rehabilitation program for PFP still reported pain, and 74% had reduced their physical activity at a 5-year follow-up.[7] The apparent lack of long-term success in treating this condition may be because the underlying factors that contribute to the development of PFP are not being addressed. Although it is generally agreed that the etiology of PFP is multifactorial in nature, it is generally accepted that the root cause or causes of this condition are not well understood.[8–10]

The difficulty involved in treating PFP reflects the complexity of the patellofemoral joint and the multifactorial nature of the disorder. To treat this condition effectively, the clinician must clearly identify the primary cause or causes of the pain. The purpose of this chapter is to provide the reader with an understanding of the relevant anatomy, kinesiology, and biomechanics of the patellofemoral joint and to review current theories related to the etiology of PFP, evaluation methods, and treatment strategies.

FUNCTIONAL ANATOMY

The patellofemoral joint consists of the articulation of the patella and the trochlear surface of the femur. The patella is an integral part of the knee extensor mechanism and plays a key role in normal knee function and lower extremity biomechanics. The ability of the patellofemoral joint to improve the mechanical efficiency of the extensor mechanism and to accept and redirect forces depends on a host of factors, including the joint's osseous structure and contributions from various soft tissues, such as the quadriceps musculature, quadriceps tendon, patella tendon, and retinaculum. Clinicians must have an understanding of the anatomical structure of this joint to appreciate both normal and pathological function.

Osseous Structure

Patella

Contained within the quadriceps tendon, the patella has the distinction of being the largest sesamoid bone in the body. The patella consists primarily of cancellous bone covered by thin, compact lamina; its axial length is approximately 4 to 4.5 cm (1.6-1.8 inches), and it is approximately 5 to 5.5 cm (2-2.2 inches) wide. The thickness of the patella varies considerably, attaining a maximum height of 2 to 2.5 cm (0.77-1 inch) at its central portion.[11]

The articular surface of the patella is divided into the medial and lateral facets by a vertical ridge (median ridge) that roughly bisects the patella (Figure 22-1).[12] The lateral facet often is slightly larger than the medial facet.[13] The medial facet is subdivided by a less prominent vertical ridge that separates the medial facet proper and the smaller, odd facet (see Figure 22-1). The articulating surfaces of the patella are covered with aneural hyaline cartilage, the thickest cartilage in the body.[14] Maximum cartilage thickness is found at the central portion of the patella (approximately 4-5 mm) and decreases from the median ridge to the medial and lateral borders.

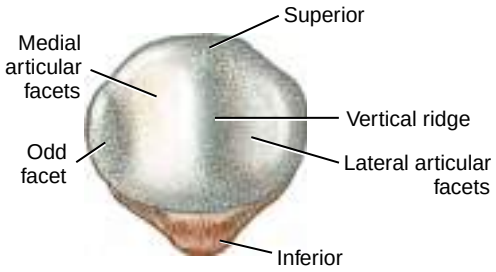

Figure 22-1 Articular side of the patella. (From Neumann DA: *Kinesiology of the musculoskeletal system: foundations for rehabilitation*, ed 2, St. Louis, 2010, Mosby.)

Trochlear Surface of the Femur

The femoral condyles form the trochlear groove that provides the articulating surface of the femur. Similar to the articular surface of the patella, the trochlear surface is divided into medial and lateral facets, the lateral facet being larger and extending more proximally and anteriorly than its medial counterpart (Figure 22-2). The larger lateral femoral condyle provides a bony buttress that helps provide lateral patellar stability.[15] The trochlear groove is shallower proximally than distally, indicating that bony stability is compromised as the patella moves superiorly during terminal knee extension. The cartilage covering the trochlear surface of the femur is much thinner than that covering the patella (i.e., 2-3 mm).[14]

Soft Tissue Structures

Synovium

The synovial lining of the patellofemoral joint, which is essentially the synovium of the anterior portion of the knee, has three components: the suprapatellar synovium, the peripatellar synovium, and the infrapatellar synovium. These three portions blend imperceptibly with each other, allowing free communication with the knee joint proper.[16] The peripatellar synovium creates a small synovial fold or fringe less than 1 cm (0.5 inch) wide that surrounds the patella; this generally is regarded as the true synovium of the patellofemoral joint.[14] Inflammation or scarring of this synovial fold (i.e., plica) can produce symptoms similar to those of cartilage degeneration.[17]

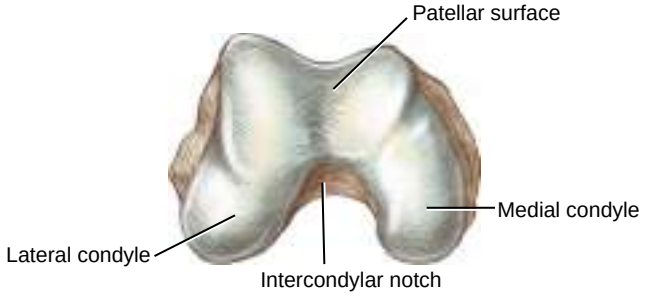

Figure 22-2 Inferior aspect of the distal end of the femur. (From Neumann DA: *Kinesiology of the musculoskeletal system: foundations for rehabilitation*, ed 2, St. Louis, 2010, Mosby.)

Portions of the Synovial Lining of the Patellofemoral Joint

- Suprapatellar synovium (pouch)
- Peripatellar synovium (plica)
- Infrapatellar synovium

Fat Pads

Three fat pads occupy the anterior knee: the quadriceps fat pad, the prefemoral fat pad, and the infrapatellar fat pad (Figure 22-3).[18] The infrapatellar fat pad, or Hoffa's fat pad, is the largest fat pad in the region and has been studied extensively because of its proposed role in various pathologies.[18–22] It is a voluminous structure located just inferior to the infrapatellar pole.[19] It extends inferiorly to the deep infrapatellar bursa at the insertion of the patellar ligament into the tibial tuberosity. Hoffa's fat pad attaches to several structures, including the intercondylar notch via the ligamentum mucosum, the patella tendon, the inferior pole of the patella, and the anterior horns of the menisci.[18]

The quadriceps fat pad, also known as the *anterior suprapatellar fat pad*, lies superior to the suprapatellar pole between the distal quadriceps tendon anteriorly and the suprapatellar recess posteriorly.[23] Just deep (posterior) to the suprapatellar recess and the suprapatellar bursa is the prefemoral fat pad, which is anterior to the femoral shaft and superior trochlear groove.[16]

Fat Pads of the Patellofemoral Joint

- Infrapatellar (Hoffa's) fat pad
- Quadriceps (anterior suprapatella) fat pad
- Prefemoral fat pad

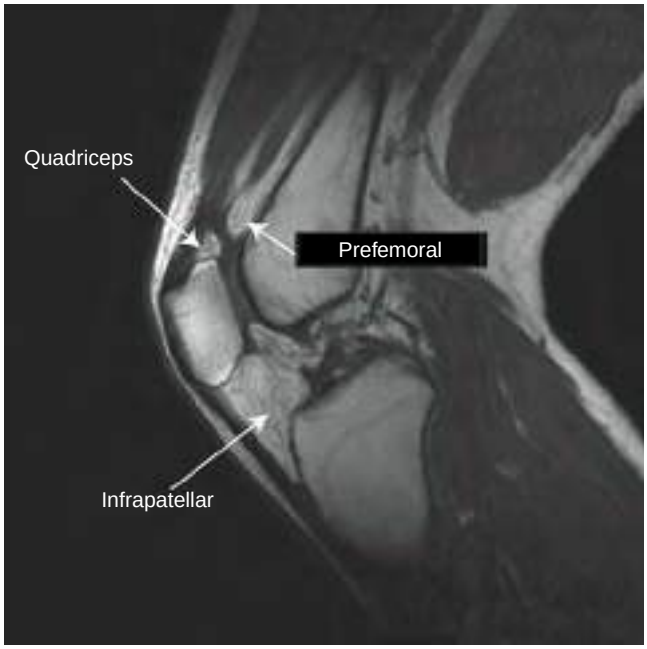

Figure 22-3 Sagittal magnetic resonance imaging (MRI) scan of the knee showing the fat pads that occupy the anterior aspect of the knee.

The fat pads of the knee house neurovascular projections. The infrapatellar fat pad is highly vascularized and highly innervated. Terminal extensions of the inferior genicular arteries anastomose in the infrapatellar fat pad, richly supplying it and its synovial coverings.[21] Substance P immunoreactive pain fibers are widespread and equally distributed throughout the fat pad, retinaculum, and synovium.[22]

Several functions have been proposed for the fat pads, including secretion of synovial fluid, occupation of dead space, and joint stability. Current research concludes that the infrapatellar fat pad appears to play a role in biomechanical support and neurovascular supply to the adjacent structures.[18]

Proposed Functions of Fat Pads

- Synovial fluid secretion
- Occupiers of dead space
- Joint stability
- Neurovascular supply

Soft Tissue Stabilizers

Because the patellofemoral joint lacks a tightly closed capsule, external assistance is required to achieve patellar stability within the trochlear groove; this assistance is provided by soft tissue stabilizers. In general, the soft tissue stabilizers of the patellofemoral joint can be described as passive stabilizers or active stabilizers.

Passive Stabilizers

Passive stabilizing structures include the patella tendon inferiorly and the medial and lateral retinaculum (Figure 22-4). The patella tendon functions to transmit the forces generated by quadriceps contraction to the tibia. This structure typically is oriented slightly lateral with respect to the long axis of the tibia, thereby creating a slight lateral pull on the patella.[14]

Passive Patella Stabilizers

- Patella tendon
- Medial retinaculum
- Lateral retinaculum

The normal patella retinaculum consists of layered, fibrous connective tissue that traverses the medial and lateral margins of the patella with attachments to the femur, tibia, patella, and patellar ligament.[24] The superficial fibers of the retinaculum originate from the vastus lateralis (VL) and vastus medialis (VM) fascia, linking the quadriceps muscles to the patella (Figure 22-5).[25] This linkage is responsible for the dynamic influence of the quadriceps muscles on the patellofemoral joint during active knee motion.

The lateral retinaculum is composed of two distinct portions: a thinner superficial layer and a thicker deep layer. The deep layer is further divided into three fibrous components: the epicondylopatellar band (or lateral patellofemoral ligament), the deep transverse retinaculum, and the patellotibial band (Figures 22-6 and 22-7). These

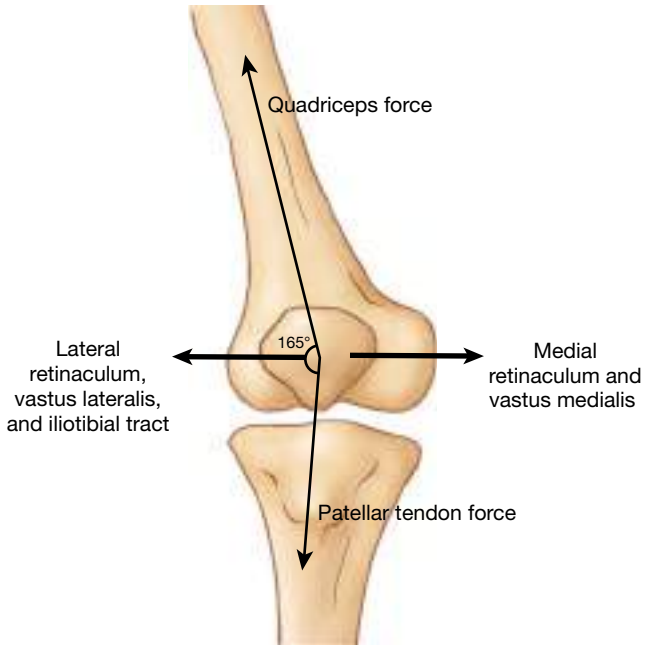

Figure 22-4 Active and passive soft tissue stabilizers of the patella. (From Andrews JR, Harrelson GL, Wilk KE: *Physical rehabilitation of the injured athlete*, ed 4, Philadelphia, 2012, Saunders.)

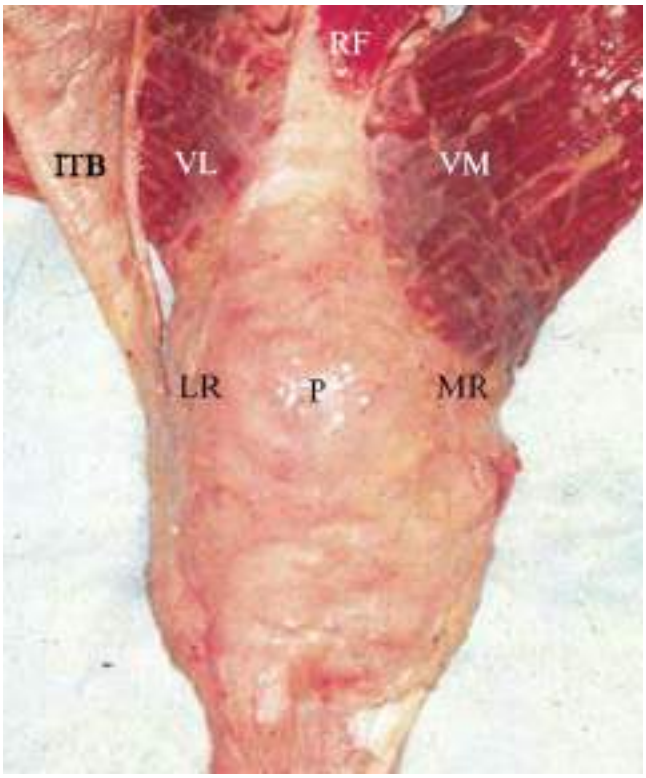

Figure 22-5 Cadaveric dissection showing interdigitation of the quadriceps musculature and iliotibial band with the peripatellar retinaculum. *VM,* Vastus medialis; *RF,* rectus femoris; *P,* patella; *VL,* vastus lateralis; *ITB,* iliotibial band; *LR,* lateral retinaculum; *MR,* medial retinaculum.

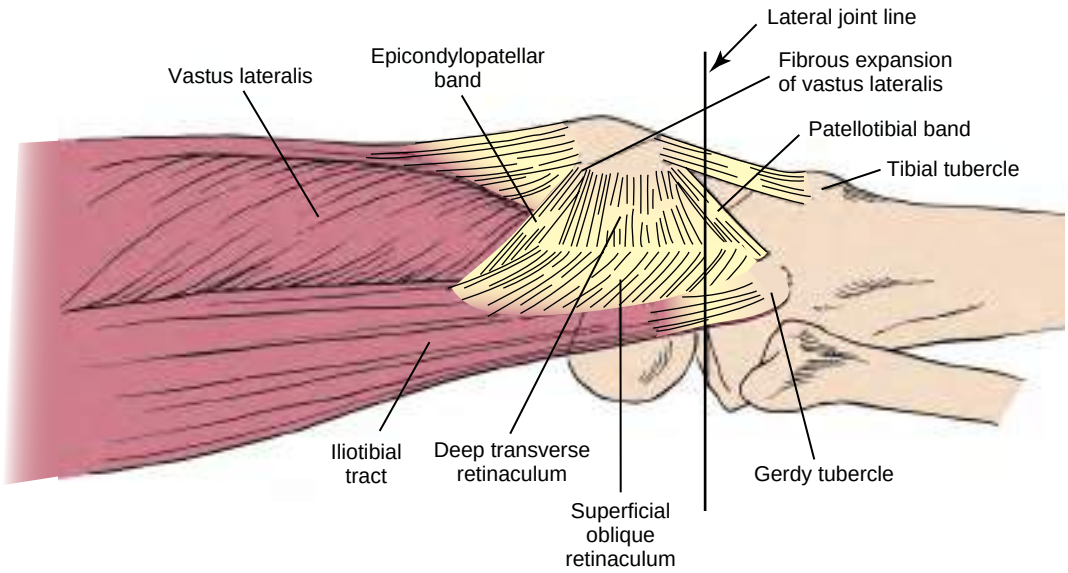

Figure 22-6 Anatomy of the lateral extensor mechanism and retinaculum showing the orientation of the elements that make up the superficial and deep layers. (Redrawn from Fulkerson JP, Gossling HR: Anatomy of the knee joint lateral retinaculum, *Clin Orthop* 153:183-188, 1990.)

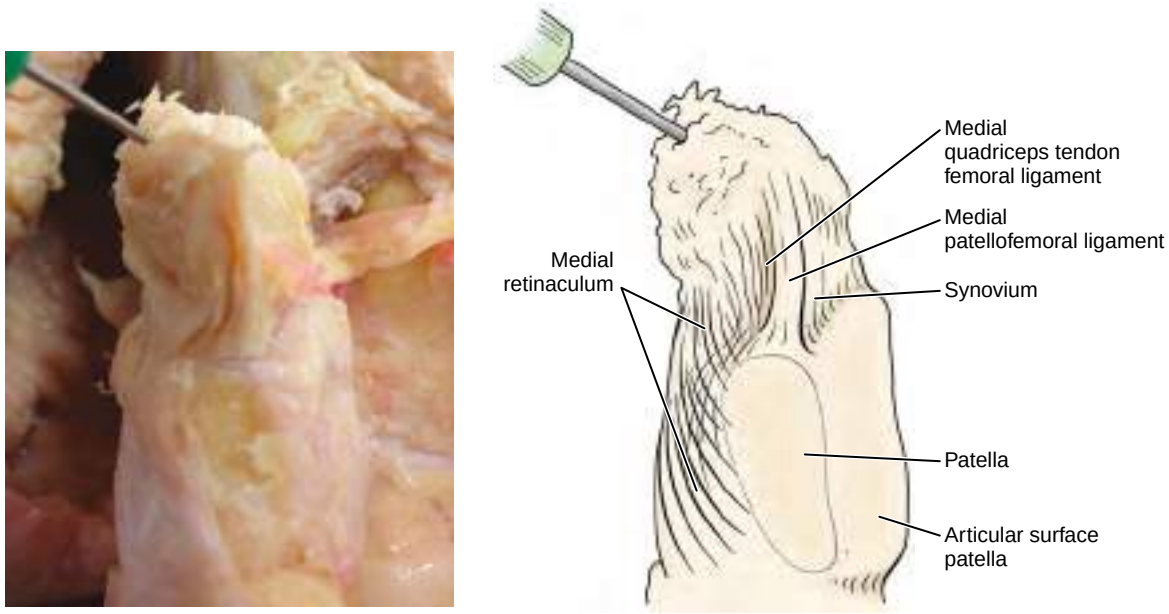

Figure 22-7 **A,** Transverse section of patella and medial retinaculum. **B,** Illustration to show how medial retinacular and medial patellofemoral ligament (MPFL) and medial quadriceps tendon-femoral ligament (MQTFL) blend in with extensor expansion over patella.

structures connect the patella to the iliotibial band (ITB) and help prevent medial patella excursion.[25] Because most of the lateral retinaculum originates from the ITB, this structure is drawn posteriorly with knee flexion, placing a lateral force on the patella.[26]

The medial retinaculum includes the medial patellofemoral and medial quadriceps ligaments. This complex forms a tough, fibrous layer that helps limit lateral patellar excursion. The components of the medial retinacular complex are sometimes surgically imbricated or replicated in the interest of restoring medial support for the patella after a lateral dislocation.[27]

The specific role of the peripatellar retinaculum as a frontal plane stabilizer of the patellofemoral joint has been well established.[28,29] However, because of its unique orientation, the peripatellar retinaculum plays a

complementary load-sharing role with respect to the patellar ligament by resisting tensile forces created by the extensor mechanism.[30] Similar to the patellar ligament, the patellar retinaculum provides distal inferior support for the patella through the medial and lateral meniscopatellar ligaments, which connect the patella to the tibia.[28]

The lateral retinaculum contains small nerve endings, which suggests that this structure can be a source of symptoms.[14] In addition, Sanchis-Alfonso et al.[31] reported on the widespread presence of substance P in this area. Fulkerson et al.[32] reported that nerve injury in the lateral retinaculum can be a source of pain and may be related to chronic tension.

Active Stabilizers

Active stabilizers of the patella consist of the four heads of the quadriceps femoris muscle (the VL, VM, vastus intermedius [VI], and rectus femoris [RF]), which fuse distally to form the quadriceps tendon. These muscles, which can be identified at their insertion into the patella, provide dynamic control of the patellofemoral joint.

Active Patella Stabilizers

- Vastus lateralis
- Vastus intermedius
- Vastus medialis
- Rectus femoris

The RF inserts into the anterior portion of the superior aspect of the patella, with the superficial fibers continuing over the superior aspect of the patella and ending in the patellar tendon. The VI inserts posteriorly into the base of the patella but anterior to the joint capsule. Both the VL and VM insert into their respective sides of the patella and reinforce the medial and lateral retinaculum.[33,34]

The lower fibers of the VM insert more distally on the patella and at a greater angle from the vertical compared with the VL. In a detailed anatomical analysis, Lieb and Perry[35] determined the angle of insertion of the various heads of the quadriceps muscle with respect to the vertical axis. The fiber alignment in the frontal plane was as follows: VL, 12° to 15° laterally; RF, 7° to 10° medially; and VM, upper fibers, 15° to 18° medially, lower fibers, 50° to 55° medially (Figure 22-8).[35] The fibers of the VI were found to lie parallel to the shaft of the femur.

The distinct and abrupt change in the fiber orientation between the superior and inferior portions of the VM led Lieb and Perry[35] to designate the inferior portion the **vastus medialis oblique (VMO)** and the superior portion the **vastus medialis longus (VML).** Although the fiber orientation of the VMO makes this structure particularly effective in providing medial patella stability,[35] there is debate as to whether the VMO and VML

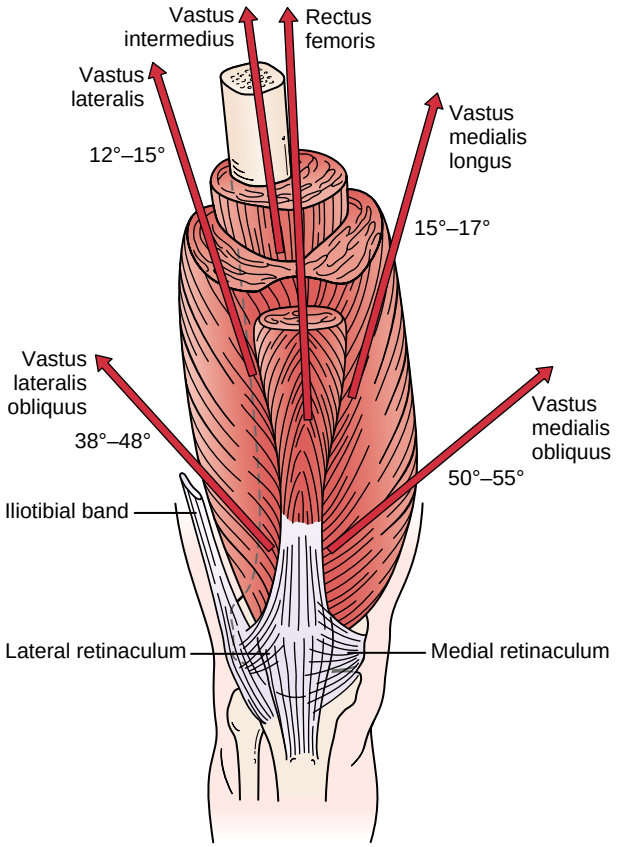

Figure 22-8 Components of the quadriceps–femoris complex. Note the angle of insertion of the various components of the complex. The orientation of the muscle fibers dictates the line of action and the pull on the patella. (Modified from McConnell J, Fulkerson J: The knee: patellofemoral and soft tissue injuries. In Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 697, Philadelphia, 1996, WB Saunders.)

should be considered separate anatomical structures. In a detailed anatomical study of 324 cadaver specimens, Hubbard et al.[36] reported that there is no aponeurotic sheet of epimysium anatomically separating the VMO from VML. This finding has led the authors to conclude that the VMO should not be considered a separate and distinct muscle.

As a result of the posterior origin of the vasti (linea aspera), any quadriceps muscle contraction (regardless of knee flexion angle) results in compressive forces acting on the patellofemoral joint (Figure 22-9). Even when the knee is fully extended, substantial joint compression can occur. The posterior angulation of the VM and VL fibers has been reported as approximately 55° from the vertical.[37]

In summary, the bony confines of the trochlea combined with the passive and active soft tissue stabilizers define the limit of patellar excursion and contribute significantly to stability of the patellofemoral joint. The balance between medial and lateral stability is essential for maintaining appropriate alignment of the extensor mechanism and normal biomechanics of the patellofemoral joint.

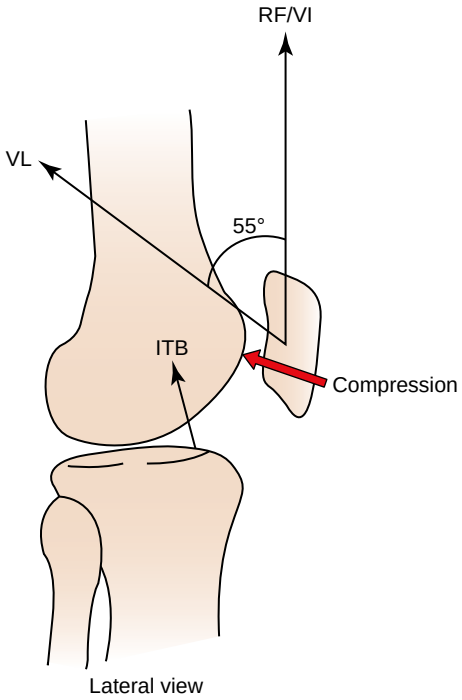

Figure 22-9 The posterior angulation of the vasti with respect to the femur results in compression of the patella with quadriceps contraction, regardless of the knee flexion angle. *VL,* vastus lateralis; *RF,* rectus femoris; *VI,* vastus intermedius; *ITB,* iliotibial band. KINESIOLOGY

Normal Patellar Kinematics

The inability to visualize the relationship between the patella and the trochlear groove makes clinical assessment of patella tracking an imprecise task. Also, identifying abnormal patella motion is difficult if "normal" patella tracking has not been clearly defined. Kinematic magnetic resonance imaging (KMRI) has been used to quantify patellar movement during resisted knee extension from 45° flexion to full knee extension (0°).[38,39] Assessment of patella kinematics in this arc of knee motion is clinically relevant, because this is the range in which tracking abnormalities occur. KMRI has a distinct advantage over static imaging procedures in that the contribution of the extensor mechanism to patellofemoral joint kinematics can be assessed.[39]

Frontal Plane Movements

The normal position of the patella is slight lateral displacement throughout knee flexion and extension. The normal pattern of patellar motion in the frontal plane is characterized by slight medial displacement from 45° to 15° knee flexion, followed by slight lateral displacement at the end range of extension (15° to 0°).[40] This motion has been described previously as the C-curve pattern.[41] The estimated amount of medial and lateral movement is about 3 mm in each direction based on quantitative analysis.[40]

The tendency of the patella to displace medially during knee extension is related to the geometry of the femoral trochlear groove. Because the lateral femoral condyle typically is larger and projects farther anteriorly than the medial condyle, the trochlear surface is angled slightly medially when viewed from distal to proximal positions (Figure 22-10).[42] In addition, the shift from medial to lateral patellar translation during terminal knee extension can be explained, in part, by the screw home mechanism of the knee. During terminal extension of the non–weight-bearing knee, the tibia rotates laterally as a result of the unequal curvature between the femoral condyles.[43] As was demonstrated by van Kampen and Huiskes,[42] patellar motion is highly influenced by rotation of the tibia, and lateral rotation induces a lateral patella displacement.

Transverse Plane Movements

During knee extension from 45° to 0°, the patella tilts medially (5° to 7°) from a laterally tilted position of 10°.[40] As with medial and lateral patella displacement, this motion pattern appears to be related to the geometry of the femoral trochlear groove.[40] The fact that the patella typically is laterally tilted throughout knee extension suggests that patella malalignment is more an issue of degree rather than position.

Sagittal Plane Movements

The motions of the patella in the sagittal plane consist of flexion and extension. *Flexion* is defined as the motion in which the inferior pole of the patella moves posteriorly, whereas *extension* is defined as the motion in which the

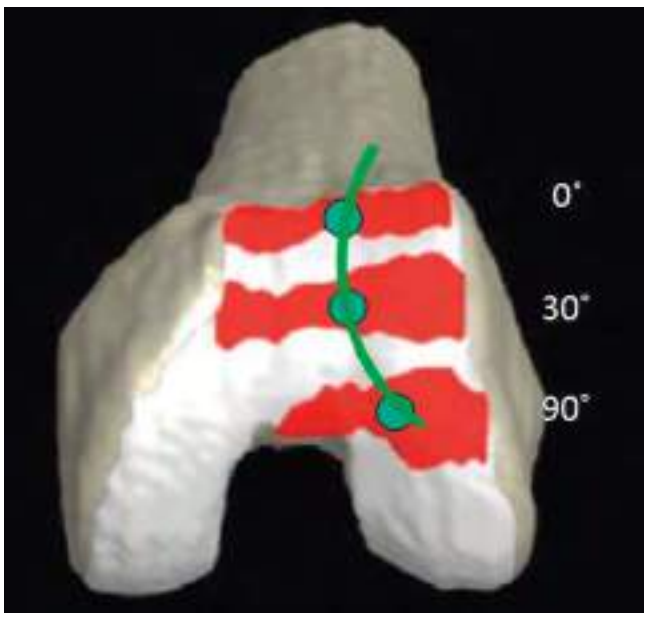

Figure 22-10 Patellar motion in the frontal plane is dictated by the shape and orientation of the trochlear groove as the knee flexes and extends.

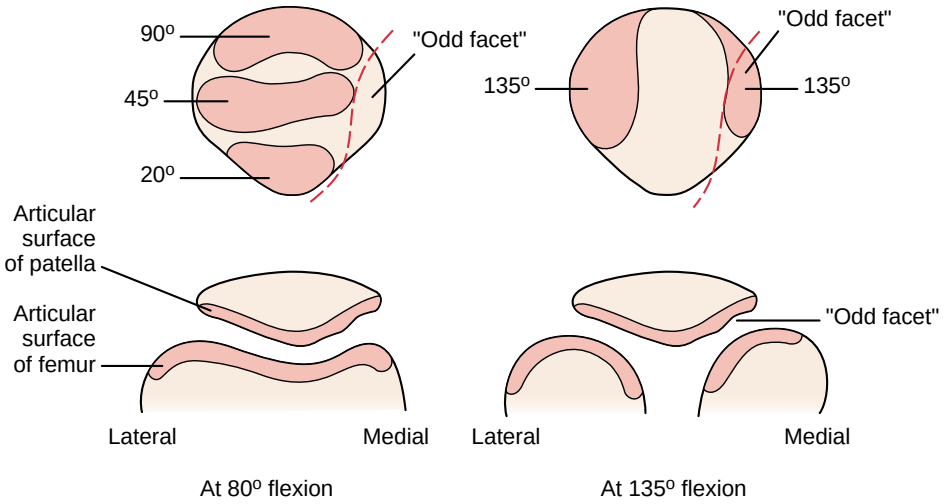

Figure 22-11 Contact area patterns on the patella as a function of the knee flexion angle. In general, contact area increases with increasing knee flexion. (Modified from Magee DJ: *Orthopedic physical assessment*, ed 6, p 767, St. Louis, 2014, Saunders/Elsevier.)

inferior pole moves anteriorly. Flexion of the patella occurs in conjunction with knee flexion; however, the magnitude of patellar flexion is about 20° less than that of knee flexion.[42] For example, when the knee is flexed to 60°, the patella typically is flexed to 40°. Similarly, as the knee extends, the patella also extends from the flexed position.[42]

Patellofemoral Joint Contact Area

During knee flexion, the patella moves from the superior (shallower) portion of the trochlear groove to the inferior (deeper) portion.[40] As such, the articulating surface of the patella on the femur varies throughout the range of knee motion. Movement from full extension to 90° flexion results in a band of contact that moves from the inferior to the superior pole of the patella (Figure 22-11).[44] Normally, the odd facet makes no contact during this range. Between 90° and 135°, the patella rotates laterally with the ridge between the medial and odd facets, making contact with the medial condyle. At 135°, the odd facet and the lateral portion of the lateral facet make contact, as does the quadriceps tendon (see Figure 22-11).[44]

Because the patella enters the deeper portion of the trochlear groove during knee flexion, the area of contact between the patella and the trochlear groove increases. With the quadriceps contracted, the patellofemoral contact area has been reported to increase from 146 mm^2 at 0° to a maximum of 345 mm^2 at 60°.[45] This increase in contact area with increased knee flexion functionally serves to distribute joint forces over a greater surface area, thereby minimizing joint stress.

Frontal Plane Influences

Fulkerson and Hungerford[14] described the natural tendency of the patella to track laterally as the "law of valgus." This tendency is a result of the valgus orientation of the lower extremity. As the quadriceps muscle follows the longitudinal axis of the femur, the quadriceps angle (Q angle) is formed, creating a lateral force vector that acts on the patella (Figure 22-12). This predisposes the patella to lateral tracking forces with quadriceps muscle tension.[46]

Figure 22-12 The orientation of the quadriceps force vector and patella ligament force vectors creates a lateral force acting on the patella. (From Powers CM: The influence of altered lower-extremity kinematics on patellofemoral joint dysfunction: a theoretical perspective, *J Orthop Sports Phys Ther* 33:639-646, 2003.)

Clinically, the Q angle is measured as the angle formed by the intersection of a line drawn from the anterosuperior iliac spine (ASIS) to the midpoint of the patella and a proximal extension of a line drawn from the tibial tubercle to the midpoint of the patella.[47] The Q angle is greater in women than in men because women have a wider pelvis; the average Q angle is 15° to 18° in women and approximately 12° in men.[15] This variation between the genders may partly explain the higher incidence of PFP in females, because a larger Q angle creates a larger valgus vector and therefore a potentially greater predisposition to lateral tracking.[48]

JOINT BIOMECHANICS

The patellofemoral joint is susceptible to the largest loads in the body.[49] Because abnormal forces and stresses are thought to be a primary factor in the origin of PFP, it is important that clinicians understand the normal biomechanics of this joint.

Function of the Patella

The primary function of the patella is to facilitate knee extension.[50] This mechanical attribute has been described in detail and has been shown to increase the functional lever arm of the extensor mechanism.[50] Documentation of strength losses in subjects who have undergone patellectomy supports this concept. Fletcher et al.[51] reported a 49% reduction in the torque output of the extensor mechanism after patellectomy.

The quadriceps muscle lever arm varies throughout the knee range of motion, with reported maximum values ranging from 4.9 cm (1.9 inches) at 30° flexion[52] to 7.8 cm (3.1 inches) at 15° flexion.[53] The effectiveness of the patella diminishes with full flexion because the patella sinks into the trochlear groove, reducing the anterior displacement of the quadriceps tendon. The extensor lever arm is only slightly reduced with full extension (4.4 cm [1.7 inches]).[52]

Apart from improving the moment arm of the quadriceps muscle, the patella provides protection for the articular cartilage of the trochlea and prevents excessive friction between the quadriceps tendon and the femoral condyles, permitting the patellofemoral joint to tolerate high compressive loads. The patella also acts as a guide for the converging heads of the quadriceps muscle, facilitating transmission of the muscular forces to the patella tendon.[50]

Patellofemoral Joint Reaction Force

Because the quadriceps is the only muscle to cross the patellofemoral joint, the patellofemoral joint reaction force (PFJRF) is determined by the force and moment balance of the quadriceps force vector and the patella ligament force vector.[54] Early biomechanical descriptions of the patellofemoral joint characterized this articulation as a frictionless pulley where the patellar ligament force (F_{PL}) was assumed to be equal to the force applied by the quadriceps tendon (F_Q).[55,56] However, subsequent experimental studies and mathematical representations of the patellofemoral joint suggested that the patella also acted as a lever, thereby creating a force differential between the quadriceps tendon and the patella ligament.[54] This force differential is thought to occur as a result of the varying geometry and shape of the distal femur and patella, as well as the changing point of contact between the patella and femur as the knee flexes and extends.

The PFJRF is the measurement of compression of the patella against the femur and is dependent on the angle of knee flexion, as well as the degree of muscle tension.[57]

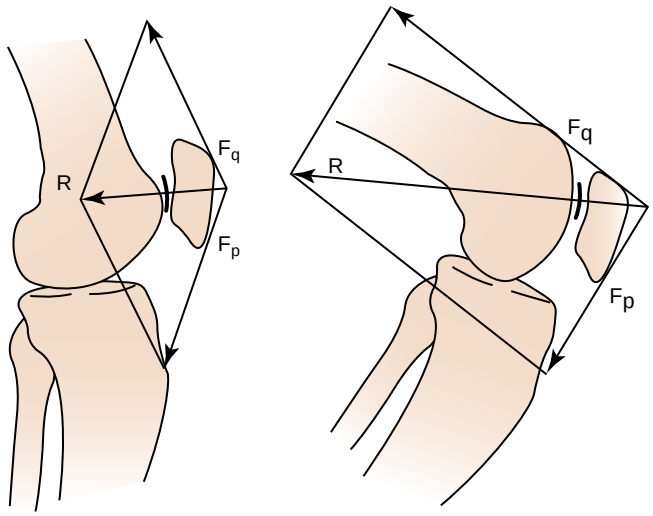

Figure 22-13 The patellofemoral joint reaction force increases as a function of quadriceps force and knee angle. F_q, Force of the quadriceps tendon; F_p, force of the patella tendon; R, patellofemoral joint reaction force. (From McConnell J, Fulkerson J: The knee: patellofemoral and soft tissue injuries. In Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation*, p 700, Philadelphia, 1996, WB Saunders.)

The resultant value of the quadriceps muscle force vector and the patella tendon force vector is equal and opposite to the PFJRF, which evokes compressive stresses on the patellofemoral articular cartilage (Figure 22-13).[58] Previous investigations have indicated that the PFJRF for level walking is approximately 1 times body weight; it is 3.8 times body weight during stair ascent and descent[59–61] and can be as high as 7 to 11 times body weight during running.[62]

Patellofemoral Joint Stress

From a mechanical standpoint, patellofemoral joint stress (or pressure) is defined as the PFJRF divided by the patellofemoral joint contact area. A high PFJRF is not necessarily harmful to the patellofemoral joint, because this force can be offset by a large contact area. However, a high joint reaction force combined with a small contact area may be detrimental.

Numerous studies have been undertaken to measure stresses directly from cadaveric knees using pressure-sensitive film. In addition, patellofemoral joint stress has been estimated in vivo by dividing the estimated PFJRF by the patellofemoral joint contact area obtained from the literature or MRI. It has been reported that peak patellofemoral joint stress can vary from 2 megapascals (MPa) for level walking to 6 MPa for stair ambulation.[59,60]

PATHOMECHANICS

As mentioned earlier, the cause of PFP can be elusive, and it may have multiple origins. For example, tissues such as the subchondral bone, synovium, retinaculum, and fat pad have been implicated as potential sources of

patellofemoral joint symptoms.[63] Excessive mechanical stresses in these tissues are believed to stimulate pain receptors. Dye[63] proposed that differential loading of innervated tissue and the loss of tissue homeostasis may be responsible for the genesis of patellofemoral symptoms. In turn, restoration of tissue homeostasis (i.e., alleviation of stress in irritated tissue) is thought to reduce symptoms.

Several studies have provided evidence supporting the concept of differential loading as a factor in the development of pain.[60,64,65] Because the primary goal of conservative and surgical management of PFP is to reduce pain and improve function, it is important that the clinician understand the mechanisms that may contribute to abnormal joint loading.

As outlined by Fredericson and Powers,[66] factors that contribute to excessive patellofemoral stress can be broken down into three categories: local factors (abnormal patellofemoral joint mechanics), biomechanical factors (abnormal lower extremity kinematics), and overuse.

Local Factors: Abnormal Patellofemoral Joint Mechanics

When the patella is not properly situated within the trochlear groove owing to improper alignment or maltracking, contact between the patella and trochlear surfaces is diminished and stress is increased. Two of the more common examples of abnormal patella alignment and maltracking are excessive lateral patellar tilt and lateral patellar subluxation.

Excessive Lateral Pressure Syndrome

Ficat et al.[67] first proposed excessive lateral pressure as a causative factor in patellofemoral articular cartilage pathology. These authors proposed that the laterally tilted patella increased the compression between the lateral facet and the lateral femoral condyle (Figure 22-14). This patellar posture also unloads the medial facet.

Tilting of the patella can be isolated, or it can be associated with lateral patellar subluxation.[68–70] Chronic lateral tilt is determined radiologically and has been reported to have a deleterious effect on the articular cartilage. Lateral facet overload and deficient medial facet contact can lead to articular cartilage degeneration at both sites. Abnormal articular cartilage loading of the lateral facet may cross the threshold of cartilage resistance, leading to failure.[14] The primary area of lateral facet degeneration corresponds to the areas of contact in the 40° to 80° knee flexion range.[71]

The mechanism of medial facet articular cartilage damage in excessive lateral pressure syndrome (ELPS) appears to be different from that of lateral facet degeneration, because this area is susceptible to deficient contact. This form of degeneration likely can be attributed to impaired nutrition to the cartilage, because diminished joint compression results in decreased flow of synovial fluid.[72] Seedholm et al.[71] have stated that areas of relative contact deficiency develop mild degenerative changes and are most probably asymptomatic. When combined with the shearing of the medial facet associated with lateral patellar subluxation, more extensive medial facet degeneration may occur.[14]

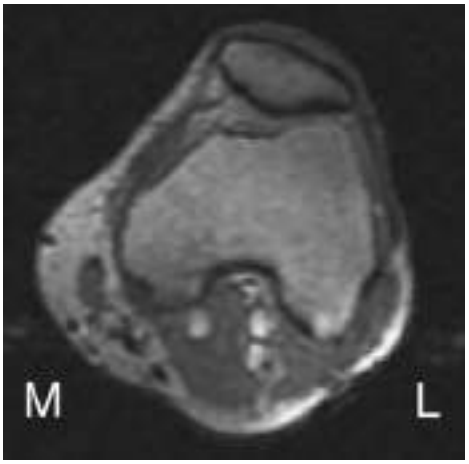

Figure 22-14 Axial MRI of the patellofemoral joint showing excessive lateral tilting of the patella, resulting in increased pressure between the lateral facet and the lateral femoral condyle. *M*, medial; *L*, lateral.

Etiology of Excessive Lateral Patella Syndrome. The natural history of ELPS has been described as being congenital followed by adaptive shortening of the lateral retinaculum.[14] The significance of a tight lateral retinaculum is the increased posterolateral pull on this structure with knee flexion. This, in turn, accentuates lateral facet compression. Insall[73] stated that adaptive shortening of the lateral retinaculum was more likely the result of habitual lateral patella tracking.

Disruption of the medial stabilizers (the VM and the medial patellofemoral ligament) also has been implicated as a possible cause of excessive lateral patella tilt. Ahmed et al.[74] conducted a mechanical study to measure the static pressure distribution on the retropatellar surface. The results from 24 cadaveric specimens showed that a release of VMO tension created a pressure shift that was transferred almost entirely to the lateral facet of the patella. In addition, the change in the orientation of the pressure zone suggested a considerable frontal plane rotation of the patella relative to the femur.

Evidence exists that the shortened retinaculum and/or insufficient dynamic medial stabilizers contribute to lateral patellar tilt. Fulkerson et al.[75] demonstrated the effectiveness of surgical release of the lateral retinaculum in reducing lateral patella tilt. Based on preoperative and postoperative computed tomography (CT) evaluation, these authors reported a mean tilt improvement of 6° at 10° knee flexion and 15° at 20° knee flexion. These improvements brought the tilt angles of these subjects well within the normal range, as demonstrated in the control group. Douchette and Goble[76] demonstrated the importance of quadriceps muscle weakness and tightness of the lateral structures as contributors to ELPS. These authors found a significant decrease in patella tilt in patients who participated in an

8-week program of quadriceps muscle strengthening and ITB stretching. In addition, 84% of the previously symptomatic patients were pain free after this program.

Lateral Patellar Subluxation

Patella subluxation is abnormal medial or lateral movement of the patella. Abnormal patellar tracking, such that transient medial or lateral displacement occurs during flexion and extension, has been documented as a cause of articular cartilage damage and pain.[77,78] Subluxation of the patella is differentiated from patella instability or dislocation in that the patella stays in the trochlear groove rather than leaving it (i.e., dislocating).

In general, subluxation typically involves increased lateral displacement of the patella[14]; however, medial displacement also can occur.[79] Fulkerson and Hungerford[14] described three types of subluxation: minor recurrent subluxation, major recurrent subluxation, and permanent lateral subluxation. In minor recurrent subluxation, the patella deviates little from its normal course; this type of subluxation is not associated with clinically apparent relocation. In major recurrent subluxation, the patella comes across the lateral trochlear facet and returns to the trochlear groove with an audible snap. Permanent lateral subluxation is a stable lateral displacement in which there was no centering of the patella.

Etiology of Lateral Patella Subluxation. As mentioned previously, both static and dynamic structures provide resistance to the natural lateral forces acting on the patella. Disruption of the normal equilibrium of forces may lead to patella malalignment and associated pathology. To understand the etiology of a patient's symptoms and to formulate an effective treatment program, the clinician must understand the specific mechanisms involved.

Bony Abnormalities. Anatomical variations of the patella or distal femur (or both) can contribute to recurrent lateral patellar subluxation. Patellar or trochlear dysplasia compromises the inherent stability afforded by the bony structure, making the patella more susceptible to laterally directed forces. Wiberg[13] proposed a system for classifying patella shapes based on axial view radiographs:

- *Type I:* Both facets are slightly concave and symmetrical, and the medial and lateral facets are equal in size (Figure 22-15).

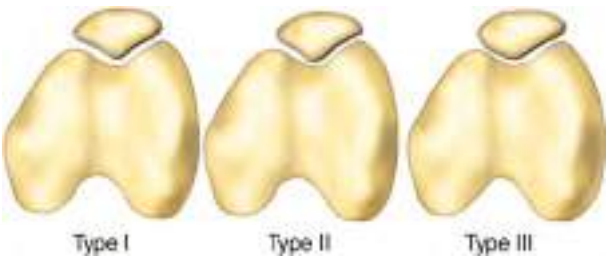

Figure 22-15 Classification of patella shapes based on axial view radiographs. (From Hunter RE, Sgaglione NA: *AANA advanced arthroscopy: the knee,* Philadelphia, 2010, Saunders.)

- *Type II:* The medial facet is distinctly smaller than the lateral facet. The lateral facet is concave, whereas the medial facet is more flat (see Figure 22-15). Wiberg found this to be the most common shape of the patella.
- *Type III:* The medial facet is slightly convex and considerably smaller, with marked lateral facet predominance (see Figure 22-15). Wiberg considered this shape a frank dysplastic form.

Apart from the shape of the patella, its position with respect to the trochlear groove can be a potential causative factor in lateral subluxation. **Patella alta,** as described by Insall,[46] is evident when the resting position of the patella is above the femoral groove (Figure 22-16). The high-riding patella does not sink adequately into the trochlear groove with knee flexion and therefore is prone to lateral displacement. In addition, individuals with patella alta are predisposed to elevated joint stresses, because the contact area is minimal, particularly when the knee is extended.[80] Patella alta is detected with lateral radiographs, and a positive sign is a patella tendon that is 20% longer than the patella. The excessive length of the patella tendon is thought to be the primary cause of this condition.[81]

Another bony etiological factor related to lateral patella subluxation is **trochlear dysplasia.** The trochlear groove of the femur, especially the larger anterior protrusion of the lateral femoral condyle, provides significant bony stability for the patella.[82] The normal trochlear facet (sulcus) angle was established by Brattstrom[82] using radiological techniques. Evaluation of 100 normal knees showed that the values for sexes were similar, with a mean angle of 143° for males and 142° for females. Higher sulcus angles represented a shallower trochlear groove and were associated with recurrent patella subluxation (Figure 22-17).[82,83] According to Hvid et al.,[84] a sulcus angle greater than 150° indicates trochlear dysplasia.

Studies by Powers[69] and Varadarajan et al.[85] have reported that the sulcus angle is significantly correlated with mediolateral patellar displacement and tilt. In contrast, Harbaugh et al.,[86] as well as Teng et al.,[87] reported that the inclination of the lateral anterior femoral condyle, as opposed to the sulcus angle, was more important in determining lateral tracking of the patella. In addition, the angle of inclination of the lateral trochlea has been reported to be associated with cartilage and bone marrow lesions on the lateral aspect of the patellofemoral joint.[88]

Abnormal Skeletal Alignment. Abnormal skeletal alignment has been reported to have a profound effect on the magnitude of the Q angle and the subsequent laterally directed component of the quadriceps muscle force.[78,89] Huberti and Hayes[89] documented the deleterious effects of an increased Q angle by measuring patellofemoral contact pressures in 12 fresh cadaver specimens. These authors found that a 10° increase in the Q angle resulted in a 45% increase in peak contact pressure at 20° of knee flexion. In half of these specimens, the area of patella

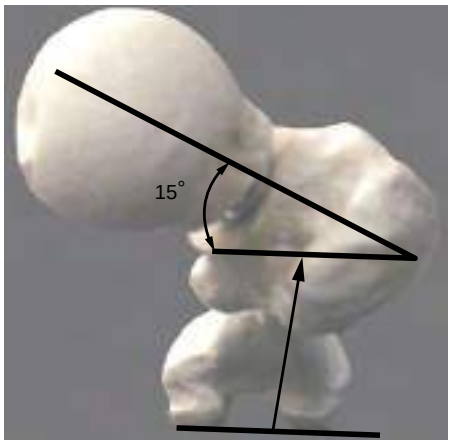

Figure 22-18 Femoral anteversion is measured by comparing the femoral neck and posterior condylar axes in the transverse plane. Normal anteversion is approximately 15°.

contact shifted laterally and the peak pressures were evident on the medial portion of the lateral facet.

An increased Q angle often is present with rotational malalignments of the femur and tibia. Such abnormalities include excessive femoral anteversion, lateral tibial torsion and/or lateral displacement of the tibial tubercle, and genu valgum.

- *Excessive femoral anteversion:* In the transverse plane, the neck of the femur forms an angle of about 15° with the transverse axis of the femoral condyles (Figure 22-18). This places the femoral head anterior to the femoral condyles. An increase in this angle, or *excessive femoral anteversion,* is associated with medial femoral rotation (Figure 22-19).[90–93] Excessive femoral anteversion and subsequent medial femoral rotation cause the trochlear surface of the femur to be placed medially with respect to the tibial tubercle, functionally increasing the Q angle.[94] Clinically, this is manifested by a toed-in gait and the appearance of "squinting patellae."[90]
- *Lateral tibial torsion and/or lateral displacement of the tibial tubercle:* A laterally displaced tibial tuberosity with respect to the midline of the tibia and the anterior superior iliac spine (ASIS) acts to increase the Q angle.[14] This anatomical variation typically is the result of increased lateral tibial torsion.
- *Genu valgum:* Increased valgus angulation of the femur and tibia in the frontal plane is called genu valgum. Genu valgum also is postulated to increase the valgus force vector of the quadriceps muscle (Figure 22-20).[94]

Soft Tissue Influences. Both contractile and noncontractile soft tissue structures can contribute to the lateral forces acting on the patella. Although these effects may be present in conjunction with the abnormalities already described, their potential influence on lateral patellar tracking must be assessed if an effective treatment is to be formulated.

Passive Structures. As mentioned previously, the lateral retinaculum has been implicated as a cause of

Figure 22-19 Excessive femoral anteversion is associated with increased femoral medial (internal) rotation. Note that this posture increases the quadriceps angle (Q angle). (Courtesy Michael Sherlock, M.D., Lutherville, MD. In Zitelli BJ, McIntire SC, Nowalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis*, ed 6, Philadelphia, 2012, Saunders.)

Figure 22-20 Increased angulation of the femur and tibia in the frontal plane is described as genu valgum. Note that this posture increases the Q angle. (From Zitelli BJ, McIntire SC, Nowalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis,* ed 6, Philadelphia, 2012, Saunders.)

excessive lateral patellar tilt and is capable of exerting a lateral force on the patella, potentially contributing to subluxation. Because the lateral retinaculum has an extensive attachment to the ITB, contraction of the tensor fascia lata muscle may exert a dynamic lateral force through this connection.[95] In some cases this attachment may be excessive, causing recurrent dislocation of the patella. Puniello[26] demonstrated a strong relationship between ITB tightness and decreased passive medial patella glide in a group of 17 subjects with patellofemoral dysfunction. Hughston and Deese[96] reported a high incidence (50%) of medial patella subluxation after lateral retinacular release, which indicates that this structure also plays a role in pulling the patella laterally.

Dynamic Structures. Historically, a force imbalance between the VM and the VL has been accepted as a principal cause of patella subluxation.[97–99] As such, clinical emphasis has been placed on the dynamic factors associated with patellar instability (i.e., VM weakness). The VM has been identified as the primary structure capable of counteracting the VL in maintaining patellar alignment. VM insufficiency has been associated with muscle atrophy,[97,100] hypoplasia,[97] inhibition caused by pain and effusion,[101,102] and impaired motor control.[103]

According to Fox,[97] hypoplasia of the extensor mechanism is found to a varying degree in 40% of the population. This hypoplasia manifests as incomplete development of the VM, because it is the last of the quadriceps muscle to develop phylogenetically.[97] The effect of an underdeveloped VM is a patellar alignment that is influenced by an overpowering VL; more specifically, the patella is situated more laterally and proximally. The more hypoplastic the VM, the more lateral the position of the patella. In addition, the superior and lateral pull of the patella can cause the development of patella alta. This hypoplasia also has been theorized to influence the development of the tibia, because the unchecked pull of the VL can result in lateral tibial rotation, lateral placement of the tibial tubercle, and genu recurvatum.[97]

Fox[97] theorized that the VM was the weakest muscle phylogenetically and therefore the first component of the quadriceps muscle to atrophy after injury or disuse. Fox considered the potential muscular imbalance between the medial and lateral dynamic stabilizers as a result of this atrophy or weakness to be the major predisposing factor for "hypermobile patella syndromes." Atrophy of the VM was observed by Smillie,[104] who stated that the apparent wasting of the VM was associated with the inability to complete terminal knee extension. To the contrary, Lieb and Perry[35] stated that apparent atrophy of the VM was the result of a thinner fascial covering (i.e., half the thickness) compared with the VL, which made atrophy of the VL less perceptible.

Atrophy of the quadriceps muscle group is thought to be caused by reflex inhibition,[101] with the stimulus being pain[105] or effusion.[106] Inhibition is the result of afferent stimuli from receptors in or around the injured knee that prevent activation of the α-motor neurons in the anterior horn of the spinal cord.[107] Spencer et al.[101] reported that infusion of only 20 to 30 mL of saline into the knee joint exceeded the threshold for quadriceps muscle inhibition, in

contrast to other authors, who have proposed much larger volumes (e.g., 100 mL).[101] In an attempt to determine whether selective inhibition of the different heads of the quadriceps muscle was possible, Spencer et al.[101] examined Hoffman's reflex in the individual muscles after intra-articular infusion of saline into the knee. Although the VM appeared to be affected more by small amounts of induced effusion, no statistically significant differences were seen. This finding supported previous work that showed that reflex inhibition caused by effusion affects the entire extensor mechanism and does not predispose the patellofemoral joint to an imbalance of dynamic forces.

Documenting imbalances between the VM and the VL in patients with PFP has been of primary interest to the practicing clinician, because conservative treatment of this disorder typically focuses on restoring normal function of the dynamic stabilizers. Despite the interest in the function of the quadriceps femoris in patients with PFP, evidence supporting the concept of vasti muscle imbalance as a cause of lateral patella subluxation is limited.

Because in vivo strength assessment of the individual vastus muscle is not possible, electromyography (EMG) has been used to compare the relative recruitment of these muscles, under the rationale that decreased activity or impaired timing of the VM relative to the VL may indicate compromised medial patellar stability. Many investigators have studied the EMG activity of the dynamic patellar stabilizers in individuals with PFP; however, the results of these studies are equivocal. Some studies have found significant differences in VM and VL activity in patients with PFP,[108–110] whereas others have not.[111–114] Similarly, some authors have reported that the onset of VL activity precedes that of VM activity in persons with PFP[115,116]; however, vasti timing differences have not been reported in all studies.[117] Direct comparisons of these studies are difficult because of differences in experimental technique, methods of quantifying EMG, and the inherent variability associated with such data.

Another reason for the inconsistent results in these investigations may be the inherent variability among patients with PFP. Because the etiology of PFP has been considered a dynamic entity, a deficiency of the medial stabilizers logically should result in lateral displacement of the patella. However, radiological examinations have documented that fewer than 50% of patients with PFP show isolated lateral subluxation.[118] This suggests that lateral patellar tracking is not a universal finding in this disorder, and therefore such an inference cannot be generalized to all patients.

Etiology of Medial Patella Subluxation. Medial subluxation of the patella is less commonly seen than lateral patellar subluxation. The causes of lateral patellar subluxation are related more to anatomical and soft tissue abnormalities, whereas the etiology of medial subluxation is almost always iatrogenic.[79,96] This condition most commonly is caused by excessive medialization of the extensor mechanism in realignment surgery or by lateral retinacular release in which little or no patella lateralization was done preoperatively.[96]

Abnormal Lower Extremity Kinematics

Researchers recently have recognized that the patellofemoral joint can be influenced by the segmental interactions of the lower extremity.[94,119] Abnormal motions of the tibia and femur in the transverse and frontal planes can have a substantial effect on patellofemoral joint mechanics and therefore PFP. An understanding of how the lower kinetic chain can influence the patellofemoral joint is important, because interventions to control abnormal lower extremity mechanics are not focused on the area of pain but rather on the joints proximal and distal to the patellofemoral joint (i.e., the hip and/or foot and ankle). As noted previously, structural deformities can lead to an increase in the Q angle and the lateral forces acting on the patella; however, abnormal motions of the lower extremity also can be contributing factors.[94,119] Three principal lower limb motions can influence the *dynamic* Q angle: tibial rotation, femoral rotation, and knee valgus.

Tibial Rotation

The Q angle can be influenced distally through motions of the tibia. Lateral rotation of the tibia moves the tibial tuberosity laterally, thereby increasing the Q angle, whereas tibial medial rotation decreases the Q angle by moving the tibial tuberosity medially (Figure 22-21, *A*). In turn, tibial rotation is influenced by subtalar joint motion. Subtalar joint pronation causes medial rotation of the tibia, and supination causes the tibia to rotate laterally. Normal subtalar joint pronation occurs during the first 30% of the gait cycle, during which the tibia rotates medially 6° to 10°.[120] This motion occurs in response to the medial rotation of the talus as it falls into the space created by the inferior and lateral movement of the anterior portion of the calcaneus.

As a result of this close biomechanical relationship between the rearfoot and the tibia, abnormal pronation has been linked to several lower extremity conditions, including patellofemoral joint dysfunction. Typically, pronation is considered abnormal if the amount of motion is excessive or occurs at the wrong time (i.e., when the foot should be supinating). When excessive pronation is related to various clinical entities, an assumption is made that abnormal pronation results in excessive tibial medial rotation and that this motion places a rotatory strain on soft tissues of the lower extremity. Although this may be the case with respect to the tibiofemoral joint, the same assumption does not hold true for the vertically aligned patellofemoral joint. In fact, excessive tibial medial rotation caused by subtalar joint pronation would actually *decrease* the Q angle and the lateral forces acting on the patella (see Figure 22-21, *A*).

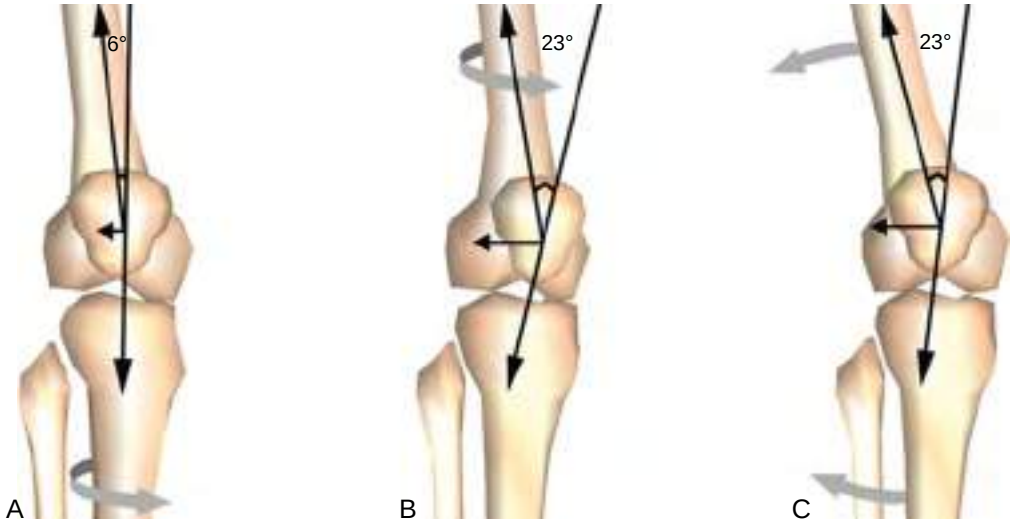

Figure 22-21 Schematic of the influence of femoral and tibial motion on the Q angle. **A,** Tibial medial (internal) rotation results in a decrease in the dynamic Q angle. **B,** Femoral medial (internal) rotation increases the dynamic Q angle. **C,** Femoral adduction or tibial abduction results in knee valgus and an increase in the dynamic Q angle. (From Powers CM: The influence of altered lower-extremity kinematics on patellofemoral joint dysfunction: a theoretical perspective, *J Orthop Sports Phys Ther* 33:639-646, 2003.)

This discrepancy was discussed by Tiberio,[121] who described a scenario in which excessive pronation could affect normal patellofemoral joint function. Tiberio postulated that to achieve knee extension in midstance, the tibia must rotate laterally relative to the femur to ensure adequate motion for the screw home mechanism. To compensate for this lack of tibial lateral rotation because of the failure of the foot to resupinate, the femur would have to rotate medially on the tibia such that the tibia was in relative lateral rotation. This compensatory medial rotation of the femur would permit the necessary screw home mechanics to allow for knee extension. However, excessive medial rotation of the femur would move the patella medially with respect to the ASIS, thereby increasing the Q angle and the lateral component of the quadriceps muscle vector (Figure 22-21, *B*). This would appear to be a plausible biomechanical means by which pronation could influence the patellofemoral joint; however, to do so, such motion ultimately would have to influence the femur.

An assumption made in the scenario just described is that if excessive pronation is evident in midstance, then excessive medial rotation of the tibia also should be evident. However, Reischl et al.[120] reported that the magnitude of foot pronation did not predict the magnitude of tibial or femoral rotation. Also, the magnitude of tibial rotation did not predict the magnitude of femoral rotation, which indicates that excessive rotation of the tibia did not translate into excessive femoral rotation. This is not surprising, considering that the knee has the potential to absorb rotatory forces through its transverse plane motion. It should be noted that all subjects in this study demonstrated pronation and tibial medial rotation during early stance. However, this motion was not a 1:1 ratio. Individual factors, such as the orientation of the subtalar joint axis and the amount of transverse plane motion between the rearfoot and the lower leg, likely influence the degree to which pronation can influence the magnitude of tibial rotation.

Femoral Rotation

The Q angle can be influenced proximally through motions of the femur. As described previously, increased femoral medial rotation results in a larger Q angle, because the patella is moved medially with respect to the ASIS and tibial tuberosity (see Figure 22-21, *B*). Consequently, femoral lateral rotation minimizes the Q angle, because the resultant line of action of the extensor mechanism is more in line with the ASIS.

Apart from increasing the Q angle and the laterally directed forces on the patella, femoral medial rotation can influence patella alignment and tracking. Because the patella is tethered in the quadriceps tendon, it is not obligated to follow the motions of the femur (i.e., trochlear groove), especially when the quadriceps muscles are contracted. In fact, during weight-bearing activities, medial rotation of the femur can occur independent of patella motion, thereby bringing the lateral anterior femoral condyle in close approximation to the lateral facet of the patella. Using dynamic MRI methods under weight-bearing conditions (i.e., a single-leg partial squat), Powers et al.[122] demonstrated that the primary contributor to lateral patella tilt in a group of individuals with patella instability was femoral motion (medial rotation), not patella motion (Figure 22-22). This finding was confirmed in a follow-up study a few years later.[123] The findings of these studies call into question the long-held assumption that lateral patella subluxation is the result of the patella moving on the femur. Although this may be the case during non–weight-bearing activities in which the femur is fixed (i.e., during knee extension in sitting), these studies provide evidence that lateral subluxation of the patella during

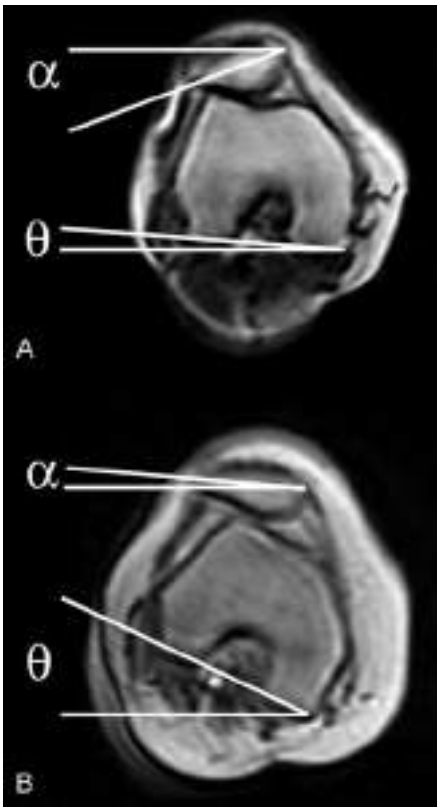

Figure 22-22 Influence of femoral rotation on lateral patella tilt at 0° knee flexion. During the non–weight-bearing condition **(A),** lateral patella tilt was the result of patella rotation (α) on a relatively horizontal femur (θ). During the weight-bearing condition **(B),** lateral patella tilt was a result of medial (internal) rotation of the femur (θ) under a relatively horizontal patella (α). (From Powers CM, Ward SR, Fredericson M et al: Patellofemoral kinematics during weight-bearing and non-weight-bearing knee extension in persons with lateral subluxation of the patella: a preliminary study, *J Orthop Sports Phys Ther* 33:677-685, 2003.)

weight-bearing activities may be the result of the femur rotating underneath the patella.

A biomechanical study by Souza and Powers[124] reported that females with PFP exhibited significantly greater peak hip medial (internal) rotation than did a control group (7.6° versus 1.2°), when averaged across three different tasks (running, step-down, and landing from a jump). Clinically, weakness of the hip lateral (external) rotators (i.e., gluteus maximus and deep rotators) may underlie the tendency of the hip to "rotate the thigh inward" during weight-bearing tasks. This concept is supported by several studies that have reported hip strength deficits in this population.[124–126]

Knee Valgus

Apart from abnormal motions in the transverse plane, excessive frontal plane motions can influence the patellofemoral joint. Most notably, valgus at the knee increases the Q angle, because the patella is displaced medially with respect to the ASIS (Figure 22-21, *C*). In comparison, a varus position of the knee decreases the Q angle, because the patella is brought more in line with the ASIS.

Knee valgus can be the result of thigh adduction, tibial abduction, or a combination of these two (see Figure 22-21, *C*). Excessive femoral adduction during dynamic tasks can be the result of weakness of the hip adductors, particularly the gluteus medius. The upper fibers of the gluteus maximus and the tensor fascia lata also assist in abduction at the hip and, if weak, may contribute to excessive thigh adduction. Structural abnormalities of the femur (i.e., excessive anteversion and coxa valga) can reduce the moment arm of the gluteus medius, which may result in a functional weakness.[127] Tibial abduction can be the result of excessive pronation or frontal plane motion at the ankle. However, tibial abduction also could be an accommodation to femoral adduction, because the proximal tibia is obligated to follow the distal femur.

Overuse

Because only 50% of patients with PFP have tracking abnormalities, other factors must be involved. If patellofemoral joint function and gait mechanics are normal, patellofemoral joint pathology may be related to excessive activity levels or overuse. For example, the peak PFJRF during weight acceptance has been calculated as 7 to 11 times body weight for healthy runners, a value estimated to be near the physiological limit of the involved tissues.[62] Therefore, for a given knee flexion angle, high forces result in elevated patellofemoral joint stress and may be problematic because of the repetitive nature of such activity. This concept is supported by the work of Thomee et al.,[128] who studied 40 women with PFP and concluded that chronic overloading and temporary overuse were the primary causes of symptoms.

Overuse injuries are a function of the magnitude of the applied force and the number of cycles the load is applied. For example, as the load increases, the number of repetitions necessary to cause injury decreases. Conversely, as the load decreases, the number of repetitions necessary to cause injury increases. Activities commonly associated with overuse histories include long-distance running and cycling.

Summary

Figure 22-23 summarizes the potential factors that may lead to patellofemoral joint dysfunction and pain. To treat PFP effectively, the clinician must address the root causes of the pain and dysfunction. Therefore the goal of the examination is to identify the likely cause or causes of symptoms so that the most effective interventions can be applied.

Clinical Note

To treat patellofemoral pain effectively, the clinician must determine the root causes of the pain and dysfunction, of which there are many.

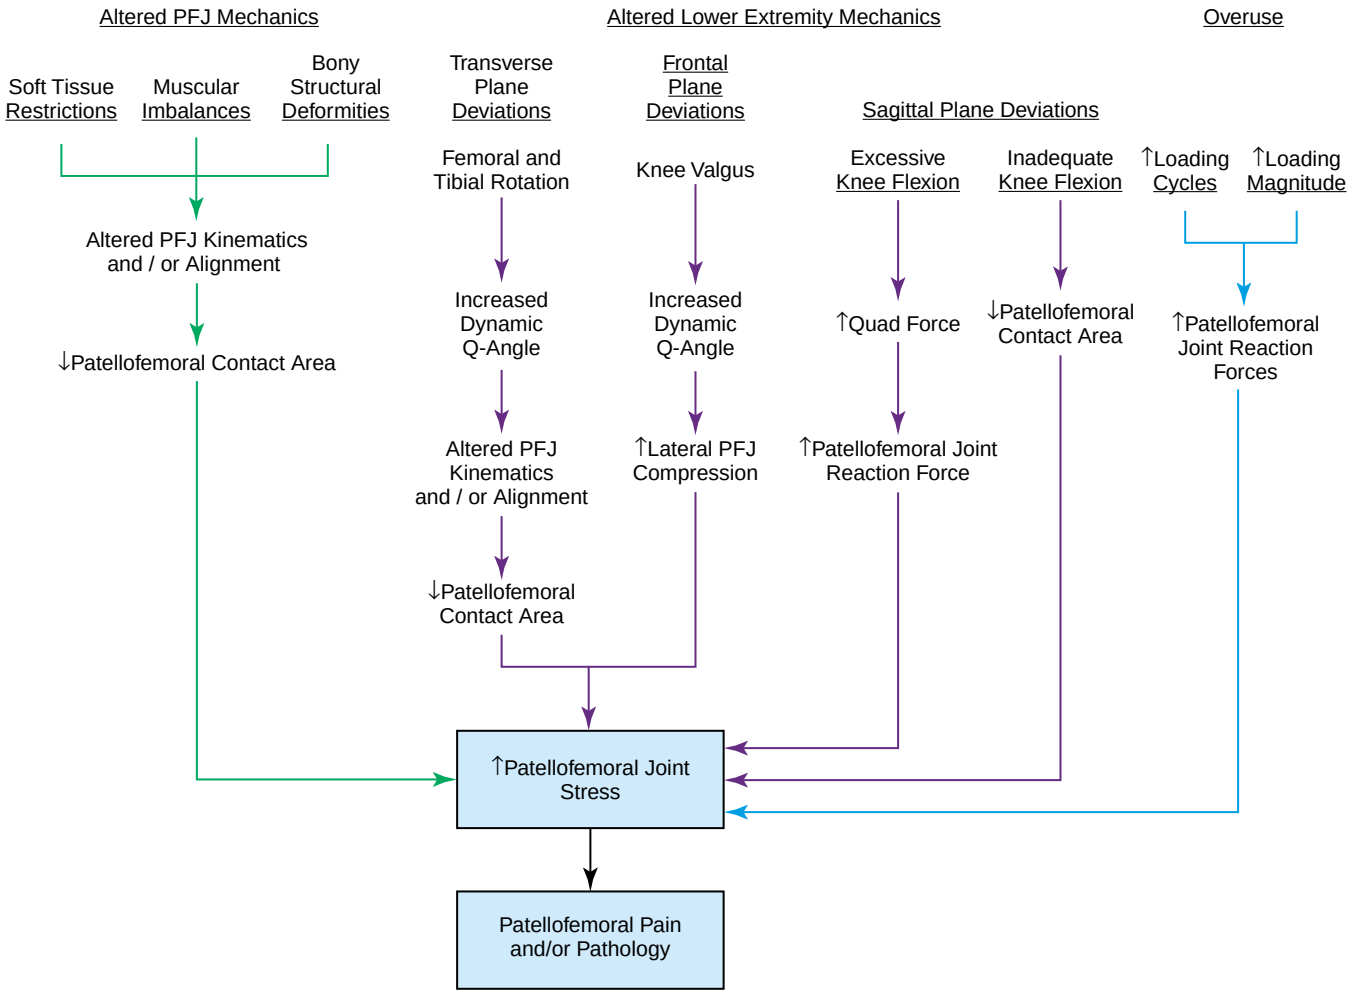

Figure 22-23 Flow diagram of potential mechanisms of patellofemoral pain and/or pathology. *PFJ,* Patellofemoral joint; *Quad,* quadriceps.

EXAMINATION

The goal of the examination is to obtain pertinent data to allow the formulation of a hypothesis about the cause of the symptoms. The examination should include both subjective and objective physical components.

Subjective Examination

The subjective examination is essential for making an accurate diagnosis. When taking a patient's history, the clinician should determine what problems are important and what types of examinations may be useful. Key information to obtain includes the patient's current complaints, symptoms, and the mechanism of injury.

Patients typically report pain as diffuse and arising from the anterior aspect of the knee.[128] However, sharp, "stabbing" symptoms can be elicited with provocative testing. Pain often is induced by activity and aggravated by functions that increase patellofemoral compressive forces, such as ascending and descending stairs, inclined walking, squatting, and prolonged sitting. The sensation of "giving way" also may be reported and should be differentiated from tibiofemoral joint instability (i.e., ligament tear) or quadriceps muscle inhibition.

Pain along the medial and lateral borders of the patella is a common complaint, and retropatellar and inferior pain often is reported. Patients frequently report crepitus during knee flexion, but this should not by itself cause concern, because asymptomatic patellofemoral crepitus is very common.[129] Painful crepitus may be related to tightness of the deep retinacular tissues, plicae, or patellofemoral joint instability; it is not necessarily suggestive of arthritic changes.

According to Grelsamer and McConnell,[130] the location of symptoms may indicate the specific structures involved and provide direction with respect to a differential diagnosis:

- *Lateral:* Small nerve injury in the lateral retinaculum
- *Medial:* Recurrent stretching of the medial retinaculum/medial patellofemoral ligament
- *Retropatellar:* Articular cartilage damage; stress borne on subchondral bone
- *Superior:* Quadriceps tendonitis/tendinosis
- *Inferior:* Patella tendonitis/tendinosis; fat pad irritation

Throughout the history process, it is important to ascertain whether the patient's disability is related to pain or instability. Generally speaking, the onset of PFP is insidious and progression is slow. A specific episode or event is not always reported. However, the clinician should pay careful attention to the patient's perceived cause of the injury, making note of changes in lifestyle, activity levels and, with athletes, training habits. A slow onset of symptoms may indicate an underlying biomechanical error or structural faults that manifest themselves over time. A rapid onset of symptoms may be associated with overuse and may or may not have an underlying biomechanical cause.

Histories related to traumatic injury (i.e., direct falls on the patella) or instability related to pain are fairly obvious and self-explanatory. However, biomechanical abnormalities or structural faults may have been present before the injury (e.g., pronation, excessive femoral anteversion), and these factors may be responsible for the perpetuation of symptoms.

Physical Examination

The physical examination should include (1) testing procedures necessary to make a differential diagnosis; (2) evaluation of the patellofemoral joint, including alignment, mobility, and dynamic motion; and (3) assessment of lower extremity alignment and function.

Differential Diagnosis

To diagnose PFP accurately, the clinician must rule out other structures as potential sources of anterior knee pain symptoms.

Patella Tendonitis/Tendinosis. The symptoms of patella tendonitis/tendinosis can be very similar to those of PFP, because pain is often induced by activity, especially during high-speed eccentric contractions of the quadriceps muscles. A clear distinction can be made between tendonitis/tendinosis and PFP through careful palpation. Local tenderness to the quadriceps tendon (i.e., superior to the patella) and patella tendon (i.e., inferior to the patella) indicates tendonitis/tendinosis and should not be confused with retropatellar pain or medial or lateral patella pain.

Iliotibial Band Friction Syndrome. ITB friction syndrome is characterized by localized pain in the lateral aspect of the knee (i.e., lateral epicondyle of the femur). Occasionally crepitus or "snapping" can be palpated as the ITB crosses the lateral femoral condyle (approximately 30° flexion). Occasionally, this is mistaken for patellofemoral joint crepitus.

Meniscal and Ligamentous Structures. Structures of the tibiofemoral joint should be ruled out as possible causes of symptoms. Meniscal tests, such as joint line tenderness, McMurray's test, Apley's compression test, and the bounce home test, should be performed to rule out meniscus injury.[131] Likewise, ligamentous tests (e.g., Lachman's test, varus and valgus stress tests) should be performed, especially in patients with traumatic histories and/or acute swelling.

Referred Pain. Referred pain from compression and/or irritation of the L3 or L4 nerve roots can manifest itself as vague pain along the lateral border of the thigh. Patients should be carefully screened to rule out lumbar spine pathology.

Evaluation of the Patellofemoral Joint

The examiner should observe any redness, swelling, warmth, dystrophic changes, or obvious joint deformity. In addition, the presence of quadriceps muscle atrophy should be determined (either qualitatively or quantitatively with a tape measure). With athletes, quadriceps muscle atrophy may not be present.

Selective atrophy of the VMO in relation to the rest of the vasti is controversial and has not been consistently demonstrated across studies.[132,133] Because the VMO is the most visible of the vasti (as a result of its superficial fibers and thin retinacular covering), atrophy may be more apparent in this muscle. Atrophy of the VL is much more difficult to visualize, because most of its fibers are deep and wrap around to the posterior femur; for this reason, the clinician must be cautious about attributing PFP symptoms solely to VMO atrophy, because this atrophy may be a general indication of weakness in all the quadriceps muscles.

Tests for Effusion. Because quadriceps muscle inhibition is associated with slight (minimal) swelling, general observations about effusion (e.g., joint warmth, redness) should be made. Typically, PFP of a nontraumatic nature is associated with only mild effusion. Severe effusion likely indicates a more serious ligamentous injury. Major effusion can be assessed by compressing the patella into the trochlea. A positive ballotable or "floating" patella sign is seen when the patella quickly "rebounds" or "floats" when compressed into the trochlea.[131]

Minimal joint effusion can be assessed with the knee extended by "milking" fluid from the suprapatellar pouch and the lateral side of the knee into the medial side of the knee. A small bulge medially is a positive sign of mild swelling.[131]

Patellar Alignment. The patella should be assessed for gross alignment abnormalities. Typically this is done with the patient in supine, the knee extended, and the quadriceps muscle relaxed. According to McConnell[134] the most commonly observed abnormalities in individuals with PFP are as follows:

- *Lateral glide (i.e., lateral displacement):* The distance from the medial epicondyle of the femur to the center of the patella is greater than the distance from the lateral epicondyle of the femur to the center of the patella (Figure 22-24, *B*). Normally, the two distances are equal (Figure 22-24, *A*).
- *Lateral tilt:* The lateral border of the patella is lower than the medial border (as viewed in the transverse plane; Figure 22-24, *C*).

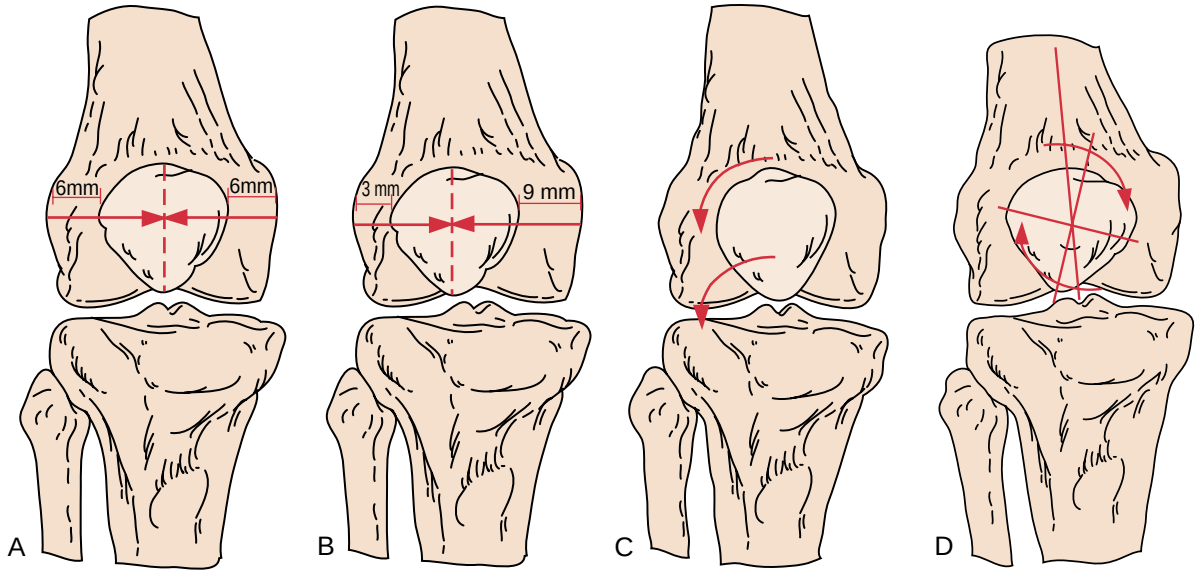

Figure 22-24 Assessment of the patellar glide component. Ideally, the patella should be centered on the superior portion of the femoral articular surface at 20° flexion. **A**, Ideal alignment. **B**, Lateral glide of the patella. **C**, Lateral tilt of the patella. **D**, Lateral rotation ("spin") of inferior pole of patella. (Modified from McConnell J, Fulkerson J: The knee: patellofemoral and soft tissue injuries. In Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* pp 711-712, Philadelphia, 1996, WB Saunders.)

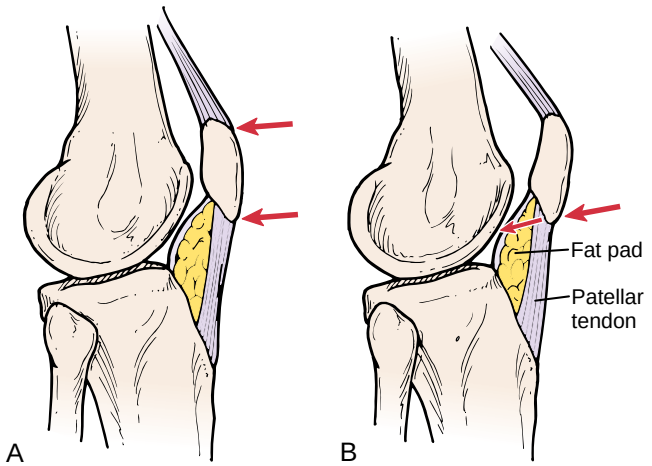

Figure 22-25 Assessment of the anteroposterior component of the patella. Ideally, the superior and inferior poles of the patella should be in line with the long axis of the femur. Excessive inferior tilt of the patella may irritate the infrapatellar fat pad. **A**, Ideal alignment. **B**, Posterior tilt of the inferior pole. (Modified from McConnell J, Fulkerson J: The knee: patellofemoral and soft tissue injuries. In Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 712, Philadelphia, 1996, WB Saunders.)

- *Lateral rotation:* The inferior pole of the patella is rotated externally with respect to the midline of the thigh (as viewed in the frontal plane; Figure 22-24, *D*).
- *Inferior tilt:* The inferior pole of the patella is tilted posteriorly compared with the superior pole (sagittal plane; Figure 22-25).

Although this classification system is widely used, both the validity and reliability of these techniques in assessing patella alignment have been challenged.[135,136] Care must be taken in the interpretation of the results of patellar alignment testing, especially because the resting position of the patella tends to be one of slight lateral displacement and lateral tilt. Only obvious abnormalities should be considered relevant.

McConnell's Assessment Criteria for Patella Alignment

- Lateral glide (displacement)
- Lateral tilt
- Lateral rotation
- Inferior tilt

Passive Patella Mobility. In addition to static alignment, passive patella mobility should be evaluated. Because motion of the patella is necessary for normal joint function, assessment of patella mobility is an important component of the examination. The patella should be able to freely glide superiorly and inferiorly, as well as medially and laterally. Also, the clinician should be able to tilt the patella medially to raise the lateral border. Quite often patella mobility is restricted after prolonged immobilization or surgery. Tightness of the lateral retinaculum is the most common limiting factor and manifests as decreased medial patella glide and inability to tilt the patella medially. As the patella moves inferiorly and superiorly and the knee flexes and extends, adequate motion is essential to ensure normal knee motion.

When assessing passive patellar mobility, the clinician also should note excessive translations and/or apprehension to such movements. Excessive lateral translation of the patella may indicate tearing of the medial patellofemoral

ligament. Patient apprehension to a lateral glide of the patella suggests recurrent patella dislocation

Patella Tracking. Active patella tracking is best observed with the patient in the sitting position. The patient should be asked to extend the knee slowly while the clinician observes the motion of the patella. As mentioned previously, normal motion is characterized by slight medial motion as the knee extends followed by slight lateral motion in terminal knee extension. Patellar subluxation typically occurs during terminal knee extension; therefore particular attention should be focused on this part of the range. As with static patellar alignment, only large deviations should be considered significant. Clinicians must keep in mind that subtle subluxations are very difficult to pick up, because a large "gray zone" exists between normal and abnormal.

The clinician also should be aware of any painful arc of motion and should note the range in which pain is reproduced. Pain typically is more evident during the last 20°, because greater quadriceps muscle forces are necessary to complete terminal knee extension, and the patellofemoral joint contact area decreases (resulting in elevated patellofemoral joint stress).

As the knee is extending, the examiner should make a qualitative assessment of the state of quadriceps muscle contraction. Does the knee appear to have difficulty completing terminal extension (suggestive of quadriceps muscle weakness), or is muscle "quivering" present (suggestive of reflex inhibition)?

Quadriceps Muscle Weakness. General quadriceps muscle weakness or atrophy (or both) is a hallmark of PFP. However, ascertaining whether true weakness is present is difficult, because pain commonly is reproduced with quadriceps muscle contraction and the patient may be hesitant to give maximal effort, thereby invalidating results.

Tests for Soft Tissue and Muscle Tightness. Tightness of various soft tissues and muscles that cross the knee can have an adverse effect on patellofemoral joint function. In particular, tightness of the RF muscle and tensor fascia lata–ITB complex should be evaluated.

Tightness of the RF muscle can result in excessive patellofemoral joint compression, especially when the knee is flexed and the hip is extended. This posture is particularly evident during the swing phase of the running cycle or with the trail limb during lunging tasks. The length of the RF muscle is best assessed using Thomas's test.[137] With the patient supine, both knees are brought to the chest to flatten the lumbar lordosis. The leg being tested then is allowed to extend such that it comes to rest on the table in a neutral position. If the knee cannot flex to 90° with the hip in a neutral position, the RF muscle is considered to be tight.

As noted previously, the interdigitation of the ITB and the lateral retinaculum suggests that tightness of this structure may produce a lateral force on the patella, potentially contributing to lateral subluxation and ELPS. Ober's test assesses for tightness of the ITB and tensor fascia lata. For this test, the patient is placed in the side-lying position. The examiner passively abducts and extends the patient's upper leg with the knee straight or flexed to 90°. The examiner then slowly lowers the thigh so that the tendon rides over the greater trochanter of the femur.[137] If tightness or contracture is present, the leg remains abducted and does not come to the neutral position.

Assessment of Lower Extremity Alignment and Function

As noted previously, evidence suggests that PFP and dysfunction may be related to abnormal lower extremity mechanics. For this reason, careful assessment of lower extremity alignment and dynamic function is an important aspect of the physical examination.

Standing Posture. The patient should be observed during relaxed standing. The examiner also should observe the alignment of the knee in the sagittal and frontal planes, as well as the transverse plane alignment of the lower extremity.

Sagittal Plane Alignment of the Knee. The knee should be evaluated for hyperextension or excessive knee flexion. Knee hyperextension (i.e., genu recurvatum) may result in compression of the inferior pole of the patella into the infrapatellar fat pad. A hyperextended knee also may indicate quadriceps muscle weakness or inhibition, because the patient may rely on the posterior capsule for stability rather than active quadriceps muscle contraction.

Excessive knee flexion requires greater amounts of quadriceps contraction to maintain this posture. Also, an inability to extend the knee fully may indicate a meniscus problem. In turn, the quadriceps contraction increases the compressive forces acting on the patellofemoral joint. Excessive knee flexion may be related to loss of terminal knee extension after surgery (particularly anterior cruciate ligament [ACL] reconstruction), hamstring tightness, hip flexion contracture, or weak calf muscles.

Frontal Plane Alignment of the Knee. Some have suggested that valgus and varus alignment of the knee is related to the structure of the proximal femur. For example, the normal inclination between the femoral neck and the femoral shaft is 125°.[138] A reduction of this angle (i.e., coxa vara) results in a valgus orientation of the knee. An increase in the angle of inclination results in a varus orientation of the knee. Knee valgus tends to increase the Q angle and the lateral forces acting on the patella, whereas knee varus has the opposite effect. However, coxa valga reduces the lever arm of the gluteus medius muscle, thereby reducing the torque-producing capacity of this muscle.[139]

Transverse Plane Alignment of the Lower Extremity. Medial rotation of the femur (i.e., medial femoral torsion) results in "squinting patellae," whereas lateral rotation of the femur (i.e., lateral femoral torsion) results in the patella pointing outward (i.e., "grasshopper eyes"). (Note: Torsion implies actual anatomical rotation of the femur, not the physiological movement of the femur.) Femoral medial rotation may indicate excessive femoral anteversion or femoral torsion, whereas femoral

lateral rotation may suggest femoral retroversion or lateral femoral torsion. Careful attention must be paid to whether foot pronation is evident and whether the entire lower extremity is in a posture of medial rotation or whether the medially rotated position of the femur appears to be an isolated entity.

Dynamic Function. Perhaps one of the most important aspects of the examination is observation of dynamic movement. This observation should include analysis of level walking, as well as higher demand activities, such as running, ascending and descending stairs, squatting, and jumping, especially if assessing active people. Careful attention should be paid so as to identify movement patterns that increase quadriceps demand and/or increase the dynamic Q angle. Observations also should be made with respect to the speed of ambulation, the force of impact during loading response, and any reproduction of symptoms. Components of the dynamic evaluation should be used to confirm or refute suspected abnormalities based on static testing procedures. Movements should be observed from both the frontal and sagittal views.

Sagittal View. The primary deviations for which the examiner should watch in the sagittal plane are inadequate knee flexion or hyperextension during weight acceptance and excessive knee flexion during stance. Decreased knee flexion during weight acceptance and knee hyperextension during the stance phase may indicate a **quadriceps avoidance gait pattern** caused by weakness or pain. The functional significance of inadequate knee flexion during weight acceptance is that shock absorption is impaired, and the tibiofemoral joint may be susceptible to excessive impulse loading. In addition, decreased knee flexion reduces the contact area between the patella and femur and therefore may contribute to elevated joint stress.

Excessive knee flexion during stance increases PFJRFs, because the quadriceps muscles are overly active supporting the flexed knee posture. Causes of excessive knee flexion include knee flexion contracture, hamstring tightness or spasticity, hip flexion contracture, meniscus pathology, and weak calf muscles.[140]

Frontal View. In the frontal view, rotation and valgus of the lower extremity are particularly important. An attempt should be made to evaluate for the following abnormalities:

1. Does the patient pronate the foot excessively? If so, does this result in excessive medial rotation of the tibia and femur?
2. Does the patient exhibit excessive medial rotation of the femur? If so, does this medial rotation tend to be present throughout the gait cycle (suggesting a fixed, bony deformity, such as excessive femoral anteversion), or does the patient "collapse" into medial rotation during weight acceptance? The latter is more indicative of poor muscular control or weakness of the hip lateral rotator muscles (Figure 22-26).
3. Does the patient exhibit excessive adduction of the femur and/or a contralateral pelvic drop? This indicates poor muscular control of the hip abductor muscles.

In many instances, frontal and transverse plane abnormalities are not readily evident during walking; therefore higher demand or functional activities specific to the patient need to be assessed. The **repetitive step-down test** is useful in this respect. The patient stands on a 0.2-m (8-inch) step and then lowers himself or herself with the painful leg and touches the heel to the floor (Figure 22-27). This is repeated 10 times without stopping unless the movement becomes too painful for the patient.

In general, an attempt should be made to determine whether frontal and transverse plane deviations

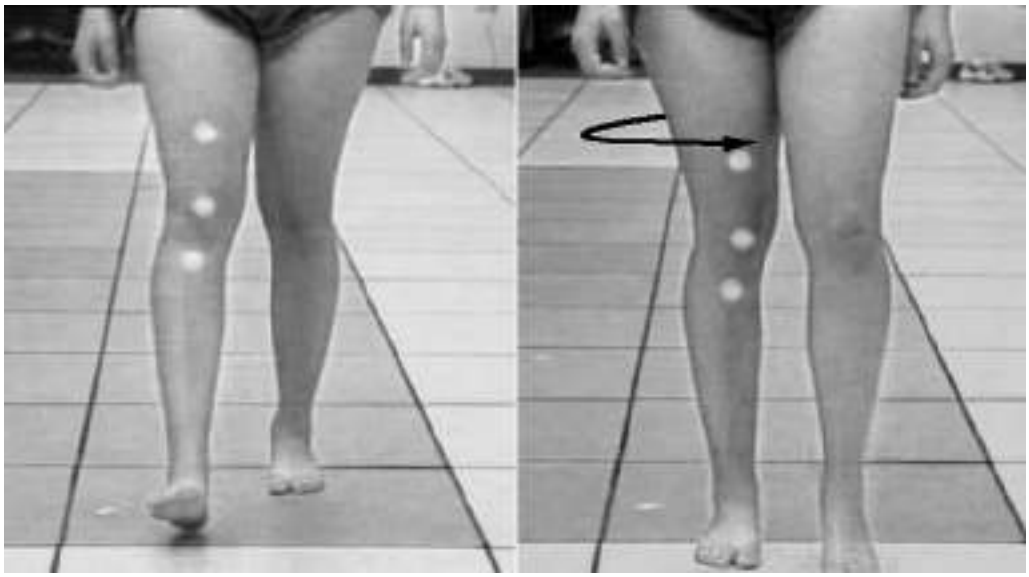

Figure 22-26 Frontal plane observational gait analysis of an individual with patellofemoral pain. Note the collapse into femoral internal rotation in midstance. Markers placed on the distal thigh, patella, and tibial tuberosity aid visualization of segment motions.

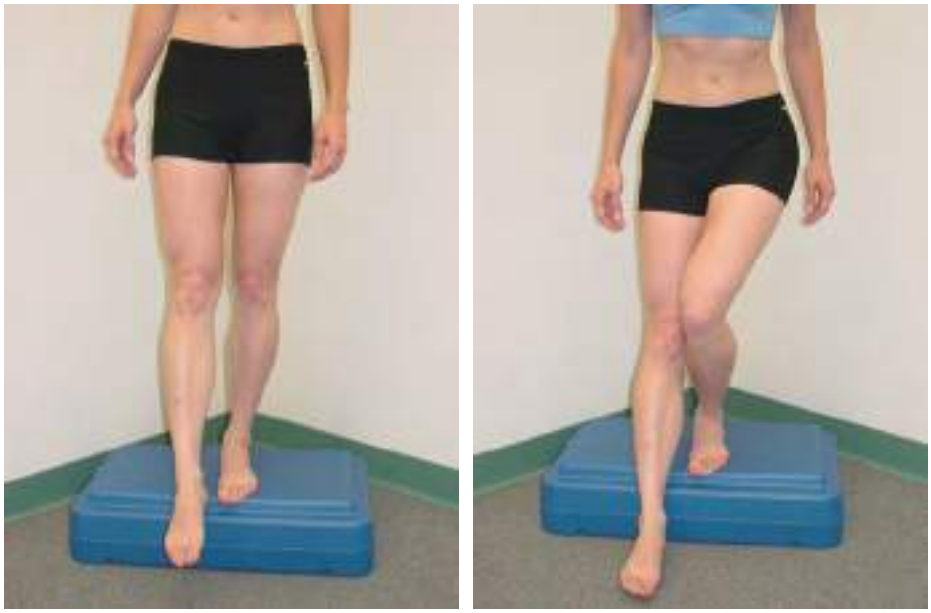

Figure 22-27 Assessment of lower extremity dynamic control. The patient slowly lowers herself with the extremity of interest and touches the heel to the floor without transferring weight to the descending limb. This patient shows medial collapse of the knee (excessive femoral adduction and medial [internal] rotation).

are occurring from the foot upward or from the pelvis downward. If the primary cause of the abnormality is identified, the correct treatment can be applied (i.e., proximal control through the hip versus distal control through the foot).

Additional Tests. Depending on the findings of the assessment of lower extremity alignment and dynamic function, the clinician may require additional information to formulate a hypothesis about the cause of the posture or motion abnormalities. The following tests may be useful:

- *Muscle testing of the hip lateral (external) rotators, abductors, and hip extensors:* If excessive dynamic medial rotation and/or adduction of the femur is observed during the dynamic assessment and muscle weakness is suspected, muscle performance testing of the hip abductors, lateral rotators, and extensors is warranted.
- *Assessment of hip range of motion:* Hip range of motion should be evaluated because restricted lateral rotation range of motion can bias a patient into a medial rotation position. Tightness of the hip flexors also can create a medial rotation bias. Hip flexor tightness can be assessed using Thomas's test, as described previously.
- *Craig's test of femoral anteversion:* Excessive femoral anteversion can contribute to medial (internal) rotation of the femur and can have a significant influence on the patellofemoral joint. Craig's test is performed with the patient prone and the knee flexed to 90°. The examiner palpates the posterior aspect of the greater trochanter of the femur, and the hip then is passively rotated medially and laterally until the greater trochanter reaches its most lateral position (Figure 22-28). The degrees of anteversion can be estimated based on the angle of the lower leg with the vertical. Normal femoral anteversion is 15°. It should be noted, however, that the measurement error with Craig's test is approximately 12°, so care must be made in the interpretation of findings.[141]
- *Foot evaluation:* If subtalar joint pronation is identified as a potential contributor to faulty lower extremity mechanics, the foot should be examined closely for fixed, bony deformities (e.g., rearfoot varus, forefoot varus), muscle tightness (e.g., gastrocnemius and soleus), and weakness of dynamic stabilizers (e.g., tibialis posterior and peroneal muscles).

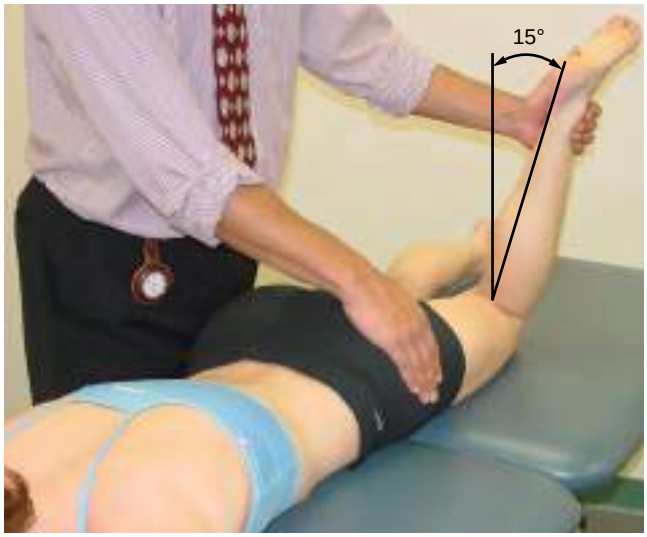

Figure 22-28 Craig's test of femoral anteversion. The examiner palpates the greater trochanter of the femur and rotates the femur internally and externally until the greater trochanter is at its most laterally prominent position. The angle of anteversion is estimated by measuring the angle created by the tibial shaft and a vertical line. Normal femoral anteversion is approximately 15°.

DIAGNOSTIC IMAGING

Basic Radiographic Methods

The anteroposterior (AP) view is used to evaluate the patella for any fracture or bipartite configuration and for gross positional changes, such as dislocation or abnormalities of patella height. Asymmetry of the femoral condyles may indicate abnormal femoral torsion or femoral neck anteversion. A 30° knee flexion, weight-bearing, posteroanterior (PA) view is most important for evaluating joint space and assessing for evidence of osteoarthritis.

Radiographs for Patellofemoral Pain

- Anteroposterior view in extension
- Anteroposterior view in 30° flexion
- Lateral view in full extension
- Lateral view in 30° flexion
- Axial view in 45° flexion
- Tangential view

The lateral view in full extension and at 30° knee flexion is used to determine patellar height and the patella's relationship to the trochlea. At full extension, the lateral view should show the distal articular surface of the patella just at the center of the trochlea. Other authors have proposed reliable methods for assessment of patella alta and patella baja.[81,142]

The patellofemoral joint also is visualized on an axial or tangential view. The axial view describes the parallel relationship of the x-ray beam with respect to the axis of the anterior tibia, whereas the tangential view describes the perpendicular relationship of the x-ray beam to the joint surfaces.[143] Both of these methods provide cross-sectional information about the relationship of the patella to the trochlear groove.[141] Overall, the most useful axial radiograph is the simple 30° or 45° knee flexion axial view. It is most important to ensure an accurate, reproducible 30° or 45° flexion view. A wooden leg holder with pins at the desired flexion angle is helpful.

For reproducible tangential views, certain requirements must be met. The x-ray beam and x-ray plate must be perpendicular to prevent distortion.[143,144] Views with the knee flexed more than 45° may be used[141,143,145] but are much less helpful. The position of potential maximum instability is 0° to 30°, but this position is technically difficult to capture on an axial radiograph.[146,147] For the most reliable and reproducible results, 45° seems to be the preferred position.[148] Some authors contend that tangential projections throughout the range (i.e., 30°, 60°, and 90°) are vital to the assessment of dynamic tracking of the patella.[146,147]

Computed Tomography

CT offers the advantage of a specific, definable plane. In general, CT is best performed using a midpatella transverse image, including the posterior condyles of the femur. This view enables the clinician to understand the relationship of the articulating midportion of the patella with its reciprocal portion of the trochlea at any degree of knee flexion. Midpatella transverse images through the posterior condyles with the knee flexed at 0°, 15°, 30°, and 45° provide an excellent depiction of how the patella enters the trochlea during flexion (Figure 22-29). The images may be taken with the quadriceps contracted or relaxed.

Magnetic Resonance Imaging

Early MRI had limited value in the evaluation of patients with PFP. The use of MRI was prohibitive, based on time and expense and on the quality and usefulness of the information obtained about patella position and tracking. More recently, however, CT and MRI have been used to image the patellofemoral joint during active or dynamic flexion and extension activities.[39,118,149,150] Kinematic and conventional modes of MRI of the patellofemoral joint offer advantages over CT in that they do not require radiation, and they allow depiction of important passive and active soft tissue stabilizers of the patellofemoral joint.[39,118,149] It has been suggested that dynamic or kinematic MRI, which allows assessment of the contribution of activated muscles and other soft tissue structures, is more sensitive than static imaging for demonstrating patellofemoral alignment and tracking abnormalities.[39] Statistically significant differences in patella tracking patterns and imaging parameters (e.g., patella tilt angle, bisect offset, lateral patella displacement) between active

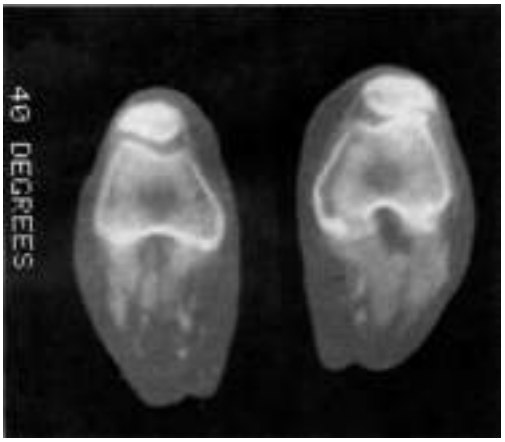

Figure 22-29 CT scan of lateral patella tilt and displacement with the knee in 40° flexion. Precise midpatella transverse CT images at 0°, 15°, 30°, and 45° knee flexion give an accurate impression of patella alignment. (From McConnell J, Fulkerson J: The knee: patellofemoral and soft tissue injuries. In Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 709, Philadelphia, 1996, WB Saunders.)

and passive knee extension have been demonstrated by Brossmann et al.[149] To date, constraints have been encountered in the form of image acquisition time (i.e., 0.5-1 images/sec).[39,118,149] The use of echoplanar MRI in the future may dramatically reduce image acquisition time and greatly improve resolution, allowing images of moving or changing structures to be acquired at near-real-time rates of 10 to 16 frames/sec.[151]

The use of quantitative and semiquantitative scoring of cartilage using MRI has grown in recent years. Several investigators have explored patellar cartilage compositional properties in vivo, quantified through T1rho or T2 relaxation time mapping, delayed gadolinium-enhanced MRI of cartilage (i.e., dGEMRIC), or sodium imaging.[152–156] These studies have generally found evidence of disruption of the normal biochemical composition of the articular cartilage in persons with PFP and patellofemoral joint osteoarthritis. Cartilage T1rho and T2 relaxation mapping allows for identification of prearthritic changes and has been shown effective at predicting future development of cartilage lesions.[152] However, challenges with high cost, long MRI scan times, and postprocessing time burdens have remained as critical barriers to widespread clinical adoption of these methods.

Semiquantitative scoring systems also have been described for morphological features of patellar cartilage and surrounding tissues. Specialized scoring systems designed expressly for patients following ACL injury or cartilage repair interventions, as well as those with primary knee osteoarthritis, have been described.[157–161] These scoring systems generally include categorical variables for various morphological features (e.g., cartilage lesions, meniscal tears, bone marrow edema) and are scored in several anatomical subcompartments (including patella and trochlea). It should be noted that these scoring systems are insensitive to incremental worsening of cartilage before lesion development, often limited by scores of "normal" or "increased signal inhomogeneity." However, once a lesion is present, there are several categorical levels to describe the lesion. Although these scoring systems are not designed for subtle compositional changes associated with PFP, they have been widely studied and provide valuable disease severity metrics for patients with advanced disease.

Bone Scan

A bone scan can reveal whether true intraosseous dysfunction is present and may localize the source of pain. A positive bone scan result after knee trauma objectifies the problem. It may even demonstrate whether there is more activity proximally or distally in the patella and may reveal a problem in the trochlea or elsewhere. Dye et al.[162] have been particularly influential in emphasizing the dynamic function of bone in PFP and the usefulness of following this with bone (radionuclide) scans.

CONSERVATIVE (NONOPERATIVE) TREATMENT

The treatment of PFP should be dictated by objective data obtained through a thorough examination. Treatment decisions also should be based on a solid scientific and biomechanical rationale. Once the examination has been completed, data should be compiled and a hypothesis formulated regarding the cause of the pain. The clinician should attempt to classify patients based on whether the suspected mechanism is a result of local patellofemoral joint dysfunction, lower quarter dysfunction, or overuse. Treatment decisions should focus on the identified impairments.

Treatment Classification for Patellofemoral Pain Based on Mechanism

- Local patellofemoral joint dysfunction
- Lower quarter dysfunction
- Overuse

Patellofemoral Joint Dysfunction

Specific treatment strategies for patellar malalignment and/or altered patellofemoral joint mechanics should be based on identified causes. As mentioned previously, possible contributing factors are bony and structural abnormalities, tightness of lateral structures, decreased patella mobility, and quadriceps muscle weakness. From a rehabilitation standpoint, little can be done to correct bony deformities. Although the influence of the Q angle can be minimized through the interventions described later in this chapter, conditions such as patella alta, trochlear dysplasia, femoral anteversion, and a laterally displaced tibial tuberosity are likely to require surgical intervention.

Tightness of Lateral Structures

If tightness of the lateral retinaculum is found to be contributing to ELPS or lateralization of the patella, treatment interventions should include soft tissue mobilization techniques (e.g., passive stretch, transverse frictions, deep tissue massage) to increase extensibility of the retinaculum. Soft tissue techniques in the area of the ITB and its interdigitation with the lateral retinaculum may prove useful (Figure 22-30). Because the ITB is a very dense, fibrous tissue, some clinicians question whether this structure can be stretched; however, longitudinal deep tissue massage may facilitate the breaking up of adhesions between the ITB and the overlying fascia.

Stretching of the tensor fascia lata also should be considered, because this muscle can influence the tension in the ITB (Figure 22-31). Also, patellar mobilization and patellar taping techniques (discussed in a later section) can be used for passive stretching of the lateral

Figure 22-30 Soft tissue techniques in the area of the iliotibial band and its interdigitation with the lateral retinaculum may prove useful for increasing patella mobility. The arrow indicates the line of force application.

structures. Low-load, prolonged passive stretching (L3D technique) is preferred so as to take advantage of the creep effect of soft tissue.

Decreased Patellar Mobility

Patellar oscillatory mobilization techniques combined with passive stretching should be performed to improve patellar mobility superiorly and inferiorly, as well as medially and laterally (see Figure 22-31). If the patella lacks normal mobility, forces may be concentrated in localized areas. The most common reasons for reduced patella mobility are prolonged immobilization, postoperative scarring, and quadriceps tightness.

When oscillatory mobilization techniques are performed, care should be taken to prevent excessive patellofemoral joint compression. To facilitate mobilization of the patella, the knee should be in extension or only slightly flexed (Figure 22-32). If the knee is flexed beyond 20°, the patella becomes seated within the trochlear groove which limits mobility of the patella.

Clinical Note

Generally speaking, an inferior glide of the patella facilitates knee flexion, whereas a superior glide of the patella facilitates knee extension. Mediolateral patellar mobilization restores the normal patella translations that occur during knee flexion and extension.

Quadriceps Muscle Weakness or Inhibition

Rehabilitation of the extensor mechanism continues to play a significant role in the treatment of PFP. With quadriceps muscle inhibition, pain and swelling must be controlled before a quadriceps exercise program is initiated. Pain modalities (e.g., transcutaneous electronic stimulation [TENS]), as well as methods to minimize effusion (e.g., ice, electrical stimulation), should be used as necessary.

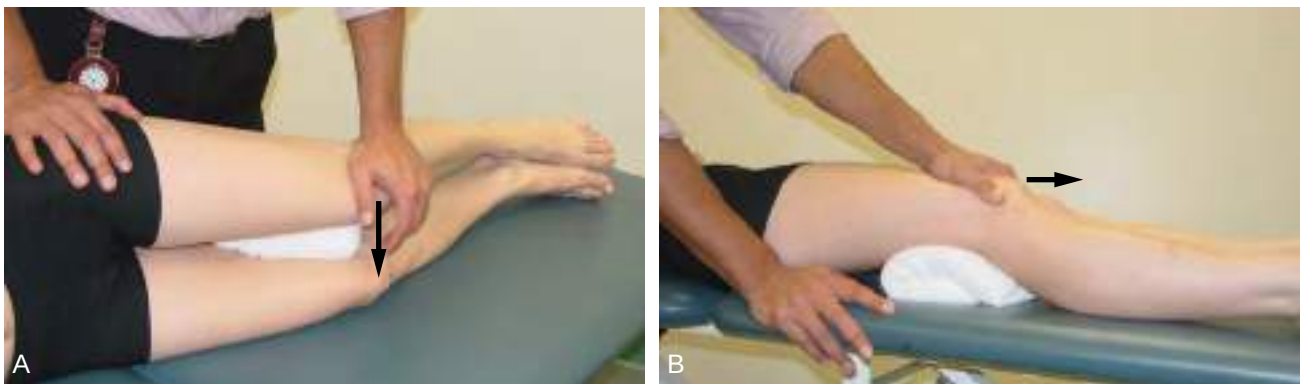

Figure 22-32 Patellofemoral joint mobilization techniques. Examples of medial glide (**A**) and inferior glide (**B**). Care should be taken to prevent direct joint compression. The arrows indicate the lines of force application.

As mentioned previously, the treatment of PFP using therapeutic exercise traditionally has focused on restoring dynamic patella stability through strengthening of the VMO. Such clinical practice is based on the assumption that the VMO is disproportionately weak relative to the VL, even though the strength of the VMO cannot be quantified in vivo.

Theories on VMO Strengthening. The concept of VMO strengthening is based on the belief that the VMO can be selectively recruited, independent of the VL, through various exercises.[98,134,163] The most common activities that have been postulated to facilitate VMO strengthening are various quadriceps muscle exercises (e.g., straight leg raises, isometric quadriceps sets, terminal knee extension), hip adduction, and medial tibial rotation.

A review of 20 existing EMG studies revealed that altering lower limb alignment or adding co-contraction through hip adduction does not preferentially enhance VMO activation relative to the VL.[164] This finding suggests that *isolated* recruitment of the VMO does not occur with exercises that are commonly prescribed for the treatment of PFP and that selective strengthening is unlikely. Even if greater EMG activity could be elicited in the VMO relative to the VL, the magnitude of VMO contraction would have to be at least 60% of maximum to stimulate hypertrophy.[165] As such, it appears that isolated recruitment or strengthening of the VMO through selected exercises may not be a realistic goal and that any emphasis on selective strengthening of the VMO most likely translates into a general quadriceps muscle strengthening effect.[166]

General Quadriceps Muscle Strengthening. Convincing evidence indicates that improving quadriceps muscle strength is an important aspect of treatment for PFP. For example, a study by Natri et al.[167] revealed that restoration of quadriceps muscle strength was a significant predictor of improved long-term outcomes (i.e., 7-year follow-up). Furthermore, work by Powers et al.[168] suggests that enhanced locomotor function in individuals with PFP is associated with increased torque of the quadriceps femoris muscle, which lends support to the concept of strengthening as a useful treatment option. A systematic review of the literature related to quadriceps strengthening in persons with PFP concluded that there was strong evidence that isolated quadriceps strengthening was more effective in reducing pain and improving function than education alone.[169]

Despite the apparent benefits of quadriceps muscle rehabilitation in patients with PFP, the mechanism by which strengthening improves PFP symptoms and functional ability has not been fully established. However, data provided by Chiu et al.[170] suggest that quadriceps strengthening increased patellofemoral joint contact area. An increase in contact area could reduce patellofemoral stress and therefore pain.

The goal of the therapeutic exercise program should be to facilitate quadriceps muscle strength while minimizing patellofemoral joint stress. Clinicians can benefit from an understanding of the biomechanics of weight-bearing and non–weight-bearing exercises, two methods commonly used to strengthen the knee extensor mechanism.

Weight-Bearing versus Non–Weight-Bearing Exercises. During non–weight-bearing knee extension (i.e., resistance applied at the ankle), the amount of quadriceps muscle force required to extend the knee steadily increases as the knee moves from 90° to full knee extension.[166] This increase in force is attributed to a decrease in mechanical advantage of the knee extensor mechanism.[171] In addition to the increase in quadriceps muscle force as the knee extends, the patellofemoral contact area steadily decreases. This combination of increased quadriceps muscle force and decreased contact area during terminal knee extension results in greater patellofemoral joint stress and pressure than what is seen with greater knee flexion angles in which the quadriceps muscle force is not as great and the contact area is larger.[166]

Conversely, during weight-bearing exercises (e.g., squatting), the quadriceps muscle force is relatively minimal when the knee is extended and steadily increases as the knee flexes.[166] The increase in force is distributed over a greater surface area, because the contact area also increases as the knee flexes. The greater contact area prevents excessive patellofemoral joint pressure during flexed knee activities.[166]

Based on the biomechanics of the patellofemoral joint, non–weight-bearing exercises such as straight leg raises and terminal knee extensions should be avoided, as should weight-bearing activities such as deep squatting. These recommendations are supported by the work of Steinkamp et al.[172] and Powers et al.,[173] who reported that greater patellofemoral stress was evident during a weight-bearing exercise (leg press) at 48° to 90° knee flexion and during a non–weight-bearing exercise (knee extension) at 48° to 0° knee flexion (Figure 22-33).

Quadriceps muscle strengthening apparently can be performed safely throughout the 0° to 90° knee flexion range by varying the mode of exercise. Both weight-bearing and non–weight-bearing exercises can be used to promote quadriceps muscle hypertrophy; therefore a comprehensive strengthening program probably should incorporate both types so that strengthening can be performed throughout a large arc of motion. The data of Steinkamp et al.[172] and Powers et al.[173] can be used as a general guideline, but the exact exercise prescription will vary from patient to patient.

Electromyographic Biofeedback as an Adjunct to Strengthening. EMG biofeedback can be a valuable tool for helping the patient facilitate contraction of the quadriceps muscle. For example, patients can be instructed to monitor their quadriceps muscle activity while performing functional tasks such as step-downs and partial squats. The goal is to provide patients with immediate feedback to increase general quadriceps muscle recruitment, especially during eccentric contractions (Figure 22-34). Although comparison of raw EMG signals between muscles (i.e., to document "muscle imbalance") is not appropriate,[166]

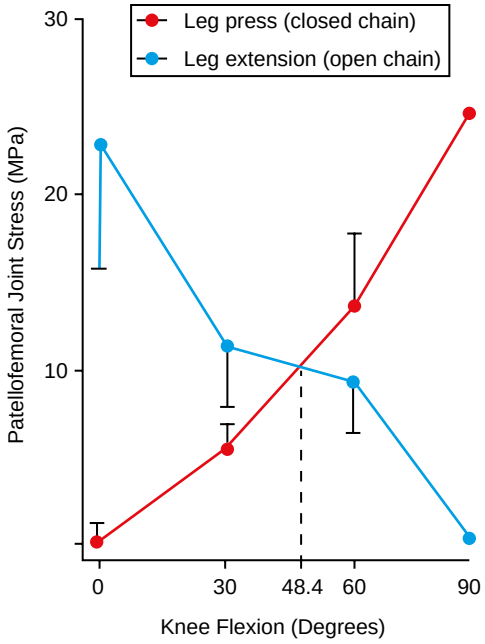

Figure 22-33 Patellofemoral joint stress as a function of knee angle during open- and closed-chain activities. The greatest stresses occur at high knee flexion angles during closed-chain activities and at low knee flexion angles during open-chain activities. (From Steinkamp LA, Dillingham, Markel MD et al: Biomechanical considerations in patellofemoral joint rehabilitation, *Am J Sports Med* 21:438-444, 1993.)

Figure 22-34 Electromyographic biofeedback can be used to facilitate quadriceps recruitment during functional tasks.

EMG biofeedback can be a useful tool for assessing general quadriceps muscle activation.

Taping and Bracing as an Adjunct to Strengthening. External patellar supports are commonly used in the management of PFP, typically as an adjunct to other treatment methods (e.g., strengthening). The primary goal of patellofemoral joint bracing and taping is to centralize the patella within the trochlear groove, thus improving patellar tracking.[174] The various patellofemoral braces on the market have used a number of methods to improve patellar tracking, including neoprene sleeves with patellar cutouts, lateral buttresses, air bladders, and various Velcro straps (Figure 22-35). However, the clinical effectiveness of patella stabilizing braces is questionable.[175,176] In contrast, the patellar taping technique described by McConnell[130,134] has been shown to be an effective option to reduce pain (Figures 22-36 and 22-37). In this protocol, rigid strapping tape is applied to the patella to correct malalignment (as determined by clinical evaluation). Various clinical studies support the therapeutic success of use of patellar taping to reduce pain in conjunction with other treatment methods.[177–179]

The fact that the various forms of external patellar supports have proved to be effective in reducing symptoms immediately after application[180–182] indicates that such orthoses have a mechanical effect on the patellofemoral joint. Although the literature supports the premise that bracing and/or taping reduces pain, the mechanism underlying this pain reduction does not appear to be related to changes in patellar tracking. For example, kinematic MRI studies have shown that patellar bracing has little effect on patellar tracking.[183,184] However, alternative mechanisms have been proposed. Using high-resolution MRI, Powers et al.[185] reported that patellar bracing had only a small influence on patellar alignment (i.e., lateral tilt and displacement); however, large increases in contact area between the patella and the trochlear groove were observed (Figure 22-38).

Figure 22-35 Patellofemoral joint brace used to control excessive lateral patella tracking (True-Pull, DJO Global, Inc., Vista, CA). The proximal and inferior straps attached to the lateral buttress are designed to limit lateral patella displacement.

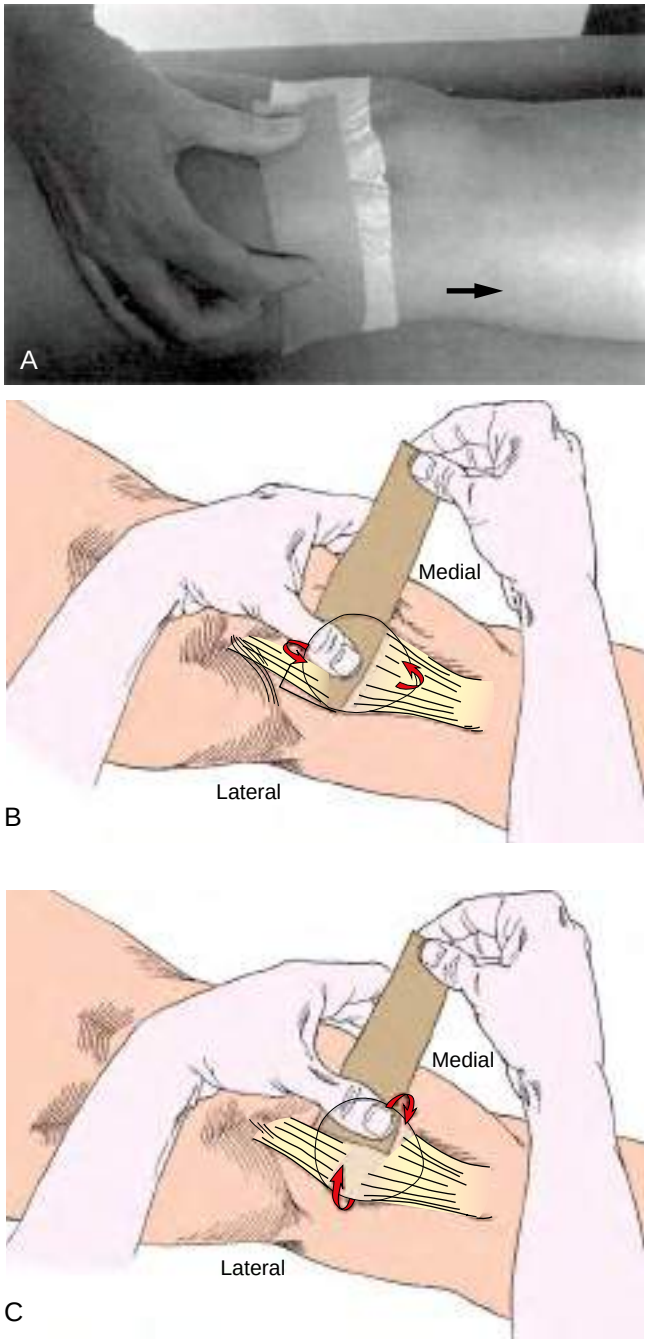

Figure 22-36 Correction of posterior and lateral tilt of the patella. **A** and **B,** To correct an inferior tilt, tape is placed on the superior half of the patella. An anteroposterior force is exerted on the superior aspect (the base) of the patella to lift the inferior pole (the apex) up and away from the infrapatellar fat pad. **A** and **C,** To correct a lateral tilt, anteroposterior pressure is placed on the medial half of the patella to lift the lateral border away from the femur while the tape is started at the midline of the patella and pulled medially. (From McConnell J, Fulkerson J: The knee: patellofemoral and soft tissue injuries. In Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 715, Philadelphia, 1996, WB Saunders.)

From a biomechanical standpoint, any increase in contact area distributes the forces over a greater surface area, thereby reducing joint stress (i.e., force per unit area). The results of the study by Powers et al.[185] suggest that changes in patellar alignment, by themselves, may not be responsible

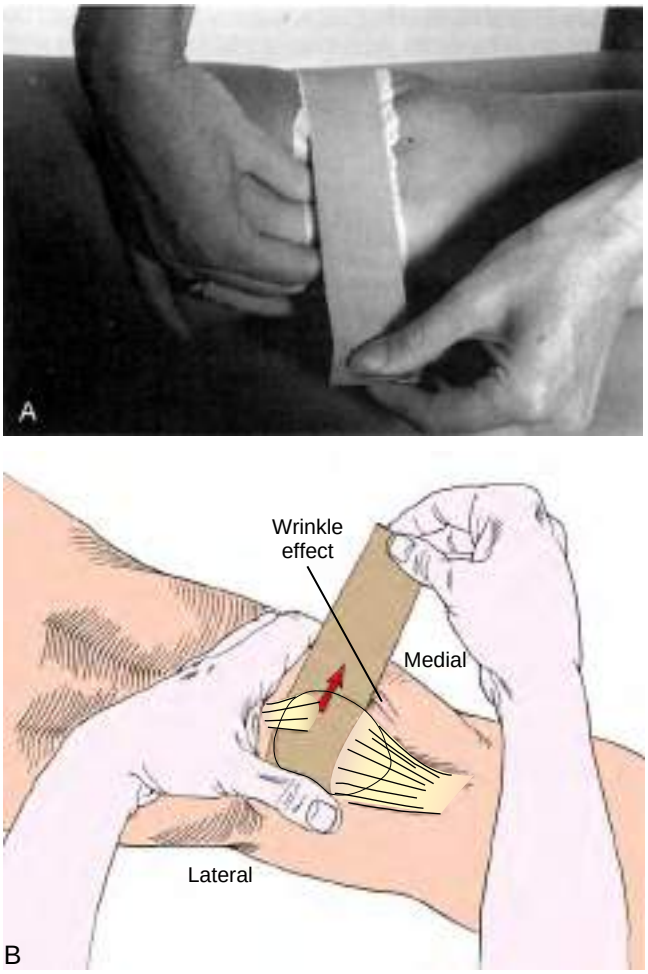

Figure 22-37 Correction of patella glide (excessive lateral tracking). **A** and **B,** Tape is placed just lateral to the lateral border of the patella and is used to glide the patella medially in the femur. The clinician's thumb helps glide the patella medially, if necessary, while the fingers pull the skin toward the patella, creating a wrinkle effect. Tape is anchored on the posteromedial aspect of the medial condyle. Tape is not brought into the popliteal fossa, because this may irritate the skin in this area. (From McConnell J, Fulkerson J: The knee: patellofemoral and soft tissue injuries. In Zachazewski JE, Magee DJ, Quillen WS, editors: *Athletic injuries and rehabilitation,* p 715, Philadelphia, 1996, WB Saunders.)

for the alleviation of pain with bracing. A follow-up study by Powers et al.[186] confirmed this hypothesis. Biomechanical modeling methods were used to demonstrate that application of a patellofemoral brace resulted in a reduction in both pain and patellofemoral stress in individuals with long-standing symptoms.[186] The reduction in stress was reported to be related to an increase in the patellofemoral joint contact area (as determined with MRI).

The literature makes it clear that external patellar supports can offer pain relief. This is significant from a clinical standpoint, because pain may influence quadriceps muscle inhibition. If the goal of conservative treatment of PFP is to strengthen the extensor mechanism, pain reduction is likely to facilitate recruitment of the quadriceps muscle. Such a reduction in pain allows for adequate exercise progression and subsequent muscle hypertrophy.

Lower Extremity Dysfunction

In considering a treatment approach for abnormal lower extremity motions, it is important that the clinician keep in mind that altered mechanics can be driven from the foot upward or from the hips and pelvis downward. The ultimate goal in treatment of the lower extremity is to restore normal dynamic alignment and function. In many cases, interventions should be applied to both ends of the kinetic chain for maximum benefit.

Clinical Note

Treatment of patellofemoral pain syndrome involves not only treating the knee but also addressing leg and foot problems and especially balanced strength and endurance of the muscles of the hip.

Abnormal Foot Pronation

The decision of whether to use foot orthotics to control abnormal foot pronation should be based on a careful examination of the patient's gait or running pattern (or both). Patients who exhibit abnormal pronation and corresponding medial rotation of the tibia and femur are candidates for orthotics. If the patient shows excessive pronation but that motion does not appear to be transferred proximally (i.e., it is absorbed at the talocrural joint), orthotics may not be indicated. The clinician may want to consider a temporary orthotic to evaluate whether this approach is effective.

There is mixed evidence regarding the use of orthoses either in isolation or in combination with an exercise-based program for patients with PFP. However, at least one randomized, controlled trial[187] supported the short-term use of orthoses over placebo. The orthoses evaluated in this study were prefabricated, commercially available products and were noted to result in significant improved pain and function at 6 weeks. However, no differences were noted between the group receiving orthoses and the placebo group at 12 weeks or 1 year. These data are consistent with the findings of Eng and Pierrynowski,[188] who found that both an orthotic group and a control group had significant reductions in pain after 8 weeks but that the orthotic group had significantly greater pain reduction than the control group. A series of studies have evaluated the predictors of success for orthoses in persons with PFP with varying results.[189–192] A systematic review on this topic concluded that foot orthoses for the treatment of PFP was most effective in older patients and those with greater forefoot valgus and rearfoot eversion, whereas exercise was more effective for younger patients.[193]

Abnormal Hip Medial Rotation and Adduction

If the femur is seen to "collapse" into medial rotation and/or adduction during the dynamic examination and this motion appears to originate from the hip or pelvis (as opposed to being influenced by tibial rotation), strengthening of the lateral rotators and abductors of the hip may be indicated. With excessive medial rotation, the emphasis should be on the gluteus maximus, because this muscle is optimally suited to control medial rotation of the femur. The posterior fibers of the gluteus medius and the deep rotators also contribute to dynamic stability of the femur; however, their lateral rotation torque capability at the femur is small in comparison. With excessive abduction, the focus should be on the gluteus medius. The upper fibers of the gluteus maximus also have an abduction component and should be addressed if excessive adduction is observed.

There is growing evidence that hip muscle strengthening is an important component of the rehabilitation plan for patients with PFP.[194–199] Two studies reported that isolated hip muscle and core strengthening resulted in superior pain relief in the short term and earlier pain relief in comparison to an exercise program focused on isolated knee muscle strengthening.[195,197] A separate randomized, controlled trial demonstrated that combining hip muscle strengthening along with knee muscle strengthening resulted in longer term reductions in pain and improved function at 1 year in comparison to a program focused solely on knee muscle strengthening.[194] Furthermore, Khayambashi et al.[199] reported that hip strengthening was superior to quadriceps strengthening in females with PFP, although it should be noted that both groups improved with respect to pain and function compared with baseline.

If hip weakness and altered hip motion are observed during the examination, patients should be placed on an exercise program that focuses on hip and pelvis stability during the performance of active lower extremity movements. According to Nadler et al.,[200] it is important to establish satisfactory lumbopelvic control to ensure that the proximal attachment sites for the hip abductors and lateral rotators are stable. Mascal et al.[201] outlined a three-phase treatment progression to enhance proximal control:

Figure 22-39 Non–weight-bearing exercise with band resistance to isolate the gluteus maximus. The hip should be extended, abducted, and laterally (externally) rotated.

Figure 22-40 Side-lying (clam) exercise to strengthen the gluteus medius. Note that the hip rotates laterally (externally) during abduction.

Treatment to Enhance Hip Control (Phase 1: Non–Weight-Bearing Hip Activation). Before dynamic weight-bearing strengthening of the hip musculature is started, patients should perform non–weight-bearing exercises with band resistance to isolate the gluteus maximus (Figure 22-39) and gluteus medius (Figure 22-40). When performing activation exercises for the gluteus medius, the patient must take care to minimize the contribution of the tensor fascia lata, because contraction of this muscle contributes to medial rotation of the lower extremity. Once the patient can isolate the muscles of interest while doing non–weight-bearing exercises and maintaining a stable pelvis, progression to weight-bearing strengthening can begin.

Treatment to Enhance Hip Control (Phase 2: Weight-Bearing Hip Strengthening). Weight-bearing exercises should include exercises performed in bilateral and single-limb stance. At this time, the patient should be introduced to the concept of a *hip strategy*. This involves doing exercises with increased hip flexion and a forward trunk lean. During a lunging exercise for example, increasing the forward trunk lean has been reported to increase the hip extensor torque along with activation of the gluteus maximus (Figure 22-41).[202] In addition, squat exercises should be performed with forward trunk posture. A band placed above the knees during squatting will facilitate the action of the gluteal muscles by adding concurrent resistance to hip abduction and lateral (external) rotation (Figure 22-42). With all exercises, care must be taken to ensure that the knee does not move forward or medial to the toes.

Figure 22-41 To increase the demand on the hip extensors, the forward lunge exercise should be performed with the trunk in a forward position.

Figure 22-42 A TheraBand can be used to facilitate hip abductor and external rotator muscle action during the squat exercise. To increase hip extensor demand, the trunk should be in the forward position.

If the patient has a difficult time maintaining proper lower extremity alignment during the initiation of weight-bearing exercises, femoral strapping can be used to provide kinesthetic feedback and to augment muscular control and proprioception (Figure 22-43). Having patients perform weight-bearing exercises in front of a mirror can be useful. Also, taping or bracing of the patellofemoral joint may be used if pain is limiting the patient's ability to engage in a meaningful weight-bearing exercise program.

Treatment to Enhance Hip Control (Phase 3: Functional Movement Training). Once the patient can perform weight-bearing strengthening exercises without pain, exercises can be progressed to become more dynamic and functional. Patients should be encouraged to return to their sport or activity gradually once they can achieve satisfactory dynamic control. With competitive or recreational athletes who will be returning to full participation, plyometric training (i.e., jump training) should be considered as part of this transition period.

Figure 22-43 Femoral strapping (SERF Strap, DJO Global, Inc., Vista, CA) can be used to improve lower extremity control and kinematics during the rehabilitation program and functional activities.

Abnormal Gait Deviations

Facilitation of normal gait function is an essential component of the overall treatment plan. This is particularly important for the athlete (especially runners), in whom even a slight gait deviation can be exaggerated and can lead to injury at other joints. Clinicians should pay particular attention to reversal of the **quadriceps avoidance gait pattern** (i.e., walking with the knee extended or hyperextended). Because knee flexion during weight acceptance is critical for shock absorption, this key function must be restored to prevent the deleterious effects of high-impact loading.

As noted previously, the primary causes of quadriceps avoidance are pain, effusion, and quadriceps muscle weakness. As these components are addressed in other aspects of treatment, the clinician should keep in mind that resolution of symptoms may not readily translate into a more "normal" gait pattern. This is particularly evident in a patient with long-term pain and dysfunction. Movement patterns can be "learned," and the patient may need to be "reeducated" with respect to key gait deficiencies. EMG biofeedback can be an effective tool for this purpose, because visualization of quadriceps muscle activity can augment the reversal of the quadriceps avoidance gait pattern.

Overuse

A lack of significant findings on the physical examination (e.g., normal patella mechanics, normal lower extremity function) suggests that the source of symptoms may be related to overuse. This is typically the case in athletes. The treatment of choice for these individuals is control of symptoms and/or effusion, combined with rest and activity modification. Muscle stretching and bracing of the patella also can be used if indicated. Reducing the repetitive forces applied through the joint allows healing of involved structures. Return to activity should be gradual and closely monitored. The training regimen should be evaluated for obvious errors, such as increasing exercise intensity too quickly and not allowing adequate time for recovery. When extended time-off is required, quadriceps and hip muscle strength should be maintained through careful application of resistive exercises (see the previous discussion).

SURGICAL CONSIDERATIONS

Conservative treatment for PFP may fail, even with the best therapy, medical management, bracing, and modification of activity. Some mechanical disorders of the knee extensor mechanism are too severe to respond fully to nonoperative treatment. Conditions that may resist nonoperative treatment include persistent patellar tilt, with or without chondrosis (i.e., cartilage deterioration) or subluxation; pathological plica; infrapatellar contracture; severe posttraumatic chondrosis-arthrosis (cartilage and joint deterioration); postoperative neuroma or scar pain; and recurrent dislocation. A tendency has arisen to use lateral release to treat any persistent anterior knee pain problem, rather than identifying a specific procedure to correct the underlying abnormality. This approach is not acceptable. For example, lateral release is appropriate only to relieve objectifiable tilt of the patella when nonoperative measures have failed.

Patellofemoral Joint Problems Requiring Surgery

- Persistent patella tilt
- Pathological plica
- Infrapatellar plica
- Severe posttraumatic chondrosis/arthrosis
- Postoperative neuroma
- Scar pain
- Recurrent dislocation

Obtaining a complete history before surgery is imperative. The clinician should determine what caused the onset of pain or instability. Was there a history of trauma, and is there any suggestion of generalized arthritis, referred pain, underlying structural deformity, or secondary pain? The clinician also should gain a feeling for the patient's personality (patients with dependent personalities are less likely to improve). If the onset of pain is spontaneous, the patient is more likely to have an underlying structural malalignment. The clinician should establish whether the primary problem is instability of the patella (i.e., subluxation or dislocation) or pain. If the problem is primarily pain, the clinician should determine whether it is more intra-articular or periarticular.

The physical examination is similar to that for a patient being evaluated for nonoperative treatment; however, greater emphasis is placed on identifying the specific sources and mechanical origins of pain, impairment, and dysfunction that require surgical intervention and that have not responded to conservative management.[203,204]

The knee should be evaluated for evidence of patella tilt, skin change, surgical scars, excessive varus or valgus, and contracture. The peripatellar retinaculum, patellar tendon, distal quadriceps, and infrapatellar area must be examined closely for evidence of neuroma, pain, and contracture. All surgical scars, including arthroscopy portals, should be palpated for induration and tenderness. Running a thumbnail along the scar easily determines pain (which, if present, suggests a scar neuroma). If the patient has had previous surgery, direct palpation should be performed to determine whether a tender residual band of the lateral retinaculum is present. Patellar alignment should be evaluated actively and passively. The examiner should note if the patella tracks laterally and if the patella appears to be above the level of the trochlea (i.e., patella alta) with the knee extended. Hypermobility, as well as abnormalities of medial and lateral displacement, should be noted. In particular, the examiner should note apprehension upon medial or lateral displacement of the patella as indicators of pathological instability. The examiner should firmly press on the patella to determine whether pain occurs on compression that reproduces the patient's complaints of discomfort. Pain reproduced by compression suggests articular cartilage breakdown (i.e., chondrosis).

The examiner also should note the degree of knee flexion pain or crepitation, because this helps localize a painful articular lesion (proximal lesions are painful in flexion past 75° to 80°, whereas distal lesions are painful close to full extension). This distal lesion, sometimes only softening of the distal pole patella, is common in young women with chronic lateral patellar tracking in early knee flexion. This is a source of unrelenting pain in some and commonly is missed, because alignment of the patella further into flexion as the trochlea deepens is often normal.

Any evidence of tilt or subluxation should be noted. In particular, the clinician must attempt to elevate the lateral patella away from the lateral trochlea to determine whether tethering of the patella laterally is present. Any alteration of normal skin temperature should be noted, such as might occur with reflex sympathetic dystrophy. The surgeon must take into consideration all diagnostic imaging studies in determining the significance of tilt or subluxation.

At the conclusion of the preoperative evaluation, the clinician should decide whether surgical treatment offers the patient a reasonable hope of improvement. A specific, correctable problem that can be defined must be identified. Is it tilt? Is arthrosis or chondrosis present, and if so, where is the lesion located? Is there a specific tender band of retinaculum or patella tendon? Does the patella track laterally so that the extensor mechanism needs to be realigned (in addition to lateral release)? Is there any evidence of neuroma or scar pain from previous surgery? Is the pain related to malalignment, or is it posttraumatic pain?

Lateral Release

Specific indications exist for lateral retinacular release, and many patients with resistant anterior knee pain do not respond to lateral retinacular release but can benefit from other surgical procedures. Surgical release of the lateral retinaculum is used to reduce a pathological patellar tilt (greater than 12°) in an individual with anterior knee pain who has minimal evidence of articular degeneration (e.g., arthrosis) or subluxation. Lateral release is not an appropriate procedure for treating many patients with significant instability (i.e., subluxation or dislocation) of the patella–extensor mechanism. Lateral release has been (and occasionally still is) recommended to treat patellar subluxations; however, axial radiography, CT, and laboratory studies using a cadaver knee model have clearly shown that lateral release does not consistently relieve signs and symptoms of patellar subluxation.[14,205]

Lateral release is not generally effective in relieving pain related to articular degeneration of the patella.[206] Once the lateral facet of the patella has collapsed and degeneration is evident,[67] releasing the lateral retinaculum does about as much to relieve contact stress on the degenerated cartilage as releasing the medial collateral ligament of a patient with medial compartment knee arthritis.

The clinician must also recognize that a lateral release is unlikely to lead to any meaningful change in a normally aligned patella that has been severely traumatized (e.g., fracture, dashboard injury) unless the patient has some secondary retinacular contracture and resulting patella tilt that needs to be released. Finally, lateral release, when done for the wrong reason, can leave a patient with a debilitating medial patella subluxation.[207]

Persistent Patella Tilt

Some patients with pathological patella tilt, with or without chondrosis or subluxation, do not respond to nonoperative treatment. In these patients the appropriate surgical procedure is best determined after the extent and location of articular lesions have been considered and the knee has been evaluated for evidence of subluxation associated with the tilt. In short, tilt with minimal evidence of articular degeneration or subluxation usually responds well to lateral release alone.[14] A possible exception is a patient with chondral softening on the medial facet, because these patients may have greater contact pressure on soft cartilage after lateral release.

Postoperative rehabilitation is aimed at maintaining the mobility of the lateral structures by taping the patella

as soon as the sutures from the arthroscopy site have been removed and keeping the patella in the trochlea. Emphasis also must be placed on training of the gluteal muscles of the hip to minimize any increase in tension in an overactive tensor fascia lata and a tight ITB.

If grade 3 or grade 4 articular breakdown[208] is present on the lateral or distal medial facet in association with patellar tilt, an anteromedial tibial tubercle transfer (Trillat's procedure) is more effective than a lateral release,[209,210] particularly with any associated lateral patellar subluxation (Figure 22-44). If articular disease is not present but symptomatic subluxation is associated with patellar tilt, Trillat's procedure may be most appropriate when all nonoperative measures to control the instability have failed to provide adequate relief.[211]

Pathological Plica

Nonoperative treatment fails in some patients because of a persistent pathological plica. Most significant pathological plicae occur in the medial infrapatellar region and can be readily identified on clinical examination. To make this diagnosis, the clinician should be able to reproduce the patient's pain by palpating the plica. In most cases the plica is a prominent, palpable band. In our experience, arthroscopic excision of a pathological plica results in relief of pain in most patients. However, Broom and Fulkerson[212] noted that pathological plicae sometimes may be associated with patellar malalignment. In patients with plicae, therefore, the examiner should be careful not to overlook other sources of pain related specifically to malalignment.

Figure 22-44 Medial tibial tubercle transfer. A distal bone–periosteum hinge is left, and one screw is used to fixate the osteotomy. The transfer reduces contact stress on the patella while the extensor mechanism has a more medial orientation, thus reducing the likelihood of lateral patellar dislocation of subluxation. (From Scott WN: *Insall and Scott surgery of the knee,* ed 5, Philadelphia, 2012, Churchill Livingstone.)

Infrapatellar Contracture

Infrapatellar contracture may occur after trauma or surgery involving the anterior knee. Although classic patella baja may occur, some patients with more subtle infrapatellar contractures may have persistent pain with relatively little evidence of contracture. Only a careful, pointed physical examination can detect this. Such patients usually have rather diffuse retropatellar tendon pain that often can be aggravated by squeezing or palpating the infrapatellar tendon area. An associated tightness of the medial and lateral retinaculum usually is noted.

In the authors' experience, once conservative rehabilitation fails, this condition must be evaluated arthroscopically, and open release of the contracture then is performed, usually through a short lateral incision. In most cases, lateral release is necessary, which often reveals a dense, tight infrapatellar fat pad. Release of the fat pad allows the surgeon to tilt the patella gradually up onto its medial edge, perpendicular to the trochlea. Complete release of infrapatellar scars, meticulous hemostasis, and immediate postoperative knee mobilization to full flexion are imperative in these patients. The results generally are excellent in properly selected patients when adequate release and debridement are performed.

Posttraumatic Chondrosis or Arthrosis

Time is particularly important in the treatment of patients who have sustained trauma to the anterior knee. The clinician should remember that intraosseous homeostasis can take 18 months or longer after injury.[213] The clinician must carefully assess the degree of pain and whether the patient can reasonably tolerate a prolonged period of activity modification and supportive management to allow spontaneous homeostasis. However, it is impossible to know whether pain relief will be obtained after such a long period, and patients with more severe pain cannot always tolerate this much time without treatment. Supportive measures include repeated ice applications, nonsteroidal anti-inflammatory medications, bracing, taping, and reassurance. Exercising, particularly resisted knee extension, is counterproductive in some of these patients.

Once the decision has been made to operate, the problem is whether the patella can be salvaged. Arthroscopic examination and debridement allow the surgeon to evaluate the extent of chondral injury once all soft tissue and retinacular problems have been addressed. At the time of an initial arthroscopic procedure, any posttraumatic neuroma, indurate (painful) retinaculum or tendon, and

thickened plica or fibrillated articular cartilage should be excised. In most patients the lateral retinaculum need not be released unless a significant tilt aggravates the problem. Patellectomy is not commonly performed as the initial procedure, because many patients may benefit from soft tissue (i.e., retinacular) and articular (i.e., chondroplasty) debridement or patella realignment. If articular debridement has been performed, the clinician initially must avoid compression on the newly debrided area and must communicate with the surgeon to determine the site of the chondroplasty. Resurfacing of a severely damaged patella, sometimes in combination with an unloading tibial tubercle osteotomy, may be helpful in attempts to salvage the joint.[203]

If arthroscopic treatment fails, a decision should be made as to whether the articular cartilage is sufficient to allow transposition of the tibial tubercle (usually either medially, anteriorly, or both) to shift contact stress from damaged to healthy cartilage. In patients with extensive articular damage and intractable pain, patellectomy and patellofemoral resurfacing may be the only viable options. Resurfacing possibilities include autologous cartilage transplantation, allograft osteochondral transplantation, patellofemoral arthroplasty, and total knee replacement.

If healthy cartilage is present proximally on the patella, the tibial tubercle may be moved anteriorly. If the best remaining cartilage is proximal and medial, the patella should be moved anteromedially. Long-term results with this procedure have been favorable.[214] If the proximal patellar cartilage is severely damaged (as it often is after a dashboard injury), tibial tubercle anteriorization is less likely to be successful. In this case patellectomy or resurfacing may need to be considered.

Postoperative Neuroma or Scar Pain

A patient who has already had surgery and who complains of persistent pain that is different from the original pain may have a postoperative neuroma or painful scar. This is a clinical diagnosis, and it usually is not difficult to determine as long as the examiner is looking for it. The thumbnail test (running the dorsum of the thumbnail over each scar) elicits the sharp pain of a neuroma in most cases. The clinician must make sure that this is not a diffuse sensitivity, suggesting reflex sympathetic dystrophy. Patients with reflex sympathetic dystrophy are not surgical candidates and may require pain management programs, sympathetic blocks, or surgical sympathectomy.

Sensitive scar or neuroma can be relieved transiently in the office by injection of a local anesthetic (this confirms the diagnosis). Administration of corticosteroids in conjunction with the local anesthetic does not usually provide lasting benefit to patients with a neuroma. In general, if nonoperative management has failed and the patient demonstrates a localized focus of pain in a scar, excision of this painful segment of tissue may be curative.

Recurrent Patellar Dislocation

Recurrent patellar dislocation can be devastating to the patellar articular cartilage, and this condition generally warrants early surgery if nonoperative treatment fails to restore stable tracking of the patella. Each patellar dislocation may result in a shearing off of articular cartilage from the medial patella facet or lateral femoral trochlea. The cartilage may be stripped from the bone so that it cannot be replaced. Consequently, restoration of stable patella tracking is important, preferably before serious cartilage damage occurs.

After an acute patellar dislocation, any fragment of articular cartilage with bone attached should be replaced anatomically, generally using an open lateral release incision and eversion of the patella to expose its medial facet for reconstruction. Very fine absorbable sutures (8-0 or smaller) may help approximate the cartilage edges.

In the authors' experience, patellar stability is best restored using a lateral release and tibial tubercle transfer as described by Trillat et al.[215] and reviewed by Cox[211] when the patella is tracking laterally with an elevated Q angle or tibial tubercle–trochlear groove (TT-TG) measurement. Overzealous medial imbrication (i.e., overlapping of free edges) poses a substantial risk of increasing contact pressure on the medial patella facet (because the medial retinaculum is oriented so that its imbrication pulls the medial patella facet posteriorly as well as medially). If damage to the medial patella already is present after dislocation, anteromedial transfer of the tibial tubercle minimizes the load increase on the medial patella while reorienting the extensor mechanism medially to minimize and eliminate the risk of lateral patellar dislocation in patients with maltracking.

Tubercle transfer, however, should not be considered in patients with trochlear dysplasia who have normal tracking of the patella. It is also important to note whether the patient has patella alta, because this too predisposes the individual to patellar instability and therefore, should be corrected by slight distalization of the tibial tubercle at the time of tibial tubercle transfer. It is most important, however, to reiterate the importance of first exhausting conservative measures before undertaking any surgical intervention.

Clinical Note

Conservative treatment measures for patellofemoral problems should be exhausted before surgical intervention is contemplated.

In cases of involving minimum degrees of subluxation and minimal trochlear dysplasia, stability usually can be

Figure 22-45 Palpation of the medial quadriceps tendon–femoral ligament (MQTFL).

restored through specific advancement of the medial retinaculum, including the medial quadriceps tendon–femoral ligament (MQTFL) (see Figure 22-7), which interdigitates with the VMO. The MQTFL remnant can be easily palpated through a small incision after the VMO has been lifted off the patella (Figure 22-45).[216,217] In our experience, after dislocation, the MQTFL remnant usually heals and provides a satisfactory structure for advancement, such that formal tendon transfer reconstruction of the MQTFL is rarely indicated. Nonetheless, full MQTFL reconstruction sometimes is needed. This procedure is technically demanding; small errors in graft placement can lead to overload and even late destruction of the patellofemoral joint.[218] Tibial tubercle transfer should not be performed in a skeletally immature patient. Lateral release and careful MQTFL advancement, properly performed, should provide adequate stability in most cases.

SUMMARY

Surgical treatment can be extremely helpful in the management of patients with anterior knee pain resistant to nonoperative treatment. It is most important to direct surgical treatment specifically to the precise cause of the knee pain. Painful articular lesions should be debrided and unloaded, painful segments of the retinaculum or scar excised, alignment corrected, tilt relieved by lateral release, pathological plicae excised, and contractures released. Surgery should not be undertaken until the clinician has a clear concept of what needs to be corrected and the patient understands the risks involved and the potential benefits. The chosen surgical procedure requires appropriate postoperative management to optimize outcomes.

CHAPTER 23

Physical Rehabilitation after Total Knee Arthroplasty

DIANE M. HEISLEIN, ERIC O. EISEMON*

INTRODUCTION

The primary indication for total knee arthroplasty (TKA) is to relieve pain caused by severe arthritis.[1,2] Osteoarthritis (OA) of the knee is prevalent, with radiographic evidence of degenerative joint disease in approximately 50% of patients age 75 years or older.[3] Furthermore, symptomatic OA develops at a rate of 1% per year in patients with a mean age of 70 years. Risk factors associated with the development of knee OA include obesity, female gender, previous knee trauma, presence of hand OA, and older age.[4] TKA is an elective procedure that is indicated when the joint no longer functions satisfactorily because of advanced disease. Because of the aging of the U.S. population and the prevalence of OA, the demand for primary total knee replacements continues to rise each year.[5–11]

Rates of Total Knee Arthroplasty in the United States[5–11]

- In 2004, approximately 267,000 primary total knee replacements were performed.
- By 2010, this number had increased significantly to more than 600,000 primary total knee replacements.
- Demand for total knee replacements is expected to exceed 3 million by 2030.

Three key elements must be considered in the decision to proceed with TKA: (1) whether the patient has debilitating pain, (2) whether less invasive treatments have failed to reduce pain and maintain the patient's desired level of activity, and (3) whether the patient is medically suited to respond to surgery. Therefore, TKA is appropriately reserved for patients with disease and symptoms that are unremitting despite judicious medical management, including anti-inflammatory medications, activity modification, weight loss, physical therapy, bracing and other biomechanical modifications, and use of a cane for ambulation. Moreover, the expected survival of the arthroplasty implant at 15 years is projected to be between 81% and 92%.[12] Actual implant survival on a per patient basis is hard to predict because it is dependent on surgical considerations, activity levels, and co-morbidities.

Indications for Knee Arthroplasty

- Debilitating pain
- Failure of conservative treatment
- Patient medically suitable for surgery

TKA has been shown to be an effective treatment for patients more than 60 years of age with end-stage OA of one or more compartments of the knee. In these patients with symptomatic OA, outcomes are excellent in part because the patient's overall activity level has diminished and their expectations after TKA (i.e., the level of physical activity possible) are reasonable. In addition, because of the activity level and age of these patients, the revision rate is minimal. In contrast, in patients younger than 60 years of age, activity levels remain high, and the higher rates of aseptic failure may be related to the unique demands that they place on the implant.[13] Therefore, revision rates remain relatively high in this group of patients, and the timing of surgical intervention must be chosen carefully. Conservative management of OA should be maximized before any decision is made to proceed with surgical intervention for this age group.

Rehabilitation after TKA is described according to the typical stages through which a patient proceeds after the surgery, including preoperative considerations, acute care, post-acute care, outpatient, and return to sports, vocation, and leisure activities. Variations in surgical procedures are discussed, including any modifications that need to be considered in the rehabilitation process; however,

*The authors, editors, and publisher acknowledge Drs. Nina Shervin and Harry Rubash for their contributions on this topic in the previous edition.

the chapter focuses on primary TKA performed for a patient with underlying severe OA because this scenario accounts for most of the TKAs currently performed.

PREOPERATIVE REHABILITATION
